A Doctor and or Health Worker's Oath

I promise to treat all patients equally, with humanity, respect and to the best of my ability.

I shall listen to their story, keep their confidences and be honest at all times.

I shall strive to bring hope, however small.

I shall endeavour to improve my knowledge, and to be aware of new treatments.

I shall admit that which I do not know and shall not be afraid to seek help from those who do.

I shall promote freedom of thought and its expression.

I shall willingly teach my skills to others.

In memory of my father, Jon Nightingale, who died in August 1997 of motor neurone disease.

Foreword to Second Edition

Do we really need another textbook of intestinal failure, especially one following a very successful first edition from Dr Jeremy M.D. Nightingale, a pioneering leader in the field? With this second edition Jeremy delivers a resounding yes!

Intestinal failure is a devastating disease. In the five decades or so since the development of parenteral nutrition, the present era more than any other has seen incredible improvements in outcomes for patients with intestinal failure. Very significant improvements have stemmed simply from the widespread recognition of the value of multidisciplinary intestinal rehabilitation, approaches to prevent complications related to parenteral nutrition through better catheter care or lipid management and incremental improvements in outcomes for intestinal transplantation. There have been remarkable advancements in the characterization and approval of intestinotrophic peptides with more along the way.

It is in this context that Dr Nightingale's updated second edition of *Intestinal Failure* could not be more timely. The book represents a herculean effort spanning five years and brings together an international authorship of experts collectively representing several decades of experience in intestinal failure. The current edition adds 27 new chapters! Of particular interest and relevance are new or updated chapters covering mesenteric ischemia, radiology in intestinal failure, encapsulating peritoneal sclerosis, pro-adaptive hormones, drug absorption, etc. To give just a few examples, the chapter on mesenteric ischemia written by the experienced team from Paris describes best practices from a multidisciplinary acute intestinal stroke unit. There is a comprehensive description and approach to managing encapsulated peritoneal sclerosis, a vexing and poorly understood condition that appears to be increasing in incidence. For the first time, there is a very thorough chapter on management of impaired drug absorption in patients with short bowel syndrome. I am especially pleased to see well-written chapters describing psychological aspects of intestinal failure, quality of life, patient perspectives, and ethical and legal aspects of nutritional support.

In his foreword to the first edition, Sir Miles Irving wrote that "Jeremey Nightingale has performed an outstanding service …the book will act as a standard text for those who need to know how to deal with patients afflicted by this difficult condition." I will go further—with this authoritative textbook, Jeremy has put together the most comprehensive text one could hope for in intestinal failure. Far from being standard text, this book will be essential reading for established experts in intestinal failure and all who aspire to have sound basic understanding to manage this challenging condition well. I anticipate that my own autographed copy will see much use!

Foreword to First Edition: 2001

To have been party to the recognition of a new specialty, encourage its development, see it acknowledged as a specialty in its own right and then bring it to a maturity and set it on its future path, all within the space of 30 years, must be regarded as both an awe inspiring experience and a privilege.

Such has been the experience of the team of authors that have contributed to this unique volume. It is remarkable that it is only 30 years since Dudrick, Wilmore, Vars and Rhoads showed that children could grow and mature normally when sustained by parenteral nutrition alone. From this classic study has developed the whole field of intestinal failure and its treatment.

This book brings together those who were the pioneers, those who refined the techniques that enabled patients to receive safe enteral and parenteral nutrition outside the hospital and those who now have the task of taking the management of intestinal failure to the next stages. The assembled chapters reveal a remarkable record of international interdisciplinary collaboration between scientists and clinicians, doctors and nurses, health economists and those with expertise in the relatively new discipline of the measurement of quality of life. What is most gratifying, however, is the inclusion of an authoritative and scientifically rigorous expression of the patient perspective. The management of intestinal failure was arguably the trailblazer in demonstrating that successful outcomes could only be obtained if the patient was incorporated as an integral part of the therapeutic team.

Jeremy M.D. Nightingale has performed an outstanding service to gastroenterology by bringing together a group of authors who provide not only an authoritative, current statement on the total management of patients with intestinal failure but also a record of the development of this specialty which will act as a reliable reference for many years to come.

This book sets the seal on Intestinal Failure as a distinct specialty and will act as a standard text for those who need to know how to deal with patients afflicted with this difficult but fascinating condition.

Sir Miles Irving

Emeritus Professor at the University of Manchester,
Newcastle Upon Tyne, Tyne and Wear, England
May, 2001

Preface

This new edition of an international multi-author textbook brings the broad subject of intestinal failure in adults and children to a wide readership. A simple, easy to remember definition of intestinal failure is presented "reduced intestinal absorption causing malnutrition and/or dehydration". It encompasses patients with many underlying diagnoses who need nutritional and/or fluid support by oral, enteral or parenteral routes due to an impairment/failure of intestinal absorption. Many of these patients will be managed in non-specialist hospitals and often without the need for parenteral support.

The second edition (62 chapters) includes updated versions of the original 34 chapters. In addition there are new chapters that cover many other aspects of intestinal failure/nutritional support including psychology, drug absorption, pancreatitis and critical care. Each chapter starts with practical key points and a summary, then follows clinical guidance and information based on the recent literature.

Doctors, nurses, dietitians, pharmacists, research workers and patients have written the chapters to give different viewpoints that relate to nutritional support in hospitals and in the community. This edition should provide an essential source of reference to all members of a nutrition support team and to specialist workers/researchers in the field.

Please send any comments, corrections, additional information or suggestions for inclusion in a future edition to the editor.

St Mark's Hospital, Harrow, UK

Jeremy M.D. Nightingale

Acknowledgements

I wish to thank my main trainers/mentors. These include Peter Willoughby, Rodney Burnham, Michael Kamm, Michael Farthing, John Mayberry, Tony Wicks, Barrie Rathbone and especially John Lennard-Jones (JLJ). JLJ was an inspirational "can do" person whose research followed from the clinical problems he managed. Following a ward round at St Mark's Hospital in 1987, when it was situated on City Road in London, he asked me which patients/problems I had found most interesting. Put on the spot, I replied that it was those with a short gut and receiving parenteral support. Thus began my research/special interest in nutritional support which along with inflammatory bowel disease has been a major part of my professional life.

Thanks go to two committees that I have been fortunate to chair; the British Intestinal Failure Alliance (BIFA) committee and the Nightingale Trust for Nutritional support. They have helped develop logical ways to manage patients needing nutritional support and are referred to when appropriate in the chapters.

I would like to thank all the authors of the first edition (published in 2001) whose contributions helped formulate many of the chapters in this new updated version.

I am grateful to the associate editors Simon Lal, Mattias Soop and Ahash Mehta who will be responsible for future editions.

I thank Nicola Burch and the nutrition support team in Coventry for helping me maintain a broad experience of all aspects of nutritional support while working on this book.

I thank all the many brave patients who have given me the knowledge, awareness and many skills that I have tried to incorporate into this book.

I particularly thank my wife (Sally) and our sons (James and Peter) for tolerating the many hours this textbook has taken to complete.

Contents

Part III Chronic (Long-Term) Intestinal Failure

Part IV Consequences of Intestinal Failure

Part V Assessment and Treatment of Intestinal Failure

Abbreviations

A&E	Accident and emergency
AA	Amino acid
AABF	Amino acid-based formula
AANH	Artificially assisted nutrition and hydration
ABD	Acid-base disturbance
ACR	Acute cellular rejection
ACS	American College of Surgeons
ACT	Acceptance and commitment therapy
ADA	Adalimumab
ADP	Adenosine diphosphate
ADP	Air displacement plethysmography
AGI	Acute gastrointestinal injury
AgRP	Agouti-related peptide
AIDS	Acquired immunodeficiency syndrome
AIO	All-in-one
AIR	Autologous intestinal reconstruction
ALP	Alkaline phosphatase
AMI	Acute mesenteric ischaemia
ANC	Acute necrotic collection
ANTT	Aseptic non-touch technique
AP	Acute pancreatitis
Apo AIV	Apolipoprotein AIV
ART	Anti-retroviral therapy
ASPEN	American Society for Parenteral and Enteral Nutrition
AST	Aspartate aminotransferase
ATP	Adenosine triphosphate
AuSPEN	Australian Society of Parenteral and Enteral Nutrition
AVF	Arteriovenous fistula
AWR	Abdominal wall repair
AXR	Abdominal radiograph
BANS	British Artificial Nutrition Survey
BAPEN	British Association for Parenteral and Enteral Nutrition
BCS	Biopharmaceutical classification system
BDA	British Dietetic Association
BDP	Beclomethasone dipropionate
BFT	Barium follow through
BIA	Bioelectrical impedance analysis
BIFA	British Intestinal Failure Alliance
BMC	Bone mineral content
BMD	Bone mineral density
BMI	Body mass index
BMR	Basal metabolic rate

BMS	Bare metal stents
BNF	British National Formulary
BO	Bowel obstruction
BP	Blood pressure
BPD	Bilio-pancreatic diversion
BPNG	British Pharmaceutical Nutrition Group
BSG	British Society of Gastroenterology
Ca	Calcium
CA	Coeliac artery
cAMP	Cyclic adenosine monophosphate
CANH	Clinically assisted nutrition and hydration
CBD	Common bile duct
CBT	Cognitive behavioural therapy
CCN2	Cellular communication network factor 2
CDED	Congenital diseases of enterocyte development
CDT	Catheter-directed thrombolysis
CE	Conforormité européenne. European conformity mark indicating a product meets the essential requirements of the relevant EU directives and standards for that product
CFTR	Cystic fibrosis transmembrane conductance regulator
CHG	Chlorhexidine gluconate
CHI	Creatinine height index
CHO	Carbohydrate
CIF	Chronic intestinal failure
CIPO	Chronic intestinal pseudo-obstruction
Cl	Chloride
CLABSI	Central line-associated bloodstream infection
CMV	Cytomegalovirus
CNI	Calcineurin inhibitor
CNS	Central nervous system
COVID	Coronavirus disease
CPPD	Calcium pyrophosphate dihydrate
Cr	Chromium
CR	Chyme reinfusion
CRBSI	Catheter-related blood stream infection
CRF	Chronic renal failure
CRP	C-reactive protein
CSD	Congenital sodium diarrhoea
CT	Computerised tomography
CTCAE	Common terminology criteria for adverse events
CTE	Computerised tomography enterography
CTE	Congenital tufting enteropathy
CTZ	Chemoreceptor trigger zone
Cu	Copper
CVC	Central venous catheter
CVID	Common variable immunodeficiency
CVT	Central vein thrombosis
DAMP	Danger-associated molecular patterns
DBD	Donation after brain death
DC	Dendritic cell
DCH	Delayed cutaneous hypersensitivity
DEXA	Dual-energy x-ray absorptiometry
DFH	Distal feeding and/or hydration

DIT	Diet-induced thermogenesis
DJ	Duodeno-jejunal
DJBL	Duodenal-jejunal bypass liner
DNA	Deoxyribonucleic acid
DNI	Drug-nutrient interactions
DPEG	Direct percutaneous endoscopic jejunostomy
DPP	Dipeptidyl peptidase
DR	Digital radiography
DTP	Differential time to positivity
EA	Enteropathic arthritis
EAA	Essential amino acids
EAF	Entero-atmospheric fistula
EATL	Enteropathy-associated T-cell lymphoma
EBV	Epstein-Barr virus
ECCO	European Crohn´s and Colitis Organisation
ECF	Enterocutaneous fistula
ECG	Electrocardiogram
ECL	Enterochromaffin-like cells
ECMO	Extracorporeal membrane oxygenation
EDS	Ehlers-Danlos syndrome
EDTA	Ethylenediaminetetraacetic acid
EEN	Early enteral nutrition
EF	Enteral feed
EFA	Essential fatty acid
EGF	Epidermal growth factor
EGFR	Epidermal growth factor receptor
EHF	Extensively hydrolysed formulae
EI	Energy intake
EMA	Endomysial antibody
EMA	European Medicines Agency
EMDR	Eye movement desensitisation and reprocessing
EPS	Encapsulating peritonitis
ERAS	Enhanced recovery after surgery
ERCP	Endoscopic retrograde pancreatography
ESG	Endoscopic sleeve gastroplasty
ESICM	European Society of Intensive Care Medicine
ESPEN	European Society of Enteral and Parenteral Nutrition (European Society of Clinical Nutrition and Metabolism)
ESPGHAN	European Society for Paediatric Gastroenterology, Hepatology and Nutrition
ESWL	Extracorporeal shockwave lithotripsy
ETEC	Enterotoxigenic
ETF	Enteral tube feeding
EUS	Endoscopic ultrasound
FABP	Fatty acid binding protein
FDA	Food and Drug Administration (USA)
FGF	Fibroblast growth factor
FISH	Fluorescence in-situ hybridisation
FMT	Faecal microbiota transplantation
FODMAP	Fermentable oligosaccharides, disaccharides, monosaccharides and polyols
Fr	French gauge (same as CH =Charrière) circumference of a tube in millimetres (Fr =diameter x π)
FU	Fluorouracil
fURS	Flexible ureteroscopy

FXR	Farnesoid X receptor
GALT	Gut-associated lymphoid tissue
GCSF	Granulocyte colony-stimulating factor
GFR	Glomerular filtration rate
GH	Growth hormone (hGH: human growth hormone)
GHR	Growth hormone receptor
GHRH	Growth hormone releasing hormone
GI	Gastrointestinal
GIP	Gastric inhibitory peptide or polypeptide, or glucose-dependent insulinotropic polypeptide
GIT	Gastrointestinal tract
GLIM	Global leadership initiative on malnutrition
GLP-1 and 2	Glucagon-like peptide-1 and -2
GLP-2R	Glucagon-like peptide-2 receptor
GORD	Gastro-oesophageal reflux
GPS	Glasgow prognostic score
GRS	Glucose rehydration solution
GSV	Great saphenous vein
GVHD	Graft versus host disease (acute or chronic)
HAART	Highly active antiretroviral therapy
HACCP	Hazard analysis critical control point
HB-EGF	Heparin-binding growth factor
HCO_3	Bicarbonate
HD	Haemodialysis
HES	Hospital episode statistics
HETF	Home enteral tube feeding
HGF	Hepatocyte growth factor
HIV	Human immunodeficiency virus
HLA	Human leucocyte antigen
HOS	High output stoma
HPAC	High amplitude propagated contractions
HPN	Home parenteral nutrition
HPS	Home parenteral support (includes fluid and nutrition)
HSC	Haematopoietic stem cell
HSCT	Haemopoietic stem cell transplantation
HVM	Hollow visceral myopathy
I	Iodine
IAP	Intra-abdominal pressure
IASP	International Association for the Study of Pain
IBD	Inflammatory bowel disease
ICAM	Intercellular adhesion molecule
ICER	Incremental cost effectiveness ratio
ICPI	Immune checkpoint inhibitor
ICU	Intensive care unit
ICV	Ileocaecal valve
IDA	Iron deficiency anaemia
IDSA	Infectious Disease Society of America
IF	Intestinal failure
IFALD	Intestinal failure-associated liver disease
IFRD1	Interferon-related developmental regulator
IFU	Intestinal failure unit
IFX	Infliximab
IGF	Insulin-like growth factor

IHD	Intermittent haemodialysis
IJV	Internal jugular vein
Il	Interleukin
ILE	Intravenous lopid emulsion
IMA	Inferior mesenteric artery
iNOS	Inducible NO synthase
INS	Intestinal insufficiency
IPA	Isopropyl alcohol
IRU	Intestinal rehabilitation unit
ITX	Intestinal transplantation
IVC	Inferior vena cava
IVF	Intravenous fluids
IVS	Intravenous saline
JCB	Jejuno-colic bypass
JIB	End-to-end jejuno-ileal bypass
K	Potassium
KGF	Keratinocyte growth factor
LAMS	Lumen apposing metal stents
LCFA	Long-chain fatty acids
LCT	Long-chain triglycerides (14–24 carbon atoms)
LFA	Lymphocyte function antigen
LFT	Liver function test.
LILT	Longitudinal intestinal lengthening and tailoring
LITRE	Looking into the requirements for equipment
LOS	Length of stay
LSB	Liver small bowel transplant
MAHA	Microangiopathic haemolytic anaemia
MAMC	Mid-arm muscle circumference
MAMP	Microbial-associated molecular patterns
MARSI	Medical adhesive-related skin injury
MARSIPAN	Management of Really Sick Patients with Anorexia Nervosa
MBD	Metabolic bone disease
MCT	Medium-chain triglycerides (6–12 carbon atoms)
MDT	Multidisciplinary team
MEED	Medical emergencies in eating disorders
MEF	Minimal enteral feeding
MELD	Model for end-stage liver disease
Mg	Magnesium
mGIF	Modified gastrointestinal failure

Part I

Introduction

Historical Overview of Intestinal Failure

John E. Lennard-Jones, Gil Hardy,
and Khursheed N. Jeejeebhoy

Key Points

1. The first resection of more than 200 cm small bowel was described in 1880 and in 1980 the term intestinal failure was first coined.
2. The first attempt at parenteral nutrition (PN) was with milk infusions in 1873 and 100 years later the first patient was reported receiving PN at home (in 1973).
3. An everted mucosal ileostomy and the development of satisfactory appliances that adhered to the skin in 1952 helped the management of many patients after a bowel resection.
4. The reasons for intestinal failure have widened from massive resections due to volvulus/strangulated hernia, Crohn's disease and mesenteric infarction to include surgical complications and dysmotility.
5. The composition of PN nutrition and the bags has been changing since the 1960s with improvements in amino acid and micronutrient formulations, the development of lipid emulsions and recently the multi-chamber bags.
6. Venous access for PN started with arteriovenous fistulas, then with safe aseptic placement catheters with their tips at the vena caval/atrial junction were used. With careful aseptic care the incidence of catheter related blood stream infection has reduced.

J. E. Lennard-Jones has died before the publication of this book.

Introduction

The term 'intestinal failure' was used by Irving and colleagues in the title of a paper published in 1980 [1]. In the following year, a book chapter by Fleming and Remington gave the first definition as a 'reduction in functioning gut mass below the minimal amount necessary for adequate digestion and absorption of nutrients' [2]. Irving and his colleagues popularized the term when they described their work in a specially designated 'Intestinal Failure Unit' for the treatment of complex intestinal disorders [3]. A key feature of this unit was the ability to provide safe, effective, long-term parenteral nutrition. The phrase 'intestinal failure' began in surgical practice as a unifying concept for apparently different conditions all of which have the common feature that the normal absorptive function of the small intestine is impaired, usually to such an extent that parenteral feeding is needed [3]. It is now recognized that some patients can also be treated by giving extra or special nutrients via the intestine. The definition of intestinal failure in the first edition of this book is of 'a reduction of intestinal absorption that, without treatment or compensatory mechanisms, results in malnutrition and/or dehydration'. This includes the need for enteral or parenteral supplements (nutrition and fluid) to maintain a normal nutritional/hydration state. Malabsorption of a single nutrient, such as Vitamin B_{12}, or the need for a special diet to exclude a damaging component such as gluten, is not included within this definition.

Loss of intestinal absorptive function can be complete or partial. Intestinal failure may be described as *acute* when it is reversible in the short term or *chronic* if long-term treatment over weeks, months, or longer is required especially if continued treatment is needed at home. The conditions leading

J. M.D. Nightingale (ed.), *Intestinal Failure*, https://doi.org/10.1007/978-3-031-22265-8_1

to intestinal failure are such surgical conditions as intra-abdominal sepsis and ileus, a high volume entero-cutaneous fistula, intestinal obstruction or temporary severe malabsorption after extensive small bowel resection or it can be due to chemotherapy.

Parallel Developments

Developments in different disciplines since the middle years of last century have led to our current understanding and treatment of intestinal failure. First, the application to both normal subjects and those with intestinal resection of new laboratory techniques, has advanced understanding of small intestinal function. Second, the scope of surgical treatment has extended to include more complex operations on the intestine so that intestinal failure occurs more frequently, and is often more severe, than hitherto. During the same time period medical causes of intestinal failure have been recognized. Third, clinical necessity has stimulated the application of innovative techniques to treat the condition in the short- or long-term. These parallel developments in time will be described sequentially in the following review.

Advances in Knowledge

Sites of Nutrient Absorption and Effect of Resection

Many of the laboratory measurements, now regarded as routine, were developed at the beginning of the second half of the twentieth century. For example, a widely used method for measurement of fat in faeces was first reported in 1949 and microbiological techniques for the measurement of folic acid or vitamin B_{12} in blood were devised in 1956 and 1961 respectively. Radio-isotope methods for measuring vitamin B_{12} absorption were developed in the late 1950s.

In 1957 the first direct measurements of nutrients in human intestine was made by Borgstrom et al. [4] who fed a liquid meal with an unabsorbed marker and using intubation sampled the intestinal contents at various distances to determine the absorption of nutrients as the bolus fed progressed down the small bowel. They found that over 90% of all macronutrients namely carbohydrate, protein and fat were absorbed within 100 cm of jejunum [4]. Although in intact human subjects fat absorption was complete in the jejunum, Intestinal resection studies showed that after jejunal resection feeding increasing amounts of fat did not increase loss in stool indicating that the remaining ileum could maintain normal fat absorption despite the absence of the jejunum which is the normal site of fat absorption. In contrast when the ileum was resected fat malabsorption increased with increasing amounts of fed fat [5–7]. Based on intubations studies of Borgstrom et al. [4] ileal resection should have no effect on fat absorption. This paradox was solved in the 1960s by the observation that bile salts necessary for fat absorption are recycled through the ileum and during a meal, calculations by Borgstrom et al. suggest that the bile salt pool is recycled twice. Hence loss of the ileum depletes the bile salt pool in the jejunum and reduces fat absorption. Intestinal resection studies also showed another unique function of the ileum namely vitamin B_{12} absorption [5].

The need of patients with distal ileal resection for parenteral supplements of vitamin B_{12} is now well recognised.

Fluid and Electrolyte Fluxes

In addition to macronutrient absorption the small bowel was shown to be the site of massive fluid and electrolyte fluxes. The intubation studies by Borgstrom et al. [4] indicated that the ingested meal is diluted three to five times as it passes the duodenum. Seminal studies showed that the jejunum had large pores and absorption was mainly by solvent drag leaving the luminal electrolyte concentration similar to plasma. While there was coupled sodium and glucose active transport throughout the small bowel [8–10], osmotic gradient was not maintained in the jejunum. Hence a hyperosmotic meal of milk and doughnuts caused a greater dilution in the proximal bowel than a steak meal of lower osmolality. In contrast there was an osmotic gradient between plasma and lumen in the ileum where there were smaller pores and especially in the colon [11–13].

Effect of Malabsorption on the Colon

Malabsorption of bile salts results in these salts entering the colon where they promote water secretion and thus diarrhea. Bile acid malabsorption caused by ileal resection causes fat malabsorption. After resection of the ileum the entry of bile salts and fatty acids into the colon stimulated colonic peristaltic motor activity and inhibited water and electrolyte absorption by long-chain fatty acids entering the colon was shown in the 1970s and 1980s to be a potential factor in causing diarrhoea in patients with a short small intestine anastomosed to colon [14, 15]. The mechanism of increased oxalate absorption by the colon in patients with a short gut, leading to hyperoxaluria and oxalate renal stones, was unraveled in the 1970s as due to a combination of colonic calcium binding by long-chain fatty acids and the effect of a higher than normal concentration of bile salts on the colonic mucosa [16].

Adaptation of the Residual Small Intestine After a Partial Resection

Experiments in animals, dating from the early years of the century, but particularly from the late 1960s onwards, have shown that when a length of small intestine is resected, with anastomosis of the proximal jejunal and distal ileal segments, marked hypertrophy with increased absorptive function of the distal ileum occurs [17]. It seems that the distal ileum which plays little part in normal nutrient absorption has a capacity for increasing its absorptive role when nutrients reach it due to proximal resection of intestine. Functional investigation in man has shown increased absorption of water, sodium, glucose and calcium in the jejunum [18–20], but villous hyperplasia has not been demonstrated in man when distal intestine is resected with formation of a terminal jejunostomy [21]. These findings were explained in the 1990s by the findings that isolated glucagon- like peptide 2 (GLP2) produced by L cells of the ileum and colon increased intestinal epithelium proliferation [22].

Development of Surgical Practice

Extensive Resection

The first resection in humans of more than 200 cm of small intestine has been attributed to Koberle in 1880, and 55 of such operations were reported up to 1912 [23]. Most such operations until the middle years of the century were performed as an emergency for removal of non-viable intestine infarcted due to strangulation or volvulus. Thus, in a 1935 review of 257 cases the commonest reasons for resection were volvulus in 76 and strangulated hernia in 45 (Table 1) [24]. Mesenteric artery or vein occlusion constituted only 13% of the cases at that time, whereas by 1969 the proportion had risen to 48% [25]. This change may reflect a decreased incidence of hernial strangulation, increasing age of the population and the fact that surgeons became willing to resect a long length of infarcted intestine in the knowledge that treatment was now available to compensate for the resulting malabsorption.

Extensive small bowel resection for vascular insufficiency of the central portion of the small bowel usually spares the proximal and distal ends. Such operations lead to removal of mid-small bowel with jejuno-ileal anastomosis and retention of the colon. The distal ileum has considerable potential for adaptation and the colon, with its capacity for avid absorption of sodium and water, prevents severe fluid and sodium depletion. These cases, with a reasonable good prognosis, still occur but the knowledge that parenteral therapy is available (see below) now allows surgeons to resect even the whole small bowel for a condition such as desmoid tumour of the mesentery. There are now also many people in whom the residual intestine is limited to a relatively short length of residual jejunum ending in a stoma.

Table 1 Reasons for 'extensive' and 'massive' intestinal resections in adults in 1912 and 1935

Flint 1912: 'Extensive' intestinal resection [23]

Strangulated hernia	45
Mesenteric thrombosis	34
Tuberculosis	16
Mesenteric tumours	14
Uterine perforation	11
Adhesions/bands	7
Other	54
Total	**257**

Construction of a Stoma

The surgery of ulcerative colitis was greatly facilitated by the development and introduction of an everted mucosal ileostomy in 1952 and the development of satisfactory appliances adherent to the skin during the same period [26]. From time to time colectomy for ulcerative colitis is complicated by a vascular accident which leads to loss not only of the colon but also a large part of the small bowel with creation of a terminal jejunostomy.

This operation may be needed electively for the treatment of Crohn's disease when there is extensive involvement of both small and large bowel. Thus in a series reported in 1992 of 86 patients each with less than 200 cm of small bowel remaining, 38 had a jejunostomy as the result of surgical treatment for Crohn's disease or ulcerative colitis [27].

Entero-Cutaneous Fistula

A high volume entero-cutaneous fistula is similar in its effluent to a high jejunostomy, but is often complicated by sepsis. While maintaining nutrition parenterally, surgeons can now delay definitive operation for a high-volume entero-cutaneous fistula until sepsis is dealt with, the anatomical

situation is defined and the patient's general condition is optimal. Treatment in this way has greatly reduced the mortality of this condition.

Characterization of the Resection

The term 'extensive' small bowel resection was reserved in the earlier literature to describe removal of at least 200 cm. This length was chosen because it was believed to represent about one-third of the small intestinal length and experimental work suggested that up to this proportion can be removed without detriment to weight and strength. These observations failed to take account of the variable length of the human small intestine. In 1935, Haymond [24] drew attention to this variability and observed correctly that 'a resection of a large amount in one individual would constitute a different percentage of the total length in another'. Before closing the abdomen after a resection, surgeons should thus measure the length of residual intestine along the anti-mesenteric border, and define the proportions of proximal and distal intestine.

Follow-up observations have shown the prognostic importance of these records. Patients with less than 200 cm of small bowel remaining fall into three groups: those with an anastomosis between residual jejunum and ileum proximal to an intact colon; those with anastomosis of small bowel to colon; and those with a terminal small intestinal stoma [27]. The prognosis as regards the need for long-term parenteral nutrition (PN) therapy depends in each group on the length of residual small bowel [28] but those with a colon can tolerate shorter lengths of small bowel than those with a jejunostomy. The role of residual ileum and colon to allow the bowel to adapt and permit patients to return to oral nutrition after resection and initial dependence on home parenteral nutrition (HPN) was demonstrated in the 1990s. The findings showed that the presence of ileum and colon allowed very short bowels to become independent of PN followed by the presence of colon alone joined to jejunum and those least likely to become independent of PN were those with a jejunostomy [29].

Surgical Treatment of Intestinal Failure

Although procedures [30, 31] have been performed with some success to lengthen a short residual intestine or delay passage of its contents to allow absorption to occur, the main hope of surgical advance centres on intestinal transplantation [32]. Rejection of the graft remains a problem but the successful result when an identical twin was the donor pointeds to the success of the surgical technique; the problems to be overcome remain mainly immunological [33].

Recognition of Medical Causes of Intestinal Failure

A number of congenital disorders associated with intestinal failure were described during the 1970s and 1980s. For example, a rare congenital defect of intestinal villus formation in babies [34] and a number of different familial types of pseudo-obstruction have been identified [35]. The latter may present as a myopathy in which the intestine becomes wide, atonic and subject to bacterial overgrowth or as a disorder of the myenteric nerve plexus which leads to obstructive episodes without mechanical cause. Chronic pseudo-obstruction has also been recognized later in life secondary to a systemic disorder such as scleroderma or as a sporadic condition of unknown cause.

Development of Treatment

Enteral Nutrition (Table 2)

The earliest enteral feeds were given rectally by enema. The ancient Egyptians gave wine, whey, milk and/or barley broth nutrient enemas [36]. John Hunter gave one of the earliest orogastric feeds documented in 1790 to a patient who had had a stroke. He used a pig bladder as a reservoir for an egg, water, sugar, milk or wine feed and this was squeezed into the stomach through a feeding tube, made by a watchmaker, consisting of a whale bone and eel skin [36]. Feeding tubes were at first large and made of rubber, gradually these have been refined to radio-opaque fine-bore tubes initially made of polyvinyl chloride but now largely replaced by silicone or polyurethane [37]. While the first gastrostomies and jejunostomies were fashioned at laparotomy, they are now mostly placed using endoscopic and radiological techniques [38–42].

In 1943 milk protein was used to make casein hydrolysates as the protein component of a feed, subsequently some feeds have been based on soya bean or egg white. Carbohydrate was first given as glucose or sucrose, but in

Table 2 Key developments in enteral nutrition

BC	Nutrient enemas used by Ancient Egyptians [36]
1790	Oro-gastric feeding tube [36]
1867	Soft rubber tubing for gastric lavage [37]
1876	Surgical gastrostomy [38]
1885	Surgical feeding jejunostomy [39]
1910	Oro-duodenal feeding [40]
1943	Casein hydrolysates [36]
1952	Surgically placed needle jejunostomy [41]
1963	Chemically defined (elemental) diet for space travel [36]
1980	Endoscopic gastrostomy [41]
1981	Radiological gastrostomy [42]
1990s	Immunomodulation (glutamine, arginine and MCTs)

order to keep the osmolality low, glucose-polymer mixtures derived from the hydrolysis of corn starch were used [36, 43]. Lipid as long-chain triglyceride was derived from soya, corn or safflower oils, and lipid as medium-chain triglyceride from coconut oil.

Parenteral Nutrition (Table 3)

Fluid and electrolyte balance has been maintained in patients with intestinal failure since the earliest days of intravenous fluid administration. One of the earliest reports of giving intravenous nutrition was when three patients who had cholera and were considered about to die, were given intravenous fresh (still warm) cow's milk, two of these patients survived [44]. Isotonic, or slightly hypertonic, solutions of glucose were given by peripheral infusion but not enough to provide an adequate energy source because higher concentrations caused thrombosis of the vein. The problems to be solved before intravenous feeding could become a reality, were to devise solutions which provide a non-irritant form of amino-nitrogen for synthesis of protein and an adequate energy source.

Intact protein, other than human plasma or albumin, tends to be allergenic. These whole proteins were used in the first half of the twentieth century for temporary nutritional support but expansion of the circulating plasma volume and slow turnover of the protein were limiting factors. Early workers suggested that amino acid solutions might be effective but it was not until 1937 that an amino acid solution produced by hydrolysis of casein was first shown to be a practicable method of treatment [45]. By 1943, a review recorded treatment of at least 500 patients with this product and included a reference to combined treatment with an intravenous lipid emulsion (ILE) [46]. A casein enzymatic hydrolysate, in which amino acids and small peptides were separated from residual large peptides by dialysis, was widely used in Europe during the 1950s and 1960s, and a fibrin hydrolysate was used in America. Intensive work defined the optimal amino acid composition, including the ratio of essential to nonessential amino acids and the need to provide the amino acids in an L-form. It was recognized that a mixture of crystalline amino acids would have the advantage of providing flexible solutions of known composition and such a solution was first used clinically in 1940 for intravenous nutrition in children [47]. However, the initial technical difficulty, and thus high commercial cost, of such solutions delayed their introduction for routine use until the 1960s and early 1970s, since when they have superseded the use of protein hydrolysates.

Table 3 Key developments in parenteral nutrition

1873	Milk infusions to treat cholera [44]
1937	Protein hydrolysates (amino acids) infusions [45]
1952	Subclavian vein catheterization using infraclavicular approach [48]
1961	Lipid emulsion [50]
1965	Complete Parenteral Nutrition using central catheter [50]
1968	Hypertonic glucose infused into a large vein [56]
1970	Long-term parenteral nutrition ('the artificial gut') using arterio-venous shunt [57]
1973	All-in-One system for ambulatory PN [60]
1973	Home PN using a tunneled catheter [67]
1973	Teflon-cuffed tunnelled silicone rubber catheter [68]
2000	Multi Chamber Bags for PN [71]

An ILE offered the possibility of a rich caloric source which would not be osmotically active. However, there were many initial difficulties. Low molecular weight triglycerides were found to be acutely toxic. Cotton seed oil and soya bean oil emulsions had low acute toxicity and between 1948 and 1972 Meng and colleagues in Nashville USA studied the former in animal and human models [49], but unfortunately a minor impurity gave rise to toxic effects. Consequently the product was withdrawn and ILE were not approved for use by the United States Food and Drug Administration (FDA) until 1972.

Meanwhile development of the soya bean oil ILE, emulsified with egg yolk phosphatides, continued in Sweden. The product, which mimicked the structure of chylomicrons, proved non-toxic in animals and was used successfully in humans for the first time during the early 1960s [50]. During a 1963 conference in London, organized and chaired by Meng, the Swedish group, led by Wretlind and Schuberth described their research on the experimental and clinical development of this preparation, which was approved for use in UK and many other European countries in 1962 and is still in use today. This was a major advance and, there was an immediate surge of interest in the use of ILE as a high energy source of essential fatty acids.

In 1965 Lawson [51] was able to provide PN using protein hydrolysate, glucose and lipid, separately through a central venous catheter and Sherwood Jones and Peaston reported that in the ICU at Whiston hospital, Liverpool, "*intravenous feeding is routinely instituted if either oral or tube feeding is contraindicated or complicated by side-effects*" [52]. Fructose, sorbitol, xylitol and ethanol were all popular as alternative energy sources in Australia, Germany and the UK in the 1970's/'80's [53–55] but all have metabolic disadvantages compared to glucose. Which is metabolically the most suitable energy substrate. However, at only 4 kcal/g the quantity needed was limited by the need to keep the volume of infusate physiological and avoid thrombosis of peripheral veins. Dudrick and colleagues overcame the high osmolality problem in 1968 by infusing hypertonic glucose into a large central vein where the blood flow is adequate to dilute the solution and thus avoid local phlebitis and thrombosis [56]. This technique was widely adopted in America where ILE were unavailable, and administration of

PN through a central vein has been standard practice, particularly for long-term parenteral feeding. Some patients with chronic intestinal failure require prolonged, even lifelong, parenteral feeding. There was excitement when the concept of an 'artificial gut' based on the experience of prolonged renal dialysis was introduced by Scribner and colleagues in 1970 [57]. The original technique based on intermittent infusion via an arterio-venous fistula was successfully adopted in Australia, New Zealand and The Netherlands where there are still some long-term PN patients managing this technique at home [58, 59]. In 1973, the Broviac silicone rubber catheter with a Dacron cuff to seal and fix it within a skin tunnel, proved satisfactory and nine patients were treated at home in USA [60, 61]. This remains a long-term catheter of choice.

Solassol and Joyeux in the 1970's, pioneered the first 'All-in One' (AIO) admixtures, in a single re-usable silicone rubber container, that could be prepared aseptically in their hospital pharmacy [62]. The novel French PN system was administered to cancer and bowel disease patients, in Montpellier, via a small portable pump. This innovative system reduced the number of manipulations and daily infusion time to 8 hrs, allowing the patient to become ambulatory and eventually to manage their PN at home (HPN). However, because of stability and microbiological concerns at that time, AIO admixtures were not immediately popular outside of France and mixing any other solutions with ILE was discouraged by Wretlind [63]. In Canada, Jeejeebhoy and colleagues described an alternative system for HPN using a tunneled silicone for short bowel patients and published details of 13 patients treated at home for up to 23 months [64]. At the same time Jarnum reported on Danish experiences with long term HPN patients in Copenhagen since 1967 [65, 66]. In UK, the use of the tunnelling technique was first mentioned in 1978 and 25 patients treated at different centres were described in 1980 at a conference held for the purpose [67, 68]. HPN is now a standard technique in many countries for patients with long-standing intestinal failure who cannot be treated successfully using an enteral regimen.

During the 1970s and 1980s much R&D was conducted on nutrient solutions to ensure optimal ratio of energy to protein, relative proportions of different amino acids, and content of vitamins and trace elements. The safety of the technique of fluid administration both in hospital and at home was improved. For example, the original need for multiple bottle changes and additions was simplified in the 1970's by adopting the French approach but aseptically mixing the ingredients in a single disposable 3 litre bag [68, 69]. Sophisticated pumps have been developed to control the rate of flow and warn of air bubbles or line blockage. Air bubbles in the solution have been minimized, and stability enhanced by manufacturing the bag from oxygen impermeable plastics [70]. The need for expensive hospital-based Aseptic Units (ASU) for compounding PN has now diminished, with industry manufacturing a range of 'ready-to-use' multi chamber bags (MCB) with the nutrients sterilized in separate chambers, that can be stored at room temperature, resulting in long shelf lives prior to mixing. MCB, introduced in Europe during the 1990's, significantly improve pharmacy workload, can be more cost effective and may reduce risk of bloodstream infections [71, 72].

Most important of all, protocols and educational programs, that cover PN prescription, compounding and administration, have been developed to minimize infection and venous thrombosis so that the risk of these complications is now low when care is provided by an experienced team [73].

Resection and Anastomosis

Metabolic studies of patients after resection date back at least to 1938. An example of an investigation aimed at improving management is a report in 1949 of giving a patient with short gut a liquid feed made up of protein hydrolysate, milk, cream and glucose compared with a normal diet [74]. The patient retained only 15 cm of jejunum anastomosed to transverse colon. She had lost weight from 64 kg to 42 kg, complained of weakness and dizziness (blood pressure 80/60), abdominal pain and bloating, and passed 3–6 stools daily. This is a vivid description of the chronic poor health of a patient at that time with a major resection of small intestine. The synthetic diet did not help her but it is interesting to note that she was taking only 1345 kcal daily in her normal diet which contained 48 g of fat.

It gradually became apparent that patients with a short small intestine in continuity with colon benefit from a low fat, high carbohydrate diet. Such patients need to eat more energy-giving foods than normal to compensate for malabsorption. A child reported in 1961 who had lost the whole of his jejunum and retained only 39 cm of ileum showed immediate improvement on a low fat, high protein, high carbohydrate diet. Weight loss was reversed, a growth spurt commenced and diarrhoea diminished [75]. Similarly, an adolescent who retained only 13 cm of jejunum and 5 cm of terminal ileum did well when dietary carbohydrate and protein were increased and part of the fat intake was replaced by medium-chain triglycerides [76].

The work of Booth et al. [6] and Andersson et al. [77] during the 1960s and 1970s showed that a low fat diet decreases diarrhoea, loss of divalent cations (calcium and magnesium) and urinary oxalate. It is only in recent years that a further benefit of increased dietary carbohydrate has been demonstrated; unabsorbed carbohydrate entering the colon is fermented by colonic bacteria yielding short-chain fatty acids which are absorbed as a source of energy [78, 79].

Terminal Jejunostomy

A patient who underwent an extensive small bowel resection in 1958 which left 120 cm of small bowel ending in a jejunostomy was troubled mainly by profuse drainage from the stoma [80]. When investigated in 1973, the jejunostomy effluent at times exceeded the volume of nutrients taken by mouth. Such profuse losses, with incipient sodium and magnesium deficiency, are a common problem in patients with a short gut and a jejunostomy.

Developments in treatment to minimize sodium losses from the jejunostomy have been threefold. First, it was shown that when such a patient drinks water, or a dilute sodium solution, there is a net sodium loss from the jejunostomy [81, 82]. When a normal person drinks water, sodium enters the upper intestine from the blood but this sodium is re-absorbed by the ileum or colon; in these patients it is lost from the body via the stoma. Second, the same research showed that the coupling of sodium and glucose absorption can be utilized to promote sodium absorption [81, 82]. Thus such patients should restrict their water intake and substitute a glucose-electrolyte solution. Animal and human experiments showed that the concentration of sodium in this solution should be at least 90 mmol/L to promote sodium absorption in the upper gut [83]. Third, opiate drugs, such as codeine phosphate or loperamide and octreotide can make a small contribution to reducing losses [84, 85]. Lastly, drugs which reduce gastric [86, 87], or all digestive secretions [88, 89] can benefit patients in whom the diluting effect of these digestive juices leads to a greater fluid output than taken by mouth.

Comparisons of oral intake and jejunostomy loss have shown that many patients absorb 60% or less of energy in their diet [90]. Thus, they need to eat more than normal or, if absorption is only about 30%, receive a parenteral supplement. In certain patients total jejunostomy loss exceeds the volume of food and fluid taken by mouth. Such patients cannot survive without parenteral supplements [91]. Unlike patients with an intact colon, fat is not deleterious to patients with a jejunostomy and is a valuable source of energy [92–94].

Pharmacological Treatment of Short Bowel

The observation that GLP2 will allow proliferation of small bowel epithelium [22] and increase small bowel function could not be applied in clinical practice because this hormone was rapidly hydrolysed by dipeptidyl-peptidase and after injection has a very short existence in circulation. In 1999 an analogue (teduglutide) with prolonged action biosynthesized by NPS Allelix [95] .as shown by subsequent controlled trials by Jeppeson et al. showed that it was capable of improving intestinal function in patients on HPN so as to reduce the need for Parenteral Nutrition [96].

Conclusion

The concept of intestinal failure, the reasons for it, physiological understanding of impaired intestinal absorption and the development of treatments have largely occurred during the last 50 years. It is perhaps because this concept is relatively new that the term is not yet part of core medical teaching, as is the case with cardiac, respiratory, hepatic or renal failure. The following chapters do much to establish intestinal malabsorption, severe enough to require replacement therapy, as another universally recognized type of system failure.

Normal Intestinal Anatomy and Physiology

Jeremy M.D. Nightingale and Robin Spiller

Key Points

1. The components of the gut all function as one with all parts communicating (by nerves or hormones) with each other (intestinal orchestra).
2. Endogenous gut secretions while consuming a normal diet (about 2 kg) amount to about 4 L/24 h.
3. Small intestinal length is very variable at 160–1510 cm while colon length is 100–330 cm.
4. Jejunal mucosa has leaky intracellular junctions so its contents are near to iso-osmolar with plasma.
5. Macronutrients are broken down to small molecules (e.g peptides and oligosaccharides) by pancreatic enzymes and only to small hyperosmolar ones as they are absorbed by the intestinal mucosa.
6. Lipids are absorbed along the whole small intestine.
7. Colonic peptide hormones slow gastric emptying and gut transit (e.g. peptide YY) and increase upper gut mucosal growth (e.g. GLP2).
8. Humans are hind gut fermenters. Healthy adults have more than 1000 species of bacteria most belonging to the phyla with *Bacteroidetes* and *Firmicutes*. The bacteria are increasingly recognised not only for producing short chain fatty acids, vitamins and amino acids but for their role in diseases.
9. Luminal content is constantly being sampled by M cells and dendritic cells as part of immunological surveillance.

Introduction

The gastrointestinal tract extends from the mouth to the anus and includes many vital organs that secrete, mix and gradually break down food into molecules that can be absorbed. (Fig. 1).

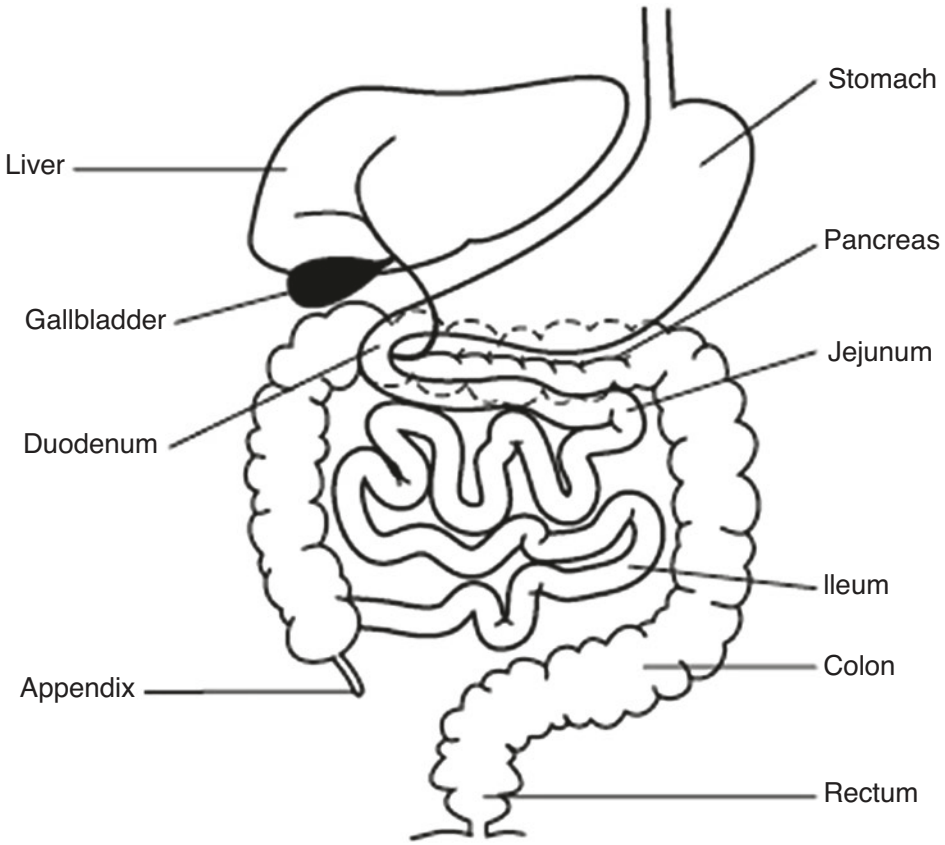

Fig. 1 Normal gastrointestinal anatomy

Oesophagus

The oesophagus is a muscular tube about 25 cm long; its function is to propel the food bolus from the pharynx to the gastric cardia. It is lined with a tough squamous epithelium. The upper two-thirds has striated voluntary skeletal muscle and the lower one-third involuntary smooth muscle [1]. About 2 kg of food and drink pass down it each day, diluted and lubricated by about 500 ml of saliva from lingual, sublingual, sub-mandibular and parotid salivary glands. Food viscosity is reduced by the acts of chewing, dilution and swallowing which stimulate a tenfold increase in salivary flow.

Stomach

The adult stomach is an acidic storage area that can hold up to 1.5 [1]. It starts digestion and delivers partly processed food at a controlled rate into the duodenum. It consists of two functionally different parts: the fundus and the antrum.

The fundus is mainly a storage area in which gastric juice is secreted and mixed with food to begin digestion. In addition to the many mucus-secreting cells found throughout the stomach, the fundal parietal cells secrete 0.1 M hydrochloric acid and intrinsic factor. During fasting the gastric pH ranges from 1.8 to 2.0; addition of food buffers this, raising the luminal gastric pH to 4–5. It should be noted that mixing is not perfect and a rim of secreted acid with pH 1 exists can form an "acid pocket" just below the lower eosophageal sphincter, which may be important in reflux oesophagitis. Acid kills most micro-organisms, denatures protein, making it more susceptible to hydrolysis, and converts inactive pepsinogen to pepsin, which is the active form of the enzyme. Intrinsic factor, a mucoprotein with a molecular weight of 55,000, binds B_{12} and this complex is absorbed in the distal 60 cm of ileum [2]. Fundal chief cells secrete pepsinogen and rennin. Pepsin is important in the breakdown of collagen, as it cleaves protein at the site of aromatic amino acids. Rennin (chymosin), which coagulates milk, may be produced by infants only.

Partly digested food from the fundus enters the antrum. The antrum has less of a secretory role and is responsible for mixing food and grinding it into small particles. Repetitive antral contractions occurring at 3 per minute propel chyme towards the pylorus, whose closure causes frequent retrograde flow. This to-and-fro flow produces shearing that reduces most food particles to less than 2 mm in diameter, a size at which they can pass through the pylorus into the duodenum. These shearing forces are weak (65 N) compared to those in the mouth (masticatory force 150 N) and so if food is not adequately, chewed chunks of material like meat will

empty as indigestible residue and will only empty with the MMC at the end of gastric emptying and thus may enter the small bowel as large chunks which will be less efficiently digested.

Thus the pylorus acts as a sieve [3]. Endocrine G cells in the antrum release gastrin, which stimulates the fundal parietal cells to secrete acid. The mixture of food, drink and secretion leaving the stomach is called chyme. Although the surface area of the stomach is small and the epithelium relatively impermeable, some molecules (e.g. alcohol and aspirin) can be absorbed from the stomach.

Duodenum

The duodenum is the widest part of the small bowel. It is 20–25 cm long and extends from the pylorus to the duodenojejunal flexure. In its structure it is essentially the same as the jejunum in that a villus structure starts absorption, but it contains submucosal bicarbonate-secreting glands of Brunner. The alkaline secretion from these glands helps to neutralize the gastric acid and provide a pH closer to the optimum for pancreatic enzymes to work. In the second part of the duodenum, alkaline pancreatico-biliary secretions are added to the chyme. The pancreatic enzymes are responsible for breaking macronutrients (protein, carbohydrate, lipid and nucleic acids) into smaller molecules (peptides, oligo/disaccharides, fatty acids/glycerol and nucleotides). Bile contains bile salts that aid lipid digestion and absorption; it also contains some end products of metabolism such as haemoglobin, cholesterol and some drugs. Bile is concentrated by the 7–10 cm long gallbladder which can hold 30–50 ml of fluid [1]. When lipid-containing chyme is within the duodenum, the gallbladder contracts and the sphincter of Oddi relaxes so that concentrated gallbladder bile is secreted into the duodenum.

Volume of Gastrointestinal Secretions

The work of Borgström et al. [4] and Fordtran and Locklear [5] provides an estimate for the daily volume of intestinal secretions when a normal diet is consumed. They have shown, using non-absorbed markers in healthy subjects, that about 4.0 L of endogenous secretions pass the duodenojejunal flexure daily. This quantity is made up of about 0.5 L saliva, 1–2 L gastric juice [6] and 1.5 L of pancreatico-biliary secretions (0.6 L is pancreatic juice [7]). Thus, each day about 6 L of chyme pass the duodeno-jejunal flexure. The process of digestion usually adds further secretions in the upper jejunum, increasing the flow still further until the mid jejunum when absorption comes to predominate and flow decreases progressively until only 1–2 L enter the colon (Table 1).

Table 1 Approximate daily volume and composition of intestinal secretions produced in response to food

	Volume (litres)	pH	Na	K	Cl (mmol/L)	HCO_3	Mg	Ca
Saliva	0.5	7	45	20	44	60	0.7	1.3
Gastric juice	2.0	2	10	10	130	0	0.5	2.0
Pancreatic juice	0.6	8	140	10	30	110	0.2	0.3
Hepatic bile	0.9	7	145	5	100	28	0.6	2.5
Small bowel secretion	1.8[a]	7	138	6	141	<5	<0.1	2.5
Serum		7.4	140	4	100	24	1.0	2.4

[a]This fluid is released and absorbed on the mucosa and rarely needs to be taken into account in calculating fluid losses. Estimates of its electrolyte composition are unreliable [8]

Jejunum and Ileum

The proximal two-fifths of the small bowel is called the jejunum, and the distal three-fifths the ileum. The jejunum diameter is 4 cm, and that of the ileum 3.5 cm. The small intestinal absorptive area is vastly increased by the villi, there being 20–40 per mm of small bowel [1]; villi are longer and more numerous in the jejunum than in the ileum (Fig. 2). The endothelial cells that line the villus are made in the crypts and migrate to the villus tip from where they are shed; these cells have a life span of only 2–5 days. The jejunum has many circular folds and is thicker, more vascular and muscular than the ileum but it has few lymphatics. The ileum has few circular folds and it contains many lymphoid follicles [1].

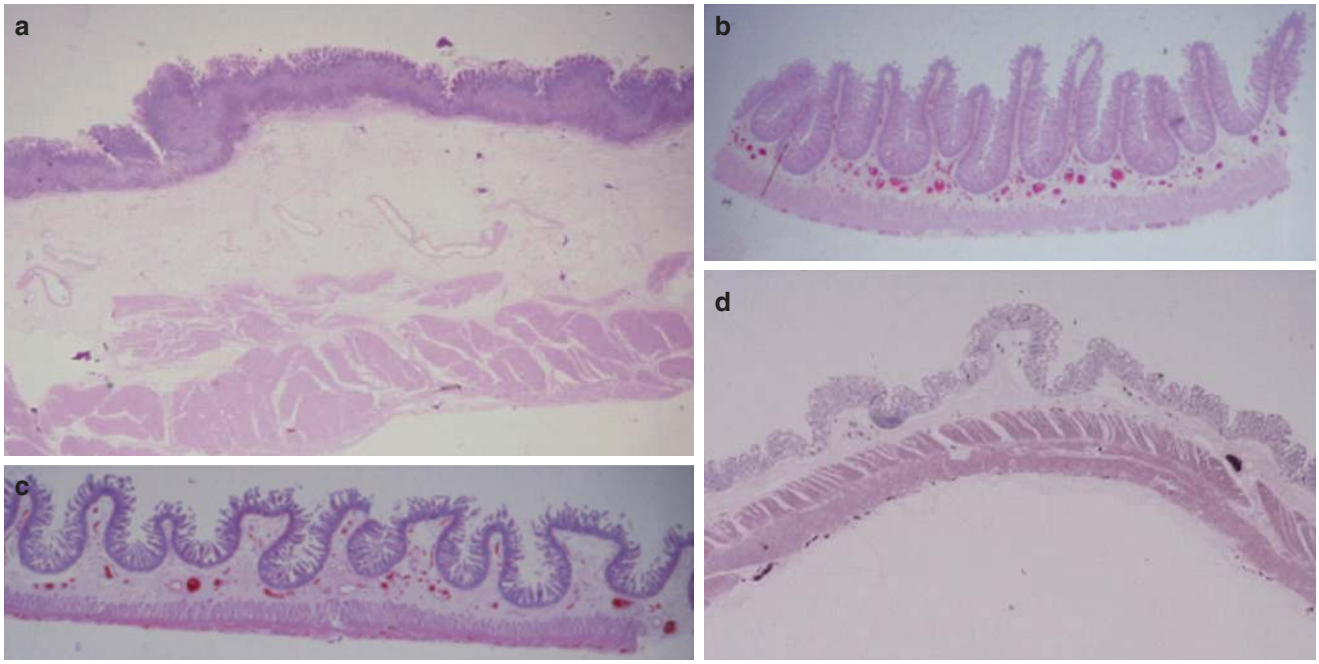

Fig. 2 Histological full-thickness sections of (**a**) stomach, (**b**) jejunum, (**c**) ileum and (**d**) colon. Kindly provided by P Domizio

Length of the Small Intestine

The normal human small intestinal length from the duodenojejunal flexure to the ileocaecal valve as measured at autopsy, by a small bowel enema or at surgery varies from 160–1510 cm (Table 2) [9–22] and is shorter in women and in most studies correlates with height. The full intestinal length is achieved by 10 years of age [9]. Congenital cases of patients having problems due to a short length of intestine have been reported [23]. Radiological measurements of small bowel length give shorter results than those obtained at autopsy or surgery, partly because radiographs are only in two dimensions. A small bowel enema [21, 22] causes bowel distension leading to overall shortening. The bowel may also be apparently shortened when measurements are made after passing a small flexible polyvinyl plastic tube through the nose to the caecum [20] as this causes the bowel to concertina around the tube [24]. The differences in length between fully stretched small bowel and non-stretched small bowel and between fully stretched small bowel and laparoscopic bowel was 137 ± 19 cm and 32.4 ± 11.4 cm, respectively [19].

An appreciation of the wide range of normal small intestinal length is important and emphasizes the need, after a bowel resection, to refer to the remaining length of small intestine rather than to the amount resected.

[a]Autopsy measurements from pylorus, all others from the duodeno-jejunal flexure (duodenum = 25 cm)
[b]21 of these patients had small bowel and 4 others colonic Crohn's disease but their small intestinal lengths were not different from 13 patients without Crohn's disease

Digestion and Absorption in the Small Intestine

Water, Sodium and Chloride

Although some water and sodium may be absorbed before chyme reaches the jejunum in most normal subjects, a meal continues to be diluted by secretions at a distance of 100 cm distal to the duodeno-jejunal flexure [4, 5]. This distance is clinically important: if a patient has a stoma situated in the upper 100 cm of jejunum, the volume that emerges from the stoma is likely to be greater than the volume taken by mouth. Such a patient will be in negative fluid and sodium balance after any food or drink [25]. Most meals have a low sodium content (10–40 mmol/L), generating a steep concentration gradient between the lumen and plasma. Sodium-rich salivary and pancreatico-biliary secretions raise the luminal level, as do intestinal secretions, so that the sodium concentration at the duodeno-jejunal flexure reaches about 90 mmol/L and increases further towards 140 mmol/L in the terminal ileum [5].

Jejunal mucosa is more permeable to water, sodium and chloride than ileal mucosa. It allows back diffusion through leaky intracellular junctions so the jejunal contents become iso-osmolar. Thus water movements in response to an osmotic gradient in the jejunum are nine times as great [26] and sodium fluxes twice as great [27] as in the ileum. Sodium absorption in the jejunum can occur only against a small concentration gradient, depends upon water movement, and is coupled to the absorption of glucose and some amino acids [28]. When the small bowel is intubated and perfused with solutions containing different amounts of sodium, absorption of sodium from the perfusate occurs if its sodium concentration is 90 mmol/L or more, while secretion of sodium into the lumen occurs if the concentration is less. Several studies have shown that maximal jejunal absorption of sodium from a perfused solution occurs at a concentration of around 120 mmol/L [29–31]. In contrast, the ileum can absorb sodium against a concentration gradient, and movement of sodium is not coupled with glucose or other nutrients. The ileum is important in conserving sodium and water when the body becomes depleted since, unlike the jejunum, the ileal mucosa can increase its sodium absorption in response to aldosterone [32]. Some chloride is actively absorbed in the ileum in exchange for bicarbonate.

Macronutrients

The salivary, gastric and pancreatico-biliary secretions reduce large molecules (e.g. polypeptides, polysaccharides, nucleotides) into medium-sized ones (e.g. oligopeptides, oligosaccharides and nucleosides) within the gut lumen. They are not designed to create small molecules (e.g. amino acids, glucose or nucleic acids) as these would be hyperosmolar and thus cause water secretion and an osmotic diarrhoea. The final breakdown to small molecules occurs at the mucosal brush border immediately before absorption (Table 3). Intubation studies in healthy subjects have shown that most polysaccharides, proteins and fats are digested and absorbed within the upper 200 cm of the small intestine [4]. The site of absorption of a meal depends upon its nature. Fibre may trap water and impede access to the mucosa and/or bind digestive enzymes reducing their efficacy. In general meat and salad are absorbed high in the jejunum, while milk and doughnuts are absorbed more distally, after a large amount of water has been secreted.

Table 3 Content and function of most upper gastrointestinal secretions

Secretion	Content	Functions/released/activated by
Saliva	α-Amylase	Converts starch to oligosaccharides, maltose, maltotriose and α limit dextrins. Needs pH 7, inactive in gastric acid
	Lipase	From lingual glands, cleaves MCTG to MCFA/glycerol, active at pH 2.5–6. Irreversibly inactivated at pH < 2.4 [33]
Gastric juice	HCl	Denatures protein, kills micro-organisms, activates pepsinogen released by gastrin, food, cholinergic agents and hypoglycaemia
	Pepsin(ogen)	Hydrolyses bonds by aromatic amino acids (tyrosine and phenylalanine) and leucine (collagen) at pH 2–3. Activated by acid
	Lipase	Cleaves MCTG to MCFA/glycerol, acid stable
	Intrinsic factor	Binds B_{12} and the complex is absorbed in the terminal ileum
	Gelatinase	Liquefies gelatine
Pancreatic juice	Bicarbonate	To neutralize acid and provide optimum pH for pancreatic enzymes, released by secretin
	α-Amylase	Starch to oligosaccharides, maltose, maltotriose and α limit dextrins
	Lipase	1 and 3 glycerol/fatty acid bonds hydrolysed, inhibited by acid
Endopeptidases	Trypsin(ogen)	Cleaves bonds next to arginine and lysine. It is activated by enterokinase an enzyme produced by duodenal mucosa and by itself. It activates all other pancreatic proteolytic enzymes
	Chymotrypsin(ogen)	Cleaves bonds by tyrosine, tryptophan, phenylalanine, methionine and leucine. Activated by trypsin
	(pro)Elastase	Cleaves bonds by alanine, glycine and serine, activated by trypsin
Exopeptidases	(pro) Carboxypolypeptidase A	Cleaves bonds by valine, leucine, isoleucine and alanine (contains zinc), activated by trypsin
	(pro) Carboxypolypeptidase B	Cleaves bonds by arginine and lysine
	DNA/RNAases	Nucleotides to nucleosides
	Esterase	Cleaves cholesterol esters
	(pro)Phospholipase A	Cleaves lecithin to lysolecithin
Bile	Bile salts (primary/ secondary)	Bind fat to form globules; then, after lipase has acted, form small micelles which transport the lipid to the brush border
Mucosa[a]	Bicarbonate	Neutralizes acid generated in process of digestion
	Enterokinase	Activates trypsin
Disaccharidases		Disaccharides to monosaccharides
	Maltase	Maltose to glucose
	Isomaltase	Isomaltose to glucose
	Sucrase	Sucrose to glucose and fructose
	Lactase	Lactose to glucose and galactose
	Trehalase	Trehalose to glucose
	α-Dextrinase	α Limit dextrins to glucose
Exopeptidases		
	Aminopeptidase	Peptides to amino acids hydrolysis starting at amino end
	Dipeptidases	Dipeptides to amino acids
Nucleosidases		Cleave nucleoside to nucleic acid and hexose/pentose

(): the name of the enzyme in its inactive secreted form

[a]Mucosal brush border (secretion of glycoprotein enzymes)

Carbohydrate and Protein

Saliva and gastric and pancreaticobiliary secretions break down carbohydrate and protein to oligosaccharides and oligopeptides. The final stage of carbohydrate and protein digestion therefore occurs on the mucosal brush border where oligosaccharides are broken down to monosaccharides and oligopeptides are broken down to amino acids immediately before absorption. In the jejunum, glucose and galactose absorption is partly coupled with that of sodium; fructose absorption occurs largely via the facilitative transporter GLUT5.

Protein is digested by enzymes that cleave protein either at specific points in the middle of proteins, endopeptidases (pepsin, trypsin, chymotrypsin and elastase), or work systematically from the ends, exopeptidases. Carboxypeptidases from pancreatic juice start at the carboxyl end while aminopeptidases on the brush border start at the amino end.

Lipid

Triglycerides and fatty acids separate into a lipid phase and do not contribute to the osmotic forces that dominate fluid flux across the small intestinal mucosa. Salivary and gastric lipase are active in the gastric juice and start digestion by splitting monoglycerides from triacylglycerol. Monoglycerides combine with bile salts to generate micelles. Shearing forces around the pylorus are believed to contribute to emulsification, the process that generates fatty droplets in the duodenum. This requires agents such as bile salts and lecithin to lower surface tension, thereby acting like soap and keeping the droplets in solution. The increased surface area of lipid is acted upon by co-lipase and lipase which cleave fatty acids from triglyceride mainly at the 1 and 3 positions. This enzymatic reaction continues as the products (free fatty acids and 2 monoglycerides) are immediately bound by bile salts to form micelles, allowing them to diffuse to the mucosal brush border for active absorption. There, fatty acid binding proteins allow removal of fatty acids from the micelles, which then diffuse back into the lumen to solubilize more lipid. The micelles protect the brush border from the damaging effects of free fatty acids.

The liver makes two bile acids, cholic and chenodeoxycholic acid. These are conjugated with glycine or taurine in the ratio 3:1. The taurine conjugates are more soluble and are present in a greater amount in people who eat meat than in vegetarians. Each day, one-third to one-quarter of the primary bile acids undergo anaerobic bacterial dehydroxylation within the terminal ileum and colon. This dehydroxylation takes place at position 7 and results in the formation of the secondary bile acids, deoxycholic acid and a little relatively insoluble lithocholic acid respectively. Most lithocholic acid is sulphated and amidated and lost in the stool. Normal human bile therefore consists of 50% cholic acid, 39% chenodeoxycholic acid, 15% deoxycholic acid and 5% lithocholic acid. The individual bile salt pool amounts to 3–5 g that circulates through the entero-hepatic circulation 5–14 times daily. This circulation is important for the action of some drugs, such as loperamide, that enter it; if the entero-hepatic circulation is disrupted (e.g. by an ileal resection) higher than normal doses of loperamide are needed for the same effect. Cholesterol also undergoes secretion in the bile and reabsorption in the small intestine, the balance of which has an important effect on serum levels. Reabsorption can be reduced by poorly absorbed plant phytosterols such as sitosterol, which competitively inhibit cholesterol uptake into micelles [34]. Fibre supplementation reduces reabsorption of bile salts by increasing ileal contents' viscosity. Ispaghula and pectin are particularly effective, while bran is ineffective. This is important because bile salt excretion stimulates bile acid synthesis from cholesterol and hence lowers serum cholesterol [35].

Long-chain fatty acids (C14–20) are absorbed and formed into chylomicrons which pass via the thoracic duct to the systemic circulation. Medium-chain fatty acids (C6–12) are absorbed in the small and large bowel and pass directly into the portal venous system; they are readily oxidized in the liver via a carnitine independent pathway.

Nucleotides

Deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) are broken down to nucleosides by pancreatic DNA/RNA endonucleases and exonucleases, which cleave from either the middle or the end of the molecules respectively. Phosphodiesterase hydrolyses nucleotides from the 3′ end. The resulting nucleosides are split into nucleic acids and pentoses by nucleosidases at the brush border immediately before absorption.

Micronutrients

Vitamins

Water-soluble vitamins are actively absorbed from the upper intestine, with the exception of vitamin B_{12} which is selectively absorbed from the distal 60 cm of ileum [2]. The fat-soluble vitamins A, D, E and K, essential fatty acids and cholesterol do not have specific active uptake mechanisms but dissolve in the lipophilic centre of the micelles; this allows these hydrophobic molecules to diffuse through the

aqueous chyme to reach the lipid outer membrane of the brush border into which these lipophilic substances readily diffuse.

Minerals

Magnesium

Magnesium is an important cation that is a cofactor for many intracellular enzymatic reactions while its extracellular concentration modulates neuromuscular excitability; 50% is in bone. Each day, about 10–20 mmol of magnesium are consumed, of which about one-third is absorbed, principally by a gradient-driven saturable process occurring mainly in the distal small intestine and colon [36]. The proportion absorbed varies according to the amount of magnesium in the diet. When the total dietary magnesium is increased to 24 mmol in a healthy person only 24% is absorbed, while if the dietary intake is reduced to 1 mmol 76% is absorbed [37]. The jejunal absorption of magnesium, like that of calcium, is increased by 1,25-dihydroxycholecalciferol [38]. Magnesium in the circulation is 30% bound to albumin. The serum levels, however, are an unreliable index of magnesium status, and severe deficiency can occur when the serum levels are normal [39]. Under conditions of magnesium deprivation the kidney can reduce magnesium excretion to less than 0.5 mmol/day [40]. Aldosterone increases [41] and parathormone reduces renal magnesium excretion [42]. Very little magnesium is found in the intestinal secretions (Table 1).

Calcium

Of the calcium ingested, 30–80% is normally absorbed, mainly by active transport in the upper small intestine. The transport is facilitated by 1,25-dihydroxycholecalciferol, lactose and protein. Phosphates, phytates and oxalate form insoluble complexes with calcium and thus inhibit calcium absorption.

Iron

Normally, only 3–6% of the iron ingested is absorbed; this is sufficient to replace losses of 0.6 mg/day in men and 1.2 mg/day in women. Gastric acid dissolves insoluble iron salts and facilitates the reduction of ferric iron (Fe^{3+}) present in most food to ferrous iron (Fe^{2+}) which can be actively absorbed in the upper small bowel. This reduction depends on ascorbic acid, which is actively secreted in gastric juice, and other reducing agents in the diet. The amount of iron entering the circulation via the iron export protein ferroportin 1 is carefully controlled by the liver-derived regulator, hepcidin. Only a small amount is allowed to enter the circulation, while the rest is bound to apoferritin to form ferritin within a mucosal cell. This poorly absorbable complex enters the gut lumen when the mucosal cell is shed and is thus lost from the body.

Zinc

Like iron and calcium, zinc is mainly absorbed in the upper small intestine; blood levels peak 2–3 h after ingestion. Endogenous, particularly pancreatic, secretions contain substantial amounts of zinc. Intestinal luminal levels of zinc fall distally as it is actively absorbed, a process facilitated by the absorption of dipeptides. Once absorbed, it is bound to albumin and circulating macroglobulin. Excretion is via sweat and in urine and faeces. Zinc absorption is, like that of calcium, impaired by dietary phytate and oxalate [43]. Geophagia (ingestion of clay) is associated with severe zinc deficiency characterized by hypopituitarism and dwarfism [44]. Zinc deficiency is frequent in patients with Crohn's disease as there are excessive faecal losses together with a poor intake [45].

Copper

This potentially toxic metal is rapidly absorbed and loosely bound to albumin. It is rapidly taken up by the liver and avidly secreted into the circulation bound to caeruloplasmin. Deficiency is extremely rare; it can cause a microcytic anaemia and twisted abdominal hair. The main clinical problem in copper metabolism is failure to excrete it adequately. Urine excretion is normally low and the main route of excretion is via bile where copper forms a complex with a fragment of caeruloplasmin which prevents its reabsorption. Defective excretion is seen in Wilson's disease, an autosomal recessive trait characterized by caeruloplasmin deficiency and hence an accumulation of copper in the liver with resulting fibrosis.

Ileocaecal Valve

The ileocaecal valve consists of two semilunar flaps projecting into the lumen of the large bowel at the junction of the caecum and colon. Two main functions are classically attributed to the ileocaecal valve: (1) to control the passage of ileal contents into the caecum, so allowing adequate time for digestion and absorption; and (2), more importantly, to prevent the regurgitation of caecal contents into the small bowel [46]. These functions are questionable: in patients

who had had a right hemicolectomy for localized colon cancer, transit of a scrambled egg meal from the small to large bowel was qualitatively and quantitatively the same as in healthy subjects [47]. The mean anaerobic bacterial count in the distal ileum is 10^4/ml compared with 10^8/ml in the caecum; the mean coliform content is 10^3/ml in the ileum and 10^6/ml in the caecum [48]. No major episodes of colo-ileal reflux occur when the ileocaecal valve has been removed [47], thus the bacterial population in the ileum is unlikely to be changed. Ileal peristalsis is probably the main factor that keeps the number of bacteria in the small bowel so much lower than in the colon. The ileum can differentiate between liquid and solid but the ileocaecal junction cannot [49].

Colon

The average length of the colon at autopsy is about 1.6 m (range 0.8–3.3) [8, 9, 11], being longer in men than in women. The unstretched colon at colonoscopy is much shorter at about 0.9 m and its undisturbed volume averages 551 ml [50]. The colon has many haustra and its longitudinal muscle is reduced to three longitudinal bands (taeniae coli) [1]. It has the functions of absorbing water (up to 6 l/day) [51], sodium, minerals (e.g. magnesium and calcium), some vitamins and fermenting unabsorbed non-starch carbohydrate to short-chain fatty acids (acetate, propionate and butyrate). The appendix and terminal ileum may secrete antimicrobial substances to regulate the colonic bacterial flora. The functions of the right and left sides of the colon are different. The right side is mainly involved with water and sodium absorption and with fermentation (to produce short chain fatty acids and amino acids); the left colon is largely a storage and propulsive organ. The colon avidly absorbs sodium and chloride against a high concentration gradient and so normal stool contains very little sodium and chloride.

Evidence that the colon can absorb nutrients and minerals comes from reports dating as far back as ancient Egypt of various mixed enema solutions containing such ingredients as milk, egg, beef broth, wine or brandy being used to give nutrition support [51], and from the fact that magnesium poisoning can occur from magnesium sulphate enemas [52].

Gastrointestinal Motility

The gut is innervated by the vagus nerve (parasympathetic) which contains 90% sensory (afferent) and 10% efferent neurones. Information travels from the gut lumen to the brain via mucosal free nerve endings and entero-endocrine cells. These cells, whose microvilli extend into the gut lumen, respond to a range of stimuli including bacteria toxins, pH, osmolality and lipid, as well as direct contact. Stretch of the gut wall may also activate tension receptors in the muscle layers. The gut is additionally innervated from the spinal (sympathetic) nerves. There is a complex interchange of information between the submucosal and myenteric plexus and the brain. The pattern of gastrointestinal motility depends upon whether an individual is in a fasted or fed state. The electrical activity recorded from the gut does not always correspond to the pressure activity.

Stomach and Small Intestine

Fasting

During fasting, three phases of pressure activity can be identified: during phase I there is no activity; irregular activity occurs during phase II; phase III is characterized by strong rhythmic contractions starting in the stomach and spreading distally. Phase III, also called the interdigestive migrating complex or migrating motor complex (MMC), occurs every 90 min (range 50–140) and lasts for 5–10 min in any one area; it takes about 90 min to reach the terminal ileum. Although the MMC shows great regularity in a trained laboratory dog, in man its frequency and form varies both between and within an individual [53]. Some MMCs start in the stomach while the majority commence in the mid-jejunum, many petering out before reaching the terminal ileum. The MMC is strongly propulsive and is thought to be responsible for clearing the last part of a meal from the stomach and small intestine, thus having a 'housekeeper' function [54]. Loss of the MMC is associated with small bowel bacterial overgrowth [55].

Just before the MMC, there is an increase in the concentration of gastric acid and pepsinogen secreted, followed by an increase in the concentration of secreted pancreatic enzymes and bicarbonate [56]. These secretions may be the reason why, even in the fasting state, there is some output from a high jejunostomy.

Fed

In the fed stomach, a wave of depolarization (gastric slow wave or basic electrical rhythm) is associated with a peristaltic wave that starts in the mid-stomach and spreads to the pylorus every 20 s (3/min). Liquid from a mixed liquid and solid meal starts to empty as soon as it reaches the stomach, and 50% of 200 ml orange juice consumed with a pancake has left the stomach at 98 min. If the liquid is taken alone, the rate of gastric emptying is much faster. The solid emptying usually occurs in a linear fashion after a variable lag phase (usually 20–30 min) during which the meal remains in the

fundus undergoing digestion and dilution by gastric secretions. Thus the time taken for 50% of a solid pancake to leave the stomach is 150 min [57].

The frequency of the slow wave, which is now thought to originate in the interstitial cell of Cahal, varies from 12/min in the jejunum to 8/min in the ileum. Small bowel contractions can be segmental or peristaltic (rate 2–25 cm/s), peristalsis predominating in the duodenum while segmenting contractions predominate further distally. Peristalsis can cause very rapid transit if there is no inhibitory feedback from nutrients; thus water can reach the caecum in 15 min. Even with nutrients, the first part of a liquid meal can travel very rapidly, reaching the caecum in just 14 min for liquid and 24 min for solid [57]. This first sample then excites inhibitory feedback responses which slow gastric emptying to allow time for digestion and absorption. After the bulk of a meal has been emptied from the stomach, 'fasting' activity resumes.

Colon

Most of the time there is segmental contracting non-propulsive activity within the colon which allows mixing of the colonic contents and time for absorption. Several times a day, high-pressure propulsive peristaltic waves propel some of the colonic contents to the rectum ('mass movement'). Isotope studies have shown that the first part of a meal remains in the colon for a median of 31 h (range 24–48). In normal subjects most of a meal will have left the bowel within 3 days of being eaten. Colonic transit is slower in women [58]. On a Western diet, stool weight is about 200 g/day.

Controlling Mechanisms

Appetite

Body weight is a result of the balance between food intake and energy expenditure/losses. There are many factors that control appetite (regulated in the hypothalamus) and thus food intake (hunger and satiety). They include the hormone ghrelin which is the only known orexigenic gut hormone that promotes appetite while many anorexigenic gut hormones, including cholecystokinin (CCK), pancreatic polypeptide (PP), peptide YY (PYY), glucagon-like peptide (GLP)-1, and oxyntomodulin reduce appetite. Leptin is another hormone that is secreted exclusively by white adipose tissue adipocytes and reduces food intake and body weight [59]. Some bacterial metabolites (e.g. SCFAs which inhibit gastric emptying) reduce appetite.

Gastrointestinal Tract

The rate of gastric emptying is normally controlled by both neural and hormonal mechanisms so that chyme is delivered into the intestine at a rate optimal for digestion and absorption. There are at least four gastrointestinal sites which, depending on their luminal contents, may affect gastric emptying: the stomach itself, the proximal small bowel, the distal small bowel, and the colon and rectum. Large volume [60], high nutrient density (e.g. lipid-based) [61], hyper- or hypo-osmolar solutions [62] or acid [63] meals all slow gastric emptying. A painful stimulus applied outside the gut will also delay gastric emptying [64], as do various inflammatory cytokines released during infections. The upper small intestine regulates the rate of gastric emptying: studies in dogs have shown that the longer the length of duodenum and jejunum exposed to glucose [65], acid [66] or lipid (sodium oleate) [67], the greater the delay in gastric emptying. An infusion into the human ileum of lipid [68–70], protein hydrolysate [71] or carbohydrate [72, 73] delays proximal small bowel transit, and lipid [69, 74, 75] and carbohydrate [76] also delay gastric emptying. The effect of nutrients in the ileum in delaying gastric emptying and small bowel transit is referred to as the 'ileal brake'.

Evidence for two mechanisms, one delaying gastric emptying and the other delaying small bowel transit, comes from experiments which show that intravenous naloxone prevents intralipid infused into the ileum from slowing small bowel transit but does not prevent it from slowing gastric emptying [77, 78].

Events within the colon affect the rate of gastric emptying. Balloon distension in the colon or rectum of animals [79–82] and man [83] causes a rapid inhibition of gastric and intestinal contractions and tone, so delaying gastric emptying and intestinal transit. This is probably the result of a neural mechanism as the effect in animals can be abolished by splanchnic nerve excision [80, 81]. However, there is also a hormonal component as balloon inflation of the rectum causes delayed inhibition of motility in denervated jejunal loops [82]. When unabsorbed nutrients reach the colon in patients with jejunum anastomosed to colon, there is rapid slowing of gastric emptying [57]; this is probably caused by raised peptide YY levels [84] and is referred to as the 'colonic brake'.

Gastrointestinal Hormones

A hormone is a blood-borne chemical messenger that has an identifiable structure, is released in one part of the body and, after passing in the blood stream, has a physiological action in another part, even when all neural connections between

the two parts have been severed. It should also be possible to inject the hormone and induce its physiological effects.

The various gastrointestinal hormones are described here in some detail not only because they are important in controlling the activity of the gut but because they are used and may be increasingly used in the future to treat some patients with intestinal failure. Most of the hormones fall into one of two families according to their molecular structure: the gastrin family (gastrin and cholecystokinin) or the secretin family (gastric inhibitory peptide, glucagons, secretin and vasoactive intestinal peptide). The hormones (Table 4), which all are produced in response to luminal stimuli, have four main areas of action: (1) to control gastric emptying or secretion (gastrin and somatostatin); (2) to regulate the rate of digestion (cholecystokinin, secretin, gastric inhibitory peptide and motilin); (3) to slow the rate of gastrointestinal transit (GLP-1, neurotensin and peptide YY); or (4) to promote intestinal growth (GLP-2, enteroglucagon and neurotensin). Only five—gastrin, secretin, CCK, GIP and motilin—are true hormones, the others being better regarded as neuromodulators with a principally local or paracrine action. The link with the nervous system is important and many hormones are released after vagal stimulation (e.g. gastrin, somatostatin, pancreatic polypeptide and VIP).

Ghrelin

Ghrelin is a 28–amino acid peptide hormone, produced mainly in the stomach and is the only known orexigenic gut hormone (increases appetite/hunger and reduces satiety). It binds to the growth hormone secretagogue receptor (GHSR) 1a which is highly expressed in the hypothalamus and brain stem. It has been shown to stimulate appetite in both lean and obese humans, and intravenous infusions given to healthy volunteers, at a concentration similar to that observed after a 24 h fast, increase appetite and food intake by almost 30%. There is animal evidence that blocking its signaling results in a reduced body weight [85]. Ghrelin levels rise pre-prandially and decrease to baseline levels within the first hour after a meal.

Gastrin

Gastrin exists as two forms produced by the G cells situated in the gastric antrum, duodenum and jejunum. Big gastrin, G34, is found mainly in the duodenum; it has plasma half-life ($t^{1/2}$) of 42 min and is the most abundant form in the circulation in the fasting state. Little gastrin, G17, which is mainly found in the gastric antrum, has a $t^{1/2}$ of 5 min and is a more powerful stimulus in causing gastric acid secretion. Gastrin release is caused by amino acids and peptides in the stomach and by vagal nerve stimulation as occurs with hypoglycaemia or hypercalcaemia. Both forms of gastrin are inactivated in the small bowel and kidney, which may in part explain the hypergastrinaemia seen after an extensive small bowel resection or in patients with renal failure. Gastrin stimulates gastric acid and pepsin secretion in the stomach partly by causing histamine release from enterochromaffin-like (ECL) cells. Gastrin increases antral smooth muscle activity and may have a trophic effect. Excess gastrin gives rise to the Zollinger–Ellison syndrome which is characterized by duodenal and jejunal ulcers [86] and diarrhoea; the diarrhoea is the result of malabsorption caused by the excess gastric acid inhibiting pancreatic enzyme function and micelle formation.

Somatostatin

Somatostatin has been referred to as ‘endocrine cyanide’ as it reduces the circulating levels of all known gastrointestinal peptide hormones, most anterior pituitary hormones, and many others (e.g. calcitonin and renin). By endocrine, paracrine and neurotransmitter actions, it inhibits most gastrointestinal functions. It reduces gastric, pancreatic and biliary secretions [87] and reduces pentagastrin-stimulated salivary flow [88]. It slows small bowel transit, may delay gastric emptying, reduces gastrointestinal blood flow and reduces the absorption of carbohydrate, lipid and amino acids. Tumours that produce excess somatostatin (somatostatinomas) may give rise to a triad of diabetes, gallstones and malabsorption [89].

Cholecystokinin

Cholecystokinin (CCK), which was shown to be the same as pancreozymin in 1966, is rapidly metabolized by the liver. It acts as a primary regulator of upper gastrointestinal function as it balances lipid and protein digestion with the rate at which they are delivered to the small intestine. It reduces the amount of chyme reaching the upper small intestine by causing satiety [90–92] and reducing gastric emptying, while at the same time promoting digestion by causing gallbladder contraction and pancreatic secretion [93]. There are two types of CCK receptors: CCK-A in the gallbladder, pancreas

Table 4 Gastrointestinal hormones

Hormone	Amino acids	$t^{1/2}$ min	Main site	Released by	Main functions
Ghrelin	28	*35*	Parietal cells of the gastric fundus	Fasting (inhibited by food esp. protein/CHO)	Increase appetite
Gastrin	17/34	5/42	Antral G cells	Protein	Gastric acid secretion
				High serum calcium	
				Pepsinogen secretion	
Somatostatin	14/28	3	Antral/pancreatic D cells	Food (especially lipid) or acid in duodenum	Reduces salivary, gastric and pancreatico-biliary secretions
					Slows gastric emptying
					Slows small bowel transit
					Reduces portal blood flow
					'Endocrine cyanide'
Cholecystokinin (CCK)	8/33	2/5	Duodenum/jejunum I cells	Lipid and protein	Pancreatic secretion (B)
					Gallbladder contraction (A)
					Inhibits gastric emptying
					Pancreatic growth
					Satiety and memory
Secretin	27	3	Duodenum/jejunum S cells	Acid	Pancreatic bicarbonate secretion
				Starvation	Pancreatic growth
					Pepsinogen secretion
Gastric inhibitory peptide (GIP)	42	20	Duodenum/jejunum K cells	Lipid and carbohydrate	Inhibits gastric secretion
					Inhibits gastric motility
					'Incretin'[a]
Motilin	22	4.5	Duodenum/jejunum M cells	High-fat meal Alkali	Increases gastric and small intestinal motility
					Causes MMC
Pancreatic polypeptide	36	7	Pancreas	Hypoglycaemia	Gallbladder relaxation
					Reduces pancreatico-biliary secretions (not HCO_3)
Vasoactive intestinal peptide (VIP)	28	<1	Upper small intestine, colon	Intraduodenal acid	Relaxes smooth muscle
					Increases blood flow, pancreatic
					HCO_3 secretion, intestinal secretions
					Inhibits gastric secretion
Neurotensin	13	1.5	Ileum N cells	Fatty meal in upper gut	Inhibits gastric secretion, pancreatic bicarbonate secretion
					Relaxes gallbladder
					Villus/crypt growth
					Glycogenolysis
Peptide YY (PYY)	36	9	Ileum/colon L cells	Lipid or bile salts in ileum/colon	Slows gastric emptying, small bowel transit
					'Ileal and colonic brakes'
					Reduces gastric secretion, small bowel water/electrolyte absorption
Pancreatic glucagon	29	10	Pancreas A cells	Amino acids in duodenum	Inhibits pancreatic secretion
				Hypoglycaemia	Relaxes smooth muscle
					Increases blood glucose
Glucagon-like peptide-1 (GLP-1)	31	4.5	Ileum/pancreas	Rapid gastric emptying	Inhibits gastric secretion
				Lipid and carbohydrate	Inhibits gastric emptying
					'Incretin'[a]
Glucagon-like peptide-2 (GLP-2)	33	2.5	Ileum/colon L cells	Nutrients in ileum/colon	Small and large bowel villus/crypt growth
					Reduces gastric antral motility
Glicentin ("Enteroglucagon")	69	NK	Ileum/colon L cells	Nutrients	Villus growth
					Slows gut transit

(continued)

Table 4 (continued)

Hormone	Amino acids	$t^{1/2}$ min	Main site	Released by	Main functions
Oxyntomodulin	37	12	Ileum/colon L cells	Nutrients	Reduces gastric and pancreatic secretion Reduces gastric emptying Reduce appetite Incretin[a]

NK not known
[a]An 'incretin' augments the rise in plasma insulin level after oral glucose

and intestine, while CCK-B predominates in the stomach and brain. Only the first eight amino acids are needed for potency at these receptors.

Secretin

Secretin was the first of all hormones to be discovered in 1902 by Baylis and Starling who observed bicarbonate and pancreatic secretions to occur from a denervated pancreas after acid was instilled into the duodenum, and after injections of small bowel extracts [94]. It is released by duodenal and jejunal mucosa in response to acid (pH <4.5) [95], starvation and alcohol. It is metabolized in the vascular system and kidneys.

Gastric Inhibitory Polypeptide

Gastric inhibitory polypeptide (GIP) was originally thought to be an 'enterogastrone' (a substance from the bowel that inhibits gastric activity) as it is released by fat, especially long-chain fatty acids derived from triglyceride hydrolysis [96], glucose in the duodenum and to a lesser extent by amino acids. While it inhibits gastric acid secretion (also pepsin and gastrin secretion) [97] and gastric motility, these effects may not be of physiological importance in man [98]. Its main action is probably as an 'incretin' for, if GIP is infused together with glucose, a greater rise in plasma insulin occurs than if glucose alone is infused [99]. It is inactivated and cleared by the kidney.

Pancreatic Polypeptide

Pancreatic polypeptide has actions directly opposite to those of CCK. It is released rapidly after a meal but its levels remain raised long after the other hormone levels have returned to normal and its role may be to promote the storage of bile and pancreatic enzymes before the next meal [100]. It is metabolized by the liver and excreted by the kidneys. Fasting levels of pancreatic polypeptide increase with age [101] and this could contribute to the increased incidence of gallstones with age.

Motilin

Motilin release from the duodenum and proximal jejunum is stimulated by a high-fat meal and suppressed by a carbohydrate or protein meal [102]. Mixed meals thus have little overall effect on circulating motilin levels [102]. In man, unlike dogs, acid in the duodenum (not alkali) causes its release [103]. Motilin may inhibit gastric emptying at a high but physiological plasma level and promote it at a low level [104]. Motilin probably plays only a minor role in the control of normal gastric emptying; for acid infused into the duodenum or fat ingestion both delay gastric emptying yet cause motilin release [102, 103]. Motilin, however, is the only gastrointestinal hormone that has been shown to increase the rate of gastric emptying.

Motilin may be responsible for inducing the MMC, as there is a cyclical rise in plasma levels before the complex occurs and an infusion of motilin causes them to occur with increased frequency [105]. Motilin analogues such as macrolide antibiotics (e.g. erythromycin) cause premature phase III-like intense contractions of the gastric antrum and small bowel. These contractions accelerate gastric emptying and may be used to treat gastroparesis; however, the intense cramps from the small bowel contractions and diarrhoea may cause the course of antibiotics to be aborted.

Vasoactive Intestinal Peptide

Vasoactive intestinal peptide (VIP) acts mainly as a neurotransmitter but has some hormonal actions. It is metabolized locally. It is a powerful smooth muscle relaxant, and thus systemically causes hypotension, flushing and tachycardia. Its main role may be to increase the blood flow to the gut following a meal. At high levels it inhibits gastric acid secretion while stimulating pancreatic bicarbonate and intestinal fluid secretion. Tumours producing VIP (vipomas) were first reported in 1958 and are an extremely rare cause of profuse watery diarrhoea with stool volumes of 2–11 l/24 h associated with hypokalaemia and achlorhydria [106]. Symptoms may respond to injections of a long-acting synthetic somatostatin analogue, which will inhibit VIP secretion.

Neurotensin

Neurotensin is so named because it caused vasodilatation and hypotension in the rat; it also increased vascular permeability [107]. It is rapidly broken down into two fragments, each having a long half-life and being biologically active [108]. Neurotensin is found in N cells which are located mainly in the ileal mucosa; few are found in the jejunum and almost none in the colon [109]. The mechanism of neurotensin release is complex: lipid in any form taken orally or administered into the proximal jejunum causes a high and rapid rise in neurotensin levels, more so than if administered distally into the ileum [110]. It is probable that fat in the upper small intestine primes the ileal N cells by a neural or hormonal mechanism so that they can release neurotensin when exposed to this fat [110]. Neurotensin promotes small bowel growth [111].

Peptide YY

Peptide YY has structural similarities to pancreatic polypeptide. It consists of 36 amino acids with a tyrosine at each end and hence was called peptide YY [112]. It is distributed throughout the small and large intestine from duodenum to rectum (there is none in the stomach) and increases in amount from the ileum to the rectum (concentrations: jejunum 5 pmol/g, terminal ileum 84 pmol/g, ascending colon 82 pmol/g, sigmoid 196 pmol/g and rectum 480 pmol/g [113]). It coexists in the L cells with GLP-2/enteroglucagon [114, 115] and has a 70% sequence homology with the neurotransmitter neuropeptide Y. High levels of peptide YY are observed in situations in which unabsorbed nutrients reach the colon, such as tropical sprue or chronic pancreatitis [116], dumping syndrome [117] and after an ileal resection which leaves the colon in situ [84, 118]. Low levels occur in jejunostomy and ileostomy patients as their colons have been removed [84, 118].

Peptide YY may be the major hormone responsible for the ileal and colonic brakes [70, 84, 119] which slow gastric emptying and small bowel transit when unabsorbed nutrients reach the ileum or colon. Although peptide YY is stored in the same cells as GLP-2/enteroglucagon, it is unlikely to exert a major trophic effect on the gastrointestinal tract [120].

An infusion of peptide YY at a level that reproduces post-prandial concentrations causes a sustained natriuresis, probably by reducing plasma renin and aldosterone [121]. Peptide YY abolished the flushing associated with a vipoma [122].

Glucagon-Like Peptides

The existence of a bowel source of a glucagon was first realized in 1961 when the non-specific antisera for glucagon detected immunoreactive material in the gut as well as the pancreas [123, 124]. The plasma levels of this ‘enteroglucagon’ were determined by measuring total glucagon-like immunoreactivity using antisera to the middle and N-terminal portion of the glucagon sequence. Pancreatic glucagon was measured with specific C-terminal directed antisera. The enteroglucagon levels were derived by subtracting the pancreatic glucagon level from the total glucagon-like immunoreactivity [125]; This value is higher than the pancreatic glucagon level.

Enteroglucagon, as first described, consists of several different molecules all derived within the L-cells in the jejunum, ileum, and colon, often with PYY (especially in the distal gut) [114, 115] these include GLP-1, GLP-2, glicentin, and oxyntomodulin. Glicentin is probably the main molecule detected as “enteroglucagon”. The greatest concentration of enteroglucagon activity is found in the ileum and colon (duodenum 15 pmol/g, jejunum 58 pmol/g, ileum 275 pmol/g, colon 179 pmol/g and rectum 96 pmol/g) [125]; there is none in the gastric fundus and antrum. High levels may occur if there is a loss of small bowel absorptive surface area, such as in patients who have undergone small intestinal resection or jejuno-ileal bypass surgery for obesity [126].

Much information about the role of enteroglucagon in man come from the study of a single patient with a tumour that secreted enteroglucagon; it caused villus hypertrophy and increased intestinal transit time [127, 128].

The structure of human proglucagon (160 amino acids), the common precursor from which all glucagon-like molecules are post-synthetically modified, was determined in 1983 [129]. The processing of the molecule is different in the pancreas and intestine. In the pancreas it is cleaved to produce glicentin-related pancreatic polypeptide (GRPP), pancreatic glucagon and a large fragment called the major proglucagon-derived fragment (MPGF). MPGF contains GLP-1 and GLP-2. In the intestine proglucagon is cleaved to produce glicentin (69 amino acids), oxyntomodulin, both of which have glucagon activity and the glucagon-like peptides (GLP-1 and GLP-2) [130, 131]. It appears that the different molecules are produced preferentially in different sites of the intestine (e.g. GLP-1and oxyntomodulin in the small bowel and GLP-2 and glicentin in the more distal ileum/colon).

Pancreatic Glucagon

Pancreatic glucagon consists of 14 amino acids which are in the same position as in secretin, thus it can inhibit the pan-

creatic secretory response to secretin. It increases blood glucose by stimulating hepatic glycogenolysis. It is metabolized in the liver. Pancreatic glucagon is used therapeutically to relax the stomach for a barium study, and is used as a positive inotrope to treat β-blocker overdoses. Glucagonomas produce a mixture of products and are characterized by necrolytic migratory erythema, weight loss and diabetes.

Glucagon-Like Peptide-1 (GLP-1)

GLP-1 immunoactivity is co-localized with glucagon in the pancreas α-cells and enteroglucagon in the L cells in the ileum [131]. GLP-1 is secreted at the same time as pancreatic glucagon and enteroglucagon [132]. GLP-1 plasma levels rise most when gastric emptying is fast [133]. GLP-1 levels peaked 15 min after a solid meal and 15 min before insulin [133]. GLP-1 has been shown to stimulate insulin release [134, 135] and it is a more powerful 'incretin' than GIP [134]. Agonists are used to treat diabetes. It slows gastric emptying and reduces gastric secretions and there may be an effect in promoting mucosal growth so it is used in patients with a short bowel (see Chapter "Pro-adaptive hormones in the rehabilitation of adult patients with a short bowel").

Glucagon-Like Peptide-2 (GLP-2)

GLP-2 has been synthesized and its receptor characterized [136]. Its structure is highly conserved throughout all mammalian species (only 1 amino acid different in the rat). It is an enterocyte-specific growth hormone that in mice causes small and large bowel villus/crypt growth and increases small and large bowel length and weight. In mice, it also reduces body weight loss and restores mucosal integrity after colitis has been induced with dextran. In pigs, it reduces gastric antral motility [137].

As GLP-2 stimulates mucosal growth, analogues (e.g. teduglutide) have been made and given therapeutically to patients with a short bowel to promote adaptation (see Chapter "Intestinal Adaptation").

Oxyntomodulin (OXM)

OXM is named after its inhibitory action on the oxyntic glands of the stomach, it is a naturally occurring 37-amino acid peptide hormone found in the the L-cells in the small and large bowel, together with GLP-1 and it decreases gastric and pancreatic acid secretion, reduces gastric emptying, and is an incretin, suppressing appetite and causing weight loss. OXM binds to both the glucagon-like peptide-1 (GLP-1) receptor and the glucagon receptor. OXM and GLP-1 are 5–30 min after food ingestion and in proportion to meal energy content. It has a plasma half-life of approximately 12 min.

Glicentin

Glicentin was named "gli-" for "glucagon-like imunoreactivity" and "-cent-" because it was thought to be composed of 100 amino acid residues. Later it was found to consist of only 69 amino acids. Residues 33 to 61 corresponded exactly to the sequence of pancreatic glucagon. While this may be mainly what was detected as "enteroglucagon", it may not have a major role in slowing gastrointestinal transit and increasing mucosal growth.

Kinetic Architecture of the Gut

The proliferative zone is restricted to the basal two-thirds of the crypt in the small bowel and most of the colon, and to the neck region in the stomach (Fig. 3). A small number of cells at the base of this proliferative zone give rise to all the other epithelial cells [138] and can be regarded as the 'stem' cells [139]. These stem cells are of great significance as they may be the prime sites for growth control (and the main target for carcinogenesis) since they do not migrate, whereas their daughter cells are transitory and disposable. Stem cells may divide slowly and be extremely radio-sensitive; they may also be pre-programmed to self-destruct if their DNA template is badly damaged [140]. The daughter cells produced in the stem cell zone migrate up the crypt and undergo three or four 'transit' divisions before they leave the cell division cycle and differentiate to take on their functional role for their last few days before being lost. Cell death can either be a passive process, as in cell necrosis, or it can be the energy-requiring, active, gene-directed, endonuclease-activating process known as apoptosis [141]. Cell loss from the villus tip was once thought to be a passive sloughing of cells, but now is considered an active apoptotic process.

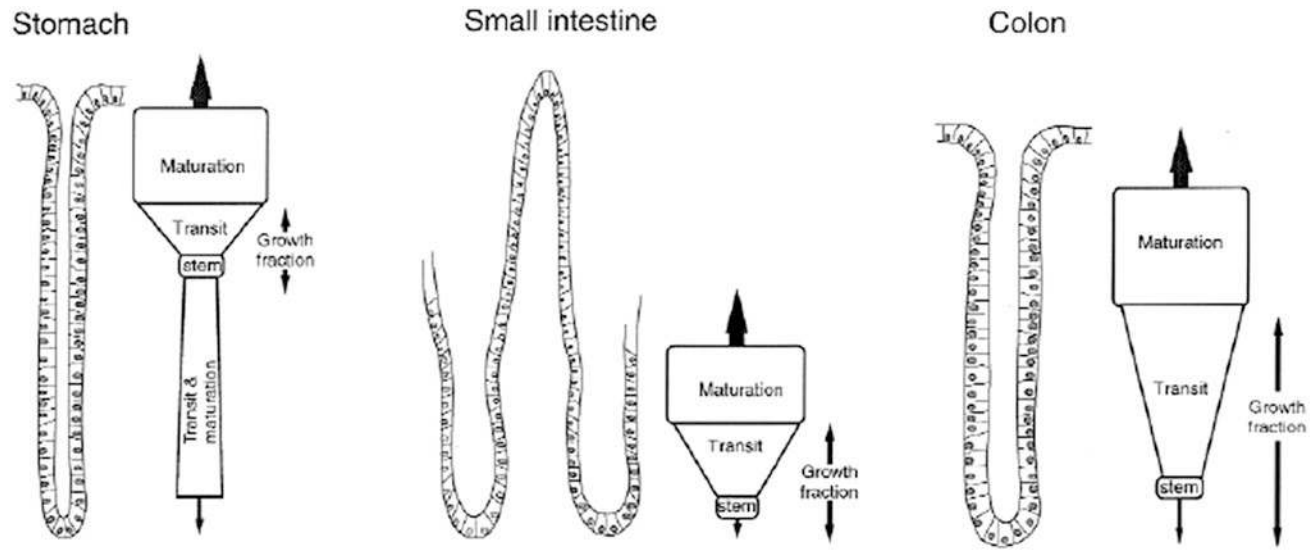

Fig. 3 Kinetic architecture of the main regions of the gastrointestinal tract. Kindly provided by RA Goodlad and RJ Playford

Crypt Proliferation

Cell division can be divided into four phases, which make up the cell cycle. Chromosomes can readily be seen separating at mitosis, which is called the M phase. The daughter cells then enter the first portion of interphase, the post-mitotic, pre-synthetic gap called G_1. Cells can either remain in G_1 or go on to the next phase of the cell cycle, the S phase, in which DNA synthesis occurs. There is then a short, second gap phase, known as G_2, in which the cell prepares for mitosis and assembles the spindle proteins. The output of cells from the crypt depends on three main factors: (i) the duration of the cell cycle; (ii) the proportion of the crypt involved in proliferation, known as the growth fraction; and (iii) the size of the crypt. Proliferative activity is not constant: there are marked circadian rhythms in proliferative activity in the gut. Some of these may be inherent but others appear to be coupled to the food intake pattern several hours previously and may be more pronounced in the colon [142].

In addition to control of cell production in the crypts, the gut can also increase its cellularity by a process of crypt division or fission, in which a crypt can be seen to develop a septum at its end; the septum then enlarges until two new crypts are created. This process is known as the crypt cycle [143]. Increased crypt fission is seen in the adult after intestinal damage [144] and after intestinal resection [145].

Immunological Functions

The huge surface area necessary for absorption renders the gut vulnerable to invasion and necessitates a complex series of defences to exclude pathogens while allowing absorption and oral tolerance of dietary antigens. The importance of this function is underlined by the fact that diarrhoeal diseases in infancy remain the commonest cause of premature death world-wide. Further evidence of the importance of adequate mucosal immunity is seen in AIDS patients who frequently suffer debilitating wasting and diarrhoea from viral, bacterial and protozoal infections. Non-immune defences are also important; these include salivary lysozyme which attacks bacterial cell walls, lactoferrin which chelates iron, thereby preventing the growth of organisms that need it, destruction of ingested organisms by gastric acid and digestive proteases, together with exclusion of pathogens by the mucus barrier and effective clearing of gut contents by propulsive motility patterns. Bile salts and antibacterial peptides secreted from Paneth cells in the base of the crypts, known as 'defensins' are also important, as are antibiotics secreted by the normal colonic flora.

Organization of the Mucosal Immune System

The mucosal immune system is provided by the gut-associated lymphoid tissue (GALT), which contains 10^{10} cells/m and accounts for 80% of the total body immunocytes. This tissue can be divided into organized and diffuse compartments. The organized GALT comprises isolated lymphoid follicles and Peyer's patches, which are collections of follicles containing precursors of T- and B-cells, commonest in the terminal ileum and proximal colon. These respond to antigenic stimulation, increasing rapidly on exposure to bacteria following birth, peaking in adolescence, and declining gradually thereafter. The diffuse GALT includes immunologically committed T- and B-cells (plasma cells producing

predominantly IgA immunoglobulin) found diffusely throughout the lamina propria and acting as the effector limb of the immune response.

Antigen Sampling

Ingested bacteria, viruses and other dietary antigens are absorbed by specialized M cells that overlie the aggregates of ileal lymphoid tissue (Peyer's patches). These cells, which account for about 10% of epithelial cells overlying the follicles, are flattened and specially adapted to rapidly pinocytose bacteria and other dietary antigens and pass them to macrophages and lymphoid cells that lie within intraepithelial 'pockets' in the M cell. Some bacteria, such as Shigella, have taken advantage of this process and use the M cell to breach the gut barrier and subsequently spread from enterocyte to enterocyte [146]. Macrophages are the main but not the sole [147] antigen-presenting cells; they take up antigens and, after processing them, present them to T-cells bound to class II major histocompatibility complex (MHC) antigens on the macrophage surface. The T-cells have receptors, structurally similar to immunoglobulins, which recognize specific antigens. They are composed of two subunits, most commonly of α and β type or less commonly of γ and δ type. These bind to the antigen–MHC complex and are thereby activated, a process facilitated by CD8 or CD4 adhesion molecules which bind to a constant region of either the class I or II MHC molecules respectively. Class II MHC molecules are expressed on antigen-presenting cells (mainly macrophages but also some epithelial cells), but class I MHC may be expressed by almost any cell in the body. These bind 'foreign' or 'neo' antigens derived from the cytosol of infected or altered cells such as viral antigens or tumour products. This process of antigen presentation takes place mainly in the dome of the lymphoid follicle, after which antigen-specific T- and B-cell precursors migrate along the lymphatics to the mesenteric lymph nodes where they mature and clonally expand. Further migration via the thoracic duct allows distribution to the entire gut lymphoid tissue. This homing back to the gut depends on the expression of adhesion molecules, such as lymphocyte function antigen (LFA-1) on the lymphocyte and up-regulation of adhesion molecules known as 'addressins' such as VCAM-1 (vascular cell adhesion molecules) and ICAM-1 or 2 (intercellular adhesion molecules), on the endothelial cells in the lymphoid follicle [148]. There B-cells differentiate into plasma cells producing immunoglobulin, mostly IgA, while activated T-cells act as cytotoxic lymphocytes as well as T-helper cells facilitating immune response to further antigenic exposure.

Intraepithelial T-cells are predominantly CD8+ (cytotoxic phenotype) with only 10% being CD4+ (helper T-cells). Their role is unclear but they are markedly raised in coeliac disease, a condition in which the T-cell receptors are predominantly of the γδ type rather than the more usual αβ type. The significance of this finding is as yet unclear but it appears to be a marker of disease susceptibility, being found in asymptomatic relatives [149].

Dendritic Cells

Dendritic cells (DCs) are antigen-presenting cells derived from bone marrow precursors and form a widely distributed cellular system throughout the body and are especially important throughout the intestine. Similarly to the M cells, they sample gut luminal content, capturing (phagocytosing), processing, and presenting antigens to naive T lymphocytes to activate them so triggering adaptive immunity.

Gut Microbiome

The composition of gut microbiota (bacteria, viruses, protozoa and fungi) is commonly quantified using DNA sequencing based methods, which may also allow analysis of metabolic potential (using metagenetic analysis). Healthy adult humans each typically harbor more than 1000 species of bacteria belonging to relatively few known bacterial phyla with *Bacteroidetes* and *Firmicutes* being the dominant phyla, followed by *Actinobacteria*, and *Proteobacteria*. An individual's microbiome changes rapidly after birth, acquiring microbiota from mother and immediate close contacts and thereafter steadily acquiring adult characteristics during adolescence, becoming quite stable over time in adulthood with later changes with ageing, at all times showing considerable inter-individual variation. Diet and other environmental factors also affect the composition of the microbiome. The gut microbe–host interactions have effects on metabolism, immune, and neuroendocrine responses. The gut microbiota plays a role in nutrient and mineral absorption, synthesis of enzymes, vitamins (e.g. vitamin K) and amino acids, and the production of short-chain fatty acids (SCFAs). The fermentation by-products acetate, propionate, and butyrate are important for gut health and provide energy for epithelial cells, enhancing epithelial barrier integrity, and provide immunomodulation and protection against pathogens. Urea can be secreted into the colon and there is converted into essential and non-essential amino acids according to the individuals need [150]. Changes in microbiome may relate to many diseases including IBD, rheumatoid arthritis, ankylosing spondylitis, type 1 diabetes and obesity.

Probiotics are live bacteria and yeasts that, when administrated in a viable form and in adequate amounts, are beneficial to human health. Prebiotics (microbiota accessible

carbohydrates or fermentable dietary fibre) are a substrate that is selectively used by host micro-organisms to confer a health benefit. Synbiotics contain a mixture of prebiotics and probiotics.

Faecal microbiota transplantation (FMT) has become a well-accepted treatment for recurrent relapsing *Clostridium difficile* infection which can be extremely difficult to cure with antibiotics as they aggravate the underlying depletion of the microbiota [151, 152].

Comparative Anatomy

Plant-eating animals digest complex carbohydrate (e.g. cellulose) either in the upper gut or in the caecal/colonic area. Ruminants have an expanded lower end of the oesophagus that forms most of the four-chamber stomach (e.g. sheep and cattle); in plant-eating birds the mid-oesophagus expands to form the crop [153]. Non-ruminants (e.g. horses, rabbits and plant-eating birds) have a long blind-ending caecum. Protozoa, both in the rumen and caecum, assist bacteria in the fermentation of plant material. Animals that digest roots, nuts and wood (e.g. pigs and elephants) have long small and large intestines. Largely carnivorous animals such as dogs and cats have a relatively short small intestine, a very small caecum and a short muscular colon [154]. Man, as an omnivore, is similar to the pig, having a colon intermediate in size between that of herbivores and carnivores.

Definitions, Classification and Severity of Intestinal Failure

Jeremy M.D. Nightingale

Key Points

1. Intestinal failure (IF) may be defined as reduced intestinal absorption causing malnutrition and/or dehydration.
2. IF may be classified according to predicted duration as short (type I-acute), medium (type II-prolonged acute) or long term (type III-chronic).
3. Further classification is based upon the disease processes, residual anatomy and pathophysiology. This gives five groups: extensive small bowel mucosal disease, intestinal dysmotility, mechanical obstruction, fistula(s) and short bowel/bypass.
4. The severity of IF can be graded according to the type of nutritional/fluid support given.
5. The severity of IF is a continuum and intestinal rehabilitation aims to maximize gut function while using the least invasive route for nutrition/and or fluid support.

Introduction

Patients needing clinically assisted nutrition and hydration (CANH) (previously termed artificial nutritional support) are likely to have one (or more) of three problems: Inadequate oral intake, digestive failure, or absorptive (intestinal) failure that results in them being referred to a nutritional support team (NST) (Fig. 1).

Intake (oral) failure is most commonly due to a failure to swallow or anorexia with associated malnutrition. A swallowing disorder is most commonly due to neurological problems (e.g. stroke, motor neurone disease, multiple sclerosis, cerebral palsy, trauma, persistent vegetative state, dementia or Parkinson's disease) or due to cancer of the head and neck. These patients often have a functional

gastrointestinal tract (distal to the oesophagus) so are appropriate for feeding into the gut (enteral nutrition). Some have an eating disorder (e.g. anorexia nervosa) and some are unable to consume sufficient nutrition/fluid from eating and drinking for other reasons.

Digestive failure may result from the stomach being removed or bypassed or due to a failure of pancreatico-biliary secretions (e.g. pancreatitis, cystic fibrosis or pancreatic resection/bypass). These patients may benefit from pancreatic enzyme replacement in addition to oral/enteral feeding.

Absorptive (intestinal) failure has multiple underlying aetiologies. Its definition, classification and severity are discussed below.

Definition of Intestinal failure

In 1981, Fleming CR and Remington M proposed the first definition of intestinal failure as a "reduction in functioning gut mass below the minimum amount necessary for adequate digestion and absorption of nutrients" [1].

In the first edition of this book (2001), intestinal failure was defined as" reduced intestinal absorption so that macronutrient and / or water and electrolyte supplements are needed to maintain health and/or growth. Undernutrition and/or dehydration result if no treatment is given or if compensatory mechanisms do not occur. IF was also classified as mild, moderate or severe, according to the method by which nutritional supplementation was given; orally, enterally (by tube) or parenterally [2, 3].

In 2005, Jeejeebhoy KN considered IF as when gastrointestinal function is inadequate to maintain the nutrition and hydration of the individual without supplements being given orally or intravenously [4]. In his lectures he likens the gut to an "intestinal orchestra" such that if any one part fails (e.g. stomach liquidizing, pancreas digesting or small intestine absorbing) then the overall function (absorbing nutrition and/or fluid) fails.

In 2015, the European Society of Enteral and Parenteral Nutrition (European Society of Clinical Nutrition and Metabolism) (ESPEN) devised recommendations on definition and classification of IF. IF was defined as "the reduction of gut function below the minimum necessary for the absorption of macronutrients and/or water and electrolytes, such that intravenous supplementation (IVS) is required to maintain health and/or growth [5]. ESPEN defined "intestinal insufficiency" (or "deficiency" in those languages where "insufficiency" and "failure" have the same meaning) (II/D), as the reduction of gut absorptive function that doesn't require IVS supplementation to maintain health and/or growth [5]. Therefore, the ESPEN definition of IF coincides with severe IF, whereas the ESPEN definition of II/D comprises both the moderate and mild IF, as defined and classified in the first edition of this book.

In 2019/20, the England NHS specification used the term severe IF for those patients needing PS [6].

In 2021, the ESPEN definition of IF has been included in the 11th revision of the International Classification of Diseases (ICD-11: DA96.05 Intestinal failure), which is the global standard for diagnostic health information [7].

For many diseases reference is made to a system failure, though sometimes the phrase "failure" is thought to be negative. Hence other terms including impairment, insufficiency, inadequacy, injury, deficiency and disease, have all been used and currently the phrase intestinal rehabilitation is used when possible (e.g. in naming an IF unit). This book keeps the term IF but considers that it may change in the future.

Classification of IF

Expected Duration

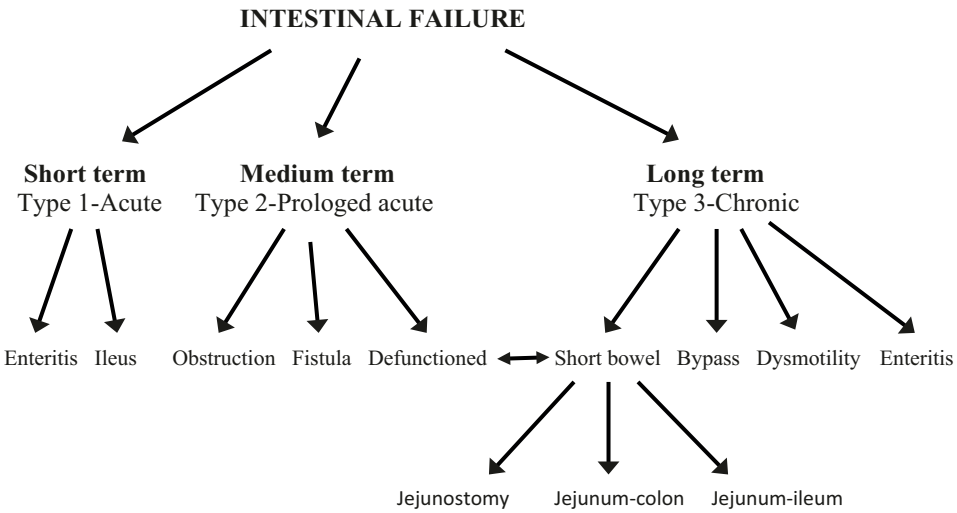
Most diseases are first classified based upon expected duration of illness as acute (short term illness that resolves) or chronic (long term illness that may be progressive). While this is still true for IF, there are 3 accepted groups: short (type 1-acute), medium (type 2-prolongedacute) and long term (type 3-chronic). Together short and medium term make up the acute group of previous classifications [2, 5].

Short term (Type I or acute IF) is usually a self-limiting condition (e.g. post-operative ileus, enteritis – infective or from chemotherapy). It lasts for less than 28 days.

Medium term (type II ot prolonged acute) is a prolonged and often more severe condition that is potentially reversible. The patients may be metabolically unstable, requiring complex multi-disciplinary care often in a high dependency unit for weeks or months. These patients usually have abdominal sepsis (often due to perforation/fistulisation), ischaemia or intestinal obstruction. This state usually lasts less than 6 months or until reconstructive surgery is performed. This group also includes those who have a resection (e.g. for ischaemia or Crohn's disease), a temporary short bowel (usually a jejunostomy) so need nutritional support before electively having bowel continuity restored [3].

Long-term (type III or chronic IF) can be due to gastrointestinal resection(s) short bowel (or gastrectomy), gut bypass (as in the surgery for obesity) or small bowel dysfunction or a chronic enteritis. The patients are metabolically stable, requiring nutritional and/or fluid support for more than 6 months and often for many years. It is most commonly irreversible unless a small bowel transplant is performed.

Fig. 2 Classification of IF



Disease Process, Residual Anatomy and Physiology

The second part of the classification is based upon the disease process (also referred to as the patho-physiological process), residual anatomy and physiology. This results in five major groups: extensive small bowel mucosal disease, intestinal dysmotility, mechanical obstruction, fistula(s), and short bowel/gut bypass (Fig. 2). A postoperative ileus is the most common reason for short term IF while a leaking gut/fistula is the most common reason for medium term IF. A short bowel is the most common reason for long-term IF and divides mainly into those with a jejunostomy and those with a colon in continuity.

Notes on Fig. 2**.**

Extensive small bowel mucosal disease is referred to as enteritis and can be a short or a long-term situation.

Dysmotility is represented in the short term by an ileus and in the long term by an enteric myopathy or neuropathy.

Any medium term condition can become long-term. For example if defunctioned bowel if not brought into circuit then the patient will be classified as having a short bowel (long-term IF).

Underlying Disease

The third part of classification is naming the specific diseases which can be included in one or more of the disease process/anatomical/physiolocical groups (Table 1) [2, 5].

Table 1 Common underlying diseases causing IF

Short term	
Mucosal disease	Gastroenteritis (includes HIV), chemo or radiotherapy
Dysmotility	Post-operative ileus (increased bowel handling, saline excess, medication and sepsis), pancreatitis and metabolic (e.g. low K)
Medium term	
Obstruction	Adhesions, neoplasia (includes desmoid) and hernias
Fistula	Post-operative complications, Crohn's disease, irradiation damage
Defunctioned	
Long term	
Short bowel	Crohn's disease, ischaemia (arterial/venous), surgical complications,trauma, volvulus, neoplasia (e.g. desmoid), atresia, gastroschisis or necrotizing enterocolitis
Bypass	Bariatric surgery, tumor and adhesions
Dysmotility	Myopathy (e.g. chronic intestinal pseudo-obstruction (CIPO)), neuropathy or idiopathic
Mucosal disease	Crohn's disease, coeliac disease, chronic ischaemia, irradiation damage, congenital (e.g. microvillus atrophy) or autoimmune enteropathy

Severity of IF

In other diseases the severity is graded upon a simple measure (e.g. ejection fraction in cardiac failure, blood gases in respiratory failure or glomerular filtration rate/creatinine in renal failure). There are measures of gut function that include xylose absorption, fasting plasma citrulline, non-fasting plasma apolipoprotein A-IV, or percentage energy absorption after a test meal (or with a normal diet). The results are

variable and balance studies are laborious and not performed in most units.

As no one test has been accepted to grade the severity of IF, the type/amount of nutritional support is used as a proxy indicator of gut function (Fig. 3).

In the previous edition of this book, the severity of IF was graded according to the type of nutritional support given *severe IF:* parenteral nutrition (PN) and/or parenteral saline are required because health cannot be sustained by exposing the small bowel mucosa to more, continuous or altered nutrients and/or electrolytes; *moderate IF:* an enteral tube is used for the administration of macronutrients and/or a glucose/saline solution; *mild IF:* dietary adjustments, oral nutrients and/or a glucose/saline solution (or sodium chloride supplements) are needed. Patient with mild IF are the most common group and are often unrecognized.

An ESPEN one-year prospective study in adults, categorized the IF into 5 groups of severity according to the type and the volume of the required PS, (PN volumes of <1, 1–2, 2–3 and >3 L/day or fluid and electrolyte alone), to be used in clinical practice and research. Clinically an aim for rehabilitating a patients having PS is to reduce the time over which an infusion given, then permit days off the PS before it is stopped [8, 9] (Fig. 3).

The use of the type of the nutritional support required as a proxy of gut function is helpful to define cost, economic impact, and severity of the disease. However, a grey zone of overlapping occurs between the categories, severe, moderate and mild IF (or IF and II/D according to ESPEN). Only 60–80% of patients admitted initially to a UK IF unit for PN ultimately go home receiving PS [9]. This may be due to factors more related to the management expertise of the professions caring for the patients and to the patient compliance with treatment than to the severity of the condition. In some cases, patients with mild/moderate IF may be categorized as severe IF (or II/D categorized as IF), because PS is prescribed instead of an otherwise effective oral/enteral support [7]. The same may occur when a patient doesn't comply with the prescribed drug and/or the dietary advice aimed to improve the intestinal absorption or to reduce the intestinal losses of fluid, so that PS is required. Indeed, the conversion of a patient from PS to oral/enteral nutrition/fluid may vary between units and also may depend upon the expertise of a unit in maximizing residual gut function. For example, giving a mucosal growth factor, establishing complete distal feeding by enteroclysis or restricting oral hypotonic fluids in patients with a jejunostomy or jejunally feeding a patient with dysmotility may alleviate the need for PS. Also, the opposite may occur, when units with low expertise in giving PS treat patients with severe IF (or IF) by a scarcely effective oral/enteral nutrition, so that they are classified as moderate/mild IF (or II/D). Furthermore, some patients may frequently change their diagnosis and classification depending upon whether they are given PS or if it is stopped. Finally, a patient may change with time, due to compensatory mechanisms, treatment (including growth factors or distal feeding) and patient compliance, from having severe IF to mild/moderate IF (or IF to II/D). For example, a patient who has had a massive small intestinal resection, and in whom intestinal adaptation has occurred, with careful dietary advice and appropriate drug therapy may be able to stop PN over 6 months to 3 years.

Research is required for a simple and objective indicator to measure the degree of intestinal dysfunction as a continuum [10].

Acknowledgements I am grateful to Loris Pironi, Khursheed Jeejeebhoy, Ezra Steiger and Mattias Soop for commenting on this introduction.

Part II

Acute (Short and Medium Term Reversible) Intestinal Failure

Postoperative Ileus

Ian Bissett and Dileep N. Lobo

Key Points

1. Avoid perioperative fluid overload.
2. Employ a standard enhanced recovery after surgery (ERAS) protocol.
3. Minimise the use of opioids.
4. Utilise minimal access techniques.
5. Prevent blood loss.
6. Don't re-operate for postoperative ileus.

Introduction

In this chapter we will consider the definition and incidence of this condition, explore the burden of prolonged postoperative ileus (PPOI) on both the patient and the health system, describe of the pathophysiology of PPOI and the main risk factors for its occurrence, list interventions that may prevent or reduce the occurrence of PPOI and present the evidence for the treatment of established PPOI. The chapter concludes with a proposed management strategy.

Definition and Incidence of Ileus

Postoperative ileus is an abnormality of the motility of the gastrointestinal tract that prevents the normal ingestion and absorption of food and elimination of waste products. Symptoms depend on the site of dysfunction. Involvement of the stomach and proximal small bowel is characterised by nausea and vomiting while more distal dysfunction results in lack of passage of flatus or stool and abdominal distension from the bowel dilatation. This dilatation of the bowel can be identified on abdominal X-ray or CT scan as bowel distension with air-fluid levels in the absence of a clear transition point to collapsed bowel on CT (Fig. 1). It is generally accepted that there is a period of 'normal' or physiological gut dysfunction following major abdominal surgery that should resolve spontaneously after a day or two. Prolongation of this period or the reoccurrence of it after return of normal function postoperatively have been recognised as Prolonged or Recurrent Postoperative Ileus.

Various definitions of PPOI have been proposed in the past including the necessity to insert a nasogastric tube after surgery, nausea and vomiting, inability to tolerate oral diet and failure to pass stool or flatus.

A novel study from the Netherlands included patients undergoing elective surgery for colonic cancer and compared scintigraphic studies of gastric emptying on day 1 and colonic scintigraphy on days 2 and 3 with specific symptoms associated with return of gut function [1]. They showed that the best measure of return on GI function was the combined measure of tolerance of solid food and defaecation. This also correlated inversely with length of hospital stay. They did not, however, provide a definition of PPOI but rather considered that all patients had postoperative ileus until both defaecation and tolerance of oral food had been achieved.

In an attempt to clarify the definition of PPOI, Vather et al. carried out a systematic review and global survey amongst those who had recently published in this area [2]. This study differentiated between normal physiological bowel dysfunction that follows surgery and when this becomes pathological as PPOI. Based on this survey they defined PPOI as the presence of any 2 of the five cardinal symptoms on or after day 4 post operatively. These are nausea or vomiting, inability to tolerate an oral diet, failure to pass flatus or stool, abdominal distension, and radiological signs of PPOI. Each of these were carefully defined. This definition provides not only the essential elements to be included but also a timeline for the commencement of

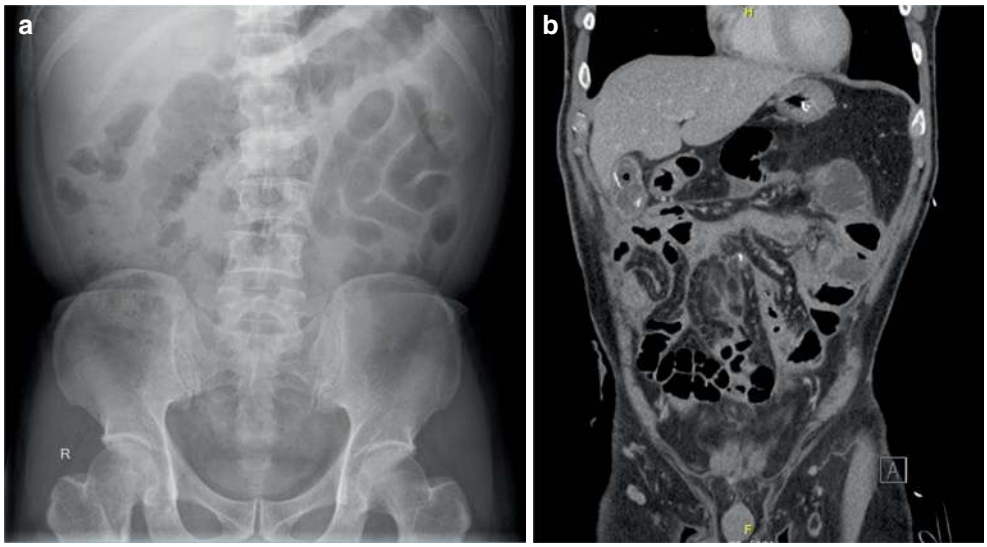

Fig. 1 A 57 year old man seven days following proctectomy and ileoanal pouch. (**a**) A plain abdominal film demonstrating distension of the small bowel and stomach. (**b**) A coronal abdominal CT demonstrating distention of the entire small bowel with a nasogastric tube visible in the stomach

PPOI. Subsequent studies have utilised this definition in their randomised clinical trials [3–5].

The incidence of PPOI varies greatly between studies from 3% to greater than 30% [3, 6]. This variation is likely to be explained by the difference in populations included in the studies, whether the data were collected prospectively and most importantly the definitions used. A recent systematic review that included 54 studies reported a pooled rate of 10% for PPOI. Unfortunately the definition of PPOI differed across the studies with the commonest definition being the reinsertion of a nasogastric tube. They showed that the rates varied depending on the definition used [7]. A snapshot study over six weeks in 10 hospitals in United Kingdom reported that 22.5% of the patients having a left or right-sided colonic resection required nasogastric tube insertion [8]. A very large study out of United States using American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP) data for patients undergoing colectomy identified prolonged postoperative ileus as the most common complication, occurring in 10% of the patients [9]. Recent prospective studies using the definition proposed by Vather et al. have identified that more than one patient in four is likely to develop PPOI following a colorectal resection [3, 10].

Burden of Ileus (Effect on Morbidity and Cost of Stay)

Prolonged postoperative ileus has major negative impacts on the patient. The patient may initially appear to be progressing well but then develops nausea and abdominal distension. Vomiting follows and the bowels cease functioning. This often requires insertion of a nasogastric tube and if it does not resolve quickly intravenous feeding is required. For patients it is frightening, unpleasant and extremely disheartening. PPOI is associated with an increase in hospital stay, prolonged intravenous fluid administration and several major complications. The most serious and sometimes fatal complication is aspiration pneumonia but bronchopneumonia, thromboembolic events, electrolyte imbalance and psychological distress are also frequently associated. Recent studies have identified it as the commonest postoperative complication after colorectal surgery [9]. This complication along with anastomotic leak caused the greatest increase in hospital stay and total treatment cost following colectomy [9].

This increased cost associated with PPOI has been estimated by Goldstein et al. to be greater than $1.5 Billion annually in USA alone [11]. A study utilising the Premier Perspective Database in USA assessed nearly 20,000 patients with colectomy. Postoperative ileus was associated with a 29% increase in length of stay and a 15% increase in cost after adjusting for the influence of all other factors [12].

Pathophysiology

The aetiology of PPOI is multifactorial. Its initiation is associated with activation of inflammatory cells, autonomic dysfunction, opioid stimulation of gut opioid receptors, electrolyte abnormalities, direct injury to the intestine and derangement of gastrointestinal hormones. These interactions, triggered by both a somatic and a visceral insult and resulting in the final gut dysmotility of PPOI, are summarised in Fig. 2.

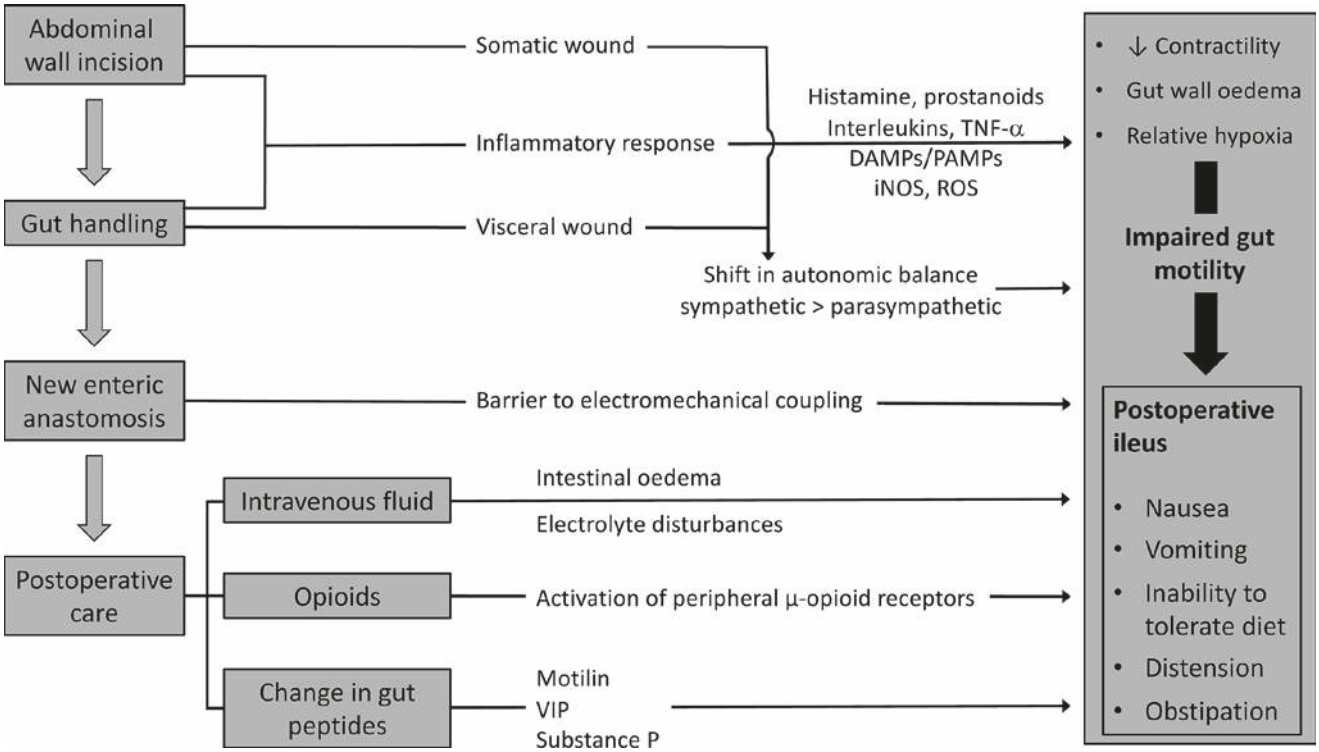

Fig. 2 Pathophysiological basis for the development of a postoperative ileus. DAMPs, damage-associated molecular patterns; PAMPs, pathogen-associated molecular patterns; VIP, vasoactive intestinal peptide, TNF-α, tumour necrosis factor alpha, iNOS, inducible nitric oxide synthetase, ROS, reactive oxygen species [13, 19] with permission [13].

Risk Factors

Multiple risk factors for PPOI have been identified in retrospective analysis of data including; increasing age, male gender, pre-existing chronic airway disease, increasing perioperative opioid consumption, increasing intra-operative blood loss and the formation of an ileostomy [6, 14–16]. These are summarised in Table 1. In a prospective study in colorectal surgery patients using a precise definition of PPOI the factors that were independently identified out of 92 different variables were; male gender, decreasing preoperative albumin, open or converted technique (vs laparoscopic), increasing wound size, operative difficulty, operative bowel handling, red cell transfusion, intravenous crystalloid administration over postoperative day 0–3, and delayed first mobilization. These factors were then combined to create an I-Score that differentiated between those with a low, intermediate and high risk of developing PPOI [17].

Table 1 Risk factors and possible mechanisms for postoperative ileus [6, 14, 16, 18–25]. Adapted from Bragg, et al. [19], with permission

Risk factor	Possible mechanisms
Increasing age [6, 24]	Reduced overall capacity to recover from surgical insult [24]
Male gender [16]	Greater inflammatory response to surgery [21] Increased pain threshold in males, [18] resulting in higher catecholamine release [22]
Low preoperative albumin concentration [16]	Increased oedema and intestinal stretch
Acute and chronic opioid use [6, 14]	μ-opioid receptor stimulation reduces peristalsis [20, 24]
Previous abdominal surgery [6]	Increased need for adhesiolysis, increased bowel handling
Pre-existing airways/ peripheral vascular disease [16]	Reduced physiological reserve
Long duration of surgery [14, 16]	Increased bowel handling [23] and opioid use
Emergency surgery [18, 21]	Increased inflammatory and catecholamine response; secondary causes of POI
Blood loss and need for transfusion [6, 14, 16]	Increased crystalloid administration resulting in oedema [25]
Procedures requiring stomas [21]	Oedema in abdominal wall muscle and cut bowel

Prevention of PPOI

An understanding of the pathophysiology of and risk factors for PPOI as described above provides a foundation for the possible interventions that may reduce the risk of developing this condition. Many of the advances in the perioperative management of patients undergoing major elective abdominal surgery potentially impact on the trigger factors for PPOI. The advent of Enhanced Recovery after Surgery (ERAS) protocols has seen a much greater emphasis on optimising the patient's physiology in the perioperative setting. Recent evidence suggests that the ERAS protocol may actually have an anti-inflammatory effect at both the gut wall and mucosal level [26]. Systematic reviews of ERAS have consistently demonstrated reduced complications and earlier discharge from hospital [27, 28]. Increased volume of crystalloids in the perioperative setting was an independent risk factor for development of PPOI in Vather's study and those of VandeHei et al. and Lobo et al., [17, 29, 30] but this finding has not been confirmed in other randomised studies [31–33]. A possible mechanism relating the association of fluid overload with PPOI is summarised in Fig. 3 [25].

A recent systematic review of preventive measures for PPOI has summarised the different interventions [34]. These include early feeding, chewing gum, epidural anaesthetic, laparoscopy, peripheral μ-opioid receptor antagonists, prokinetic agents, non-steroidal anti-inflammatories, and coffee.

Early Enteral Feeding

Early feeding has become a central plank of the ERAS pathway, RCT evidence of its efficacy in reducing PPOI is inconsistent. In the eleven RCTs that were reviewed by Chapman et al. six showed a significant reduction in time to flatus, stool or oral tolerance, two of which also showed a reduction in length of hospital stay [34]. Early enteral feeding is widely accepted as beneficial and safe in postoperative management

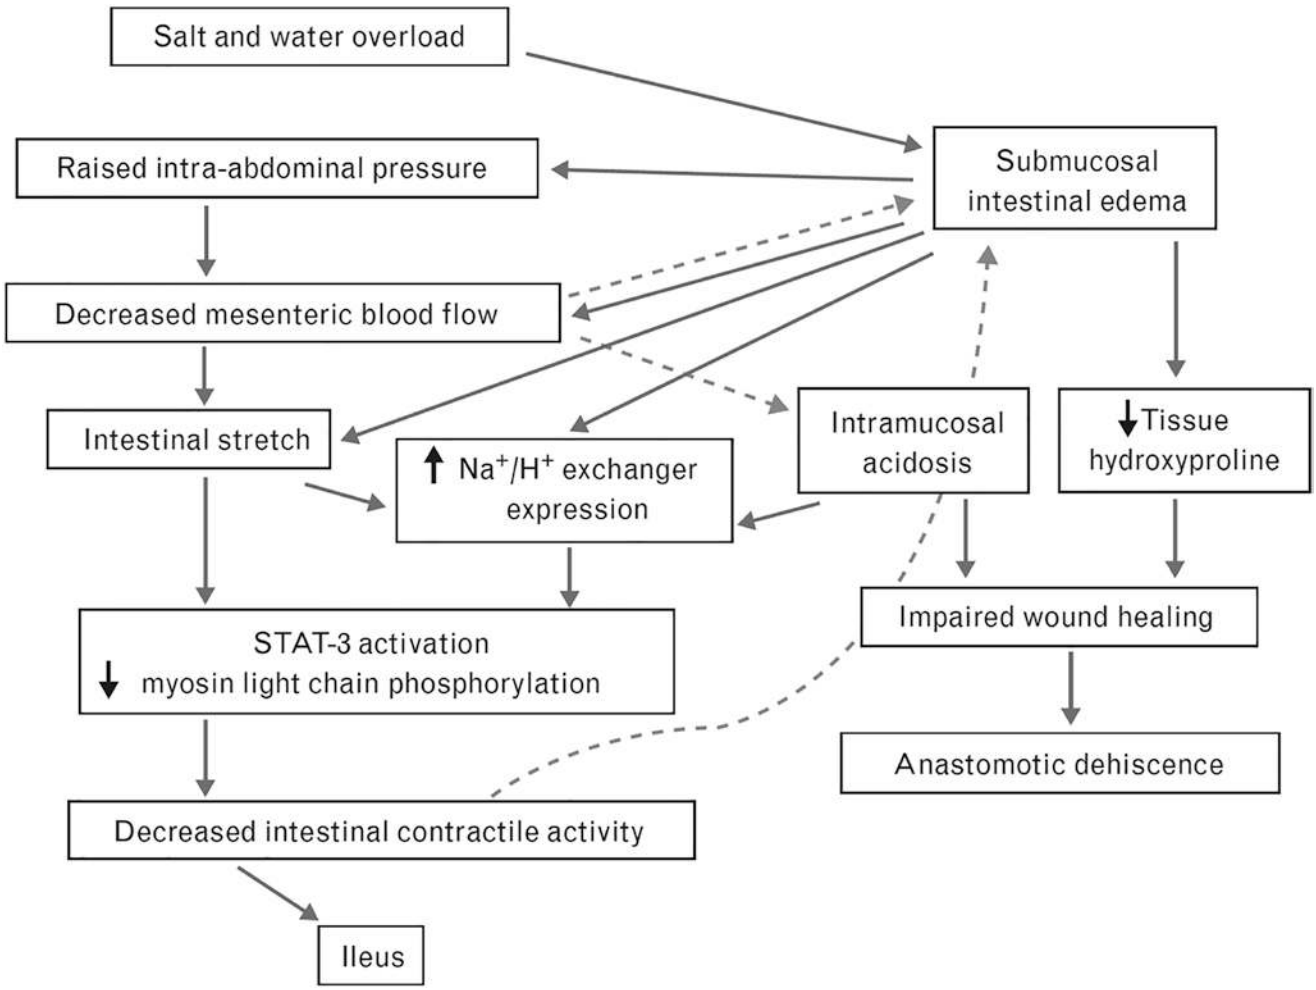

Fig. 3 Mechanisms for adverse effects of salt and water overload on gastrointestinal function, summarising data from human and animal studies. (From Chowdhury and Lobo [25], with permission)

of elective abdominal surgery with a likely benefit in hastening the return of normal intestinal function.

Chewing Gum

Chewing gum in the immediate postoperative period has the potential to stimulate salivation, swallowing and gastrointestinal hormones. A systematic review of eleven randomised studies has assessed this intervention in promoting intestinal recovery after surgery. There was no significant reduction in time to normal oral intake or time to flatus or stool in the high-quality studies but five other studies that were prone to bias did have significant reductions in time to pass flatus and/or stool. A Cochrane review that included 81 randomised studies and 9702 participants did demonstrate a reduction in time to flatus and stool but no other benefit in terms of tolerating food or shortening length of stay [35]. The reviewers state that most of the included studies had a high risk of bias. Chewing gum has little risk of causing harm and may be beneficial in reducing the time to return of normal intestinal function.

Epidural Anaesthetic

There is robust evidence provided in a Cochrane review including more than 20 studies and over 100 patients that epidural anaesthesia leads to a decrease of time to passage of stool and flatus in patients undergoing open surgery, but that there is no decrease in nausea and vomiting in the first postoperative day [36]. The evidence for a benefit in laparoscopic surgery is however much less clear. A large retrospective case matched study of US data found that in laparoscopic colorectal surgery epidural is associated with longer hospital stays, higher expense and a greater risk of urinary tract infections [37]. The benefits of epidural anaesthesia are probably limited to those undergoing open surgery.

Laparoscopy

The laparoscopic approach to surgery has repeatedly been demonstrated to result in a more rapid return of gastrointestinal function and reduction of PPOI [17, 38]. Randomised studies that have specifically addressed this issue, using gastrointestinal transit studies as the outcome, have shown laparoscopy was associated with improved gastrointestinal motility [39–41].

Alvimopan

Alvimopan is a peripheral μ-opioid receptor antagonist without central effects. It has been compared with placebo in 5 randomised clinical trials, four of which demonstrated an improvement in gastrointestinal function using a combined upper and lower GI function measure [42–45]. At present it is only available in USA in restricted centres but it has the potential to mitigate the opioid-related gut dysmotility that so often impairs postoperative recovery.

Prokinetic Agents

Multiple prokinetic agents, although theoretically promising, in practice have mostly been disappointing. However, the serotonin 4 receptor agonists, cisapride and mosapride have demonstrated enhanced gastrointestinal recovery [46, 47]. Cisapride has been withdrawn because of its significant cardiac side-effects, but other Serotonin 4 receptor antagonists, such as prucalopride are under investigation.

Non-steroidal Anti-Inflammatory Drugs

A systematic review that identified 10 RCTs comparing non-steroidal anti-inflammatory drugs (NSAIDs) with placebo in the perioperative setting found that those receiving NSAID passed both flatus and stool earlier, and tolerated a diet sooner than those receiving placebo [48]. The possible role of NSAIDs in anastomotic leak needs to be considered when deciding on the use of these agents. The studies addressing this are conflicting, but to date the selective COX-2 inhibitors have not been implicated in increasing the risk of this complication [49].

Coffee

Coffee has been proposed as an agent to reduce postoperative gut dysmotility. A randomised clinical trial comparing decaffeinated coffee, caffeinated coffee and water in the postoperative period demonstrated accelerated passage of stool and tolerance of solid diet in the decaffeinated group compared with both of the other groups. This suggests that some component of coffee rather than caffeine may stimulate earlier return of normal GI function [50].

Treatment of Prolonged Postoperative Ileus

Although the interventions above have been associated with prevention of PPOI, the treatment of an established PPOI is more problematic. At the outset a precipitating intra-abdominal complication such as anastomotic leak, intra-abdominal abscess or mechanical obstruction should be sought (usually with a contrast enhanced CT scan) and

Fig. 4 A coronal CT of a 77 Year old male following right hemicolectomy demonstrating distended small bowel with the distension bowel distension also involving the anastomosis.

treated appropriately if identified (Fig. 4). The foundation of treatment of PPOI, however, is conservative and involves optimising the patient's physiology. The main features of this are: correction of fluid and electrolyte balance, reduction of opioid administration, decompression of a distended gastrointestinal tract and ensuring ongoing nutritional requirements are met.

The specific electrolytes associated with PPOI that have been reported are hypokalaemia, hyponatraemia, and hypocalcaemia [51]. Regular monitoring of these electrolytes with appropriate correction of abnormalities is required. Often patients will also have a burden of extra fluid leading to oedema of multiple tissues including the intestinal wall. Overzealous replacement of fluids must be avoided and this can be achieved by providing maintenance as isotonic dextrose-saline at a rate of 1–1.25 ml/kg/h and replacing gastric losses with an equivalent volume of balanced isotonic crystalloid solution including supplemental potassium.

Patients in the postoperative setting with PPOI may have both postoperative wound pain and discomfort associated with intestinal distension. The management of this requires a careful balance to ensure that the analgesia is adequate to control the pain without producing opioid-induced intestinal dysmotility. This can often be achieved using regular paracetamol, NSAID medication and tramadol while keeping the amount of opioid analgesia to a minimum. Alvimopan may also be used if it is available and opioids cannot be avoided.

Most patients with PPOI will require a nasogastric tube and this should be inserted if there is recurrent vomiting even if this is low volume as it may represent an overflow of a very distended stomach. Distressing abdominal distension may also be markedly relieved by insertion of a nasogastric tube. Aspiration with subsequent pneumonitis is perhaps the commonest cause of death in those with PPOI and adequate emptying of the stomach is likely to reduce the chance of this serious complication.

A combined analysis of two placebo controlled, randomised clinical trials of the use of Gastrografin in an established postoperative ileus has demonstrated an earlier onset of oral intake in those receiving Gastrografin [52]. However, the study of only 108 patients was not able to demonstrate either a shorter hospital stay or duration of the composite PPOI definition used in the studies. A potential risk associated with Gastrografin is the severe, often fatal, pneumonitis associated with its aspiration and therefore it should only be used when the stomach is known to be empty.

Patients' nutritional requirements need to be considered as oral intake is not feasible in the context of PPOI. Parenteral feeding should be initiated by 7 days postoperatively and earlier for those presenting with malnutrition to ensure that the patient does not suffer serious nutritional decline during management of PPOI [53]. Prolonged under-nutrition in the postoperative setting is associated with increased complications and mortality [54]. Provision of 25 kcal/kg and1.5 g/kg protein (based on ideal body weight) in the administered PN is likely to lead to an improvement in nitrogen balance [53]. The patient should be transitioned back to enteral nutrition as soon as tolerated.

Summary

Prolonged postoperative ileus is the commonest postoperative complication following colorectal surgery and is associated with a large burden of expense. Perioperative measures to reduce its incidence include careful avoidance of fluid overload, minimally invasive surgical approaches, adherence with ERAS principles, avoidance of postoperative opioids, early feeding and mobilisation postoperatively, non-steroidal anti-inflammatories and possibly gum chewing and coffee. Interventions once PPOI is established are primarily conservative aimed at optimising nutrition and physiology. See Table 2 prevention and Table 3 treatment below.

Table 2 Prevention

Intervention	Strength of evidence	Summary of evidence	Patient group
Early feeding	++ SR	Early feeding is safe and may reduce time to postoperative gut recovery	All
Early mobilisation	+ OS	Delayed mobilisation is a risk factor for prolonged postoperative ileus. No consensus regarding optimal mobilisation interventions	All
Avoidance of opioids	+ Large OS	Increased use of postoperative opioid analgesia impairs recovery of gut motility and prolongs length of stay. Minimise opioid analgesia postoperatively	All
Minimally invasive surgery	++ SR	Laparoscopic surgery leads to clinically significant reductions in time to gut recovery and reduces postoperative ileus compared to open surgery	All
Avoidance of fluid overload	+ RCTs, large OS	Perioperative fluid overload may impair gut motility postoperatively. Restrict IV fluid where possible, using a chloride-restricted crystalloid	All
NSAIDs	+ SR	Use of perioperative NSAIDs reduces time to passage of flatus, stool and tolerance of diet in patients undergoing open bowel resection. Role in laparoscopic resection is unclear	All
Alvimopan	++ SR	Alvimopan improves time to gut recovery and reduces ileus after open surgery. It may reduce ileus after laparoscopic surgery. The cost effectiveness of Alvimopan in an enhanced recovery setting is unclear	Open surgery
Thoracic Epidural	++ SR	Thoracic epidural reduces time to passage of flatus and stool after abdominal surgery. Unproven benefit in laparoscopic surgery	Open surgery
Prokinetics	++ SR	Currently used prokinetics (erythromycin, metoclopramide) are unlikely to improve postoperative gut recovery and to reduce postoperative ileus	NR
Chewing gum	+/– SR	Chewing gum is safe postoperatively and leads to small improvements in time to gut recovery. Clinical relevance is unclear	NR
Coffee	+/– Small RCTs	Coffee may improve postoperative gut recovery but the evidence is of low quality	NR
Novel agents (Prucalopride)	+/– RCTs	Serotonin-4 receptor agonists, such as Prucalopride, may reduce postoperative ileus and improve time to pass flatus and stool after colorectal surgery	Await further studies

SR Systematic Review, *RCT* Randomised Clinical Trial, *OS* Observational Studies, *NR* Not recommended

Table 3 Treatment

Correct electrolytes	+ OS	Electrolyte disturbances (sodium, potassium, calcium and magnesium) impair gut motility and may prolong postoperative ileus	All
Balance IV fluids with losses	+ OS	Maintenance fluid with a balanced crystalloid solution, instead of 0.9% saline, based on patient hydration status. Replacement of gastric losses with an equivalent volume of potassium-rich crystalloid	All
NG placement if required	+ OS	Selective use of nasogastric tube for patients with postoperative nausea and vomiting for symptomatic relief. Not all patients with prolonged postoperative ileus require NGT insertion	Selective use as required
Optimize analgesia	++ OS	Opioid analgesia should be used sparingly during postoperative ileus. Use of paracetamol, non-steroidal anti-inflammatories and tramadol may be effective	All
Provide PN if prolonged	+ OS	Commence parenteral nutrition if patient is unable to tolerate adequate oral intake for 7 days postoperatively. Can commence earlier if evidence of preoperative malnutrition	Selective use as required
Alvimopan	+/–	Alvimopan reduces the incidence of postoperative ileus after colorectal surgery. Not yet proven to reduce the duration of an established ileus	Await further studies
Hyperosmolar radiocontrast media (Gastrografin)	+ RCTs	Gastrografin given at the onset of prolonged postoperative ileus may improve time to tolerance of diet and passage of flatus/stool. Further studies are required	Await further studies

Acute Surgical Intestinal Failure. Sepsis and Enterocutaneous Fistula(s)

Akash Mehta, Carolynne Vaizey, Jeremy M.D. Nightingale, and Gordon Carlson

Key Points

1. Sepsis is the main cause of death in patients with acute intestinal failure so must be continually suspected, detected and treated.
2. Up to 50% of post-operative fistula(s) heal spontaneously.
3. Oral/enteral feeding can be used in preference to parenteral feeding if small bowel effluent is draining adequately rather than collecting and there is more than 100 cm functional small intestine available.
4. Definitive surgery for enterocutaneous fistula(s) should be delayed until the patient's condition has been fully optimised. In many cases, notably with fistulation in an open abdomen, this involves a delay of 6 months or more after fistulation occurred.

Introduction

Acute intestinal failure has been recognized as a specific clinical entity for many years [1], and occurs when there is a potentially reversible cause (Table 1). In surgical patients acute intestinal failure is usually associated with enterocutaneous fistulas, intestinal obstruction and ileus. In these circumstances, fluid and electrolyte absorption, as opposed to nutrient absorption, may be the principal clinical problem.

Most cases of acute intestinal failure are short lived, require artificial nutritional support for fewer than 14 days and are managed in non-specialized units. Although the incidence of acute intestinal failure in these circumstances is unknown, it is extremely common, and the vast majority of such cases present to and are managed in non-specialized units. When an epidemiological assessment is restricted to those cases in which referral to a specialist intestinal failure unit is made for the management of severe acute intestinal failure, the annual incidence of intestinal failure requiring specialist treatment is slightly in excess of 5.5 new patients per million population [2]. This figure may be an underestimate of the true incidence of acute intestinal failure associated with intestinal fistula, complex metabolic derangement or postoperative abdominal sepsis, as many of these cases are managed with difficulty in non-specialist centres.

Table 1 Causes of acute intestinal failure. Adapted from Pettigrew and Hill 1984 [16]

When the gastrointestinal tract is 'blocked'
Mechanical obstruction
Paralytic ileus
Intestinal pseudo-obstruction
When the intestinal tract is too short
Massive resection
Internal or external fistulas
When the intestinal tract is inflamed
Inflammatory bowel disease
Severe infective enteritis
Radiotherapy
Chemotherapy
When the gastrointestinal tract fails to function adequately for other reasons
Intra-abdominal sepsis
Multiple organ failure
Acute pancreatitis

Table 2 Criteria for referring patients with acute intestinal failure to a specialist unit

Persistent intestinal failure beyond 6 weeks complicated by venous access problems
Multiple fistulas within a totally dehisced abdominal wound
Total or near total (<30 cm remaining) enterectomy
Recurrent venous access problems due to sepsis or thrombosis
Persistent severe abdominal sepsis
Persistent nutritional or metabolic problems associated with a high output stoma or fistula
Any patient with an intestinal fistula beyond the expertise of the referring hospital

In the UK, future estimates of the true incidence of severe acute intestinal failure are likely to become more accurate following the development of specialized integrated intestinal failure centres for the management of patients (Table 2).

Small Bowel Obstruction

Small bowel obstruction is usually short-lived and, in most patients, will only cause type 1 intestinal failure. It is one of the most common causes of emergency surgery presentations and admissions and is mostly managed in non-specialized units [3], with only a small proportion of patients transitioning into type 2 intestinal failure and requiring more specialist input.

Acute bowel obstruction occurs due to interruption to the antegrade flow of intestinal contents; the most common cause of small bowel obstruction in industrialised countries is postoperative adhesions (70%), followed by malignancy, inflammatory bowel disease, and hernias. Malignancy and volvulus are the commonest causes of large bowel obstruction [3].

The management of acute small bowel obstruction is well established and encompasses early contrast-enhanced cross-sectional imaging, with early consultant-led multidisciplinary decision-making regarding surgery (and a possible role for enteric water-soluble contrast agents).

Although intestinal failure caused by (adhesional) small bowel obstruction is usually type 1 and therefore short-lived, 2 recent reports on the assessment and management of (small) bowel obstruction in the United Kingdom and Ireland have highlighted the relatively low levels of early nutritional assessment and intervention in this patient category, with poor nutritional status at admission being an independent predictor of reduced survival after presentation with small bowel obstruction [3, 4]. In particular, patients not undergoing immediate surgery to address small bowel obstruction were less likely to receive parenteral nutritional support [4].

In a minority of patients, small bowel obstruction either recurs early after surgery, persists despite intervention, or cannot be operated on immediately and requires an elective operation. In these cases, ongoing intestinal decompression alongside active nutritional intervention is necessary; this may be achieved by insertion of a venting gastrostomy/jejunostomy or, rarely, a long-term nasogastric tube. Venting gastrostomy/jejunostomy placement is typically achieved either endoscopically (PEG or PEJ) or, for gastrostomies, by interventional radiology (RIG); however, specifically in patients with ongoing small bowel obstruction, percutaneous access to the stomach or small bowel may be hindered by the presence of dilated loops of small bowel interposed between the anterior abdominal wall and stomach or jejunum. In these instances, a long-term indwelling nasogastric tube may be the only means of achieving and maintaining adequate decompression, but this should obviously not be considered a permanent solution.

The above demonstrates that surgical intestinal failure, whether type 1 or type 2 (the focus of the remainder of this chapter), is a serious condition, associated with high rates of mortality, and early nutritional assessment and intervention is warranted in all such patients.

Aetiology and Pathogenesis

Acute intestinal failure occurs as a consequence of conditions which primarily or secondarily affect the gastrointestinal tract (Table 1). Within a specialized intestinal failure unit, the most common underlying condition responsible for intestinal failure is Crohn's disease (Fig. 1), and the principal

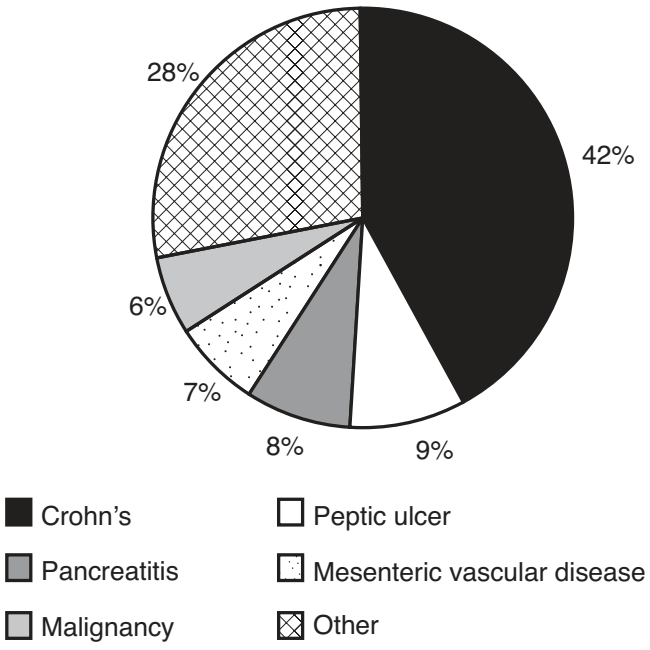

Fig. 1 Aetiology of acute intestinal failure in a specialized unit. (Adapted from Scott et al. [2])

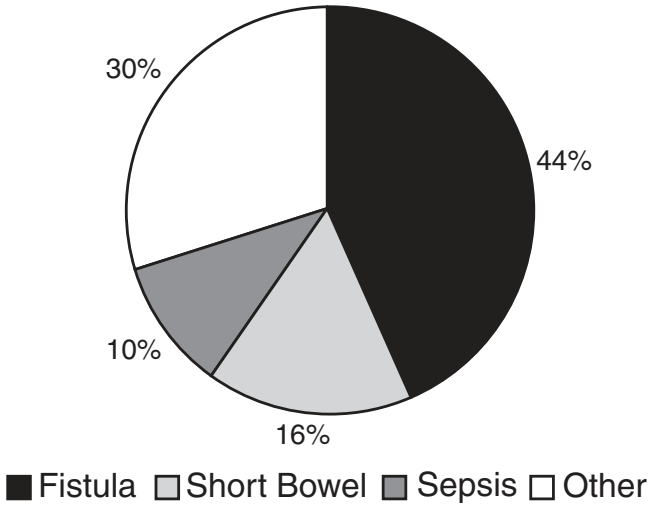

Fig. 2 Clinical problems leading to acute intestinal failure. (Adapted from Scott et al. [2])

reason for acute intestinal failure is the development of an intestinal fistula (Fig. 2). This population of patients is very different to that seen in most hospitals, because the majority of cases (62%) referred to specialized units will require surgical treatment [2].

Intestinal Fistulas

A fistula is defined as an abnormal communication between two epithelialized surfaces. A fistula communicating with a hollow viscus is called an internal fistula and one communicating with the skin an external fistula. In some cases, notably when a fistula has developed within an open abdomen, there is said to be an "enteroatmospheric fistula". A fistula can be single or complicated. An intestinal fistula is said to have a high output if more than 500 ml is produced in 24 h [5].

In non-Crohn's patients enterocutaneous fistulas most commonly develop as a postoperative complication from either partial breakdown of an intestinal anastomosis or inadvertent bowel injury (Table 3). Death from enterocutaneous fistulas is most commonly due to sepsis (>80% of deaths); other causes of death include electrolyte imbalance (e.g. due to high fistula outputs), undernutrition, massive bleeding or progression of the underlying disease. Spontaneous closure of a fistula may occur within 6 weeks of its first appearance in up to 50% of patients. This tends to occur only in postoperative fistulation. Table 4 lists some of the factors that make spontaneous closure unlikely. In the vast majority of such cases a fistula will fail to heal because there is mucocutaneous continuity, distal obstruction or disease at the fistula site. Although there is little published evidence, the chance of spontaneous closure of a fistula may also be reduced if a patient is undernourished, septic (as indicated by a low serum albumin or transferrin) or has another systemic problem (e.g. cardiac, respiratory, renal or hepatic failure).

Table 3 Aetiology & pathogenesis of enterocutaneous fistula

Surgery
Anastomotic leak
Abdominal closure
Serosal tear
Obstruction / Stricture (adhesions)
Peri-operative management
Abdominal sepsis
Smoking
Poor glucose control
Low albumin
Excessive fluid resuscitation
Disease
Crohn's
Malignancy
Diverticula(s)
Irradiation damage

Table 4 Factors indicating an enterocutaneous fistula is unlikely to close spontaneously

Distal bowel obstruction
Diseased bowel at the fistula site (e.g. Crohn's, irradiation or malignancy)
Discontinuity of the bowel ends
Active disease, foreign body or continuing sepsis/abscess at the site of the fistula
Mucocutaneous continuity (i.e. bowel mucosa is visible on the surface of the abdomen)
Short fistula track
Multiple (complicated) fistulas

The pathogenesis of acute intestinal failure is often multifactorial and complex. For example, many patients with an intestinal fistula also have an intra-abdominal abscess. In some cases, an intestinal fistula may have developed as a consequence of impaired anastomotic healing because the anastomosis was constructed within a pre-existing abscess cavity (typically in Crohn's disease) or in a patient with established sepsis.

Management

The initial priorities in the management of the patient with acute intestinal failure are the correction of electrolytes and hydration, the detection and management of sepsis, wound management and pain control (Table 5).

It is important to note that the management of sepsis is of overwhelming importance because inadequately treated sepsis is the most common cause of death in patients with complicated acute intestinal failure. In the management of intestinal fistulas, control of sepsis has been shown to be the major determinant of successful outcome [6].

Table 5 Principles of managing acute intestinal failure

Immediate (minutes-hours)	Early (1–2 days)	Late (2–12 weeks)
Resuscitation including water/electrolyte (Na^+, Mg^{2+}) balance	Nutrition	Anatomy—mapping – fistula—site/drainage – proximal + distal gut – length/quality – presence and nature of abdominal wall defect
Treat sepsis	Reduce stoma/fistula output	Procedure—this should preferably be carefully planned and may need to be deferred for at least 6 months
Wound management	Psychosocial	Treatment of underlying disease
Pain control	Mobility	

Diagnosis and Management of Acute Intestinal Failure

Acute intestinal failure is a complex condition requiring a truly multidisciplinary management strategy. Various useful algorithms have been suggested for the different components of such strategies, of which SNAP (Sepsis management, Nutritional optimisation, Anatomical mapping, Planning of surgery) is the most popular. It was devised to resemble the ABC of trauma resuscitation, listing the most serious issues in order of importance. Regardless of the mnemonic employed, the management strategy for patients with acute intestinal and concomitant abdominal wall failure should always address the management of sepsis, wound care, nutritional support and optimisation (including the management of high fistula/stoma outputs), intestinal mapping, prehabilitation and surgical planning.

Intravenous correction of electrolytes and hydration is an immediate and potentially life-saving priority for these patients. Ongoing control of hypotonic fluid intake is usually required for high output fistulas and stomas.

As stated above, the management of sepsis is of overwhelming importance because inadequately treated sepsis is the most common cause of death in patients with complicated acute intestinal failure (Table 6). In the management of intestinal fistulas, control of sepsis has been shown to be the major determinant of successful outcome [6].

Table 6 Principles causes of death in enterocutaneous fistula patients

Sepsis
Electrolyte imbalance
Bleeding
Undernutrition
Underlying disease

Diagnosis and Management of Abdominal Sepsis

There is evidence that intestinal function is impaired in sepsis, as a consequence of mucosal oedema [7], defective enterocyte maturation [8] and down-regulation of nutrient transporters [9]. When combined with the increased metabolic demand and impaired fuel utilization associated with sepsis [10], the presence of impaired intestinal function may lead rapidly to a state of cachexia not unlike that observed in advanced malignant disease [11]. In addition, nutritional support, however aggressive, is unlikely to be successful in the restoration of lean body mass in the presence of sepsis [12]. A major priority in managing the patient with acute intestinal failure is therefore to detect and eradicate sepsis. Other factors may also be of importance in the development or maintenance of acute intestinal failure, particularly in the setting of critical illness: changes in intestinal motility undoubtedly occur and although their aetiology is unclear, may cause difficulty with enteral feeding. In general, reduced intestinal motility is observed [13], possibly as a consequence of impaired absorption of fluid, altered nervous and regulatory peptide control of motility patterns [14], decreased intestinal blood flow [15], and bacterial colonization of the small intestine (which may itself develop as a consequence of impaired motility [16]). In addition, handling of the gut at surgical operation may result in ileus because of the development of an inflammatory response within the intestinal muscle [17]. Finally, other factors that may contribute to impaired motility are pulmonary and liver disease and centrally acting sedative and narcotic drugs [18]. The net effect of these changes, which may disturb gastric and colonic motility to a greater extent than small intestinal motility, is to cause abdominal distension, nausea and vomiting.

The diagnosis of sepsis should be entertained in any patient with a history of gastrointestinal surgery who is fail-

Table 7 Markers of hidden sepsis

1. Pyrexia (often absent in malnutrition)
2. Tachycardia
3. Raised inflammatory markers
• WBC, Platelets
• CRP
• Ferritin/B_{12}
4. Persistent hypoalbuminaemia
5. Abnormal liver function tests (jaundice)
6. Hyponatraemia
7. Low phosphate
8. Failure of muscle mass to increase with nutritional support

ing to make satisfactory progress (Table 7). Failure to respond to adequate nutritional support is a classical sign of sepsis. The classical picture of a high white cell count and high CRP may not be present but more subtle signs of raised platelets and low ferritin and B12 should be heeded. Although swinging pyrexia, leucocytosis and abdominal signs are classical features of sepsis, they are not invariably present, especially in malnourished patients. Hypoalbuminaemia, hyponatraemia, hypophosphataemia or unexplained jaundice may be more subtle signs of abdominal sepsis and should lead to a careful search for a septic focus. In some cases this may prove to be within the chest or urinary tract or may relate to central venous lines but the abdomen should be suspected whenever abdominal surgery has been performed.

Whilst ultrasound may be of value in the detection of subphrenic or pelvic collections this may be difficult to perform in the presence of large abdominal wounds, stomas and drains [19]. A plain chest radiography may show elevation of the diaphragm and basal collapse with a 'sympathetic' pleural effusion indicative of a subphrenic abscess.

Computed tomography (CT) is, in general, the most effective imaging modality (Fig. 3) and, if combined with oral contrast, will distinguish intra-abdominal or pelvic abscesses from immotile, fluid-filled loops of bowel [20, 21]. The diagnostic accuracy of CT scanning in abdominal sepsis is of the order of 97%.

Especially when intestinal failure first becomes apparent, patients may be profoundly septic. The compulsion to "jump in" in an attempt to surgically address the underlying issue (especially in case of iatrogenic intestinal failure) may lead to further enteric injury and loss of intestinal mass. Every attempt should be made to manage sepsis with a combination of antimicrobial treatment and targeted percutaneous (radiological) drainage procedures, with due consideration given to targeted and careful surgical drainage procedures for clinically significant collections not amenable to radiological drainage [5].

Once a focus of abdominal or pelvic sepsis has been diagnosed, prompt drainage is mandatory. Antibiotic therapy may be of value in the management of patients with sepsis

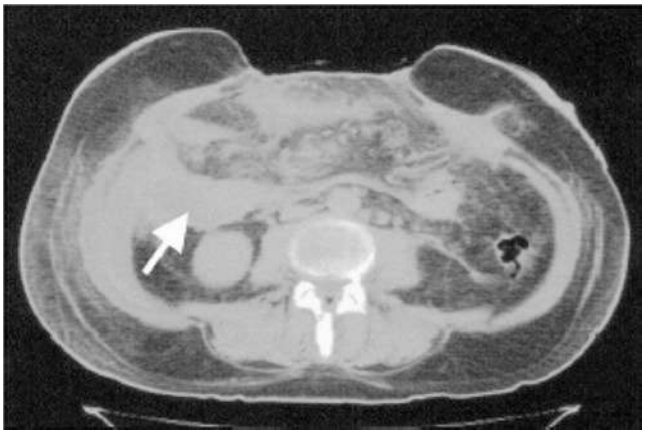

Fig. 3 CT scan showing intra-abdominal abscess (arrowed)

Fig. 4 CT scan showing percutaneous drainage (arrowed) of intra-abdominal abscess shown in Fig. 3

but it will not lead to the resolution of sepsis unless combined with treatment of the abscess cavity itself. Fortunately, it is increasingly possible to use percutaneous drainage of abscesses under radiological guidance because of improved imaging and drainage techniques. As abscess cavities enlarge, they tend to assume a globular shape and push neighbouring structures aside [21]. Large drains (8–10 F) can be inserted into abscess cavities under local anaesthetic (Fig. 4). Drains can also be upsized under local anaesthesia. If more than one drain is inserted simultaneously, the cavity can be irrigated regularly with saline to ensure adequate and prolonged drainage. Often, the drains are kept in place and a contrast study performed through one of them to ensure that the abscess cavity has collapsed prior to drain removal.

Increased size of percutaneous drains and the ability to insert multiple drains and irrigate means that the need for surgical exploration has markedly reduced.

However, in some cases, percutaneous drainage of abscesses is likely to be ineffective. This is particularly likely where there is discontinuity between the bowel ends, or a CT

scan has shown multiple interloop abscesses, and where the pus is of particularly thick consistency (for example in infected pancreatic necrosis). In such cases surgical exploration may be required, especially if sepsis persists or deteriorates. Intestinal manipulation should be kept to a minimum and the surgical exploration should be aimed at drainage and, in some cases, exteriorization of the proximal bowel.

Where intra-abdominal contamination is severe and sepsis continues, with further collections of infected fluid, or where the underlying focus of sepsis cannot be removed (for example in necrotizing pancreatitis), further attempts to deal with sepsis are necessary. A variety of approaches have been advocated, including radical peritoneal debridement [22], and continuous postoperative peritoneal lavage [23], neither of which has been shown to be effective. Other options include repeated laparotomies, either on demand or as planned procedures. Controlled trials of repeated planned laparotomy for severe abdominal sepsis have not shown that it improves survival and the therapeutic value of each successive operation diminishes with an associated risk of intestinal injury, leading to secondary intestinal fistula formation [24–26].

An alternative approach in such cases is to leave the abdomen open and fashion a laparostomy. As discussed in more detail in the "Abdominal Wall Repair in Intestinal Failure" chapter, although laparostomies have a role in damage control settings (primarily trauma and mesenteric ischemia), they are to be avoided in other settings [27–29]. Moreover, if the abdomen is left open at the index operation, there must be a definitive plan to achieve delayed primary fascial closure [29]. The open abdomen is fistulogenic; moreover, laparostomies create a significant problem for the future with the formation of a giant incisional hernia, which is difficult to repair with good outcomes and low morbidity.

Although there are many strategies to avoid having to leave the abdomen open and/or to achieve delayed fascial closure, the technique of choice is that of mesh mediated fascial traction (MMFT) combined with negative pressure wound therapy (NPWT) [27–29], as described in more detail in the "Abdominal Wall Repair in Intestinal Failure" chapter.

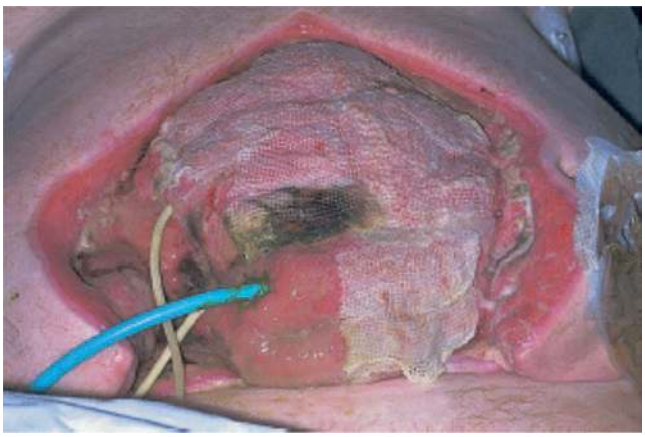

Fig. 5 Newly-created laparostomy wound

Fig. 6 Laparostomy wound after 6 weeks, showing viscera covered with dense granulation tissue

In the (hopefully rare) instances that an abdomen is left open, the laparostomy (Fig. 5) is allowed to heal by secondary intention and, initially, fistulating loops of bowel become fixed within a dense mass of granulation tissue (Fig. 6). Intestinal continuity can generally be safely established by a further laparotomy undertaken 6 months later when the peritoneal cavity has become re-established [30]; the best indication of this is prolapse of the fistulating bowel segments (Fig. 7) [5].

Fig. 7 Prolapse of a fistula within a completely healed laparostomy wound

Wound Care

In the presence of an intestinal fistula, maintenance of skin integrity is of major importance and should be considered at an early stage. The output of intestinal fistulas, particularly from the proximal gastrointestinal tract may be massive and if inadequately controlled, may cause widespread skin destruction. It is important therefore to involve a stoma nurse specialist in the care of such patients. Fortunately, a wide variety of stoma and fistula appliances are presently available (see Chapter "Care of intestinal stoma and enterocutaneous fistula(s)"). Large Eakin bags can be cut to suit the shape of the abdominal wall and, when combined with suction catheters and Stomahesive® paste, will control the vast majority of fistulas. In certain cases it may be almost impossible to adequately control the output of a fistula. This is, for example, likely to be the case where a high output fistula has developed in the base of a deep or an irregularly shaped wound or in a large area of granulation tissue. Improved stoma care products including fistula isolation may be employed to avoid repeated leakages. In some cases, it may be necessary to undertake a limited surgical exploration, simply to exteriorize a loop stoma proximal to the fistula. A period with a well-fashioned high output proximal loop stoma is usually preferable to an unmanageable fistula.

Intestinal failure is often accompanied by abdominal wall failure which, especially in the presence of enteric fistulas, poses significant challenges to patients, family and nursing staff. Mortality is especially high in patients who fistulate within an open abdomen (enteroatmospheric fistulas), particularly because of the difficulties in controlling abdominal sepsis. The development and application of a custom-made wound management system (traditionally by tissue viability and stoma care nurses) is an often laborious and time-intensive process, but crucial to avoid further wound breakdown and ongoing low-grade sepsis in the abdominal wall.

Nutritional Support and Optimisation

Early nutritional intervention in these often catabolic patients is essential in order to prevent and mitigate further deconditioning and encourage wound healing as well as increase the likelihood of spontaneous closure of enteric fistulae and increase the success rate of further major surgical procedures whilst limiting the associated morbidity. Although a substantial proportion of patients will require parenteral nutritional support, efforts should be made to explore the possibilities of enteral feeding, supplemented by enteroclysis/fistuloclysis ("distal limb feeding") [5, 31].

High stoma and fistula outputs should be assessed in the context of the patient's intestinal anatomy and any intra-abdominal sepsis. Once the latter has been sufficiently addressed, management of the high output state should focus on addressing not just the volumes, but also the nature of oral intake and include the use of antimotility and antisecretory medication (Table 8) (see Chapter "Management of a high output stoma, jejunotomy or uncomplicated enterocutaneous fistula").

In general, the aim of nutritional support in the patient with acute intestinal failure is to provide at least basal requirements of energy and nitrogen until normal diet can be tolerated. Nutritional intervention should be considered whenever [32]:

- Starvation for longer than 5 days is expected or has occurred, whether as a result of impaired intake or gastrointestinal disease.
- The underlying disease has led to an increase in nutritional requirements beyond that which can be provided by a 'normal diet'.
- Nutritional depletion already existed prior to the onset of acute gastrointestinal failure.

Table 8 Therapy to reduce a stoma/fistula output

Drink little hypotonic fluid (up to 1 L/24 h)		
Drink a glucose-saline solution (sodium 90–120 mmol/L, up to 1 L/24 h)		
Drug therapy	– antimotility	– loperamide up to 40 mg qds
		– codeine phosphate up to 60 mg qds
	– antisecretory	– omeprazole 40 mg bd (titrate so stomal pH >5)
		– occasionally octreotide 50 μgm bd
Magnesium correction		– oral magnesium aspartate or oxide, or topical magnesium chloride
		– hexahydrate spray
		– 1 alpha cholecalciferol
Nutrition		– low fibre/residue diet

The vast majority of patients with acute intestinal failure will require nutritional support. In many cases with a short-lived period of intestinal failure (e.g. ileus), this will only be necessary until intestinal function has returned to normal. However, in patients with severe acute intestinal failure associated, for example, with a proximal intestinal fistula, nutritional support is likely to be required until the fistula has closed spontaneously or until optimal conditions for surgery to close the fistula have been achieved. In the case of the patient with a combination of a fistula and an open abdomen, this may take more than 6 months and under these circumstances it may be appropriate, in an otherwise fit individual with satisfactory home circumstances, to discharge the patient with a suitable regimen of artificial feeding, pending definitive surgery. The decision regarding the optimal route of nutritional support (enteral versus parenteral) depends on the developmental "stage" of a given enterocutaneous fistula and the length of proximal small bowel (Fig. 8).

In general, the presence of a complex fistula with an associated cavity is usually a contraindication to enteral feeding, and successful enteral feeding requires an adequate length of healthy bowel above the fistula track without an associated abscess.

There is some anecdotal evidence to suggest that, in patients who are well nourished, the time to maturation of a fistula track is relatively short, whereas in patients who are already undernourished, the process of maturation can be much slower.

There is some evidence that administration of proximal enteral feedings even in the presence of a high output distal enterocutaneous fistula is of no harm and may help enhance fistula closure [33].

Especially in patients with a degree of intestinal obstruction/stricturing distal to the fistula, a low fibre enteral support option would be appropriate. In patients without distal obstruction, serious consideration should be given to the possibility of distal limb feeding by enteroclysis/fistuloclysis [5, 31].

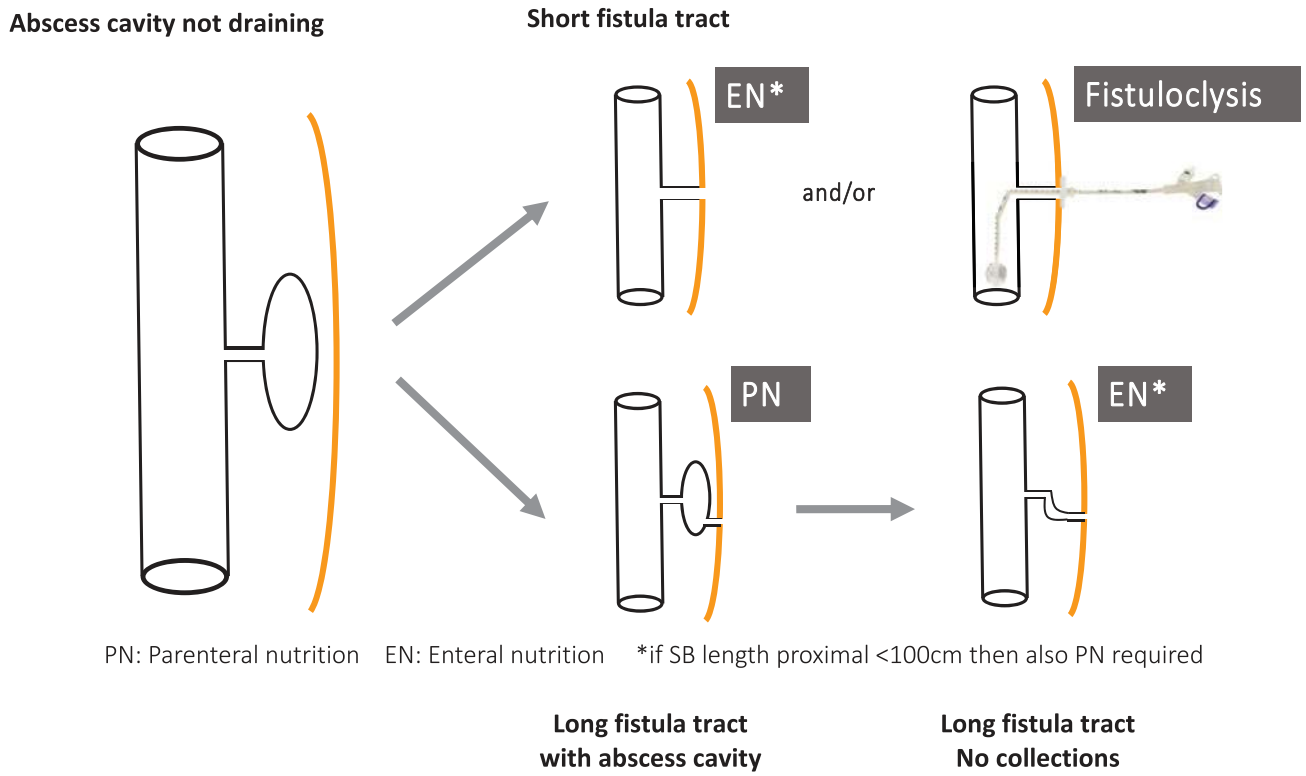
The decision regarding optimal route of nutritional support also depends on the length of small bowel still in circuit. Although this can be more accurately assessed on contrast-enhanced cross-sectional imaging, the aspect (colour and consistency) of fistula effluent often provides clues as to the length of upstream small bowel and the preferred route of nutrition.

In patients with an estimated small bowel length of <50 cm upstream of a fistula, parenteral nutrition will be necessary to ensure adequate nutritional support; in patients with >100 cm, enteral support may be sufficient, although this may need to be supplemented by intravenous fluid/electrolyte supplementation.

Therefore, the traditional treatment of enterocutaneous fistulas of almost exclusive TPN + NBM may no longer be appropriate in a substantial proportion of patients; in the early stages of fistulation, TPN may be appropriate but may be replaced by enteral nutrition once a fistula track has become firmly established.

Enteral Nutrition

As a general principle, the enteral route should be used for nutritional support whenever possible. Enteral feeding is safer, more physiological, may preserve intestinal mucosal integrity and is certainly far less expensive than parenteral nutrition. There is no evidence to suggest that enteral nutrition is inferior to parenteral nutrition in the maintenance of nutritional status or in allowing the spontaneous closure of enterocutaneous fistulas, provided enteral feed can be delivered to healthy intestine [33]. In acute intestinal failure, however, enteral feeding may be impractical or inappropriate. Although postoperative 'ileus' generally affects predominantly the stomach and colon, rather than the small intestine, the resulting abdominal distension may cause intolerance of enteral feeding, with nausea and vomiting. One study of aggressive early postoperative enteral feeding after upper gastrointestinal surgery has suggested that the resulting abdominal distension may lead to respiratory impairment [34]. Nevertheless, successful enteral feeding has been achieved early in the postoperative period [35]. A combination of nasoenteric tube, prokinetic drugs and thoracic epidural analgesia (allowing the avoidance of opiates) may make enteral nutrition easier to tolerate [36, 37], and studies have also indicated that enteral feeding may even be safe and effective in acute pancreatitis [38]. Enteral nutrition may prove satisfactory in patients with a low output distal ileal or colonic fistula but is inappropriate when there is obstruction



Note there is often a stricture of the bowel just distal to the fistula site. Image kindly provided by Dr Simon Gabe (St Mark's Hospital) redrawn from Dr Jeremy Nightingale lecture slide.

Fig. 8 Development of enterocutaneous fistulas and consequences for nutrition. (Note there is often a stricture of the bowel just distal to the fistula site. Image kindly provided by Dr. Simon Gabe (St Mark's Hospital) redrawn from Dr. Jeremy Nightingale lecture slide)

or a fistula of the upper gastrointestinal tract, unless access can be gained to the gut below the diseased segment.

As stated, consideration should be given to "using" the distal, out of circuit bowel for nutritional support as well as to prevent mucosal atrophy [5, 31]. Distal feeding, either with enteral feed alone or by chyme reinfusion, requires specialist nursing and dietetic input, as well as quite an effort on the part of the patient; however, preliminary data shows that the defunctioned gut, once distally fed, changes its metabolome and microbiome to that of healthy, in-circuit intestine. Limited data also suggests that, in selected patients with enough small bowel in situ distal to a proximal fistula, distal feeding might reduce the dependence on parenteral nutrition [39].

Parenteral Nutrition

For the majority of patients with acute intestinal failure, parenteral nutrition will be the preferred modality of nutritional support. This may either be because of the presence of disease of the intestine, which precludes satisfactory enteral nutrition, an inability to tolerate enteral nutrition or altered nutritional requirements such as those associated with severe sepsis or injury.

If the anticipated period of nutritional support is fewer than 14 days, parenteral nutrition can be provided safely via a peripheral vein. However, the ability to provide TPN for prolonged periods via the peripheral route is limited by the development, in many cases, of thrombophlebitis [40]. This can be minimized by the use of lipid-containing regimens (which have a lower osmolality than glucose-based regimens and are therefore less irritant to venous endothelium) [41], by adding heparin and hydrocortisone to the feed and by the application of nitrate patches to promote venodilatation at the feeding site [42]. While standard intravenous cannulae can be used, purpose-designed peripheral feeding lines, which are of extremely small calibre and made of inert polyurethane are available and have been used with success [41, 43]. Despite these manoeuvres it may not be possible to administer more than 3 L of TPN without phlebitis because of the flow rates required in small veins. Central venous TPN is therefore recommended in patients with large fluid requirements or acutely ill adult patients, who may have

energy requirements greater than 2000 kcal/day. Central venous TPN is also necessary where it is evident that a prolonged period of parenteral feeding is likely to be required. For expected relatively short periods of TPN (months rather than years), peripherally inserted central venous catheters (PICCs) may be used, whilst for patients requiring prolonged (years rather than months) TPN, true central vascular access (e.g. Hickmann or Broviac catheters) will be more appropriate [44].

The ability to manage complex cases of acute intestinal failure associated with abdominal sepsis or fistulas is, to a very considerable extent, dependent upon the ability to provide complication-free parenteral nutrition. Irrespective of the route chosen for venous access, a strict aseptic technique is essential. The lines used for nutritional support should be set aside for this purpose alone and maintained by dedicated nursing teams according to a strict aseptic protocol. It has clearly been established that under these conditions, catheter-related sepsis rates are negligible [2].

Intestinal Mapping

The anatomy of the digestive tract and abdominal wall is almost always significantly disrupted in patients with acute intestinal failure. These changes will often affect decisions regarding nutritional support, the likelihood of spontaneous fistula closure and, ultimately, the proposed strategy for definitive surgical procedures. Crucial information regarding the current anatomy of the digestive tract may often be gained by meticulous perusal of operative records; this will also often yield valuable information on what, if any, attempts were made at abdominal wall closure, whether prosthetic mesh was used, and, if so, in which plane and position. Further mapping of the intestinal anatomy is based on imaging; in most centres, the mainstay of this mapping is a CT of the abdomen and pelvis with intravenous and positive oral contrast (supplemented with arterial phase scans for patients with a history of mesenteric ischemia). In addition, contrast-enhanced studies of those sections of the digestive tract which are out of circuit and not amenable to oral contrast enhancement, are often warranted, especially to assess the patency and length of distal bowel when distal limb feeding is being considered and to rule out any distal obstruction which might need to be addressed prior to or during definitive surgical management; these modalities include loopograms, tubograms and fistulograms. In Crohn's disease, full restaging of the disease (both of the small bowel and the colorectum) should be considered. Intravenous urography, endoscopic retrograde cholangiopancreatography, CT-mesenteric angiography and other mapping modalities may also be required, depending upon the anatomy of the fistula.

Taken together, the information gathered from these various sources forms a comprehensive map of the patient's anatomy which can be used to guide further management and optimisation, as well as to enable adequate planning of the definitive surgical procedure(s). Most clinicians have found it helpful to amalgamate all the information from different sources and schematically represent these in one single anatomical diagram, which has been useful for other healthcare professionals involved in the care of the patient, in determining the challenges to enteral nutrition and to inform patients about their own anatomy and what further surgery would involve. It has also proved useful in planning surgical procedures. Figure 9 below provides an example of this schematic representation of the anatomy of a patient who, after undergoing an abdominoperineal excision of rectum, underwent a repeat laparotomy due to stoma necrosis and full thickness dehiscence; his abdominal wall defect was bridged with an absorbable mesh and unfortunately, he developed multiple enterocutaneous fistulae (ECFs). A CT of the abdomen and pelvis with intravenous and positive oral contrast was performed, followed by a series of fistulograms to assess the segments of small bowel between the various ECFs as well as the distal small bowel, and a water-soluble contrast enema study via his end colostomy to assess the colon.

A similar approach can be used to document postoperative anatomy, where surgery has deliberately led to temporary intestinal failure and temporary enteroclysis is being considered, as well as to guide further targeted imaging, etc. An example of this is provided in Fig. 10 below, showing the anatomy of a patient who had previously undergoing a partial jejunal resection en bloc with the splenic flexure, an ileocolic resection with a double barreled ileocolostomy and more recently underwent resection of a fistulating ileal Crohn's phlegmon; during this procedure he underwent restoration of continuity of his ileocolostomy as well as his left-sided colon, defunctioned by exteriorising his ileal resection limbs as a double barreled stoma.

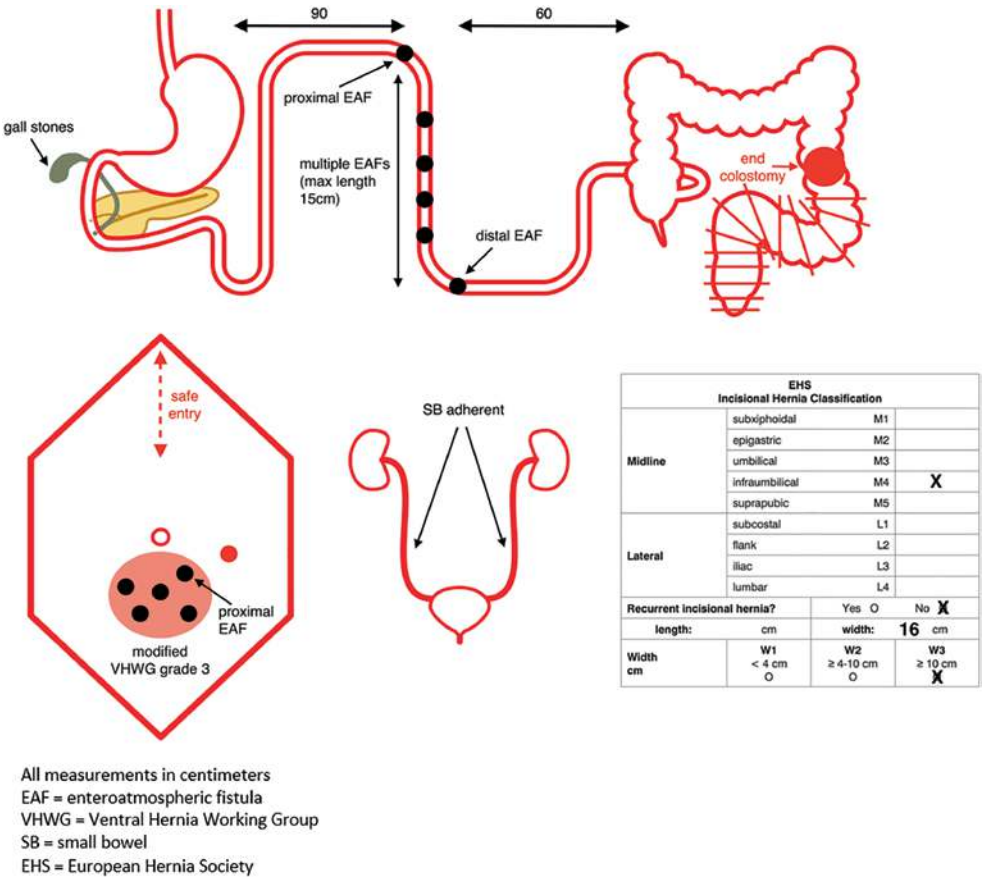


Fig. 9 Diagram to show mapping of a patient with multiple enterocutaneous fistulas

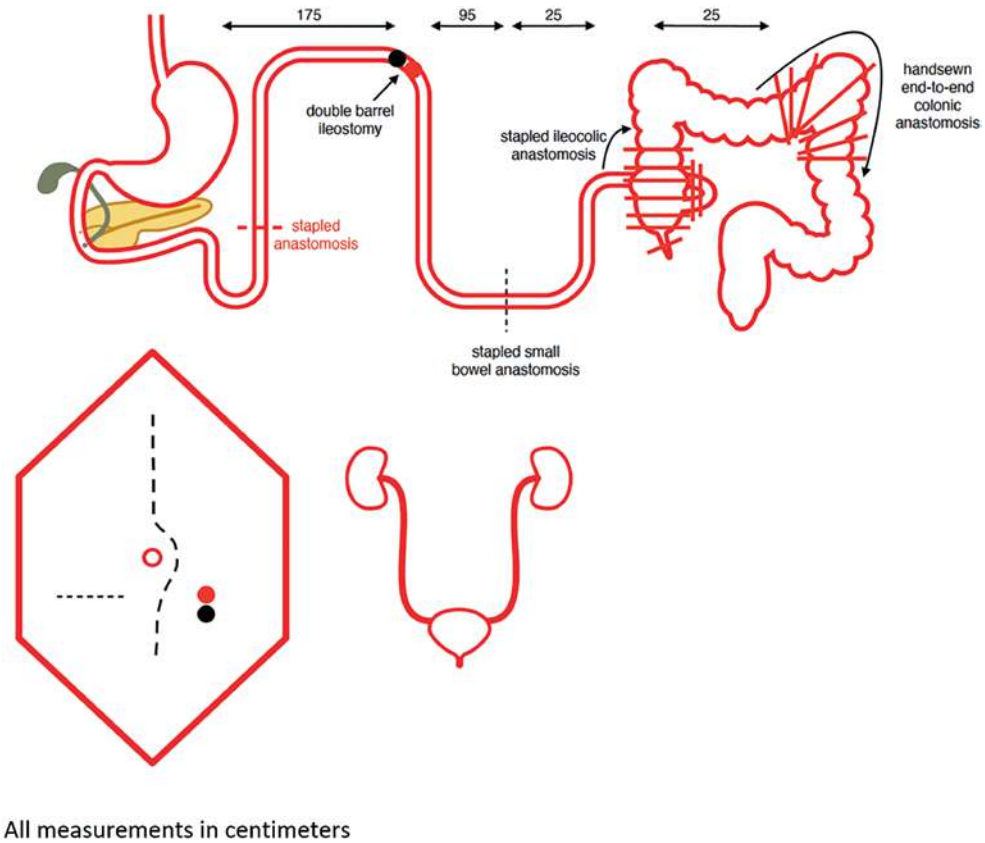

Fig. 10 Diagram to show mapping of a patient with double barrel (loop) ileostomy

Prehabilitation

Prehabilitation encompasses all of the aforementioned considerations regarding nutrition and wound care, but goes beyond these principles in formulating a pathway (quite often personalised) to enable the team and the patient to work towards their common goal of offering the patient a definitive procedure with the highest possible chance of success with the lowest possible risk of complications. Although individualised, basic components of such a prehabilitation "programme" should include the following:

- Exercise and cardiovascular fitness.
- Smoking cessation.
- Nutritional assessment and optimisation including micronutrient status and consideration of distal limb feeding (also as a trial of integrity of downstream bowel over and above radiology).
- Controlled weight loss (ideally to a BMI of less than 30).
- Acceptable diabetic control (measured by HbA1C levels with a cut-off point frequently agreed at 7.3% or 56.3 mmol/mol).
- Anaemia and iron status correction.
- Psychological well-being and preparation, expectation management, shared decision making on priorities and what the patient considers a good outcome.
- Assessment of superficial abdominal lipocutaneous tissues if significant weight loss from when catabolic and what to do with pannus.
- Analgesics and opiate weaning preop to provide headroom for perioperative analgesia.

Definitive Treatment

Once sepsis has been excluded or eradicated and nutritional and metabolic support initiated, the management of acute intestinal failure is directed at the underlying cause. Clearly, definitive treatment will depend upon the exact cause of intestinal failure. In many cases, the cause will be self-limiting (for example in paralytic ileus, severe infective diarrhoea or uncomplicated acute pancreatitis) and recovery can be expected.

Aggressive medical therapy may be required to deal with the underlying cause in some cases (e.g. high-dose steroid therapy for Crohn's disease, or anticoagulation for patients who have sustained a mesenteric vascular occlusion because of thrombophilia). Patients who have undergone resections due to mesenteric ischemia on a background of thrombo-occlusive vascular disease may need to be considered for arterial revascularization prior to restoration of intestinal continuity. Specialist (endo)vascular input into the MDT is essential for this relatively small but highly complex group of IF patients.

Attempts should be made to alleviate any obstructions/strictures distal to a fistula. For example, a patient with an enterocutaneous fistula proximal to a strictured ileostomy will benefit from either stoma dilatation or a stoma revision (via a local approach), even if just as a temporizing measure to mitigate fistula output.

Many fistulas (possibly up to 60%) will close spontaneously within 4–6 weeks of supportive treatment. One major intestinal failure unit has reported 46.4% spontaneous closure rate with conservative management alone after a median follow-up of nearly 2 years, with borderline significant difference in fistula closure rates between low versus high output fistulas (58.8% vs. 18.2%, respectively) [45]. In addition, epithelialization of the track negatively affects fistula healing; long fistula tracks epithelialize slowly and therefore have a greater chance of healing. The range for closure is estimated 3–90 days and, although closure can still occur beyond 90 days, the chances of this are quite small.

Medical Therapy for Enterocutaneous Fistula(s)

The role of medical agents in promoting fistula closure is controversial. Somatostatin was discovered in 1972 and is a naturally occurring peptide hormone. It has an inhibitory effect on gastrointestinal secretion. It is used in the management of upper gastrointestinal hemorrhage, secretory diarrhea, dumping syndrome, and peptide-secreting neuro endocrine tumors because of its antisecretory action. As the plasma half-life is 1 to 2 min, it must be administered by continuous intravenous infusion. Somatostatin reduces the secretion of a range of gastrointestinal hormones, including gastrin and cholecystokinin, which in turn reduce gastric and pancreatic secretions. In addition, somatostatin reduces splanchnic blood flow, reduces the rate of gastric emptying, and inhibits gallbladder contraction. As a result of the short half-life, a number of synthetic analogues have been developed, and of these, octreotide is used most commonly in the treatment of gastrointestinal fistula. Its significantly longer half-life allows it to be given by intermittent subcutaneous injection (usually 3 times daily). Despite the similarities, the receptor binding properties of somatostatin and octreotide are not identical and their actions may not be equivalent. Somatostatin receptors comprise a family of 5 heptahelical membrane proteins encoded by 5 related genes that map to separate chromosomes. The clinically used somatostatin analogues, octreotide and lanreotide, act mainly by binding to somatostatin receptors 2 and 5 and this may contribute to a comparatively less effective outcome (Fig. 11).

Fig. 11 Somatostatin receptors subtypes and affinity of somatostatin and octreotide for each

	Receptor subtype				
	SSTR 1	*SSTR 2*	*SSTR 3*	*SSTR 4*	*SSTR 5*
Somatostatin-14	++	++	++	++	++
Octreotide	–	++	+	–	++

+ +, high affinity; +, moderate affinity; –, does not bind

The evidence regarding the role of somatostatin and its analogues in non-pancreatic intestinal fistulas is conflicting and inconclusive at best. Although several small, uncontrolled trials suggest that octreotide (a somatostatin-analogue) may reduce fistula output and decrease the time to fistula closure, the expected effect on fistula closure rate with somatostatin and its analogues is small, and the effect on more distal fistula outputs is not well established [46, 47]. Although a meta-analysis did show favourable outcomes with use of somatostatin and analogues in the treatment of enterocutaneous fistulas, the studies included in the meta-analysis were small, with wide variability in study design and patient characteristics. On balance, it seems unlikely that octreotide will help fistula closure where local factors are in favour of continued fistula patency, however, and, in addition, the use of octreotide is not supported by the findings of more carefully designed randomized trials which have failed to show evidence of benefit [48–50]. The European Society of Coloproctology consensus statement on the surgical management of intestinal failure in adults does not support the routine use of somatostatin and its analogues in patients with enterocutaneous fistulas [5].

Other non-surgical strategies aimed at closure of enterocutaneous fistulas have been developed and reported, with varying degrees of success. Percutaneous catheter management of abscess-fistula complexes and fistula tracks has been reported to lead to fistula closure in 57–100% of patients, although it is unclear what the criteria for this treatment were and how many of these fistulas would have closed spontaneously without any intervention. Fistula track embolization has been reported utilizing a wide range of substances, including fibrin glue, synthetic glues, and biological plugs. None of these has been studied in a controlled fashion and many have been reported in the successful closure of low-output fistulas, where spontaneous closure may have been reasonably expected without any intervention.

Definitive surgical treatment for acute intestinal failure attributable to intestinal fistulas will be required if spontaneous fistula closure does not occur. Internal fistulas will not, in general, close spontaneously. External gastrointestinal fistulas are unlikely to close spontaneously if the factors outlined in Table 4 are present.

Table 9 The risk of mortality and ECF recurrence associated with reconstructive surgery relative to the last laparotomy

	Early	3–12 weeks	6–12 months	>12 months
Mortality	30–100%	7–20%	3–9%	0–3%
ECF recurrence	40–60%	17–31%	10–14%	3%

Patients who are referred to a specialized unit for management have usually selected themselves by virtue of the underlying pathology or failure of spontaneous fistula closure. The exact nature of surgery required will depend upon the anatomy and aetiology of the fistula but the general principles are as follows: attempts to deal definitively with the fistula should not be made until the patient is well, free from sepsis and adequately nourished. Surgical intervention should be planned and is usually delayed. In the case of IF associated with ECF, early operative intervention to close the fistula is contraindicated by the associated high mortality due to re-fistulisation, sepsis, malnutrition and difficulties with fluid balance [51].

Delaying surgery for 6–12 months after the last operation has been shown to reduce both the mortality and fistula recurrence rates at subsequent definitive surgery (Table 9) [45, 52–54].

It is desirable to leave at least 6 months between the previous laparotomy and definitive surgical treatment to allow for softening of adhesions within the abdomen. This may necessitate discharging the patient on home parenteral nutrition. Re-operative surgery of this nature is extremely technically demanding and adequate amounts of time should be set aside. Sharp, rather than blunt dissection is required to avoid tearing the bowel at the site of adhesions and segments of bowel with fistulas should be resected rather than bypassed. Intestinal anastomosis should only be attempted if the patient is free from sepsis, well-nourished and local conditions are entirely favourable. It is particularly important to avoid leaving an anastomosis within an old abscess cavity as this will inevitably lead to re-fistulation. In patients with a jejunostomy and an intact colon, consideration should be given to intestinal re-anastomosis, even if it will not prevent the need for long-term parenteral nutrition. Once intestinal continuity

is restored the additional absorptive area of the colon may reduce fluid and electrolyte requirements and thus the frequency and/or volume of TPN required. Diarrhoea is often surprisingly easy to control with loperamide, codeine phosphate and/or cholestyramine.

Outcome of Treatment for Acute Intestinal Failure

Acute intestinal failure varies widely in nature, from transient postoperative ileus after major abdominal surgery, to life-threatening abdominal sepsis with multiple intestinal fistulas. Generalized statements about outcome are therefore unlikely to be helpful. Prior to the antibiotic era and the use of nutritional support, the mortality associated with the development of an enterocutaneous fistula was in excess of 60%, with many patients succumbing to the combined effects of sepsis and undernutrition [55]. Prior to the advent of safe parenteral nutrition [56], it proved impossible to maintain nutritional status in patients who had undergone massive enterectomy, and death inevitably resulted from progressive inanition.

The prognosis for patients with even the most complex manifestations of acute intestinal failure has improved considerably over the last three decades, as a result of improvements in surgical technique, intensive care medicine, antimicrobial chemotherapy, stoma/skin care and nutritional support. The principle factors which now adversely affect outcome are sepsis (which if severe is still associated with a mortality in excess of 30%), co-morbidity and underlying disease. A large prospective study of 300 admissions with intestinal failure to a specialized unit over a 7-year period recorded a mortality rate of 13%. The major adverse prognostic factors on admission were increasing age and hypoalbuminaemia, the latter indicative of severe sepsis. The healthcare costs associated with the management of patients with complicated acute intestinal failure have not been published but may be considerably in excess of £60,000 per consultant episode in the UK and it is appropriate that expertise be concentrated in a small number of specialized units. The multifaceted nature of the problems faced by patients with acute intestinal failure makes a team approach to management mandatory and it is important to note that nurses, dieticians, pharmacists and physiotherapists are all essential, in addition to medical practitioners, for a successful outcome [5, 57].

Mesenteric Ischemia

Alexandre Nuzzo, Yves Castier, and Olivier Corcos

Key Points

1. Mesenteric ischaemia can be acute or chronic, non-occlusive (low-flow states, vasospasm) or occlusive (venous or arterial thrombosis or embolism), segmental or extensive.
2. In those less than 60 years old the aetiology is likely to be a haematological abnormality and in those older than 60 atherosclerosis or a cardiovascular abnormality.
3. An acute mesenteric ischemia is suspected from the history of sudden unremitting abdominal pain. Normal plasma lactate levels are observed in the early stage of mesenteric ischemia and cannot rule out the diagnosis. Contrast-enhanced computed tomography (CT) is the most definitive way of making the diagnosis and differentiating an arterial from venous infarction.
4. If an early diagnosis is made an attempt should be made to revascularize the gut, even before a resection for a definite infarction. However if advanced ischaemia there may be a severe reperfusion injury. Surgeon should aim to restore blood flow before doing a resection, except in the case of instable patients in whom emergent resection is indicated first
5. After the resection, secondary elective reanastomosis of remaining small bowel to ileum/colon reduces the need for parenteral support, increases survival and quality of life.
6. A specialized intestinal stroke center may improve the acute management of these patients allowing revascularization, preventing irreversible necrosis, and when a laparotomy is necessary reducing the amount of bowel that is resected.

Introduction

Acute mesenteric ischemia (or intestinal ischemia) represents the most severe and the most challenging of digestive vascular disease. The progression to mesenteric infarction (or intestinal necrosis) is an irreversible complication potentially leading to a resection of a large amount of small intestinal and resulting in short bowel syndrome or death [1]. Thus, any intestinal ischemia should be recognized and treated at a reversible, early or chronic stage [2]. In the absence of validated and available biomarkers, the diagnosis requires a high degree of clinical suspicion and an urgent specific therapy with two linked objectives: saving the gut, to save the life of the patient [3]. Developed on the model of "stroke units", a new intensive care unit dedicated to the acute care of AMI offering expert multimodal and multidisciplinary 24/7 management has been implemented in Paris, France. The first results of this intestinal stroke center have shown high rates of survival without intestinal resection in most patients. In this chapter, the latest scientific and clinical knowledge on AMI as well as a treatment strategy will be presented.

Definition of Mesenteric Ischemia and Anatomy

Mesenteric ischemia is defined by (1) an intestinal injury, secondary to (2) a vascular insufficiency in the territory of the splanchnic vessels, in (3) the absence of an alternative

J. M.D. Nightingale (ed.), *Intestinal Failure*, https://doi.org/10.1007/978-3-031-22265-8_6

diagnosis. The perfusion disorder can be acute or chronic, non-occlusive (low-flow states, vasospasm) or occlusive (venous or arterial thrombosis or embolism), segmental or extensive [1, 4].

The digestive tract vascularization is ensured by the three main arteries originating from the anterior face of the abdominal aorta (Fig. 1 and Table 1):

- the celiac artery (CA) which supplies the stomach, the duodenum, the first centimeters of the jejunumn, the bile ducts, the pancreas and the spleen;
- the superior mesenteric artery (SMA) which supplies the small bowel, the ileocecal valve and the right colon;
- the inferior mesenteric artery (IMA) which supplies the colon from the right angle to the upper rectum. The middle and lower rectums are supplied by the middle and lower rectal arteries, branches of the internal iliac arteries.

The topography of digestive ischemic lesions generally depends on the territories of vessel involved. Consequently, the distal occlusion of a branch of the SMA (embolism or vasculitis of small vessels, for instance) may lead to a segmental and focal ischemia, while a proximal thrombus is more likely to be complicated by extensive intestinal and right-side colon necrosis. Conversely, non-occlusive ischemia is more likely to present as multifocal ischemia, involving watershed areas of the GI tract with large superficial mucosal injuries rather than wall deep.

The GI tract arteries are terminal (straight vessels), perforating the digestive wall on the mesenteric edge, dividing into intramural arterioles penetrating through each villus up to its summit and connecting on a wide submucosal capillary network without constituting an arterial-venous shunt. These capillaries form intramural venules which run parallel to the arterioles, at the base of the villus. This micro-vascular network facilitates the diffusion of oxygen at the base of the villus and makes of the top of the villus the most sensitive area to ischemia. The villous venules merge into straight veins and empty into the mesenteric veins and the portal system. The right and left parts of the colon are vascularized by the superior and inferior mesenteric arteries, respectively. Left-side colon ischemia, which represents the most common type of digestive vascular injury, is generally mild, self-limited and the consequence of a transient decrease in microvascular blood flow from a non-occlusive (vasospasm) and/or drug-induced origin [5]. Instead, ischemia affecting the right colon is associated with a vascular lesion of the

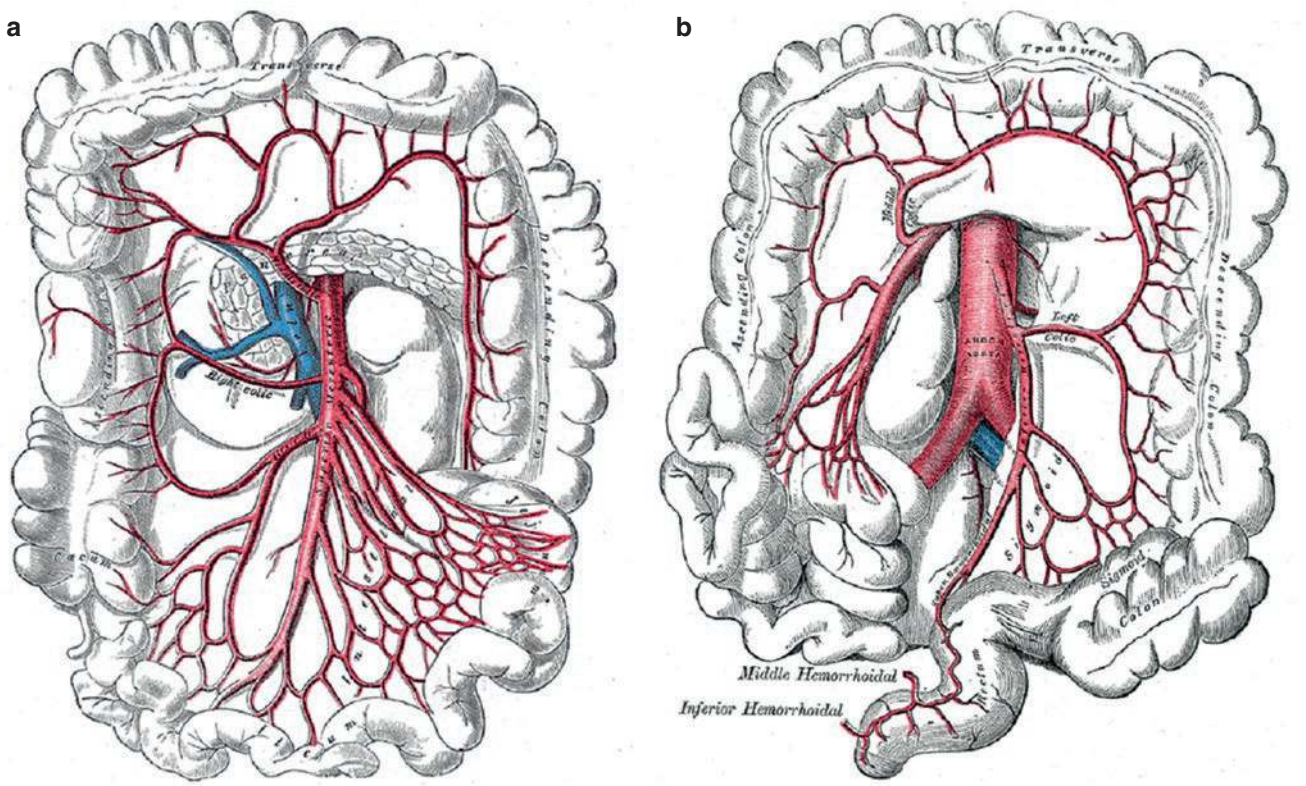

Fig. 1 Gastrointestinal tract arterial vascularization. (Source: Anatomy of the human body. 20th edition. Henry 1918). The superior mesenteric artery supplies the entire small bowel and the right side of the colon (**a**), whereas the left side of the colon is supplied by the inferior mesenteric artery (**b**)

Table 1 Intestinal injury location depending on the mechanism and the type of vascular insufficiency

Splanchnic vessel	Organ supplied	Intestinal injury location	
		Proximal occlusive ischemia *(ex: atherosclerotic thrombosis)*	Non-occlusive, or distal occlusive, ischemia *(ex: embolus, vasculitides)*
Celiac artery	Stomach, Duodenum, proximal jejunum, Gallbladder and bile ducts, Pancreas, Liver, Spleen	Gastric & duodenal or duodeno-jejunal ulcers, cholecystitis, pancreatitis, spleen infarcts	Gastro-intestinal segmental and multiterritory ischemia
Superior mesenteric artery and vein	Jejunum, ileum Right and traverse colon	Extensive small bowel and/or right-side colon ischemia	
Inferior mesenteric artery and vein	Left-side colon, upper rectum	Left-side colon ischemia with frequent rectum sparing	

SMA in 25% of patients and then should be considered as a segmental form of AMI [6].

Pathophysiology

Acute mesenteric ischemia (AMI) should be considered as one stage of a multistep process (Fig. 2) leading, from a digestive vascular insufficiency, to intestinal necrosis, organ failure and death. Ischemia begins early and superficially and then spreads in deep and surface of the intestinal wall. Vascular insufficiency is initially the trigger for an inadequacy between inputs and requirements for energy substrates by overcoming the adaptive processes of a digestive territory. This loss of homeostasis results from a sudden decrease or interruption of the splanchnic-mesenteric blood flow. The decrease in splanchnic blood flow in the proximal circulation induces a deep extension of the ischemia which then becomes transmural and gangrenous.

Conversely, when perfusion abnormalities relate to intraparietal arterioles, lesions of ischemia remain superficial. Intestinal vascular insufficiency leads to hypoxia, first with mucosal and submucosal consequences. The hypoperfusion of the intestinal mucosa is responsible for an early hypoxic cellular desquamation of the intestinal villi. Polymorphonuclear neutrophils are early major actors that adhere and migrate to the ischemic site to ensure the removal of tissue debris during necrosis. Mucosal and submucosal cells switch to anaerobic glycolysis with local production of lactate which initially is fully metabolized by the liver. The increase in intracellular acidosis blocks the anaerobic metabolism and the membrane pumps involved with ionic and acid-base regulation. This leads to a profound alteration of cellular homeostasis and, ultimately, to cell death by apoptosis [7–9].

Initially, there is a dissociation between high portomesenteric blood lactate levels and normal peripheral blood lactate levels due to the active liver metabolism [4]. Systemic lactic acidosis is, therefore, a late phenomenon, which often indicates intestinal necrosis and the onset of organ failures [10]. Associated endothelial lesions can lead to platelet, pro- and anti-thrombotic agents (protein C, S, and antithrombin) consumption that cause a hemorrhagic syndrome.

Furthermore, the intestinal neuro-hormonal regulation of vasomotricity is associated with the activation of the renin-angiotensin-aldosterone system, to try to maintain a mucosal oxygen extraction rate. This induces a reflex splanchnic arterial vasospasm, irrespective of the initial vascular mechanism, that may prolong and worsen ischemia despite the revascularization treatment. This vasoconstriction accompanies, for example, situations of hypovolemia, during which digestive ischemia develops before clinical hemodynamic instability [11, 12].

The disruption of the epithelial barrier resulting from mucosal alterations (Fig. 3) leads to interactions between microorganisms, bacterial antigens, endotoxins of the intestinal lumen and the mucosal and submucosal immune system. The stimulation of innate immunity will result in local then systemic inflammatory pathways activation such as TLR, NF-KB or TNF [13, 14]. Through the bloodstream, bacteria, endotoxins, cells degradation products and activated immune cells translocate and promote systemic inflammation response syndrome (SIRS). Cytokines, chemokines, cellular and bacterial debris can also reach the pulmonary circulation from the lymphatic circulation and thus cause acute respiratory distress syndromes [15, 16]. The translocation of bacteria and/or bacterial products into the mesenteric lymph nodes and/or bloodstream is reported in intestinal ischemia in up to 25–100% of experimental animal models. It further increases the SIRS making the ischemic small bowel an infection site [17]. The absence of a rapid recovery of a sufficient digestive perfusion leads to irreversible transmural necrosis with peritonitis. Without intestinal resection, the SIRS leads to multiple organ failure and death [16].

In the model of the "gut origin of sepsis", the gut was considered to be the 'motor' of multi-organ failure [11, 15, 16, 18]. Aside from its barrier function, the gut contains growth factors, adenosine, and hormones, which are potential mediators for the modulation of intestinal inflammation and repair, due to their roles in cellular proliferation, differentiation, migration, apoptosis, and autophagy [19–23]. Physiologically, the gut could initiate and propagate sepsis due to the ability of bacteria, endotoxins, and other antigens

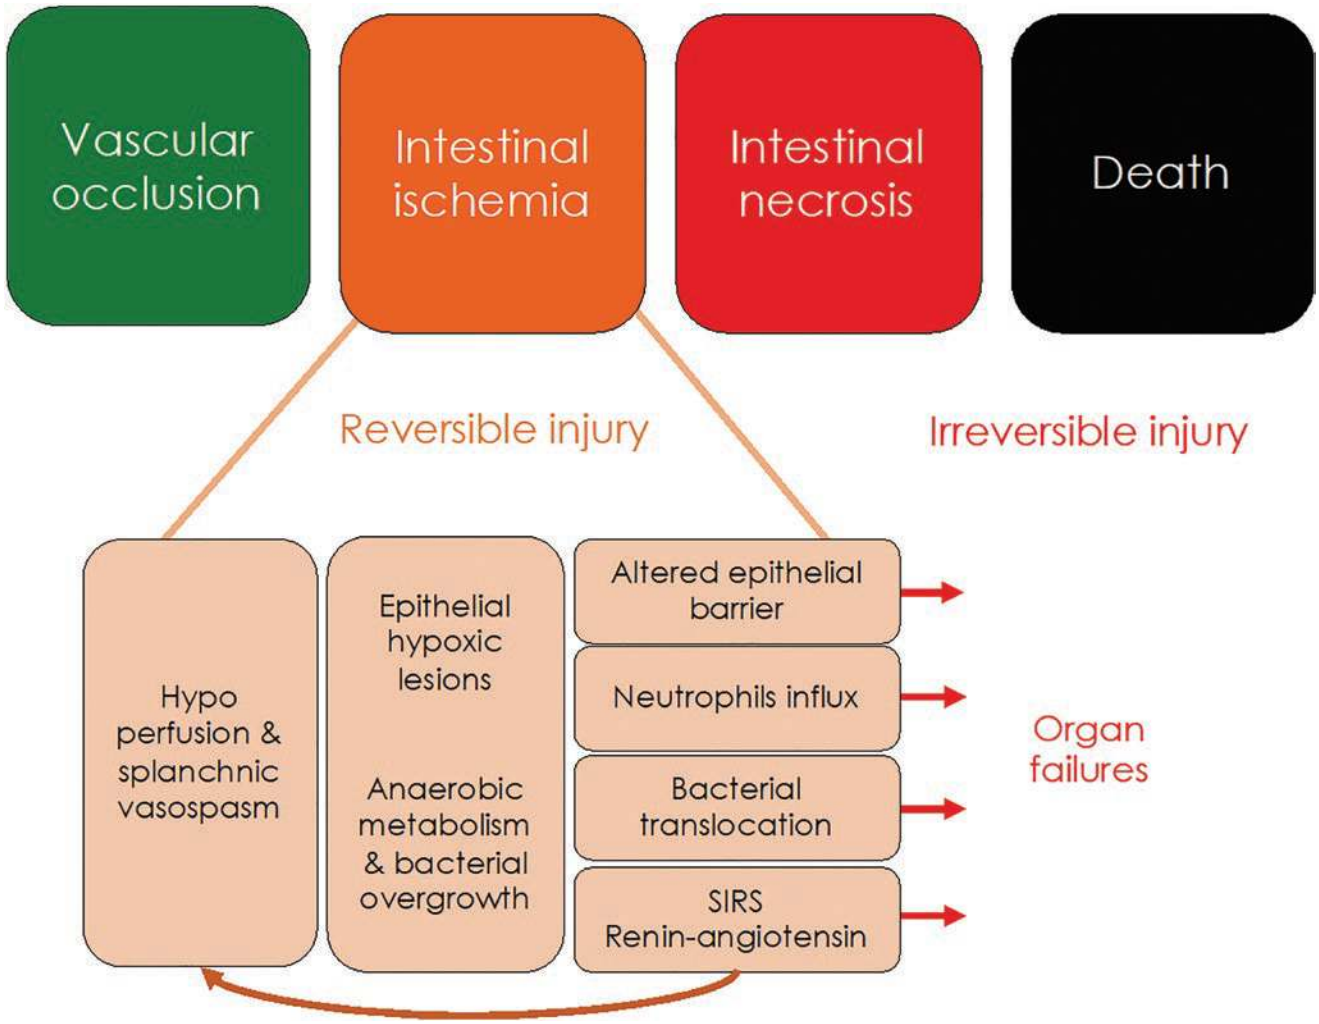

Fig. 2 Multistep pathophysiology of acute mesenteric ischemia. *Intestinal ischemia should be considered as the reversible stage of a pathophysiological multistep process leading to necrosis and death*

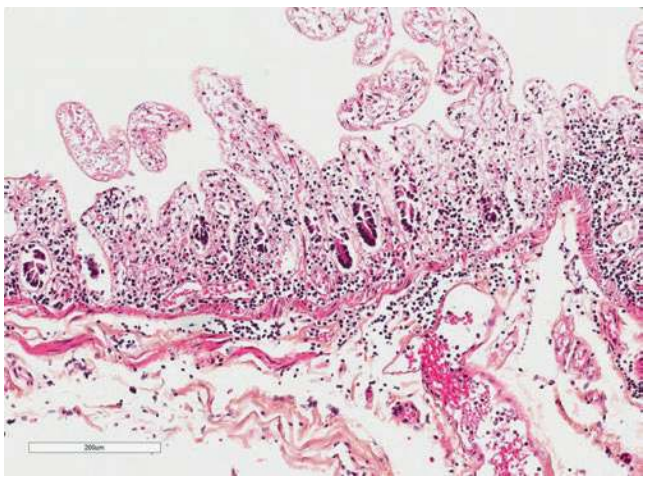

Fig. 3 Pathological analysis of acute ileal ischemia. *Acute ileal ischemia characterized grossly by congestive small bowel loops and superficial mucosal ischemia starting at the tip of the villi*

to translocate, along with the production of pro-inflammatory cytokines and toxins [11]. In The 'Three Hits Model' Deitch et al. added the phenomenon of reperfusion injury [24]. In the 'Gut-Lymph' theory, bacteria, cellular components, immune cells, cytokines and chemokines generated by the injured gut travel via the lymphatics to reach the pulmonary circulation, activating alveolar macrophages, and contributing to acute lung injury, acute respiratory distress syndrome and multi-organ failure related to AMI [15, 16, 25]. The systemic consequences of bowel ischemia and necrosis are lethal in most patients in the absence of curative treatment including revascularization [26, 27]. However, reoxygenation of the digestive mucosa can also paradoxically worsen epithelial and vascular lesions, due to an oxidative burst mechanism causing the influx and death of neutrophils with the formation of neutrophil extracellular traps and the secretion of their granular content [28].

Another mechanism of epithelial self-digestion would contribute to aggravate this alteration of the gut barrier function via proteolysis of tight enterocytic junctions by bilio-pancreatic secretory enzymes [22]. This quite recent concept describes the effect of pancreatic enzymes on the intestinal barrier altered by ischemia. Self-digestion contributes to the worsening of intestinal ischemic lesions and the development of the related systemic inflammatory response. Degradation products of pancreatic enzymes, residues of bacterial products pass through the lymphatic, hematogenous or peritoneal barrier and are likely to induce a loco-regional but also systemic reaction [20, 21]. In animal models, inhibition of these enzymes results in a decrease in intra-parietal micro-bleeding, in the systemic inflammatory response, and even in mortality in some studies [22]. The action of these enzymes would involve degradation of inter-enterocytic tight junction's proteins such as E-cadherin. Moreover, these enzymes would also induce a cleavage of the pro-metalloproteinases into active metalloproteinases [23].

Mesenteric vein thrombosis can be anterograde (primary occlusion of the straight veins, generally secondary to an enteritis or an intra-abdominal inflammatory process) or retrograde (primary occlusion of the portal vein, generally secondary to portal hypertension). In this context, the occurrence of intestinal ischemia may be more likely in case of the occlusion of second order radicles of the superior mesenteric vein and in the context of arterial insufficiency/associated arteriosclerosis [19]. Downstream the portal/mesenteric vein thrombosis, the hepatic consequences are weakly marked due to rapid compensatory mechanisms such as hepatic arterial vasodilation and the development of a cavernoma, visible as early as a few days after thrombosis.

Epidemiology

Incidence

Given that the clinical diagnosis of mesenteric ischemia is still a challenge, the incidence of digestive vascular diseases is still difficult to assess and then potentially largely underestimated. However, it is likely increasing due to an increase in the population at cardiovascular risk and improvements of its recognition by CT scanning [27].

Based on autopsy studies in Sweden, Acosta et al. estimated an incidence of 13/100,000 person-years between 1970 and 1982, when autopsy rate was 87% [29, 30]. In a US comprehensive database and population analysis in Maryland, Crawford et al. reported a statewide admission rate of 10/100,000 inhabitants per years during 2009–2013 [31]. These figures are consistent with epidemiological studies on chronic mesenteric ischemia with an estimated incidence of 9.2/100,000 inhabitants per years from a Dutch prospective database between 2014 and 2019 [32]. The incidence of arterial AMI increases exponentialy with age, with an incidence of 25/100,000 person-years after 70 years old, and a peak incidence of 217/100,000 person-years after 85 years-old [29, 30, 32].

Causes

Main causes of mesenteric ischemia can be classified according to the two main mechanisms of vascular insufficiency, often associated: (1) occlusive mesenteric ischemia (85%), due to atherosclerotic lesions, embolism or thrombosis, involving splanchnic artery (70%) and/or vein (15%), and (2) non-occlusive mesenteric ischemia (15%) caused by mesenteric vasospasm secondary to a systemic low flow or a vasoconstrictive drug. Each of these forms can occur on pathological vessels (atheroma, dissection, dysplasia, vasculitis) or on healthy vessels. In the latter case, the origin of the occlusion is often due to a systemic cause of thromboembolism (cardiogenic embolism, thrombophilia, myeloproliferative syndrome) and/or a regional risk factor (inflammatory or infectious intra-abdominal process or neoplasm, portal hypertension).

The main cause of arterial mesenteric ischemia is atherosclerosis. Although the prevalence of significant splanchnic arterial atheromatous stenosis in the general population is high (17 to 50%), most are asymptomatic [33]. In this setting, the incidence and predictive factors for the onset of mesenteric ischemia are unknown. Other causes of mesenteric arterial occlusion include embolism, vasculitides, infectious arteritis, fibromuscular dysplasia, median arcuate ligament syndrome, dissection and hypercoagulability [1, 4]. Their respective prevalence and incidence have not been precisely evaluated.

Causes of venous mesenteric ischemia include portal hypertension, intra-abdominal inflammatory processes (pancreatitis, inflammatory bowel disease, sepsis, trauma), malignancies, hematologic disorders, and thrombophilia.

Risk factors for non-occlusive mesenteric ischemia include vasoconstrictors (noradrenaline, cocaine (not uncommon in young adults)) and hypovolemia (sepsis, hypotension, dialytic depletion) [18, 34]. (Table 2) The knowledge on the risk factors of AMI might be incomplete given that half of patients, no prior cardiovascular or prothrombotic history is found [35]. As a result, AMI should be considered regardless of the patient's age and cardiovascular history.

Table 2 Main causes of mesenteric ischemia

Mesenteric ischemia		Causes et facteurs favorisants à rechercher
Occlusive	Vascular disease	– Atherosclerosis – thrombosis – Embolism (cardiogenic and arteriogenic) – Aneurysm, dissection – Fibromuscular dysplasia – Vasculitides, neuro-endocrin tumors, radiation enteritis – Vascular injury (endovascular or open vascular surgery, trauma, compression by a mesenteric malignancy)
	Hypercoagulability	– Intra-abdominal inflammatory process, cancer or surgery – Inherited thrombophilia (prothrombin gene mutation G20210A, favtor V Leiden, antithrombin, protein S and C deficiencies, increased factor VIII) – Hematological disorders (polycythhaemia, myelofibrosis, thrombocythemia, JAK2 V617F mutation, antiphospholipid antibodies, paroxysmal noctrunal haemoglobinuria) – Malignancies – Oral contraceptive, pregnancy, obesity – Portal hypertension, congestive heart failure – Other: CMV, nephrotic syndrome, SARS-COV-2 infection
Non-occlusive		– Low flow states (hypovolemia, shock, dialysis) – Extra-corporal life support, clamping in vascular surgery – Toxic/iatrogenic (cocaine, amphetamine, catecholamines) – Sickle cell disease, leukostasis – Heavy exercise (marathon runners) – Electrocution and burns

Prognosis

In a systematic review of 45 studies including 3692 patients, acute mesenteric ischemia (AMI) was consistently fatal without adequate treatment [26]. Despite treatment, mortality varied from 40% (venous ischemia) to more than 80% (arterial ischemia), the main prognostic factors being the precocity of the diagnosis and treatment, the occurrence of transmural necrosis, the mechanism of ischemia (venous vs arterial) and the age of the patient [36]. In the 2010s, our most recent results have shown that multimodal and multidisciplinary SURVI management made it possible to obtain a survival of 91%, without intestinal resection in 58% of cases, [4, 10] making AMI a potentially disease fully reversible at its early stage [2]. However, the late recognition of the diagnosis and intestinal necrosis, at the stages of peritonitis and multi-visceral failure, explain the mortality still reported today by other centers and the prevalence of short bowel syndrome in survivors [37].

Diagnosis of Mesenteric Ischemia

Clinical Suspicion

In the absence of a biomarker allowing a rapid non-invasive diagnosis, the clinician's only weapon remains his diagnostic suspicion and confirmation by the contrast-enhanced abdominal CT scan. At this stage, the time of onset of acute abdominal pain should be considered as the starting point for a countdown leading, without prompt and adequate treatment, to intestinal necrosis and death. Contrary to popular belief, most patients with AMI present to the emergency department at a potentially reversible, but still insufficiently recognized early stage. Indeed, 50% of patients present initially with no known cardiovascular history, without surgical abdomen, without organ failure and without elevation of plasma lactate [35, 38, 39].

The acute abdominal pain is constant, apart from the particular case of the intensive care patient receiving a sedation [1, 4]. Pain can be inaugural or succeed to symptoms of chronic mesenteric ischemia in 30% of patients, the diagnosis of which is most often overlooked [29, 35]. Pain is typically sudden ("vascular") or rapidly progressive, intense and requiring opioids, continuous and relentless, peri-umbilical or diffuse, and contrasts with an abdominal palpation initially falsely reassuring. It can be associated with vomiting (48%), diarrhea (31%), digestive hemorrhage (18%) and an inflammatory biological syndrome which, inconstant and/or too late have no diagnostic value [10, 39].

Biomarkers

While biologic abnormalities—such as leucocytosis or lactic acidosis – have been documented in patients with AMI, their performance to establish the early diagnosis is poor [40, 41]. Worse, in a cohort study, a delayed diagnosis was more likely when initial plasma lactate levels were <2 mmol/L suggesting that physicians might be misguided by unremarkable plasma lactate levels. The high complexity of the layered intestinal wall structure increases the diversity of the proteins and metabolites released in AMI. Their hepatic metabolism through the hepatic portal system results in substantial overlap with liver proteins and metabolites. These factors, along with the heterogeneity of the disease, explain why identifying clinically reliable biological early markers of

AMI has been unsuccessful so far [1, 4, 41]. Three blood biomarkers have gained attention over the past decades: citrulline, a marker of enterocyte function; I-FABP, a marker of enterocyte damage; and D-lactate, a marker of intestinal barrier dysfunction and microbial translocation [41–44]. As a result, these tests are increasingly used in basic and clinical research as indirect markers of an ischemic intestinal injury in a broad range of emergency clinical settings. However, their alleged diagnostic performances have only been assessed in small heterogeneous cohorts. Besides, conflicting results have been reported, and most of the studies consist of preoperative data in late-stage necrotic AMI patients [45]. Early diagnosis remains a critical clinical and research challenge as it would allow early management and consequently improve the dire prognosis of AMI. To meet this challenge, relevant new biomarkers may be identified using non-targeted multi-omics discovery approaches in large cohorts of early-stage AMI patients admitted in dedicated units.

Diagnostic Imaging

The cornerstone of the diagnosis is contrast-enhanced computed tomography (CT). Its excellent reported sensitivity and specificity [46] suggest that it may be used as the first-line imaging technique. However, lower sensitivities were reported when the CT scan was performed during both arterial and venous phases (83%) or venous phase only (72%) [35], or when in the real-life setting, the clinical suspicion was not always mentioned to the radiologist, [47] resulting in either an inappropriate IV contrast protocol and/or an analysis that did not focus on the mesenteric vessels [48]. Finally, the unenhanced CT scan should be avoided because it does not detect signs of AMI, causing a significant delay in diagnosis [35]. A recent study focused on the impact of contrast-enhanced multidetector CT on the survival in patients with acute superior mesenteric artery occlusion; in-hospitality mortality rate was 42% for patients who underwent contrast-enhanced multidetector CT, *versus* 71% for patients not examined with CT [48]. As a result, CT should be performed as quickly as possible after the onset of symptoms in all patients, and include contrast-enhanced images to visualize both mesenteric vessels and digestive structures, including in the presence of renal insufficiency, the risk of overlooking an AMI greatly exceeding that of the injection of the contrast agent [1, 4, 49, 50].

CT plays a double role in patients with AMI. First, diagnosis is reached based on the combination of two sets of features that parallel the pathophysiology of the disease: 1/ vascular insufficiency, and 2/ ischemic intestinal injury. Second, CT should help identify negative prognostic factors, suggestive of extensive necrosis, or complications which will guide the treatment of revascularization, [51] and the indication for digestive surgery [10].

Vascular Imaging Findings

Intra-luminal defects or occlusions of the mesenteric vessels are highly specific for the diagnosis (94–100%), but reported sensitivity is rather low (12–15%) [52]. Yet, in our experience, vascular anomalies are encountered in more than 75% of patients. In occlusive forms of AMI, CT allows visualization of the site of the vascular obstruction and helps distinguish emboli from thrombosis. It also depicts other vascular anomalies such as calcified or non-calcified plaques, or rare dissections. In non-occlusive mesenteric ischemia, CT may show narrowed veins, flattened inferior vena cava [53], diffuse irregularities or stenoses of the SMA and SMA branches, and poor visualization of intestinal arcades and intramural vessels [54], as described by Siegelman et al. with angiography [55].

Bowel Imaging Findings

Numerous findings associated with intestinal ischemic injury, including bowel wall thickening or thinning, spontaneous wall hyper-attenuation on unenhanced CT acquisition, decreased or absent bowel wall enhancement, bowel dilatation, pneumatosis intestinalis and portal venous gas, peritoneal fat stranding and ascites. These features are often associated, and bear different prognostic value [49] (Fig. 4).

Prognostic Value of CT

CT helps distinguish early from late forms of AMI by depicting imaging features of necrosis or complications. (Fig. 4) From this perspective, radiologists should not only recognize bowel ischemia on CT, but also differentiate it from bowel necrosis that requires surgical resection. Free intraperitoneal gas is the only pathognomonic finding of bowel perforation, and therefore of wall necrosis in patients with AMI [56]. Yet, it is a delayed feature, and patients need to be diagnosed and treated before this occurs. Another important finding is pneumatosis intestinalis. Importantly, pneumatosis intestinalis may occur in ischemic bowel segments that have not yet undergone transmural infarction. Duron et al. found that 47% of patients with AMI showing pneumatosis still had viable bowel, with only partial mural ischemia without transmural infarction on surgical or pathological analysis [57]. Patients with associated porto-mesenteric venous gas are more likely to have transmural infarction than those with pneumatosis intestinalis alone. In AMI of arterial origin, bowel dilatation and decreased wall enhancement have been shown to be more frequent in cases of bowel necrosis [10]. A recent prospective study from our group identified both features in univariate analysis, with necrosis in 68% of cases when bowel wall enhancement was decreased, and in 64%

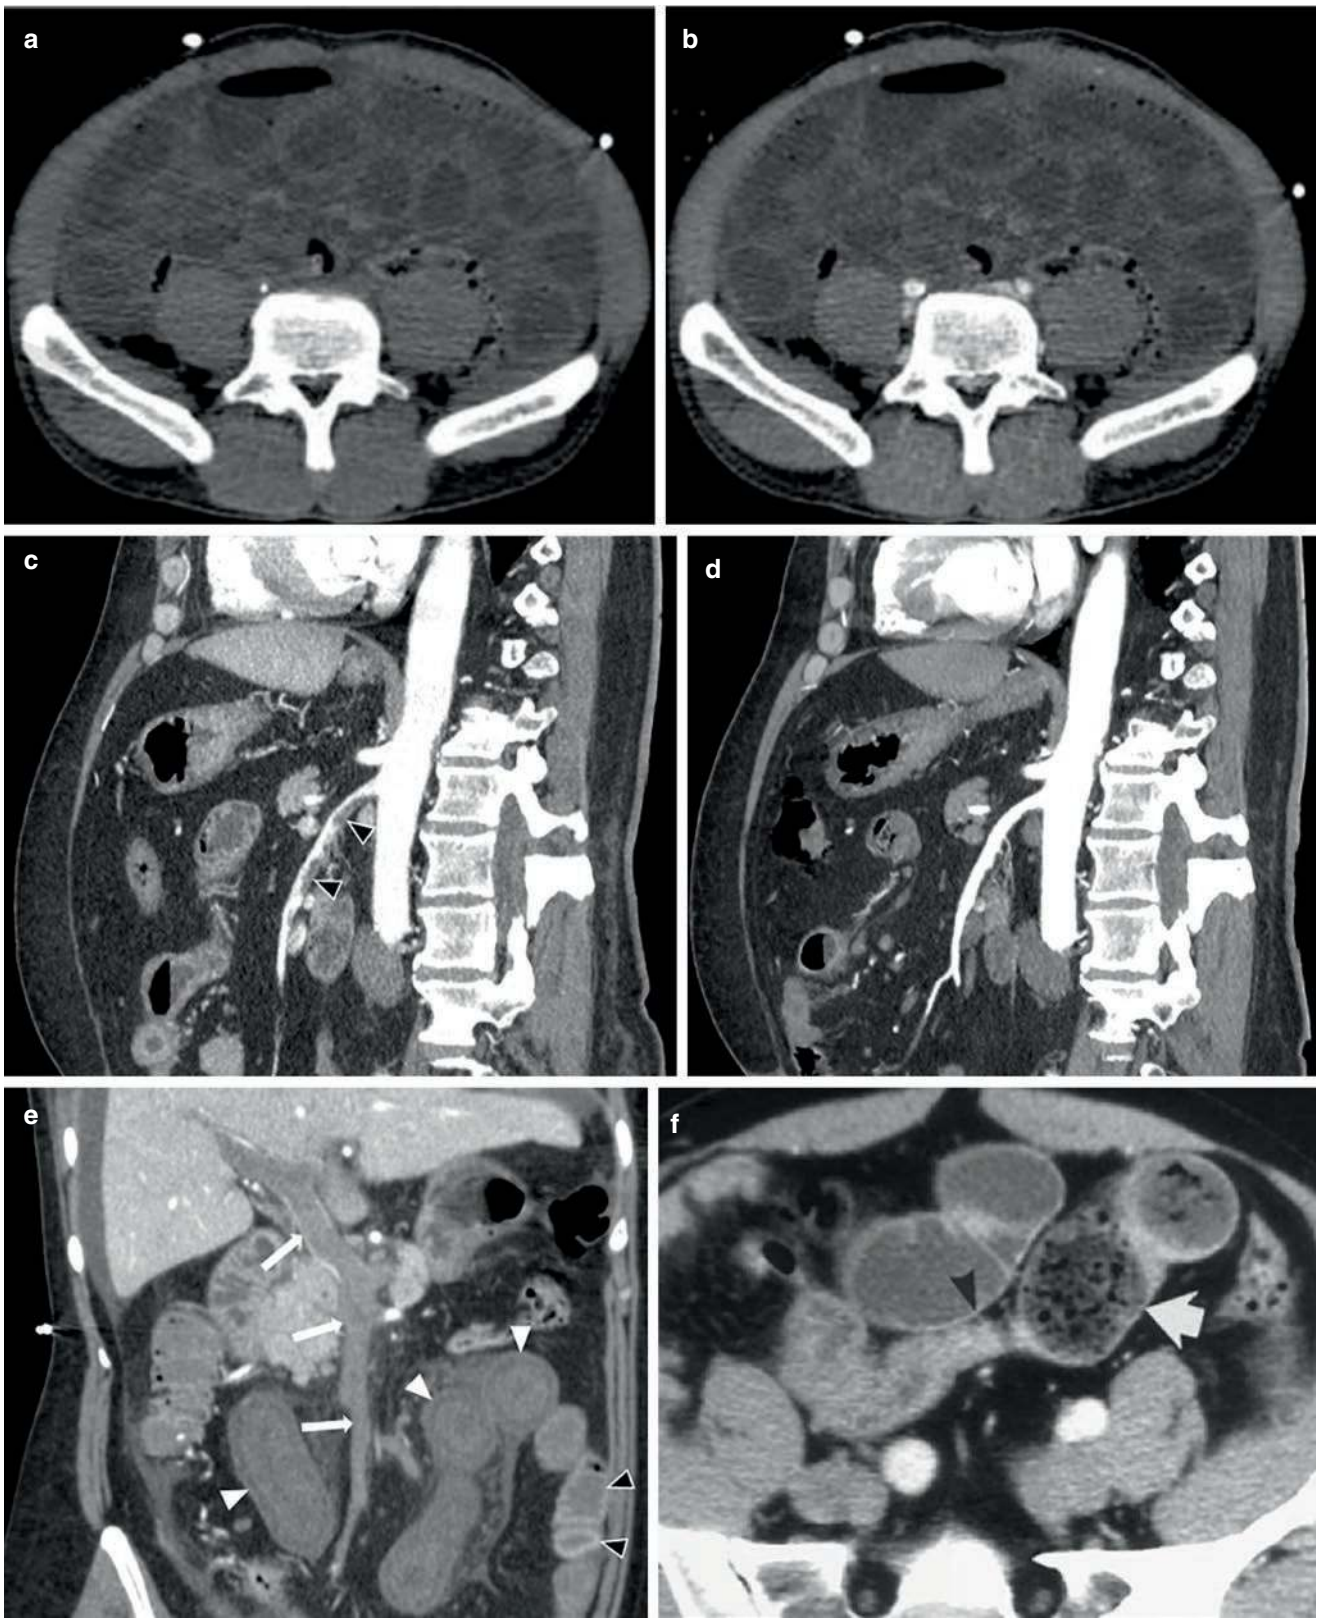

Fig. 4 The contrast-enhanced abdominal CT-scan: the cornerstone of the diagnosis. when bowel loops were dilated. Only bowel dilatation was significant in multivariate analysis [10].

Treatment of Acute Mesenteric Ischemia

Management in Dedicated Stroke Units

In the 2010s, our unit showed that a multimodal and multidisciplinary management of AMI, focused on preserving intestinal viability in a specialized intestinal stroke center, could decrease the rate of intestinal resection, as well as improve short- and long-term survival [58]. These results demonstrated that intestinal ischemic injury during AMI is potentially reversible, and that intestinal necrosis could be considered an unwanted outcome and a late complication [2, 10]. Following these results, in 2016, a 8-bed dedicated intestinal stroke unit was created at Beaujon Hospital, Paris University, France, that provides 24/7 standardized multimodal and multidisciplinary care to AMI patients referred from all hospitals in the Paris area.

Preventing the progression from reversible to irreversible intestinal ischemic injury should be a primary goal in the management of AMI. Indeed, in our experience mortality goes from 2% in early AMI to 35% when intestinal ischemia is treated at the stage of irreversible necrosis [59]. The treatment strategy developed in our intestinal stroke unit simultaneously follows three main objectives: (Fig. 5).

1. Prevent worsening, SIRS and organ failure by a specific medical protocol for intestinal ischemia (Table 3);
2. Preserve the non-necrotic intestine by systematic revascularization;
3. Resect intestinal necrosis according to a non-invasive risk score (Fig. 5), before its complications (perforation, peritonitis).

This multidisciplinary emergency strategy is coordinated by a gastroenterologist and requires a structure with available 24-h revascularization and intestinal resection, in an intensive care environment and in collaboration with an intestinal failure unit. A specific medical protocol targeting each step of the pathophysiological process of intestinal ischemia is administered upon diagnostic confirmation, regardless of the mechanism and form of the AMI. Systematic administration of oral antibiotics yielded a protective effect against transmural intestinal necrosis (HR = 0.16, 95% CI: 0.03–0.62, $p = 0.01$) [59]. Oral antibiotics may prevent intestinal necrosis by (1) decreasing the luminal bacterial load which interacts with the intestinal innate immune system through the disrupted epithelial barrier, (2) limiting local and systemic inflammation which results from bacterial interaction/translocation, and (3) improving their luminal bioavailability in the context of vascular occlusion or low flow. Given the life-threatening risk of translocation in AMI, most experts recommend early and widespread use of antibiotics consistent with our experience [1, 36, 60, 61].

The effectiveness of the treatment is judged on the disappearance of the pain. Any persistent digestive clinical symptom (pain, food intolerance, hemorrhage, persistence of a failure) should suspect for residual ischemia. Exclusive parenteral nutrition is offered until the ischemia is relieved, especially when there is pre-existing undernutrition or a short bowel syndrome. Although a Chinese study suggests that enteral nutrition should be systematically considered, many biases inherent in the retrospective and univariate nature of the analysis limit its interpretation [62]. In practice, oral and / or enteral feeding should be resumed gradually only after joint disappearance of pain and biological inflammatory syndrome.

In the particular case of non-occlusive ischemia, the therapeutic priority is to restore and maintain sufficient splanchnic hemodynamics by treating the cause of hypoperfusion (hypovolemia, sepsis, heart failure, hemorrhage), by preferring fluids to the use of catecholamines (Figs. 5 and 6). Despite the absence of vascular occlusion, the similar ischemic injury of the digestive mucosa justifies the maintenance of the common medical protocol. In the absence of rapid improvement, an arteriography with intra-arterial infusion of vasodilators (papaverine) is recommended. Surgical treatment is therefore offered as a last step in case of the patient worsening or immediately in the event of peritonitis / perforation.

Revascularization

As with any vascular emergency, early revascularization is the only therapy that can prevent/limit irreversible necrosis and its life-threatening complications [58]. Depending on the accessibility of vascular lesions and local expertise, arterial revascularization is ideally carried out percutaneously first and before any digestive surgery in order to preserve a maximum of viable small intestine [4, 51].

Endovascular Strategies

If a vascular impairment is reachable, percutaneous revascularization (intra-arterial thrombolysis, angioplasty-stenting, thrombectomy) should be considered. Recent literature reports a success rate of endovascular revascularization of 87% [63]. The choice of techniques depends on the etiology, and the localization of the vascular occlusion.

To date, no randomized controlled studies have compared an up-front endovascular approach with open surgery for the treatment of AMI. Because AMI is a relatively rare and urgent condition, such trials are unlikely to be performed.

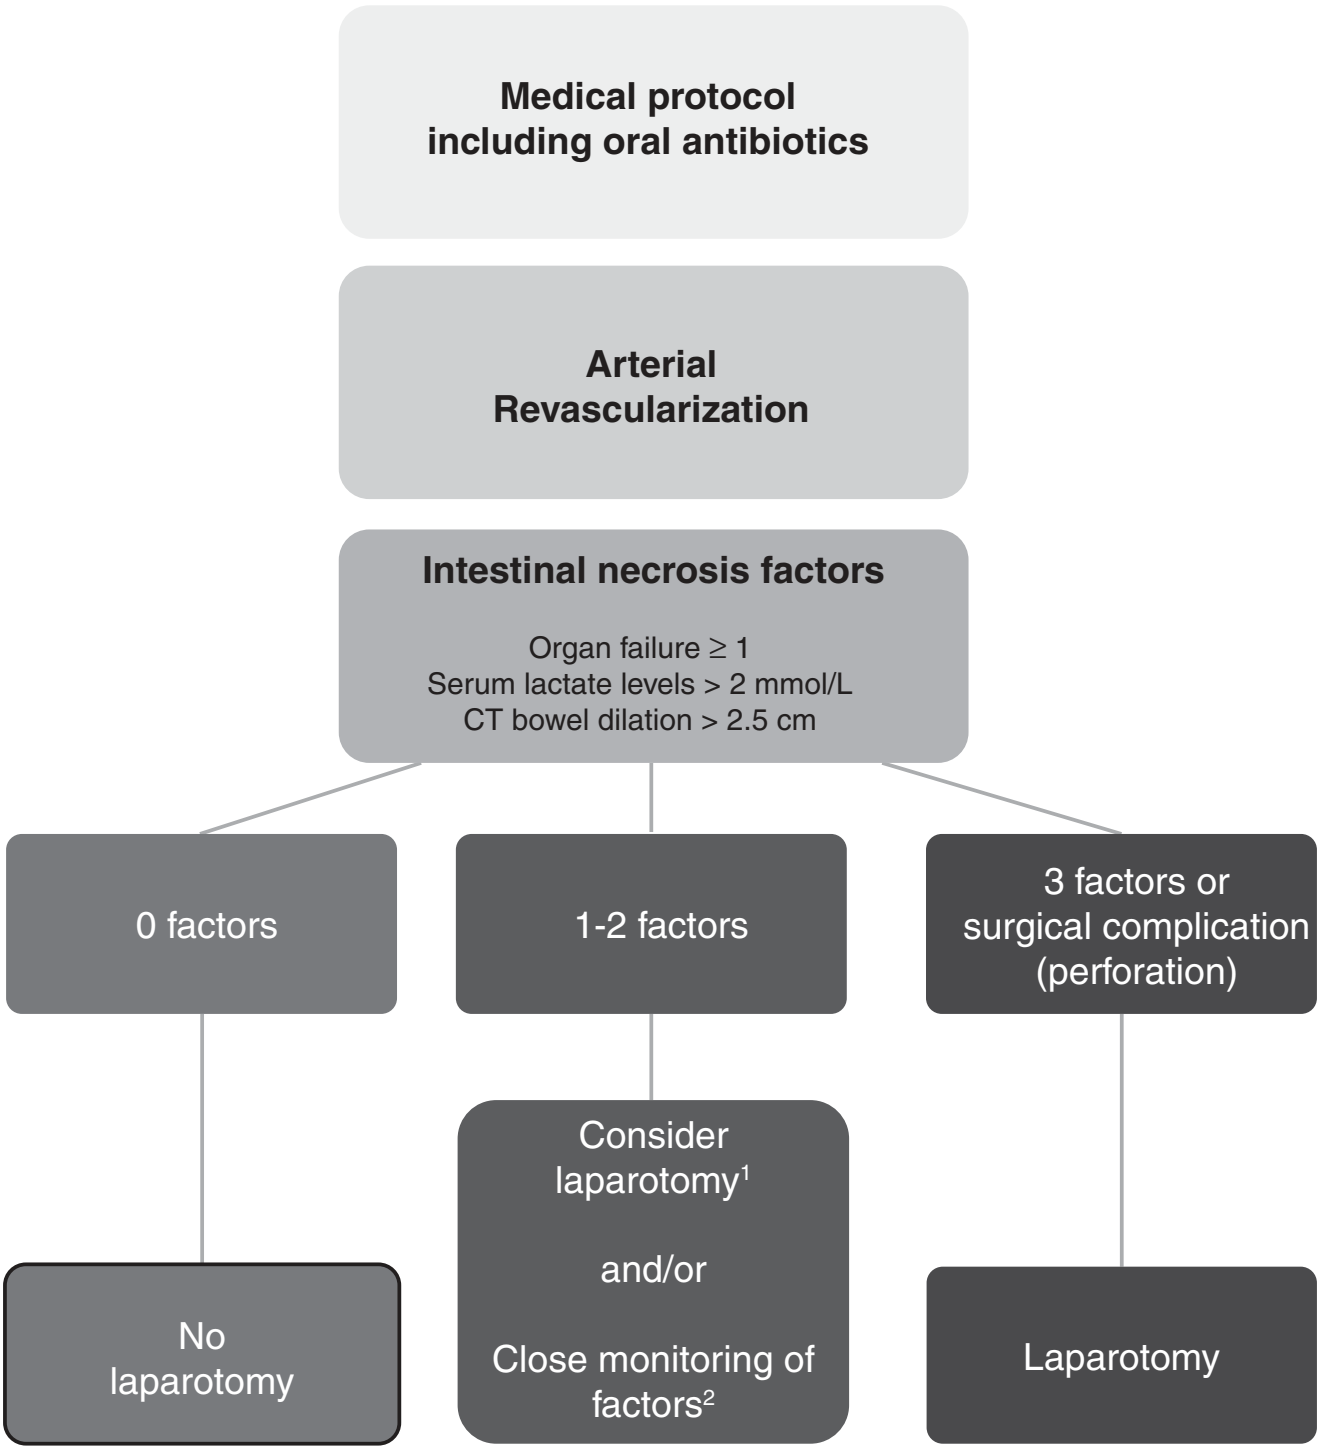

Fig. 5 Treatment algorithm used in the intestinal stroke unit. (1) Consider laparotomy, especially when the factors value is high and when a revascularization is not feasible. (2) Consider close monitoring, especially when the factor value is close to the upper normal cut-off and when an improvement is expected with successful revascularization

Most published studies are therefore retrospective monocentric series, with all methodological biases associated with such study design. A group from the University Hospital of Kuopio, Finland, recently reported a consecutive series of patients with AMI treated over a five-year period. Endovascular treatment was applied as first-line in 88% of the patients [64]. Mortality was acceptable (32%) yet the endovascular strategy failed in 50% of the patients, and a surgical bypass was finally achieved. The 30-day mortality rate was lower than that reported by Endean et al. after surgi-

Table 3 Systematic medical protocol provided in the intestinal stroke unit [58.

Common medical protocol	Blood volume resuscitation (Mean arterial pressure >65 mm Hg, Urine output >0.5 mL kg−1 h−1)
	Curative unfractionated heparin therapy (Anti-Xa target: 0.4–0.8)
	Oral digestive decontamination
	PO gentamicin 80 mg/d
	PO metronidazole 1.5 g/day
	IV proton pump inhibitors
	IV pantoprazole, 80 mg/day
	Oxygen therapy
	Food resting
	PN if prolonged >5 day
Conditional medical protocol	IV aspirin 100 mg/day if arterial thrombosis or revascularization
	IV piperacillin-tazobactam 12 g/day if SIRS or organ failure
	Upper gastrointestinal aspiration if ileus
	Blood transfusion if hemoglobin level

IV intravenous, *PO* orally, *SIRS* systemic inflammatory response syndrome

cal strategy alone (62%) [65]. Recently, a review conducted by Zhao et al. reported that radiological revascularization should be considered as a first-line therapy in patients with a low suspicion of intestinal necrosis [66].

The analysis of population registers makes it possible to obtain data of greater value. Swedvasc, the Swedish vascular register, founded in 1987 comprises more than 90% of all vascular surgical procedures in a country of 9.5 million inhabitants. Two publications from Swedvasc reported the results of revascularization of the superior mesenteric artery for AMI for the periods 1987–1998 and 1999–2006 [67, 68]. Overall, total surgical activity quadrupled from 1999 to 2006, while the number of endovascular revascularizations increased sixfold. If overall mortality decreased, this decline was observed only in patients treated with endovascular strategy. Long-term survival was also better after endovascular strategy. The difference between the two periods could be explained by a difference in patient severity, but the length of the resected intestine was similar in both groups and the endovascular strategy was identified as an independent factor of survival in multivariate analysis (odds ratio 3.7). However, as in the Kuopio Hospital experience, one of the main reasons for successful endovascular strategy was the possibility of surgical revascularization if the former fails.

Similar observations emerge from the analysis of the National Inpatient Sample (NIS) based in the United States [69]. The NIS is a database of 20% of the hospitalization episodes of nearly 1000 hospitals. Of the 679 patients with AMI treated between 2005 and 2009, 514 (76%) were treated by surgical revascularization and 165 (24%) by endovascular procedure. The proportion of patients who had endovascular repair increased from 12% in 2005 to 30% in 2009. Mortality was 39% after surgery and 25% after endovascular procedure. Among survivors, the proportion of patients requiring total parenteral nutrition was also significantly higher after surgery than after endovascular strategy (24% versus 14%) [69]. Thus, although Level I evidence is lacking, this data seems convincing.

This approach of surgery *versus* endovascular revascularization, seems to us to be limited and erroneous. If endovascular interventions are sometimes performed alone, optimal patient management must combine the two approaches in a complementary perspective, the benefits of each being able to support those of the other. Indeed, the majority of patients treated with the endovascular route have laparotomy and intestinal resection in a second phase. However, the mean length of the resected small intestine is significantly shorter than with surgery alone [51].

Open Vascular Surgery

Vascular surgery is often required to restore the mesenteric revascularization in order to improve the prognostic of the AMI (increase survival and prevent intestinal failure). The most common situations when revascularization is done surgically are:

- surgical abdominal exploration is needed and urgent
- surgical exploration has already been done by the visceral surgeon
- endovascular procedures failed to restore the mesenteric revascularization
- vascular surgeon and/or radiologist consider that the case not appropriate for endovascular revascularization
- contraindication to endovascular technique (local thrombolysis for example)
- visceral surgeon is not familiar with endovascular procedures but is able to perform basic vascular surgery (embolectomy for example)

In our experience, the three most common surgical vascular procedures to restore the blood flow in the superior mesenteric artery (SMA) are: (1) the SMA embolectomy, (2) the retrograde SMA bypass, (3) the retrograde open SMA stenting. The vascular surgeon may need to harvest a segment of saphenous or femoral vein. Hence, we recommend having one of the thighs prepared in the surgical field in anticipation of possible access. A radiologic system to perform arteriography during the procedure is mandatory (C-arm fluoroscopy or hybrid operating room). All the vascular surgical procedures need systemic heparinization.

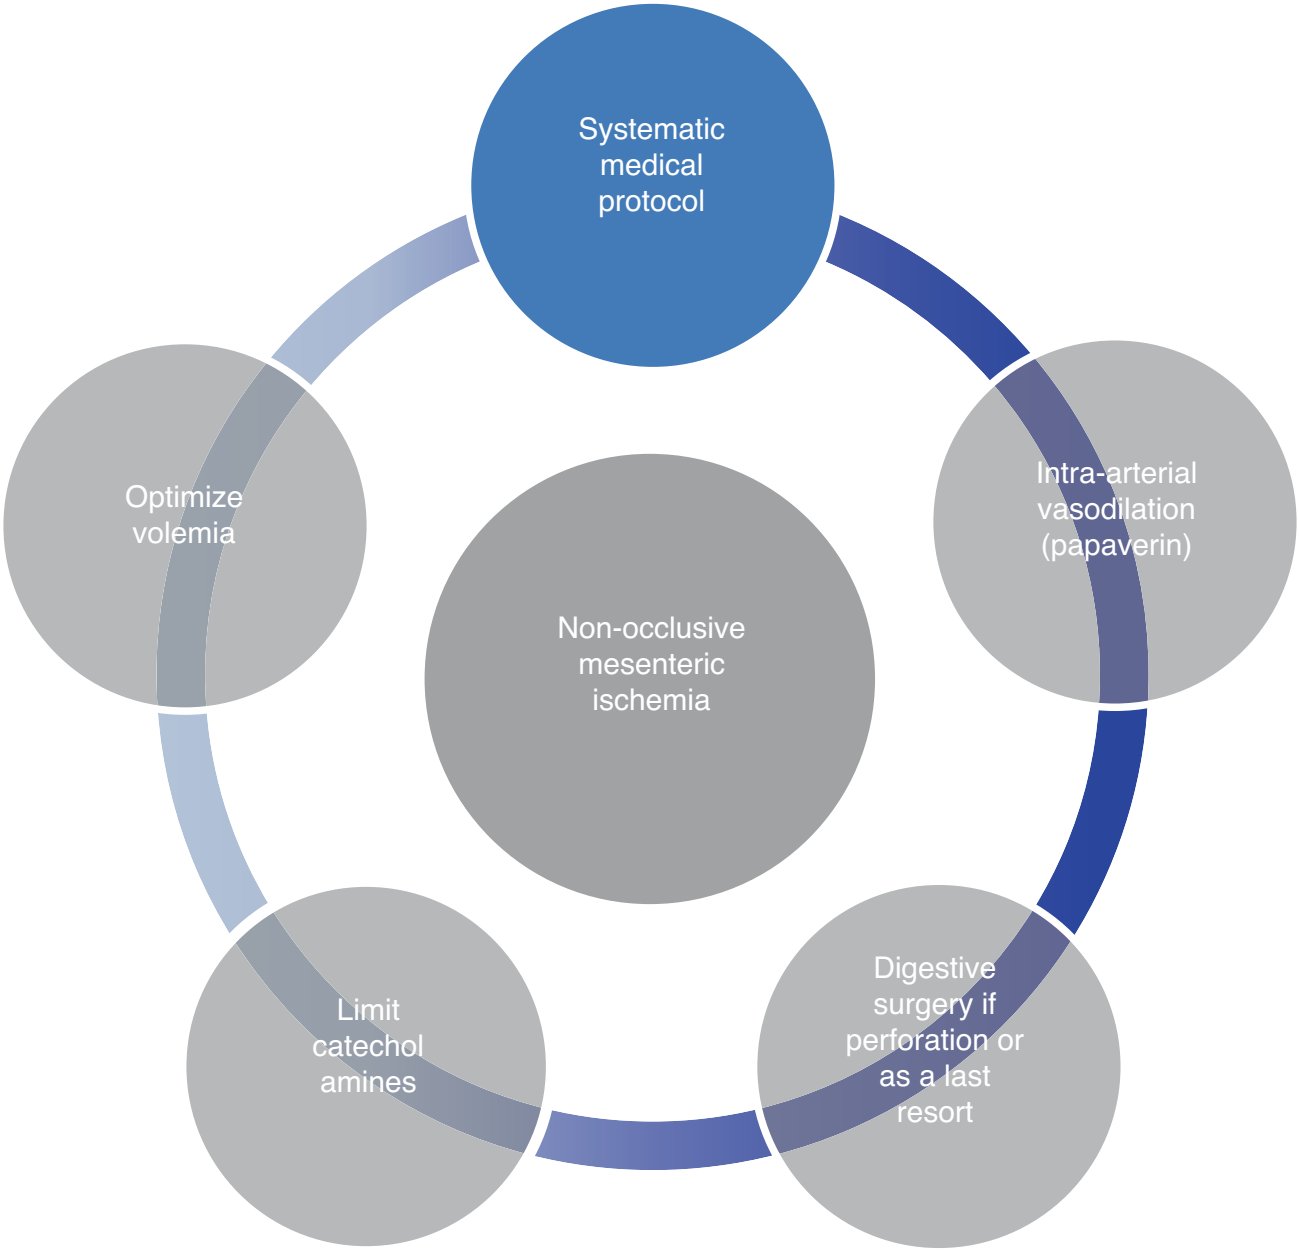

Fig. 6 Treatment principles of non-occlusive mesenteric ischemia

SMA Embolectomy

Anterior exposure to the SMA for straightforward embolectomy is achieved by elevating the omentum and transverse colon, the small intestine is wrapped and retracted to the right. A segment of the proximal SMA between the middle and the right colic branches is isolated. Circumferantial dissection is required to isolate and to control any of the jejunal branches in this segment. The artery is open transversely if the SMA has a sufficient diameter and is not too atheromatous. For diminutive or diseased vessels, we firmly recommend performing a longitudinal arteriotomy using a patch closure (prosthetic or a saphenous patch). Great care must be taken to avoid damage or rupture to fragile collaterals of the SMA. When necessary, small Fogarty embolectomy catheters are used. After all macroscopic clot is cleared, we can consider administration of a single dose of thrombolytic agent into the distal mesenteric vessels. An arteriogram can be performed at the end of the procedure to assess the quality of the revascularization.

Retrograde SMA Bypass

Antegrade bypass using the distal thoracic aorta or suprarenal aorta as the inflow source is not recommended in case of AMI. A retrograde bypass based on the infrarenal aorta,

a previous aortic graft, or the iliac artery is strongly preferred with the advantage of avoiding cross-clamping the aorta. Most retrograde reconstruction deals with only the SMA, but reconstruction of the common hepatic artery can also be achieved by tunneling the graft retroperitoneally or via the transverse mesocolon. As the graft assumes a C-shaped configuration, it is important to avoid graft elongation, angulation or kinking. Synthetic bypass grafts (Dacron or externally supported polytetrafluoroethylene) are preferred because of the better size match, ease of handling, availability and kink resistance. The choice of conduit is heavily influenced by the degree of abdominal contamination and the perceived risk of subsequent infection. Therefore, if good-quality vein is available (saphenous vein or femoral thigh vein), it is preferred in the presence of significant peritoneal soilage. In the presence of a diseased SMA, an endarterectomy may be necessary before doing the distal anastomosis. Reports suggest that retrograde grafts perform as well as antegrade grafts [70].

Retrograde Open SMA Stenting (ROMS)

The ROMS technique uses a hybrid approach via midline laparotomy to expose de SMA combined with endovascular retrograde stenting. Because several of these patients already have an indication for laparotomy to address advanced bowel gangrene or ischemia, direct surgical exposure of the SMA allows expeditious access for direct puncture. The proximity of the sheath to the lesion affords excellent support to cross a difficult occlusion with less risk of distal embolization by occlusion of side branches. Furthermore, primary stenting is an excellent method of revascularization that avoids the need to reconstruct the vessel by surgical bypass, minimizing surgical dissection and potentially eliminating the need to harvest a vein or to use a prosthetic graft for conduit.

We recommend the use of covered balloon expandable stent, 7 mm diameter stent are most often used [71, 72]. In our experience, a majority of the SMA needs an endarterectomy and we recommend to perform a longitudinal arteriotomy using a patch closure (prosthetic or a saphenous patch). ROMS during emergent laparotomy for AMI is a very promising technique and an attractive alternative to emergent surgical bypass.

Intestinal Resection

Non-invasive Predictors of Transmural Necrosis

The cornerstone of acute mesenteric ischemia surgical management in the acute phase is the diagnosis of intestinal necrosis, that will not be reversible despite revascularizations procedures [3, 51, 73]. However, the identification of patients with intestinal necrosis has been shown as difficult. Indeed, no clinical sign or laboratory study is specifically associated to intestinal necrosis, [60, 61] as even serum lactate might be normal in necrotic patients or elevated in patients with reversible ischemia, due to dehydration and decreased oral intake [60]. In this setting, we performed a prospective cohort study of 67 patients with acute mesenteric ischemia, of which 34% presented with intestinal necrosis [10]. From this group organ failure, elevated serum lactate≥ 2, and bowel loop dilation (defined as a diameter > 2.5 cm) on CT scan were independent factors predictive of intestinal necrosis. On the basis of these findings, the incidence of intestinal necrosis rose from 3% in patients with no predictive factor to 38%, 89%, and 100% in patients with 1, 2, and 3 factors, respectively. Therefore, in routine clinical practice, we consider that all patients presenting with 2 or more factors should undergo immediate explorative surgery to assess for intestinal viability [10] (Fig. 5).

If a surgical exploration is decided upon, this procedure should be, whenever possible, carefully planned according to the feasibility of a revascularization procedure. In highly unstable patients and/or in patients with overt peritonitis, we advocate a primary blood flow restoration procedure prior to a surgical resection, as this might reduce the extent of intestinal resection and reduce the risk of secondary necrosis of the remnant bowel [51]. In all other patients, we routinely perform a radiological or surgical revascularization procedure prior to the explorative laparotomy, for the same reasons.

Surgical Approach

Very few studies reported the use of laparoscopic approach for the management of acute mesenteric ischemia [74–78]. Despite this small series, the European Society for Trauma and Emergency Surgery guidelines does not recommend the use of minimally invasive approach for acute mesenteric ischemia, due to the paucity of reported evidence [60]. In our experience, laparoscopic approach is not the gold standard approach for the management of acute mesenteric ischemia as: (1) the complete visualization and viability assessment of the small bowel and colon might be difficult, (2) patients' tolerance of the pneumoperitoneum might be compromised, especially in unstable patients, (3) surgical revascularization procedures require an open approach. We usually perform an open approach in our patients, reserving a laparoscopic approach in cases of difficult diagnosis and especially in non-occlusive patients [76].

Bowel Viability Assessment

Most of the time, necrotic bowel will be clearly identifiable during the laparotomy, and will be based on the bowel color, motility and bleeding of cut ends [60, 79, 80]. (Fig. 7) As described before, this viability should be assessed after revascularization procedure, whenever possible. However, viability assessment might sometimes be difficult, especially

Fig. 7 Acute arterial mesenteric infarction. Resection specimen showing transmural intestinal necrosis from arterial intestinal ischemia

in cases of hypotension, vascular impairment, and the concurrent use of vasopressors. In such patients, the use of doppler ultrasound of the vascular arcade, [81] fluorescein angiography, [82] and indocyanine green angiography [83] have been reported but have failed to gain widespread use. In our practice, we usually perform a frozen section examination in order to avoid unnecessary extensive resection.

Vacsular surgeons from our center use to feel for the arterial SMA pulse, but it is not indicative of the quality of the reperfusion and the quality of revascularization of the collaterals of the SMA and distal arteries. CT angiography is preferred for this purpose. Differentiating arterial from venous infarction is also done using the the CT-scan images. At surgery venous AMI usually leads to more congestive "blue" colored bowel, a more proximal injury (jejunum), but lower/slower progression to infarction than arterial AMI.

Damage Control Surgery

The strategy of Damage Control Surgery includes an abbreviated laparotomy with resection of necrotic bowel and the absence of anastomosis or stoma [79, 84, 85], in an attempt to reduce the operative time and to prioritize the resuscitation in intensive care unit. For many surgeons, it has become the standard of care for acute mesenteric ischemia management. However, this strategy imposes the realization of a second-look surgery, which is usually performed 48 h after the primary procedure.

In our routine practice, we do not advocate such strategy for all patients. As stated in the European Society for Trauma and Emergency Surgery guidelines published in 2016, Damage Control Surgery might only be performed in patients with severe septic shock, [60] which in fact represent a minority of patients. We favor a strategy that includes the establishment of stomas of all resected bowel segments, as this may have several advantages: (1) To avoid unnecessary second look laparotomy – indeed, Park *et al.* reported the outcomes of patients operated on for acute mesenteric ischemia and reported that an additional bowel resection was performed during the second look in the minority of patients (11/23), thus exposing the majority of patients to the risk of an unnecessary laparotomy; [86] (2) The presence of a stoma allows the direct evaluation of the remnant bowel viability, as the mucosa can be easily evaluated and, if necessary, biopsied; and (3) this strategy does not expose the patient of the complications of intestinal anastomosis, as anastomotic leakage is frequent is those patients that will receive intensive resuscitation and vasopressor injections [60]. We never perform any anastomosis in the acute phase of acute mesenteric ischemia management. In this setting, during bowel resection, care should be taken to facilitate the intestinal continuity restoration. Double end stomas should be preferred over single stomas in separate incisions, as this will allow to perform intestinal continuity restoration through an elective approach, rather than a midline laparotomy.

Extensive Bowel Resection

In severe patients, with extensive intestinal necrosis requiring large bowel resection, the surgeon might face a philosophical decision whether to expose the patient to a short bowel syndrome, requiring total parenteral nutrition, or not to do anything. This decision may be based on the associated comorbidities, and the long-term probability of patient discharge from medical assistance. In the past the difficult decision to close the abdomen and not resect was often made after intra-operative discussions with the intensivists, the gastroenterologist, and the nutritionist in charge of the patient. However with the success of long-term parenteral support and the fact that many patients, even if the remaining small bowel length is very short (less than 50 cm), will stop the parenteral support when the colon is in continuity [38, 87] and/or if a growth factor (e.g. teduglutide [88]) is given, this decision is now rarely made and we propose an aggressive strategy regarding small resection.

Follow-Up and Rehabilitation

Post-ischemic Stenoses and Disorders

When it does not progress to transmural necrosis, any mesenteric ischemia can cause functional intestinal "sequelae", especially dysmotility disorders. In most cases, these lesions may appear when the intestinal injury has exceeded the healing capacity mechanisms and has progressed to stenosing parietal fibrosis and/or chronic mucosal ulcers. Occurring within a variable delay after refeeding, post-ischemic disorders present as pseudo-occlusive syndrome, chronic diarrhea and/or septic episodes of digestive origin (microbial translo-

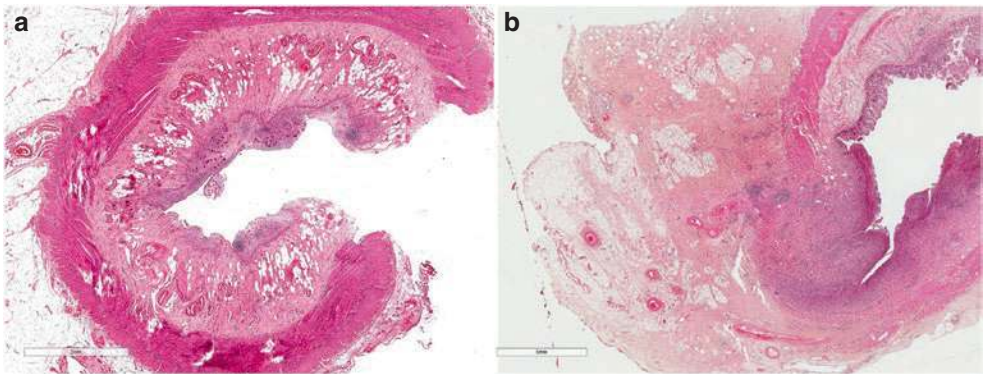

Fig. 8 Histopathological picture of post-ischemic enteritis. (**a**) Resection specimen showing a non-penetrating chronic post-ischemic enteritis: the mucosa is destroyed, ulcerated with submucosal fibrosis, increased angiogenesis, and normal underlying muscularis propria. (**b**) Resection specimen showing a chronic post-ischemic enteritis with fistula: the mucosa is ulcerated with a deep fistula infiltrating a fibrosed muscularis propria

cations). The treatment is generally surgical. In some cases, the motility disorder is transient and could be linked to the intestinal smooth muscle response to ischemia-reperfusion. Indeed, recent physio-morphological studies of gastrointestinal peristalsis by magnetic enteromyography, have shown that peristalsis was early and significantly decreased in the case of chronic mesenteric ischemia and normalized after revascularization [89]. This could explain some functional GI disorders, such as gastroparesis, which refeeding after revascularization could unveil [90].(Fig. 8).

Nutritional, Vascular and Intestinal Rehabilitation

In the event of multiple vascular involvement, primary revascularization of the superior mesenteric artery should always be offered. If this is impossible, and due to the collateral network between the digestive arteries, revascularization of the celiac trunk and / or the inferior mesenteric artery can lead to resolution of the IIC [91]. In the extreme, in the patient not eligible for revascularization, clinical improvement occurred in 4 of 6 patients after infusion of iloprost (ilomedine®), a prostacyclin analog having a peripheral vasodilator, antiaggregating and immunomodulatory effect and used in the Raynaud syndrome, critical ischemia of the lower limbs and high blood pressure [92].

Proximal and/or extensive resection of intestinal necrosis can be complicated by a transient or definite short bowel syndrome. The care of these patients must be provided in collaboration with an expert intestinal failure unit [38, 93]. Rehabilitation after mesenteric infarction is threefold:

– Nutritional: screening and correction of hydro-electrolytic, caloric and / or vitamin / trace element deficits, and parenteral support;
– Vascular: detection of persistent ischemia related to a residual vascular stenosis, and secondary cardiovascular prevention with long-term anti-thrombotic treatment; [94]
– Digestive with the restoration of continuity with possible interposition of a reverse loop [95].

Reanastomosis of Defunctioned Bowel

Patients, who are maintained with parenteral support, and have had an extensive bowel resection with defunctioned ileum and/or colon remaining in situ should, if possible, have bowel continuity restored. Preference is for doing this after the acute AMI stage (the acute ischemia/reperfusion injury may compromise anastomosis healing and lead to septic complications and further infarction and resction). This restoration of continuity is usually done at least six weeks after the initial surgery, when the patient is healthy with a normal BMI, and when the aetiology of the infarction has been identified (thrombophilia screen, echocardiogram, 24 h tape and CT angiography) and treated (e.g. under 60 years old and a haematological/clotting abnormality given anticoagulation). Before surgery the defunctioned bowel is outlined radiologically to check mainly that there is no obstruction, and endoscopically to check that there is no sign of chronic mesenteric ischemia. For the latter point, CT angiography may be repeated to check that the remnant gut blood supply is sufficient. Trophic distal feeding may be given into the defunctioned ileum/colon after careful assessment of its viability and vascular patency (see Chapter “Distal feeding and hydration”). Following the re-anastomosis/stoma closure there will be a reduction in parenteral requirements (volume, energy and more nights off PS), stool frequency will decrease (althought the stool is likely to be malodourous), there is less chance of cholestasis and survival is increased. In one series

32% of patients (n = 28) with a residual small bowel length of less than 51 cm had stopped parenteral nutrition completely by 5 years from the time when continuity was re-established [38]. There is no need for a routine defunctioning colostomy (to reduce stool frequency) even when the residual small bowel length is very short (e.g. less than 20 cm).

Conclusion

Acute mesenteric ischemia is today potentially reversible when diagnosed and treated early and appropriately. The development of specialized intestinal stroke units coordinated by gastroenterologists and offering 24/24 revascularization, intestinal resection, in an intensive care environment, and in close collaboration with an intestinal failure unit, constitute both therapeutic and diagnostic hope. Moreover, the recruitment into dedicated medical and research teams is an essential prerequisite for clinical and research progress, and nurtures the hope for the future of obtaining a biomarker for early diagnosis, the clinical application of which could be generalized in the assessment and management of any abdominal pain and whose place could be major in the gastroenterology and emergency medicine of tomorrow.

Crohn's Disease

Mattias Soop and Simon Lal

Key Points

1. The limited data on the risk of a patient with Crohn's disease developing intestinal failure (IF) indicate a risk of at least 8.5% in 20 years following index abdominal surgery.
2. Crohn's disease remains one of the most prevalent underlying diagnoses among patients referred to an IF unit.
3. Half of the patients with Crohn's disease who develop IF do so due to abdominal septic complications following surgery.
4. The incidence of abdominal surgery in Crohn's disease is decreasing in population-based studies.
5. Recognition of the risk factors in abdominal surgery for Crohn's disease and judicious usage of double-barrelled stomas are vital in reducing abdominal septic complications.
6. Preoperative optimisation includes: delaying surgery until certain medications are reduced or weaned, malnutrition and anaemia are corrected by enteral or parenteral nutrition (may be exclusive), smoking cessation and eradication of phlegmons and abscesses may allow safer primary anastomosis and improve outcomes.
7. The 'Sepsis-Nutrition-Anatomy-Plan (SNAP)' algorithmic approach fosters a cohesive and systematic approach for the multi-disciplinary team required to care for patients with type II intestinal failure. This includes detailed anatomical evaluation to define fistula(s), stricturing and areas of disease activity.
8. Characterisation of the patient's pre-operative Crohn's disease phenotype and response to previous medications will facilitate a tailored approach to post-operative therapy. A pro-active approach to post-operative therapy is required, where appropriate, with early radiological and endoscopic surveillance and adjustment of medical therapy for recrudescent disease.
9. Following surgery, attention must be given to subsequent Crohn's disease management that aimed at preventing recurrent disease.

Introduction

Intestinal surgery for Crohn's disease may be for obstruction, bleeding, perforation, abscess/fistula or rarely carcinoma. Intestinal failure (IF) is a feared complication of Crohn's disease. It is traditionally assumed that the main mechanism is repeated surgical resections leading a short bowel [1]. This assumption has led to a focus on bowel-sparing strategies such as resection limited to macroscopic disease [2] and strictureplasty [3]. While such strategies appear sensible, data on the epidemiology and mechanisms of IF in Crohn's disease are limited. By reviewing these data, we will identify practices that have the greatest potential to minimise the risk of IF in Crohn's, and review special considerations in the management of IF in the context of Crohn's disease.

Epidemiology of Intestinal Failure in Crohn's Disease

In reports from intestinal failure units, Crohn's disease is frequently the most prevalent underlying diagnosis. Between 1987 and 2011, 545 patients received home parenteral nutrition (HPN) at the National Intestinal Failure Unit in Salford. Of those, 168 or 31% had Crohn's disease [4]. The corresponding proportion from the Lennard-Jones Intestinal Failure Unit at St Mark's Hospital in Harrow is 32% [5]. Notably, the proportion of patients with IF who have Crohn's disease has reduced in the last few years in Salford; while Crohn's was the

J. M.D. Nightingale (ed.), *Intestinal Failure*, https://doi.org/10.1007/978-3-031-22265-8_7

leading cause of IF in the 1980s, in recent years, the principal cause of IF in patients referred to the unit has been surgical complications in non-Crohn's conditions [4]. The same trend has also been seen in a large cohort of managed at the Rigshospitalet in Copenhagen over the last four decades [6].

For people with Crohn's disease and clinicians managing this condition, the converse statistic, the risk of developing IF in Crohn's disease, is more important. Unfortunately, the prevalence and incidence of IF in Crohn's disease are largely unknown quantities. The only published large study addressing this question is a Japanese multi-centre study of the incidence of chronic, or type III, IF after index surgery for Crohn's [7]. In this unique study, some 1700 patients were prospectively followed over an extended time period following index abdominal surgery. The cumulative incidence of type III IF (defined here as home parenteral nutrition for a period of more than 12 months) was 0.8%, 3.6% and 8.5% over 5, 10 and 20 years, respectively [7]. As some patients with Crohn's disease will develop IF as a result of extensive mucosal disease, without prior surgery, the overall risk of IF in Crohn's remains unclear. Nonetheless, the study by Watanabe et al. indicates the potential magnitude of the risk, at least following surgery [7].

Mechanisms of Intestinal Failure in Crohn's Disease

It is widely thought and taught that successive bowel resections resulting in a short bowel is the main mechanism of IF in Crohn's disease. This has led to development of bowel-sparing techniques such as resection limited to macroscopic disease [2], strictureplasty [3] and endoscopic balloon dilatation, in efforts to minimise loss of small bowel.

Few data exist on this issue. A recent study of the cause of IF in 121 consecutive patients with Crohn's disease referred to a national unit in England found that successive bowel resections were the cause only in 31% of patients referred [8]. This study found that 51% of referred patients with Crohn's disease had developed IF as a direct consequence of abdominal septic complications to intestinal surgery. Patients in this group all had re-laparotomies to address septic complications, resulting in enterocutaneous fistulation, loss of small bowel, or both. In many cases, the index operation was an elective ileocaecal resection complicated by anastomotic dehiscence or overlooked enterotomy. In this study, a further 12% of referred patients developed IF directly due to extensive mucosal disease without surgery, and the remaining 6% had a proximal small bowel stoma [8]. This large study confirms findings in an earlier study from the same centre [9].

Therefore, existing data, although scant, suggest that most patients with Crohn's disease who develop IF do so following abdominal surgery complicated by abdominal sepsis requiring re-laparotomy and that, cumulative loss of small bowel is the mechanism in a smaller proportion of patients. Minimising the risk for abdominal septic complications is therefore the most important priority in reducing the risk for IF in people with Crohn's disease.

Several studies report attempts to single out demographic characteristics and phenotype at presentation of patients with Crohn's disease who develop IF. Given that complications of abdominal surgery are the main mechanism, it is not surprising that associations between such characteristics and IF have been found to be weak; [10] not least because septic complications following any operation are likely to be more strongly associated with surgical factors, perioperative physiology and medications, rather than patient demographics and phenotype. Nevertheless, such studies have reported associations between IF and an early diagnosis of Crohn's disease, family history of inflammatory bowel disease, and penetrating disease at diagnosis [10, 11]. It must be remembered that the small number of cases in such studies limit the validity of multivariable regression performed.

Alternatives to Surgery in Crohn's Disease

Given that surgery, and specifically complications of surgery, cause most cases of IF in Crohn's disease, evidence-based and multi-disciplinary efforts to reduce both the number of operations required, and the associated risk of septic complications, will be the most effective strategies to reduce IF in this population.

The overall incidence of abdominal surgery in Crohn's disease is currently falling. Recent population-based studies have shown that the rate of abdominal surgery in people with Crohn's disease has decreased steadily during the past decades in Canada, the Netherlands, Sweden and other regions [12–14]. This observation, as well as the relative reduction in Crohn's disease as a principal cause of IF in the UK and Denmark as outlined earlier, [4, 6] may be attributed to shifts in medical management of the disease, improved training and specialisation of inflammatory bowel disease (IBD) clinicians, centralisation of IBD care, increasing multidisciplinary management and, perhaps, increased patient empowerment in the management of the disease through advocacy through patient organisations leading to increased awareness of therapeutic options available. Indeed, cohesive working between the patient, physicians, dietitians, IBD nurses, pharmacists, psychologists and surgeons is now recognized as the cornerstone to ensuring optimal care is tailored to the individual [15].

Many interventions have been shown to directly reduce the rates of surgery or the risk of postoperative recrudescent Crohn's disease. Smoking is the strongest modifiable risk factor for recrudescent disease following surgery for Crohn's disease, increasing this risk by 150% [16]. Smoking cessa-

tion should therefore be a central component in the management of Crohn's disease. This intervention needs to be intensive and prolonged, necessitating investment of adequate resource, in order to be successful [17].

Biologic monoclonal antibody therapy has become the backbone of medical therapy for Crohn's disease, and population-based data suggest that the emergence of this class of medication has been associated with a reduced rate of abdominal surgery, [18]. One in five patients with luminal Crohn's disease present with a so-called Crohn's mass, due to an abscess or a phlegmon [19]. Traditionally, the finding of a Crohn's mass has been considered an indication for laparotomy and bowel resection, as medical therapy alone has been thought insufficient to heal penetrating disease. Data from the current biologic era suggests this may no longer be an absolute rule. In a small case series of 13 patients who presented with a phlegmon or an abscess at Beth Israel Hospital in Boston, 11 avoided surgery using a combination of antibiotics, percutaneous drainage and infliximab, while two required delayed surgery [20]. In a larger study, 55 of 95 patients who presented with an intra-abdominal abscess at Mayo Clinic in Rochester were managed non-operatively with a combination of percutaneous drainage, antibiotics and immunomodulator and/or anti-TNF therapy. While all patients in this group responded to non-operarative treatment, 12 of the 55 patients required abdominal surgery during the subsequent 45 months [21]. A meta-analysis of the role of percutaneous drainage in intra-abdominal abscesses in Crohn's disease suggests that this approach may help avoid laparotomy in up to 30% of patients [22].

As the above studies indicate, case selection is important and many patients with intra-abdominal collections will still require surgical resection. Also in this group, a staged approach with initial percutaneous drainage is likely to reduce morbidity and stoma rates and may make laparoscopic resection more realistic. Percutaneous drainage, rather than surgery, is therefore the initial approach recommended by the European Crohn's and Colitis Organisation (ECCO) [23]. Furthermore, when septic complications following surgery do occur, percutaneous drainage has an additional important role in treating peri-anastomotic abscesses, thereby avoiding immediate relaparotomy in selected cases [24].

In recent years, endoscopic balloon dilatation has also taken a key place in the management of short strictures, in particular anastomotic strictures. In the largest case series to date, 776 dilatations were performed in 178 patients with strictures <5 cm in length. The technical success rate was 89% and the perforation rate 1.4%. After 5 years, 64% of patients had avoided surgery [25]. The ECCO guidelines place endoscopic balloon dilatation as the preferred technique to manage symptomatic short anastomotic strictures, but such procedures should only be performed by an experienced practitioner and in an institution with 24-h surgical service due to the risk of early or delayed perforation [23].

Reducing Postoperative Morbidity in Abdominal Surgery for Crohn's Disease

Despite strategies aimed at reducing the need for surgery discussed above, bowel resection will remain a pillar of management in Crohn's disease. Indeed, a recent multi-centre randomised trial demonstrated that laparoscopic ileocaecal resection of primary unifocal disease may result in better outcomes than initial medical therapy, suggesting that surgery should be part of 'top-down' management [26, 27].

A key strategy to prevent IF in Crohn's disease is to reduce the risk of abdominal septic complications when surgery is required. Specifically, this entails reducing the risk of sepsis from anastomotic dehiscence and overlooked enterotomies.

The data on risk factors for anastomotic complications in Crohn's disease are abundant and relatively consistent [28–30]. The low number of events (dehiscence) is a caveat for multivariable regressions often presented in such studies. Nevertheless, risk factors that are frequently identified include: intra-abdominal abscess at the time of surgery, steroid usage (≥10 mg prednisolone daily or equivalent) within 2 weeks of surgery and preoperative weight loss (>10%). Recrudescent disease, hypoalbuminaemia and smoking are other risk factors identified in some studies [17, 28].

A contested issue in inflammatory bowel disease surgery is whether concurrent biologic therapy increases perioperative morbidity, and anastomotic complications in particular. The largest prospective published study on this issue in Crohn's disease is a French multi-centre study in 592 patients. Following adjustments for differences in disease severity, an increase of overall morbidity and intraabdominal septic complications in patients treated by preoperative anti-TNF therapy was demonstrated [31]. It is important to note that data associating systemic steroid therapy and postoperative morbidity are stronger and more consistent than the data on biologic agents, hence most clinicians regard steroid therapy as the more hazardous of the two classes [32–34].

Recognition of risk factors present enables a more informed decision-making at surgery, in particular regarding whether to form a primary anastomosis at resection. For patients with significant risk factors, a double-barrelled (split) stoma should instead be formed, which can then subsequently be reversed via a peristomal incision when risk factors have been fully addressed [34].

Importantly, nearly all of the risk factors discussed above are modifiable. Preoperative optimisation pathways for surgery for Crohn's disease have recently been proposed, combining interventions that correct or minimise the impact of

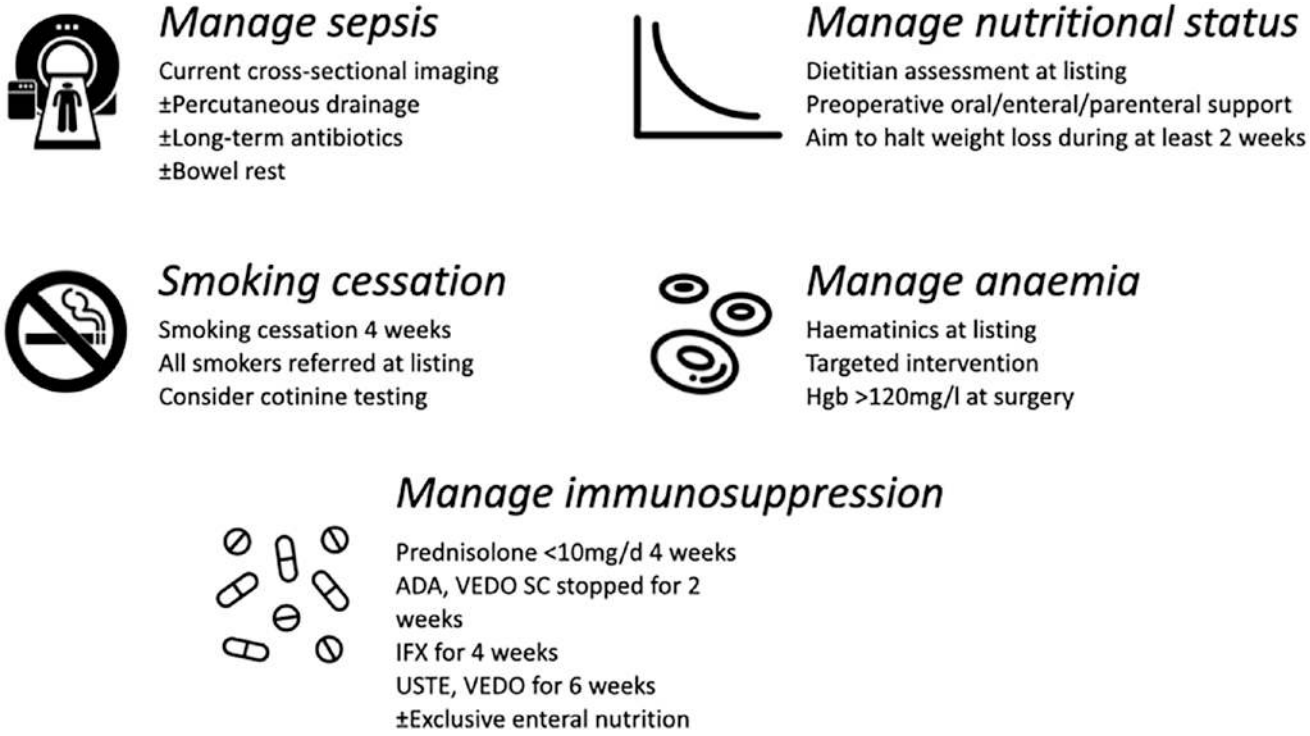

Fig. 1 Example of a preoperative optimisation pathway that can be used in surgery for Crohn's disease. As data are still emerging on several components, chosen targets are pragmatic. ADA, adalimumab. IFX, infliximab. VEDO, vedolizumab. USTE, ustekinumab

identified risk factors [35–37]. Such pathways complement enhanced-recovery pathways for patients undergoing surgery for Crohn's disease [38]. They aim to reduced overall risk, reduce the risk of anastomotic complication and minimise stoma rates.

Furthermore, by down-staging Crohn's disease and eradicating Crohn's masses, a laparoscopic approach may be possible in more cases. Laparoscopy has specific benefits in Crohn's disease. In addition to the well-described short-term benefits on postoperative recovery, [39] laparoscopy results in less wound morbidity and reoperation rates than laparotomy [40]. Cumulatively, this advantage becomes increasingly important in the patient with Crohn's disease who may require several abdominal operations during their life. Laparoscopy is therefore the recommended modality for surgery for Crohn's disease in the ECCO guidelines, [23] and is possible also in penetrating disease treated prior to surgery [41].

The duration of preoperative optimisation pathways described varies from 4–8 weeks, during which malnutrition, smoking, sepsis and steroid and/or biologic therapy are addressed. For steroid therapy, one proposed target is to reduce the dose to <10 mg prednisolone daily (or equivalent) for a period of 4 weeks [29]. For biologic agents, safety data are still emerging. In practice, an estimate of safe wash-out periods for each drug has to be made. During this period, exclusive enteral diet is increasingly used to minimise the risk of disease flare-up and to correct malnutrition, [42, 43] and often parenteral nutrition is indicated. An example of a preoperative optimisation pathway for IBD surgery is summarised in Fig. 1.

It is important to monitor patients during such preoperative optimisation, and to recognise that some patients are too unwell to allow full optimisation. In those cases, early surgery is safer, with exteriorisation of the bowel as stomas, and laparotomy rather than laparoscopy is often required.

Reducing the Risk of Recrudescent Disease After Surgery for Crohn's Disease

A well functioning IBD unit with clear communication between surgical and medical teams is required to time initiation of medications aimed at reducing the risk of recrudescent disease and resume monitoring of disease activity.

The literature on post-resectional medical therapy is too large to summarise here. A large network meta-analysis has comprehensively reviewed this literature in 2015 [44]. This landmark status update demonstrated that anti-TNF monotherapy is by far the most efficient therapy (relative risk of clinical recrudescence 0.04 compared to placebo) followed by antibiotics (RR 0.26), immunomodulator therapy (RR

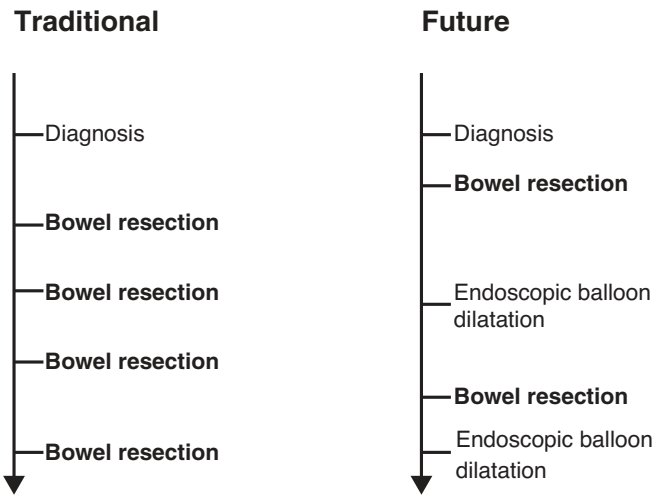

Fig. 2 A challenge in contemporary management of Crohn's disease: To reduce the lifetime incidence of abdominal surgery, and to make each operation safer, as compared to traditional surgery. Current data from several regions of the world suggest that these changes are already occurring

0.36) and mesalasine (RR 0.60). Therapy should be tailored to the individual patient, taking into account factors such as disease phenotype and previous surgeries. Regardless of post-resectional medical therapy, early surveillance with ileocolonoscopy after 6 months after ileocaecal resection, with step-up of medical therapy when recrudescent mucosal disease is found, has been shown to reduce the risk of endoscopic recrudescence on colonoscopy performed at 18 months [45].

With optimal disease surveillance, medical therapy, judicious surgery with preoperative optimisation and usage of endoscopic balloon dilatation when possible, a picture emerges with safer operations being performed more widely spaced out during the lifetime of people with Crohn's disease, (Fig. 2) as indeed demonstrated by recent population-based studies. Future data will show whether this will result in a reduced incidence of intestinal failure in Crohn's.

Management of Type II Intestinal Failure in Crohn's Disease

The management of IF in Crohn's disease is no different than the general management of IF and, indeed, much of the SNAP (Sepsis, Nutrition, Anatomy, Procedure) protocol (see Chapter "Acute surgical intestinal failure. Sepsis and enterocutaneous fistula(s)") was developed specifically for Crohn's disease [46].

Briefly, sepsis control is the first priority, because sepsis is the cause of death in the majority of the 10% of patients with type II IF who do not survive [47–49]. In addition, sepsis prevents anabolism and recovery despite aggressive parenteral nutrition if it is allowed to prevail [50]. Early interventional radiology is a key resource in management of type II IF, as it achieves source control in most cases [51]. Occasionally, early relapatotomy is required for source control [52].

Clinicians who do not regularly manage type II IF may be tempted to embark on definitive surgery early after presentation, in an attempt to restore gastrointestinal continuity and discharge the patient in nutritional autonomy. However, early reconstructive surgery is detrimental for two important reasons. Firstly, a majority of postoperative enterocutaneous fistulas heal spontaneously within the first 8 weeks. Bowel rest and parenteral nutrition may be helpful and are reasonable interventions during this period [48]. Secondly and more importantly, results of definitive surgery for persistent fistulas are directly related to the interval allowed for local, physiological and psychological recovery to occur. Fistula recurrence rates are as high as 25% when definitive surgery is performed within the first couple of months, [53] but below 5% after 12–18 months. During this interval, most patients are at home with parenteral nutrition while they recover nutritionally, and also psychologically, from previous surgery and complications.

In Crohn's disease, surveillance of disease remains important during this phase. Disease recrudescence is rarely seen in practice during this phase, perhaps because the gastrointestinal tract is rarely in continuity and the amount of small bowel may be reduced. Rarely, aggressive medical therapy is indicated once, of course, any sepsis has been eradicated.

Management of Type III Intestinal Failure in Crohn's Disease

Safe HPN allows long-term survival in type III IF. In the longest and largest series published, data collected over 30 years suggest that long-term survival depends primarily on underlying diagnosis [4]. Overall 10-year survival was 59% in this series for all disease types, with patients with Crohn's disease having the best survival of the diagnostic groups [4].

As in type II IF, it is an empirical observation that flare-ups of Crohn's disease activity are rare. This may be due to reduction of the intestinal length, lack of gastrointestinal continuity, particularly lack of colonic continuity reducing any risk of anastomotic recurrence. When it does occur, it can present insidiously as increasing fistula or stoma output, failure to thrive, weight loss, jaundice or unexplained systemic inflammation.

When flares do occur, standard medical management principles apply, modified by often impaired absorption of orally administered medications. It is important to consider the individual's previous phenotype in this setting and, in those with a previous aggressive small bowel phenotype

should be considered for prophylactic Crohn's disease therapy, with on-going monitoring for recurrence. While concern may exist for catheter-related infections in patients receiving immunosuppressive medications, recent data from the authors' unit demonstrate that the risk of such infections is not increased in patients with Crohn's disease receiving therapy and that a meticulous approach to catheter care and training is the cornerstone to preventing catheter infections, enabling very low infection rates to be achieved over many decades in experienced units that foster a multidisciplinary approach to care [4, 54].

Mortality directly related to HPN accounts for some 15% of deaths, and is caused specifically by catheter related bloodstream infections, and more rarely, IF-associated liver disease [4]. Furthermore, there is no doubt that HPN can negatively impact on an individual's quality of life [55]. For the large proportion of patients where standard gastrointestinal reconstructive surgery is not possible, such as in true short bowel syndrome, life-long HPN has been the only option until recently.

Over the past decade, three novel therapies have emerged that allow selected patients with type III IF to become less dependent on HPN, and in some cases to entirely wean off HPN. Patients who develop either IF-associated liver disease requiring intestine and liver transplantation or those with loss of reliable venous access are candidates for intestinal transplantation. In the UK, Crohn's disease is the most common underlying condition [56].

A less invasive surgical approach, possible in some patients, is intestinal lengthening and tapering, procedures initially developed in children to treat bacterial overgrowth associated with a short bowel (see Chapter "Surgery for Patients with a Short Bowel and Tissue Engineering"). The first procedure, longitudinal intestinal lengthening and tailoring (LILT), was developed in the 1970s by Bianchi in Manchester, UK, [57] and was complemented some 30 years later by the serial transverse enteroplasty procedure (STEP) developed by Kim in Boston, MA [58]. In adults, these are rare procedures and case series totalling 30 cases have recently been published with favourable results [59, 60]. Patients with Crohn's disease who have a low risk for recrudescent disease have undergone intestinal lengthening in the United States with good outcomes, although data are limited [1, 60].

Finally, growth factor therapy has recently emerged as an alternative for selected patients with short bowel syndrome (see Chapter "Pro-adaptive Hormones in the Rehabilitation of Adult Patients with a Short Bowel"). So far, a glucagon-like peptide 2 (GLP-2) analogue has been the most successful agent in reducing dependency on HPN [61]. The published experience in type III IF associated with Crohn's disease is favourable [62].

Case selection is key for favourable outcomes and safety for these three novel therapies. In England, proposed surgical candidates are discussed at the bimonthly National Adult Small Intestinal Transplantation forum, which advises on whether to proceed.

Peritoneal Adhesions and Encapsulating Peritoneal Sclerosis

Titus Augustine, Alison Culkin, and Mattias Soop

Key Points

1. Adhesions are common after abdominal surgery and up to 5% will need a repeat admission for them. The chance of developing them increases with the number of abdominal operations.
2. Adhesions/intraperitoneal fibrosis may be caused by ischaemia, infection, abrasions, spillage of gastrointestinal contents, desiccation, excessive heat/light/electrocautery/sutures, fibres/glove powder and some medications. Reducing these factors reduces the chance of developing adhesions.
3. Adhesions may cause recurrent episodes (partial or complete) of bowel obstruction. These episodes may be reduced by a low fibre diet. They may also be associated with infertility.
4. Adhesions and adhesion-related readmission to hospital are more common after open than laparoscopic surgery
5. Topical agents reduce the formation of adhesions but have not been shown to reduce readmissions or reoperations for adhesions.
6. Encapsulating peritoneal sclerosis (EPS) is the most severe form of adhesions and may cause a frozen abdomen on which surgery is very difficult.
7. Patients with adhesions/EPS are encouraged to chew their food well before swallowing. A low insoluble fibre/low residue diet can reduce the chance of obstructive symptoms occurring.

Adhesions

What Are They?

Adhesions in the peritoneal cavity are non-anatomical attachments between visceral and/or parietal peritoneal surfaces. They can be congenital or acquired. Congenital adhesions can range from complete peritoneal encapsulation, a rare cause of bowel obstruction in children and adults, to congenital bands that can cause internal herniation and volvulus. Studies reveal that 5–27% of those who have never had abdominal surgery have abdominal adhesions [1, 2]. This prevalence increases with age, suggesting that adhesions often form secondary to abdominopelvic events such as diverticulitis [2].

Adhesions are most prevalent in people who have had previous surgery. Prospective data from the pre-laparoscopic era demonstrated that the prevalence of adhesions in people undergoing laparotomy increased from 11.5% in people who had not undergone previous surgery to 93% in those who had [2]. Most of the adhesions noted had formed between the greater omentum and the abdominal wall scar.

Histological studies of postoperative adhesions reveal that they are typically collagenous bands initiated either by peritoneal injury or bleeding or a combination [1]. In the past, foreign bodies were the dominant cause of postoperative adhesions, but this has likely diminished as talcum powder, starch and textile materials have become replaced by safer materials [1].

Additional causes of acquired adhesions between surfaces in the peritoneal cavity include neoplasia, endometriosis, radiotherapy and a range of infections such as chlamydia and tuberculosis.

Adhesions in the Context of General Surgery

Peritoneal adhesions play a role in the pathogenesis of an array of symptoms and conditions of affected organ systems. Gastrointestinal and gynaecological complaints are the most common. Here, we will focus on complaints seen in general surgery that may or may not be associated with adhesions.

Abdominal Pain

Chronic or recurring abdominopelvic pain is common after abdominal surgery and adhesions are often thought of as an important cause of such symptoms. However, the evidence linking adhesions themselves and pain is poor. There is supportive experimental evidence, such as the findings of sensory nerve fibers in adhesions [3, 4].

It is not straightforward to scientifically study the role of adhesions as a cause of symptoms, as intraperitoneal adhesions are so prevalent in the population [2]. We instead have to rely on studies of adhesiolysis to examine this role. In a landmark study from the Netherlands, 100 patients with long-term abdominal pain after laparotomy underwent diagnostic laparoscopy and, if adhesions were found, randomised to laparoscopic adhesiolysis or no further dissection [5]. Three to 12 months after laparoscopy, pain scores decreased in both study groups, with no differences between groups. This suggests a placebo effect, and no additional effect of adhesiolysis on pain.

Seventy-three patients were then followed up at 12 years [6], and at this timepoint significantly worse outcomes were found in the group that had undergone adhesiolysis, including more frequent pain and use of analgesics and, perhaps most significantly, an increased number of reoperations to address adhesions.

Thus, while it remains possible that adhesions cause abdominal pain, adhesiolysis has no benefit in the short term, and an adverse impact in the long term, on this symptom. It should be avoided as a therapy for pain alone.

Intestinal Obstruction

It is clear that peritoneal adhesions, whether congenital, postoperative or otherwise acquired, are a dominant cause of small bowel obstruction: meta-analysis suggests that 56% of cases are caused by adhesions [7].

The magnitude of the problem of postoperative adhesions has been extensively studied in the so-called SCAR studies, registry studies that followed large cohorts who had abdominal surgery in Scotland. In the SCAR-1 study, 29,790 patients who underwent laparotomy in 1986 were retrospectively studied for 10 years [8]. One in three patients were readmitted to hospital during this time period. Most were readmitted more than once, resulting in a total number of readmissions of 21,347. Of those readmissions, 5.7% were documented as being caused by adhesions, in most cases by findings at surgery. In a much larger number of readmissions, 38% of the 21,347, adhesions were judged to be "possibly" causative based on a set of criteria. The SCAR-1 study established that readmission to hospital after open abdominal surgery is common and frequently directly or possibly caused by adhesions. The subsequent SCAR-2 study assessed changes during the time period 1996–1999, observing no change in the risk of readmission after open abdominal surgery [9].

The SCAR-3 study further analysed a cohort operated in the financial year 1996 with regard to types of index surgery [10]. The risk of readmission for documented adhesions during the subsequent 5 years was 3.8% for the whole cohort, and 5.2% excluding appendectomy. The risk was particularly increased following panproctocolectomy (15.4%), total colectomy (8.8%) and ileostomy procedures (10.6%) and decreased following small bowel surgery (1.8%) and appendicectomy (0.9%) [10]. The risk in patients who previously had had open abdominal surgery was twice that of those who had not. Although multivariable analyses were not performed, univariable analyses suggested that increasing age appeared to protect against readmission for adhesions, and Crohn's disease did not change the risk [10].

The concept that some patients form adhesions more readily than others is supported by long-term follow-up in the LAPAD study from the Netherlands [11]. In this study of 604 patients who had elective abdominal surgery in a single centre from 2008 to 2010, 32% were found to have severe adhesions, mostly from previous laparotomies, while 68% had mild or no adhesions. During a relatively short median follow-up of 46 months, 38 of the 604 (6.3%) re-presented with adhesive bowel obstruction. On multivariable regression, the finding of severe adhesions at index surgery was a strong predictor of subsequent adhesive small bowel obstruction [11].

In summary, some 60% of cases of small bowel obstruction are caused by adhesions, and in the long term of 4–10 years, at least 5% of patients undergoing abdominal surgery will be readmitted with proven adhesive bowel obstruction. Of note, these data are from cohorts of patients who nearly all underwent open surgery. The impact of minimally invasive surgery on adhesion-related morbidity is examined below.

Morbidity During Future Operations

Another consequence of adhesions is lengthy adhesiolysis during future intraperitoneal operations. This is not only time-consuming, but is associated with increased morbidity. The initial LAPAD study focused on adhesiolysis as a risk factor for adverse outcomes [12]. In this prospective study, 755 elective open or laparoscopic abdominal operations were observed. Adhesiolysis was required in 475 operations, and in 50 of those (10.5%) an accidental enterotomy was made. Adhesiolysis added a median of 20 (range 1–177)

minutes to the operation. The risk was of enterotomy was particularly increased in operations requiring more than an hour of adhesiolysis. In the 280 operations during which adhesiolysis was not required, no enterotomies were made. The difference in enterotomy risk helps explain several associations between adhesiolysis and adverse outcomes seen in this study, such as postoperative sepsis, increased length of hospital stay and increased costs [12].

Cost to Healthcare Services

Calculating the economic costs of adhesions is complicated as it encompasses the costs of clinic and emergency visits, diagnostic tests, hospital admissions, surgery performed to treat adhesions, adhesiolysis during other peritoneal surgery, loss of income from admissions, and other costs.

The LAPAD study estimated that the mean hospital cost for each patient undergoing elective surgery increased from USD 14,063 in those without adhesions to USD 18,579 in those with adhesions in the Netherlands in 2010 [12].

A Finnish population-based study estimated that, at 1999 currency levels, annual direct hospital for small bowel adhesion in the country was GBP 2,077,796, similar to the costs of treating rectal cancer throughout the country [13].

Adhesions in the Context of Intestinal Failure

Although extensive peritoneal adhesions have long been recognised as a cause of intestinal failure [14], data on this association are scarce. In the largest published series of long-term (3 months or longer) parenteral nutrition, mechanical obstruction was the mechanism of intestinal failure in 20/545 (3.7%) of patients treated at the Irving National Intestinal Failure Unit in Manchester, UK during the period 1978–2011 [15]. In a snapshot study from the same unit in 2017, the proportion was 15/273 (5.5%) cases [16]. However, these studies included patients with cancer as the underlying diagnosis, and the number of patients with benign adhesions is likely to be less.

Given the prevalence of peritoneal adhesions in the population, the risk of developing intestinal failure through this mechanism can reasonably be assumed to be small. Empirically, cases where benign adhesions are the dominant cause of intestinal failure are unusual. Where this occurs, adhesions are often the result of multiple operations, previous peritonitis and/or implanted mesh.

A much more common clinical challenge is the patient with small bowel dysmotility who has previously undergone surgery, often subtotal colectomy for suspected slow-transit constipation. Such patients frequently have radiological findings consistent with both intestinal dysmotility and adhesive obstruction. Assessing the contribution of adhesions in such cases is crucial in order to predict the likelihood that surgical adhesiolysis will improve intestinal function. Helpful tools in this assessment include longitudinal imaging to identify any fixed transition points, histopathology with specific immunohistochemistry on full-thickness small bowel samples to identify known dysmotility disorders such as visceral myopathy [17], and in selected cases a trial of a loop enterostomy proximal to a suspected obstructive site to assess whether function in the proximal small bowel normalises.

Diagnosis

Diagnosing Adhesions

In the absence of concurrent small bowel obstruction, adhesions in the peritoneal cavity are not visualised by static radiological imaging such as computed tomography or magnetic resonance imaging. However, dynamic ultrasonography is emerging as a promising diagnostic modality, in particular in the obstetric field. In the so-called visceral slide test, the viscera are visualised by ultrasound in different regions of the abdomen, and the extent of movement in response to normal or forced respiration is assessed. Restricted or absent movement, or slide, is thought to reflect peritoneal adhesions. A recent meta-analysis of 25 observational studies focused on the periumbilical area, commonly used for laparoscopic access to the peritoneal cavity [18]. A positive predictive value of 60.4% and, more importantly, a negative predictive value of 99.2% was demonstrated [18]. The gold standard used in these studies was the findings on laparotomy or laparoscopy. While this finding has implications for minimally invasive surgical techniques, better data are needed on visceral slide sonography in the rest of the abdomen.

Abdominal dynamic magnetic resonance imaging, or cine-MRI, is a similar technique that has been evaluated with promising results [19]. In a head-to-head comparison, dynamic ultrasound and MRI both performed well, and cine-MRI was superior in detecting adhesions between viscera such as small bowel [20].

Dynamic imaging is yet to enter routine clinical practice, but the techniques are available and could prove valuable in investigating unclear symptoms or preparing for complex abdominal re-operative surgery. The gold standard in diagnosing adhesions remains direct visualisation at surgery. During surgery it is also possible to systemically assess and grade adhesions (Fig. 1). Several scores have been proposed. The Zühlke score described in 1990 is based on the histopathology of adhesions, grading them from weak to thick [22]. The increasingly used peritoneal adhesion index (PAI) instead describes the severity of adhesions in the regions of the abdomen, and provides a summative score (Fig. 2) [23]. In brief, adhesions observed at surgery are scored 0 (no adhesions)–3 (very strong vascularised adhesions). The

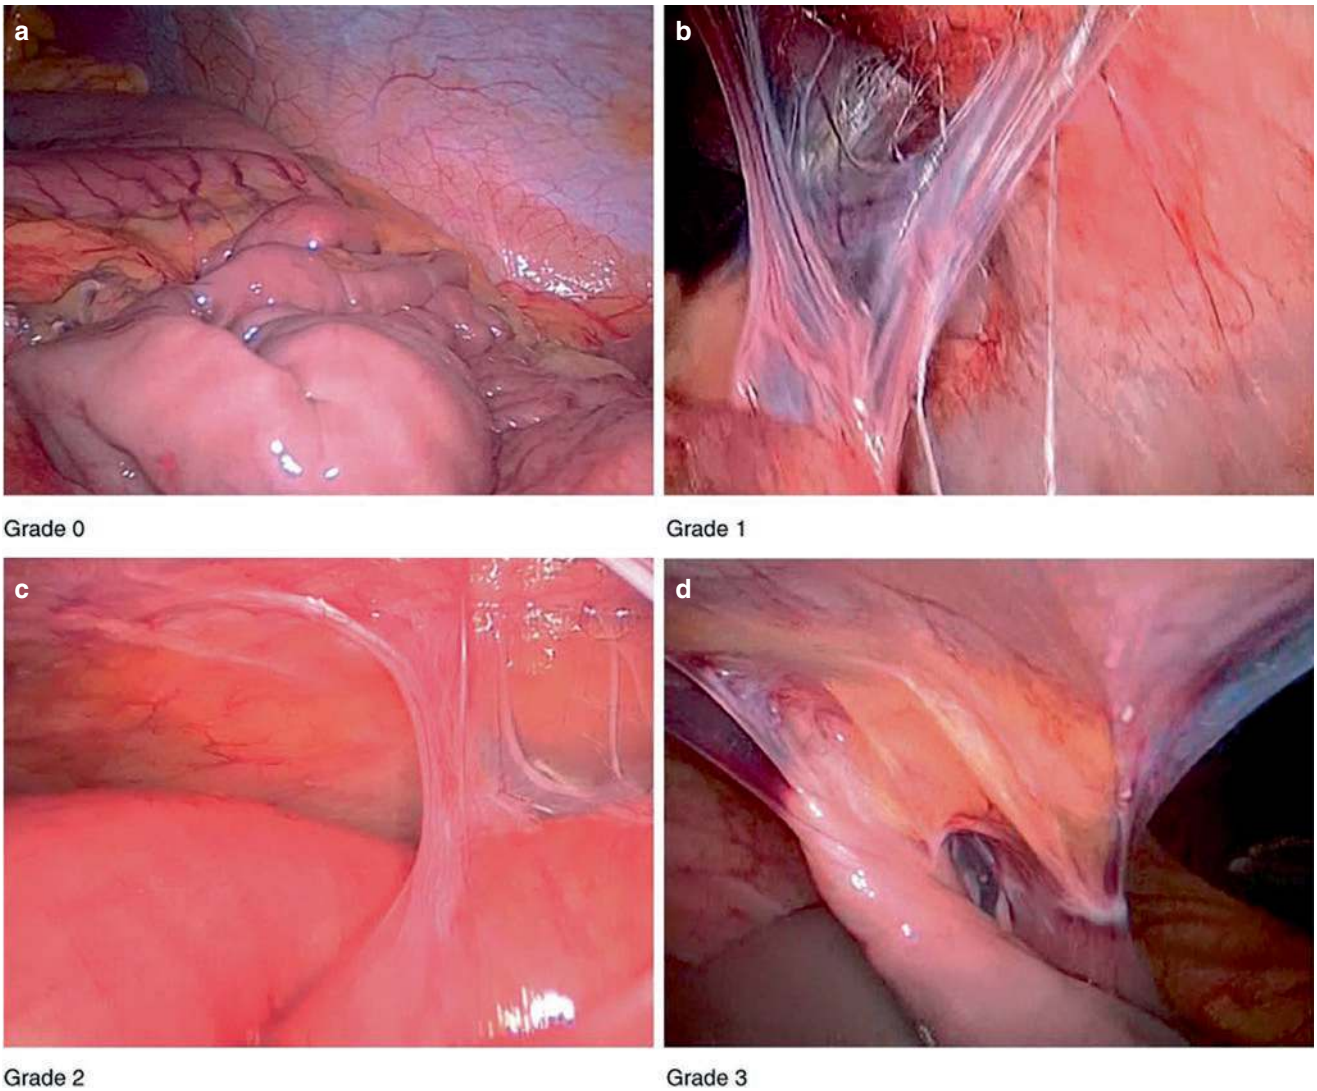

Fig. 1 Severity of adhesions. (**a**) no adhesions (grade 0); (**b**) flimsy thickness, avascular (grade 1); (**c**) moderate thickness, limited vascularity (grade 2); and (**d**) dense thickness, vascularized (grade 3). (Hull et al., Adhesions after laparoscopic and open ileal pouch–anal anastomosis surgery for ulcerative colitis, Br J Surg, 2012, 99(2);270–5, by permission of Oxford University Press [21])

abdomen is divided in nine even regions, and adhesions in each region are scored on this scale. A tenth score is determined for inter-loop adhesions. The ten scores are added up and the sum is the total PAI score.

Diagnosing Adhesive Intestinal Obstruction

When adhesions are complicated by concurrent intestinal obstruction, the clinical presentation and radiological findings are more sensitive and specific. The patient often presents with a sudden onset of colicky central abdominal pain which is worse in the ileum than jejunum and may follow eating a fibrous/grisly bit of food (often not well chewed). This may be followed by vomiting, a yellow/green vomit suggest proximal small bowel obstruction and a dark brown fluid a more distal one. The bowel/stoma may stop working. The abdomen may be distended with loud bowel sounds. If an obstruction resolves it is followed for 1–3 days by diarrhoea or if a stoma a high output.

Useful radiology includes plain abdominal X-ray and cross-sectional imaging, and findings include dilated small bowel up to the point of obstruction (diameter above 3 cm), air–fluid levels and an absence of gas in the colon. Cross-sectional imaging often confers additional information, such as the cause of obstruction and can show signs of ischaemia.

A difficulty arises when a patient presents with intermittent symptoms suggesting small bowel obstruction. Ensuring that urgent diagnostic imaging is obtained before symptoms resolve is the only way to diagnose obstruction in such cases.

A similar problem is posed when diagnosing low-grade small bowel obstruction. Such relative obstruction may not

1 Filmy adhesions, blunt dissection

2 Strong adhesions, sharp dissection

3 Very strong vascularized adhesions, sharp dissection, damage hardly preventable

PAI ☐

Fig. 2 Peritoneal Adhesion Index (adapted from Coccolini et al. [23]). Each area of the abdomen is ascribed an adhesion related score. The sum of the scores will result in the PAI

result in pre-stenotic dilatation, resulting in a sensitivity of CT in this condition of only 50% [24]. Enteroclysis, in which contrast is delivered directly into the small bowel at a high rate through a nasojejunal tube, is more sensitive to detect low-grade obstruction; indeed, some studies suggest the technique is near 100% sensitive [25].

Prevention

The literature reviewed above shows that surgical adhesiolysis is followed by formation of new adhesions. There is currently no other treatment of adhesions. Therefore, prevention in routine surgical practice is a crucial priority to reduce the considerable morbidity and costs associated with adhesions.

Surgical Technique

Several surgical techniques have been proposed to decrease adhesion formation following intraperitoneal surgery (Table 1). They include minimally invasive approaches; closure of the parietal peritoneum; avoidance of foreign bodies such as glove powder, sutures and meshes; prevention of infection; and peritoneal lavage. A 2012 meta-analysis found no effects of such techniques on rates of subsequent clinically significant adhesions or adhesions on subsequent surgery [26].

In regards to minimally invasive surgery, however, the amount of high-quality data has matured further since this meta-analysis. There is now high-grade evidence that supports the hypothesis that laparoscopic surgery significantly decreases subsequent adhesion-related morbidity. The SCAR study group retrospectively studied 72,270 patients who underwent laparoscopic or open abdominal or pelvic surgery in the period 2009–2011 [26]. After 5 years, 1.7% in the laparoscopic cohort vs. 4.3% in the open surgery cohort had been readmitted to hospital with proven adhesion-related morbidity, mainly adhesive small bowel obstruction. Adjusting for confounders, the authors found that laparoscopy reduced the risk of adhesion-related readmission within 5 years of surgery by 32% [27].

Data from the series of large randomised trials that first evaluated safety and efficacy of laparoscopic colon and rectal cancer resection have mostly been unable to demonstrate effects on long-term adhesion-related morbidity [28–30]. One recent randomised trial did demonstrate reduces rates of adhesions in the minimally invasive surgery group [31]. A recent meta-analysis of randomised trials pooled 4656 patients and did not find an association between laparoscopy and rates of adhesion-related morbidity [32]. The lack of effect in randomised trials is not surprising given the low event rate. Very large study groups would be required to definitively demonstrate an effect of laparoscopy on adhesions in a randomised design.

In summary, available randomised trials are small in relation to the event rate of measurable outcomes, and arguably the best evidence available is large clinical registry data. The recent, large SCAR study update provides strong support for the reasonable notion that less tissue damage results in less formation of adhesions.

It is also reasonable to suggest that, regardless of surgical approach, atraumatic surgical technique and meticulous attention to detail is important in preventing adhesion formation, although this factor is difficult to quantify and study. Both tissue injury and bleeding play a role in initiating adhesion formation, and are best minimised. Tissue injury is minimised by focused sharp dissection, avoiding blunt dissection, optimum settings in energy devices, careful retraction of tissues and using inert irrigation fluid at body temperature.

Table 1 Adhesion prevention strategies

Awareness of risk factors
Increasing age
Number of previous laparotomies
Complexity of the procedure
Location of the procedure (increased in pelvic procedures)
Crohn's disease
Resections for colonic cancer
Proctocolectomy, total colectomy, ileostomy
Conservatively treated localised peritonitis (appendicitis, diverticulitis)
Surgical technique
Careful tissue handling
Sharp dissection using sharp instruments
Avoid crushing tissue
Avoid unnecessary dissection
Attention to detail with ligatures
Optimum tissue beyond ligature to reduce ischemic tissue
Avoid excessive redundant ends of non-absorbable tissue
Avoid bowel exposure and desiccation
Avoid drying of tissue, in exposed area with adherence of clot
Use laparoscopic technique if possible
Robotic techniques
Avoid peritoneal suturing during wound closure
Use of physical antiadhesion barriers
Seprafilm® Adhesion Barrier (Cambridge, MA; Genzyme Corporation)
Gore Preclude Surgical Membrane Adhesion Barrier Flagstaff, AZ; Gore and Associates Inc.
Gynecare Interceed Absorbable Adhesion Barrier (Somerville, NJ; Johnson and Johnson)
Adept Solution: Adhesion Reduction Solution (Deerfield, IL; Baxter Healthcare Corporation)
Intercoat (AC AG Group, Kaltenkirchen, Germany)
Fibrin Sheet (TachoComb, Tokyo, Japan)
Antibiosis techniques to reduce bacterial translocation
Mechanical bowel preparation
Antibiotics
Pharmacologic agents (anecdotal and experimental)
Antiinflammatory agents (Steroids, NSAIDS)
Tamoxifen (Synthetic nonsteroidal antiestrogen agent, with antifibrotic properties)
Anticoagulants including heparin, ancrod.
Calcium channel blockers
Vitamin E
Halofuginone

Topical Biochemical Agents

Given the significant prevalence of adhesions following intraperitoneal surgery and their associated morbidity

and costs, their prevention by chemical and pharmacological agents has been a large and active research field. Strategies evaluated include systemic agents such as anti-inflammatory drugs and anticoagulants, and chemicals applied topically in the surgical wound. To summarise this field, to date none has been widely applied in clinical practice.

A Cochrane meta-analysis of randomised and pseudo-randomised trials of topical agents, most recently updated in 2009, concluded that a hyaluronic acid/carboxymethyl membrane reduced the incidence and severity of adhesions as assessed at a second, planned operation months later (Odds ratio 0.15), but did not affect the need for unplanned reoperation for adhesive small bowel obstruction (Odds ratio 0.84) [33]. It cautioned that some data suggested an increased risk of anastomotic dehiscence when the agent was applied near an anastomosis. The hyaluronic acid/carboxymethyl membrane was the only agent for which sufficiently high-quality data were available for meta-analysis [33].

A 2014 meta-analysis included non-randomised studies in addition to randomised trials, and made similar conclusions regarding effects of topical agents on adhesion formation, reoperative rates, and importantly on anastomotic complications [34]. Furthermore, other adverse effects were also evaluated, and found to be no different between treatment and control groups. These included wound healing complications and abscess formation. The latter conclusion has been challenged, however, as a preliminary report of a large observational study was not included [35]. This study of 1885 patients who underwent proctectomy and ileal pouch-anal anastomosis reported an increased incidence of pelvic sepsis in patients treated with hyaluronic acid/carboxymethyl membrane (10.2%) when compared to those who were not treated (6.8%, P 0.016) [36].

In the absence of clinical efficacy, it is difficult to support routine usage of hyaluronic acid/carboxymethyl membranes or any other agents to prevent adhesions. Some centres routinely use the membranes around the two limbs of a temporary diverting loop ileostomy as it traverses the abdominal wall, in order to reduce adhesions when it is taken down some 6–12 weeks later. Such usage appears safe and advantageous. It is also reasonable to consider the agent when reoperating patients with a known capacity to form troublesome adhesions.

Systemic Agents

Non-steroidal anti-inflammatory drugs are the most widely studied but their clinical efficacy is questionable. Corticosteroids have poor efficacy and are associated with immunosuppression and delayed wound healing. Fibrinolytics have a risk of impaired wound healing and/or bleeding.

Management in the Context of Intestinal Failure

While type 3 intestinal failure is rarely attributed solely to intraperitoneal adhesions, they are an important factor in the management of type 2 intestinal failure, specifically in determining the timing of reconstructive surgery. For many reasons discussed extensively in chapter "Acute Surgical Intestinal Failure. Sepsis and Enterocutaneous Fistula(s)", reconstructive surgery for IF is typically delayed until 6–12 months after the most recent surgery. One of the key considerations is the maturation and, ideally, resolution of adhesions. There is no longitudinal data on these processes, but it is a common clinical observation that reoperative surgery within the first 2–3 months is very technically challenging with dense and often still inflamed adhesions; that reoperative surgery after a period of years is much more frequently straightforward and the adhesions encountered soft and filmy. The difficulty is determining the ideal time point between these extremes when relaparotomy is reasonably safe.

Useful clinical tests are simple inspection and palpation of the abdomen. A soft, flexible abdominal wall is promising. If there is a stoma or an enterocutaneous fistula, it is highly useful to observe its movement when the patient coughs or strains; free movement and a slight prolapse of the bowel is a good sign that the abdominal viscera are not rigidly held in a frozen abdomen. If clinical examination suggests that the abdomen is dense and inflammation not yet resolved, it is best to delay reconstructive surgery and re-evaluate after 6 months.

In type 3 IF, adhesions are often present and the challenge is to assess their relevance. As mentioned above, this is particularly the case in conditions associated with impaired small bowel motility, such as dysmotility syndromes.

Encapsulating Peritoneal Sclerosis

Encapsulating peritoneal sclerosis (EPS) is the most severe form of adhesions/intraperitoneal fibrosis and is a descriptive abdominal manifestation of a spectrum of aetiologic conditions [37]. A diagnosis of EPS in the current era is considered synonymous with the clinic-pathologic syndrome which is an important morbidity of long-term peritoneal dialysis. All forms of peritoneal sclerosis with or without encapsulation can lead to intestinal dysfunction and eventual intestinal failure. The pathophysiologic mechanism in the different diseases varies depending on the specific aetiology. Clinical manifestations occur when there is the formation of a membrane or peritoneal sclerosis which causes adhesions, between bowel loops, and also between the bowel and the parietal peritoneum, causing restriction of gut

motility. With progression of disease, the gut can become cocooned and completely encased, causing progressive intestinal failure. The biologic processes underlying the individual aetiology, disease progression and presentation are varied and multifactorial and clinical presentations can be subtle and mimic other pathology, leading to delayed diagnosis or late presentations. The overarching clinical picture however is one of GI dysfunction associated with intraperitoneal inflammation associated with progressive nutritional deficiency, eventually leading, if untreated to an acute presentation requiring surgical intervention. On a background of significant associated comorbidity, there may be a high risk of mortality or intestinal failure.

The diagnosis of EPS is often made late and in a large number of cases only at surgery. Early diagnosis requires a knowledge and suspicion of the condition in the clinical context, and is confirmed by combining the clinical history, presentation and imaging, surgical findings and histology. EPS is not a histological diagnosis. Surgery remains the mainstay of treatment, and best results are obtained in centres which have experience with managing this relatively rare condition. However, the overall management is complex, requiring a number of disciplines, with nutritional support and surgery playing a key role in management.

The Peritoneum Structure, Physiology and Function

The peritoneal cavity is a potential space, separating the parietal peritoneum, covering the inner walls of the abdomen and the pelvis and the visceral peritoneum covering the abdominal viscera and the bowel. The surface area of the peritoneum is over 1.8 m^2 in area, with an interface of peritoneal fluid, of approximately 100 mL, which allows lubrication and free movement of the bowel. The fluid is an ultrafiltrate of plasma, providing a frictionless environment for the abdominal organs.

The peritoneal surface is formed of a single layer of cells lining the peritoneal cavity, first described by James Douglas in 1730, and then later called the mesothelium by Binot in 1980. These mesothelial cells are 25 μm in diameter, are derived from the mesoderm and possess both mesenchymal and epithelial characteristics (Figs. 3 and 4).

Physiologically, the peritoneum plays an important role in maintaining the intra-abdominal homeostatic equilibrium. The functions of the peritoneal membrane include, transport of fluid and particulate matter, regulation of leucocyte migration, control of coagulation and fibrinolysis, antigen presentation, synthesis of inflammatory cytokines, growth factors and extracellular matrix for repair. These multiple functions enable the several important clinical therapeutic interventions via the peritoneal cavity, including peritoneal dialysis, chemotherapy and immunotherapy [39]. Kastelein et al. have provided an excellent up to date review of the embryology, anatomy, physiology, pathophysiology and pathophysiology of the peritoneum and peritoneal vasculature [40]. More recently studies suggest that exosomes contribute to peritoneal function, by the intracellular transfer of DNA, mRNA, proteins, and lipids. They are thought to play a part in regulating peritoneal membrane function [41].

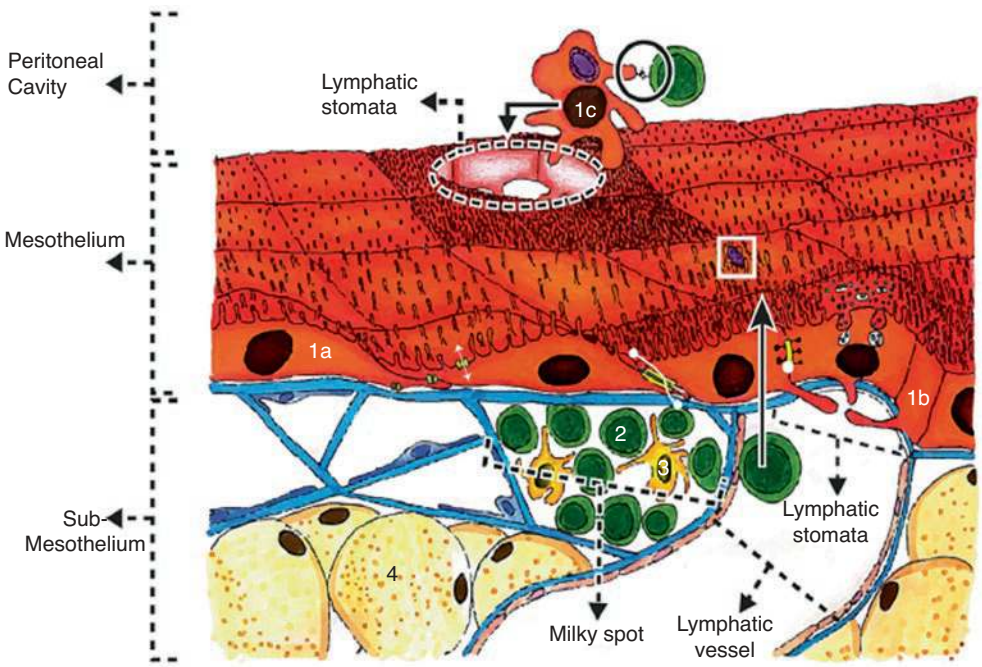

Fig. 3 A schematic representation of the peritoneum with mesothelial organization and functions. The mesothelium is composed of flat mesothelial cells (1a), and cuboidal mesothelial cells (1b). Water transport (two headed white arrow) occurs through aquaporins, while zonula adherens (two headed dot arrow) and tight junctions (white dot) give support and selective barrier properties. Mesothelial cell can also trap pathogens (white square), detach (1c), phagocyte pathogens and present antigen (black circle) for immune induction. The sub-mesothelium contains the basal membrane, the connective tissue, adipocytes (4) and the milky spots were mainly lymphocytes (2) and macrophages are found (3). Reproduced from [38]

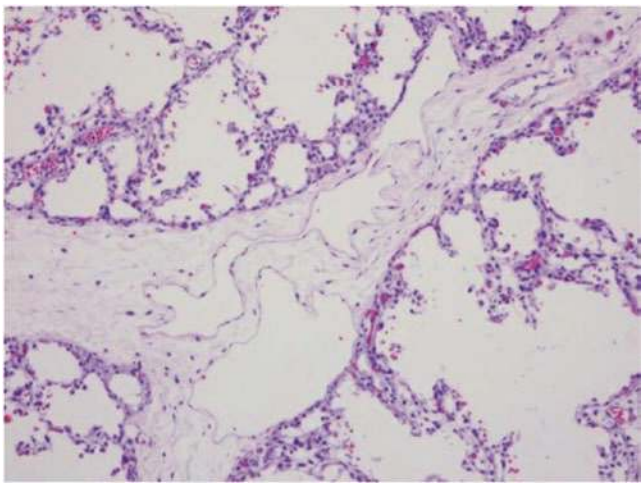

Fig. 4 Photomicrograph of normal visceral peritoneum

Classification and Aetiology of EPS

Encapsulating Peritoneal Sclerosis is currently considered synonymous with the condition which is seen as a long term morbidity of peritoneal dialysis first described by Gandhi in 1980 [42]. However there are a variety of peritoneal sclerosing conditions described unrelated to peritoneal dialysis but associated with specific other pathology. Owtschinnikow described a case of *peritonitis chronica fibrosa incapsulata* as early as 1907 [43]. The abdominal cocoon has been described as a specific entity, unrelated to renal failure or other causes. This presentation has mainly been described in China, India and the African continent with sporadic cases in the temperate regions. Various infective conditions including abdominal tuberculosis has also been described presenting with cocooning of the bowel as a clinical manifestation.

Various descriptive terms have been used to describe the abdominal presentation of these different entities, including sclerosing peritonitis [44], sclerosing obstructive peritonitis [45], sclerosing encapsulating peritonitis [46, 47] and progressive calcifying peritonitis [48]. While the combination of terms are varied, they all fundamentally describe a pathologic process, which is, a sclerosing and fibrosing inflammatory condition, which encapsulates and restricts the gut, leading to bowel obstruction.

Taking into account the incidence, clinical presentations, associations with different aetiology and the clinical and pathologic mechanisms, of the different types of peritoneal sclerotic and encapsulating conditions, it can be broadly classified into three main groups. (a) EPS secondary to peritoneal dialysis, (b) EPS as a consequence of other pathology, unrelated to peritoneal dialysis, and the specific entity (c) Primary encapsulating peritoneal sclerosis. While it can be classified clearly on the basis of etiopathology, it may be difficult to accurately classify it prior to diagnosis [49].

After its initial description in association with peritoneal dialysis by Gandhi [42], the condition has in the last four decades, become recognised as a definite entity which is an uncommon but potentially fatal complication of peritoneal dialysis. EPS associated with long term PD is potentially the most significant of these encapsulating conditions as it can be associated with significant morbidity and mortality. It is a relatively uncommon complication of PD which varies between centres, countries and over time periods. The prevalence of EPS varies from 0.4% to 8.9%, its incidence rate between 0.7 and 13.6 per 1000 patient-years. This observed variability may be multifactorial, including genetic predisposition, significant variation in practice, diagnosis, treatment and follow up of patients [50].

The Pathophysiology of Development of EPS

Due to the large number of patients on peritoneal dialysis globally and the relatively increased numbers of PD related EPS compared to the other secondary and primary EPS, the pathophysiology of this condition has been most studied.

It is now well understood that in the vast majority of cases, development of EPS requires a predisposing factor and also inciting factors. There is not much literature on genetic predisposition; however extrapolating from other genetic fibrosing conditions, there is a strong likelihood there will be a genetic predisposition in association, with long term PD. While peritoneal dialysis is considered more physiological than haemodialysis, the peritoneal dialysis solutions are hyperosmolar are have relative degrees of bioincompatibility, which causes changes to the peritoneal membrane it is in contact with. Factors which cause the bioincompatibility and peritoneal inflammatory reactions are the glucose degradation products (GDPs) after heat sterilisation, the lactate content and the low pH. The pathophysiologic process caused by these factors is similar to a sterile chronic inflammatory process or a chemical burn. It causes denudation of the peritoneal mesothelial cells, epithelial to mesenchymal transdifferentiation, and cytokine release of proinflammatory, proangiogenic cytokines, namely TGFbeta 1, IL-6, CCN2 and VEGEF (Figs. 5 and 6).

Although several precipitating factors have been described for the development of EPS, the main factor appears to be the length of peritoneal dialysis [53] and the recurrent episodes of infective peritonitis. These processes lead to the continued peritoneal inflammatory changes and a cytokine cascade and in genetically susceptible individuals, progression to clinical manifestation as EPS.

The organisms grown in infected peritoneal fluid in patients who go on to develop EPS are mainly Staphylococcus aureus, Propionibacterium acnes [54], Pseudomonas species or Fungal Peritonitis.

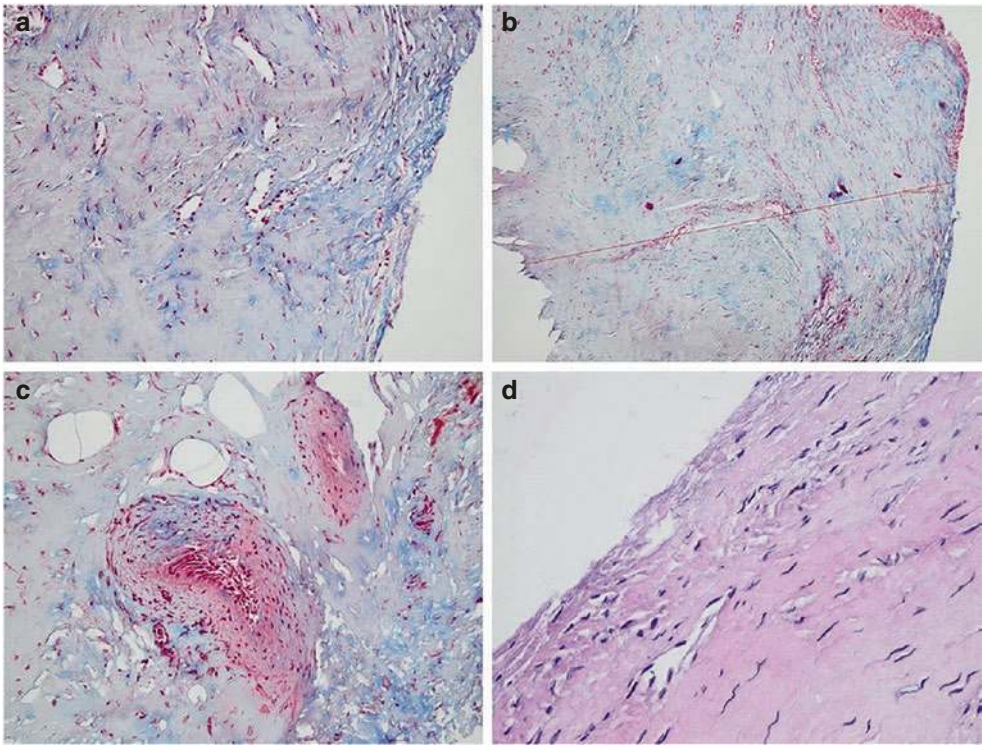

Fig. 5 Peritoneal histological examination: (**a**, **b**) the fibrous components of recent deposition, still rich in mucopolysaccharides, is in a pale color, while the more ancient fibrotic component, consisting almost exclusively of collagen, is highlighted in deeper blue. This staining highlights a recent beginning of the fibrotic process: blue is still poorly represented compared to the pale colour. The thickness of the peritoneal membrane is increased (638 μm). (**c**) Also in perivascular areas, the fibrosis spreads from the submesothelial layer towards the inside. (**d**) Marked thinning of the mesothelial layer. (Adapted from [51])

EPS has been described sporadically after organ transplantation. Lee et al. have described two cases after liver transplantation treated with a combination of surgery, steroids tamoxifen and mTOR inhibitor [55].

It has also been described as a rare complication of intestinal transplantation. In the case described, after confirmatory surgery, the patient was commenced on Sirolimus, and increased steroids and tacrolimus. There was complete resolution of the obstructive symptoms with recovery of intestinal transit [56]. EPS presenting after kidney transplantation is quite well described.

While elements of the predisposing and inciting factors play a part in the other secondary and potentially primary peritonitis, there are other interlinked disease specific factors in addition which will be briefly touched upon.

Secondary Peritoneal Sclerosing Conditions Not Related to Peritoneal Dialysis

Secondary Peritoneal Sclerotic conditions unrelated to peritoneal dialysis encompasses a very large and disparate group of conditions (Table 2). They span a spectrum of aetiopathology with, the clinical manifestations caused by, both the primary disease and the superimposed effects of peritoneal sclerosis with or without membrane formation and/or encapsulation.

The earliest cases of encapsulation were related to foreign material introduced during surgical procedures. The use of Talc, has been known to cause fibrosis [57] Talc powder was used as a lubricant for surgical gloves in the past, before its detrimental effects were identified. Silica is a component of talc, and causes fibrosis, with a characteristic and diagnostic histologic feature, the Maltese cross. EPS has been reported in a drug abuser where it is postulated that silica got into the abdomen through abdominal injections [58]. Povidone iodine used for peritoneal lavage after surgical procedures has also been reported to cause EPS [59]. Dacron fibres as a cause in an individual has been reported, however this patient was on peritoneal dialysis, and the EPS was precipitated after change of the dialysis catheter [60].

Other than externally introduced material, body fluids could precipitate EPS. Encapsulation after abdominal trauma has been described [61]. It is hypothesized that subclinical peritonitis may be the underlying cause in this case. Similarly EPS secondary to rupture of a Dermoid cyst has been reported where the authors postulate the mechanism to be a chemical peritonitis from the cyst contents [62].

Sigaroudinia et al. describe EPS as a complication of long term ventriculo-peritoneal shunts two children who required surgical enterolysis. Both of them presented with acute intestinal obstruction. The CSF was sterile in both these patients. No specific mechanism is postulated other than chronic irritation [63].

EPS has also been described as part of manifestation of systemic inflammatory diseases. It is described along with recurrent ascites in SLE. The mechanism may be related to the inflammation of serosal membranes, including perito-

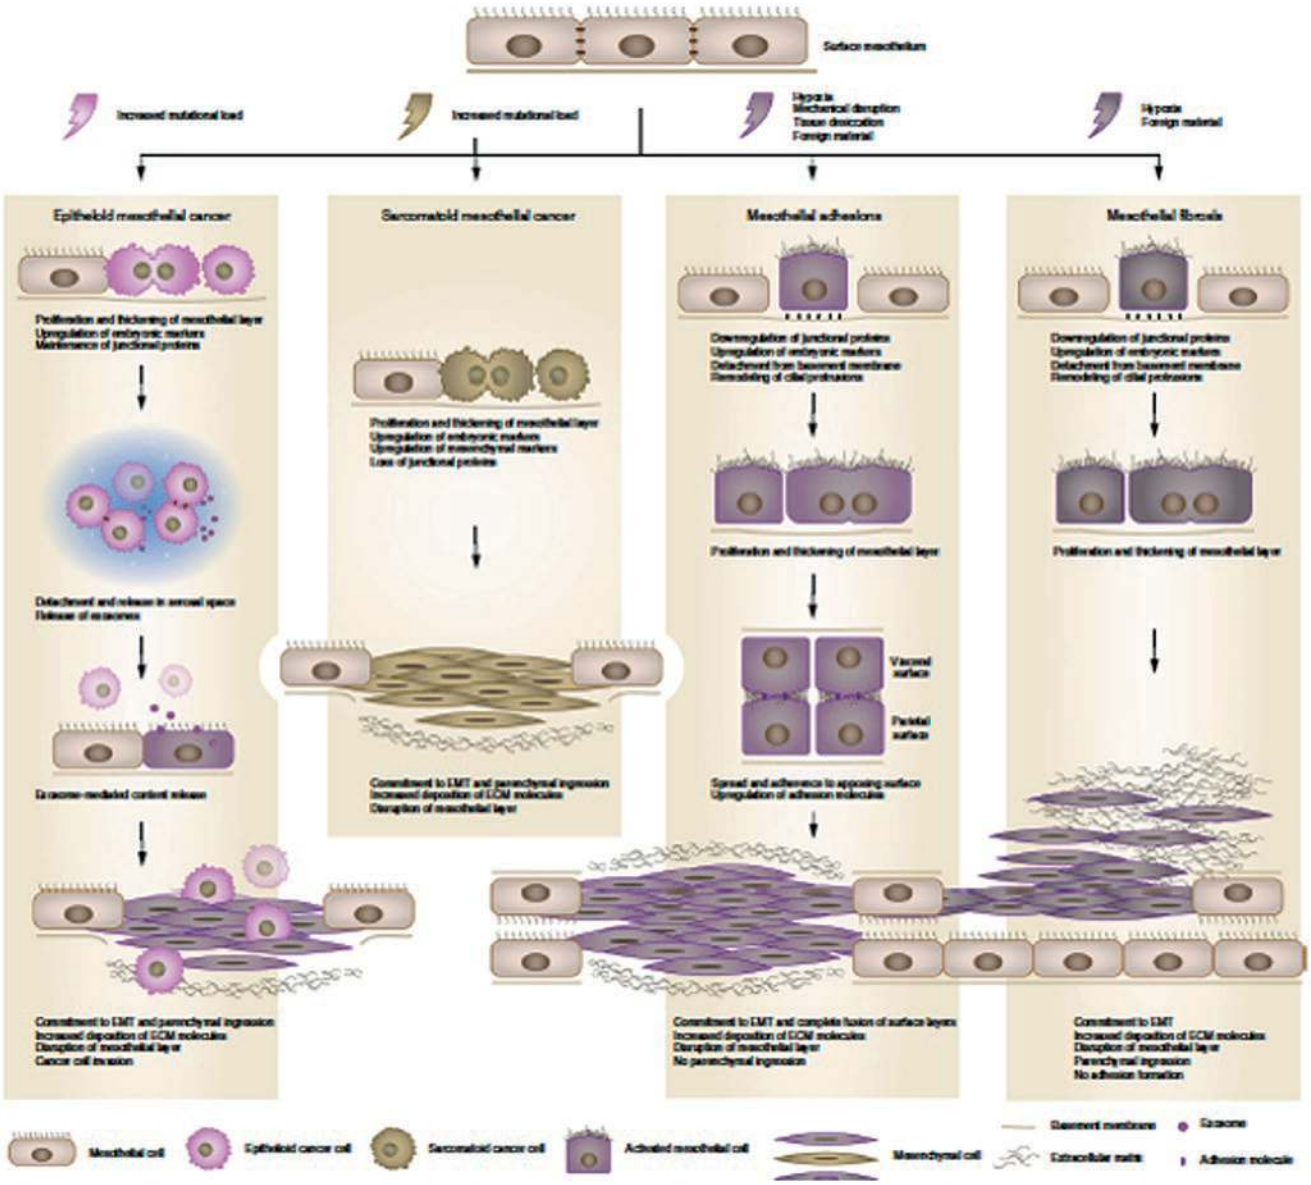

Fig. 6 Schematic representation of a cross section of the peritoneum showing mesothelial-to-mesenchymal transition (MMT) as a consequence of cancer or, for example long-term peritoneal dialysis. Reproduced from Tim Koopmans, Yuval Rinkevich: Mesothelial to mesenchyme transition as a major developmental and pathological player in trunk organs and their cavities [52]

neum, pericardium and pleura associated with SLE. On the background of a genetic predisposition, encapsulation and ascites develops [64, 65]. A similar mechanism may occur in Familial Mediterranean Fever which is associated with polyserositis [66].

Another group of diseases which are associated with EPS are the ovarian tumours. Leutenising thecomas are most closely associated with the condition. The link was first described by Clement in 1994, in six patients, where leutenizing thecomas were associated with peritoneal sclerosis [67]. The thickened peritoneum was made up of a proliferation of fibroblasts and myofibroblasts separated by collagen, fibrin and chronic inflammatory cells. The causative relation was thought to be enigmatic. Altman et al. have reviewed the linkage and identified 43 cases, and on immunohistochemistry, vimentin+/keratin+/CD34+ was found [68].

One of the first drug related causes was reported in 1975 in association with practolol for angina [69]. The patient required surgery for obstruction, where there was fibrinous adhesions and cocooning of gut which required excision and enterolysis. Subsequently other drugs in the beta blocker class have also been found to cause EPS including Timolol. Antiepileptic drugs like phenytoin have also been implicated with the authors postulating that like gingival hyperplasia, the mechanism might be increased collagen and glycosaminoglycans and peritoneal inflammations with

Familial Mediterranean fever
C: Primary EPS (the abdominal cocoon)

adhesions and cocooning [70]. Methotrexate has also been reported as an aetiological factor [71–73]. EPS associated with direct intraperitoneal chemotherapy has been reported [74, 75].

Intraabdominal tuberculosis can also present with the granulomatous tissue encasing the bowel and presenting as an abdominal cocoon. It is important that a preoperative diagnosis is made as anti-tuberculous treatment may resolve the problem. However if it presents as bowel obstruction not responding to treatment or an acute surgical emergency, surgery has to be carried out and histological confirmation obtained [76–78].

Mycobacterium fortuitum, an atypical mycobacterium has been reported, however in association with peritoneal dialysis [79]. There are several case reports of EPS associated with fungal infections,

Primary EPS

Foo et al. in 1978 published on series of cases in young girls from Singapore where the gut was encased in a membrane causing obstruction [80]. The condition was termed the abdominal cocoon. Histologically the membrane was made of thickened collagenized fibrous tissue with mild vascularization. Subsequently there have been several reports of this condition mainly from the tropics and subtropical regions. The largest number of publications on this condition comes from China, India, Turkey and Nigeria. However there have been cases also described in temperate zones [81, 82].

No underlying cause can be ascertained in primary encapsulating peritoneal sclerosis and hence the name and the differentiation from the secondary group of EPS. There have been several hypotheses, on the aetio-pathologic processes of development of this condition, including retrograde menstruation, superadded viral infection, retrograde peritonitis via the fallopian tubes and immunological reasons [83]. The condition is however also seen in men, premenopausal women and children. It is difficult to diagnose clinically preoperatively, but a CT scan can make the diagnosis. Careful dissection and excision of the thick sac with release of the small intestine leads to complete recovery in the vast majority of cases [84].

Diagnosis of EPS

The diagnosis of EPS requires knowledge of the condition and index of suspicion in patients presenting under the different contexts referred in the classification above. It should be considered in the differential diagnosis of an individual on long term peritoneal dialysis who presents with abdominal symptoms with progressive decline in nutritional status and raised inflammatory markers. The majority of patients on long term peritoneal dialysis do not develop EPS. However EPS should be considered and ruled out in any patient who has had peritoneal dialysis for a number of years (over 5), and especially so in someone with a history of multiple episodes of peritonitis.

In susceptible patients it may present soon after a transferring from peritoneal dialysis to haemodialysis, or after transplantation in someone who has been on long term peritoneal dialysis. The exact mechanism of how EPS is precipitated after this modality change is unknown.

It should also be considered in patients who have had previously had peritoneal dialysis who present with recurrent episodes of unexplained ascites, especially after transplantation or after conversion to HD.

In a significant number of patients, the diagnosis is made late after investigations for other pathology have drawn a blank. If the condition is not considered early, patients often decompensate nutritionally while being investigated for other potential pathology and in that period continue to decompensate nutritionally. In parallel with these changes, if the individual is still on peritoneal dialysis reduction in ultrafiltration will be noted along with a high transporter status. The deterioration is hastened by the underlying inflamma-

tory process in the peritoneal cavity driven mainly by the thickened and inflamed membrane.

In the early stages patients may present with vague abdominal symptoms, and then develop refractory anaemia which does not respond to iron supplementation or erythropoietin. This is also related to the chronic inflammatory process, from the thickened membrane and also pockets of loculated peritoneal collections. These collections usually contain debris, clots and fibrinous material and organisms. The CRP will be raised right from the outset and along with disease progression and there will be a downward trend in albumin levels (Table 3).

In the non PD group of EPS, the diagnosis may be even more difficult, and diagnosis depends on knowledge of association of EPS with that condition, an index of suspicion and imaging.

A significant number are unfortunately diagnosed at surgical exploration. There can be rare and unexpected presentations [85, 86]. There are also instances, where EPS can present without any pre-existing symptoms [87].

Table 3 Symptoms and clinical features of EPS

History
Peritoneal dialysis, with episodes of peritonitis
Increased risk if peritoneal dialysis over 5 years
Change of modality of dialysis within last 6 months or transplantation
Symptoms of fullness, discomfort
Abdominal distension or bloating
Fullness, early satiety, vomiting
Significant loss of weight
In late cases gross distension, obstruction
May also present acutely with obstruction, peritonitis or hemoperitoneum
Clinical features
Anaemia
Weight loss and cachexia in advanced cases
Abdominal distension
Fluid collection as ascites or loculated abdominal fluid
Palpable abdominal mass from the cocoon
Investigations
Anaemia
Raised CRP
Leucocytosis
Hypoalbuminemia
Imaging (X ray/US Scan/CT/MRI)
Thickened peritoneum
Ascites
Mesenteric retraction
Obstructive features with thickened bowel
Calcification

The above features are primarily consistent with EPS associated with peritoneal dialysis. In primary EPS and other forms of secondary EPS, the diagnosis, is one of exclusion mainly of other causes, and considering individual clinical presentations

Diagnostic Tests and Pathway for Suspected EPS

There are no specific single blood tests that point to EPS, however the combination of refractory anaemia, often a leucocytosis, hypoalbuminemia and a persistently raised CRP in the context of a patient receiving of having received PD is suggestive.

In individuals who develop post-transplant EPS, there may be derangement of transplant kidney function from a combination of inflammation, infection and dehydration from intraperitoneal fluid collections.

In the other secondary causes of EPS, the relevant disease specific investigation screens along with abdominal imaging may help make the diagnosis.

Imaging in EPS

A plain X-ray may show areas of peritoneal calcification, especially in long standing cases. Characteristic calcification on the bowel surface and the peritoneum is an important diagnostic feature which could alert the clinician to the diagnosis. An erect abdominal film may show some evidence of early obstructive features, such as air fluid levels or evidence of frank obstruction in an acute presentation. Other than these features which may enhance diagnostic suspicion of EPS, in the modern era, the role of the plain abdominal X-ray in these conditions may be redundant.

Abdominal Ultrasound is helpful in that it may show ascites and peritoneal fluid collections and in classic cases, can demonstrate the thickened membrane cocooning the gut, and dilated loops of obstructed gut (Fig. 7). For these findings to be diagnostic, they should be considered along with the clinical context. Abdominal ultrasonography is important in guiding paracentesis in some patients who present with recurrent accumulation of ascites. It is also important in the diagnosis of postoperative intraabdominal collections after enterolysis and peritonectomy.

The CT scan is the modality of choice in the diagnosis of EPS. Diagnostic features of a CT scan are peritoneal thickening, abdominal tethering, dilated gut, fluid accumulation as loculations of fluid or frank ascites, and areas of localised or generalised calcification of the peritoneum (Fig. 8). The CT findings depend on the stage and severity of the disease. In the early stage, the thickening of the peritoneum may be subtle, however, there may be suggestive features of gut tethering with some localised dilatation of loops of bowel [88, 89].

MRI Scans are also as valuable or sometimes provide more definitive detail of the pathology [90]. However either the CT scan or the MRI scan will provide diagnostic radiologic features that could lead to a confirmatory diagnosis of

EPS (Fig. 9). Cine MRI has been used as an experimental modality [91], where pathologic features of the encapsulation along with the restrictive effects of the cocoon can be demonstrated.

Vadi SK et al. have reported the use of ^{18}F-FDG PET-CT as a modality in the diagnosis of the abdominal cocoon associated with tuberculosis (Fig. 10) [92].

Laparoscopy

Once a diagnosis of EPS is considered, it can be arrived at by correlating the clinical history, clinical examination, blood tests and the radiologic imaging. However, there are situations when symptoms will still remain unexplained and obscure but point to an intraabdominal source. In these situations, laparoscopy may be useful for visualising the peritoneal cavity for definitive diagnosis, ruling out pathology and also for obtaining diagnostic samples.

The critical points in laparoscopy are to ensure that there is no perforation due to the cocooning (Fig. 11). An important decision when carrying out laparoscopy for diagnosing EPS, is planning intervention. If EPS is definitely found on laparoscopy, it may be best for surgical intervention to be planned at a later date.

Histologic Features of EPS

The diagnosis of EPS is a clinical diagnosis and not histological. Histology of the peritoneal membrane in a patient with EPS may show characteristic features that confirm the clinical diagnosis. It is also important in ruling out, secondary causes of peritoneal sclerosis or pathology including tuberculosis or malignancies. Histologic changes reflect the effect on the peritoneum caused by the hyperosmolar dialysis fluid and is seen in both the parietal and visceral peritoneum. The peritoneal membrane thickens and scleroses in long standing peritoneal dialysis, along with mesothelial

Fig. 7 A single static ultrasound image showing the liver with calcification on the surface, ascites and cocooned gut with calcification on the surface

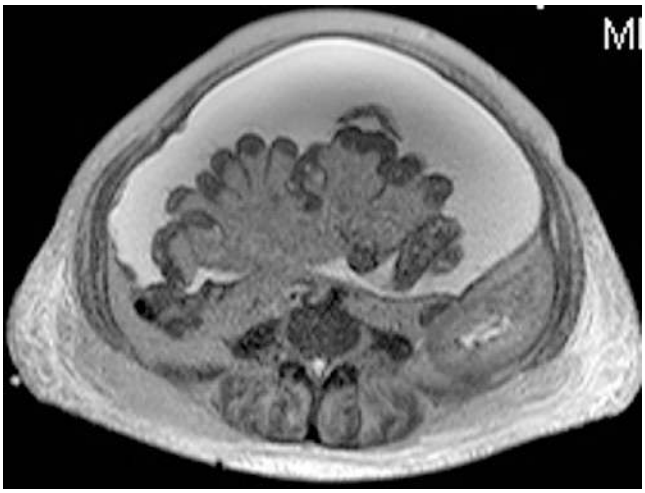

Fig. 9 An MRI scan showing the same features in the same patient, with subtle differences. The calcification is not as prominent, and the thickening of the peritoneum is not as evident in MRI scan compared to the CT scan

Fig. 8 CT scans demonstrating free fluid, thickening of both parietal and visceral peritoneum with certain areas of calcification, mesenteric retraction and some gut dilatation. The first image is of a patient with post-transplant EPS and there is a good functioning kidney in the left flank

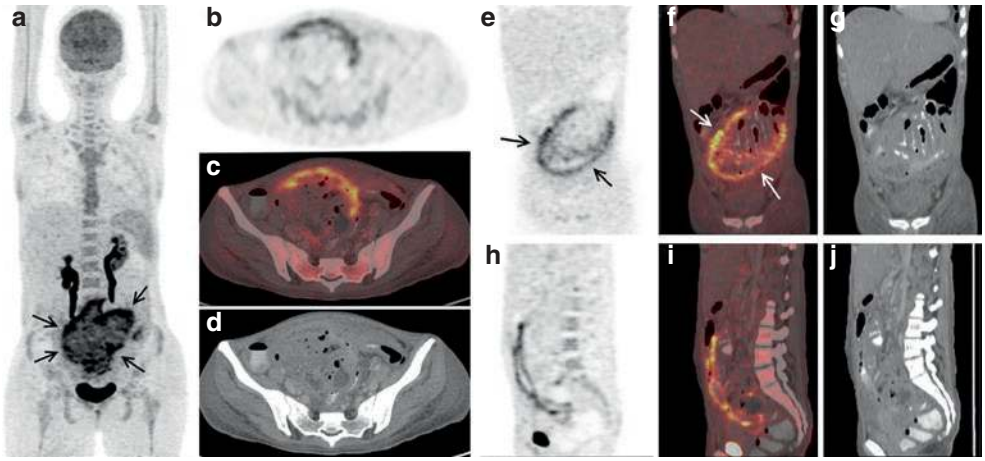

Fig. 10 FDG-avid peritoneal thickening encapsulating around the clumped jejunal and ileal loops forming a tracer-avid "cocoon" in the abdomen as shown in the MIP (**a**; arrows), axial PET (**b**), fused PET/CT (**c**), axial CT (**d**), and corresponding coronal (**e**, **f**; arrows and **g**) and sagittal (**h**, **i**, and **j**) images, suggesting sclerosing encapsulating peritonitis (SEP)

Fig. 11 A laparoscopic image showing early EPS in evolution. The ascitic fluid is turbid and there is encapsulation of the gut with neovascularization of the surface. The membrane can been seen and is thin and flimsy as it is early in its formation. If left undiagnosed or untreated, it will develop into the thick constricting collagenous membrane seen in advanced disease and will eventually calcify

denudation. Below the mesothelial layer, the compact zone thickens and is formed of myofibroblasts and fibrous collagen [93]. The vasculature in this layer undergoes changes, with medial sclerosis and hyalinization, along with neoangiogenesis [94]. Honda et al. have also described fibrin deposition, increase in the size of the fibroblasts, capillary angiogenesis and mononuclear cell infiltration were more common features of EPS rather than simple sclerosis [95]. Advanced glycosylation end-products are found in the mesothelial and sub-mesothelial layer of PD patients [96, 97].

Additional histological findings identified by different investigators include, positive immuno-histochemical staining for podoplanin [98] and upregulation of vascular endothelial growth factor (VGEF) and downregulation of mast cells [99, 100]. All these findings however are not specifically related to EPS, and could be seen in the different peritoneal fibrosing conditions.

Histology of Non-renal EPS

Histologic features of secondary encapsulating peritoneal sclerosis or peritoneal fibrosing conditions are more specific and often diagnostic when compared to EPS associated with peritoneal dialysis. Examples are peritoneal tuberculosis where typical granulomatous inflammation is seen with or without necrosis and acid fast bacilli.

In malignant encapsulation, the histologic features will depend on the specific malignancy which is causing the pathologic manifestation.

In the primary or idiopathic cases of EPS, histologically, the peritoneum will show a proliferation of fibro-connective tissue, inflammatory infiltrates, and dilated lymphatics. There will be no evidence of granulomas, giant cells or birefringent material.

Treatment of EPS

As soon as a diagnosis of EPS is made in PD related cases, it is imperative that the patient discontinues peritoneal dialysis and is established on haemodialysis. A strategy that has been tried in preventing the development of EPS is regular peritoneal lavages after discontinuation of PD. Regular lavage has been shown to help mesothelial cell repair [101].

While this is a strategy that can be attempted in the very early stages without mechanical obstruction, nutritional deficiency or significantly raised inflammatory markers, it

should perhaps be carried out in conjunction with additional medical therapy. There is no robust scientific basis.

In the group of patients presenting mainly with significant and recurrent ascites, paracentesis will be required for relief of discomfort. More than one attempt at paracentesis will be required as the peritoneal fluid may continue to reaccumulate. Depending on the individual clinical context, concomitant medical therapy may be required. In these clinical situations where there is no overt mechanical obstruction, a decision on surgical intervention, may be difficult to justify. However if there is recurrent, re-accumulation of fluid, there may be justification in surgery with a view to a peritonectomy of the thickened membrane. The membrane in these situations is often a strong impermeable fibrocollagenous membrane overboth the parietal and visceral peritoneum which prevents the reabsorption of peritoneal fluid. Once stripped off, and peritoneum excised, there is the establishment of fresh peritoneum which aids in absorption.

Medical Therapy for EPS

Various medical forms of therapy have been described for EPS, however most medical interventions are anecdotal without any specific clinical trials to determine the effectiveness of therapy and outcomes. It will also be very difficult to evaluate the impact of the medical therapy on the natural progression of EPS.

Steroids

Corticosteroids have been used as medical therapy by different teams at different points in the disease process. The rationale for steroid use is that it inhibits collagen synthesis and maturation by suppressing the inflammatory process. The beneficial effects of estradiol propionate was experimentally demonstrated in nonuremic Wistar Albino rats [102]. Kuriyama has reported good outcomes in all patients treated with steroids compared to poor outcomes in those not on steroids [103]. Several other groups have also reported on the beneficial effects of steroids in EPS [104, 105].

Tamoxifen

With a solitary case report in 1999, Tamoxifen began to be used as medical therapy largely because there was no well-defined consensus strategy for therapy of EPS once diagnose. The rationale of the authors was that Tamoxifen, a selective estrogen receptor modulator interferes with TGF beta 1, a probiotic cytokine [106]. Transforming growth factor beta 1 (TGF B1) has a stimulatory effect on matrix metalloproteins (MMP 2 and 9). MMP9 degrades Type IV and denatured collagens, TGF beta 1 production, which is stimulated by tamoxifen, might favour mesothelial healing by facilitating the removal of denatured collagen. It has been successfully used in the treatment of retroperitoneal fibrosis [107, 108] and long term therapy for idiopathic RPF has been found to be effective and safe [109].

Immunosuppression

Immunosuppressive agents other than steroids have been used to good effect by different teams. Azathioprine in combination with steroids has been shown to be effective [110]. mTOR (Mammalian target of Rapamycin) inhibitors, including Sirolimus, have been used by several groups especially in patients after transplantation, including liver transplantation with response [111, 112].

Novel Agents

Danford et al. hypothesise that while mechanical obstruction is the main underlying factor, dysmotility may play a role through the disruption of the myenteric plexus by fibrosis and increased endogenous opioids from activated lymphocytes inhibiting both propulsive motor and secretory activity in the gut [113]. Methylnaltrexone to combat inflammation associated dysmotility has been described in anti-Hu associated intestinal pseudo-obstruction [114]. Altman et al. have suggested targeting vimentin+/keratin+/CD34+ tissue in patients with leutenizing thecomas and sclerosing peritonitis [68]. ACE inhibitors may make peritoneal fibrosis progress more slowly [115]. Animal studies have found hepatocyte growth factor [116], TNP-470 [117] and antisense oligonucleotides to reduce peritoneal fibrosis [118].

Caveats in Medically Treating EPS

While medical therapy may be attractive for both the patient and the treating clinician from the point of view of avoiding a major surgical procedure with associated morbidity and mortality, it is based on anecdotal reports and small case series. There is always the potential risk that the diagnosis may be incorrect. Steroids may mask inflammation and cause continued progression of disease. Defining length of medical therapy may be difficult and disease progression during medical therapy may cause acute obstructive, infective, and haemorrhagic complications including perforations. This may require emergency surgical intervention. Surgical intervention in acute situations in patients on steroids and mTor agents can cause significant unwanted morbidity. This is due to the friability of tissue and difficult healing, increasing the overall chances of morbidity and mortality.

Surgery for EPS

There is universal consensus that in patients with encapsulating sclerosis presenting with intestinal obstruction, surgery is the most effective treatment. The underlying problem in these patients, is mechanical bowel obstruction caused by a combination of the thickened inflamed peritoneum, the fibrocollagenous membrane and adhesions. Bowel is in most instances encased in this pathologic tissue.

The principles of surgery are the very careful release of the obstructing, sclerotic and encapsulating membrane and releasing, gut so that it remains free in the peritoneal cavity, with the reestablishment of peristalsis. Surgery requires meticulous attention to detail and technique and dissection, and ensuring that in the process of releasing obstructed gut, a perforation is not made or there is bleeding from vascular tissues or vascular structures. One of the main reasons for reported poor outcomes in EPS in international literature and the high mortality is the fact that if surgical teams do not have experience with this entity, decision making and judgement during acute presentations proves extremely difficult. With acute presentations in patients especially in renal failure and on dialysis, who have decompensated nutritionally over long periods of time, managing a hostile encapsulated abdomen can prove extremely challenging. Hence best outcomes are achieved by teams who have experience in the management of the condition.

There are only a handful of centres in the world which have significant experience in the surgical management of the condition. Clinical outcomes from these centres have improved. Various different terms are used for surgery, including peritonectomy and enterolysis (PEEL) procedure [119]. Another limited procedure which has been described is Capsulotomy [120].

Preoperative Preparation and Planning

Once a definitive diagnosis of EPS has been made, therapy has to be tailored to the individual patient. A risk benefit balance decision has to be critically made after, a thorough evaluation of the patient, investigations and imaging. If the CT scans show cocooning of the gut, surgery is indicated as it is highly unlikely that any medical therapy will reverse the gut problems. Surgery is the gold standard treatment for the condition except for the most early of cases. There are numerous individual case reports and small series reports on surgery and outcomes. A small number of international centres have consolidated experience in surgical management [119, 121]. Surgical intervention is planned depending on the overall clinical state.

All patients should have a full cardiovascular assessment for anaesthesia, including an echocardiogram and if possible a cardiopulmonary exercise test. Respiratory physiotherapy prior to surgery will improve operative outcomes. Patients should be managed by experienced anaesthetists, skilled in the anaesthesia for patients with chronic renal failure with significant morbidity.

If patients present as an emergency with evidence of peritonism, where surgery is indicated immediately, it has to be carried out, although the mortality and morbidity associated with emergency surgery in EPS is over 50%. In an elective or semi elective situation, all patients should have a thorough nutritional assessment as a significant percentage of these patients will have evidence of poor nutrition [122]. Anthropometrics, will identify depleted fat and lean body mass which can increase surgical morbidity and mortality [123]. All patients undergoing surgery should have augmented and intensive preoperative nutrition including parenteral nutrition. Parenteral nutrition will in all likelihood need to be continued well into the postoperative phase, as return of gut motility with the ability for oral intake may be prolonged. It is of critical importance that parenteral nutrition be given through a dedicated access line, with all the precautions and care taken to ensure asepsis and sterility. An infected access line could cause significant morbidity and mortality. In a significant majority of these patients, there will need to be alternate access for haemodialysis.

As perioperative fluid management is critical, and inadequate dialysis can lead to fluid retention and increase perioperative morbidity, it is imperative that all patients have optimum haemodialysis prior to surgery, and ideally daily dialysis.

The aims of surgery in EPS are fundamentally to relieve the mechanical gut obstruction which is contributing to the symptoms and malnutrition and also clear as much as possible of the thickened and inflamed membrane which is contributing to the chronic inflammatory process and the anaemia. Both the parietal and visceral peritoneum will be thickened and where there is obstruction, the gut proximal to the obstruction will be thickened (Fig. 12). The surface of the bowel below the membrane will be tanned and of the thickened and encapsulating membrane however has to be balanced on the requirement to relieve intestinal obstruction and the need to avoid iatrogenic gut perforations which can precipitate enteric fistulas and exponentially increase postoperative mortality.

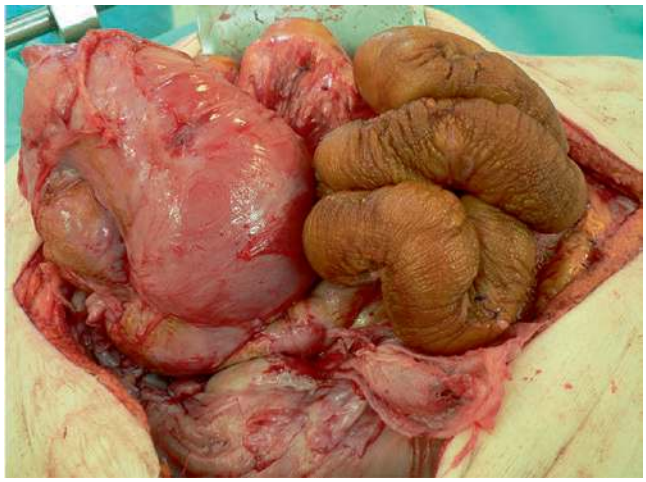

Fig. 12 Dilated proximal gut with released tanned, distal encapsulated segment, during enterolysis

Surgical Technique

Abdominal entry is through a long midline incision, after recent cross sectional CT images have been reviewed. It is important to first enter an area of the peritoneal cavity where gut is not adherent to the anterior abdominal wall, to avoid a perforation. If a perforation occurs during surgery, primary closure almost invariably fails due to the thickened and diseased tissue, leading to an enteric fistula and significantly increased mortality. The technique used in the author's centre is to develop a plane outside the abdominal cocoon, bilaterally. Once that plane has been developed, the cocoon is entered in an area where there is fluid (Fig. 13). Progress of surgery is dictated by findings on abdominal entry. Once the peritoneal cavity is entered in a suitable area, all fluid and debris is aspirated, after samples are taken for culture and sensitivity, biochemistry and for acid fast bacilli.

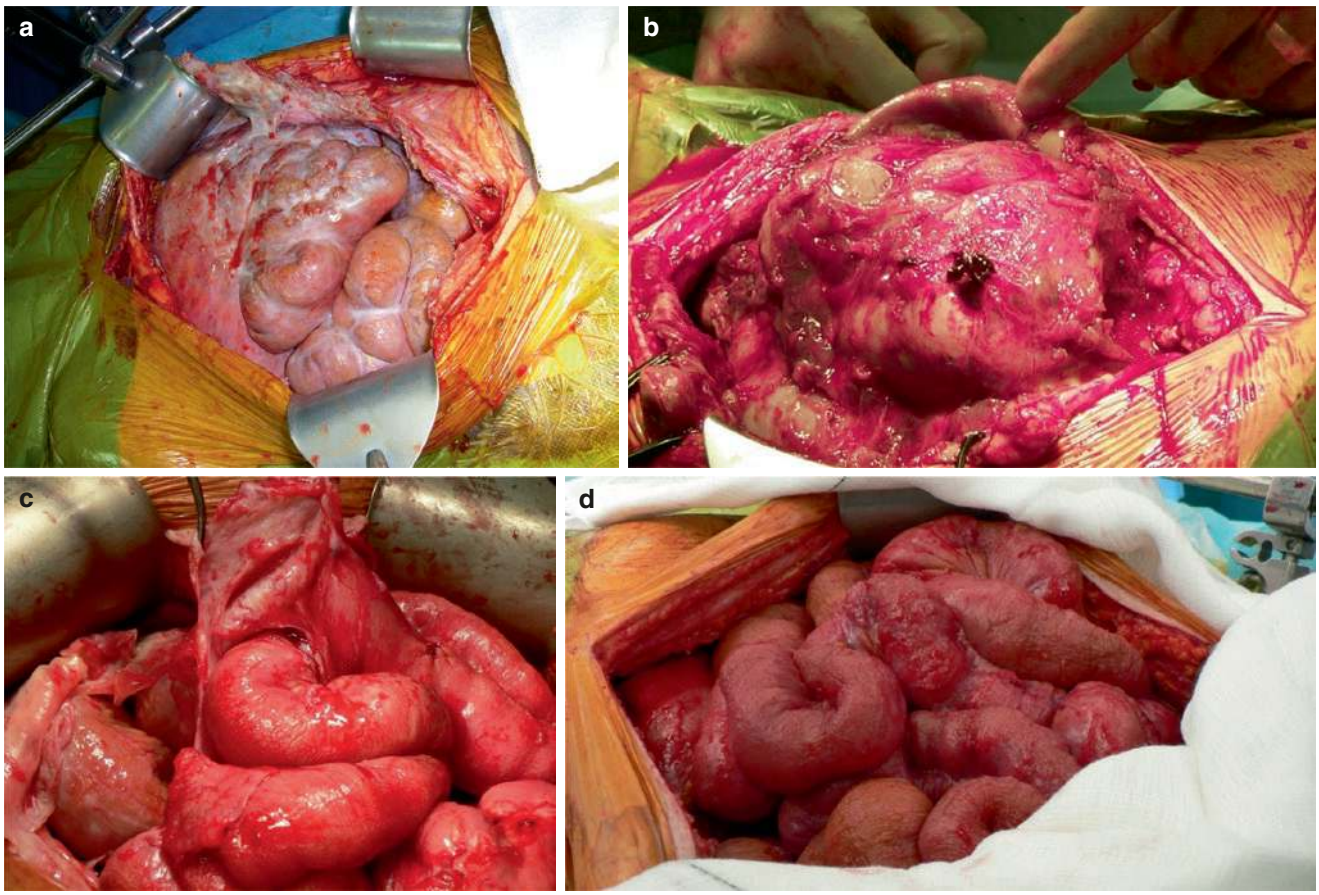

Fig. 13 The encapsulated gut with dense sclerotic adhesions between loops of bowel and also the encapsulated gut and the liver (**a** on entry outside the cocooned bowel, **b** after some dissection, **c** releasing fibrotic membrane from gut and **d** after completed enterolysis). The extremely thickened and almost calcific parietal peritoneum can also be seen and adhesions also between the sclerotic mass and the abdominal wall

The peritoneal cavity is then inspected and the exact degree of the encapsulation understood. Dissection is then commenced in an area and then meticulously extended, releasing loops of bowel, which are clumped together by the membrane. The membrane is adherent to the gut surface, by a firm interface. With careful blunt and sharp dissection the membrane can be dissected off, however it is critical that there are no perforations made. If perforations are made, the propensity for post-operative leaks and fistulation, increases significantly. A decision is made about simple closure or a stoma formation. Dissection is then carried out, releasing the entire gut, right from the DJ flexure till the ileo-caecal junction. The terminal ileum is one of the most important areas as it is the most common area affected by the sclerotic membrane.

Localised EPS

While EPS is in most situations generalised, there are situations where cocooning can be entirely localises to a segment of gut, especially the terminal ileal region [124].

The Management of Advanced Cases Where Enterolysis and Peritonectomy Is Not Possible

Cases may present acutely from time to time where at surgery the abdomen is too rigidly encased in sclerotic tissue, or badly calcified, where enterolysis and peritonectomy is technically impossible. Attempting lysis in these situations may cause perforations, bowel fistulae and mortality. In these situations, the most appropriate course of action would be to close the abdomen and considering long term parenteral nutrition. However, there are several case reports in literature where individual cases have been managed with different techniques including a loop jejunostomy in a case of recurrent EPS where the original presentation was a uretero-ileal fistula [125]. The same group has also described placement of a percutaneous gastrostomy tube with jejunal extension, to drain gastric and proximal gut secretions while providing total parenteral nutrition [126]. Combined bowel and kidney transplantation has also been reported [127]. It demonstrates the feasibility of the technique, and where renal failure too is addressed by the transplanted kidney.

Recurrent EPS

In spite of the best surgical treatment, there may be a significant risk of recurrence of up to 25% [128]. The Japanese group which has one of the largest international experiences with the condition, have utilised different techniques, including fixing the bowel with a long intestinal tube, to maintain patency, and the use of the Noble Plication technique [129].

The management of recurrent disease is exactly the same with repeat surgery and further enterolysis and peritonectomy.

Encapsulating Peritoneal Sclerosis in Children

EPS has been described in children who have had long term PD. The prevalence of EPS in European children on PD is comparable with that of the adult patients. A high index of suspicion is required for diagnosis in children with longer dialysis duration, peritonitis rate and UF failure [130, 131].

Dietary Therapy (to Avoid Obstructive Symptoms with Adhesions and EPS)

Occasionally a completely liquid diet is required to avoid obstructive type pains in patients with adhesions or EPS. Review by an experienced dietitian should be provided for all patients with chronic symptoms.

Definitions

Dietary fibre has been defined as carbohydrate polymers with ten or more monomeric units, which are not hydrolysed by the endogenous enzymes in the small intestine of humans and belong to the following categories [132]:

- Edible carbohydrate polymers naturally occurring in the food as consumed
- Carbohydrate polymers, which have been obtained from food raw material by physical, enzymatic or chemical means and which have been shown to have a physiological effect of benefit to health as demonstrated by generally accepted scientific evidence to competent authorities
- Synthetic carbohydrate polymers which have been shown to have a physiological effect of benefit to health as demonstrated by generally accepted scientific evidence to competent authorities

Plants often contain a mixture of soluble and insoluble fibre. Soluble fibre increases the viscosity of bowel contents, slowing down digestion and the absorption of nutrients. Insoluble fibre has a high water binding capacity which results in softer and bulkier bowel contents to aid the acceptable functioning of the gut. Cereal fibre is reported to have the greatest bulking effect [133]. It is these effects which has led to the use of low fibre diets in the treatment of adhesions and obstruction.

In 2014 the British Dietetic Association published a systematic review on the management of Crohn's disease. This review was unable to identify any trials to recommend the use of low fibre diets in structuring disease to minimise the risk of bowel obstruction or reduce symptoms [134]. The opinion of the group, which consisted of expert Dietitians, was that fibre should be avoided in stricturing Crohn's disease to reduce the possibility of a mechanical obstruction. In addition, a low fibre diet may be helpful in reducing peristomal pain from excess gas production. The lack of scientific evidence to support the use of a low fibre diet does not negate their use in clinical practice as it is difficult, from an ethical perspective, to conduct clinical trials where dietary fibre could result in a mechanical obstruction. The BOUNCED feasibility study at the Royal Surrey County Hospital NHS Foundation Trust is aiming to investigate the use of dietary manipulation in bowel obstruction (see below). It is envisaged the results will be influential in establishing a consensus and provide the standard for dietary guidelines for bowel obstruction.

Low Fibre

There are no clear definitions in the literature on what constitutes a low fibre diet. One study investigating the effect of a low fibre diet in patients with IBS aimed for 10 g of fibre per day [135]. Another study used <10 g of fibre as bowel preparation 1 week pre surgery [136] and therefore not applicable in the long term setting of bowel obstruction.

Low Residue

To date there are no agreed definitions of what constitutes residue and in 2012 the American Academy of Nutrition and Dietetics removed the term "low residue diet" from the Nutrition Care Manual [137]. This is because the amount of residue produced during the passage of food through the gut cannot be quantified as includes undigested food, microorganisms, gastrointestinal secretions and cells from the intestine. Therefore, for the purposes of this chapter the term low fibre will be used.

Causes of Bowel Obstruction

There is limited literature describing the dietary intake of patients with bowel obstruction but patients with recurrent bowel obstruction are known to have a reduced quality of life and their condition has an impact on their dietary intake. In a study of 48 patients with recurrent bowel obstruction ranging from two episodes during their life to monthly episodes, 90% of patients reported an impact on their diet [138]. There are many case reports in the literature regarding different types of food causing bowel obstruction in both patients who have had previous abdominal surgery and those with a virgin abdomen (Table 4).

Due to the intermittent nature of bowel obstruction, different levels of restriction may be required depending on symptoms and the degree of obstruction. Radiological images may help ascertain the degree of obstruction and inform the dietary restrictions required. Patients with severe adhesions or strictures may require a liquid diet whereas patients with partial obstruction may be able to manage some fibre containing foods. The BOUNCED study from the Royal Surrey County Hospital NHS Foundation Trust is investigating the use of a 4-step bowel obstruction diet in patients with cancer (step 1 clear fluids, step 2 all thin liquids, step 3 smooth or pureed foods only low fibre, step 4 soft sloppy foods low fibre) [139].

Each patient will have different tolerance levels which may change over time Therefore, it is important that restrictions are reviewed regularly and if possible lifted to allow

Table 4 Foods reported to have caused bowel obstruction

Foods
Fruit
• Cherry tomato
• Dried apricot
• Dried fruit
• Persimmon
• Dates
• Grapes
• Orange pith
• Peach stone
• Plum stone
• Apricot stone
Vegetables
• Artichoke
• Mushrooms
• Shitake mushrooms
• Olives
Nuts
• Brazil
• Chestnut
Seeds
• Prickly pear
• Granadilla
• Medlar
• Sunflower
Other
• Bran
• Oat bran
• Ginger
• Egg yolk
• Rice cakes

Table 5 Principles of a low fibre diet

• Wholemeal bread to white bread
• Brown rice to white rice
• High fibre breakfast cereals to low fibre versions
• Wholewheat pasta to white pasta
• No skins on potatoes
• One portion of fruit a day
• One portion of vegetables a day
• Meat, fish, cheese, eggs, tofu to be recommended to meet protein requirements

as normal a diet as tolerated to minimise symptoms. The principles of a low fibre diet (Table 5) include reducing fibre containing carbohydrates to lower fibre or fibre free alternatives. Fruit and vegetables will need to be peeled, no skins, no pips, no seeds, no pith, no stalks. It is often recommended that only one portion of fruit and one portion of vegetables are taken daily. Beans are high in fibre and therefore should be limited unless vegetarian or vegan when other low fibre protein substitutes should be encouraged (e.g. tofu).

Fluid and Electrolytes

Patients with bowel obstruction are at risk of dehydration and electrolyte abnormalities due to a reduced oral intake and vomiting [140]. Therefore, careful attention should be paid to ensuring patients are meeting fluid and electrolyte requirements as the risk of acute kidney injury (AKI) is high. The National audit of small bowel obstruction in UK found 22% of the patients were admitted with an acute kidney injury [141]. Patients should be educated about the most appropriate fluids (+/− electrolytes) to drink (if not vomiting) to maintain hydration and electrolyte status especially during an acute episode.

Micronutrients

There is no data available on the micronutrient status of patients with bowel obstruction. The low fibre diet which is inherently low in fruits and vegetables, a significant source of micronutrients, means that deficiencies may develop if the obstruction is prolonged and appropriate supplementation will be required. A clinical examination to identify deficiencies should be completed if this is suspected and a complete supplement such as Forceval® or Centrium® recommended. A Registered Dietitian can provide advice on maintaining the nutritional adequacy of a low fibre diet which is why it is important that these patients are referred for advice.

General Advice: Chew and Teeth

Many case studies have also identified the issues of poor dentition and mastication as a contributing cause of bowel obstruction [142–144]. Patients should have any dental issues identified and referral to a dentist if poor dentition is an issue.

Medications

Many medications can cause a reduction in saliva production and therefore a review of medications can be helpful to ensure only essential medication are prescribed. It is known that pharmacobezoars can form from the ingestion of drugs such as cholestyramine and antacids and so their continued use should be evaluated [145]. Furthermore, reports of obstruction resulting from the use of guar gum-containing diet pills have been reported [146] which is why a detail drug history is essential.

Fibre Containing Enteral Nutrition

Whilst there is no evidence to support the view that enteral feeds containing fibre are contraindicated, some authors support this view due to the potential risk of obstruction in those with structuring Crohn's disease [147]. A review of enteral nutrition bezoar formation [148] found 14 cases of obstruction of which at least eight occurred during feeding with a fibre containing enteral formula. Other compounding factors included anatomical changes post operatively, reduced pH, dysmotility, dehydration and medication and therefore the enteral feed may not be the sole causative agent. However, it seems prudent to avoid fibre containing enteral nutrition in cases of severe strictures and adhesions until further research is published.

In conclusion the recommendation to follow a low fibre diet will be determined by the level of the bowel obstruction and likely resolution. Patients will require a Registered Dietitian to provide education and ensure that the diet is nutritionally complete and that reintroduction of fibre containing foods can occur when it is safe to do so.

Bone Marrow and Haemopoietic Stem Cell Transplantation

Jennifer Clay, Maria Gilleece, and Clare Donnellan

Key Points

1. Haematopoietic stem cell transplantation (HSCT) may be autologous (using the patient's own cells) or allogeneic (using HLA-matched donor cells).
2. Autologous HSCT almost always uses peripheral blood stem cells and does not result in Graft versus Host disease.
3. Allogenic HSCT may use peripheral blood, aspirate from the bone marrow or, more rarely, umbilical cord blood
4. The most common indications for HSCT remain haematological malignancies; however it can be performed in patients with autoimmune conditions (multiple sclerosis, scleroderma) and has limited use in some solid malignancies (e.g. germ cell tumours)
5. The most common side-effects affect the GI tract and therefore nutritional status may be compromised.
6. The two situations in which nutritional support is commonly needed are patients with severe mucositis or those with GVHD affecting the gastrointestinal tract.
7. Regular dietetic assessment is vital—oral and enteral support should be preferred over parenteral, if this is possible

Introduction

The utility of chemotherapy alone to provide long term remission in some forms of haematological malignancy is limited, with higher doses of chemotherapy or radiotherapy being restricted by organ related toxicity, in particular the bone marrow. Stem cell transplant is utilised both to facilitate the use of higher dose cytotoxic therapy with stem cell rescue, whilst in the case of allogeneic transplant also providing a 'graft vs. tumour' effect and therefore the potential of long term remission or cure.

Both of these mechanisms have the potential to cause significant gastrointestinal toxicity, with the gastroenterology and nutrition team frequently involved with the management of such complications. The aim of this section is to provide an understanding of the process of stem cell transplant, its primary gastrointestinal complications and their management. Further details regarding stem cell transplant are available in specialised texts and reviews [1, 2].

Terminology

Bone marrow and haematopoietic Stem Cell Transplants (HSCTs) can be broadly categorised into two main classes, autologous and allogeneic.

Autologous

In autologous stem cell transplant the recipient's own stem cells are used to facilitate haematopoietic recovery following high dose chemotherapy/radiotherapy (referred to as conditioning). This is undertaken following several cycles of standard chemotherapy to debulk and control disease in the case of haematological malignancies. There is increasing use of autologous transplant for non-malignant conditions (e.g. multiple sclerosis), and in this setting no preceding chemo-

therapy is necessary, however conditioning remains essential. Stem cells are harvested from the peripheral blood following mobilisation using haematopoietic growth factors (granulocyte colony-stimulating factor (GSCF)), with or without additional chemotherapy, allowing collection from the peripheral blood by apheresis. The cells are cryopreserved, and then thawed and infused following the conditioning regimen (Fig. 1). As the patient's own cells are used there is no immunological mismatch, therefore the procedure is not associated with graft versus host disease (GvHD) or immune mediated graft rejection, there is no requirement for post-transplant immunosuppression and immune reconstitution is relatively rapid. Transplant related mortality is 3–5%. The stages of autologous stem cell transplant are summarised below [3].

Allogeneic

In allogeneic transplant stem cells are sourced from an HLA matched donor and infused into the recipient following conditioning with chemotherapy/radiotherapy. The source of the stem cells may be a relative (full matched or half matched (haplo-identical)), an unrelated living donor or cryopreserved cord blood unit identified from international registries. The mechanisms of action of allogeneic transplant also includes high dose chemotherapy/radiotherapy (conditioning), but in addition whilst certain matching criteria need to be met there is always a degree of immunological mismatch between donor and recipient (except in the case of a syngeneic twin used as a donor), which results in a 'graft vs. leukaemia' effect thought to be essential for long term disease remission. The other side to this effect is 'graft vs. host disease (GvHD)', where the donor's immunological cells recognise recipient tissues as immunologically different and cause an inflammatory reaction. GvHD can be classified as acute (aGvHD) or chronic (cGvHD). The reverse of this is graft rejection which occurs in approximately 5% of transplants. Due to these potential immunological interactions patients require immunosuppression for 3–12 months following transplant, and potentially longer if GvHD develops. Due to the combination of

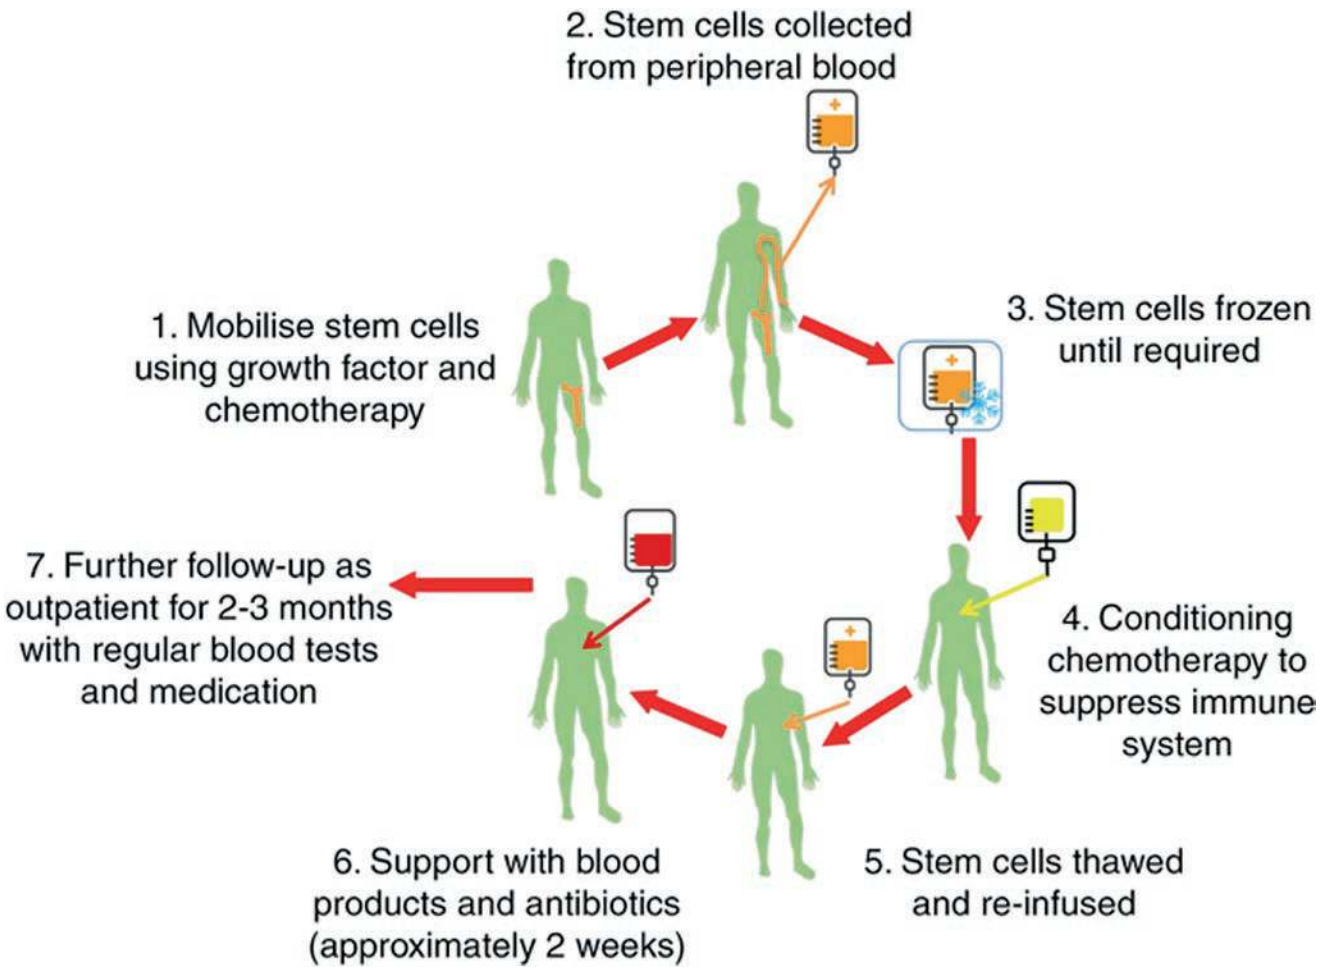

Fig. 1 The process of haematopoietic stem cell transplants (HSCT)

complications including slow immunological reconstitution, prolonged immunosuppression and GvHD the transplant related mortality (TRM) associated with allogeneic transplant is typically 10–50%.

Sources of Haemopoietic Stem Cells

Peripheral Blood Stem Cells

Peripheral blood stem cells (PBSC) are the most commonly used source of stem cells. The cells are obtained via peripheral blood apheresis following mobilisation using recombinant haematopoietic growth factors (granulocyte-colony stimulating factor (GCSF)). The circulating stem cells are then collected from the peripheral blood through a process called apheresis with blood filtered through a cell separator. PBSC have advantages over bone marrow harvested stem cells including typically a larger cell dose and faster neutrophil and platelet engraftment.

Bone Marrow

Bone marrow is collected by aspiration from the iliac crest. This procedure requires to the donor to have general anaesthetic but does not involve exposure to haemopoietic growth factors. Advantages to bone marrow stem cell source include lower rates of GvHD, and for this reason it is now most frequently used in the setting on of transplant for non-malignant conditions such as aplastic anaemia.

Umbilical Cord Blood

Cryopreserved umbilical cord blood units can be used as a stem cell source when other donor options are not available. In the paediatric setting single cord units can be used, however in the adult setting 2 units are generally required to provide adequate cell dose. Whilst a lesser degree of HLA matching is required for transplant of cord blood units compared to that required for other cell sources, the drawbacks of this cell source include slower neutrophil and platelet engraftment and delayed immune reconstitution.

Indications

Haematologic malignancy is the most common indication for HSCT. Factors considered when deciding between allogeneic and autologous stem cell transplants include the underlying disease, response to previous treatments, fitness of the patient, and donor availability. Allogeneic HSCT is performed for a number of non-malignant conditions including aplastic anaemia, thalassaemia and severe combined immunodeficiency. There is increasing interest in the utility of autologous transplant in patients with autoimmune conditions including multiple sclerosis, scleroderma and inflammatory bowel disease, along with limited use in some solid malignancies (e.g. germ cell tumours) (Fig. 2).

The British Society of Marrow and Stem Cell Transplant produce a comprehensive table of approved indications for transplant in the UK [5]. Table 1 summarises the principles of the HSCT procedure.

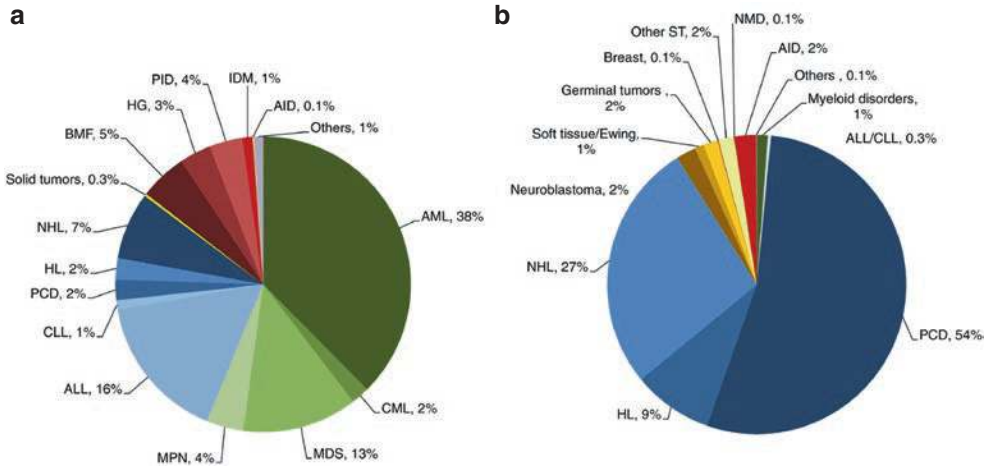

Fig. 2 Relative proportion of disease indications for HCT in Europe 2018. (**a**) Allogeneic HCT. (**b**) Autologous HCT [4]. *PID* primary immunodeficiency, *IDM* inherited disorders of metabolism, *AID* autoimmune disease, *AML* acute myeloid leukaemia, *CML* chronic myeloid leukaemia, *MDS* myelodysplastic syndrome, *MPN* myeloproliferative neoplasms, *ALL* acute lymphocytic leukaemia, *CLL* chronic lymphocytic leukaemia, *PCD* plasma cell disorder, *HL* Hodgkin's lymphoma, *NHL* Non Hodgkin's lymphoma, *BMF* bone marrow failure, *HG* haemoglobinopathies, *PCD* plasma cell disorders, *ST* solid tumours, *NMD* non malignant disorders

Table 1 Principles of HSCT procedure

1. Consideration of the patient for HSCT including MDT review.
2. Patient assessment
(a) Disease status: In general transplant outcomes are better for patient in a complete or partial response. Outcomes for those with refractory or progressive disease are universally poor.
(b) Assessment of fitness including assessment of cardiorespiratory function
3. Donor availability (allogeneic transplant only)
(a) HLA-tying (commonly called tissue typing) of patient and any potential related donors.
(b) Searching of international donor registries where a suitable related donor is not available
(c) All donors undergo medical assessment by an independent clinician to assess fitness to donate.
4. Transplant conditioning therapy
(a) Combination of chemotherapy/radiotherapy determined depending on disease and patient factors.
(b) The role of conditioning includes:
• Reduction or eradication of any residual disease present at the time of transplant
• To 'make space' to allow engraftment of infused stem cells
• Immunosuppression to prevent graft rejection and reduce the rate of GvHD
5. Transplant protocol
(a) A personalised schedule detailing conditioning, date of stem cell infusion and relevant prophylactic medications along with key donor/recipient details (e.g. HLA match, blood type, CMV status)
6. Patient undergoes transplant procedure as an inpatient or outpatient depending on local protocol.
7. Posttransplant care—initial intensive monitoring, ongoing care dependent on individual complications and disease monitoring requirements. All transplant patients will undergo long term late effects follow up.

Gastrointestinal Complications

The gastrointestinal complications of transplant can be broadly separated in to pre-engraftment (during conditioning and until 2–3 weeks post cell infusion), early (up to day 100) and late (day 100 onwards) post engraftment (Fig. 3). Pre-engraftment complications are predominantly related to the toxic effects of the conditioning protocol and medications used to manage early complications (e.g. antibiotics, anti-emetics). Post-engraftment complications are most commonly associated with GvHD and delayed immune reconstitution and therefore more frequently encountered following allogeneic transplantation than autologous.

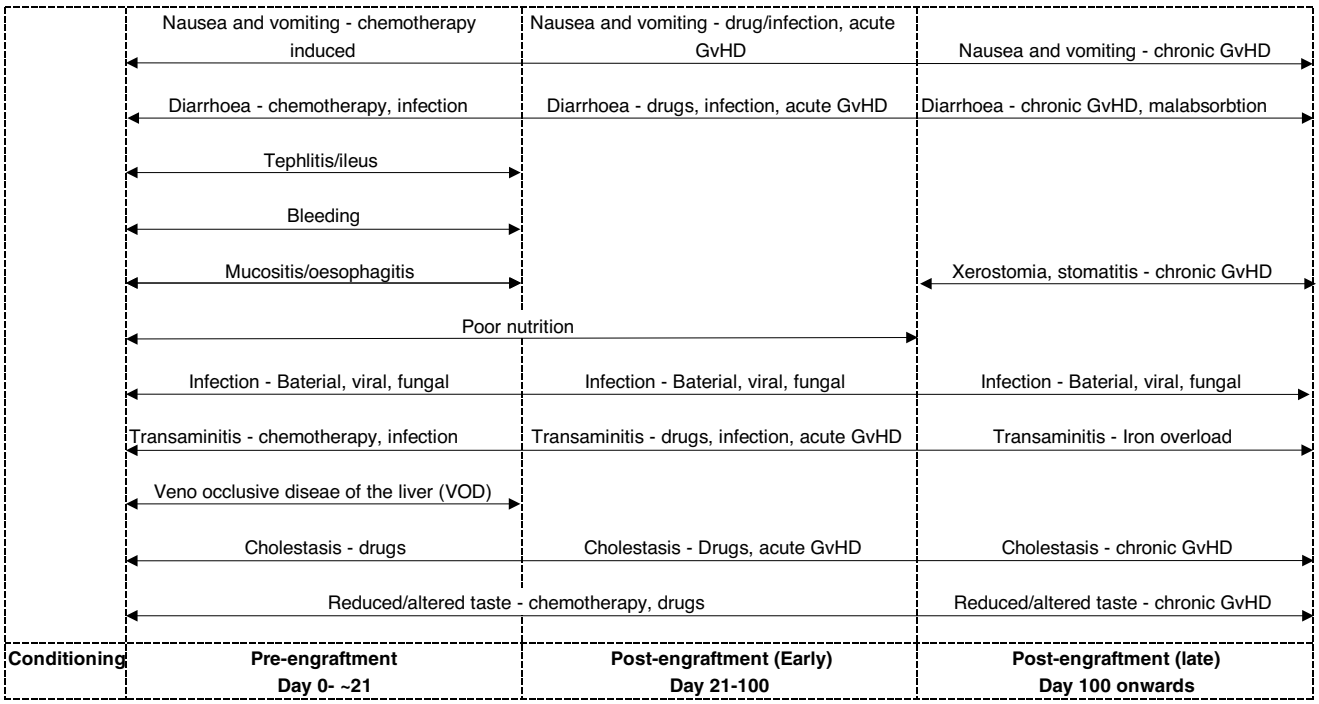

Fig. 3 The pre, early and late gastrointestinal complications of HSCT

Pre-engraftment Complications

Nausea and Vomiting

Nausea and vomiting are almost universal in the early stages following stem cell transplant due to the use of chemotherapy/radiotherapy in the conditioning regimen, the severity varies depending on the combination of chemotherapy, radiotherapy and the intensity of doses used. Preventative antiemetics should be used in all cases. Standard combinations generally include a 5-HT3 antagonist (e.g. Ondansetron) along with metoclopramide, typically given orally, intravenously or subcutaneously, depending on the patients' needs. Dexamethasone may be added to control delayed emesis associated with drugs such as cyclophosphamide and may be continued for several days [6].

In addition to the impact of chemotherapy/radiotherapy other pharmaceutical agents commonly used such as antimicrobials including co-trimoxazole and -azole antifungals along with agents used for GvHD prophylaxis such as cyclosporine and mycophenolate mofotil (MMF) may contribute to nausea.

Infection, most commonly oesophageal candidiasis, can cause nausea and vomiting and should be considered and investigated with upper GI endoscopy in cases of intractable nausea and vomiting. Due to the risk of viral reactivation staining for CMV of biopsies should be requested in all cases alongside the standard testing, this complication can occur in the absence of detectable CMV viraemia in the peripheral blood.

Mucositis

The degree of mucositis experienced by patients varies dramatically depending on the intensity of conditioning used, and in particular the use of high dose total body irradiation (TBI), with these patients almost universally experiencing severe mucositis. This complication should be considered as 'mucosal barrier injury' [7] with potentially the entire gastrointestinal tract being involved. Pain is predominantly related to oral/pharyngeal and oesophageal involvement, while diarrhoea, bloating abdominal pain and less commonly ileus are caused by lower GI involvement. Mucositis as a cause of diarrhoea is a diagnosis of exclusion, and faecal culture to exclude an infective cause should be undertaken in all cases.

Oral mucositis progresses in four phases: Phase 1—vascular/initial inflammatory, Phase 2—Epithelial, Phase 3—Ulcerative, Phase 4—Healing. Multiple scoring systems exist to enable consistent documentation of the severity of mucositis [8]. One example is the '*National Cancer Institute common toxicity criteria for grading of stomatitis*', which grades mucositis as follow:

- Grade 1—Painless ulcers, erythema or mild soreness
- Grade 2—Painful erythema, oedema, and ulceration but is able to eat
- Grade 3—Unable to eat
- Grade 4—requiring enteral or parenteral support

Where ulcers are present these should be swabbed to exclude infection, particularly of viral origin. Bleeding may occur locally in the mouth or throughout the GI tract; therefore platelet support is a key aspect of supportive care. Tranexamic acid can also be beneficial either systemically or dissolved and used as a mouthwash for oral bleeding.

Management of mucositis is predominantly aimed at symptomatic control, prevention of infection and provision of nutrition when patients are unable to eat. Prevention in the form of good oral hygiene and mouth washes such as saline and chlorhexidine are used before mucositis occurs. When patients become symptomatic analgesic mouth washes along with topical measures such as lignocaine lozenges can be helpful, however patients frequently require opioid analgesia, initially orally while able to swallow but ultimately often subcutaneously or intravenously. Subcutaneous administration through a syringe driver with a combination of opiates and antiemetics is commonly used. Diarrhoea can be managed with anti-diarrhoeal agents such as loperamide when infection has been excluded. There is a significant risk of infection with the breakdown of mucosal barriers, and most units use prophylactic anti-biotics when patients become neutropenic along with antiviral and antifungal prophylaxis. Whilst a number of agents have been used to modify locally the effect of cytotoxic therapy such as ice, prostaglandins and interleukin II benefit has not been proven.

The time to recovery from mucositis depends on the presence of infection, nutritional status and most importantly haematopoietic recovery. Whilst most patients experience a rapid improvement with neutrophil engraftment allowing them to start to eat and drink again many will experience persisting mucosal sensitivity, for example to spicy foods and loss of taste for weeks to months. In those who have been treated with TBI reduced salivary secretion may persist long term.

Infective and Neutropenic Colitis

Diarrhoea in the early post-transplant period is frequently multifactorial. Infection should always be considered and investigated. Due to the implementation of infection control measures, isolation and neutropenic diet in these patients the

rates of organisms traditionally associated with 'food poisoning' is low. The evidence surrounding 'neutropenic diets' is limited, however most units will implement restrictions such as those recommended by the British Dietetic Association [9]. Due to the use of broad spectrum antibiotics both as prophylaxis and treatment Clostridium difficile is common, with symptoms including profuse watery diarrhoea, abdominal pain and frequently fever. Treatment should be instigated depending on severity score, metronidazole, vancomycin and fidaxomicin are all included in NICE recommendations. Whilst viral reactivation is rare in the early stages post-transplant this should be considered, cases of CMV negative peripheral blood PCR but biopsy proven CMV colitis have been reported, therefore specific testing of biopsy samples for CMV should be undertaken.

Neutropenic colitis, also known as typhlitis is a rare complication thought to be caused by direct invasion of the colonic or caecal mucosa resulting in toxic mucosal necrosis. The diagnosis is predominantly radiological (colonoscopy should be avoided due to a heightened risk of perforation). Patients may complain of right iliac fossa pain. Treatment is predominantly with broad spectrum antibiotics and supportive measures including bowel rest and analgesia. Severe cases can result in megacolon or perforation, in this circumstance surgical intervention with subtotal colectomy and defunctioning colostomy may be considered, however due to the high risks associated with surgical intervention in early post-transplant patients due to pancytopenia and immunosuppression surgical intervention is deferred whenever possible [10].

Hepatic Complications

Veno-occlusive disease of the liver (VOD) is a potentially life-threatening complication following allogeneic stem cell transplant, with rates estimated to be around 8–14%. Whilst it can be seen following autologous transplant it is much less common, estimated around 3% [11]. The diagnosis is based on a clinical triad of jaundice, weight gain and tender hepatomegaly, with the potential to progress to multiorgan failure if left untreated. The pathogenesis of this condition relates to endothelial damage in hepatic venules resulting in disruption of fenestrae, inflammation and thrombus formation [12]. Historically several different scoring systems have been used (for example Seattle and Baltimore criteria), more recently the European Bone Marrow Transplant Society have developed a severity scoring system which incorporates diagnosis of late cases (after 21 days post-transplant) which are increasingly recognised to make up a significant minority of cases [13]. Investigations predominantly focus on exclusion of other causes. Liver ultrasound scan including Doppler is recommended in all suspected cases, with findings including hepatomegaly and reversal of hepatic flow considered consistent with the condition. Liver biopsy is the gold standard for diagnosis, however due to the risks associated with the procedure is very rarely undertaken. Whilst additional diagnostic investigations including biomarkers are under development, they are currently only available in clinical trials. The diagnosis of VOD remains a clinical one, and treatment should not be delayed whilst awaiting investigations.

Treatment comprises a combination of supportive care and defibrotide, an anti-thrombotic agent for treatment of VOD [14]. The mortality rate from untreated severe VOD with multiorgan failure is around 90%, therefore recognition and prompt treatment in the early stages of the condition is essential. Whilst other strategies including heparin anticoagulants and steroids have been used historically the evidence to support their use is not robust. Supportive care includes diuresis, salt restriction and in severe cases organ support.

Infection

Reactivation of both fungal and viral infections can occur in the early post-transplant stage. The widespread use of prophylactic -azole antifungals has resulted in a marked fall in systemic candida infections, with aspergillus species being the most common cause of fungal infections [15]. Presentation with liver dysfunction, hepatic tenderness and fever refractory to standard antibiotics should prompt consideration of fungal infection. Combined modality investigation with imaging, fungal biomarkers (Aspergillus antigen, Beta-D-glucan), peripheral blood cultures and where possible direct sampling of any discrete lesions should be undertaken.

Whilst CMV reactivation and other viral infections typically occur later post-transplant they should also be considered in the early phase.

Drugs and Therapeutics

There is an extensive list of medications, both prophylactic and those used to treat symptomatic and infective complications. Many of these have the potential to cause hepatic abnormalities and comprehensive review of medications and potential interactions should be undertaken in all cases of post-transplant hepatic dysfunction, with modification of agents or doses where possible.

Complications Beyond 2–3 Weeks

The majority of post engraftment gastrointestinal complications occur in the allogeneic population due to protracted and complex immune reconstitution which is variable depending

on donor-recipient factors along with stem cell source (i.e. cord vs. related donor). Following autologous transplantation there is generally rapid resolution of pre-engraftment complications, and whilst full immune reconstitution can take up to 12–18 month this rarely results in gastrointestinal manifestations.

Infection

Following allogeneic transplant both humoral and cellular mechanisms of immunity are impaired, with the process of immune reconstitution being complex and prolonged. A number of variables can impact this reconstitution, including donor-recipient compatibility, the age of the patient, presence and severity of GvHD. In addition, the use of T-cell depletion in conditioning and the need for prolonged immunosuppression for treatment of GvHD impact immune reconstitution. As such patients can be at risk of both standard and opportunistic infections for prolonged periods of time.

CMV reactivation can occur in the initial months post-transplant, with the risk dependent on the serostatus of the recipient and donor, recipient positive but donor negative representing the highest risk combination. Most centres will employ a pre-emptive strategy with regular PCR monitoring and treatment at a pre-defined level. A novel agent, Letermovir, is now available for use in CMV positive recipients to prevent reactivation [16]. CMV disease can present with a broad spectrum of organ involvement but can affect any part of the GI tract causing pain, protein losing enteropathy, ulceration, bleeding and occasionally perforation along with fever and rarely hepatitis.

Other organisms to consider include herpes simplex, adenovirus, enterovirus, cryptosporidium and candida. The differentiation of these organisms and GvHD requires endoscopic biopsy, and differentiation of infection from GvHD is essential due to treatment implications. Treatment of viral or bacterial infections with appropriate antimicrobial agents should occur, as per local guidelines.

Graft vs. Host Disease

Graft vs. host disease (GvHD) is classically separated into acute occurring within the first 100 days post-transplant, and chronic occurring after that time (Table 2). With changes to transplant protocols this boundary has become blurred with recognition of situations where acute GvHD can occur later than 100 days (for example following donor lymphocyte infusion). Table 2 outlines the current criteria used [1].

Table 2 Classification and features of Graft vs. host disease (GvHD)

Classification	Days after SCT	Features of acute GvHD	Features of chronic GvHD
Acute GvHD			
Classic acute	<100 days	Yes	No
Persistent, recurrent or late onset	>100 days	Yes	No
Chronic GvHD			
Classic chronic	No time limit	No	Yes
Overlap syndrome	No time limit	Yes	Yes

Acute Graft Versus Host Disease (aGvHD)

Acute graft versus host disease principally affects the skin, gastrointestinal tract and liver, with the majority of cases occurring within the first 100 days post-transplant. Histologic appearances within the GI tract include lymphocytic crypt infiltration, with epithelial cell necrosis. Severity ranges from individual cell necrosis to crypt loss, ulceration and epithelial denudation. The most common pattern seen in hepatic involvement is small bile duct damage [17].

Whilst aGvHD can affect any part of the GI tract it rarely involves the mouth and oesophagus. Stomach and duodenal involvement cause nausea, vomiting, anorexia and dyspepsia. Bowel involvement causes diarrhoea which is characteristically green and watery. The severity is graded predominantly based on diarrhoea volume (Table 3). Whilst the diagnosis of gastrointestinal aGvHD is sometimes made based on clinical characteristics along with proven GvHD at other sites, endoscopic biopsy should be undertaken where possible to allow exclusion of infective causes. Hepatic aGvHD has a predominantly cholestatic picture due to small bile duct destruction, and whilst other liver functions tests are commonly deranged staging is based solely on bilirubin [18].

Treatment of acute GvHD requires a combination of supportive care and immunosuppression as first line, with the degree of treatment dependent on severity and range of organ involvement. First line treatment is with corticosteroids equivalent to 1 mg/kg methylprednisolone, escalated to 2 mg/kg in refractory cases. Budesonide can be used effectively as a steroid sparing agent. In addition, optimisation of calcineurin inhibitors, and sometimes addition of other agents, for example MMF in those with liver GvHD can be considered. Evidence for second line treatments is sparse, whilst numerous agents have been investigated evidence of response is lacking in most cases. The exception is extra extracorporeal photopheresis which does have evidence of effectiveness in steroid refractory aGvHD [19]. Supportive care is essential, gastrointestinal GvHD often requires gut rest with parenteral nutrition to support nutritional require-

Table 3 Glucksberg criteria

	Stage skin based on maculopapular rash	Liver based on bilirubin	Gastrointestinal based on quantity of diarrhoea
+	25% of surface	<34–50 μmol/L	500–1000 mL
++	25–50% of surface	51–102 μmol/L	1001–1500 mL
+++	Generalized erythroderma	103–255 μmol/L	>1500 mL
++++	Generalized erythroderma with bullae and desquamation	>255 μmol/L	Severe abdominal pain with and without ileus

ments. In cases of severe gastrointestinal GvHD electrolyte imbalance can be severe and challenging to manage. Due to unpredictable absorption drugs often need to be given intravenously.

Chronic Graft Versus Host Disease

Chronic graft versus host disease (cGvHD) can evolve from aGvHD (cross over) or occur de novo after 100 days. It frequently manifests as a multisystem disorder, along with the gastrointestinal tract other organ systems commonly involved include the skin (with sclerodermatous changes), eyes, lung and endocrine system. Treatment depends on both severity and organ involvement, with targeted local therapy along with systemic immunosuppression when indicated.

Gastrointestinal tract involvement commonly presents with upper tract features such lichenoid changes, erythema along with ulceration and mucoceles. Involvement of the salivary glands can also result in sicca symptoms. These manifestations can cause significant pain and dysphagia leading to weight loss. Oesophageal involvement results in dysmotility, dysphagia and reflux. Chronic GvHD of the gut is less common, but can cause mucosal atrophy, malabsorption and fibrosis which can progress to strictures. Hepatic cGvHD ranges from mild abnormalities of liver function tests to fulminant hepatic failure. Investigation aims to exclude infective and other cases (such as iatrogenic hepatic iron loading) to ensure appropriate treatment is instigated.

The treatment of cGvHD must be tailored to manifestations in individual cases, where possible targeted topical treatment should be utilised, with systemic immunosuppression used in refractory or multiorgan involvement due to the risks associated with long term immunosuppression. Topical therapies include steroid mouth wash, tacrolimus mouth wash and artificial saliva. Regular dental assessment is important to maintain dental health, along with surveillance for oral malignancies which this patient population are at increased risk of. Assessment for malabsorption and treatment of any underlying cause such as pancreatic insufficiency should be considered in those with intestinal cGvHD. Due to the complex and often multisystem nature of cGvHD a multidisciplinary approach is essential.

Other Late Effects

Iatrogenic iron overload is common and can be associated with transaminitis. It is managed with venesection on recovery of erythropoiesis [20]. In cases with chronic anaemia post-transplant synthetic erythropoietin can be used to stimulate erythropoiesis to facilitate venesection. If this is not successful, or in those requiring on going transfusion iron chelation should be instigated.

Post-transplant lymphoproliferative disorder, driven by Epstein-Barr virus, is a rare but serious post-transplant complication. Whilst the majority of cases manifest with rapidly progressive lymphadenopathy some may present with gastrointestinal or hepatic involvement. Diagnosis is histologic. Treatment involves B-cell directed monoclonal antibodies (alemtuzumab) with or without systemic chemotherapy.

Nutritional Support

There are two situations where nutritional support may be needed—patients with severe mucositis or those with GVHD affecting the gastrointestinal tract. All patients should be assessed by appropriately trained dietitians, ideally working as part of a nutrition support team. This allows early detection of patients struggling with nutrition as being underweight (Body Mass Index <18.5) is associated with poorer outcomes from HSCT [21, 22].

As with other clinical indications for nutrition support, management should consist of optimisation of oral diet first (typically trying soft, moist foods if mucositis is present). There appears to be no role for a 'neutropaenic' or 'low bacterial' diet [22]. Enteral nutrition (EN) support can be offered if oral intake is inadequate. Unfortunately some patients find any nasoenteral tubes too uncomfortable, due to severity of the inflammation.

Parenteral nutrition (PN) should only be used when the first two approaches have been unsuccessful and should be stopped as soon as nutrition has stabilised [22]. PN does not appear to provide additional benefits to EN and brings with it additional infective and metabolic complications [21, 22].

Non-surgical Cancer Treatments

Mary Booth, Fiona James, Andrew Viggars, Clare Shaw, and Mark Teo

Key Points

1. Cancer treatment may be curative, adjuvant (reduce chance of metastases), neoadjuvant (reduce size of tumour) or palliative.
2. Chemotherapy is usually given as combination therapy.
3. After bone marrow toxicity chemotherapy primarily affects the gut mucosa.
4. Nausea and vomiting after chemotherapy usually only last up to 48 h.
5. Mucositis occurs with antimetabolites and anthracycline antibiotics and commonly occurs between 5 and 14 days after treatment. This may cause acute intestinal failure needing parenteral nutrition.
6. Some chemotherapeutic drugs (e.g. vincristine, adriamycin) may cause an irreversible enteric neuropathy.
7. Newer targeted molecular treatments (e.g. immunotherapy, tyrosine kinase inhibitors) have direct and indirect side-effects on gut mucosa and nutrition requiring specialist input.
8. The toxicity from acute irradiation typically starts 1–2 weeks following the start of radiotherapy treatment and depending on dose, can last for a few short weeks following completion and can result in the breakdown of epithelial surfaces.

Introduction

Malignant cells exhibit several hallmarks that distinguish them from normal cells [1].

These hallmarks are:

1. genomic instability,
2. sustained proliferative signalling,
3. an ability to evade growth suppressors,
4. resistance of cell death,
5. replicative immortality,
6. induction of angiogenesis,
7. cancer-related inflammation,
8. activation of invasion and metastatic spread,
9. the ability to re-programme energy metabolism, and
10. an ability to evade immune destruction.

Cancer treatments aim to target these hallmarks and preferentially eliminate cancer cells over normal cells. The availability of newer more potent cancer treatments, intensified combination multimodality regimens and earlier cancer detection has improved survival rates such that 69.3% of all cancer patients will be alive 5 years after diagnosis [2]. However, despite rapid developments in improved targeted cancer treatments, all treatments produce side effects varying in severity and according to the predominant types of target normal cells. Toxicity limits both the dose and the frequency of administration and may reduce the potential to cure some patients.

Each different cancer treatment modality can be delivered with different treatment intent (Table 1), which alters the strategy of managing treatment toxicities of complications. For example, for treatment with curative intent the focus is to maintain treatment intensity and dose by tackling toxicity aggressively with supportive measures including enteral or parenteral nutritional support, versus treatment with palliative intent where there is a lower threshold to lower dose or halt treatment.

J. M.D. Nightingale (ed.), *Intestinal Failure*, https://doi.org/10.1007/978-3-031-22265-8_10

Table 1 Cancer treatment intent and cancer site examples

Treatment intent	Aim	Cancer site examples
Curative	Cure cancer	*Chemotherapy:* Haematological and germ cell tumours
		Radiotherapy (often with concurrent chemotherapy as a radiosensitiser): Lung cancer, head and neck cancers
Adjuvant	Reduce chance of local and/or distant recurrence	*Chemotherapy:* Breast and colon cancer
		Endocrine: Breast and prostate cancer
		Monoclonal antibodies: Breast cancer
		Immunotherapy: Lung cancer
Neoadjuvant	Prior to curative treatment, to reduce size of cancer and/or to improve chance of cure	*Chemotherapy:* Breast and oesophageal cancers
		Radiotherapy: Rectal cancer
Palliative	To improve quality and/or quantity of life by reducing the disease burden, improve symptoms and extend life in palliative setting	*Chemotherapy:* Most tumour types
		Radiotherapy: Most tumour types
		Immunotherapy: Lung, kidney and melanoma cancers
		Small molecule inhibitors: Lung, kidney and melanoma cancers

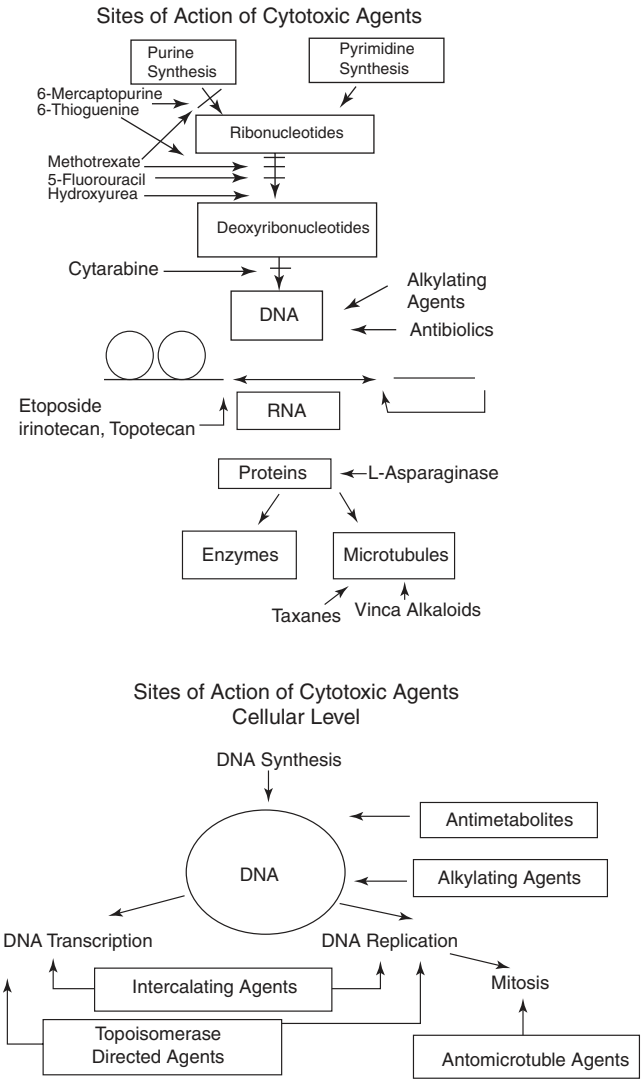

Fig. 1 Sites of action of cytotoxic chemotherapy agents

Although bone marrow suppression is a key toxicity following chemotherapy, the advent of haemopoietic growth factors, stem cell support and improved anti-microbial management protocols have reduced concerns about myelosuppression. By contrast, gastrointestinal toxicity remains a significant clinical problem frequently limiting the amount of systemic therapy that can be given, and is a common side-effect in most of the newer targeted therapies.

This chapter describes the general issues associated with non-surgical cancer treatments specifically cytotoxic chemotherapy, hormone (endocrine) treatments, monoclonal antibodies and small molecule inhibitors, immunotherapy and radiotherapy; and the role of the gastroenterologist and nutrition team in supporting patients on these treatments.

Cytotoxic Chemotherapy

Cytotoxic chemotherapy exerts its effects in a limited number of ways, leading to damage to cellular DNA. Due to the rapid proliferation and genetic instability of cancer cells, cancer cells are unable to repair chemotherapy-induced DNA damage as robustly and quickly as normal cells. Intermittent chemotherapy administration will thus lead to a steady reduction in the malignant population while, it is hoped, leaving the population of normal cells relatively unchanged [3].

Most cytotoxic drugs interfere with DNA or protein synthesis, but other mechanisms of action are increasingly utilised as rational drug development attempts to target specific differences in malignant cells but leave normal cells relatively spared (Fig. 1).

A review of all the individual cytotoxic drugs and their effects on the gut is beyond the scope of this book. Cytotoxic chemotherapy drugs are often classified into several groups according to their mechanisms of action (Table 2). Chemotherapy is rarely prescribed as a single agent, but usually takes the form of combination regimens. When combinations are used, individual agents are chosen on the basis of having different mechanisms of action and, preferably, different patterns of toxicity [4].

Table 2 Cytotoxic chemotherapy drug classes and mechanism of action

Class	Mechanism of action	Example agents
Alkylating and Platinum agents	Bind covalently with DNA, causing cross-linking of DNA strands, and DNA strand breaks, interfering with cell replication.	*Mustard gas derivatives:* Cyclophosphamide.
		Hydrazines and Triazines: Procarbazine, Temozolomide.
		Nitrosoureas: Carmustine, Lomustine.
		Platinums: Carboplatin, Cisplatin, Oxaliplatin.
Antimetabolites	Block metabolic pathways involved with DNA synthesis.	*Folic acid antagonist:* Methotrexate.
		Pyrimidine antagonist: 5-Fluorouracil, Capecitabine, Gemcitabine.
		Purine antagonist: 6-Mercaptopurine.
		Adenosine deaminase inhibitor: Fludarabine.
Cytotoxic antibiotics	Have pleiotropic effects, including alkylating activity and inhibition of topoisomerases.	*Anthracyclines:* Doxorubicin, Epirubicin.
		Other: Mitomycin C, Bleomycin.
Agents that target the mitotic spindle	Exert their action through alteration of microtubule function and thereby interfere with mitosis	*Vinca alkaloids:* Vincristine, Vinorelbine.
		Taxanes: Paclitaxel, Docetaxel.
Topoisomerase inhibitors	These agents inhibit either topoisomerase 1 or 2 and thereby prevent DNA replication	*Podophyllotoxins:* Etoposide.
		Camptothecan analogues: Irinotecan, Topotecan.
Miscellaneous	Ribonucleotide reductase inhibitor	Hydroxyurea
Miscellaneous	Retinoids	Isotretinoin, Tretinoin (ATRA)

Effect of Cytotoxic Chemotherapy on Normal Tissues

Cytotoxic agents generally have greater toxicity for cells that have higher rates of proliferation. Cell turnover varies between normal tissue types and is particularly high in the haemopoietic system, hair follicles and gastrointestinal tract. The effect of most cytotoxic drugs is not limited to malignant cells but is also seen in those normal cells that are undergoing division. It is the toxicity profile of individual drugs that is dose-limiting and governs how the agent is used.

The kinetics of chemotherapeutic agents frequently follow a dose-response curve similar to that seen with many drugs (Fig. 2a). The effects on normal tissues may be represented in similar graphs (Fig. 2b). The respective position of organs changes for different drugs. For tumour cell types in which cell death can be significantly increased with doses not limited by gut or other organ toxicity, the use of haemopoietic sparing techniques may offer significant improvement in survival rates (Fig. 2c). In cancers where tumour sensitivity is less than gut sensitivity to cytotoxic drugs, little benefit will be seen (Fig. 2d). The haemopoietic sparing techniques currently in use include treatment with haemopoietic growth factors, such as granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF), and haemopoietic stem cell transplantation, which is discussed in the next chapter.

Effect of Cytotoxic Chemotherapy on the Gastrointestinal Tract

Anorexia, cachexia and malnutrition may be prominent presenting features of malignancy, causing morbidity and mortality in patients who have advanced disease [5]. Treatment of the malignancy with chemotherapy can worsen the cachexia and malnutrition, further compromising the health of the patient [6].

The gastrointestinal tract is widely recognised as an essential organ and is involved in vital life functions such as nutrition, waste excretion and protection from external microbes and toxins. It is a complex organ, involving mouth, oesophagus, stomach, small intestine, large intestine, anus and the enteric nervous and lymphoid system. All of these crucial components are vulnerable to the effects of chemotherapy.

The effects of chemotherapy on the gastrointestinal system are wide-ranging, frequent and can be long-lasting, even beyond the cessation of chemotherapy.

Chemotherapy related GI side-effects can affect 50–80% of patients with standard chemotherapy regimens with up to 30% developing severe side-effects [7].

The main symptoms experienced by patients include:

1. Nausea and vomiting
2. Mucositis
3. Diarrhoea
4. Constipation

Nausea and Vomiting

The nausea and vomiting induced by chemotherapy occurs when the vomiting centre in the medullary reticular formation is stimulated by the chemoreceptor trigger zone (CTZ) in the area postrema of the fourth ventricle or tractus solitarius [8, 9]. Stimuli to the vomiting centre may also arise

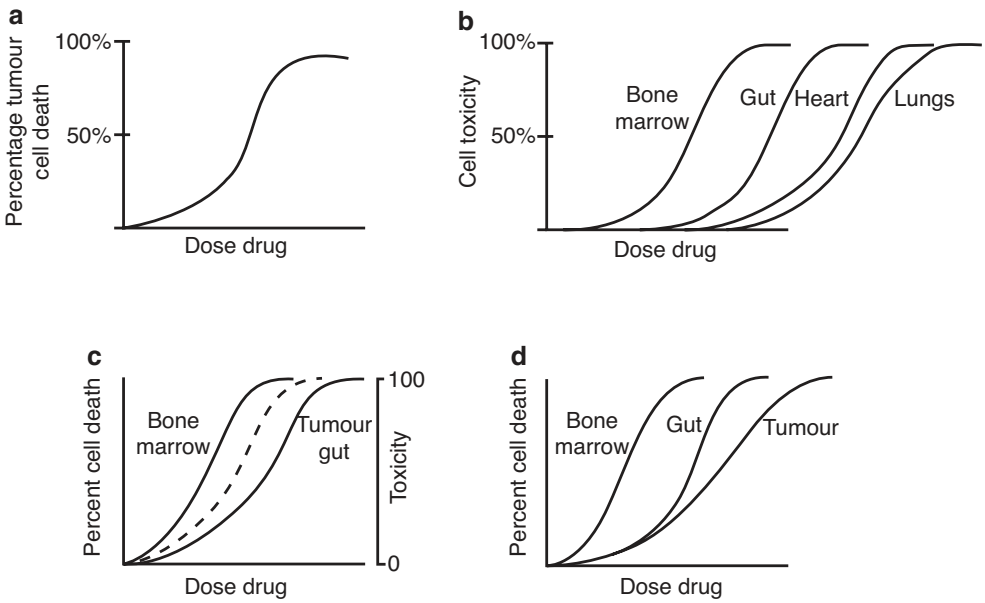

Fig. 2 (**a**–**d**) Schematic representation of the effects of cytotoxic chemotherapy on normal and malignant tissue

from afferent fibres located in the cerebral cortex, gastrointestinal tract (particularly the duodenum), heart, and vestibular apparatus. The CTZ is the predominant site of action initiating emesis caused by cytotoxic agents. The major neurotransmitters known to be involved in the emetic process are dopamine, serotonin, and tachykinins such as substance P.

Nausea and vomiting are the most common early manifestations of the toxicity caused by chemotherapy, and repeated studies have shown them to be the most distressing side effects—more so than alopecia, for example [10]. If the patient is fit, there may be no serious consequences, but in those who are already debilitated or malnourished following surgery and/or radiotherapy the addition of drug-related emesis may cause further marked deterioration in the clinical condition unless intensive nutrition support is provided.

Different chemotherapy drugs vary markedly in their emetogenic potential [11]. Nitrogen mustard, cisplatin, dacarbazine and streptozotocin induce vomiting in nearly all patients, whereas oral chlorambucil, melphalan and busulfan usually produce little nausea and vomiting. Nausea and vomiting induced by antimetabolite drugs often depends on dose and schedule. Methotrexate given in conventional doses rarely produces vomiting whereas high-dose infusions given to patients with osteosarcoma or to prevent CNS disease in lymphoma and leukaemia cause vomiting in the majority of patients.

In most patients, emesis commences within 1–6 h of administration and subsides after 24–36 h. Occasionally, delayed emesis may occur 24 or more hours after administration and may persist for up to a week (for example with cisplatin chemotherapy). Less frequently, chronic nausea and vomiting may follow chemotherapy and can be particularly difficult to treat. Once patients have experienced nausea and vomiting they may develop similar anticipatory symptoms before subsequent courses of treatment.

The management of emesis caused by chemotherapy has improved dramatically in the last 10 years. The availability of selective 5-HT_3 receptor antagonists, such as ondansetron and NK1 receptor antagonists, such as aprepitant, alongside more traditional anti-emetic drugs, such as; metoclopramide, cyclizine and corticosteroids has resulted in excellent control in the majority of patients, even with the most emetogenic regimens [11]. The aim of therapy should be to prevent emesis from the first course in order to avoid subsequent anticipatory symptoms.

Mucositis

Most GI mucositis and ulceration is caused by a direct toxic effect of chemotherapy on mucosal cells. A direct effect on mucosal cells can affect any part of the bowel and may severely compromise dietary intake. The antimetabolites and anthracycline antibiotics are the agents that most commonly damage the gastrointestinal mucosa. Symptoms usually occur 5–7 days after exposure and may last for 1–2 weeks.

The degree of damage varies according to the dose and schedule of administration of many of these drugs. The toxicity of methotrexate to the gastrointestinal epithelium, for example, depends on the duration of exposure rather than on peak concentrations [12]. Toxicity can be reduced if folinic acid rescue is given within 42 h of administration [13]. With 5-fluorouracil, toxicity is dependent on peak concentration with higher toxicity rates seen in bolus regimens compared to continuous infusions [14]. Even when mucosal damage is relatively mild, serious morbidity may ensue. Local infection with organisms such as *Candida* and herpes virus, particularly in the mouth, may cause pain and reduce subsequent

oral intake, further compromising the patient's nutritional status [15]. It is essential that the clinician is aware of this and that advice is given about topical mouth care with the provision, where appropriate, of antifungal, antibacterial and antiviral prophylactic therapy. For some patients, intravenous nutrition support or early NG/NJ feeding may be indicated if pain prevents swallowing.

Chemotherapy Induced Diarrhoea

Diarrhoea is one of the most common side effects of chemotherapy which can range from mild (with an increase in stool frequency up to 4–6 per day more than baseline) to severe with life-threatening complications. Although the underlying pathophysiology remains unclear, it is heavily associated with the development of mucositis due to direct cell toxicity and malabsorption. Studies in animal models have shown increased apoptosis in crypts within the jejunum and colon, and excessive secretions leading to diarrhoea [16].

Different chemotherapeutic regimes produce differing severities of diarrhoea, in particular those containing 5-FU and irinotecan are correlated with incidence of diarrhoea as high as 80% [7]. Management of chemotherapy induced diarrhoea involves identifying any infective causes, and contributing factors such as medications alongside supportive management and pharmacological treatment [17]. Loperamide, an oral opioid with no significant absorption from the gastrointestinal tract, is the anti-diarrhoeal agent of choice. Dosing requires an initial dose of 4 mg, followed by an additional 2 mg after each loose stool, up to a maximum of 16 mg/day. In severe or persistent diarrhoea, octreotide, a somatostatin analogue may be used.

Chemotherapy Induced Constipation

Chemotherapy induced constipation is a common issue which can also be exacerbated by antiemetic (e.g. 5-HT3 receptor antagonists) and other medications traditionally used alongside chemotherapy regimens. The vinca alkaloids (particularly vincristine), thalidomide and cisplatin cause autonomic nerve dysfunction leading to constipation in up to 90% of patients and can even cause an ileus [18–20]. The onset of symptoms usually occurs soon after drug administration, frequently within 3 days, and may be associated with peripheral neuropathy. It is important to provide prophylactic laxatives. Patients who develop an ileus should be managed conservatively with careful monitoring of fluid balance.

Hormone (Endocrine) Therapy

Hormones are substances that work as chemical messengers in the body. They affect cells throughout the body, often travelling through the bloodstream. The growth and proliferation of some cancers, such as breast and prostate cancers, are stimulated by hormones, and hence blocking these pathways can be an effective anticancer treatment. Hormone therapy is used on its own or in multi-modality treatment regimens in the neo-adjuvant, adjuvant and palliative settings. Hormone therapy falls into two broad groups; (1) those that block the body's ability to produce hormones, and (2) those that interfere with how hormones behave in the body (Table 3).

Glucocorticoid steroidal hormones, such as prednisolone and dexamethasone are frequently incorporated into cytotoxic chemotherapy regimens for its anti-emetic and anti-inflammatory effects in managing chemotherapy toxicities. Steroids also have a direct anti-tumour effect in most lymphoid malignancies and reduce cancer-related inflammation.

These agents have a favourable therapeutic ratio causing typically mild toxicity; many hormone agents can cause menopausal-like side effects including weight gain and sarcopenic obesity, as well as gastrointestinal side effects such as diarrhoea and nausea.

Table 3 Classes of hormone therapies and their mechanism of action

Hormone modulation	Mechanism of action	Cancer type	Example agents
Gonadotrophin releasing hormone agonists	Interferes with pituitary gland stimulation of the ovaries and testicles to produce oestrogen or androgens respectively	Breast	Goserelin
		Prostate	Leuprolide
			Triptorelin
Aromatase inhibitors	Blocks non-ovarian production of oestrogen	Breast	Anastrozole
			Letrozole
			Exemestane
Oestrogen receptor blockers/ modulators	Interferes with oestrogen binding to its receptor on cancer cells	Breast	Tamoxifen
		Endometrial	Fulvestrant
Anti-androgens	Interferes with oestrogen binding to its receptor on cancer cells; or suppress androgen production	Prostate	Enzalutamide
			Bicalutamide
			Abiraterone
Synthetic progesterones	Stimulates progesterone receptor	Endometrial	Medroxyprogesterone
			Megestrol

Small Molecule Inhibitors and Monoclonal Antibodies

Targeted therapies interfere with molecular targets involved in the sustained proliferative signalling of cancer. This is in contrast to non-selective cytotoxic chemotherapy which targets all rapidly dividing cells. Many targeted agents have been developed via rational drug design where targets are selected and drugs designed based on their key role in inhibiting uncontrolled cancer growth. Targeted agents may be monoclonal antibodies targeting cell surface receptors or small molecules designed to bind and inhibit specific signalling proteins. Common targets of small molecule inhibitors are tyrosine kinases, hence the use of a broad class of agents called tyrosine kinase inhibitors (TKIs).

Small molecule inhibitors may focus on extracellular and intracellular targets as they are able to translocate through the cell membrane. Monoclonal antibodies are antibodies with antigen binding domains, which have been engineered to bind with high specificity to the target of interest, typically membrane receptors. Modern immunotherapy agents which affect the immune response to cancer (described further below) are predominantly monoclonal antibodies though small molecule inhibitors are in development. The complexity of the pathways involved in cancer initiation, survival and propagation is reflected by the increasing number of targeted agents that are clinically available, in clinical testing, or in development.

The mechanism of action of small molecule inhibitors and monoclonal antibodies is dependent upon the receptor targeted and the pathway in which that receptor has a function. The specificity of such targeted agents varies, therefore some agents may have more than one site of action. Figures 3 and 4 show the various targets of action of small molecule and monoclonal antibody on the epidermal growth factor receptor (EGFR) family and the vascular endothelial growth factor (VEGF) family respectively.

In addition to the EGFR and VEGFR pathways, there are a growing number of other classes of targeted monoclonal antibodies or small molecule inhibitors used in anti-cancer agents (Table 4).

Effect of Targeted Therapies on Gastrointestinal Tract

Despite their targeted action, monoclonal antibodies and small molecule inhibitors exhibit toxicities of the gastrointestinal tract as despite being "targeted", these agents often show activity on similar kinase classes on normal cells that express the target receptor. Table 5 shows common and uncommon gastrointestinal toxicities of targeted agents and their management. Below, two specific examples of toxicities are detailed, and the management explained.

Diarrhoea is a common side effect of many targeted agents, and frequently occurs within the first 2 weeks of commencing therapy [25]. Diarrhoea may be particularly severe in cases where targeted agents are combined with conventional chemotherapy. Anti EGFR family agents are commonly associated with diarrhoea. EGFR is expressed in the normal colonic mucosa, involved in regulation chloride secretion and sodium inhibition, and therefore EGFR inhibitors may result in secretory diarrhoea [26]. Other causes of diarrhoea should be excluded, including concurrent medications and infection (in particular *Clostridium difficile* infection). In addition to the impact on quality of life, diarrhoea may also lead to fluid and electrolyte loss, subsequent renal impairment, and malnutrition.

Management is dependent upon the Common Terminology Criteria for Adverse Events (CTCAE) grade [27].

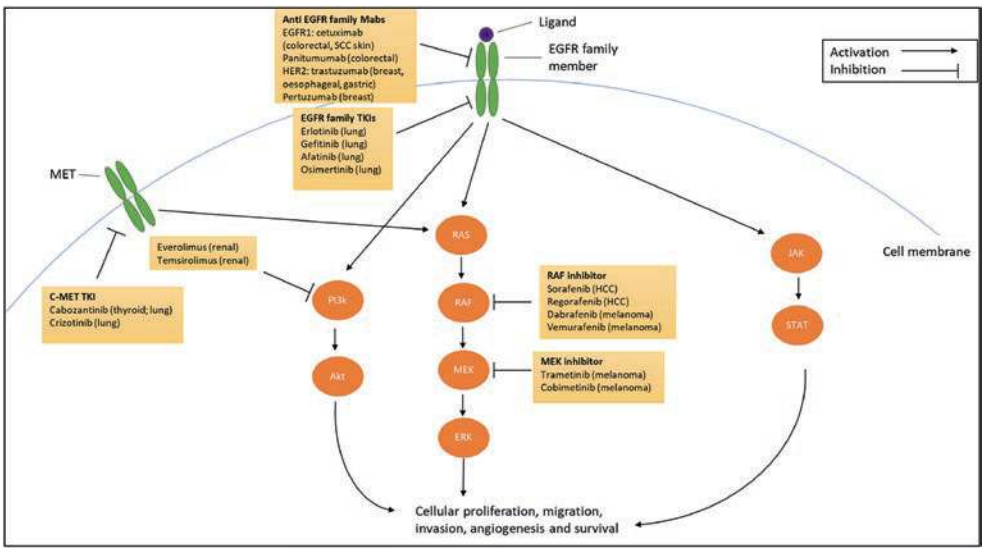

Fig. 3 Action of small molecule inhibitors and monoclonal antibodies targeting EFGR family, MET, and downstream cellular pathways, including example agents. Cancer sites agents used in shown in brackets. *Mab* monoclonal antibody, *TKI* tyrosine kinase receptor inhibitor, *HCC* hepatocellular carcinoma. (Adapted from Stone et al. [21])

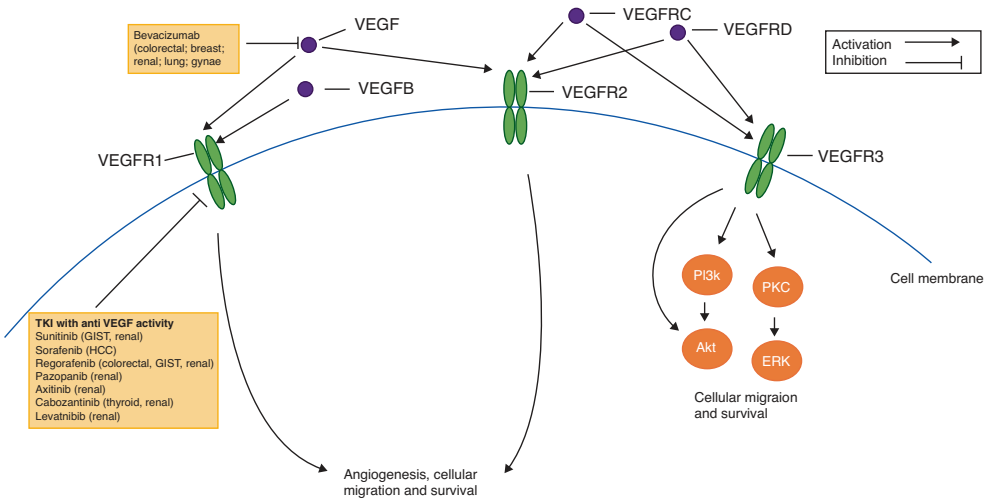

Fig. 4 Effect of on VEFG signaling pathways in cancer. Binding of VEGF ligands to VEGF receptors leads to downstream intracellular pathways resulting in angiogenesis, migration and survival. Cancer sites agents used in shown in brackets. *GIST* gastrointestinal stromal tumour; *HCC* hepatocellular carcinoma

Table 4 Targeted therapy classes with example target, cancer type this agent is used in and the potential gastrointestinal toxicities

Target pathway	Example agents	Example agent target	Cancer type	Gastrointestinal toxicities
DNA repair	Olaparib	PARP	Gynaecological cancers	Diarrhoea, nausea, vomiting, decreased appetite [22]
Cell signalling	Crizotinib, Alectinib	ALK and ROS1	ALK or ROS1 mutated non-small cell lung cancer	Diarrhoea, vomiting, constipation [23]
Cell cycle regulation	Palbociclib	CDK4 and CDK6	HER2 negative breast cancer	Nausea, diarrhoea [24]

Table 5 Gastrointestinal (GI) toxicities of small molecule inhibitors and monoclonal antibodies

	Targeted therapy class	
Gastrointestinal toxicity	Common toxicity	Uncommon toxicity
Diarrhoea	EGFR inhibitors	
Constipation	All	
Nausea and vomiting	All	
Abdominal pain	All	
Stomatitis	All	
Dyspepsia	All	
Gastrointestinal perforation	VEGF inhibitors	RAF inhibitors; temsirolimus; crizotinib
Gastrointestinal haemorrhage	VEGF inhibitors	
Fistula formation	VEGF inhibitors	
Pancreatitis		RAF inhibitors; VEGF inhibitors

Uncomplicated diarrhoea, that is patients with grade 1 or 2 diarrhoea, with no additional complications, may be managed conservatively with oral hydration and loperamide therapy in an outpatient setting. In cases of grade 3 or 4 diarrhoea fluid replacement should be via the intravenous route, which may include potassium replacement. Management is the same as previously described on chemotherapy induced diarrhoea [17].

A serious potential toxicity of anti-VEGF treatments is gastrointestinal perforation [28] most commonly bowel perforation. Bowel perforation may lead to peritonitis, fistula formation, abscess and sepsis. Management of bowel perforation should involve the multidisciplinary team including oncology, surgery, and radiology. Conservative, non-operative management options include bowel rest, antibiotics and parenteral feeding. The decision of whether or not to operate is complex, and such decision-making should take into account the severity and sequelae of the perforation, the patient's comorbidities, likely outcome of the operation, and the patient's wishes.

Immunotherapy

"Immunotherapy" is a broad term encompassing any therapy that up-regulates the immune system to target cancers. Over the years, various different methods of "switching on" the immune system have been used including vaccine therapies, intra-tumoral injections and cytokine therapies. This section focuses on the currently most commonly utilized immunotherapy; the family of drugs referred to as the immune checkpoint inhibitors (ICPIs). These drugs are monoclonal antibodies, which target the 'checkpoints' the immune system has in place to regulate autoimmunity. Examples of ICPIs include the anti-CTLA4 directed therapy (ipilimumab)

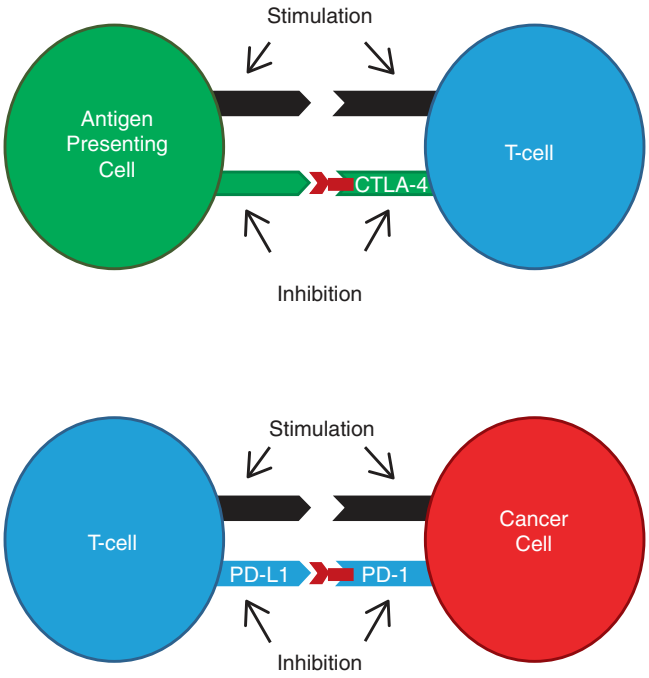

Fig. 5 Mechanism of Action of CTLA-4 and PD-1/PD-L1 inhibitors; adapted from [29]. For an immune reaction to take place there must be stimulation between a cell displaying abnormal proteins (either the antigen presenting cell or a tumour cell) and the T-cell via a receptor pathway (in black). The interaction between CTLA-4 (green pathway) and PD-1/L1 (blue pathway) blocks immune activation, which in normal cells prevent inappropriate immune activation but in cancer cells is used to evade immune destruction. When anti-CTLA-4 or anti-PD1/PD-L1 antibodies (dark red) are present, they block CTLA-4 or PD-1/L1 interaction respectively, thus allowing immune activation

or the anti-PD-1/PD-L1 directed therapies (e.g. pembrolizumab, nivolumab, atezolizumab and durvalumab).

The indications for checkpoint inhibitors are growing exponentially with ever increasing trials testing these agents in different cancers at different disease stages with different treatment objectives; given as monotherapy or in combination multi-modality treatment regimens. One of the hallmarks of cancer is the ability to evade detection by the immune system through these immune checkpoints. ICPIs are used to allow the immune system to 'recognize' cancers again (see Fig. 5). This can lead to dramatic responses of cancers to treatment and has revolutionized the treatment and survival of some cancers.

The side effects of ICPIs, however, are incredibly broad and either originate from the effect of having a systemic therapy (fatigue, nausea) or due to the effect of direct immune attack on specific organs of the body. ICPIs can lead to immune adverse effects on any organ; three of the commonly affected organ systems include the colon (colitis), liver (hepatitis) and endocrine organs including the thyroid and pancreas. Whilst this auto-inflammatory response can often be managed, this can require long-term use of high doses steroids or immunosuppressive agents, which themselves can cause long term side effects.

Effect of Immunotherapy on the Gastrointestinal Tract

ICPIs can impact the GI tract and nutrition in a multitude of actions, either through direct action on the mucosa itself, or by the effects on supporting organ systems or through toxicity from supportive agents. Table 6 gives a list of example toxicities:

Investigation and Management of Patients on ICPIs

The most important initial step is recognition that the presenting complaint could be secondary to the ICPI. This is often easy if the patient is still receiving the drug, however, toxicities of ICPIs can occur late even months following ces-

Table 6 Toxicities from ICPI and the effect on nutrition

Site/cause of toxicity (frequency)	Impact on nutrition
General drug adverse effects (very common)	Nausea is a common side effect of ICPI therapy and therefore can impact on nutritional intake
Immune-related colitis (common)	Diarrhoea, abdominal pain, bloating, urgency of defaecation and possible malabsorption. Can cause severe inflammation of the colon with a syndrome of symptoms similar to inflammatory bowel disease;
Immune-related enteritis (unknown)	Similar to colitis but with inflammation within the small bowel; can cause nausea/vomiting, bloating, malabsorption
Immune-related diabetes (uncommon)	Causing a syndrome similar clinically to type 1 diabetes mellitus; dysregulation of glucose homeostasis requiring management with insulin
Immune-related pancreatic insufficiency (uncommon)	Failure of the pancreas to produce enzymes to allow digestion of macronutrients; presents with diarrhoea, steatorrhoea, bloating, weight loss
Steroid-induced diabetes	Steroids cause altered glucose homeostasis which can cause a picture similar to type 2 diabetes, but patients can present acutely with hyperglycaemic hyperosmolar syndrome
GI infection	Either as an effect of the ICPI or secondary to immunosuppression, patients are at risk of GI infection; recent safety signals were released about the risk of reactivation of cytomegalovirus causing colitis with ICPIs [30].
Endocrine insufficiency (from common to uncommon)	Immune-related endocrine adverse effects are well recognized with ICPIs most commonly thyroid dysfunction. Less common conditions include hypopituitarism, and hypoadrenalism. Potential effects of these conditions include weight loss, nausea and anorexia.

sation of immunotherapy, which can make diagnosis difficult especially if patients did not present at an oncology unit.

There are published international guidelines (for example by the European Society of Medical Oncology [31]) on the management of ICPI-induced toxicity based on the severity of the toxicity using the Common Terminology Criteria for Adverse Events (CTCAE) grading system [27] to guide the subsequent requirement for admission, investigations for alternative causes and management options, typically the consideration of oral or intravenous steroids. In the event of lack of response to steroids, other forms of immunosuppression are then considered.

Specific Examples

Immune-Related Colitis

Patients on ICPI frequently present with diarrhoea or a change in bowel habit, often mild and relating to the consistency of stools. Presenting features are often similar to inflammatory bowel disease (IBD). For mild CTCAE grade 1 toxicity, treatment may involve just the use of simple anti-motility agents such as loperamide and exclusion of infection. In severe CTCAE grade 3+ toxicity, inpatient admission for high dose intravenous steroids and rapid further investigation including cross-sectional imaging, endoscopy and biopsy of the colon may be required. In patients with unresponsive severe symptoms, therapies often used in IBD are considered such as infliximab or vedolizumab. Specialist gastroenterology review is strongly recommended for these patients with severe toxicity. Early pre-treatment screening tests for eligibility for anti-TNF monoclonal antibody therapies (such as tuberculosis, viral hepatitis and HIV infections) should be considered for any patient presenting with severe immune-related colitis to allow prompt escalation of treatment.

Immune-checkpoint inhibitors are being used in an increasingly broad range of cancer therapies in both the adjuvant (following completion of definitive management, either surgical or concurrent chemo-radiotherapy) and metastatic setting with good outcomes and therefore these patients may have excellent survival outcomes from their cancer therapy however, the effect on quality of life in the long term due to immunotherapy can be profound. Prompt consideration and management of ICPI toxicity is therefore paramount.

Radiotherapy

Radiotherapy (RT) has been used in the management of malignant diseases for over a century. Conventional RT uses high energy X-rays or photons to cause ionization events (removal of orbiting electrons from atoms) within cells resulting in DNA damage and if unrepaired, initiating cell death pathways. RT ionization events and cancer cell death follow a probabilistic model, hence DNA damage (and cancer cell death) escalates with increasing RT dose. Thus, with high enough radiation doses, localized cancer eradication and cure can be achieved. However, in metastatic disease, RT has an important role in localized palliation of symptoms such as pain, obstruction and bleeding.

RT is becoming increasingly more targeted and sophisticated owing to significant developments in technology allowing the delivery of higher RT doses to cancers with improved cure rates while sparing normal tissue with reduced toxicity. RT continues to evolve with developments in particle therapy, such as proton therapy, which delivers radiation dose in a more confined manner compared to conventional photon RT, allowing greater sparing of normal tissue from low/intermediate doses especially to organs adjacent to the cancer, and potentially reducing long-term morbidity in some situations.

Effect of Radiotherapy on the Gastrointestinal Tract

Ionizing radiation beams travel in straight lines. Therefore, either on the way toward the tumour or after passing through it, radiation may damage the surrounding normal tissues of the body. This damage causes cessation of normal cellular functions and can cause death of the normal body tissues. This effect of radiation on normal structures causes both acute and late toxicity. It is important to note that the majority of curative RT regimens are often multi-modality, typically combined with concurrent chemotherapy as a radiosensitizer to improve cure rates but exacerbating acute RT toxicity onset and severity in addition to the chemotherapy-related toxicity.

Acute RT toxicities (those seen during a course of treatment or in the short weeks following completion) relate to the cell death of rapidly dividing cells (for example skin and mucosal surfaces) causing breakdown of epithelial surfaces. As the GI tract is lined by an epithelial membrane, any part of this receiving a dose of radiation can be affected. Acute toxicity typically subsides within a couple of months of treatment as normal tissue cells regrow and restoring the epithelial surfaces.

Late RT toxicities are related to multiple different factors including normal tissue hypoxia, inflammation, stem cell death, fibrosis and angiogenesis (formation of new vasculature). Its late onset is related to the cells of the stroma responding more slowly to radiotherapy damage. These processes can result in tissue necrosis (e.g. osteoradionecrosis of the mandible), stenosis (e.g. oesophageal strictures), telangiectasia (the development of new, fine fragile blood ves-

sels prone to bleeding), and functional changes in the gut, dependent on the site affected (e.g. bile acid diarrhoea when the terminal ileum is irradiated).

The most common cancer sites with likely acute and late effects of RT affecting gastrointestinal (GI) function include treatment for gynaecological organs (endometrium, cervix), lower GI (rectum, anus) and urology (bladder, prostate)—persistent symptoms have now been termed 'Pelvic Radiation Disease'. Other sites affected can be the pancreas, liver, oesophagus and head and neck. In addition to acute and late toxicity, due to the direct action of radiation on the gut, there are a multitude of other effects that RT has on intestinal function and nutrition. The supportive organs can also be affected; for example salivary glands, pancreas, liver or surrounding bloods vessels. In general, the effects of RT are localized to the area being treated (e.g. salivary glands affected in head and neck RT, oesophagitis in oesophageal or lung RT).

A common side effect of RT is nausea which is believed to be related to 5-hydroxytryptamine 3, neurokinin-1 (NK-1), and dopamine neurotransmitter release affecting the emetogenesis centres of the brain. RT induced nausea is most typically related to irradiation of the GI tract or brain. Management of RT induced nausea is as discussed earlier with chemotherapy induced nausea.

The acute and late toxicities affecting different regions of the GI tract are detailed in Tables 7 and 8.

Below are two examples of acute and late RT toxicities respectively.

Table 7 Acute toxicities of radiotherapy on gastrointestinal tract

Site of treatment	Effects on GI function/nutrition
Head and neck	Xerostomia, dysphagia potentially leading to aspiration, decreased enjoyment of food, alterations to consistency of the diet, mucositis/ulceration
Gustatory system (taste)	Change in tastes/cravings and decreased enjoyment leading to food avoidance
Oesophagus	Mucositis/oesophagitis, odynophagia, dyspepsia, gastro-oesophageal reflux, requirement for altered dietary consistency, dysphagia and risk of aspiration (in cervical oesophageal treatment). See worked example
Stomach	Nausea/vomiting, dyspepsia, early satiety, ulceration
Small intestine	Bloating, nausea/vomiting, borborygmi, pain/cramping, enteritis, poor absorption of nutrients, bacterial translocation, oedema leading to subacute obstruction
Large intestine	Diarrhoea, pain/cramping, dehydration, proctitis leading to food avoidance to reduce need to defaecate, oedema leading to subacute obstruction
Liver	Nausea/vomiting
Pancreas	Acute pancreatitis

Table 8 Late-effects of radiotherapy on gastrointestinal tract

Site of treatment	Effect on GI function/nutrition
Head and neck	Long term xerostomia—may affect choice of diet and fatigability of chewing, poor dentition
Oesophagus	Disordered motility, strictures
Small intestine	Bacterial overgrowth, bile acid diarrhoea, strictures
Large intestine	Proctopathy, radiation colopathy, rectal telangiectasia
Pancreas	Exocrine dysfunction, stricture of pancreatic ducts
Vascular system	Vessel damage, calcification, reduced splanchnic blood flow and reduced absorption.

Oropharyngeal/Oesophageal Mucositis

Patients receiving high RT doses to the oropharynx or oesophagus in head and neck, oesophageal and central lung cancers commonly develop acute mucositis of the oropharynx or oesophagus. It usually presents with odynophagia (pain on swallowing) and if uncontrolled, worsening dysphagia. Symptoms typically develop 2 weeks into RT treatment, progressing over the course of RT and peaking 1–2 weeks following completion of treatment.

Patients often require a change in diet to aid swallow function, changing from solid to a soft or liquid diet. The aim of treatment is supporting nutrition and controlling symptoms until recovery of the normal tissues and side-effect resolution, typically 4–6 weeks post treatment but can be up to several months with head and neck cancers.

Supportive medical therapies are focused on symptom control to aid swallowing and manage pain, for example topical lubricants (carboxymethylcellulose), oral coating solutions, oral local anaesthetics and analgesics with strong opiates often required. Active prevention and management of conditions likely to exacerbate mucositis recovery such as acid reflux (especially with concurrent chemotherapy-related emesis) with antacids and anti-emetics, and oropharyngeal/oesophageal candidiasis (due to loss of the protective mucosal surface from RT treatment and chemotherapy-related immunosuppression) with good oral hygiene and a low threshold to commence anti-fungal treatment.

If nutritional intake is inadequate, consideration has to be given to enteral feeding (typically nasogastric tube feeding). In high risk head and neck or oesophageal cancer patients, prophylactic percutaneous enteral tube insertion is often considered prior to commencing treatment. Multidisciplinary support of patients on treatment with specialist speech and language therapists and dietitians is vital to ensure weight loss is minimized due to its impact not just on patient malnutrition but also on RT treatment dosimetry and accuracy.

Pelvic Radiation Disease

Pelvic radiation disease can be defined as "transient or longer-term problems, ranging from mild to very severe, arising in non-cancerous tissues resulting from radiotherapy treatment to a tumour located in the pelvis" [32, 33]. This disease can present with multiple different GI symptoms and

can have a wide range of implicated aetiologies with the underlying cause often secondary to more than one diagnosis and may not directly relate to the effects of radiotherapy itself.

Diagnosis is often the first problem for patients, as the late GI effects of radiation are often underdiagnosed or perceived to be untreatable by healthcare professionals, or patients may not mention them, wrongly thinking they are expected to "just live with it". However, the underlying aetiologies are often treatable with good symptomatic benefit for patients. Referral to a radiotherapy late effects specialist team or gastroenterologist is recommended. For further guidance on the management of pelvic radiation disease, please refer to collaborative guidance by Andreyev et al. [34].

Effects of Chemotherapy on Radiation Toxicity

Chemotherapeutic agents are often given concurrently in curative radiotherapy regimens often as a radiosensitizer by binding to radiation-induced DNA damage and inhibiting DNA repair thus enhancing cancer cell kill [35]. Common concurrent chemoradiotherapy agents used include platinum agents, 5-fluorouracil, capecitabine and taxanes. However, radiosensitization from concurrent chemotherapy also impacts irradiated normal tissue with higher incidences of severe acute radiotherapy toxicity including acute gastrointestinal radiotherapy toxicities as listed previously in Table 6 [36].

Although enhancement of toxicity is greater when both chemotherapy and radiotherapy are given concomitantly, docetaxel, paclitaxel, gemcitabine, capecitabine and doxorubicin, and EGFR tyrosine kinase inhibitors have been reported to produce a 'radiation recall phenomenon' [37, 38]. This may occur at a site that has previously been irradiated when one of these drugs is given weeks or months later. Gastrointestinal tract recall phenomenon reported include mucositis, oesophagitis, gastritis and colitis reported.

Nutrition Support

Under-nutrition (protein–energy malnutrition) is a common issue in patients with malignancy, and studies have demonstrated a relationship between weight loss and a lower chance of responding to treatment [39, 40]. Malnutrition can contribute to morbidity in cancer patients by many mechanisms, including: increased infection risk, delayed wound healing, muscle weakness, depression, worse quality of life, reduced chemotherapy and radiotherapy response, increased surgical complications and worse survival rates [41]. Five-year survival rates may be up to 50% lower for patients with weight loss at the time of diagnosis compared with those who have retained their previous weight [42]. Cancer cachexia is not simply due to lack of adequate oral intake; rather, its pathophysiology is complex and includes a combination of systemic inflammation and hyper-metabolism alongside decreased intake.

Metabolic abnormalities in patients with cancer cachexia have been reported to include marked alterations of lipid, carbohydrate and protein metabolism [40]. Energy stores are diminished and total body water is increased. Of particular interest is the marked reduction of glutamine levels in patients with cancer cachexia [43]. Malignant cells extract glutamine with higher efficiency than any other cell in the body and this may affect normal protein synthesis. Recently, sarcopenia has been shown to be an important prognostic factor in cancer patients undergoing chemotherapy, with many recent studies showing that loss of lean body mass loss is an independent risk factor for chemotherapy toxicity, chemotherapy dose reductions, hospital admissions, and a decreased survival in these patients [44].

This evidence has emphasised a role for nutritional support in cancer patients to attempt to combat this reversible poor prognostic factor. This has been incorporated into many cancer therapy guidelines, with recent guidelines by the European Society of Enteral and Parenteral Nutrition (European Society of Clinical Nutrition and Metabolism) having advocated increased attention to nutritional support in all patients with cancer [45] and United Kingdom National Institute for Clinical Excellence best practice guidelines advocating early nutritional screening to identify malnourished patients for consideration of interventions [46].

Nutrition support in cancer patients should always be dietetic-led. Initially oral nutrition should be optimised if possible. If this fails to meet nutrition requirements, supplementary nutrition can be offered to patients via the gut (enterally), or using intravenous (parenteral) nutrition (PN) in selected patients (Table 9).

Effect of Cancer on Nutritional Status

The presence of cancer can have a profound effect on nutritional status through its effect on nutrition impact symptoms, food intake and body composition. The term disease related malnutrition refers to malnutrition along with the activation of systemic inflammation by underlying disease. The resulting inflammatory response contributes to loss of appetite and has a metabolic impact on tissues and organs. It can result in a loss of body weight, changes in body composition with a loss of muscle mass and fat along with a deterioration in physical functioning or performance status [47]. Metabolic abnormalities in patients with cancer cachexia have been reported to include marked alterations of lipid, carbohydrate and protein metabolism. Energy stores are

Table 9 Reasons for giving parenteral nutrition to patients with malignancy (a predicted 'long' survival with a good quality of life is desirable before starting parenteral nutrition)

Indications for parenteral nutrition
Gastrointestinal toxicity (mucositis/enterocolitis)
Bowel obstruction
Prolonged ileus
High-output enterocutaneous fistula
Malabsorption
Graft-versus-host-disease (GVHD)

Table 10 Terminology used to describe physiological changes occurring in cancer

Term	Description
Cachexia	A multi-factorial wasting syndrome characterised by involuntary weight loss, loss of skeletal muscle mass and fat mass [51].
Pre-cachexia	Early clinical and metabolic signs which precede loss of body weight and muscle.
Refractory cachexia	Cancer cachexia which does not respond to conventional nutritional support [51]
Sarcopenia	Low skeletal muscle mass and low muscle function [52]. Fatigue is common and physical function is limited.
Sarcopenic obesity	Low skeletal muscle mass in obese individuals. Often overlooked as body weight may appear normal, overweight or obese. Associated with poorer outcomes in relation to systemic anti-cancer treatment as associated with increased risk of toxicity and potential dose reduction of treatment [53, 54]

diminished and total body water is increased. The metabolic changes are mediated by systemic and tumour related cytokines including tumour necrosis factor-α (TNF-α), interleukin 1 (IL-1) and IL-6. Cytokines can impact on the neuroendocrine control of appetite leading to anorexia, in addition to causing wasting of skeletal muscle and reduced performance status [47].

Cancer cachexia is often not diagnosed or mentioned in a full medical assessment as there is often confusion as to its definition [48]. Percentage weight loss over time is often the main criteria with more recent definitions including a combination of factors, for example, weight loss, a simple questionnaire of sarcopenia (SARC-F), Eastern Cooperative Oncology Group performance status, appetite loss and abnormal biochemistry [49]. The Glasgow Prognostic Score (GPS), based on serum albumin and levels of C-reactive protein are also predictive tools used for the assessment of inflammation in cancer which are associated with prognosis and mortality [50].

A number of terms are used to describe the physiological syndromes that occur and these are described in Table 10.

The prevalence of malnutrition in the people with cancer varies depending on tumour type, tumour stage and the person's age with increasing age conferring a greater risk. Cancers affecting the upper gastrointestinal tract, head and neck, pancreas and lung are associated with an increased risk of malnutrition. Overall the reported range is from about 20–70% [47, 55]. Nutritional screening should be mandatory at diagnosis and at key points during the treatment pathway using a validated screening tool [55]. As the weight of populations is increasing it is essential that a normal body mass index or weight to height ratio is not used as the only method of assessment. This can hide changes in weight, body composition and food intake. Anorexia and other nutrition impact symptoms are recognised as important early indicators as a risk of malnutrition [47].

Following nutrition screening those identified as having a moderate or high risk of malnutrition should be referred for specialist dietary advice with the aim of meeting estimated nutritional requirements.

Systemic Anti-Cancer Treatment and Nutritional Status

Tolerance to systemic anti-cancer treatment (SACT) is influenced by nutritional status and body composition. Early studies demonstrated that people who had lost weight generally experienced more side effects of chemotherapy during treatment [56, 57]. This association is now recognised to be closely linked with low lean mass. Calculation of dose of SACT is based on body surface area derived from measurement of body weight. This estimate does not take into account body composition and the amount of lean mass and fat mass. Studies have shown that people who have a low lean, as measured by dual-energy X-ray scans or measurement of muscle mass from computed tomography scans (CT) have a high risk of toxicity of treatment and dose adjustment of SACT [53, 58].

Nutrition Support During Systemic Anti-Cancer Treatment

Individualised dietary advice is required for anyone deemed to be at risk of malnutrition following a diagnosis of cancer. Continual and ongoing screening should identify people who develop toxicities of treatment that impact on their dietary intake or nutritional status. Nutritional support should be part of a comprehensive approach that provides supportive care in a holistic way (Table 11). This may include psychological support, pain control, symptom control, physical activity and other aspects of daily life identified by the person themselves [60]. Increasingly physical activity in the form of both aerobic and resistance exercise is recognised as an important strategy to improve upper and lower body muscle strength [61].

The European Society of Enteral and Parenteral Nutrition (European Society of Clinical Nutrition and Metabolism) recommend the use of indirect calorimetry to predict resting energy expenditure; however, this is often not performed in routine clinical care [47]. In the absence of this measurement it is recommend to estimate energy requirements as 25–30 kcal/kg/day with 1.2–1.5 g protein/kg/day with higher

Table 11 Assessment for the provision of nutrition support [59]

Category	Examples
Anthropometry	Weight
	Height
	Body mass index
	Weight change—actual and percentage body weight from normal over 1, 3 or 6 months
	Mid upper arm circumference
Biochemistry	Electrolytes, Urea, Creatinine, Albumin and C-reactive protein (to determine modified Glasgow Prognostic Score)
Clinical	Type of SACT, expected side effects, patient reported symptoms preferably using validated symptom scores or scales.
Dietary intake	Current intake of food and fluid/nutritional intake
	Habitual food intake
	Meal pattern
	Texture of food consumed
	Foods not tolerated
	Dietary supplements consumed
Environment	Social circumstances
	Primary carer
	Arrangements for shopping, cooking
Behavioural	Food related behaviour, physical activity
Psychological	Self efficacy, self-management, mental health status
Health care utilisation	Hospitalisation, treatment planning

amounts of protein being required when depletion is severe [47]. Severely depleted patients should be managed with a slow, gradual introduction of nutrients with concurrent monitoring of electrolytes and tolerance to reduce the risk of refeeding syndrome [50].

Nutrition counselling is the first and most commonly utilised intervention for people with cancer who have a functioning gastrointestinal tract. This must include adequate symptom control particularly with respect to nausea and vomiting. Nutritional care should be undertaken within a framework of the nutrition care process taking into account multiple clinical, nutritional, sensory and social factors. For people who are struggling to maintain an adequate dietary intake, expertise from a Registered Dietitian has been shown to help improve intake of protein and energy intake [62, 63]. Some symptoms such as taste changes are particularly challenging to manage and can lead to a decrease in oral intake [64].

Oral nutritional supplements may also be appropriate to use and these have been demonstrated to improve protein and energy intake [65]. Although many trials on the use of nutritional support have not demonstrated a clear benefit for enteral nutrition in cancer patients, some of these have, unfortunately, been poorly designed. Increasingly studies are providing support for the early provision of dietary advice and nutrition support to influence the ability to withstand SACT [66].

More intensive nutrition support should be considered for patients with cachexia and increasing weight loss if aggressive therapy is to be offered [47]. For patients who are markedly malnourished and, as a result, are felt to be poor risks for chemotherapy, the use of enteral nutrition should be considered as the improvement in nutritional status may allow its subsequent use. Enteral nutrition is the preferred form of feeding if the gastrointestinal tract is functional and may be achieved by the use of nasogastric tubes or gastrostomy or jejunostomy feeding catheters if oral intake is insufficient or not possible due to tumour or the effect of treatment. Post pyloric feeding may be preferable in those who have ongoing or uncontrolled nausea and vomiting although placement and retention displacement of naso-jejunal feeding tubes may present a challenge in such cases. For longer-term EN support (particularly in patients with head and neck cancers undergoing radiotherapy) a gastrostomy tube (PEG or RIG) can be considered, often placed prophylactically prior to treatment.

Concomitant use of SACT and radiotherapy, for example in head and neck cancer, may exacerbate the toxicity of treatment. It is paramount that the provision of appropriate nutritional support is part of the treatment pathway to avoid delays in tube placement which in turn may influence ability to continue with treatment. The risks and benefits of appropriate feeding tubes should be discussed with people early in the treatment pathway enabling them to make an informed decision on the most suitable method of feeding.

Multi-Modal Interventions

Increasingly it is recognised that improvements in sarcopenia, cachexia and poor nutritional status require a multimodal approach that incorporates nutritional support and physical activity. The European Society of Enteral and Parenteral Nutrition (European Society of Clinical Nutrition and Metabolism) (ESPEN) recommend maintenance or increased level of physical activity to support muscle mass, physical function and metabolic pattern [47]. The role of drugs such as non-steroidal anti-inflammatory drugs (NSAID) to increase body weight and androgens to increase muscle mass are not supported by a sufficient body of evidence to be used routinely in clinical practice. Appetite stimulants such as progestins and steroids have studies to demonstrate their efficacy; however, their use is associated with potentially serious side effects such as thromboembolism in the case of progestins [47].

It is hoped that this multi-modal approach early in the treatment pathway will support optimisation prior to and during SACT resulting in reduced toxicity of treatment and improved outcomes. This has yet to be demonstrated in clinical trials and requires appropriate planning and support rather than waiting to identify those who have become malnourished.

Specific Nutrients and Their Influence in Cancer

The use of specific nutrients to improve nutritional status have met with varying degrees of success. Amino acids have been studied to determine their ability to increase fat free mass, however, these studies have failed to demonstrate sufficient benefits to warrant their use in routine nutritional support. Fish oil derived eicosapentaenoic acid (EPA) has been administered for its anti-inflammatory properties with the purpose of dampening the inflammatory changes that occur in cachexia. Whilst some studies have failed to demonstrate a clinical benefit from their administration, others have reported improvements in appetite, energy intake, body weight, lean body mass and prognostic benefits from fish oil enriched nutrition [67, 68]. More definitive evidence is required before fish oils can be recommended for use during SACT.

The role of glutamine in cancer continues to be controversial. It has been suggested that glutamine is semi essential in catabolic states and that glutamine depletion is linked to cancer related fatigue, performance status, poor nutritional status and inflammation in patients with solid tumours [69]. Glutamine has also been trialled as a treatment for SACT induced mucositis although studies have not provided sufficient evidence for it to be recommended for this use [47].

Can Diet Influence Gastrointestinal Symptoms of SACT?

The effect of SACT on gut mucosa is well known with diarrhoea being a common side effect of treatment. It has also recognised that this may have temporary implications for digestion and absorption of nutrients, including lactose, vitamins and minerals. Lactose intolerance during chemotherapy has been demonstrated with the use of lactose hydrogen breath tests demonstrating a rate of lactose intolerance higher than the normal population [70]. However, it is important to note that not all patients were symptomatic from lactose intolerance and lactose restriction has not been shown to be an effective method for managing gastrointestinal symptoms caused by SACT. Dietary restrictions during acute toxicity should not be imposed without evidence that they are effective as they are likely to further exacerbate the risk of malnutrition during treatment.

Are Dietary Restrictions Required in SACT?

People undergoing SACT are more susceptible to infection and should be given advice to avoid foods that are a high risk of containing pathogenic organisms. These include pate (meat or vegetarian), cheese from unpasteurised milk, raw fish (for example sushi) and uncooked eggs. Good food hygiene is paramount and advice should be available to reinforce the importance of hand hygiene, appropriate storage and heating of food. There is an ongoing debate about further food restrictions that may be imposed for people who have neutrophil counts below 0.5 or 2.0×10^9/L and whether these are both necessary and effective at reducing food borne infections [71–73]. Increasingly hospitals are reviewing their policy and in many cases are relaxing the previous restrictions that were imposed.

Parenteral nutrition (PN) should only be used in people who have a non-functioning gastrointestinal (GI) tract or in whom it is not possible to access the GI tract. Some patients may develop diffuse intra-abdominal malignancy and this may cause malabsorption or obstruction. Use of PN should also be considered for people in whom enteral nutrition has been commenced but failed to become established (for example, in immunotherapy or graft versus host disease where symptoms and intestinal failure may result in reduced tolerance to enteral nutrition). PN may also be considered for patients whose severe cachexia is the primary reason for failure of restoration of performance status and in whom treatment-associated toxicities prevent the use of enteral nutrition. There should be a reasonable expectation that antitumour therapy will produce a response, improve survival and may reduce the severity of intestinal failure so that PN may be stopped.

Some patients may develop diffuse intra-abdominal malignancy, and this may cause malabsorption or obstruction, with death due to nutritional failure, rather than cancer progression. The decision to provide home PN for such patients depends primarily on the underlying tumour type and the likelihood of it responding to chemotherapy. Chemoresponsive diseases such as germ cell tumours, lymphomas and ovarian cancers may reduce rapidly in volume with chemotherapy, and recovery can be enhanced by a period of PN. Similarly, patients who have developed severe, prolonged mucositis and enterocolitis as a result of radiotherapy may benefit from support with PN. For patients who are markedly malnourished and, as a result, are felt to be poor risks for chemotherapy, the use of enteral nutrition should be considered as the improvement in nutritional status may allow its subsequent use.

The consideration of PN versus EN in cancer patients without one of the strong PN indications (Table 9) remains controversial with a recent review and meta-analysis of over 43 studies show that EN and PN are equal in terms of mortality and nutritional complications, with a slight increase in risk of infection for PN support [74]. The use of PN in the peri-operative setting has been examined in several studies and, again, conflicting results have been obtained. Patients seem to benefit from PN after the development of a prolonged ileus following an abdominal procedure: if the patient has been unable to resume oral intake 7 days after surgery, PN may be considered. Lean body mass may be maintained as a result, improving quality of life and allowing a more rapid return to normal activities [75]. Cancer patients who undergo multiple bowel resections may develop the prob-

lems of a short bowel. Prolonged home PN may be required for those patients who are potentially cured by their surgery.

A recent study has shown that although oncologists accept that nutritional status and intervention are important, they still struggle to identify patients at risk of malnutrition and to refer those who may benefit from early nutritional intervention [48]. The ability to provide good nutritional care in these complex patients requires a multi-disciplinary team approach, including surgeons, medical and clinical oncologists, nurses, speech and language therapists, physiotherapists, occupational therapists, pharmacists and the nutrition team. There is also a requirement for ongoing education around the role of nutrition and its importance to all involved in looking after cancer patients and to the patient themselves.

Summary

Gastrointestinal toxicity from chemotherapy, radiotherapy and newer targeted agents is common and some effect on nutritional balance is almost universal. Most oncologists are increasingly aware of the importance of this toxicity as a contributory factor to the reduced quality of life and, potentially, to the survival of their patients, but feel ill-equipped in the diagnosis and management of malnutrition. Cancer survivors also often present with late non-specific symptoms with wide ranging aetiologies which can include toxicities of prior treatments, cancer recurrence, a range of non-malignant causes and psychological overlay due to fear of cancer recurrence. It can often be difficult to differentiate the specific cause of symptoms and its relationship to prior cancer treatment. There is a need for increased access to multidisciplinary nutritional support for cancer patients on treatment, and the availability of specialist late effects teams to ensure appropriate investigation and management of late morbidity in cancer survivors.

Bacterial Overgrowth and Enteric Infections

Eamonn M. M. Quigley

Key Points

1. Small intestinal overgrowth (SIBO) can occur due to alterations in intestinal anatomy (including diverticula), gastrointestinal dysmotility, or a lack of gastric acid secretion.
2. Can cause steatorrhoea and B_{12} deficiency (folate may be high).
3. The diagnosis of SIBO is commonly made on the basis of an early rise in exhaled breath H_2 following the administration of an appropriate substrate (glucose or lactulose). Criteria for diagnosis vary and must take account of accelerated small intestinal transit. Alternatively, quantitative cultures of aspirated small bowel contents may be used to make the diagnosis.
4. In clinical practice, the diagnosis of SIBO is often assumed and empirical antibiotic treatment commenced and the effect carefully monitored.
5. Chronic SIBO may justify long-term rotating oral antibiotics (e.g. co-amoxyclav, rifaximin, ciprofloxacin, metronidazole, a tetracycline or a cephalosporin) given for 6 weeks before rotating with an intervening 1–2 weeks off antibiotics. There are many different regimens.

Small Intestinal Bacterial Overgrowth

The Gut Microbiota: A Key Player in Homeostasis

As one passes down the gastrointestinal (GI) tract from esophagus to rectum the numbers and diversity of bacteria increase dramatically. Though, not as previously considered, sterile, the esophagus and stomach contain relatively low numbers of bacteria but still feature quite a diversity of bacterial species. The most dramatic increase in diversity and population numbers occurs on crossing the ileo-cecal valve into the colon where over 10^{12} bacteria per mg of feces and up to a 1000 species will be encountered. It must be conceded, however, that the detailed composition of the gut microbiota (and not just bacteria but also archaea, viruses, fungi and protozoa) continues to be defined; it is evident that culture-based techniques had dramatically underestimated the size and diversity of microbial communities within the GI tract. As molecular techniques, such as shotgun sequencing, are applied to enteric communities, their full dimensions in health and disease will be appreciated [1–3]. The same applies to the definition of small intestinal bacterial overgrowth (SIBO); as we will see later, its definition has, to date, relied upon culture or indirect approaches, such as the analysis of exhaled gases—we await the systematic application of high-throughput sequencing, metagenomics and metabolomics to its assessment. The latter may prove to be especially important by identifying those bacterial products and metabolites that actually produce symptoms and injure the intestine in SIBO. In a similar vein, while a profile of bacterial numbers along the GI tract has been described based on cultures of luminal aspirates (and used as the benchmark for defining abnormality), data, derived from either sequencing or metagenomics on bacterial populations throughout the small intestine, in health or disease, is scanty and this remains a major obstacle to our understanding of SIBO [4]. While there have been many studies of the human gut microbiota in health and a variety of gastrointestinal diseases, most have been, for reasons of obvious logistical simplicity, based on the analysis of stool samples. While such studies have revealed many of the factors that influence the development and maintenance of the gut microbiota throughout life, they may be poorly reflective of those critical interactions that occur between bacteria and the host at, or close to, the epithelial surface [4].

We do know that enteric bacteria colonize the alimentary tract at and soon after birth. Thereafter, the infant's microbiota rapidly increases in numbers and diversity to reach adult

proportions at about 2 years of age and then remains relatively constant throughout adulthood only to decline somewhat in later years [5]. These early years may be critical, not only to the development of the mature microbiome but also to shaping immunological and metabolic interactions with the host—interactions that may play a critical role in predisposing an individual to disease in adolescence and adulthood. The literature is now replete with examples of the sensitivity of the developing microbiota to various interventions (diet and antibiotics, for example) that presage later ill health. We also now have a reasonable understanding of some of the factors that shape the microbiota in adulthood—here again, diet and antibiotic use loom large with certain medications, ethnicity, host genetics, geographic location and disease itself appearing to exert impacts; ones that could readily confound the interpretation of microbiota data.

The four dominant bacterial phyla in the human GI tract are Firmicutes, Bacteroidetes, Actinobacteria, and Proteobacteria. Most bacteria belong to the genera *Bacteroides*, *Clostridium*, *Faecalibacterium*, *Eubacterium*, *Ruminococcus*, *Peptococcus*, *Peptostreptococcus*, and *Bifidobacterium*. Other genera, such as *Escherichia* and *Lactobacillus*, are present in lower numbers. It must be stressed that a number of fungal genera are normal inhabitants of the gut and include *Candida*, *Saccharomyces*, *Aspergillus*, *Penicillium*, *Rhodotorula*, *Trametes*, *Pleospora*, *Sclerotinia*, *Bullera*, and *Galactomyces*, among others. Archaea include important species such as the methane-producing (methanogenic) *Methanobrevibacter smithii.* Major differences in the distribution of bacterial taxa are evident as one moves in an aborad direction along the gut with lactobacilli, enterococci, oral streptococci and other gram-positive aerobic or facultative anaerobes reflecting the bacterial flora of the oropharynx dominating in the upper gut; for example, coliforms rarely exceed 10^3 colony forming units (cfu's)/mL of jejunal juice. The microbiology of the terminal ileum represents a transition zone between the jejunum, containing predominantly aerobic species, and the dense population of anaerobes found in the colon. On crossing into the colon, the concentration and variety of enteric flora changes dramatically with obligate anaerobes such as bacteroides, porphyromonas, bifidobacteria, lactobacilli and clostridia dominating and outnumbering aerobic bacteria by a factor of 100–1000:1.

The Gut Microbiota in Short Bowel and Intestinal Failure

There have been relatively few studies on the intestinal microbiota in SBS and/or IF. Bacterial diversity and acetate levels are markedly decreased and Proteobacteria (including pro-inflammatory Enterobacteriaceae) emerge as the predominant phylum, especially among those with type III SBS and with intestinal failure associated liver disease (IFALD) and central line-associated bloodstream infections (CLABSI) [6–9]. Lactobacilli may be increased [10]. In various studies, changes in the microbiota have also been linked to diarrhea, the need for parenteral nutrition, D-lactic acidosis, liver disease and growth failure [8–10]. The interpretation of all of these findings must remain guarded given the small sizes of the study populations and the multiple factors that may impact on the microbiota in these patients rendering it difficult to assign causality to any association between changes in the microbiota and a clinical finding.

Definition of SIBO

In its original usage the term small intestinal bacterial overgrowth (SIBO—sometimes referred to as "contamination") was introduced to describe a situation where an increase in the numbers and/or change in the type of bacteria in the small intestine resulted in clinical consequences and, specifically, those associated with malabsorption and maldigestion [11]. However, this rather narrow context has been radically expanded in recent years to encompass a broad spectrum of intestinal and extra-intestinal disorders often on the basis of imprecise methodology and/or limited data. Such studies have generated considerable controversy and thrown the definition of SIBO into sharp relief. Fortunately, a discussion of SIBO in the context of intestinal failure is largely concerned with SIBO as a contributor or exacerbator of maldigestion/malabsorption where the clinical presentation is related to effects of the contaminating organism on host morphology or function which, in turn, result in the clinical consequences typically associated with SIBO, such as steatorrhea, diarrhea, protein losing-enteropathy and/or specific deficiency states.

In this context, SIBO can be defined as "**clinical and/or laboratory evidence of maldigestion/malabsorption related to qualitative and/or quantitative alterations in the small intestinal microbiota**" [11]. Here the emphasis is on the clinical context and SIBO is incriminated, firstly, by documenting its presence, and, secondly, by demonstrating a clinical response to its eradication.

In IF, especial caution should be exercised in the diagnosis of SIBO and its treatment by antibiotics given that the use of antibiotics must be balanced against the benefits to the individual patient of energy salvage due to colonic bacterial metabolism of unabsorbed carbohydrate to short-chain fatty acids [12].

Pathogenesis of SIBO

An appreciation of the factors that protect against the development of SIBO in health helps to predict the likelihood of its occurrence in disease (Table 1). Of these, gastric acid and intestinal motor activity seem to be most important. In the stomach, acid kills and suppresses the growth of most organisms that enter from the oropharynx. In the small bowel, the cleansing action of aborad propulsive forces and, especially, phase III of the interdigestive migrating motor complex (MMC), limits the ability of bacteria to colonize the small intestine [13]. Other protective factors include the integrity of the intestinal mucosa, including its protective mucus layer and intrinsic anti-bacterial mechanisms, such as defensins and immunoglobulins; the enzymatic activities and bacteriostatic properties of intestinal, pancreatic and biliary secretions; the protective effects of the commensal flora; and the mechanical and physiological properties of the ileocecal valve [14]. One can readily appreciate that many of these protective factors may be missing or impaired in the individual with short bowel syndrome or intestinal failure. Let us now examine the contribution of these various factors to SIBO in the individual with intestinal failure (IF).

Dysmotility

Virtually every condition that has been linked to small intestinal dysmotility has been associated with SIBO with diabetic autonomic neuropathy and scleroderma being prominent examples of dysmotility-related SIBO [15–17]. In diabetes, SIBO is especially common among those with long standing, type I diabetes who exhibit other target organ pathologies, such as nephropathy, retinopathy and, most notably, autonomic neuropathy [15, 16]. Intestinal pseudo-obstruction, whether based on myogenic of neurogenic intestinal dysmotility, though an uncommon cause of SIBO, in general, looms large in any IF population [18]. Dysmotility may also be relevant to the pathogenesis of another rare cause of SIBO, jejunal diverticulosis. Morphological studies suggest that disorders of intestinal motility such as progressive systemic sclerosis, visceral myopathies and neuropathies play an important role in the formation of small bowel diverticula [19]. Disruption of the MMC appears to be an important factor leading to the development of SIBO in patients with radiation enteropathy; a not infrequent cause of IF [20].

Table 1 Factors involved in the pathogenesis of SIBO

• Dysmotility
– Intestinal pseudo-obstruction
– Scleroderma and related disorders
– Autonomic neuropathy
– Jejunal diverticulosis
– Radiation enteropathy
• Altered anatomy
– Blind loops
– Strictures
– Fistulae
– Entero-colonic anastomoses
– Loss of the ileo-cecal valve
• Hypochlorhydria
– Vagotomy
– Gastric resection
– Acid suppressive medications
• Immune deficiency
– Hypogammaglobulinemia
– Combined variable immune deficiency (CVID)
• Multifactorial
– Crohn's disease
– Radiation enteropathy
– Chronic pancreatitis
– Chronic liver disease
– Celiac disease

Altered Anatomy

A variety of surgical procedures that alter gastrointestinal anatomy have been associated with SIBO. A number of pathophysiological factors may be operative in this setting, including hypochlorhydria, formation of blind loops (depending on the nature of the surgical procedure), lack of contact between chyme and bile and/or digestive enzymes and disruption of intestinal motility. Stagnation and/or recirculation of intestinal contents resulting from strictures, fistulae, enterostomies and anastomoses also predispose to SIBO; all relevant to IF, in general, as well as to two common causes of IF, Crohn's disease and radiation enteropathy. Loss of the ileocolonic junctional region, as well as direct anastomoses between the proximal small intestine and colon, will also predispose to and promote SIBO in some IF subjects. The distinction between the ileocecal valve and the ileocolonic junctional region is important. While the ileocecal valve forms a physical barrier to reflux of colonic material from the colon into the small bowel, results from both experimental animal models and human studies have failed to identify a major effect on either bacterial translocation or SIBO following resection of just the valve [14]. These findings would lend support to the hypothesis that specialized motor patterns in the distal ileum, and not the valve itself, are the critical elements in sustaining the propulsive functions of this region [21].

Hypochlorhydria

Initially described in relation to surgical procedures that reduced gastric acid secretion, hypochlorhydria has, more recently, been invoked in the development of SIBO among individuals on long-term treatment with proton-pump inhibitors (PPIs). Though some studies suggested that long-term PPI therapy was associated with SIBO [22–24], others have failed to confirm this [25]. Furthermore, though their meta-

analysis revealed a pooled odds ratio of 2.82 for SIBO among PPI users versus non-users, Lo and Chan found that this association held true only for studies employing intestinal culture rather than breath tests for the diagnosis of SIBO [23]. Interestingly, Ratuapli and colleagues, who failed to identify a relationship between PPI use and SIBO, based their analysis on breath tests [25]. In IF it seems prudent to exert some caution in the use of PPIs.

Immune Deficiencies

SIBO has been described in association with hypogammaglobulinemia, both in inherited and acquired forms, as well as with disorders of cellular immunity, such as human immunodeficiency virus infection.

Impact of Co-morbidities

From the above it is clear that multiple factors will contribute to the pathogenesis of SIBO in IF. Diseases that may occur in the IF patient (such as Crohn's disease, radiation enteropathy [26] and diabetes, for example) may also predispose to SIBO. It is likely that multiple factors also contribute to the pathophysiology of SIBO associated with chronic renal failure, chronic pancreatitis and liver disease; all may occur in the IF patient. The cause of SIBO in chronic pancreatitis is multifactorial and includes the loss of pancreatic enzymes, a decrease in intestinal motility resulting from the inflammatory process, the effects of narcotics on gut motility and the presence, in some instances, of intestinal obstruction. Of these the association with chronic liver disease is, perhaps, the best documented. SIBO has also been frequently documented in association with liver disease and it is in this context that relationships between SIBO and systemic sepsis have been most extensively explored [27, 28]. In liver disease and of great relevance to IF, SIBO has been linked to systemic endotoxemia, spontaneous bacterial peritonitis and both overt hepatic encephalopathy and minimal hepatic encephalopathy [29–31]. Just as an altered intestinal microbiota has been linked to non-alcoholic fatty liver disease (NAFLD) [32], there is some evidence to link a disrupted microbiota, in IF, with, not only poor outcomes [10, 33], but also IFALD [6, 10, 34, 35].

SIBO: Consequences and Complications (Tables 2 and 3)

SIBO may influence gut function through direct and indirect mechanisms. Deconjugation of bile acids in the proximal small bowel will disrupt fat digestion and lead to the production of lithocholic acid, which is poorly absorbed and may be directly toxic to enterocytes. Carbohydrate malabsorption, due to SIBO, can contribute to diarrhea due to metabolism of malabsorbed carbohydrates by bacteria to form short-acid fatty acids that, in turn, increase the osmolarity of intestinal fluid and promote motility. Direct mucosal injury may also result from bacterial adherence or increased conversion, by enterotoxins, of the enzyme xanthine dehydrogenase to xanthine oxidase; indirectly, morphological changes may occur secondary to cobalamin deficiency. Regardless of mechanism, enterocyte injury leads to both a loss of activity of brush border disaccharidases and altered permeability, the later predisposing to the development, in the most severe cases, of a protein-losing enteropathy. The former will result in the presentation of more unabsorbed carbohydrates to intestinal bacteria for fermentation and could also contribute to lactose intolerance. Mucosal injury by bacterial toxins may also trigger an inflammatory response with the generation of inflammatory cytokines such as tumor necrosis factor α which may contribute to hepatic and systemic complications.

Bacterial digestion of luminal protein will leave the affected individual susceptible to malnutrition and will also contribute to hypoproteinemia and edema. Although some degree of hypoproteinemia is common, severe malnutrition is rare in SIBO. Bacterial metabolism of protein can also lead to the production of ammonia. In the context of an

Table 2 Consequences of SIBO

• Symptoms and signs
– Diarrhea

– Encephalopathy
• Laboratory findings
– Steatorrhea
– Hypoproteinemia
– Anemia
– Vitamin B_{12} deficiency
– Elevated levels of Folic acid
– Elevated levels of Vitamin K
– Deficiency of other fat-soluble vitamins
– D-lactic acidosis
– Hyperammonemia

Table 3 Complications of SIBO

• Malnutrition
• Protein-losing enteropathy
• Mucosal injury
• Encephalopathy
– Hyperammonemia
– D-lactic acidosis
• Bacterial translocation
– Gut-derived sepsis
– CLABSI
• Liver disease

impaired mucosal barrier, encephalopathy may result. Moreover, short bowel syndrome patients, especially those with an intact colon, may suffer D-lactic academia and associated encephalopathy as a result of the production of D-lactic acid by certain Gram-positive anaerobes [36, 37].

A number of phenomena combine to make SIBO an important cause of B_{12} deficiency. These include the consumption of cobalamin by anaerobes, malabsorption of the vitamin as a result of competitive binding with cobalamin from bacterially-generated metabolites of cobalamin at the ileal receptor and, in instances of more severe overgrowth, actual mucosal damage involving the binding site. Bacterial utilization of vitamins, in SIBO, has also been invoked in the development of thiamine and nicotinamide deficiency.

Deconjugation of bile acids and consequent depletion of the bile acid pool will lead to maldigestion of fat and fat soluble vitamins. Here there is one particular paradox: bacterial production of vitamin K, combined with enhanced absorption of the vitamin, due to greater permeability, may serve not only to sustain but even increase vitamin K levels to a degree that warfarin dose may need to be adjusted to maintain therapeutic anticoagulation [38]. Bacterial synthesis of folic acid may result in the rather unusual combination of high folate and low B_{12} levels in the circulation.

Bacterial Translocation and Sepsis

The possible contribution of SIBO to bacterial translocation and sepsis is an important issue in intestinal failure, a disorder where sepsis is an important cause of morbidity and mortality. Bacterial translocation is defined as the passage of viable bacteria or bacterial products, such as lipopolysaccharide, from the gastrointestinal tract to extraintestinal sites, such as the mesenteric lymph node complex, liver, spleen, kidney, and bloodstream [39–41]. Experimental animal models have shown that bacterial translocation may be promoted by mucosal inflammation, intestinal obstruction, ischemia and hypo-perfusion injury, acute pancreatitis, liver disease, prematurity, burns and trauma. SIBO, increased intestinal permeability, and impaired host immune defense, are considered to be the primary mechanisms which promote bacterial translocation. Indeed, this model of an altered luminal microbiota, impaired gut barrier function ("the leaky gut") and bacterial translocation has been invoked to explain a host of hepatic and systemic disorders. However, it must be emphasized that while animal studies support this concept, it has been poorly documented in man [42, 43].

The term gut-derived sepsis is used to describe a state of systemic inflammation and organ dysfunction associated with severe catabolic stress; it has been hypothesized that this syndrome is initiated and perpetuated by the intestinal microbiota. Although the gut plays a role in the development of sepsis syndrome and multiple organ failure, recent studies have shown that gut-derived-bacteremia, even when due to potent nosocomial pathogens, is an event of low proinflammatory potential and, is of itself an insufficient stimulus for the systemic inflammatory response and organ failure state typically seen after severe and prolonged catabolic stress. It seems much more likely that alterations in the gut's immune function and interactions between the gut-associated immune tissue and the rest of the body form the basis for this syndrome.

Central venous infection is the most frequent complication during parenteral nutrition and in IF. Although catheter sepsis is often associated with enteric organisms, Reimund et al. found that, in their 42 adult patients, *Staphylococcus epidermidis* was detected in 51% [44]. Moreover, the presence of enteric organisms in the bloodstream does not necessarily mean bacterial translocation caused by bacterial overgrowth, because of diarrhea episodes, patients often have colonization of skin and their immediate environment with enteric flora.

Diagnosis of SIBO

Although aspiration and direct culture of jejunal contents are regarded by many as the gold standards for the diagnosis of SIBO, these methods have several limitations, such as the potential for contamination by oropharyngeal bacteria during intubation, and the fact that bacterial overgrowth may be patchy and thus missed by a single aspiration. Overall the reproducibility of jejunal aspiration and culture have been reported to be as low as 38% in comparison to 92% for breath tests. In addition, these methods may be regarded as cumbersome and invasive for patients who may require repeated testing.

For this reason, a variety of noninvasive diagnostic tests have been devised for the diagnosis of SIBO based on the excretion, in exhaled breath, of hydrogen generated by the metabolism of carbohydrate by luminal bacteria. In these breath tests, the diagnosis of SIBO is established when the exhaled breath H_2 increases by more than 20 parts per million (ppm) over baseline on two consecutive samplings within 90 min of substrate ingestion [45] (Fig. 1). If methane is measured, a rise of 10 ppm is considered diagnostic (Fig. 2). These criteria assume that the small intestine is anatomically intact and that small intestinal transit is normal. It has also been suggested that a fasting breath hydrogen level that exceeds 20 ppm is indicative of SIBO; in short bowel patients where the small bowel remnant is in continuity with a functioning colon, breath test interpretation may be difficult as the baseline breath H_2 level may be very high.

Even though double peaks (SIBO and colonic peaks) have previously been defined as representing an abnormal lactu-

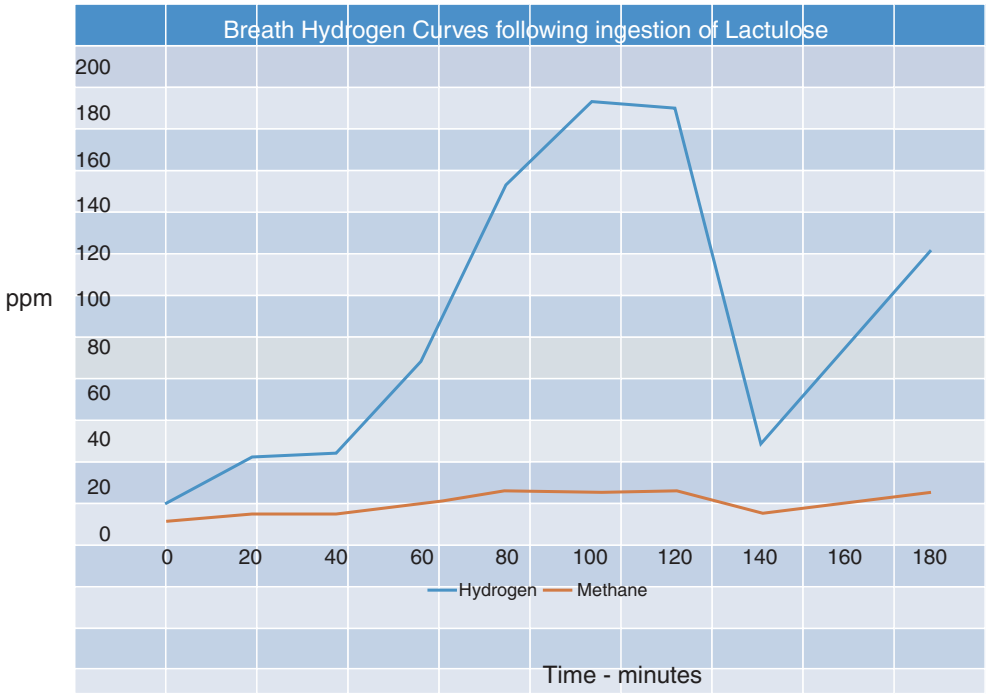

Fig. 1 Breath Hydrogen and Methane levels for 180 min following ingestion of lactulose (time 0). Note: early (>20 ppm) rise in breath hydrogen between 20 and 40 min illustrating an "early" peak and very suggestive of SIBO

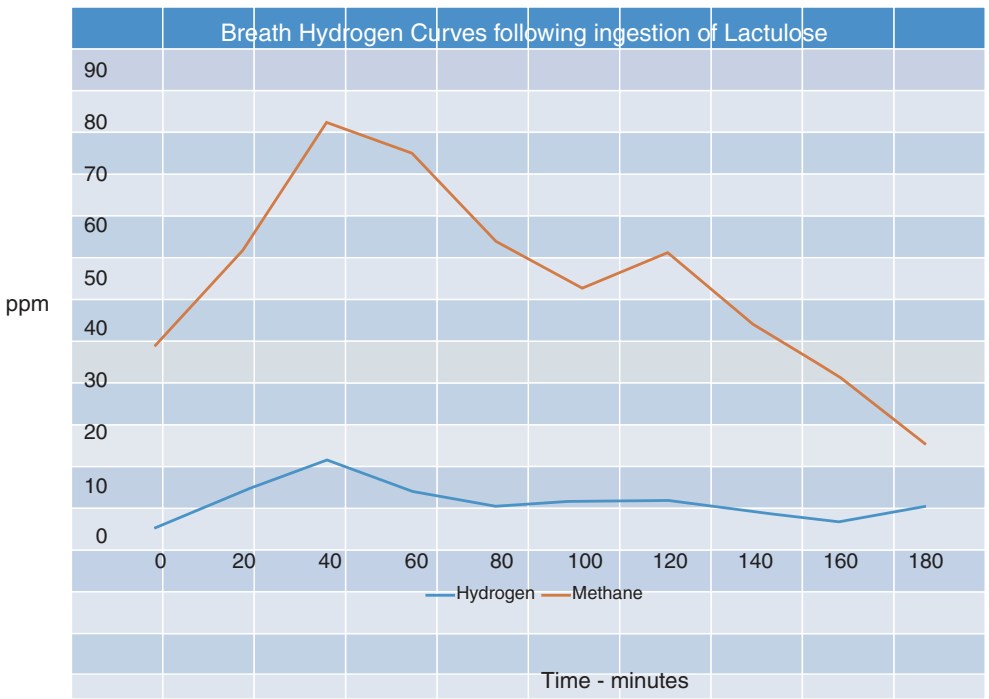

Fig. 2 Breath Hydrogen and Methane levels for 180 min following ingestion of lactulose (time 0). Note: "double peak" in methane excretion, the first at 40 min (indicative of SIBO) and the second at 120 min (consistent with arrival of the substrate in the colon)

lose breath test (Fig. 2), they may also result from rapid orocecal transit resulting in the premature delivery of fermentable substrate to cecal bacteria. Indeed, the reliability of these diagnostic techniques has been criticized in patients with intestinal failure, and especially those with short bowel syndrome, because of the rapid intestinal transit that accompanies these disorders. Interpretation of breath tests may also be complicated, in patients with short bowel syndrome, by carbohydrate malabsorption and a resultant increase in colonic fermentation. However, in support of a role for bacterial overgrowth in symptom pathogenesis, studies have reported a parallel improvement in gastrointestinal symptoms and breath tests after antibiotic therapy among intestinal failure patients with positive breath tests [46, 47]. It must also be borne in mind that false-negative or "flat" responses to lactulose administration may be found among those whose

bacterial flora has been altered by antibiotic therapy or diarrhea or in whom motility disorders coexist, situations commonly present in patients with intestinal failure. Finally, between 15% and 27% of the population do not generate hydrogen, following the ingestion of this substrate, but, rather produce methane (as illustrated in Fig. 2); the measurement of hydrogen alone will clearly underestimate the prevalence of SIBO among such individuals.

The diagnosis of SIBO remains problematic [48]. Jejunal aspiration is cumbersome and open to confounders while breath tests are fraught with problems of interpretation. We await the application of nucleic acid amplification techniques and metabolomics to SIBO; approaches that have revolutionized the study of the microbiota elsewhere.

In the IF patient, SIBO should be suspected based on the symptomatology described above but breath tests interpreted with caution. A therapeutic trial may also be considered but mindful of the negative aspects of indiscriminate antibiotic therapy.

Therapy of SIBO (Table 4)

SIBO should be suspected in patients with intestinal failure whenever they are not progressing in a normal manner, especially if patients require additional calories, lose weight, or regress in their growth. Control of SIBO can be expected to improve absorption when significant enteritis has occurred due to severe bacterial proliferation.

Surgery

Clearly, the primary goal should be the treatment or correction of any underlying disease on defect when possible. Unfortunately, several of the clinical conditions associated with SIBO, bacterial translocation and intestinal failure are not readily reversible. Nontransplantation surgical procedures and medical treatment have the same emphasis, which is to reduce the requirement for total parenteral nutrition and to reach a normal weight, height and lifestyle. Nontransplantation surgical approaches (see elsewhere in this volume) can improve intestinal function and increase nutrient and fluid absorption by either slowing intestinal transit or increasing intestinal absorption.

– Co-trimoxazole
– Tetracycline
– Metronidazole
– Ciprofloxacin
Single course—7–14 days
Intermittent therapy
Rotating antibiotics (4–6 weeks on, 2 weeks off)
Continual

Nutrition

The nutritional support of the IF patient is dealt with extensively in this volume; if SIBO is present attention should be paid to the correction of deficiencies, such as hypoproteinemia and B_{12} deficiency resultant from, or exacerbated by, SIBO.

Prokinetics

Prokinetics that accelerate intestinal transit and improve postprandial small-intestinal motility may be attractive adjuvants to the treatment of SIBO and intestinal failure. In spite of this, there are few studies about the effect of prokinetics in this group of patients and the majority have been performed in gastrointestinal motility disorders *per se.* Options are limited; cisapride, perhaps the most extensively studie drug in this context, was withdrawn due to cardiovascular effects. Although new prokinetic drugs, without cardiovascular adverse effects, such as prucalopride [49], are now available in some countries, controlled studies are needed to establish the efficacy of these drugs in the treatment of SIBO.

Antibiotics

In most instances the therapy of SIBO rests exclusively on the use of antibiotics. The ESPEN guideline recommends "*that short bowel syndrome (SBS) patients who have motility disorders, including those with dilated segments of residual small bowel, blind loop etc., and who suffer from symptoms of bacterial overgrowth, benefit from occasional antibiotic treatment. (Grade of evidence: very low). We do not recommend the routine use of antibiotics in SBS patients with a preserved colon, given the benefit of the energy salvage due to colonic bacterial fermentation of malabsorbed carbohydrate to short-chain fatty acids, in spite of a potential reduction in the production of gases and consequent symptoms related to this fermentation. (Grade of evidence: very low)*" [12]. They concluded that very little is known about the pres-

ence of small bowel bacterial overgrowth in patients with SBS; a situation confounded by the aforementioned lack of consensus regarding its definition and the lack of consensus on indications for treatment.

The objective of antibiotics in SIBO should not be to eradicate the bacterial flora but to alter it in a way that leads to symptomatic improvement. Although, ideally, the choice of antimicrobial agents should reflect in vitro susceptibility testing, this is usually impractical as many different bacterial species with different antibiotic sensitivities typically coexist. Antibiotic treatment remains, therefore, primarily empirical. Effective antibiotic therapy must cover both aerobic and anaerobic enteric bacteria and different schedules have been suggested. Although in general, a short single (7- to 10-day) course of antibiotic may improve symptoms for up to several months in between 46% and 90% of patients with SIBO and render breath tests negative in 20–75%, patients with SIBO and intestinal failure due to short bowel syndrome and/or gastrointestinal disease are more refractory to antibiotic therapy and may require either repeated (e.g. the first 5–10 days out of every month) or continuous courses of antibiotic therapy. For the latter, rotating antibiotic regimens are recommended to prevent the development of resistance. Decisions on management should be individualized and consider such risks of long-term antibiotic therapy as diarrhea, Clostridium difficile infection, intolerance, bacterial resistance, and cost. In the past, antibiotics such as norfloxacin, amoxicillin-clavulanic acid, and metronidazole for 7 days were a good option. More recently and given its minimal systemic absorption and favorable safety profile, rifaximin has emerged as an important option [50]. Rotating regimens are especially valuable in patients with visceral myopathy, scleroderma and jejunal diverticulosis and commonly feature 4–6 weeks on one antibiotic followed by a 2 week "holiday" off antibiotic followed by 6 weeks with another antibiotic, and so on.

Prebiotics and Synbiotics

A prebiotic is defined as a substrate that is selectively utilized by host microorganisms conferring a health benefit [51]. They are, typically, non-digestible but fermentable food ingredients that selectively stimulate the growth and activity of one species or a limited number of species of bacteria in the colon. Though the science behind prebiotics continues to develop, there is less clinical data and little in relation to SIBO and IF. One study found that the addition of the prebiotic preparation guar gum enhanced the efficacy of rifaximin [52].

Probiotics

Probiotics, a word is derived from the Greek and meaning "for life", are defined as live organisms that, when ingested in adequate amounts, exert a health benefit on the host [53].

Several experimental studies have suggested that the mechanism of probiotic activity is likely multifactorial. Competitive metabolic interactions with pathogens, production of bacteriocins, inhibition of bacterial translocation, enhancement of mucosal barrier function, and signaling with the epithelium and immune system have been reported as possible modes of action of probiotics strains [54].

There is also a paucity of data on probiotics in SIBO related to IF. In an isolated case of D-lactic acidosis in a patient with short bowel syndrome and recurrent encephalopathy, Uchida et al. showed that a probiotic associated with oral kanamycin was effective in ameliorating these episodes [55]. While some lactobacilli can generate D-lactic acid, others do not and the latter have actually been used to treat D-lactic acidosis [37].

Vanderhoof and colleagues suggested that, in their children with bacterial overgrowth associated with short bowel syndrome, *Lactobacillus plantarum* 299v either prevented or delayed the recurrence of symptoms following antibiotic treatment [56]. In a randomized, double-blind trial, Gaon and colleagues found that, in their 12 patients with bacterial overgrowth-related chronic diarrhea, both *Lactobacillus casei* and *acidophilus* strains *cerela* were effective for bacterial overgrowth-related chronic diarrhea, and suggested that probiotics should be used continuously [57]. In contrast, *Saccharomyces boulardii* did not significantly influence the evolution of chronic diarrhea and breath test results [58]. Stotzer et al. showed that, in their patients with long-standing bacterial overgrowth, *Lactobacillus fermentum* did not benefit symptoms or normalize breath tests [59]. Data remains, therefore, inconclusive.

Enteric Infections and Intestinal Failure

Human Immunodeficiency Virus (HIV) Enteropathy

In the previous edition of this textbook an entire chapter was devoted to HIV infection; it is a testament to the dramatic progress in treatment of this once fatal condition that HIV enteropathy merits a mere footnote in this edition. Indeed, as the incidence of opportunistic enteric infections has decreased due to more effective anti-retroviral therapy (ART), the incidence of noninfectious diarrhea (such as that

occurring as an adverse consequence of therapy and HIV enteropathy) has increased [60, 61] While diarrhea remains common among those infected with HIV, intestinal failure should now be an extreme rarity among those who have access to effective anti-viral therapy [60, 61]. Once opportunistic infections have been excluded, therapy becomes primarily symptomatic and supportive with careful attention to choosing ART agents with minimal diarrheagenic effects. While a number of medications are used on an off-label basis, crofelemer is the only therapy currently approved in the US for symptomatic relief of non-infectious diarrhea in patients with HIV on ART.

Infections in Common Variable Immunodeficiency

In a manner similar to HIV, a variety of opportunistic enteric infections, such as giardiasis [62], have been reported among those who suffer from common variable immunodeficiency (CVID). CVID is diagnosed on the basis of levels of IgG and IgA more than two standard deviations below normal in the absence of any other cause for hypogammaglobulinemia. Though rarely meriting the diagnosis of intestinal failure, chronic diarrhea in CVID can result from chronic norovirus infection. Symptoms can last for years but clinical and histological remission can result from effective clearance of the virus with ribavirin [63]. Chronic norovirus infection has been reported to cause IF, however, in children who have undergone stem cell transplants [64].

Other Infections

The literature contains individual case reports of infections leading to IF—visceral leishmaniasis in a young immunocompetent patient [65], fatal gastrointestinal histoplasmosis in a liver transplant recipient [66], disseminated aspergillosis causing IF after colectomy [67] and *Clostridium difficile* causing multiple organ failure and enteritis [68]. There are also two reports of patients possessing the NOD2 mutation developing tuberculous lymphadenitis and intestinal failure requiring home parenteral nutrition [69].

Extensive Mucosal Disease: Coeliac Disease and Eosinophilic Enteritis

Suzanne C. Donnelly

Key Points

1. Coeliac disease, the most common disease affecting the small intestine in the Western world, can be found in most countries
2. Coeliac disease is treated with a life-long gluten-free diet.
3. More severe metabolic complications of coeliac disease occur in refractory coeliac disease, ulcerative jejunitis and enteropathy-associated T-cell lymphoma
4. The development of treatment to allow gluten transgressions in coeliac disease is slow to come to market
5. Eosinophilic enteritis is a rare condition affecting the gastrointestinal tract
6. Treatment for eosinophilic enteritis currently involves oral corticosteroids

Introduction

The small intestine has a role in both secretion and absorption. Small intestinal disorders can be predominantly malabsorptive or secretory in nature but often the two co-exist with most small intestinal mucosal disease having malabsorption and excess secretions. Diarrhoea due to small intestinal disease is often non-inflammatory and of high output. The larger the surface area of small intestinal mucosa affected, the higher the outputs. Improvement of diarrhoea after fasting suggests an osmotic component to the diarrhoea and both may co-exist. Malabsorption symptoms include steatorrhoea, malodorous flatus, bloating and postprandial diarrhoea.

Coeliac Disease

The most common cause in the Western world of small intestinal disease is coeliac disease which is also known as coeliac sprue or gluten-sensitive enteropathy. It is a small intestinal disorder caused by an inappropriate immune response to dietary gluten. Ingestion of wheat, rye or barley proteins in susceptible individuals triggers an inflammatory response particularly in the proximal small intestinal mucosa causing damage to the villous architecture. In a small minority of patients this also happens with oat proteins. The disease manifests itself as a generalised malabsorption which typically presents as weight loss, diarrhoea or disorders associated with specific nutrient deficiencies such as anaemia or osteoporosis. However, since the advent of highly sensitive serological screening tests, less well-defined forms of the disease are being increasingly recognised and the terminology has changed. Treatment, at present, is the life long, complete avoidance of gluten from the diet.

Epidemiology

Early estimations of the prevalence of coeliac disease indicated that it was an uncommon disorder. A study in 1950 estimated the incidence of coeliac disease to be 1:8000 in England and Wales and 1:4000 in Scotland [1]. Since then the diagnostic process has vastly improved with the advent of endoscopic small bowel biopsy in the 1960s and highly specific serological screening methods, such as the anti-endomysial or the tissue transglutaminase antibodies. This made it possible to evaluate the true prevalence of coeliac disease showing an unsuspected frequency of clinically atypical forms of coeliac disease. A UK study screened over 7000 serum samples for anti-endomysial antibody and found that, in England, undetected coeliac disease affects approximately 1% of the adults aged 45–76 years [2]. A large, international, multicentre study investigated a wide population

J. M.D. Nightingale (ed.), *Intestinal Failure*, https://doi.org/10.1007/978-3-031-22265-8_12

sample in four different European countries [3]. On average the overall prevalence of coeliac disease was 1% with large variation between countries: 2% Finland, 1.2% Italy, 0.9% Northern Ireland, 0.3% Germany. This study also confirmed that many coeliac disease cases would be missed without active serological screening. Biagi et al. [4] cautioned that the prevalence of coeliac disease can be over-estimated if tissue transglutaminase is the only diagnostic tool.

Similar rates have been reported from the US population, 1:133 [5] and from developed countries mostly populated by individuals of European origin, Australia 1:251 [6] and New Zealand 1.2% [7]. The presence of coeliac disease is long established in many South American countries that are mostly populated by individuals of European origin. Among Brazilian blood donors, the prevalence of coeliac disease ranged between 1:681 [8] and 1:214 [9], however these may be artificially low as blood donors represent the "healthiest segment" of the population. In Argentina an overall prevalence of coeliac disease was found to be 1 in 167 in 2000 adults involved in a prenuptial examination [10].

Recent epidemiological studies performed in areas of the developing world show prevalence rates overlapping European figs [11, 12]. The prevalence of coeliac disease in North African countries was found to be 0.53% in Egypt [13], 0.79% in Libya [14] and 0.6% in Tunisia [15]. In the Middle East the prevalence was found to be 0.88% in Iran [16] and 0.47% in Turkey [17] while in India the rate was 0.7% [18].

This widespread diffusion is not surprising at all given that the causal factors, HLA predisposing genotypes (DQ2 and DQ8) and consumption of gluten containing cereals show a worldwide distribution [19].

The highest prevalence of coeliac disease is to be found in the Saharawi population of Arab-Berber origin living in Algeria and is 5.6% [20]. High levels of consanguinity, high frequencies of HLA-DQ2 [21] and heavy gluten ingestion are potential explanations for this phenomenon.

In the Far East, there are a few recent reports of coeliac disease where previously coeliac disease was thought not to exist. Coeliac disease was found in 14% of symptomatic children with diarrhoea in four major cities in China [22]. In another study, 2.6% of adults tested in the Jiangsu province, with high gluten ingestion, who had either type 1 diabetes mellitus or diarrhoea-predominant irritable bowel syndrome, had positive tissue transglutaminase serology. These adults declined endoscopy but improved symptomatically as well as clinically on a gluten-free diet. The HLA-DQ2 molecule was also found in 17% of the individuals tested [23]. With rising gluten consumption in China and a high level of consanguinity, increasing the prevalence of HLA-DQ2, in some of the population it may be that coeliac disease is more common than first thought [24]. Genetic screening of the HLA status of whole Chinese population may yield some interesting results.

There is no data about the prevalence of coeliac disease in Sub-Saharan Africa. There are however reasons to believe that coeliac disease is not common in these countries. Staple cereals such as millet and rice are mostly naturally gluten-free and the HLA-related predisposing genes DQ2 and DQ8 are much less frequent in these areas than Western countries. Coeliac disease is rare in individuals of Afro-Caribbean origin [25].

Evidence suggests that the pattern of disease is changing. A multicentre study found the average age of diagnosis in children had risen from two years in 1975 to four years in 1990 [26]. This probably reflects changes in feeding practices, for example, a prolonged breastfeeding period is highlighted by a well-documented phenomenon that occurred in Sweden in the mid-1980s. At this time there was a sharp increase in the incidence of symptomatic coeliac disease in children under two years of age [27]. Retrospective analysis of this epidemic found that there had been a two-fold increase in the average daily consumption of flour in formula feed. Furthermore, at this time only 50% of infants were breast-fed. The incidence rates fell in 1995. This coincided with an increase in the proportion of infants being breast fed at 6 months and lower quantities of flour in the formula feed. A study found breastfeeding to be protective against the onset of symptomatic coeliac disease [28]. The reason for this is unclear, although other studies have also shown a protective effect of breast-feeding against autoimmune diseases. However, a prolonged period of breastfeeding is not likely to prevent the later occurrence of coeliac disease in an individual who is genetically predisposed [29].

Manifestations of Coeliac Disease

The clinical manifestations of coeliac disease vary greatly and although this was perceived as a purely paediatric disease, the diagnosis is increasingly being made in adult life. The classical syndrome of diarrhoea, abdominal distension, muscle wasting and failure to thrive is usually seen in infants between the age of 9 and 18 months of age following the induction of gluten into their diet. Generally, the earlier introduction of gluten into the diet, the sooner the onset of symptoms, and therefore prolonged breastfeeding may postpone symptoms [30]. Anaemia is a common presenting feature of paediatric coeliac disease, and the disease can go undiagnosed where this is the only presenting feature [31]. Anorexia and vomiting are also common. Dental enamel defects have also been reported [32, 33]. Milder forms of the disease are becoming more common and children now tend to present at a later age and often with only minor symptoms [30].

In adults, coeliac disease can manifest as a variety of symptoms presenting to almost any hospital department. The presenting symptoms may be varied including gastrointestinal, metabolic, neurological or psychological. The most common presenting gastrointestinal symptom is diarrhoea which can be continuous, intermittent or alternated with periods of constipation. It may be accompanied by weight loss, bloating, anorexia or abdominal pain. Isolated increase in serum aminotransferase level caused by mild, non-progressive liver inflammation is also a common presentation [34].

Approximately 50% of coeliac patients do not have clinically significant diarrhoea and present with less severe symptoms such as lassitude, weakness or weight loss. Anaemia is a frequent finding in coeliac disease and may be the presenting feature [35]. Microcytic anaemia, secondary to iron deficiency anaemia is highly prevalent and is frequently the sole manifestation of the disease; oral iron supplementation will prove useless in these cases. Macrocytic anaemia may occur as a result of folate or B_{12} deficiency. This deficiency was previously thought to be unusual in coeliac disease because B_{12} is absorbed in the terminal ileum and coeliac pathology primarily occurs proximally. Studies have reported low serum vitamin B_{12} levels in untreated patients [36]. Low calcium and vitamin D absorption may give rise to osteomalacia and bone pain, with an increasing risk of developing osteoporosis.

Oslo Classification of Coeliac Disease

The true prevalence of coeliac disease within a population is difficult to estimate as many affected individuals will not display any symptoms; the disease is therefore undetected. Experts met, in Oslo, to agree nomenclature for the different forms of coeliac in Table 1 [37].

Table 1 Oslo nomenclature of coeliac disease

Term	Description
Classical coeliac disease	presents with signs and symptoms of malabsorption: diarrhoea, steatorrhoea, weight loss/growth failure
Non-classical coeliac disease	presents without signs and symptoms of malabsorption
Subclinical coeliac disease	is below the threshold of clinical detection. They have clinical or lab signs (IDA, enamel defects, osteoporosis, incidental VA) with no symptoms
Potential coeliac disease	normal small intestinal mucosa but increased risk of CD-positive serology
Coeliac disease autoimmunity	for those who have not had a biopsy but have at least two strongly positive tTG or EMA
Genetically at risk of coeliac disease	family members with CD that have HLA DQ2 or DQ8 positivity: 2–20% risk

Pathogenesis of Coeliac Disease

The pathophysiology of coeliac disease is not fully understood.

Coeliac disease occurs in genetically susceptible individuals in possession of particular human leucocyte antigen (HLA) class II molecules with approximately 95% of patients expressing HLA-DQ2 and the remainder HLA-DQ8 [38]. The HLA-DQ2 or DQ8 molecule is responsible for antigen recognition [39].

There are two mechanisms involved in the pathogenesis of coeliac that may be interlinked. What is not clear is the link between the epithelial response and the lamina propria response. There is an adaptive T cell response predominantly in the lamina propria as well as the innate response potentially driven by IL-15 and intraepithelial lymphocyte- enterocyte interaction. It is perhaps this response that is the initiator of the pathological process with the adaptive T cell response maintaining the inflammation. Pathological changes in the mucosa of coeliac individuals start to occur one hour after ingestion of gluten [40, 41] which is too early for an activated T cell response. Tissue transglutaminase is an intracellular enzyme that requires active secretion into the lamina propria to deamidate gluten peptides. The more peptides are deamidated the greater the available antigens for presentation to T cells. It may be that the innate response initiates the inflammatory cycle that is maintained by the adaptive T cell response.

Diagnosis of Coeliac Disease

Serology

The diagnosis of coeliac disease has changed recently in the paediatric population with the advent of improved coeliac immunological markers. Serum IgA and IgG antibodies against gliadin, reticulin, endomysium (components of connective tissue), tissue transglutaminase and deamidated gliadin peptides are detectable in individuals with coeliac disease. The expertise in immunofluorescence technique for EMA is being lost due to time constraints in modern immunology laboratories. The ease of using an ELISA based test means that IgG tissue transglutaminase antibodies are measured first line in individuals. Screening for serological markers is initially used for individuals who are at increased risk of coeliac disease: patients with non-specific symptoms; those with a family history of coeliac disease or patients with an associated condition such as Type 1 diabetes mellitus.

Approximately 2–3% of coeliac patients are IgA deficient [42] which can produce false negative EMA results. For this reason, it is recommended that serum IgA levels

be measured in those individuals at a higher risk of coeliac disease, those with symptoms or with a family history. IgA deficient individuals should be screened using an IgG based test.

Histology

The coeliac lesion predominantly affects the proximal small intestine with lessening damage occurring towards the distal small intestine. The pathology spans a spectrum of severity that has been classified into five stages by Marsh [43]: the pre-infiltrative, infiltrative, hyperplastic, destructive and hypoplastic (atrophic) lesions. These were subsequently modified by Oberhuber [44] to be able to use the classification for diagnostic purposes. The classification is summarised in Table 2. The parameters assessed in the diagnosis of coeliac disease on mucosal small bowel biopsy specimens include villous or crypt architectural changes as well as lamina propria cell density and intra-epithelial lymphocyte (IEL) cell counts.

These features form a continuum with normal mucosal architecture at one end and the classical flat lesion at the other end, which may take many years to develop. Marsh 1 is an increase in IELs counted per 100 enterocytes, the first and most sensitive index of the effects of gluten on the mucosa. Infiltration of gluten-dependent lymphocytes into the lamina propria is also seen. However, it is not pathognomonic for coeliac disease as they may be raised in infections for example. Marsh 1 is often seen in dermatitis herpetiformis, in treated coeliac disease, and in family members of those affected by coeliac disease. Figure 1 shows the histological changes of Marsh 3c lesion.

However, villous atrophy is not pathognomonic for coeliac disease as it can occur in the context of other disorders such as cow's milk allergy, giardiasis, rotavirus infection and autoimmune enteropathy [45].

Type 4 is a very rare hypoplastic lesion which is characterised by a flat mucosa but normal crypt depth and normal IEL count. It is probably a historic lesion seen in severely emaciated small children and most likely signifies malnutrition parallel findings in kwashiorkor [46].

Table 2 The modified Marsh classification

	Type 0	Type 1	Type 2	Type 3a	Type 3b	Type 3c
IEL/100 enterocytes	<40	>40	>40	>40	>40	>40
Crypts	normal	normal	hypertrophic	hypertrophic	hypertrophic	hypertrophic
Villi	normal	normal	normal	mild atrophy	marked atrophy	absent

Criteria for Diagnosis of Coeliac Disease

The required criteria for a diagnosis of coeliac disease were first proposed by the European Society of Paediatric Gastroenterology and Nutrition (ESPGHAN) in 1970 [47]. The original statement proposed that a diagnosis should be based on three criteria:

1. Structurally abnormal jejunal mucosa when taking a gluten-containing diet
2. Clear improvement of villous structure when taking a gluten-free diet
3. Deterioration of the mucosa as a result of a gluten challenge.

A patient underwent a minimum of three endoscopies for a definite diagnosis of coeliac disease. The criteria were revised in 1990 [48] after it was found that many gastroenterologists were not recommending a gluten challenge and a third biopsy. The revised criteria continue to emphasise that an initial biopsy is paramount. Histological examination showing the characteristic abnormalities, that is, lymphocytic infiltration, villous atrophy and crypt hyperplasia, on a gluten-containing diet provides the first step towards a diagnosis. In children under the age of 2 a gluten re-challenge and small intestinal biopsy is still required for the diagnosis of coeliac disease.

A definite symptomatic improvement within a few weeks of commencing a strict gluten-free diet would be consistent with a diagnosis of coeliac disease. A second biopsy may be carried out 3 to 6 months after commencement of the diet to confirm that there has been histological improvement as well as symptomatic relief [49]. If there is a symptomatic improvement but no histological recovery the gluten free diet should be verified and continued and a further biopsy taken after three months. It has been shown that complete mucosal recovery can take up to two years [50, 51]. Where there is still no histological response or symptomatic improvement it is recommended that patient compliance should be examined.

Those patients who do not respond to a strict diet may have refractory sprue, ulcerative jejunitis or intestinal lymphoma. A third endoscopy after gluten challenge is no longer a compulsory diagnostic step. It may be required however at a later date if the original diagnosis of coeliac disease is brought into question.

ESPGHAN decided in view of the improved serological testing available as well as the HLA DQ testing availability that there should be revised paediatric diagnostic criteria. This was precipitated by only 12% of paediatric gastroenterologists, who responded to a postal survey, adhered to the then current ESPGHAN guidelines [52]. The main transgression was the omission of gluten re-challenge in the under 2 age group. The algorithm proposed by the ESPGHAN working group on the diagnosis of coeliac disease is complicated but it aims to reduce the need for endoscopy which requires anaesthesia in the paediatric cohort. The new ESPGHAN diagnostic pathway in children who have classical symptoms of coeliac disease, with HLA-DQ2 or -DQ8, the genetic predisposition, and strongly positive tTG and EMA serology should not undergo endoscopic evaluation of the small intestine. Those who have the genetic predisposition and equivocal serology should proceed to a biopsy of the small intestine, as in those patients in whom the diagnosis in unclear [53].

Treatment

Gluten-Free Diet

Once a diagnosis of coeliac disease has been established, patients are advised to start a lifelong gluten-free diet. This involves the exclusion from the diet of any cereal that contains wheat gluten and prolamins from rye and barley or its derivatives, such as malt, or hybrid wheat varieties, such as spelt. The place of exclusion of oats from a gluten-free diet remains controversial. A typical gluten containing diet contains an estimated 10–20 g of gluten, derived from multiple sources and therefore a gluten free diet necessitates a calculated avoidance of many foods. A strict gluten-free diet is low in dietary fibre and folate, niacin and vitamin B_{12} [54–56]. Complying with a gluten-free diet is difficult for a number of reasons:

1. Gluten may contaminate food during harvesting, food preparation or processing [57, 58]
2. Gluten-free products are more expensive than gluten containing products and may be more difficult to source [59]
3. Dietary compliance is poor particularly in adolescents [60]
4. There is no agreed consensus on the minimal amount of gluten permitted in food: in Australia “no detectable gluten” is <5 mg/kg [61] whereas in Europe “gluten–free” is 20 mg/kg [62]
5. A wide variety of gluten sensitivities exist between patients: 50% of patients experience symptoms with an acute challenge whilst 50% do not
6. To improve palatability, many gluten-free products contain purified wheat starch which invariably contains residual gluten [57]
7. A gluten-free diet does not resolve the problems associated with the rare complication of refractory coeliac disease

Patients not adhering to a gluten-free diet are predisposed to numerous sequelae such as short stature [63], nutritional

deficiencies, early osteoporosis, secondary autoimmune disorders [64, 65], malignancies [66], infertility and poorer outcome of pregnancy [67]. However, a gluten-free diet has few side effects.

Naturally gluten–free cereals include rice, millet, maize and sorghum [68]. Quinoa, an Andean grain from Peru, has many benefits for a gluten-free diet as it is the only plant to have all essential amino acids as well as being high in minerals and vitamins. However, quinoa has similar prolamin content to wheat [69]. A recent study demonstrated that not all cultivars of quinoa are safe for coeliacs to eat as evidenced by T cell activation [70].

Products labelled as gluten-free have to adhere to strict permissible levels of gluten in Europe [62]. This standard was amended in 2008 to reduce permissible level of gluten in gluten-free foods. The change was ratified in January 2009 however manufacturers had until January 2012 to comply. Foods labelled as "gluten-free" must now contain no more than 20 mg/kg of gluten whereas foods labelled as "very low gluten" can contain between 21 to 100 mg/kg.

Oats in Gluten-Free Diet

Oats are more distantly related to wheat and are thought to be less toxic to coeliac patients. Several studies suggest that oats are safe for coeliac patients to eat [71–73] however, there are high dropout rates in both the Janatuinen studies [71, 72] in the oats group of patients. Janatuinen in his five year follow up study [72] only had 23 out of the original recruited 35 coeliac patients left, and in his study in 1995 [71] there was a 10% drop out rate in the group eating oats. Many commercially available oat products are contaminated with wheat, rye or barley [74]. Studies from Norway suggest that in a small minority of patients', non-contaminated oats are toxic [75, 76]. Avoidance of oats in the first year after diagnosis may help improve histology but an attempt should be made to reintroduce into the diet to help broaden the range of gluten-free foods.

Nutrient Replacement

Nutrient deficiencies should recede on commencement of gluten free diet but dietary supplements may be necessary. Recovery from anaemia can take between 6 and 12 months as intestinal mucosa reverts to normal [77]. After a diagnosis of CD patients should undergo a dual-emission x-ray absorptiometry scan to assess bone mineral density. Patients found to have a low BMD should be advised to strictly adhere to a gluten free diet, to avoid smoking and excessive alcohol intake, and take calcium and vitamin D supplements [78, 79].

Novel Therapies

A greater understanding of the pathogenesis of coeliac disease has allowed alternative treatments to be designed to act either as an adjuvant to a gluten-free diet, allowing for minor transgressions, or replace it all together through potential blocking of various postulated mechanisms [80]. The options include:

1. Modifying wheat in an attempt to reduce the toxic gluten epitope content
2. Degrading gluten to smaller peptides, not able to be presented to gluten-sensitive T cells, either *in vivo* or *in vitro*
3. Targeting tight junction proteins to ensure that they do not allow gluten to pass through
4. Tissue transglutaminase 2 blockade to reduce the deamidated peptides presented to gluten-sensitive T cells
5. Reducing HLA-DQ peptide presentation to gluten-sensitive T cells by amino acid substitution of gluten T cell stimulatory sequences
6. Immune system modification either by naturally occurring gluten peptide sequences or helminth infection
7. Targeting inflammatory cytokines with biological therapies, such as anti-IL15
8. Vaccination with gluten peptides in order to induce immune tolerance
9. Intra-nasal administration of T cell immunostimulatory gluten epitopes to induce tolerance

Many of the options above are a long way off from market as they are in the early stages of development and testing in animal or human subjects. However, this is a rapidly-expanding, market-driven, in part, by the wish of coeliac individuals for an alternative to a gluten-free diet. The main drawback facing researchers is that a gluten-free diet has few side effects. Therefore, for a treatment to be recommended in the treatment of coeliac disease, it has to have an acceptable low number of side effects.

Complications and Associations of Coeliac Disease

Non-responsive Coeliac Disease

Approximately 30% of individuals with coeliac disease fail to improve symptomatically with a gluten-free diet [81]. Non- responsive coeliac disease is defined as continued symptoms in patients on a gluten free diet. A study published demonstrated that 45% of non-responsive coeliac patients continued to ingest gluten, either inadvertently or deliberately. Eleven percent of non-responsive coeliac disease patients had concomitant microscopic colitis, 9% had small

bowel bacterial overgrowth (SBBO), 7% had evidence of inflammatory bowel disease as well as coeliac disease and 6% also had lactose deficiency. Some patients had more than one reason for continued symptoms. Eight out of 100 patients were found to have refractory coeliac disease (see Refractory coeliac disease below). Overall in 90% of non-responsive coeliac disease a remediable cause could be found [82].

Coeliac Disease and other Immunological Disorders

The raised prevalence of the DR3/DQ2 haplotype in patients with specific autoimmune disorders indicated a common genetic factor may confer a susceptibility to autoimmune disease. There is a well established association between coeliac disease and a number of autoimmune disorders, particularly type 1 diabetes mellitus (T1DM). 3–6% of the patients with T1DM have coexisting coeliac disease [83, 84] and share similar genetic variants [85]. Autoimmune thyroid disease (Grave's and Hashimoto's) and Sjögren's syndrome are also recognised associations. Evidence indicates that a gluten free diet may protect against the development of autoantibodies; adolescent patients not compliant with a gluten free diet have been found to have raised serum levels of antibodies against endocrine tissue [86]. A study in 1999 reported that a longer duration of exposure to gluten may give an increased risk of developing autoimmune disorders [87]. However, a subsequent study contradicted these findings [88]. This was a similar study but accounted for additional factors such as patient compliance to a gluten free diet. No correlation was found between duration of gluten exposure and onset of autoimmune disorders.

Neurological Manifestation

Neurological manifestations have been reported in coeliac patients for a number of years, but it is only recently that these neurological associations have been studied in depth. Peripheral neuropathy, myopathy, myelopathy, dementia, migrane and epilepsy are all associated with coeliac disease. A group in Sheffield, reported gluten sensitivity, based on the presence of anti-gliadin antibodies, in patients with neurological disorders of unknown cause. The majority of these patients had ataxia or peripheral neuropathy [89]. The terms gluten ataxia and gluten neuropathy have been coined to describe these disorders. Duodenal biopsy showed coeliac disease to be present in only a third of patients [90, 91]. The concept is still controversial as gluten sensitivity has also been found in hereditary ataxias, and response to a gluten-free diet in many patients is lacking [92]. Nevertheless, supporting evidence for idiopathic gluten ataxia continues to accumulate, such as the association with HLA-DQ2 and DQ8, the presence of circulating Purkinje cell antibodies and the presence of anti- tissue transglutaminase antibody in the gut and brain. Moreover, 60% of patients have evidence of cerebellar atrophy on MRI scanning and proton MR spectroscopy may also be abnormal, indicating abnormal cerebellar function [91]. The authors observed that improvement of these conditions may occur on a gluten-free diet.

The reason why some patients develop these neurological problems could revolve around a newly identified tissue transglutaminase, transglutaminase 6. Antibodies to tTG6 have been detected in a group of patients with idiopathic sporadic ataxia [93]. This work further extends the concept of gluten sensitivity beyond the bowel, coeliac disease, and the skin, dermatitis herpetiformis, to involve the nervous system.

Refractory Coeliac Disease

A rare complication of coeliac disease is refractory coeliac disease, when clinical symptoms and histological changes persist or recur after a good response to a gluten-free diet, after other causes of villous atrophy having been excluded. Intestinal mucosal recovery on commencement of a gluten free diet can take up to 2 years [50] and it may therefore be necessary to delay a diagnosis of refractory coeliac disease until at least one year on a gluten free diet.

Refractory coeliac disease can be classified according to the immunophenotype of intra-epithelial lymphocytes. Abnormal clonal lymphocytes with loss of surface markers CD8 and CD3 occur in type 2 RCD whereas in type I RCD the majority of lymphocytes have normal surface markers and T cell receptors are polyclonal [94]. Differentiation between the different types of refractory coeliac disease is important as the reported five-year survival rate varies between 40% and 58% for type 2 RCD [95–98], and 93% in type 1 RCD [97]. The main cause of death in type 2 RCD is progression to an enteropathy associated lymphoma with a 5-year survival rate of 8–20% [96, 99] as well as progressive malnutrition. Some of these patients are on parenteral nutrition to help with the management of their malnutrition and their small bowel histology do improve.

Ulcerative Jejunitis

Ulcerative jejunitis is another cause of non-responsive coeliac disease. It is a rare disorder characterised by ulceration of the jejunum and ileum. Scarring often occurs, leading to stricture formation with alternating areas of dilated small bowel. Ulcers can be of varying depth and can extend through the entire thickness of the bowel leading to perforation [100].

Like type 2 refractory coeliac disease, ulcerative jejunitis is characterised by non-lymphomatous monoclonal T cell population in the epithelium. These intraepithelial lymphocytes from Type 2 refractory coeliac disease and ulcerative jejunitis have been shown to share an identical aberrant immunophenotype to those found in enteropathy associated T cell lymphoma [101]. They are therefore considered to be part of a spectrum of neoplastic T cell disorders. As a result, the mortality is high due to obstruction, bleeding and perforation. Steroids are commonly used to treat the ulceration and a strict gluten-free diet is essential. In patients with ulcerative jejunitis, their small bowel often allows easy translocation of gut bacteria and sepsis is an early feature of this condition.

Malignancy

Early reports suggested a large increase in risk of gastrointestinal cancer in coeliac disease. With relative risk ration of 10 for oesophageal and 40 for non-Hodgkin's lymphoma, with a higher risk if non-compliant with a gluten-free diet [66]. Several other studies seemed to confirm the high relative risk of all site lymphoma in the range 30–100. Some of this data has managed to infiltrate and perpetuate itself in the literature. Most of the above data was based on cancer case-finding and inherently includes major acquisition bias. Later data suggests a more conservative doubling of risk for all cancers and, in particular, a relative risk of 6 for lymphoma [102]. Population-based studies have provided more convincing estimates of overall cancer risk and indicate only a small increase above the background population. This risk is negated if the first year after diagnosis of coeliac disease is excluded, which again accounts for a degree of acquisition bias.

The risk of both enteropathy associated T cell lymphoma and small bowel adenocarcinoma are elevated, the later many fold. A wealth of collected data exists as the incidence of cancer is one of the leading causes of concerns for coeliac patients as well as their gastroenterologists [64, 103–111].

The Italian Working Group on Coeliac Disease and Non-Hodgkin's lymphoma gathered data from 693 patients with Non-Hodgkin's lymphoma and found only 0.92% had a diagnosis of coeliac disease, with a calculated relative risk of 3 for Non-Hodgkin's lymphoma for coeliac patients, although the figure was 19 for EATL [105]. Mearin et al. [111] have reported on a prospective review in 10 European countries of 1446 Non-Hodgkin's lymphoma adults and matched controls, which indicated an odds ratio of 2.6 (1.4–4.9) for Non-Hodgkin's lymphoma. Importantly this risk was only significant for those diagnosed clinically prior to the study and not those with silent coeliac disease.

Survival from EATL is abysmal, with a five-year survival rate of 8–20% [96, 99]. As these cancers are particularly rare (0.5 to 1 in 1,000,000 annual incidence), their actual incidence in coeliac disease remains low, in the order of 1 case per 5500 patient years or less with a relative risk of 4.27 (2.36–7.74) [64]. EATL has a peak incidence in the jejunum in the sixth decade and is associated with refractory gastrointestinal symptoms, although it can present at extra-intestinal sites. It is probable that refractory coeliac disease and ulcerative jejunitis are the precursors to EATL with identical aberrant immunophenotype IELs [101]. Treatment options for these conditions are being evaluated to try to prevent progression to EATL.

Adenocarcinoma of the small intestine is a rare cancer, over represented in coeliac disease. In a British Society of Gastroenterology survey published in 2003, details of 175 cases of small bowel adenocarcinoma were collected over two years and 13% were found to be associated with coeliac disease, with two thirds presenting in diagnosed coeliac patients with a median length of diagnosis of 8 years. These patients had a 58% survival at 30 months, which equated to the absence of metastasis at presentation [107].

A recent publication suggests that patients with non-symptomatic coeliac disease have no increased risk of lymphoproliferative malignancy [112].

However, there can be some protective effects of coeliac disease. The reason behind a reduced risk of lung and breast cancers are not clear [64, 104, 113–116]. A population-based survey suggested that there are potentially adverse as well as favourable breast cancer risk profiles in coeliac disease compared to the general population [117].

Eosinophilic Enteritis

Eosinophilic enteritis is a rare primary eosinophilic gastrointestinal disorder of unknown aetiology which is characterised by the rich infiltrate of eosinophils on histological examination of the mucosa [118–120]. It is part of a group of eosinophilic disorders of gastrointestinal tract involving the oesophagus, small intestine and colon. Eosinophilic enteritis causes a wide array of symptoms such as abdominal pain, nausea, vomiting, diarrhoea, bloating or ascites. Table 3 shows the array of symptoms for each of the diseases. As these symptoms are non- specific, a high index of suspicion need to be maintained in order to diagnoses eosinophilic enteritis.

Table 3 Primary eosinophilic gastrointestinal disorders

	Eosinophillic oesophagitis	Eosinophillic enteritis	Eosinophillic colitis
Forms	Atopic Non-atopic Familial	Mucosal Muscular Subserosal	Atopic Non-atopic
Definition	Eosinophillic infiltration of the oesophageal mucosa without other intestinal segment involved	Gastrointestinal symptoms and eosinophilic infiltration of one or more intestinal segment	Children Eosinophillic infiltration of the colon Atopy or cow's milk protein allergy
Main clinical characteristics	Dysphagia Vomiting Food impaction	Abdominal pain Diarrhoea Obstruction Ascites	Diarrhoea Rectal bleeding

From ref. [121] Pineton et al

Diagnosis

Eosinophils normally reside in the lamina propria of the gut apart from the oesophagus. The eosinophil count of the lamina propria increased from duodenum to caecum and reduces from caecum to rectum. This means that the cut off values for the diagnosis rely on the accurate location of the tissue sample. In the duodenum, most studies quote a level of 20 eosinophils per high power field (×400) for the diagnosis of eosinophilic enteritis [122]. Apart from eosinophils in the lamina propria, other signs on histology in favour for eosinophilic enteritis are eosinophils in the epithelial or muscle layers, degranulation of eosinophils, villous atrophy, crypt hyperplasia or abscesses, and epithelial degenerative or regenerative changes.

The diagnosis of eosinophilic enteritis requires pathologic eosinophilic infiltration of at least one part of the intestinal wall and the exclusion of secondary eosinophilia. Eosinophils could be seen in any segment of the small intestine but were most commonly seen in the stomach and duodenum. They could also be seen in any layer within the small intestine: Klein et al. [119] described three anatomical variants based on the eosinophilic infiltration of the mucosa, intestinal muscle or. Thus, the diagnosis of eosinophilic enteritis requires the symptoms associated with a pathological eosinophilic infiltration of the small intestine with the exclusion of secondary causes of eosinophilia (in Table 4).

Table 4 Secondary causes of eosinophilia

Diagnosis	How to investigate
Hypereosinophilic syndrome Persistently elevated eosinophil count ≥1500 eosinophils/mm^3 for at least 6 months	• Clinical observation with testing for involvement of either the heart, nervous system or bone marrow • Testing for mutations involving the PDGFRA and FIP1L1 genes • T cell clonality
Gut infections	
Intestinal parasites Ascariasis, toxocariasis, trichinosis, schistosomiasis, teniasis, ankylostomiasis, trichuriasis, stronglyoidiasisenterobiasis	Patient medical history, stool parasite examination, serology (toxocariasis, trichinosis, schistosomiasis, teniasis), antiparasitic treatment
Helicobacter pylori, *Escherichia coli*, *Shigella*	Gastric biopsies, stool and blood cultures
Drugs and toxic substances Gold therapy, oral hypoglycaemiac agents, psychotropic drugs, antibiotics, NSAIDs	Patient medical history
Inflammatory bowel disease	Upper GI endoscopy and colonoscopy
Coeliac disease	Anti-tissue transglutaminase antibody and distal duodenal biopsy demonstrating villous atrophy
Vasculitis and autoimmune diseases Periarteritis nodosa, eosinophilic granulomatosis with polyangiitis, scleroderma	ANCA, anti-nuclear antibodies, vascular biopsies, clinical examination
Malignancy	Imaging studies, histology

Clinical Characteristics and Natural History of Patients with Eosinophilic Enteritis

Patients with eosinophilic enteritis can present with a variety of non-specific symptoms [122, 123]. Common symptoms would be abdominal pain, diarrhoea, bloating and nausea whereas jaundice, ascites, rectal bleeding and vomiting are less frequently seen. They often present with a complication of their disease as the index presentation [124]. The clinical presentation depends on the depth of intestinal wall involved. This was classified by Klein et al. [119] into three different forms of the disease according to the layer of intestinal wall involved:

- The mucosa form characterised by predominant mucosal inflammation causing diarrhoea, abdominal pain, signs of malabsorption or protein losing enteropathy

- The muscular form characterised by intestinal strictures with abdominal pain, nausea and vomiting which can lead to obstruction
- The subserosal form characterised by an eosinophilic-rich ascites with bloating and abdominal pain.

The occurrence of these forms varies in the literature, in part due to less surgical specimens being sent to help diagnose the muscular form of the disease [122, 125].

Patients with eosinophilic enteritis may vary in their presentation depending on how extensively the gut is involved. The most common sites to be involved would be the stomach and proximal small intestine, seen between 40–80% of patients with eosinophilic enteritis. The more extensive the disease the more likely to have protein losing enteropathy, malabsorption and iron deficiency anaemia. Biopsies of all parts of the gastrointestinal tracts are required to diagnose the enteritis.

An elevated peripheral eosinophil count can be seen [125]. More than 70% of patients with eosinophilic enteritis will have a transient high (>500/mm^3) eosinophil count during a flare. If the eosinophil count is >3000/mm^3, then the patient is likely to have predominantly subserosal involvement. An absence of peripheral eosinophilia should not exclude the diagnosis of eosinophilic enteritis.

Elevated IgE levels can also be seen in approximately 505 of patients. In eosinophilic patients with protein losing enteropathy, malabsorption or intestinal inflammation hypoalbuminaemia, iron deficiency, steatorrhoea and a high CRP can be seen [124].

Imaging studies are often non-specific and only intestinal biopsies will lead to the diagnosis. Upper gastrointestinal endoscopy and ileo-colonoscopy may be macroscopically normal or show slight erosions, oedema, erythema or nodules [126]. Capsule endoscopy can be used to examine the whole small intestine but does not allow biopsies of the areas [127].

The natural history of the disease follows three courses [125]:

- A single flare (42%)
- A recurring course with multiple flares and period of full remission from 2 months to several years (37%)
- A continuous course (21%)

Pineton de Chambrun et al. [125] found patients with predominantly mucosal disease accounted for 80% of patients with continuous course to their disease. Over 50% of the cases of patients with a single flare, without disease recurrence, had subserosal forms of the disease. There was also no occurrence of myeloproliferative disorders. Reed et al. [128] found that only a third of patients with eosinophilic enteritis remained in remission, with the many patients presenting with a persistent or progressive disease course.

Treatment

The treatment of eosinophilic enteritis can be challenging as there are no clear recommendations and very little evidence base in the literature [129]. Treatments which have been already used and evaluated are discussed below however, 40% of patients will have a spontaneous remission of eosinophilic enteritis.

Diet

Several dietary strategies have been proposed. If there is a clear and limited precipitant, identified on food allergen testing, then this should be avoided. When many or no allergens have been identified, a more aggressive empiric elimination diet or elemental diet can be tested. There is not enough evidence in the literature to recommend these in routine management.

Corticosteroids

The use of corticosteroids is one of the main treatments of the patients with eosinophilic enteritis [130, 131]. Most case series have reported good efficacy of corticosteroids with clinical remission achieved in 50–90% of patients with eosinophilic enteritis [128, 132].

Treatment should be started at 0.5 to 1 mg/kg for a few weeks before tapering the dose over 6 to 8 weeks [129]. After this approximately 20% of patients will have steroid dependency requiring low dose prednisolone to maintain clinical remission. To avoid the side effects of corticosteroids, Budesonide could also be used. Budesonide is effective at 9 mg per day for the induction and maintenance of clinical remission in patients with eosinophilic enteritis [133–140]. The dose can be tapered to 6 mg and then 3 mg per day for maintenance therapy, if required.

Azathioprine

Azathioprine can be used in patients with eosinophilic enteritis who are either refractory to or dependent on corticosteroids. The usual dose of eosinophilic enteritis patients is similar to the dose used in inflammatory disease patients at 2–2.5 mg/kg [141].

Biologics

There have been some reports of biological agents being used in eosinophilic enteritis. Mepolizumab, an anti-IL5 monoclonal antibody, having previously been used in eosinophilic oesophagitis, may be an alternative to patients with a complicated disease course. Mepolizumab was reported as having improved the tissue and peripheral eosinophilia in four patients with eosinophilic enteritis but it did not relieve symptoms [129]. Omalizumab, an anti IgE monoclonal antibody, has also been tested for the treatment of eosinophilic enteritis with improvement in histology [142]. Infliximab and adalimumab, two anti-tumour necrosis factor monoclonal antibodies, were reported as effective in inducing remission in refractory eosinophilic enteritis in some case reports [143].

Other Treatments

Other treatments used to treat patients with eosinophilic enteritis include antihistaminic drugs, montelukast and sodium cromoglycate [131]. Montelukast, a selective leukotriene inhibitor used to treat asthma, can be used at 5–10 mg per day [51–56]. Sodium cromoglycate, a mast cell stabiliser blocks the release of immune mediators and subsequent activation of eosinophils, has only had a few case reports [144]. Ketotifen, a second generation H1-antihistamine agent, is used to inhibit the release of mast cell mediators [145]. The results of these drugs in patients with eosinophilic enteritis are conflicting and need further larger, prospective studies.

Intestinal Failure in Critical Care

Moran Hellerman Itzhaki and Pierre Singer

Key Points

1. Nutritional assessment and requirements on an intensive care unit (ICU) can be difficult to determine. Weight changes, indirect calorimetry (measuring CO_2 production) and a CT scan at L3 are helpful.
2. It is estimated that 1% muscle mass is lost per day on ICU.
3. In acute injury (trauma/major surgery) nutritional support aims to provide 70% of the nutritional target by day 3 and increase further in the post-acute phase.
4. Glutamine and Ω3 fatty acid supplements may be beneficial especially glutamine for burns (>20%) and trauma patients.
5. Relatively tight blood glucose control aims to keep the blood glucose to less than 10 mmol/L.
6. If there is a gastric aspirate of more than 500 ml at any time (often occurs with sepsis) then postpyloric feeding and prokinetic drugs should be considered.
7. Opiate drugs, cyclizine and many other drugs can inhibit gastrointestinal motility.
8. Enteral nutrition (EN) is preferred but if it fails to provide the target amount, supplementary parenteral nutrition may be given.

Introduction

Intestinal failure is a common condition in critically ill patients that may lead to severe morbidity or even death. Early diagnosis and proper treatment are mandatory to prevent such complications. This chapter will discuss the recognition of malnutrition and the complex planning nutritional support in the critically ill with emphasis on nutritional targets, macronutrients and the place of supplements in nutritional therapy. Specific populations, such as those with sarcopenia, diarrhea and the refeeding syndrome will be discussed in detail, along with current topics in intensive care such as COVID-19.

Definition and Etiology

Intestinal failure has been defined as "the reduction of gut function below the minimum necessary for the absorption of macronutrients and/or water and electrolytes, such that intravenous supplementation is required to maintain health and/or growth. The reduction of gut absorptive function that doesn't require intravenous supplementation to maintain health and/or growth, can be considered as "intestinal insufficiency"" [1]. The estimated prevalence of acute intestinal failure in the acute hospital setting varies between 1.3% and 61% [2]. In the intensive care unit (ICU) about 8% of the patients suffer from intestinal failure [2]. Intestinal failure is classified into three types. Type 1 is an acute and self-limiting condition associated with critical illness or postoperative period. Type 2 is a less common form of acute intestinal failure following catastrophic abdominal events combined with sepsis and metabolic complications. It usually requires intense management with prolonged intravenous support. Type 3 is a chronic form of intestinal failure, either as a consequence of type 2 acute IF or of a chronic medical condition [1]. Acute IF in critically ill patients was graded by Blaser et al. according to severity of the symptoms and the interventions required (Table 1) [3]. The clinical manifestations of intestinal failure in critically ill patients vary according to specific pathophysiologic processes. The short bowel syndrome most commonly develops following extensive bowel resection, either as part of an acute exacerbation of a chronic disease or due to abdominal catastrophic events (trauma, ischemia, perforation, etc.). It will usually manifest as extensive intestinal loss of fluids and electrolytes. Intestinal fistu-

Table 1 Classification of acute gastrointestinal injury (AGI)

AGI Grade	Definition	Clinical presentation
NO AGI	No GI malfunction	No GI symptoms
AGI grade 1	Risk for GI failure	• Nausea and/or vomiting (Post abdominal insult) • Absence of bowel sounds (following abdominal surgery, anesthetic or opioid therapy, shock) • Mild diarrhea • Abdominal distention
AGI grade 2	GI malfunction with symptoms requiring treatment	• Gastroparesis/large GRV • Severe diarrhea (causing fluid and electrolytes imbalance) • IAH (12–15 mmHg) • Visible GI bleeding
AGI grade 3	GI dysfunction progress despite treatment with systemic deterioration	• Large GRV/Vomiting/GI paralysis persist despite treatment • Severe IAH • Severe diarrhea • Abdominal sepsis • Ileus
AGI grade 4	Life threatening GI failure	• Bowel ischemia/necrosis • GI bleeding causing hemorrhagic shock • Acute colonic pseudo-obstruction • Abdominal compartment syndrome

Modified from Blaser et al. gastrointestinal failure in the ICU. Curr Opin Crit Care 2016; Apr 22(2):128–141
AGI acute gastrointestinal injury, *GI* gastrointestinal injury, *GRV* gastric residual volume, *IAH* intra-abdominal hypertension

lae may also occur as a complication of chronic inflammatory bowel disease, a persistent abdominal infection or a surgical complication. A fistula may cause a similar loss of fluid and electrolytes as well as a systemic metabolic response that is a part of sepsis. Chronic processes, such as intestinal tumors or chronic inflammation, are generally not acute in nature. However, the clinical implications of mechanical obstruction may be severe and life threatening, often requiring intensive care. Intestinal dysmotility is a common manifestation of IF in ICUs. Many factors are associated with its development, the most common being medications, systemic inflammation, post-operative states and metabolic disorders. It may then present as non-mechanical bowel obstruction (paralytic ileus) and delayed gastric empting (gastroparesis), both of which will be discussed later. Malabsorptive conditions often manifest as diarrhea. This is common in critically ill patients, are often secondary to medical treatments, infection or artificial nutrition, and may require close monitoring and nutritional supplementation [2].

Screening and Assessment of Malnutrition

In order to identify critically ill patients at risk of acute IF that may benefit from nutritional support, nutritional screening and assessment must be performed. Malnutrition is a common phenomenon, with reports of prevalence rates as high as 50% among hospitalized patients, depending on their clinical status, age and medical condition [4]. Critically ill patients are particularly vulnerable owing to the acute nature of their illness and co-morbidities potentially limiting their ability to eat and absorb food. There are many objective and subjective methods of assessing the risk of malnutrition in hospitalized patients, with the subjective global assessment (SGA) being one of the few tools validated in the ICU setting [5]. SGA includes five anamnestic components (weight changes, nutrition intake, gastrointestinal (GI) symptoms, functional capacity and metabolic stress) and two physical components (signs of muscle wasting and fluid balance). Laboratory parameters such as albumin and prealbumin levels are extremely affected by inflammation/saline administration and are therefore not useful for the diagnosis of malnutrition [6, 7]. Rattanachaiwong et al. compared several diagnostic tools for malnutrition in ICU patients and found the nutrition risk screening (NRS) to be more sensitive and specific than the SGA [8]. In 2019 the European Society of Enteral and Parenteral Nutrition (European Society of Clinical Nutrition and Metabolism) (ESPEN) proposed the global leadership initiative on malnutrition (GLIM) criteria for the diagnosis of malnutrition. The GLIM criteria include phenotypic characteristics like unintentional weight loss, low basal metabolic index (BMI) and loss of muscle mass, and etiologies including reduced intake or absorption, inflammation and disease severity [9]. A paper published by Theilla et al. found that the GLIM criteria had a high sensitivity of 85% and specificity of 79% compared to the SGA, considered to be the gold standard in the ICU [10]. They concluded that the GLIM criteria are acceptable for use in the ICU. Reduced muscle mass is not only a phenotype of malnutrition but also a strong predictor of increased mortality, prolonged mechanical ventilation and a protracted hospitalization course [11, 12]. Assessment of body composition may provide insight into patient-specific characteristics of malnutrition. Body composition may be studied using several commercially available methods. Bioelectrical impedance is a quick, non-invasive, low-cost technique that does not expose the patient to radiation and is performed at the bedside. Bioimpedance uses low voltage electrical currents to identify different components of the body. Conduction alternation allows for the measurements of the fat mass and the fat free mass (FFM). FFM is mainly composed of water, proteins and carbohy-

drates [12]. A long-established method for assessing body composition is dual energy X ray absorptiometry (DXA). DXA was originally used to measure mineral bone density but now can be used to measure all three major tissue components of the body (fat mass, lean mass and bone mineral mass) [13] DXA is well validated and requires slight radiation exposure. However, it is rarely used in the ICU as it seldom available [12]. Computed tomography (CT) may be employed to assess body composition. It offers information on specific compartments, including dividing adipose tissue into visceral and subcutaneous and characterizing specific skeletal muscle groups. One technique is the use of single slice CT, usually at the level of L3, which provides information on several muscle groups, and correlate with whole body muscle mass [14]. In a retrospective study of 240 ICU patients, Weijs et al. examined the effect of low skeletal muscle area on mortality. A single slice CT scan showed reduced muscle area in 63% of the patients in both sex groups, with evidence of increased mortality compared to those with preserved muscle area (OR 3.86 [1.8–8.26]) [15]. A major disadvantage of this technique is the exposure to radiation, rendering it difficult to justify without other indications. The patient's clinical condition and the risk of mobilizing a patient outside of the ICU must be considered as well. Point of care ultrasound is an increasingly popular technique used in the ICU that provides the clinician with viable information at the bedside without radiation exposure. When ultrasound was studied for body composition assessment, it showed only moderate correlation with other modalities. The lack of consensus on the preferred site and method of measurement makes existing clinical data hard to compare [12].

Sarcopenic Obesity As previously mentioned, the risk of sarcopenia in the ICU is extremely high, with a prevalence of more than 90% and muscle mass loss of nearly 1% a day [16]. Accelerated catabolism, inadequate nutrition and immobilization are all major causes for sarcopenia in the critically ill. Obesity is another common condition in the ICU as worldwide prevalence increases. Although obesity holds an increased risk for co-morbidities and may limit treatment options, there is evidence for decreased ICU mortality in obese patients compared to non-obese, sometimes referred to as the obesity paradox [17]. Muscle mass in obese individuals is highly related to physical activity and age. In addition, characteristic muscle changes seen patients with obesity may impair muscle function. Given the impact of sarcopenic obesity on ICU patients' outcomes, specific measures should be taken to minimize it [4]. Other than intense physical therapy, personalized nutrition strategies are needed. Recent guidelines recognize the pitfall of using "ideal body weight" to calculate energy requirements in obese individuals as it neglects the metabolic demand of adipose tissue. It is therefore advocated by some to add a correction factor of 20–25% of excess weight (actual body weight - ideal body weight) to the ideal body weight [18]. Another strategy is to combine a relatively low number of calories with high protein intake (2–2.5 g/kg/day) [19].

Nutritional Targets

The importance of determining the proper nutritional targets for critically ill patients is well documented. In a large Cohort study, Zusman et al. showed a non-linear connection between the caloric intake of ICU patients and 60-day mortality. As caloric intake increased and reached 70% of resting energy expenditure (REE) assessment, mortality was reduced**.** On the other hand, mortality increased as caloric intake was above 100% of REE [20]. The clinical course of critical illness is divided in several phases. The hyperacute phase of hemodynamic instability often leading to ICU admission. The acute phase composed of the early period with marked catabolism and metabolic instability and the late period characterized by stabilization of metabolic disturbances and significant muscle wasting. This will be followed by the post-acute phase of persistent inflammation or rehabilitation [18]. In the acute phase there are alternation in hormone levels such as glucagon, cortisol and epinephrine increasing insulin resistance and gluconeogenesis. In addition, cytokines release including TNF-α, IL-1, IL-2 and IL-6 increases protein breakdown and insulin resistance. Increased glucose production, lipolysis and protein breakdown all lead to significant endogenous substrate production observed in early phases of acute illness [21]. In order to avoid overfeeding it is recommended to start nutritional support gradually with the nutritional target of 70% of REE in the first three days of ICU admission and gradually increase nutritional support upon patient's stabilization until reaching 80–100% of REE by day 5–7 [18]. Indirect calorimetry (IC) has been established as the gold standard for REE measurement [18, 22–24] and is considered the best strategy to reduce over/under feeding [18, 22]. Nevertheless, this technology is not available in all intensive care units and not applicable in clinical situations such as mechanical ventilation in high oxygen concentrations (FIO2 > 0.7), chest drains, and usage of nitric

oxide or helium. Predictive equation for REE estimation such as Harris-Benedict, Faisy-Fagon or Penn State have shown poor agreement with IC [25]. A recent large retrospective study by Zusman et al. demonstrated poor accuracy of the predictive equations [26]. An alternative method is to estimate energy expenditure from carbon dioxide production (VCO_2) values obtained from the ventilator in invasively ventilated patients [27]. Many respirators can measure VCO_2 and calculate REE by using the Weir formula and determining the respiratory quotient (RQ). This approach is controversial, as while some studies show high levels of accuracy, others show less encouraging results [28, 29]. One of the main limitations of measuring VCO_2 is the need for a predefined RQ. RQ, defined as the division of $VCO_2$by VO_2, is a constant influenced by many factors, including ventilator settings and acid-base balance, all of which are extremely dynamic in critically ill patients. In a retrospective study by Kagan et al., an RQ of 0.89 showed the best correlation between IC and VCO_2 measurement [30]. Nonetheless, it seems that the use of VCO2 measurement is the best alternative to IC if the latter is not available, with better accuracy than predictive equations. After determining the estimated energy expenditure, 70% of estimated needs should be prescribed in the first days of ICU admission and full nutritional support should be reached within three to seven days [18].

Non Nutritional Calories products that contain high caloric index and with little nutritional value are considered non nutritional calories (NNCs). In the intensive care these are mostly derived from the dextrose, citrate and the drug propofol. If nutritional plans do not take these "hidden" calories into account, the risk of overfeeding increases. Propofol is a general anesthetic commonly used in the ICU. It contains soybean oil, egg phospholipids and glycerol. Propofol contains 1.1 kcal/ml which translate into several hundred daily calories for the average sedated patient in the ICU [31]. 5% Dextrose contains 3.6 kcal/g, meaning a 1 liter infusion of 5% dextrose provides around 200 kcal of NNCs. Citrate is a regional anticoagulant used in continuous renal replacement therapy (CRRT). Its caloric value is difficult to calculate as it varies from between various preparations. It also depends on blood flow, infusion rate and filter characteristics of the CRRT circuit. Trisodium citrate, for example, contains 3 kcal/g [31]. A retrospective study examining the relevance of NNCs in the ICU revealed that in the first day of ICU admission about 31% of the patient's caloric intake were NNCs. By day 4 that number decreased to 6% [31]. It is important to know that on day 1 patients tend to receive a very little nutrition, largely precluding the risk of overfeeding.

Macronutrients

The nutritional composition of macronutrients require adaptations as the clinical condition changes. **Carbohydrate** absorption is delayed during critical illness. However, the glycemic response to carbohydrate ingestion is prolonged, in effect increasing the incidence of hyperglycemia [32]. Carbohydrates are essential in nutritional formulas in order to reach caloric targets, but the recommended upper limit for carbohydrates is 5 mg/kg body weight/min. Low carbohydrate enteral formulas were introduced in the past to critically ill patients in order to facilitate ventilator weaning. The hypothesis that low carbohydrate would lead to low carbondioxide production did not translate into clinical benefit [33]. Low carbohydrate formulas are mainly prescribed to diabetic patient for better glycemic control [34]. These formulas failed to show significant benefit in lowering glucose variability in the general ICU population [35]. As earlier parenteral nutrition formulas contained mostly carbohydrates, hyperglycemia posed a serious concern for patients receiving them. As technology progressed and lipids emulsions became more stable, the amount of carbohydrates in parenteral nutrition decreased and so did the prevalence of hyperglycemia. Glycemic control is still considered a crucial issue in the management of critically ill patients and it comprises not only controlling absolute glucose concentration but also glucose variability and time in optimal glucose range. In 2001 van den Berghe et al. examined the effect of tight glycemic control (glucose between 4.4 and 6.1 mmol/L) in critically ill surgical patients. Her group found that tight control led to improved mortality rates [36]. However, these results have not been reproduced. In the NICE-SUGAR 2009 study, intensive glycemic control led to increased hypoglycemic events and mortality. The authors suggested blood glucose level targets of 10 mmol/L or less, as they had better outcomes compared to lower values [37]. According to recent studies there is no optimal glucose value below 10 mmol/L that shows additional mortality benefit [38]. Several studies in critically ill patients have shown that high glucose variability increased mortality independently of mean glucose levels [39–41]. As previously mentioned, prognosis improved the longer patients spent within the proper glucose range, and those achieving good glycemic control for more than 80% of the time had better clinical outcomes [42, 43].

Lipids are another cornerstone of nutrition formulas. Enteral formulas are rich in lipids, either medium chain triglycerides (MCTs) or long chain triglycerides (LCTs). Fish oil is rich in the omega-3 (Ω-3) polyunsaturated fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid

(DHA). These affect the inflammatory process, including in the immune response, coagulation, vasoactivity and bone metabolism. They are also essential for neuronal, behavioral and visual development [44, 45]. A recent systematic review showed the benefit of supplemental fish oil in patients with acute respiratory distress syndrome (ARDS), decreasing the length of ICU stay and increasing ventilator-free days, but had no effect on mortality. The authors noted these results should be interpreted with caution as the review was based on low quality trials [46]. ESPEN guidelines conclude that enteral formulas enriched with omega-3 fatty acid may be safely administered, while high dose omega-3 fatty acid preparations should be avoided [18]. Lipid emulsion designed for parenteral nutrition have been improved, starting from soybeans as a source for LCTs to MCT based emulsions, followed by olive oil based formulas and finally formulas enriched with fish oil. Soybean oil contains high levels of omega-6 (Ω-6). There is increased concern regarding the use of omega-6 fatty acids, specifically Linoleic Acid (LA) due to their pro-inflammatory and immunosuppressive effects [47, 48]. LA also suppresses the synthesis of EPA and DHA, potentially reducing their beneficial effects. Olive oil based formulas are considered good alternatives. In a meta-analysis by Dai et al., the authors concluded these formulas were safe, were associated with increased antioxidant levels as well as lower Ω-6 levels while not leading to significant differences in most liver enzymes [49]. Pradelli et al. performed a meta-analysis on the effects of Ω-3 enriched parenteral formulas and found their use was associated with lower infection rates, shorter ICU stays and non-significant trends for reduced mortality rates [50]. The ESPEN guideline authors conclude that lipid emulsions enriched with fish oil based fatty acids may be safely prescribed to patients receiving PN [18].

Protein intake is crucial for reducing muscle loss [51]. Protein and calorie targets may not always go hand in hand. The ESPEN guidelines advocate a protein target of 1.3 g/kg/day during critical illness [18]. The quality and origin of the proteins should also be taken into consideration. The amount of essential and non-essential amino acid, protein efficiency ratio, protein utilization and absorption make animal protein the optimal choice [52]. Nicolo et al. showed a reduction in mortality and length of stay when achieving more than 80% of desired protein intake [53]. Compher et al. showed similar results [54]. In a retrospective observational study of critically ill patients, Zusman et al. showed a linear association between protein intake and mortality [20]. For every gram of ingested protein there was a 1% reduction in mortality. However, the EAT-ICU prospective randomized trial compared standard nutritional care of 1.2 g/kg/day protein to a goal directed group based on indirect calorimetry and nitrogen balance measurements that received a minimum of 1.5 g/kg/day from day 1. There was no effect on morality, organ failure or infection rates [55]. In certain clinical situations such as burn victims, frail patients, cancer patients or patients suffering from acute kidney injury it is generally recommended to provide increased protein intake [56, 57]. It is still unclear whether the timing of protein administration affects patient outcomes. Bendavid et al. found early protein administration to be associated with increased survival (HR 0.83) in patients receiving protein>0.7 g/kg/day in the first 3 days following ICU admission [58]. On the other hand, Koekkoek et al. found that early high protein intake (>0.8 g/kg/day in the first 3–5 day of admission) was associated with higher 6 month mortality [59].

Amino-Acid Enriched Formulas Glutamine (GLN) is considered a non-essential amino acid as long as it is sufficiently synthetized by the skeletal muscle. In certain clinical conditions such as critical illness and burns, GLN levels decrease and mortality is increased [60] while the immune response is decreased [61]. In the REDOXS trial published in 2013, the administration of GLN supplements to critically ill patients with multi-organ failure was associated with higher mortality [62]. In another RCT from 2014 (the METAPLUS study), the prescription of an immune modulating nutrition that included GLN did not have any clinical beneficial effect and even led to an increase in 6 month mortality [63]. The ESPEN guidelines conclude that GLN supplementation should be administered in burn patients with burns >20% body surface area in the first 10–15 days of enteral nutrition and it may be considered in critically ill trauma patients in the first 5 days of enteral nutrition, perhaps longer if impaired wound healing is evident [18]. Other than these specific populations, GLN supplements are not recommended in the ICU. *β*-Hydroxy-*β*-methylbutyrate (HMB) is a metabolite of the amino acid Leucine and its positive effects on muscle mass by increasing protein synthesis and decreasing muscle catabolism have been well studied [64]. In a meta-analysis on the effect of HMB in clinical practice, results were conflicting. Only a small number of studies included critically ill patients, HMB was administered alongside GLN and arginine and it was used in different points along the hospitalization course [65]. In 2020 Nakamura et al. published a RCT examining the effect of HMB, GLN and arginine supplements on muscle loss in critically ill patients [66]. The study failed to show any decrease in muscle loss.

Micronutrients

Vitamins and trace elements are curial for proper function of metabolic processes and micronutrients deficiency can be life threatening [67]. Critically ill patients with decreased intake and increased catabolism are at additional risk to develop such deficiency. Trace elements are also known for their anti-oxidative properties and are sometimes given in higher doses in specific clinical conditions. Sepsis is one of the fields were high dose selenium have been studied [68]. In an RCT by Bloos et al. administrating high loading dose of selenium (1000 μg) followed by continues intravenous infusion of selenium to patients in septic shock or sever sepsis did not affect mortality [69]. In cardiac surgery Schmidt et al. showed significant decrease in the use of vasopressors by using high dose selenium preoperatively and during ICU stay but with effect of perioperative SOFA score. Patients with renal failure and renal replacement therapy suffer from Selenium and Zinc deficiency. Studies however have failed to normalize Selenium and Zinc level by intravenous supplements further highlighting the significant loss in these patients [70–72]. In burn victims there is substantial loss of trace elements especially Copper, Zinc and selenium and supplements of 5–8 times the recommended dietary intake is advised [73]. Finally, bariatric patients suffer from significant trace elements loss due to lack of absorption. This can lead to neuropathy, anemia, weakness etc.… resolution of symptoms may occur with intravenous supplementation [73].

The Best Route: Enteral Vs Parenteral Nutrition

When deciding on the best route to provide nutrition, a few factors must be taken into consideration. Enteral nutrition (EN) preserves intestinal function and it is the preferred option in a patient unable to consume sufficient oral intake [18]. It is however associated with more gastric and intestinal complications [74]. With Parenteral nutrition it is easier to reach caloric target [75] but some studies report higher rates of infectious complications [76]. In early studies comparing EN to PN there was significant reduction in infection rate however it was most prominent in subgroup of patients receiving significantly higher caloric intake resulting in more hyperglycemic events and liver function abnormalities. Also, studies conducted before the implementation of programs for the prevention catheter related blood stream infection, reveal a significantly higher rate of PN complications [77]. The CALORIES trail, an RCT comparing EN to PN in critically ill patients found no difference in mortality between the two groups. It is important to note that although in this study nutritional support was started early (within 36 h of admission), most patients did not reach the caloric target of 25 kcal/kg/day [78]. The NUTRIREA-2 study compared EN to PN in critically ill patients with shock that required mechanical ventilation with similar results, finding no difference in 28 day mortality or infection rates between the two groups. The risk of gut ischemia was significantly higher in the group of patients receiving EN [79]. In the clinical practice guidelines by the European society of intensive care medicine (ESICM), early EN was preferred over early PN. Their meta-analysis showed no benefit in mortality but did show a reduced infection rates in patients receiving EN. The same guidelines also recommend withholding enteral nutrition support in cases of upper GI bleeding, gastric residual volume >500 ml/6 h, bowel obstruction, bowel ischemia, abdominal compartment syndrome or high output fistula [80]. EN is not necessarily preferred over PN, and supplemental PN in patients receiving EN is in increased use. Heidegger et al. showed reduced infection rates when reaching 100% of target REE early (on day 4 of admission) compared to late (on day 8 of admission) using supplemental PN. The rates of nosocomial infections were significantly lower in the supplemental PN group, with a hazard ratio of 0.65 [81]. On the other hand, a large multi-center randomized controlled trial by Casaer et al. compared early (within 48 h of admission) to late supplemental PN (after 8 days of admission) in critically ill patients. Patients in the late supplemental PN group had significantly lower rates of infections, longer ICU and hospital stays and lower probabilities of prolonged mechanical ventilation and need for renal replacement therapy (RRT) [82]. ESPEN guidelines states that EN is preferred over PN in patients with intact GI tracts. However, PN is clearly indicated if caloric targets cannot be reached or if enteral feeding is not feasible [18].

Enteral Nutrition

There are many commercially available EN formulas. Most provide 100% of daily requirement of vitamins and trace elements when adequate calories are provided.

Timing A meta-analysis of randomized control trails compared early to late EN in critically ill patients and showed favorable outcomes in terms of mortality and the development of pneumonia in patients receiving early (within <24 h) enteral nutrition [83]. In the ESICM clinical practice guidelines early EN is preferred over delayed EN [71, 72]. ESPEN guidelines for clinical nutrition in the ICU recommend starting EN within 48 h of admission, aiming to provide 70% of REE and gradually increasing the caloric intake to no more than 100% of REE [18].

Continuous Versus Intermediate Feeding There is an ongoing debate whether to administer EN continuously or in intermittent boluses. Theoretically there are advantages for each method, but most studies fail to show significant differences. In artificially fed patients, muscle synthesis seems to come to a halt after 2–3 h despite continuous feeding. This "muscle full effect" may be due to the muscle inability to continuously absorb amino acids [84]. Even though bolus feeding helped to overcome that effect in healthy volunteers [85], a recent RCT comparing continuous to intermittent feeding early in the course of critical illness failed to show any effect on muscle loss [86]. It is not always feasible to reach caloric targets in ICU patients. Prolonged feeding cessations are common as patients are often sent to imaging studies or surgical procedures, experience high GRVs and there are many potential technical difficulties such as feeding tube removal or equipment failure, and feeding regimen progression is often lacking. Bolus feeding may potentially allow for better timing of nutritional support and help to overcome many of these technical difficulties [85]. McNelly et al. found that a larger percent of critically ill patients receiving bolus enteral feeding reached the 80% caloric target and 60% protein target [86]. On the other hand, an RCT by Chowdhury et al. found that bolus nasogastric feeding in healthy adults actually leads to higher GRVs and increased superior mesenteric artery blood volume [87]. Rhoney et al. showed similar results in brain injured patients [88]. In fact, many studies have shown no clinically relevant difference between the two modalities [89, 90]. Another emerging practice is deliberate intermittent fasting in order to induce ketogenesis and encourage autophagy [91]. Ketogenesis, ketogenic diets and ketone supplementation had some success in small animal and pediatric studies [92, 93] but RCTs are required in order to assess the clinical application. The ESPEN guidelines promote the use of continuous over bolus enteral feeding in critically ill patients [18].

Feeding Tube Placement EN can be delivered to the stomach (gastric feeding) or into the intestine (post pyloric feeding). Some studies have shown that post pyloric feeding was associated with lower rates of pneumonia [94] and better feeding tolerance [95], leading the American society of parenteral and enteral nutrition (ASPEN) and the society of critical care medicine (SCCM) to recommend the diversion of enteral infusion to the lower GI tract in patients who show signs of feeding intolerance or who are at high risk for aspiration [21]. When choosing feeding route one must consider that post pyloric tube placement requires skills, may cause feeding delays and is not without complications. Thus, most guidelines recommend that the majority of critically ill patients receive gastric feeding [18, 21].

Gastric Residual Volume Gastric intolerance can be assessed by measuring the GRV. Reignier et al. studied in a multicenter RCT the effect of not monitoring GRV on the risk of ventilator associated pneumonia in mechanically ventilated critically ill patients. Not measuring GRV was non inferior to routine (every 6 h) GRV measurements [96]. GRV measurements are currently not recommended as a routine monitoring tool but rather as means for diagnosing feeding intolerance if it is suspected. Large GRV (>500 ml/6 h) may signify feeding intolerance that requires action. Prokinetics, either erythromycin and/or metoclopramide, are recommended by most societies and the surviving sepsis campaign in cases of high GRV [21, 97]. In a meta-analysis by Singer et al., erythromycin had a clear advantage over metoclopramide and a treatment course of 48 h is recommended in patients with GRV > 500 ml [18]. If feeding intolerance persists, post pyloric feeding should be considered. Of note, although GRV > 500 ml is traditionally defined as a marker for feeding intolerance, studies have shown increased risk for mortality even in lower GRVs (>250 ml) [98, 99]. When dealing with a high GRV in a critically ill patient, contributing factors like the use of opiates, electrolyte abnormalities and hyperglycemia should be addressed [100].

Stress Ulcer Prophylaxis Stress gastritis in critically ill patients has been well documented for many years. Hemodynamic instability and coagulopathy can cause splanchnic hypoperfusion and gastric mucosa ischemia leading to significant complications [101]. The use of pharmacological stress ulcer prophylaxis has become the standard of care in ICUs but it is not clear whether they prevent clinically significant GI bleeding events [102]. In fact, studies have shown no added benefit to pharmacological prophylaxis over early enteral nutrition [103, 104].

Diarrhoea Diarrhoea is a common symptom in critically ill patients with an estimated prevalence of 14–21% [105]. Enteral feeding has long been considered a risk factor for diarrhea. A systemic review by Gramlich et al. did not find conclusive association between EN and diarrhea [106]. Thibault et al. found that EN was not a risk factor of diarrhea by itself, but when reaching >60% of caloric targets the risk of diarrhea increased by 1.75 (1.02–3.01) [107]. The use of antimicrobial treatment was also highly associated with diarrhea. It is essential to consider infectious causes in critically ill patients who develop diarrhea and treat accordingly. *Clostridium difficile* infections should be considered not only in patients receiving antibiotic therapy. Once infection has been ruled out, non-infectious etiologies should be raised. Non-infectious diarrhea may be a symptom of the pri-

mary disease such as pancreatic insufficiency, Intoxication or even lactose intolerance. In these cases, the trigger should always be treated first. Medication is another important cause for diarrhea in the critically ill. Laxatives and prokinetic drugs are obvious culprits, but antibiotics and antifungal medications must be considered as well. Diarrhea can also be related to the patient's specific diet. If this occurs in the orally fed patients, intake should consist of small meals with isotonic fluids, while in tube fed patients EN should be delivered continuously. If the diarrhea persists, consider changing enteral formula and reducing feeding rate [105].

Refeeding Syndrome Dramatic shifts in fluids and electrolytes can occur when feeding starts after prolonged starvation. This is referred to as refeeding syndrome and it can be lethal. Malnourished patients are particularly vulnerable, more so after initiation of artificial nutrition. This makes screening ICU patients for malnutrition crucial, as is continuous monitoring for its signs, namely hypophosphatemia. Diagnosing refeeding at its early stages is of key importance in order to prevent further complications. When refeeding is suspected or expected, slow progression in caloric intake is advised with close monitoring of electrolyte levels [18] (chapter "Refeeding Problems").

Parenteral Nutrition

PN provides intravenous nutrition to patients who are unable to tolerate EN or need supplemental nutrition to reach their caloric targets. As previously mentioned, in the case of a major GI failure (e.g. upper GI bleeding, bowel obstruction, bowel ischemia), PN should be used instead of EN [92]. Parenteral formulas contain carbohydrates, lipids, proteins, trace elements and vitamins, optimally in a composition suited to patient specific needs. In the past each of the elements were delivered separately but over time the three in one, or "All-in-one" (AIO) commercial admixtures where introduced. The use of AIO systems requires only one venous access, reducing infectious complications. They also save preparation time and prevent pharmacological mistakes [108–110]. Ready to use AIO commercial bags have become extremely common since they were first introduced, but personalized AIO compound bags are still an option when the clinical condition demands specific consideration [111].

Timing Doig et al. examined the effect of early PN (within 24 h of admission) compared to standard treatment in critically ill patients who had a contraindication for EN. No statistically significant different was found in mortality, infection rate and quality of life [112]. The optimal timing for nutritional support should be based on individual parameters. In the early stages of acute illness, large amounts of endogenous substrates are released from tissues and risk of overfeeding may increase [113].

Special Conditions

Shock Both ESICM clinical practice guidelines and ESPEN guidelines for nutrition in critically ill patients recommend delaying enteral nutrition in cases of uncontrolled shock and sever hemodynamic instability [18, 114]. Clinical studies are scarce but theoretically administering EN in uncontrolled shock may exacerbate splanchnic hypoperfusion and even lead to bowel ischemia. There is, however, evidence that early EN (<48 h) in patients receiving vasopressors at stable levels reduces mortality compared to delayed EN [115]. That is why the use of vasopressors does not necessarily defer EN.

Sepsis The catabolic nature of this acute illness makes septic patients highly prone to malnutrition. Septic patients are also likely to develop GI feeding intolerance subjecting them to increasing energy debt. On the other hand, in the early stages of acute illness endogenous substrate utilization supplies most of the patient's energetic needs, increasing the risk of overfeeding when delivering exogenous supplementation [18]. This phenomenon may explain the results of the aforementioned EPaNIC trial, where late initiation of PN decreased ICU mortality, hospital mortality, infection rates, mechanical ventilation days and the number of days on RRT [82]. A prospective large study by Weijs et al. found that septic patients did not benefit from early high protein intake (≥1.2 gr/kg) [116]. In contrast, non-septic patients receiving early high protein intake had a significant decrease in mortality (OR 0.42, 0.21–0.83). To summarize, nutrition in septic patients should be prescribed on a case-by-case basis after carefully evaluating patient's individual metabolic status.

Acute Kidney Injury and Renal Replacement Therapy Acute kidney injury (AKI) is a major health concern, with reported incidence of nearly 10% of hospitalized patients and 50% of ICU patients [117, 118]. Renal impairment negatively affects metabolic characteristics. Protein catabolism is enhanced, insulin resistance increases, lipolysis is reduced, fat clearance is impaired and the anti-oxidative system is suppressed owing to a pro-inflammatory status [119]. Hellerman et al. retrospectively examined substrate utilization in ICU patients with AKI. The study showed that patients with AKI consumed less carbohydrates and oxidized

much more lipids than expected [117]. Although commercial formulas contain mainly carbohydrates, the guidelines suggest increasing lipid intake while decreasing carbohydrate derived calories [119]. The same guidelines recommend patients with AKI and an acute/critical illness gradually receive 1.3 g/kg protein a day. Overall, there is no recommendation for a specific EN or PN formula for patients with AKI. However, if there are electrolyte abnormalities or significant fluid overload, concentrated, low electrolytes "renal" formulas should be preferred [119]. ICU patients who develop AKI are at increased risk for hospital mortality that may be as high as 50%. Moreover, about 5–6% of the patients will need renal replacement treatment (RRT) [120]. As in all ICU patients, patients requiring RRT should undergo IC to determine nutritional targets. Existing evidence suggests that the presence of RRT does not alter REE [121]. When prescribing a nutrition plan, additional calories from substrates like citrate, glucose or lactate provided in dialysate and replacement fluids should be taken into account. RRT can increase protein loss and therefore patients on intermittent hemodialysis (IHD) should receive 1.3–1.5 g/kg/day of protein and patients on CRRT should receive 1.5–1.7 g/kg/day [3]. Restricting protein intake during renal failure in order to postpone RRT may be considered, but only outside the acute illness scenario. Trace elements and vitamins require special consideration in patients undergoing CRRT, as they are lost on filter membranes. Monitoring and supplementing trace elements (especially selenium, zinc and copper) and vitamins (especially vitamin C, folic acid and thiamine) levels is advised [119].

COVID-19 Since the COVID-19 outbreak in 2020, there is an increasing number of ARDS patients in the ICU, experiencing prolonged hospitalizations and often recovering slowly time [122]. COVID-19 is characterized by an inflammatory burst (often referred to as "cytokine storm"), respiratory distress, hypercatabolism, reduced intake and prolonged immobilization, making patients extremely susceptible to malnutrition and muscle wasting [123]. Recent recommendations on nutrition in COVID-19 ICU patients emphasize a few practical aspects of treatment. Due to the workload during COVID-19 pandemic, often only vital procedures are performed, and the possible risk of viral spread during IC measurement may pose a threat to caregivers. Guidelines recommend the use of IC only after day 10 of hospitalization or in patients receiving full PN plan [124]. The significant energy deficit of COVID-19 patients before ICU admission makes them vulnerable to the refeeding syndrome, requiring careful electrolyte monitoring. The use of sedatives such as propofol in high doses increases the risk to develop the propofol infusion syndrome. Close monitoring of blood lactate levels, blood gases, creatinine phosphokinase (CPK) and triglycerides allows for early diagnosis [124]. EN is still the preferred route for feeding, even in patients in the prone position, despite the theoretical risk for gastroparesis and vomiting. A prospective study by Saez de la Fuente et al. found no significant difference in EN feeding intolerance, defined as high GRVs or frank vomiting, in patients in the prone position [125]. The same applies for the use of vasopressors or paralytic agents [124]. Special consideration should be made to nutritional support after liberation from mechanical ventilation. It is recommended to carefully evaluate extubated patients with suspected dysphagia and continue tube feeding if necessary. Upon initiation oral intake is rarely enough to reach nutritional targets and supplemental PN should be considered [124].

Extra Corporal Membrane Oxygenation (ECMO) ECMO is increasingly employed in ICUs, all the more so since the outbreak of the COVID-19 pandemic. ECMO patients are the most severely ill patients, very often experiencing multiorgan failure, long ICU and hospital stays and are predisposed to develop bacterial translocation and sepsis. That being said, early EN should still be administered if no other contraindication exists [18]. PN is also feasible in ECMO patients if so indicated, but lipid solutions must not be infused directly into the circuit to prevent lipid deposits and clotting [126]. The ECMO technique uses foreign materials that may aggravate the inflammatory response and induce significant loss of micro- and macronutrients [126]. A single dose ex-vivo study by Estensen et al. revealed a significant decrease in the levels of the amino acid isoleucine and of vitamins A and E [127]. This suggests some circuit loss as seen in other forms of extracorporeal life support systems [128]. On The other hand, Lindberg et al., in another ex-vivo study, found no difference in vitamin levels, lipid profile or total proteins [129]. Unlike RRT, there is no recommendation to provide ECMO patients with any additional micro- or macronutrient supplementation. Of note, the nutritional requirements during ECMO therapy are difficult to predict. These patients have an extremely dysregulated inflammatory response, are often septic and tend to require hemodynamic support. It is not currently feasible to measure REE in ECMO patients via IC and the use of the simple 25–30 kcal/kg/day is recommended, using the ideal body weight [21].

Monitoring

Patients in the ICU suffering from intestinal failure require intense monitoring to prevent complications, evaluate effectiveness of treatment and adjust nutrition plan. Table 2 sum-

Table 2 Assesment, nutritional targets and monitoring tools in patients in different stages of intestinal failure

	Acute	Post-acute	Chronic
Time	<1 week	1–3 weeks	>3 weeks
Assessment	GRV, diarrhea, stoma output	GRV, diarrhea, stoma output	Number of stools, consistency of stool, vomiting
Route	EN/PN	EN/PN	EN/PN
Energy	IC—70% of REE, trophic feeding	IC—100% of REE	IC—120% of REE
Protein	1 g/kg[a]	1.3 g/kg[a]	1.5 g/kg[a]
Monitoring	Nitrogen balance, urea, Electrolytes, fluid Balance, liver function tests[b]	Nitrogen balance, urea, electrolytes, fluid Balance, liver function tests[b]	Electrolytes, liver function tests, albumin, vit B1, Vit B12, Vit B6, selenium, zinc, vit D, DXA

GRV gastric residual volume, *EN* enteral nutrition, *PN* parenteral nutrition, *IC* indirect calorimetry, *REE* resting energy expenditure, *vit* vitamin

DEXA dual-energy X ray absorptiometry

[a]Ideal body weight

[b]*AST* aspartate transaminase, *ALT* alanine transaminase, Bilirubin, *GGT* gamma glutamyl transferase

marizes common monitoring tools in patients in different stages of intestinal failure. Physical examination is an essential part of the assessment. In the critically ill, especially those suffering from intestinal failure, special care must be taken to look for signs of muscle wasting, weight loss by daily weighing and the development of edema. Events of vomiting, bowel movement, complaints of abdominal pain and the presence of diarrhea should be documented. As mentioned, GRV measurements are not a part of routine patient monitoring, but it should be measured and accounted for when intestinal failure is suspected. Fluid status is important as it may require a change in nutrition plan along with other interventions. Laboratory tests should be obtained, including electrolytes levels (sodium, potassium, phosphate, magnesium) for nutritional adjustments and screening for the refeeding syndrome. Increased blood lactate levels may indicate intestinal ischemia and/or shock. Elevated Inflammatory markers such as white blood cell count or C-reactive protein may signify active inflammatory or infectious intestinal pathology. Indirect calorimetry should be a part of the evaluation of every ICU patient and should be repeated if the patient's clinical status changes. Finally, assessment of body composition should be performed by any of the common methods (Bioelectrical Impedance, DXA, CT, and ultrasound).

Eating Disorders in Adults

Paul Robinson and David Russell

Key Points

1. Eating disorders are common and can appear in any medical context.
2. The main types involve weight loss, binge eating ad vomiting and intermediates occur.
3. Having an eating disorder is not a lifestyle choice. The patients are driven by extreme concerns about weight and shape that they cannot control.
4. Anorexia nervosa is the psychiatric disorder with the highest standardized mortality ratio
5. If you are a non-specialist and you meet an acutely ill patient with an eating disorder, look up "Medical emergencies in eating disorders (MEED)" guidelines 2022 which have replaced the senior and junior MARSIPAN ones and follow its advice.
6. The outcome for eating disorders is not that bad, but not good enough, with around half making a full recovery, more if the patient is young and has a short history.
7. The literature is large. We recommend The NICE guideline [1] and the MEED guidelines[1] [2]. Available on-line

Basic Information

Definitions: What are eating disorders?

And why are they of interest to general medical services?

Eating disorders originate in a conviction, shared by many in the West, especially females, that one's body weight is too high and body shape too large. Whereas most people with this conviction might moderately reduce their nutritional intake often with little long term impact on weight, patients with some eating disorders take these behaviours to extremes and add others. They may be successful in reducing weight and can end up profoundly malnourished or they may lose a smaller amount and proceed to overeating (binge eating) and compensatory behaviours such as vomiting or laxative abuse. This introduces two of the currently recognised eating disorders anorexia nervosa and bulimia nervosa. The difference between common dieting and an eating disorder is that the patient takes dieting to such an extreme that their life can be at risk [1–3]. The reasons they do that are not fully understood, but genetic, developmental, family, social and cultural factors are all believed to play a part [3].

Another presentation is that of the patient whose weight is in the obesity range and who engages in binge eating, sometimes following attempts to lose weight. In this case there are

J. M.D. Nightingale (ed.), *Intestinal Failure*, https://doi.org/10.1007/978-3-031-22265-8_14

no compensatory behaviours and the condition is called Binge Eating Disorder (Box 3) although this can occur at normal weight.

A fourth eating disorder associated with nutritional restriction but not body image disturbance is ARFID or avoidant restrictive food intake disorder.

All these eating disorders have been defined in the most recent version of the American Psychiatric Association classification, the DSM 5 [4] and the essentials of the three main conditions are listed in Boxes 1, 2, and 3. Pica, which is the consumption of non-nutritive substances, and Rumination Disorder, with recurrent regurgitation of gastric contents, have also been included under eating disorders in the DSM 5. Atypical eating disorders are now classed as Other Specific Feeding and Eating Disorder (OSFED) and Unspecified Feeding or Eating Disorder (UFED).

Box 1 DSM-5 Criteria for Anorexia Nervosa

According to the DSM-5 criteria, to be diagnosed as having Anorexia Nervosa a person must display:

- Persistent restriction of energy intake leading to significantly low body weight (in context of what is minimally expected for age, sex, developmental trajectory, and physical health).
- Either an intense fear of gaining weight or of becoming fat, or persistent behaviour that interferes with weight gain (even though significantly low weight).
- Disturbance in the way one's body weight or shape is experienced, undue influence of body shape and weight on self-evaluation, or persistent lack of recognition of the seriousness of the current low body weight

Subtypes: Restricting type and Binge-eating/purging type.

Box 2 DSM 5 Criteria for Bulimia Nervosa

According to the DSM-5 criteria, to be diagnosed as having Bulimia Nervosa a person must display:

- Recurrent episodes of binge eating. An episode of binge eating is characterised by both of the following:
  - Eating, in a discrete period of time (e.g. within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances.
  - A sense of lack of control over eating during the episode (e.g. a feeling that one cannot stop eating or control what or how much one is eating).
- Recurrent inappropriate compensatory behaviour in order to prevent weight gain, such as self-induced vomiting, misuse of laxatives, diuretics, or other medications, fasting, or excessive exercise.
- The binge eating and inappropriate compensatory behaviours both occur, on average, at least once a week for three months.
- Self-evaluation is unduly influenced by body shape and weight.
- The disturbance does not occur exclusively during episodes of Anorexia Nervosa.

Box 3 DSM-5 Criteria for Binge Eating Disorder

According to the DSM-5 criteria, to be diagnosed as having Binge Eating Disorder a person must display:

- Recurrent episodes of binge eating. An episode of binge eating is characterised by both of the following:
  - eating, in a discrete period of time (e.g. within any 2-hour period), an amount of food that is definitely larger than most people would eat during a similar period of time and under similar circumstances.
  - a sense of lack of control over eating during the episode (e.g. a feeling that one cannot stop eating or control what or how much one is eating).
- The binge eating episodes are associated with three or more of the following:
  - eating much more rapidly than normal
  - eating until feeling uncomfortably full
  - eating large amounts of food when not feeling physically hungry
  - eating alone because of feeling embarrassed by how much one is eating
  - feeling disgusted with oneself, depressed or very guilty afterward
- Marked distress regarding binge eating is present
- Binge eating occurs, on average, at least once a week for three months
- Binge eating not associated with the recurrent use of inappropriate compensatory behaviours as in Bulimia Nervosa and does not occur exclusively during the course of Bulimia Nervosa, or Anorexia Nervosa methods to compensate for overeating, such as self-induced vomiting.

Definitions

The definitions of the main eating disorders as described in DSM5 are listed in Boxes 1, 2 and 3. Anorexia nervosa is characterised by self-induced low weight, avoidance of weight gain and a disturbance in body image. In bulimia nervosa the patient attempts to lose weight and may have some success, but then is overcome by urges to eat and suffers episodes of binge eating followed often by vomiting or laxative abuse. Binge eating and vomiting may also complicate low weight anorexia nervosa. In binge eating disorder distressing binge eating occurs unaccompanied by compensatory behaviours. This condition is often associated with obesity and is commonly seen in patients seeking bariatric surgery. Usually the diagnosis of an eating disorder is not difficult because of the weight loss, unexplained by other conditions, body image concerns, resistance to weight gain, binge eating, vomiting or laxative abuse. However, if the prevalence of eating disorders within a particular environment (e.g. a diabetic or gastroenterology clinic) is sought, clinicians may use the SCOFF questionnaire [5] which is very brief and has very high sensitivity (case detection) but a lower specificity (more false positives).

Epidemiology

Estimates vary in different studies but on average [6] the figures for prevalence in the West are 0.4% of young women for anorexia nervosa 1% for bulimia nervosa and 1–2% for binge eating disorder. Hence taking AN and BN together the prevalence of an eating disorder among young women the prevalence of eating disorders is about 3–4%. Men also suffer from anorexia and bulimia nervosa at 10–30% of the female data and for binge eating the sex ratio is about 3 men to 5 women. Hence eating disorders are sufficiently common for all doctors to be liable to see an affected patient in the course of his or her practice.

Different Presentations of Eating Disorders

Sir William Osler, one of the founders of the Johns Hopkins Medical School coined the term "The great imitator" when describing syphilis and its multifarious manifestations. These days several diseases compete for this description and eating disorders have a good case. Because eating disorders appear (whether or not the physician is aware) in almost every medical clinic, the most important clinical presentations will be described in turn.

Acute Nutritional Deficiency

This is one of the most alarming presentations in clinical medicine. The front-line doctor will usually consult Wikipedia (check "Anorexia Nervosa", "Admission to hospital"), even though respectable publications do not allow their articles in a reference list. The patient is usually but not always a young female and the history may be fairly brief with two or three months of severe dietary restriction sometimes with vomiting or laxative abuse, or the patient may have well established anorexia nervosa of several years duration. She may be carried into the emergency room or brought in on a wheelchair. She will show severe muscle wasting and her appearance may be reminiscent of a concentration camp survivor. In contrast with her emaciated appearance, she may be alert and bright although she may equally be cognitively impaired with slurred speech, depending on central nervous system nutrition. The assessing doctor in the emergency room may suspect a malignancy or other wasting condition. However, an eating disorder should be suspected from the age and gender of the patient, and confirmed as in the following conversation in which the patient is concealing some of her symptoms:

Doctor: You seem to have lost a lot of weight. Can you tell me how this happened?

Patient 1 (female age 19): I don't know, it just went down without me noticing.

Doctor: How do you feel about the weight loss?

Patient 1: I don't mind it really. I still feel that I could lose just a little more. Although I don't mind if it stays like this. I feel so weak. Can you help me?

Doctor: Well, starting to increase your food would really help that.

Patient 1: Can we do that later? I don't feel ready just now.

The doctor will be highly suspicious that anorexia nervosa might be the diagnosis, and attempt to contact a relative to obtain further information that might indicate recent food refusal, body image preoccupation or evidence of vomiting. If tests are required to exclude other disorders which might present in this way such as Addison's Disease or tuberculosis, they should be done quickly and management of the malnutrition, with a probable diagnosis of anorexia nervosa, should begin.

In the history, ask about recent nutrition, excess water drinking, a history of fractures and muscle weakening, with difficulty climbing stairs, overeating and vomiting. Ask if others have noticed and expressed concern about weight loss and whether anyone (relative, doctor) has mentioned anorexia. What does the patient think might be wrong?

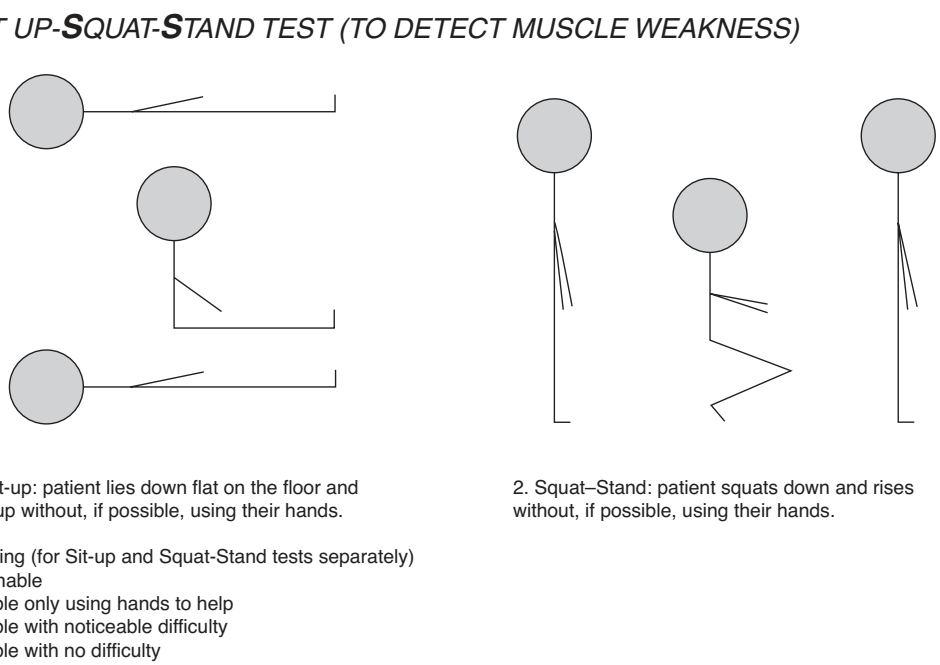

Fig. 1 The SUSS test (Royal College of Psychiatrists. With permission) [7]

Continuing with physical examination, look for swelling of the parotid glands (bingeing and vomiting), lanugo hair (fine downy hair on the back, face and elsewhere) and muscle atrophy. Check the dorsa of the dominant hands for calluses due to induced vomiting (Russell's sign). If the patient is not obviously weak, ask her to do the SUSS test (Sit Up Squat Stand) (Fig. 1). This is a reliable test of muscle power with the following scale: 0: unable to rise from squatting or sit up from lying flat, 1: Able to rise or sit up only by using hands to help, 2: Able to rise or sit up but with noticeable difficulty, 3: able to rise or sit up with no difficulty.

Check the pulse which may be under 50 or less at low weight, and see if the patient gets dizzy on standing. Check the lying and standing BP and see if the difference is >20 mm Hg. Measure the core temperature. Hypothermia occurs in malnourished patients who sometimes deliberately expose themselves to cold in order to shiver and hence lose more weight.

The pathophysiological changes attribute to starvation are summarised in Box 4. The clinically significant ("red flag") manifestations of these pathophysiological changes on anorexia nervosa are summarised in Box 5.

The investigations that apply specifically to an eating disorder are urea and electrolytes, liver function tests, calcium, phosphate, magnesium and electrocardiogram. Hypokalaemia suggests vomiting or laxative abuse, hyponatraemia may indicate excess water drinking, sometimes to conceal weight loss when on the scale and raised urea and creatinine may indicate dehydration or, sometimes, renal insufficiency. Raised transaminase levels are common and appear to be related to malnutrition. They may increase transiently during refeeding but then go back to normal. There is almost never an indication for liver biopsy. Blood glucose can fall as metabolism moves from carbohydrate based to fat based when glycogen stores have become exhausted. The patient may be alert because the brain is using fatty acids for energy. She may however require glucose and hypoglycae-

Box 4 Pathophysiological Changes of Starvation

Starvation

- Reduced carbohydrate fuel source leads to increase: (1) Ketosis (2) Proteolysis
- Loss of lean body mass affects major organs
- Atrophy of the myocardium → poor contractility and ↓ Cardiac Output Thiamine deficiency
- Gastrointestinal atrophy → malabsorption and dysmotility

(1) Translocation bacteria (2) Gastroparesis

- Pancytopenia – increase in infection
- Intracellular loss of electrolytes—(K^+/PO_4^{--}) and intracellular water
- Micronutrient Deficiency-trace elements and vitamins
- Insulin secretion, GH release and thyroid function are all diminished → the basal metabolic rate slows down to 20% to 25% to conserve energy
- Consequently, the body becomes bradycardic, hypothermic, and hypotensive

Box 5 Red Flag Findings in Severe Eating Disorders (See MEED [2])

System	RED Finding	Note
BMI	<13	BMI can be higher if weight loss rapid
Weight loss	>1 kg per week	
CVS	HR < 40 bpm	
	Standing SBP < 90 mm Hg with syncope	
Dehydration	Clinically present	
Core temperature	<35 °C	
Muscle strength	SUSS test (Fig. 1) score < 2	Or use Hand Grip Strength
Comorbidities	Sepsis, bleeding	
	Diabetes Mellitus: HbA1C > 10%	
ECG	Any significant abnormality	Bradycardia, T wave changes
	Prolonged QTc	
Biochemistry	Na K P. Ca	Reduced P, K, Mg suggest refeeding syndrome. Reduced Na suggests water loading and reduced K suggests vomiting or laxative abuse
	Low Glu (<3mmol/L) or if diabetic HbA1C>10%	
	Transaminases up to 3× ULN	
Haematology	Reduced WBC Rarely pancytopenia	
Food refusal	<500 kcal per day	
Activity	Compulsive exercise	
Purging	Self induced vomiting, Laxative abuse	
Self harm, suicide	Self poisoning, suicidal thoughts/ intent	

mia should not be neglected. The blood count may show mild anaemia, usually of mixed origin (mostly iron deficiency and marrow hypoplasia) and platelets can be low in extreme malnutrition and accompanied by a purpuric thrombocytopaenic rash and pancytopenia in gelatinous transformation of the marrow [8]. The ECG can show almost any abnormality with ST and T changes which suggest ischaemia, but which probably indicate reduced energy delivery to the heart, and prolonged QTc (>450 ms) which is thought to predict serious cardiac arrhythmias.

The nutritional management of a patient such as the one described comprises three phases: resuscitation, repair and repletion [9]. The role of the emergency department is to resuscitate and perhaps begin the other phases. A detailed guide to managing this clinical situation is provided in the MEED guidelines and textbook [2, 7, 10] which readers are advised to consult. A broad outline will be provided here. The MEED guideline, are accompanied by the MeeD checklist (Fig. 2) applicable to all ages and this will be described in order to highlight the essential clinical approaches in this very difficult situation.

The first column covers assessment: 1. Does the patient have anorexia nervosa? The diagnosis may be apparent either from information from the patient or relative as described above. If there is doubt, and this will be unusual, ask the opinion of the on-call psychiatrist. 2. Are there significant risk factors? a. Low BMI, <13 in adults indicate high risk. b. Rate of weight loss: has weight been lost at over 1 kg per week for two consecutive weeks? c. Little or no nutrition for >5 days. This predisposes to refeeding syndrome. d. Abnormalities on examination, in blood tests and ECG all contribute to risk.

The middle column is concerned with refeeding. 1. Is the patient so ill that intensive care is required? 2. Are there risk factors for refeeding syndrome (RFS)? This is dealt with elsewhere in this book. Here it should be mentioned that in anorexia nervosa, abnormal electrolytes, very low BMI, and significant co-morbidities (see checklist) all increase the risk of RFS. Advice is given to begin refeeding at low rates if the risk of RFS is vey high, but to build up quickly in order to avoid the equally dangerous underfeeding syndrome (UFS) in which too few calories are provided with sometimes fatal results. 3. If the risk of RFS is not too high, begin with higher rates of refeeding and 4. Give thiamine and 5. Monitor closely.

The right hand column is for general management. 1. Are medics and psychs collaborating closely? This is very important. It is not acceptable for the psychiatrists to leave the scene until the patient is better. Equally, physicians must make sure that the mental health staff, who could be from an eating disorder service (best) or from a liaison or general psychiatry service, are called and involved in treatment planning and staff support. 2. Are the staff trained? Usually not. The senior staff must make sure that staff on every shift, especially if from an agency, are familiar with the patient's symptoms, likely behaviour and potential problems and their management. A one side sheet of paper detailing the treatment plan and what to do if things go wrong should be given to all staff working directly with the patient. 3. Are there psychological factors that increase risk? Falsifying weight is common in patients with anorexia nervosa who are afraid that weight loss or failure to gain weight might lead clinicians to increase their calories, begin tube feeding, arrange admission to an eating disorders inpatient unit, or begin proceedings to force nutrition under the Mental Health Act. Methods vary and test the powers of observation and deduction of the clinician.

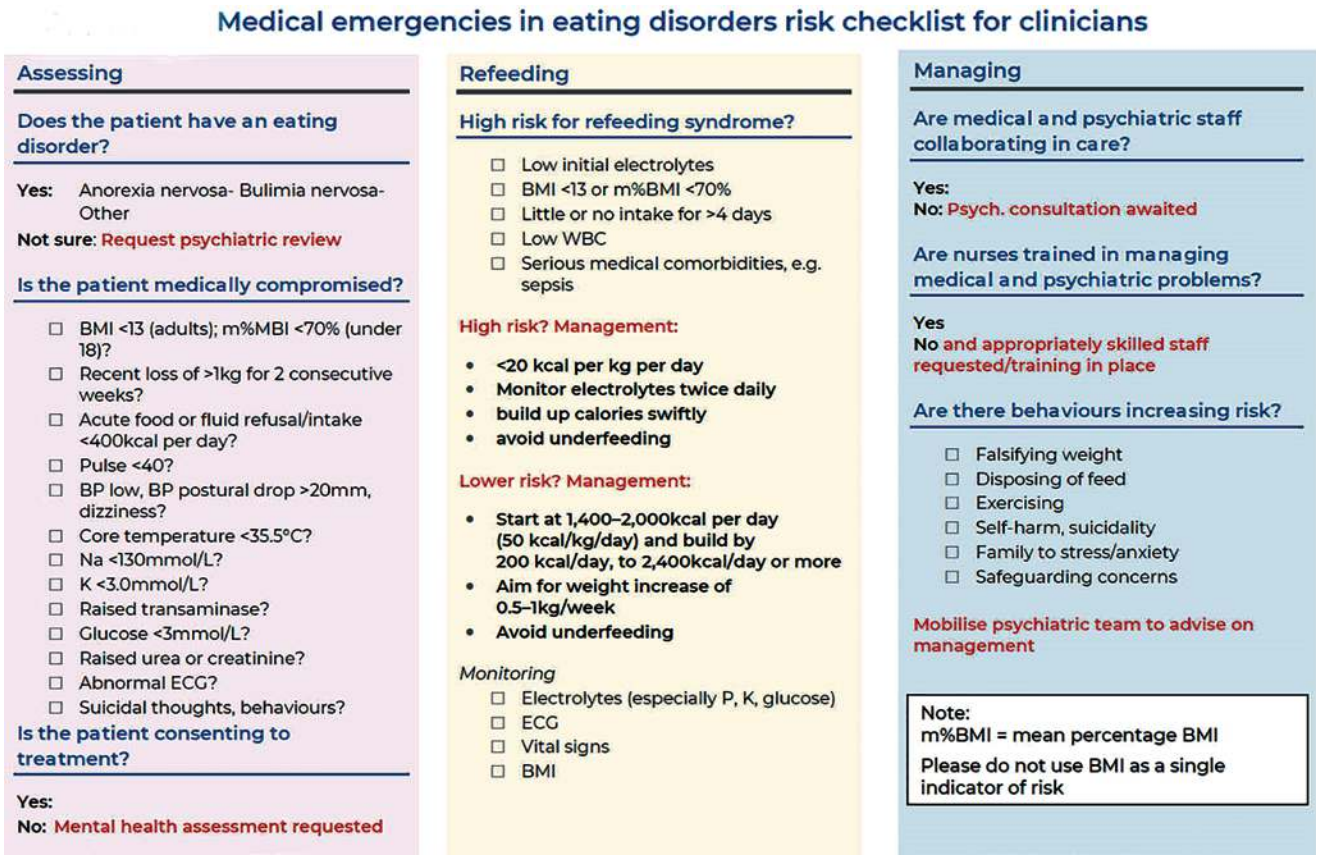

Fig. 2 The MEED Checklist (Royal College of Psychiatrists. With permission)

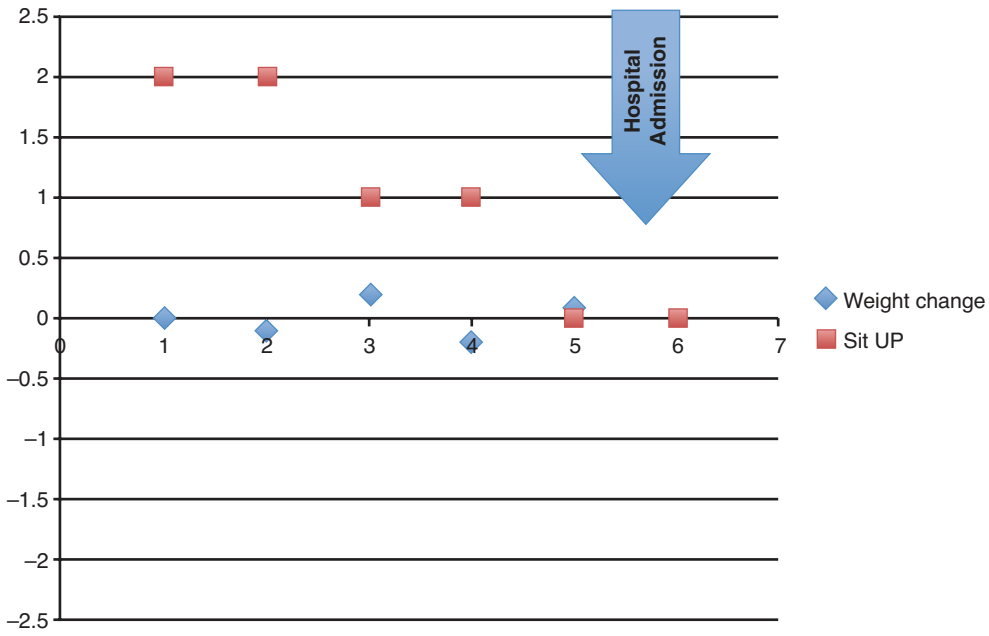

Fig. 3 A graph of weight change in kg (diamonds, from 37.5 kg) each week and the Sit Up test on the same day (squares). The weight stays stable but the Sit Up scores decline. The patient is admitted (down arrow) and weight immediately falls by 2 kg

Patient 2 was being seen in the outpatients' department for severe anorexia nervosa. Her weight was 37.5 kg and her BMI 13.5. Every week she was seen in the clinic she was weighed and the SUSS test (see above and [7]) was performed. Her weight appeared to be stable and her BMI was above the high risk range (<13). However, her Sit Up test declined and on the basis the consultant decided to admit her to hospital against her wishes. After admission her weight immediately fell to 35.5 kg, BMI 12.8. Her comment was "Doctor, I'm so glad you admitted me. I couldn't have

managed to drink any more water." She was drinking 2 litres of water whenever she was weighed prior to admission. (See Fig. 3*).*

Patient 3: This patient was being seen by a therapist in an outpatient clinic and being weighed weekly. Her BMI was 15.5 (weight 41.7 kg) so she was not regarded as very high risk. However, her therapist that she thought that the patient was looking thinner. Two days later the patient was admitted to a medical ward in status epilepticus. She was treated and woke up from the fit 24 h later. Her sodium on admission was 119 mmol/L (normal range 135–145) and two days later she weighed 35.1 kg (BMI 13). She admitted to massive water loading prior to her therapy for fear of admission. When asked how she managed to "gain" 8 kg she said that she would go into the shower, place the shower rose in her mouth and turn on the water.

Disposing of food: This is a common practice in hospital and at home and is sometimes evidenced by the family cat becoming obese! In hospital, patients have been known to dispose of nasogastric feed in the sink, the toilet and even into a pillow into which a hole has been drilled.

Patient 4: A patient with anorexia nervosa and a borderline personality disorder was admitted to a general psychiatric ward with a BMI of 13. She spent four weeks there and appeared to be eating well. However her weight stayed exactly the same and eventually she was discharged because of lack of progress. After she left a smell was noticed in her en-suite bathroom. Investigation revealed a large amount of rotting food when the side panel of her bath was unscrewed.

Secretive exercise: This is also common. Many acute hospitals have signs encouraging staff and others to use the stairs rather than the lifts. Our patients need no second invitation. Because they are often not confined to the ward, even though they should probably be confined to bed, the patients use the stairs as an indoor gym, sometimes with 12 floors to run up. Other common forms of exercise are less obvious. Micro-exercising means the use of small muscles to increase calorie consumption and patients will be noticed to be wiggling their toes or fingers or, sometimes knitting furiously. Standing is another variant and some patients refuse to sit, knowing that maintaining the erect posture increases calorie use. Lastly, wearing inadequate clothing in cold weather is a form of micro-exercise because the patient is aware that if she shivers she will use more energy.

Managing exercise and micro-exercise can be a challenge. The patient can be strongly advised not to leave the ward, and to stay in bed until her BMI has improved and this approach will work for some patients. However, keeping a reluctant patient on the ward when she is not detained under the Mental Health Act is not legally defensible and if it is thought that exercise is adversely affecting her recovery and she is in a dangerously poor state of nutrition, a discussion with the psychiatrist about the Mental Health Act may be justified. Even if a patient is on a "section" and is kept on the ward, it is very difficult to prevent micro-exercise. Initially, advice from a nurse who may be observing the patient one to one can be helpful, but a determined patient may continue. Again, if it is thought to be impairing her response to nutrition, it may be justified to use small doses of a benzodiazepine such as Lorazepam [7]. This can be hazardous, however, because of the potential for hypotension these drugs bring, in a patient who may already be hypotensive. There has been some interest in the use of Olanzapine [11] in the treatment of anorexia nervosa at a dose of around 5 mg. It may have some effect on weight, although this is disputed and being further investigated, but the drug may also have a beneficial effect on agitation and it would not be unreasonable to use it in patients with micro-exercising.

Suicidal Behaviour and Self-Harm

This is a large and very important subject and can only be dealt with cursorily here. A proportion of patients with eating disorders express suicidal thoughts and some even see starvation as a more acceptable way to die (e.g. for their families) than other methods. 20% of patients with anorexia nervosa who die do so by suicide [12]. Patient should be asked about suicidal ideation and psychiatric assistance obtained for patients with suicidal ideas. Self harm is characteristic in patients with eating disorders who also suffer from borderline personality disorder, but it also occurs in a proportion of patients who do not fulfil criteria for BPD [13]. Self harm can be very difficult to deal with on a medical ward, especially if the patient is resistant to attempts to improve nutrition. A meeting between the medical and the psychiatric team is essential and a clear management plan developed. Sometimes patients, usually female, may cut or burn a part of the body that they find most unacceptable, such as the stomach. A real danger with such a patient is the possibility of escalating levels of observation so the patient can find herself with one or two special nurses, sometimes with restraints on one or both wrists. Such treatment naturally requires a compulsory order, but even then it can be hard to justify continuing it for days or even months which has occurred in some cases. Escalating treatment can seem to be a motivating factor as in the following patient who was interviewed in an inpatient unit for eating disorders:

Doctor: How is it that you came to need two nurses looking after you?

Patient 5: Well I noticed that Jenny got her own nurse when she started cutting, so I did the same. Then when Jenny started cutting the other arm, so did I and I've now got two special nurses, like her, although I don't like it because I have hardly any freedom and both my wrists are bandaged to the bed.

Family Distress and Anxiety

When a patient is admitted for care to an inpatient bed, especially in a medical unit, the family members are well aware that their loved one is in a very dangerous medical state. They may also realise that eating disorders are not very well understood on the unit, and that experts in the subject may not be on the scene. Their anxiety is at very high levels, and is increased by shortage of information. The combination of fear for their loved one's survival, concern about competence and lack of information can lead to behaviour which may seem irrational. One family arranged for an uncle, a retired anaesthetist, to come and provide a second opinion which conflicted with the views of the consultant, leading to much heat and little light. In another case, the mother became convinced that the nurses were sexually interfering with her son who was on the ward with extreme malnutrition and a paranoid psychosis, probably of nutritional origin.

Such incidents are more easily prevented than stopped, and a number of principles can be suggested for managing the relationship with relatives.

1. Include at least one relative in discussions about the patient's care. Most patients over 18 will agree to their relatives being involved in treatment decisions.
2. Rather than deal with all members of the family, it is useful to ask them to nominate one member as the family representative, both for meetings and phone calls.
3. Make sure that information is available regularly; say every few days, so that the family's knowledge is up to date.
4. When there is clear distress which is not satisfactorily dealt with by the above measures, designate a sensitive and experienced team member to meet with the relative and attempt to resolve issues by providing support and information.
5. Because complaints are not unknown, staff should make sure that they document and justify their treatment decisions in case they are later examined.
6. As long as the collaboration between medical and psychiatric personnel is occurring as advised above, relatives can be reassured that experts in both the psychological and medical aspects of the condition are working together, and be invited to meet both sides, preferably together.

Safeguarding Concerns

Safeguarding for adults at risk because of mental disorder refers to the responsibility of staff looking after them to make sure they are not subject to abuse or neglect. The inpatient medical setting does not often provide examples of such abuse or neglect by carers or relatives of patients with eating disorders, although in some cases laxatives have been smuggled into the ward at the request of the patient and this could fall under safeguarding. On discharge home, staff must be clear that care is appropriate and as helpful as possible, which it almost always is, so that neglect or abuse does not take place after discharge.

In general, the MEED recommendations are designed to facilitate joint work between psychiatric and medical experts, and when there is doubt, the last recommendation in the right hand column should always be enacted "Mobilise psych team to advise on management".

Electrolyte and Micronutrient Imbalance

Hypokalaemia

Patient 6: A primary care physician referred a male patient of 32 to the emergency department. He was underweight, had been vomiting regularly for several years and had recently fainted. A serum potassium level was 1.9 mmol/L (normal range 3.5–5 mmol/L). The doctor in the emergency department noticed that his teeth were almost all worn away, with some fillings "standing proud".

Low potassium occurs quite commonly in the course of eating disorders. Self induced vomiting as a form of weight control occurs in bulimia nervosa and also in the bulimic form of anorexia nervosa. Among atypical eating disorders, patients of normal weight who purge without binge eating (termed "Purging disorder") are also at risk. The patient may or may not have relevant symptoms and although some patients describe muscle cramps or episodes of loss of consciousness consistent with cardiac arrhythmia, the problem is most often identified in a routine blood test. Low potassium can also occur after loss of the ion in diarrhoea, induced by extreme laxative abuse, and also sometimes because of very low intake in anorexia nervosa, restricting subtype. Examination may not be instructive, but the ECG may show U waves and other abnormalities (Fig. 4).

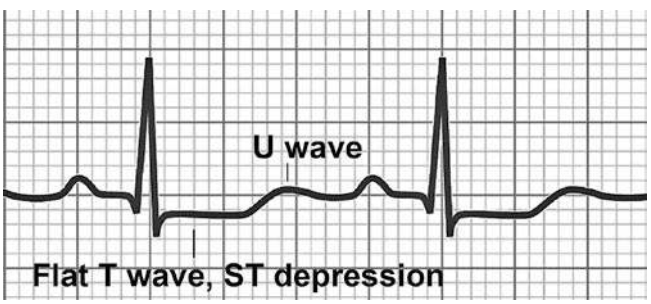

Fig. 4 ECG characteristics in hypokalaemia showing ST depression, T flattening and a U wave

The cause of hypokalaemia in eating disorders varies with the patient's behaviour. In the above case, the problem was repeated self induced vomiting over many years. Vomitus does not contain much potassium, and the mechanism of hypokalaemia appears to be mediated by loss of hydrogen ions from gastric juice, leading to a metabolic alkalosis. The attempt to correct this and restore body pH to normal, results in H+ being retained and K+ lost and this increases renal excretion of potassium and leads to hypokalaemia. However, the process can continue for some time while potassium, which is primarily intracellular, leaks out of the cells and maintains serum potassium levels. Only when total body depletion of potassium is substantial does hypokalaemia show itself.

In other situations, such as laxative abuse, the cause of hypokalaemia is loss of potassium in the stool, whereas in restrictive anorexia nervosa, the most likely cause is chronic under-ingestion of potassium. Lastly, patients with eating disorders, some of them doctors, nurses and pharmacists, may abuse diuretics in an attempt to reduce body water and achieve weight loss, which of course does not reflect any change in fat mass. The action of diuretics, especially the more powerful ones such as furosemide, is to stimulate the loss of sodium and potassium, and hypokalaemia can be the result. The metabolic effects of hypokalaemia are widespread and are serious and if unrecognised can be fatal.

Box 6 Consequences of Hypokalaemia
Sequelae of Hypokalemia

- Cardiac
  - Arrhythmias, cardiac arrest, increased digitalis sensitivity, orthostatic hypotension, EKG changes (T wave flattening or inversion, U waves, ST segment depression)
- Gastrointestinal
  - Constipation, ileus, exacerbation of hepatic encephalopathy
- Metabolic
  - Glucose intolerance, hypokalemic metabolic alkalosis
- Neuromuscular
  - Areflexia, hyporeflexia, paralysis, parenthesis, respiratory depression, rhabdomyolysis, weakness
- Renal
  - Decreased urinary concentrating ability, polyuria and polydipsia, nephropathy with decreased glomerular filtration rate, myoglobinuria (secondary to rhabdomyolysis)

Managing Hypokalaemia

The physician can safely assume that loss of potassium (K), whatever the route is likely to continue. Change in attitude to body image takes time and therapy and in the short term is unlikely. There have been reported cases of patients with hypokalaemia due to bulimia being given an intravenous infusion of potassium chloride until the serum potassium is in the normal range and then sent home with no follow up. This is a very dangerous practice and can result in the death of the patient. At the very least the patient requires regular and frequent (every few days) blood tests to monitor electrolytes, as well as support and therapy from an expert eating disorders practitioner. Secondly, considering that there is a large total body deficit of potassium, an infusion for a day is unlikely to replenish it, and longer treatment is required.

Intravenous potassium chloride is certainly an appropriate lifesaving intervention if potassium levels are very low. This can be followed by oral potassium chloride tablets to continue the process of repletion, bearing in mind that the patient may have resumed vomiting and potassium loss may therefore have resumed. Monitoring should take place every few days to detect recurrent low levels of potassium. In clinics without access to intravenous infusion (such as outpatient eating disorders clinics) the following schedule can be followed:

9 am: Blood test for potassium level
10 am–4 pm: If hypokalaemic perform ECG and give potassium chloride tablets every 2–4 h
4 pm: Repeat Blood test for K level
Send home if level > 3.5 mmol/L
Subsequent days: Repeat Blood test for K level
Send home if level > 3.5 mmol. Continue to monitor K.
If still hypokalaemic refer to emergency dept.

Another approach which is theoretically interesting is to give the patient (with intractable hypokalaemia due to vomiting) a proton pump inhibitor drug such as Lansoprazole [14]. The theory is that if the stomach can be prevented from secreting acid then vomiting should not lead to alkalosis, and so potassium does not need to be exchanged for hydrogen in order to keep the body's pH normal.

Hypoglycaemia

Low blood sugar is frequently observed in patients with low weight due to anorexia nervosa. The carbohydrate stores of the body, glycogen in muscle and liver, have often been exhausted as a result of a low calorie, especially a low carbohydrate, diet, and sometimes by exercise, either overt or "micro". In complete starvation glycogen is exhausted by

24–48 h [15]. At that point energy delivery to essential organs (brain and heart) is continued by switching to triglycerides and ketones produced by the liver and by day 3 some 30% of energy needs are provided in this way. Fat cannot be transformed to glucose, but protein can, through gluconeogenesis, although the amounts are limited and protein breakdown occurs, for example in muscle.

Hence, the hypoglycaemia seen in severe anorexia nervosa may not have the same clinical impact as the same low level of glucose seen after, for example, an overdose of insulin. The patient may be alert and functioning, because the brain is being fed with energy through ketones.

Patient 7: A young woman with anorexia nervosa was an inpatient on a medical ward. Her blood glucose, by finger-prick, was low at 2.5 mmol/L. At around midnight the on-call doctor rang the senior physician to report that the blood glucose machine was recording a level of zero. The physician asked if the patient was conscious and was assured that she was in animated conversation with nurses and other patients. The physician concluded that the machine must be faulty. The patient was found dead in the morning. The glucose monitoring machine was found to be functioning normally.

Hence, in spite of very low blood glucose the patient may be deceptively well. The management of this situation demands good clinical judgement. The low glucose can, as seen above, be fatal. However, the body has shown major adaptation to lack of carbohydrate and the amount of glucose required may be less than is given in an insulin overdose. It is probably safe to provide enough glucose to maintain serum levels within the normal range, with a combination of oral, bolus and intravenous glucose, but each case needs careful thought and closely monitored treatment. Glucose refeeding can induce acute thiamine deficiency in patients with severe malnutrition. Prophylactic intravenous thiamine is strongly recommended prior to giving any oral or intravenous glucose.

Other major electrolyte disturbances that can occur due to severe starvation or as a result of refeeding are hypophosphatemia and hypomagnesemia. The clinical manifestations are summarised in Boxes 7 and 8.

Box 7 Sequelae of Hypophosphatemia

- Decreased cardiac ATP
→ CCF
→ arrythmias
- CNS
  - Delirium
  - Seizures
  - paraesthesia
- Muscular skeletal
  - Rhabdomyolysis
  - Diaphragm dysfunction
- Haematological
  - Reduced RBC 2-3 DPG – oxygen dissociation curve to the left
  - Haemolysis
  - Reduced WCC function

Box 8 Sequelae of Hypomagnesemia

- Cardiac
  - Arrythmias, tachycardia, torsade de pointes
- Gastrointestinal
  - Abdominal pain, anorexia, diarrhea, constipation
- Neuromuscular
  - Ataxia, confusion, fasciculations, hyporeflexia, irritability, muscle tremors, painful paresthesias, personality changes, positive Trouseau's sign, seizures, tetany, vertigo, weakness

Renal Insufficiency

Eating disorders can cause renal failure by different mechanisms. Many patients with anorexia nervosa restrict not only calories, but also water and after months of such deprivation, the kidneys can be severely damaged.

Patient 8: A woman of 19 who had withdrawn from treatment the year before contacted one of the authors by email as follows: "Dear Dr, I think I need help. Maybe something can be done? Signed x". An urgent appointment was arranged and the history obtained that for the previous year, she had consumed, every day, only a small pie and half a glass of water. She was severely underweight and tests showed that she was in acute renal failure. She was admitted to a medical ward and a glucose infusion was set up, in order to encourage her kidneys to begin functioning again. She noticed that the infusion contained glucose, ie calories, and switched it off during the night. The nurses noticed what she had done and restarted the drip. However, she died a few hours later.

Apart from fluid restriction, the most common metabolic problem affecting renal function is hypokalaemia, discussed above. Patients who maintain very low levels of serum potassium for long periods may sustain progressive renal tubular damage and the result can be end stage renal failure, requiring dialysis sometimes followed by transplantation.

Refeeding Syndrome

Refeeding syndrome (RFS) is covered in chapter "Refeeding Problems". In eating disorders patients there are a few points worth noting (Figs. 5 and 6).

1. In discussions between physicians and psychiatrists during the MEED consultations, it was clear that RFS was more commonly seen by the physicians than the psychiatrists. The reasons for this are not readily apparent, but differences in practice did emerge, with patients in medical beds being given initial rates of feeding well below those admitted to eating disorder specialist beds. One likely explanation is that patients admitted medically may have had more major medical co-morbidities such as infection and cardiac problems and to be fed nasogastrically, than those admitted to eating disorder services. They may also have had lower BMI levels, simply because they had waited for treatment longer, become more ill and hence had required an emergency medical bed rather than a psychiatric admission. There may also have been differences in attitude between the two types of specialist, with physicians having had more experience of severe RFS than psychiatrists and hence being more cautious. In the end, the advice in MEED provides for lower initial kilocalorie provision for patients with the highest risk of RFS, and higher provision for the rest. However, it was stressed that to avoid Under Feeding Syndrome, calories should be increased rapidly while monitoring for the emergence of RFS.
2. Refeeding syndrome is more likely to occur in admitted patients, especially when enteral feeding is given. However, RFS has been described in a patient with anorexia nervosa who, during admission, began binge-eating [16]. This complication has also been observed in outpatients and the need for moderation in refeeding should also be conveyed to community patients with anorexia nervosa undergoing nutritional treatment in outpatients or day care. In practice, most patients' reluctance to eat and gain weight makes the emergence of RFS in patients on oral refeeding rather uncommon.

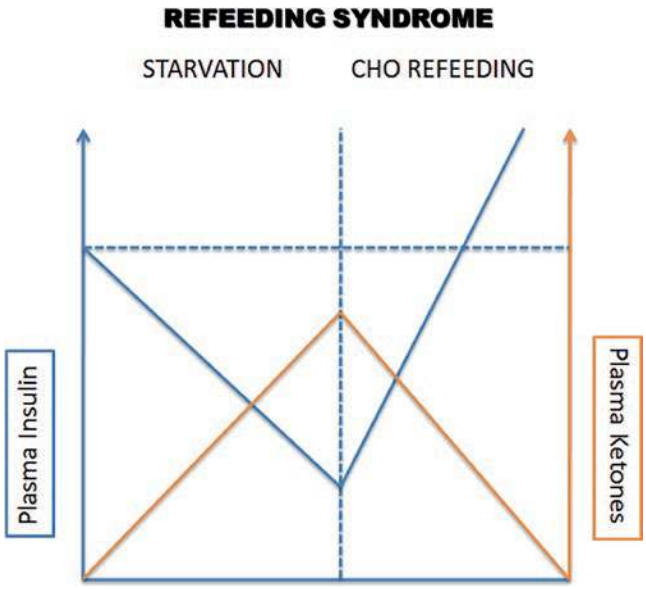

Fig. 5 Metabolic changes in starvation and carbohydrate refeeding

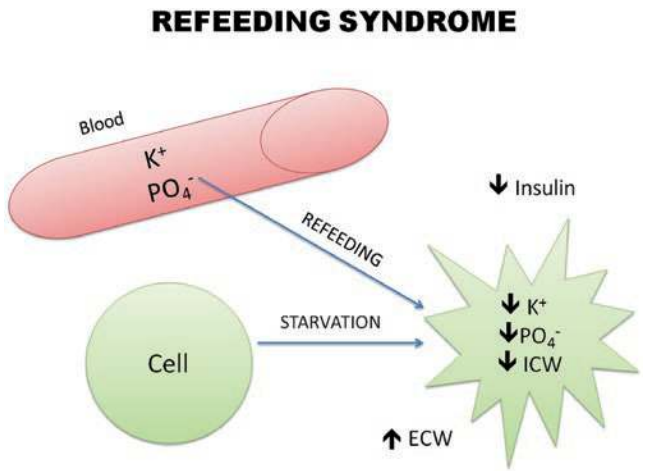

Fig. 6 Electrolyte and body water (Intracellular and extracellular) changes in starvation and refeeding

Fractures

The presence of fractures in a young person not associated with major trauma should alert the physician to the possibility of an eating disorder. The context can be the emergency department, where a patient may present with fracture of any bone, and the fracture may have occurred after relatively minor trauma. Patients with eating disorders who exercise by walking for hours may present with fractures in the foot ("march fractures") which seem to be the result of repeated minor trauma in a patient with osteoporosis. Other medical services including primary care can be consulted as a result of bone or joint pain, fractures or loss of height.

Patient 9: The man of 37 had suffered from anorexia nervosa since his teens with chronically low weight and frequent admissions. He was known to have severe osteoporosis. He was seen in an outpatients clinic and proudly announced that his anorexia had recovered. He explained that he had worked out his Body Mass Index and found that it had risen to 19. Further enquiry and examination demonstrated that his weight had remained the same, 45 kg, but his height had reduced from 1.74 m (BMI 14.9) to 1.54 m (BMI 19) over the previous 3 years as a result of spinal vertebral collapse fractures causing a kyphosis. The patient was advised to use his former height in order to work out his BMI.

Bone involvement in anorexia nervosa is progressive as long as weight is low. Within a year or two of onset, many patients are found to have osteopenia on the Bone Mineral Density "Dexa" scan. The T score in the spine and hip will be between <1 and <2.5. As years go by osteoporosis in more frequently observed (T score ≤2.5) and the rate of fractures increases. The aetiology of osteopenia in anorexia nervosa is complex. Unlike post-menopausal osteopenia, bone loss cannot be slowed using sex hormones [17]. The exception to this rule is that in adolescents with anorexia nervosa bone loss may be reduced by physiological doses of oestrogen delivered transdermally [18]. Sex hormones may therefore play a part in aetiology. Other hormones such as cortisol, which is increased in anorexia nervosa and which can reduce bone density may be relevant while the reduction in stress on bones which accompanies chronically low weight, in a process analogous to the osteopenia experienced by astronauts during periods of weightlessness may also be important. Nutritionally determined lack of calcium, vitamin D and protein are also candidates. Weight loss does seem to be the key factor, because restoration of weight leads to a reliable improvement in bone density [19] although it is not clear that complete bone recovery can occur.

Treatment with bisphosphonate drugs such as alendronate has been suggested as treatment for osteoporosis associated with anorexia nervosa. There effectiveness is in doubt [17, 20]. However, they have very long half lives in the body as they are bound to bone tissue (example half life 10.9 years for Alendronate) and treatment of a patient who may later become pregnant is controversial. One approach would be to restrict the use of bisphosphonates to patients with anorexia nervosa and severe osteoporosis in men and in women after childbearing age.

Gastrointestinal Symptoms

Many symptoms of eating disorders involve the gastrointestinal tract. It is therefore not unexpected that gastrointestinal disturbances can present to different physicians at varying levels of acuteness. Self-induced vomiting, which often accompanies anorexia nervosa and bulimia nervosa as well as an atypical eating disorder, purging disorder, which is mainly characterised by vomiting as a method of weight control. Enlargement of the parotids occurs in patients who vomit and also in those who binge-eat without vomiting. The parotids are usually non-tender and the occasional histological examination [21] has shown sialadenosis (non-inflammatory enlargement). Sore throat, sometimes with scratches on the pharyngeal mucosa, may accompany self-induced vomiting, and haematemesis due to oesophagitis related to reflux, or occasionally an oesophageal tear (Mallory-Weiss syndrome) in which case the bleeding may be massive and the patient gravely ill, have been described [22]. Patients with anorexia nervosa have delayed gastric emptying probably related to undereating and starvation [23, 24] and this can predispose to early satiety and, if large quantities of food are consumed, a danger of acute gastric dilatation and rarely perforation [25]. Occasionally oesophageal perforation has been reported in anorexia nervosa [26]. In patients with laxative abuse, very large doses of stimulant laxatives may be taken daily, initially in an attempt to speed calories through the gut, but later in response to increasing constipation and tolerance to the effects of laxatives. The patient may complain of diarrhoea, but in more chronic cases, constipation is seen and this may be resistant to laxative treatment. In a few instances, a "floppy colon" is seen, with severe constipation and rectal prolapse [27] which may require surgical treatment and sometimes colonic resection and a colostomy.

Acute abdominal pain in a very underweight patient with anorexia nervosa can be caused by pressure of the superior mesenteric artery on the duodenum (superior mesenteric artery syndrome, [28]) and requires urgent surgical treatment. Recurrent abdominal pain and colonic symptoms may be diagnosed as being due to Irritable Bowel Syndrome. The possibility of an eating disorder should be borne in mind before this conclusion is reached, although the conditions can co-exist.

Amenorrhoea and Infertility

Loss of weight usually leads to amenorrhoea and the association of low BMI and amenorrhoea should signal the possibility of an eating disorder, usually anorexia nervosa. Amenorrhoea is also common in patients with binge eating [29] and many patients with bulimia nervosa are found to have polycystic ovaries on ultrasound [30]. The association is not understood but women with bulimia nervosa in the latter study who had recovered showed normal ovarian morphology suggesting an effect of symptoms on the ovaries. Some patients with bulimia nervosa have lost significant amounts of weight, even though they are within the normal weight range, and this might contribute to amenorrhoea.

All patients referred for or applying for infertility treatment should be screened for eating disorder symptoms. Providing, for example, in-vitro fertilization to a woman who is seriously underweight as a result of anorexia nervosa [31] provides an ethical dilemma, because of the increased risk of pregnancy complications [32] and risks to the nutrition of the infant and child [33]. In the view of the authors, such patients should receive psychological and nutritional treatment for their eating disorder before embarking on infertility treatment.

Psychiatric Symptoms

Eating disorder symptoms such as food restriction, binge eating, vomiting and laxative abuse are of course psychiatric symptoms. However, here we draw attention to the comorbid symptoms such as depression, suicidality and self-harm which often accompany eating disorders and which may present to primary and secondary care and to emergency services. The mortality rate for patients with anorexia nervosa is one of the highest of all psychiatric conditions and a substantial percentage of those deaths are by suicide [12]. Hence, any patient with an eating disorder should be asked about suicidal thoughts and intentions and appropriate referrals considered if they are present. Moreover, a substantial proportion of patients with eating disorders [13] present with deliberate self harm, which may be part of a borderline personality disorder. The combination of an eating disorder and a borderline personality disorder requires complex treatment so that both conditions are taken into account. Drug and alcohol misuse can further complicate the picture and may require attention in their own right. Recognition of these interacting problems, which are sometimes the long term sequelae of childhood sexual abuse, in primary and secondary medical care, can be very helpful in triggering appropriate referral and reducing the rate of hospitalization and increasing symptoms that can otherwise occur [34].

Eating Disorders in the Clinic: Summary and Concluding Remarks

From the above review, which has been far from exhaustive, it can be seen that patients with eating disorders can turn up in almost any clinic in a health system. Acuteness of presentation varies from the cachectic patient near death carried into the emergency department, to the chronically ill patient with SEED (Severe and Enduring Eating Disorder, [35] presenting with symptoms due to osteoporosis, laxative abuse or social isolation, amongst many others. The task of the non-psychiatrist is to recognise the eating disorder and to treat the medical complications bearing in mind that eating disorder symptoms often make treatment, especially if it leads to improved nutrition, very difficult. There is no doubt that some clinical staff in all areas of work, faced with a patient who is obviously in need of treatment, but who is doing her best to avoid and sabotage that treatment, may lose sympathy for the patient, and that can affect the patient's care. Our advice is to try and view the patients as in the grip of a process that they cannot control, which leads to these sabotaging behaviour, and to avoid blaming the patient. In addition to the belief that the patient is to blame for the symptoms "doing it to herself", there is also a widespread belief that there is not very much hope for these patients and this also can affect staff reactions to them. In fact the eating disorders have a recovery rate of around 50% and that improves as patients with shorter illnesses are treated. There is evidence, for example in anorexia nervosa, that treatment within 3 years of onset can substantially improve prognosis [36].

Treatment of eating disorders follows, in general a bio-psycho-social model of care. Bio: The "bio" part of this triad involves assessment of general medical state, of risk to health and life and treatment of those medical problems, some of which have been discussed here. This includes resuscitation of a patient in an extreme state of nutritional deficiency or electrolyte imbalance, managing refeeding safely and monitoring and treating some of the chronic sequelae of eating disorders such as osteoporosis and infertility. Under the "bio" heading we also have physical treatments for psychological disorder. In eating disorders, treatment of undernutrition can be seen as such an intervention and this includes offering and supervising meals and occasionally, if life is at risk, imposing nutrition by oral or nasogastric feeding under the Mental Health Act.[2] There are many drug treatments in psychiatry and most of them have been tried in eating disorders. Antidepressants which are effective in many patients with depressive illness seem much less effective when weight is low [37] perhaps because of the neuro-transmitter changes that may occur at low weight. In bulimia nervosa however, antidepressants, such as Fluoxetine 20-60 mg daily, have been found to have a significant impact on bulimic symptoms and are recommended in NICE for eating disorders [1, 38]. They are less effective than psychological treatments and the patient may relapse when the drug is withdrawn, and it seems to the present authors that the role of antidepressants in bulimia nervosa should probably be restricted to patients who remain unwell after a course of psychological treatment such as cognitive behavioural therapy. This approach has been tested and found to give better results than treatment with either method separately [39]. Neuroleptic drugs such as Olanzapine [40] have been used in anorexia nervosa on the basis that they cause weight gain in patients with schizophrenia. They may have an effect on BMI, fear of weight gain and general anxiety in anorexia nervosa but the treatment remains controversial and large randomised trials are awaited. On an even more experimental basis, brain treatments such as repetitive transcranial magnetic stimulation (rTMS) [41] and deep brain stimulation (DBS) [42] have both been tested in trials with some encouraging but not conclusive results in patients with severe intractable anorexia nervosa.

The main treatments in eating disorders are psychological. These include assessment of motivation to change using the methods developed in the treatment of alcohol misuse

[2] https://www.gov.uk/government/publications/code-of-practice-mental-health-act-1983.

Table 1 The 6 phases of motivation

Level of motivation	Description	Typical statement
Pre-contemplation	Denial	There's nothing wrong with me. It's everyone else's problem. They need to change
Contemplation	Acceptance there might be a problem, but not acting to change it	I think my eating is problematic, and maybe my weight, but I can handle it and don't need to change it just yet.
Preparation	Preparing to take action to address the problem	This problem is affecting my life seriously. I'm planning to get help to address it
Action	Acting to alleviate the problem	I'm now in treatment and am struggling to deal with the problem
Maintenance	Taking steps to reduce the risk of relapse	I'm a lot better and need to remain alert to the possibility of relapse
Relapse management	Re-establishing control during a relapse	My symptoms came back and I'm putting a lot of effort into getting them under control again

[43]. This essentially involves interviewing the patient in a way that elicits his or her attitude to the illness, its negative (and positive) aspects, and the pros and cons of change. The patient may be asked to write a letter to "My eating disorder as my friend" and "My eating disorder as my enemy" in order the make explicit the ambivalence about change that is often present in patients with eating disorders, in preparation for a discussion with the patient about change, including how much change and at what rate. The different levels of motivation are illustrated in Table 1.

The motivational sequence, which can also be seen as a cycle, can be applied to any problem in which behaviour can affect health adversely including weight loss in obesity, diabetic control, dietary approaches to hypertension and renal disease, as well as misuse substances such as alcohol and other drugs. In eating disorders treatment, elements of motivational enhancement can be found in many approaches and rather than a stand-alone therapy it is probably better seen as an important component of treatment. The main psychological treatment that has been found to be effective in controlled trials in eating disorders is cognitive behaviour therapy for bulimia nervosa (CBT-BN) [44]. This approach initially concentrated on the behaviours which lead to eating disorder problems (such as restriction, binge eating and vomiting) and on the cognitions, such as body image disturbance and low self esteem, underlying such behaviours. More recently there has been a recognition that emotional dysregulation (inability to control or manage unpleasant feelings such as depression, anxiety or anger) have an important role in eating disorders and treatment of those problems has been included in CBT-BN. CBT has been extended (CBT-E) to include other eating disorders such as anorexia nervosa [44] and trials are awaited. Other therapies have been used which primarily address emotional and relational problems (Interpersonal therapy [45] and mentalization based therapy [46]) and one approach, Cognitive Remediation Therapy, [47] has been introduced which addresses the detail focus and cognitive rigidity that particularly occurs in low weight patients.

Social: This is a big area and includes family based therapy, sometimes provided in multiple family groups which is particularly indicated for younger patients with anorexia suffering from a relatively short (<3 years) illness [48], support and education for carers and families of patients with eating disorders [49], and attention to the major social and occupational problems encountered by patients with eating disorder, especially after several years of illness [50].

Should the health worker, whether doctor, dietitian, nurse or psychologist, be a generalist or a specialist? As in most areas of health, the more you know about a subject the better the likely deal is for the patient. Thus, initial treatment of a diagnosed eating disorder should, we believe, be from a specialist in the field, or a generalist who is working closely with a specialist, for example as supervisor or collaborator. This may be in a specialist outpatient, day patient or inpatient setting. When non-specialists are involved because of specific circumstances, as in the case of the patient admitted via the emergency department to a medical bed, we recommend that the medical team involves the eating disorder specialist or liaison psychiatrist as soon as feasible, and that care is shared with frequent joint review and consultation, as recommended in MEED. In non-emergency cases, as long as the patient has been assessed and treated by a specialist team, follow up can reasonably come from primary care or another non-specialist health worker. It is in the early cases (less than 3–5 years from onset) that we have evidence that specialist care can make the greatest difference to prognosis. After that the evidence is not so strong. It should also be emphasised that however long the history, complete recovery, although less likely, is never impossible and all of us in the field have seen patients recover completely after 20 or 25 years of continuous illness, sometimes for reasons that we cannot fathom.

Intestinal Failure in Children: A Paediatric Surgical Perspective

Alexander L. Macdonald, Hannah Thompson, and Mark Davenport

Key Points

1. 'Surgical' short bowel whether congenital or acquired, is the commonest cause of intestinal failure in infancy and childhood
2. Remaining intestinal length is more meaningful when expressed as a percentage of the normal expected intestinal length for the infant's age/weight
3. Initial surgical management should adhere to the principles of preservation of enteral mass and continuity by distal refeeding and avoidance/early closure of stomas
4. Autologous intestinal reconstruction (AIR) has potential to deliver enteral autonomy.
5. Longitudinal Intestinal Lengthening and Tailoring (LILT) and Serial Transverse EnteroPlasty (STEP) represent the mainstay of contemporary AIR and combine increasing length and improving propulsive proficiency in a single procedure

Introduction

Intestinal failure in neonates and infants primarily results from insufficient intestinal mass—i.e. a 'short bowel' which is insufficient to maintain adequate nutrition to support normal physiology and growth. Consequent long-term dependency upon parenteral nutrition (PN) may result in significant morbidity and mortality from intestinal failure associated liver disease (IFALD); catheter related bloodstream infections (CRBSI); and metabolic and renal disease. Early adoption of synergistic medical and surgical strategies to augment the natural physiological process of adaption and maximise the potential for enteral autonomy are critical to long-term survival in this population.

A. L. Macdonald · H. Thompson · M. Davenport (✉)

Definition

Normal small bowel length in term infants (derived from autopsy and multi-visceral transplant donor studies and measured un-stretched at the anti-mesenteric border) is typically considered to be 300 cm with potential to reach 600 cm by adulthood [1, 2]. Traditionally the actual length of the remaining bowel has been used for prognosis though agreement and consensus on what constituted "short" was seldom achieved. A more recent trend has been to express the remaining functioning intestinal length in terms of a percentage of the *expected normal length* for an infant of that age or weight. This distinction is particularly important in pre-term infants as in this population bowel lengths will more than double in late gestation from normal physiological growth alone (e.g. 'normal' length between 19–28 weeks gestation is observed to be 142 ± 22 cm increasing to 304 ± 44 cm by 35 weeks [1]). This makes the finding of 20 cm of remaining small intestine in a 27-week premature infant perhaps less concerning than the same finding in a term infant as it still has considerable functional reserve. So where to draw the line? Recent work has suggested that infants with <10% of the expected length have demonstrably poorer outcomes [3] and certainly those with less than 40 cm remaining are likely to require long-term PN as well as adjuvant medical and surgical strategies to promote enteral autonomy.

Aetiology of Short Bowel

Figure 1 illustrates the leading causes of surgical short bowel in the paediatric age-group. There are two equally prevalent causes in infancy with completely different characteristics: necrotising enterocolitis (NEC) and gastroschisis. The former is almost invariably found in the preterm infant—particularly those <30 weeks gestation—with multiple other co-morbidities (e.g. cerebral haemorrhage), whilst the latter are usually isolated anomalies in otherwise normal term infants. The usual reason for intestinal loss in gastroschisis is

J. M.D. Nightingale (ed.), *Intestinal Failure*, https://doi.org/10.1007/978-3-031-22265-8_15

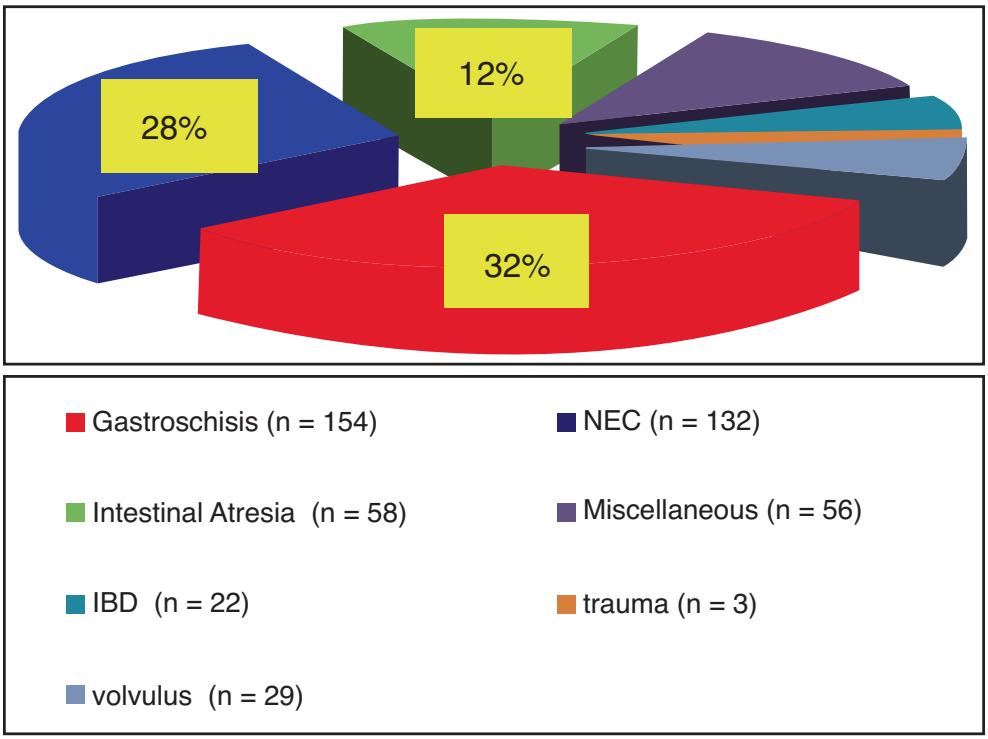

Fig. 1 Aetiology of short bowel syndrome (n = 477). Data are taken from the British Intestinal Failure Survey (BIFS) (2005–2013)—and defined by need for parenteral nutrition beyond 28 days. Abbreviations: NEC necrotising enterocolitis; IBD inflammatory bowel disease

Fig. 2 Closed Gastroschisis. Necrotic midgut and typically the only viable residual bowel is an intraabdominal consisting of a short length of jejunal atresia and a corresponding segment of colon distal to the exit colon atresia. (Reprinted with permission from [4])

due to in-utero closure of the defect with resultant ischaemic compromise of the entire extra-abdominal midgut (known as a 'closed' or 'closing' gastroschisis [4]) (Fig. 2). The third most common cause of short bowel is due to a congenital intestinal atresia—typically jejunal atresia—which is associated with distal intestinal loss and gross dilatation of the remaining proximal bowel [5]. While the limited enterocyte mass is clearly important in short bowel sometimes dysmotility may also lead to major difficulties in achieving enteral autonomy. The residual bowel in gastroschisis and intestinal atresia seem particularly affected by this functional deficit.

Initial Medical Management

Initial surgical intervention should seek to minimise disruption to physiological intestinal adaptation and further surgical intervention is indicated when medically augmented adaptation fails to achieve enteral autonomy. It is thus important to understand both the physiology of adaptation and to appreciate what constitutes optimal medical augmentation.

Adaptation is the physiological process by which the remaining intestine increases its absorptive capacity following resection. The capacity for adaptation is dependent upon the type of bowel remaining. Loss of ileum represents the more significant insult as ileum has the greatest potential for compensation. Ileum is essential for the secretion of cholecystokinin and secretin as well as the resorption of bile acids. Resection of ileum thus leads to increased gastric acid secretion (as a consequence of loss of hormonal secretion) and osmotic diarrhoea (as a consequence of bile salts entering the colon) [6].

In promoting maximal potential for adaptation medical management seeks to; augment the physiology of adaptation; deliver safe parenteral nutrition; and minimise the complications of short bowel.

Enhancing the Physiology of Adaptation

Intestinal adaptation is stimulated by enteral nutrients and consequently a mainstay of promoting adaptation is the early introduction of enteral feeding regardless of the remaining intestinal length. Breast milk contains gastrointestinal hormones, immunogenic factors and amino acids, however it has a high lactose content the absorption of which may be hindered by the reduced surface area and enzyme activity that is inherit with short bowel. An extensively hydrolysed formula with a higher proportion of glucose polymers is thus an acceptable alternative. Bolus feeding is often poorly tolerated in short bowel and continuous feeding has the advantages of increased transit time, increased absorption and a lower risk of osmotic diarrhoea. The increased rate of oral aversion in tube-fed infants should be recognised and proactive strategies (such as "tasters" and trophic oral feeds) should be employed to minimise the long-term impact.

Adaptation may be pharmacologically stimulated by administration of exogenous trophic hormones. Human growth hormone (hGH) combined with the amino acid glutamine has been show to enhance adaptation and absorption improving both weight gain and lean body mass. However in the majority of published trials the effects are short-lived with a return to baseline shortly after cessation of therapy. At present there is insufficient evidence to support routine use of hGH and glutamine regimens in children with short bowel [7].

The proteinogenic amnio acid glucagon-like peptide-2 (GLP-2) analogue teduglutide acts to promote growth of intestinal mucosa and has regulatory approval for use in children >1 year. In open-label trials, teduglutide (0.025 or 0.05 mg/kg/d) was associated with trends toward reduction in PN requirements with the higher dose resulting in a 52% reduction in PN calorie requirement [8]. Reported disadvantages include: its high cost (£260 per 1.25 mg vial—price valid in 2017); reversal of effect on discontinuation of treatment; and concerns regarding malignancy with long-term use in children [3].

Short chain fatty acids (SCFAs) are the breakdown products of carbohydrates and are mediators of GLP-2 release. SCFAs can enhance absorption by up-regulating the glucose transporter proteins GLUT2 and SGLT-1 [9] and the addition of SCFAs to PN has been demonstrated—in animal models—to both prevent TPN-associated mucosal atrophy and enhance intestinal adaptation [10].

Delivering Safe Parental Nutrition

Delivery of parenteral nutrition must be both safe—minimising PN associated complications—and sustainable through preservation of venous access routes.

Liver Disease

Long-term use of TPN in infants can result in a subtype of cholestatic liver disease latterly termed Intestinal Failure Associated Liver Disease (IFALD). This in itself is probably the single most important reason for mortality in the paediatric age-group and causes cholestasis and steatosis leading to macrophage activation, liver fibrosis and ultimately liver failure. IFALD is related to the duration of PN with a fivefold increase observed per week of PN administration [11] and the 'immaturity' of the liver when the PN starts. Sepsis may also have a profound detrimental effect on worsening IFALD. The key preventative strategy is to establish enteral autonomy but it may also be minimised using 'hepatoprotective' PN formulations and specifically lipid emulsions derived from fish-oil (Omegaven®) or a mixture of fish oil, olive oil and soybean (Smoflipid®) that are less inflammatory and cholestatic [12–14].

Catheter Related Bloodstream Infections (CRBSIs)

PN is delivered via a single lumen cuffed tunnelled venous catheter of an appropriate size for the infant (suitable catheters are available in sizes of 2.7Fr upwards). Nowadays, lines should probably be inserted using percutaneous image-guided techniques as this is associated with lower rates of infection and critically—in infants that may have limited viable access routes—allows for considerably more uses of a given vessel [15, 16].

Short bowel patients are particularly susceptible to sepsis with rates as high as 68% [17]. Multiple factors contribute to this including; reliance on central venous catheters; concurrent presence of stomas; a more permeable GI epithelial barrier with consequent bacterial translocation [18] and a general paucity of physiological reserve. CRBSIs result in sepsis, thrombosis and loss of vascular access routes. The risk of CRBSIs is increased by frequent access to the catheter for administration of IV fluids or blood sampling and poor aseptic technique when inserting, changing and accessing catheters.

A systematic focus on aseptic techniques enshrined in so-called 'enhanced catheter care bundles' minimises the incidence of CRBSIs. Comprehensive bundles comprise; the use of chlorhexidine-impregnated patches at exit sites; daily bathing; ethanol line locks; two nurses for catheter care in a distraction-free environment; peripheral phlebotomy; the bundling of routine blood tests; and changing PN administra-

tion sets every 24 h. Successful implementation can lead to dramatic (85%) reductions in CRBSI rates [19] and incidences as low as 0.42 CRBSIs per 1000 catheter days are achievable [20].

Managing the Complications of Short Bowel

Disruption to Enterohepatic Circulation of Bile Acids

Loss of ileum disrupts the enterohepatic circulation of bile acids [21]. These unabsorbed bile acids irritate colonic mucosa resulting in a secretory diarrhea. Bile acids may be bound by cholestyramine and exogenous administration of the bile acid ursodeoxycholic acid (UCDA) may be utilised to improve the enterohepatic circulation by exchanging hydrophobic for hydrophilic bile acids improving bile flow and reducing cholestasis [22, 23].

In PN dependent infants with evidence of significant cholestasis UCDA has been demonstrated to shorten the duration of cholestasis and reduce peak bilirubin levels with effects seen within 1–2 weeks. However discontinuation of UCDA results in relapse [24].

Bacterial Overgrowth

Stasis resulting from dilatation and sumping produces an environment for bacterial overgrowth which is measurably present in up to 60% of surgical short bowel patients [25]. This can lead to; bacterial consumption of enteral nutrients and vitamins; de-conjugation of bile acids; accumulation of toxic metabolites (such as D-lactate); bacterial translocation and subsequent septicaemia. Clinically overgrowth is manifest as abdominal pain, anorexia, vomiting, diarrhea, cramps, and a metabolic acidosis from the accumulation of D-lactic acid which can lead to the significant complication of D-lactate encephalopathy. D-lactic acidosis may be avoided by judicious management of carbohydrate intake and enteral antibiotics. However overzealous management of symptoms with antibiotics can contribute to further overgrowth and appropriate stewardship through antibiotic-free period and cycling of agents is important. An alternative strategy is probiotic therapy with non-D-lactate producing bacteria [26].

Rapid Intestinal Transit

Where transit is rapid the judicious use of agents such as loperamide to reduce peristalsis can delay transit times and increase absorptive potential by increasing the duration of exposure of nutrients to the available mucosal surface area [27].

Hyperacidity

Increased gastrin levels due to loss of the gastrin-metabolising function of the bowel results in increased gastric acid production in up to half of infants with short bowel. Hyperacidity may result in: peptic injury to the stomach and small bowel; systemic acid-base imbalance; and inactivation of pancreatic enzymes with consequent malabsorption [28]. Acid suppression with agents such as the proton pump inhibitor, omeprazole, may mitigate these sequelae.

Surgical Management

The surgeon has a critical role to play both at the time of the initial finding of short bowel in an infant (the initial laparotomy) and in the weeks to follow.

The principles of initial surgical management (Box 1) comprise:

1. Comprehensive documentation of the findings at laparotomy
2. Preservation of intestinal mass
3. Facilitation of post-operative refeeding
4. Early establishment of intestinal continuity
5. Autologous intestinal reconstruction (AIR)

Box 1 Initial Principles in the Surgical Management of Short Bowel

Initial surgical principles
• Document length, quality and type of remaining bowel
• Preserve continuity and intestinal mass where possible
• Undertake distal refeeding and early closure of stomas
• Facilitate the creation of proximal dilatation when future AIR is thought to be likely necessary

The Initial Laparotomy

The length, type and quality of remaining bowel should be clearly recorded. Where viability is in question, a second look laparotomy at 24–48 h should be planned to minimise the requirement for resection. The length of bowel and the degree of dilatation present is key to both prognosis and the planning of future surgical interventions and so must be accurately measured and documented. It is also important to note the presence or absence of the ileocaecal valve (ICV) as its loss has been identified by some authors as an independent risk factor for requirement for future AIR. However it simply may indicate loss of a significant part of the colon in the pathology and the true significance remains controversial [29, 30].

At initial laparotomy the advantages and disadvantages of the creation of defunctioning stomas as against preservation of enteral continuity must be carefully weighed. Anastomosis

and preservation of continuity increases the potential for early enteral adaptation by maximising the absorptive surface available and prolonging transit times [31]. Preservation of intestinal continuity should thus be aimed for as the primary surgical strategy. This is particularly important in infants with >40 cm of small bowel and an intact ICV as this particular group is likely to achieve enteral autonomy by adaption alone [32]. However in those with shorter remaining bowel lengths early continuity is likely to result in high stool output and significant perianal excoriation [3]. If a stoma is chosen then it is important to bring out the distal bowel as a mucous fistula in order to gain the post-operative possibility of content re-feeding.

Necrotising Enterocolitis

In the context of neonatal acquired short bowel, necrotising enterocolitis (NEC) represents a unique surgical scenario. Unlike congenital short bowel (e.g. intestinal atresias) the remaining bowel isn't prone to significant dilatation and dysmotility [33]. Consequently outcomes are potentially relatively favourable but only if measures are taken to preserve intestinal mass from the outset. To this end when faced with the neonate with extensive and/or multifocal disease at the initial laparotomy the surgeon should consider either forming a high de-functioning jejunostomy (up to 10 cm from the duodenal-jejunal flexure) or undertaking a 'clip and drop-back' procedure [34, 35]. With the clip and drop-back technique any clearly necrotic bowel is excised but segments that are of questionable viability are initially retained by oversewing their ends/sealing them with LIGACLIP®s and dropping them back into the abdomen. With both approaches the diseased bowel is initially left in situ and whilst this may place a significant septic burden on the neonate it allows for the possibility of the recovery of a meaningful proportion of the intestine. In the clip and drop-back technique the abdomen is re-entered within 48–72 h, whereas when a high jejunostomy has been created re-laparotomy is typically postponed for 4–6 weeks.

Refeeding

Where stomas have been created at the initial laparotomy distal refeeding should be instituted as early as possible (Fig. 3). Refeeding is undertaken by regularly recycling the proximal effluent into the distal stoma under gravity via a soft catheter (e.g. a Jacques catheter) [32]. In addition to 'priming' the distal bowel prior to closure of the stomas, refeeding provides an additional source of calories through the colonic absorption of short chain fatty acids [3]. In situations where either the viability of the distal bowel is questionable or the development of a distal stricture is considered possible (e.g. in NEC) a distal contrast 'loopogram' should be performed with a water-soluble contrast agent prior to commencement of refeeding.

Fig. 3 Refeeding. Luminal content is aspirated and then slowly reinfused using a soft catheter into the distal mucus fistula

Autologous Intestinal Reconstruction

Following the initial laparotomy a significant proportion of infants will undergo successful enteral adaptation and achieve enteral autonomy without the need for further intervention. However for those infants who fail to achieve enteral autonomy despite optimal medical strategies to promote adaptation further surgical intervention in the form of autologous intestinal reconstruction (AIR) should be considered.

Aims of AIR

Intestinal dilatation which occurs as part of intestinal adaptation leads to stasis and secondary dysmotility resulting in bacterial overgrowth, increased risk of translocation and consequently sepsis. Indeed the presence of dilatation has been identified as an independent risk factor for prolonged PN requirement and decreased survival [33]. While AIR can-

not increase absolute enterocyte mass it can increase available bowel length and reduce the luminal dimeter. This results in an increase in transit times and perhaps an increase in mucosal surface area exposed to luminal contents facilitating absorption. The bowel length achieved post-AIR has been shown to correlate significantly with the percentage requirement for PN in the first post-operative year [36]. The reduction in the luminal diameter improves the efficacy of peristalsis reducing stasis and the associated bacterial overgrowth that results in complications of translocation, sepsis and malabsorption.

AIR should thus be considered in the setting of any infant who fails to achieve EA despite optimal medical management necessitating prolonged continuation of PN or in those infants thought unlikely to ever achieve EA by adaptation and conservative means alone. Additionally AIR should be considered in the presence of intestinal dilatation of a degree that is likely to be resulting in stasis/dysmotility (Box 2).

Box 2 Indications for and Contraindications to AIR in Children

Indications for AIR
• Failure to achieve enteral autonomy
• Intestinal dilatation
Relative contraindications to AIR
• Significant IFALD
– portal hypertension
– thrombocytopaenia and coagulopathy
– cirrhosis
• Ultrashort bowel length (<10 cm)
– probably futile

AIR is however contraindicated in certain scenarios and particularly in the presence of significant IFALD manifest as high-grade fibrosis and/or the presence of portal hypertension). In this context consideration should be given to liver or combined liver and small bowel transplantation the specifics of which are out-with the scope of this chapter. AIR may still have a role in this population as a bridge to transplant for those infants too young/small to receive organs. Typically the youngest recipient would be older than 2 years of age.

Intestinal dilatation is the *sine qua non* of autologous reconstruction. Typically dilatation of a segment/segments of bowel greater than 4 cm or more than twice the normal luminal diameter for age are quoted as necessary to undertake successful AIR [37].

One has to be realistic about the prospects of significant benefit in infants with ultra-short bowel. Clearly in a scenario where the remaining intestinal length is 10 cm or less, then even achieving a doubling of this length following successful AIR is unlikely to afford a significant nutritional benefit.

Timing of AIR

Intestinal adaptation typically starts within 48 h of the original insult/bowel resection and whilst it occurs most rapidly in the first year it is a continuous process that can take up to two years to complete [38, 39]. As a general principle AIR should be undertaken at the point where the child has shown a plateaux in their capacity to tolerate advancement of enteral nutrition. However, clearly there is a balance to be struck between postponing AIR for a sufficient enough period of time as to allow medically augmented adaptation to occur and minimising the time for which the child is dependent on PN (and exposed to its associated complications). AIR has been reported to have been undertaken as early as the first day of life [40] and as late as 15 years [41] but generally techniques such as the LILT and STEP are undertaken in infancy at around 2–3 years of age. However some would now advocate that when the future need for AIR is considered inevitable then earlier intervention should be undertaken—e.g. within the first year of life—to take advantage of the normal rapid growth and development that occurs in this period [42]. In predicting the eventual need for AIR the underlying aetiology of the infants short bowel should be taken into consideration. Certain pathologies like small bowel atresia have been reported as being a 13-fold more likely to require AIR whereas others like NEC are eightfold less likely to require AIR [33].

AIR Procedures

A variety of procedures fall under the umbrella term autologous intestinal reconstruction. These include: intestinal tapering; segmental reversal of the small bowel (SRSB); colonic interposition; the Iowa procedure; the longitudinal intestinal lengthening technique (LILT); serial transverse Enteroplasty (STEP) and spiral intestinal lengthening and tailoring (SILT).

Intestinal tapering [43] is relatively straightforward way of correcting a dilated segment and facilitating anastomosis. As it means discarding at least some mucosa it tends to be reserved for situations where bowel length is not critical. Imbrication may achieve the same effect but needs to be done with non-absorbable sutures otherwise it tends to come apart with time.

Segmental Reversal of the Small Bowel (SRSB) [31] refers to a procedure in which a segment (typically 3 cm) of small bowel is interposed distally in an antiperistaltic orientation. This acts to slow transit time, prolonging contact time with nutrients and increasing absorptive potential. This procedure may also be used as a means to produce the proximal dilation necessary for other AIR procedures. A segment of colon may also be interposed in in an antiperistaltic orien-

tation to achieve a similar effect without the need to resect small bowel. Alternatively, the colon may be interposed in an isoperistaltic orientation and the colon's generally slower motility and greater capacity to absorb fluid and electrolytes is relied upon to improve enteral tolerance [44].

The Iowa procedure was described by Ken Kimura in 1992 [45] and is a two-stage procedure whereby a dilated loop is split longitudinally and the antimesenteric segment is attached to an autologous host organ (e.g. liver) allowing for the generation of a collateral blood supply. At a subsequent laparotomy this bowel is reincorporated in an isoperistaltic manner as a 'new' loop. There is very little evidence of its practical use.

Aside from tapering, most of these procedures have failed to find a role and are now predominately only of historical interest. At present this leaves the LILT and STEP procedures as the mainstay of contemporary AIR surgery in children, together with the newly introduced technique of SILT.

Longitudinal Intestinal Lengthening Technique

The principle of the longitudinal intestinal lengthening technique (LILT) was first proposed by the Maltese paediatric surgeon Adrian Bianchi while working in Manchester, UK in the 1980s [46]; initially using an experimental animal model of short bowel and then first undertaken that same year on a 4 year old with 40 cm of small bowel, PN dependence and limited venous access [47]. The child achieved EA within 10 weeks and the procedure has gone on to gain widespread acceptance. LILT takes advantage of the anatomical observation that the small intestinal blood supply separates within the mesentery to one side or the other someway short of the actual bowel wall. This allows the bowel to be divided along its axis and at 180^0 anti-mesenterically with complete vascular preservation (Fig. 4a). The two intestinal "halves" are then tubularised and isoperistaltic continuity restored (Figs. 4b–d, and 5a, b).

Serial Transverse EnteroPlasty

The serial transverse enteroplasty (STEP) procedure was first described by Kim et al. in Boston, USA in 2003 (initially on a porcine model and then on a 2 year old boy) [48]. Owing largely to its ease of application it has gone on to achieve widespread adoption and to date numerous centres participate in an international registry. Firstly small mesenteric "windows "are created, then a GIA stapler is fired part way across the bowel diameter. This is repeated at equal intervals and from alternate sides (Fig. 6a) to create a zig-zag channel of about 1–2 cm diameter (Fig. 6b). The STEP can be undertaken as a primary procedure or applied to a segment of bowel previously lengthened by the LILT. Additionally STEP may be reapplied to bowel previously lengthened by STEP which has re-dilated in what is termed the ReSTEP procedure [49].

Spiral Intestinal Lengthening and Tailoring

Spiral intestinal lengthening and tailoring (SILT) was described by Cserni in Debrecen first on a synthetic bowel simulator in 2011 [50] and then in 2014 on a 3 year old girl with 15 cm of jejunum following a midgut volvulus [51], this represents the most recent of the reported AIR techniques in children (Fig. 7). Continuous spiral lines are marked between the mesenteric and antimesenteric border of the bowel at 45–60° to the longitudinal axis of a loop. These lines are incised and the bowel is stretched over a catheter and the edges sutured in a continuous fashion to produce a tube of longer length but narrower diameter. Its proposed advantages are that it involves minimal handling of the mesentery and—unlike STEP—does not disrupt the orientation of the bowel's muscle fibres. To date the reported experience of this technique is limited to case reports and small case series [52].

Outcomes of AIR and Choice of Technique

LILT and STEP represent the mainstay of AIR in children. Both techniques are attractive as they are single stage procedures that result in both a lengthening of the intestine and a reduction in calibre without requiring sacrifice of intestinal mass. Meaningful comparison of the outcomes of these two procedures (Table 1) is hindered by small numbers; heterogenous patient populations and a paucity of comparable long-term follow-up data (owing in part to the more recent inception of STEP in 2003 vs 1980 for the LILT). Thus any direct comparison should be interpreted with caution. However published outcome data to date would suggest that whilst LILT would appear to result in a greater proportion of infants successfully weaning from PN it is associated with a higher transplant rate [37]. This seemingly conflicting data is likely in part a consequence of the availability of longer-term follow-up data for the LILT.

LILT is a technically more challenging undertaking but certainly not beyond the reach of most neonatal surgeons. STEP however is relatively straightforward if one can get one's hands on a linear stapler (preferably an EndoGIA™) and is perhaps more versatile and may be applied to any length of dilated bowel including the duodenum [53]. Intestinal re-dilatation occurs following STEP at a greater rate than is reported following LILT [37], however unlike the LILT (which cannot be repeated on the same segment of bowel as the mesentery has already been split) STEP may be repeated as a ReSTEP procedure [49]. Complications arising from STEP include bleeding from staple-line ulcers (which can be life-threatening [54]), perforation and fistula formation.

Ultimately the choice of the most appropriate AIR procedure ought to be a combination of the surgeon's experience/familiarity with a particular procedure and the infants age

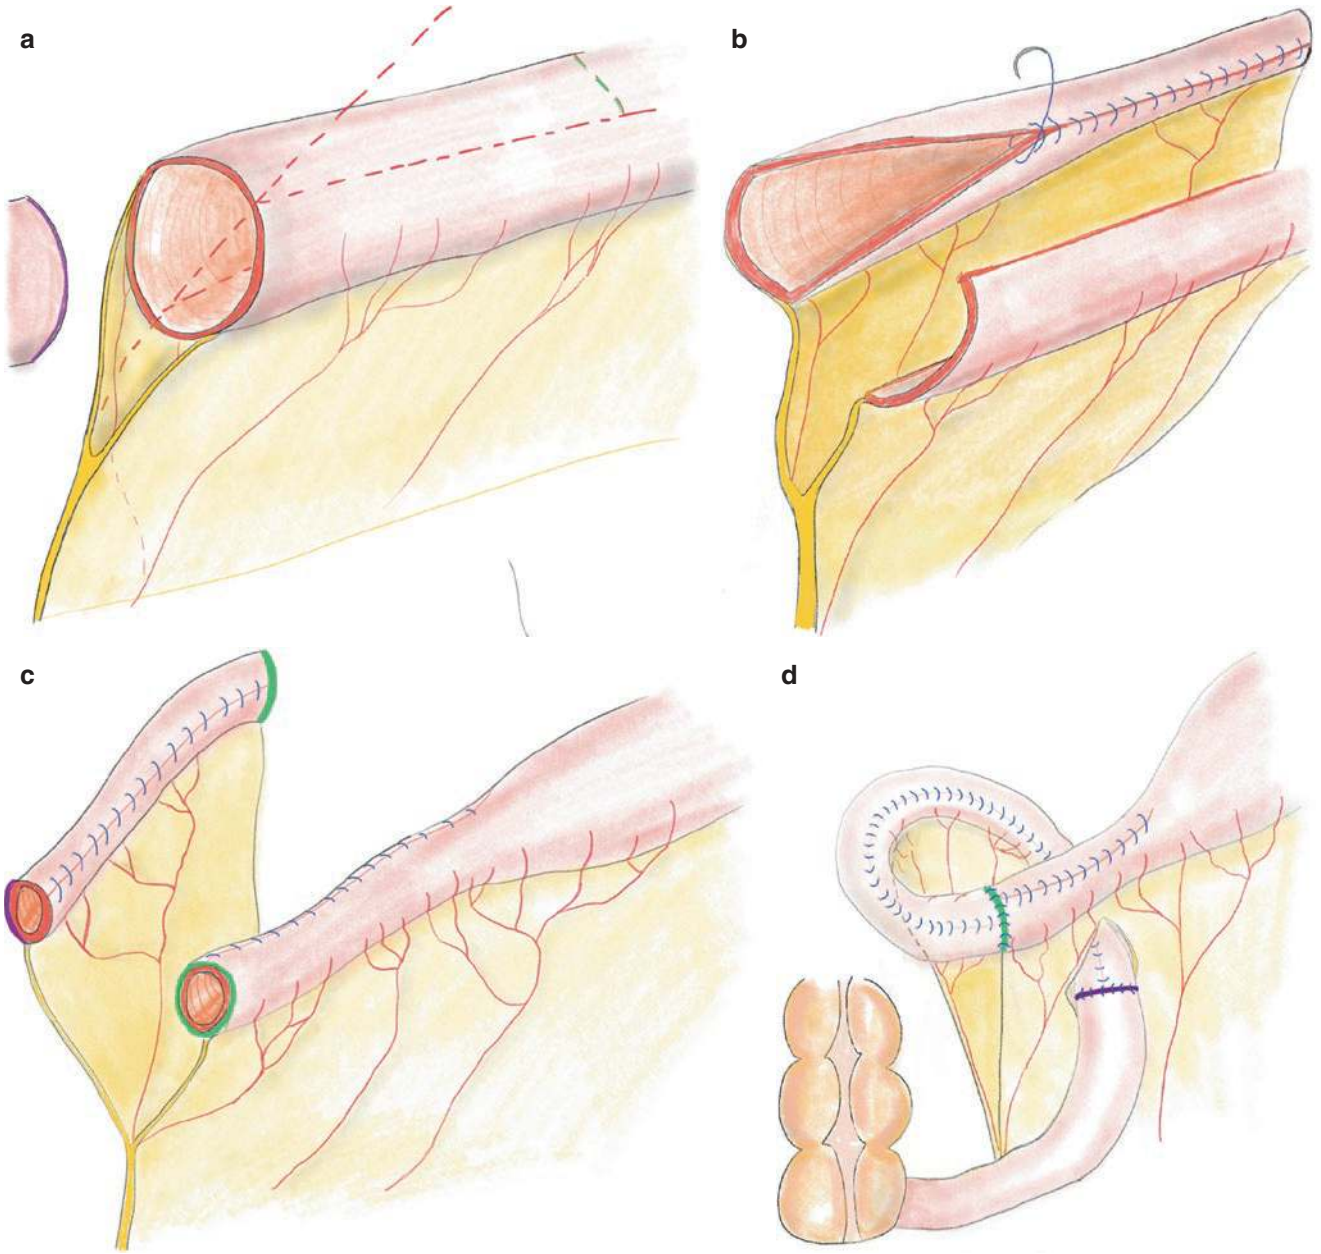

Fig. 4 Longitudinal intestinal lengthening technique (LILT). (**a**) The bowel is divided antimestenterically along its axis at 180° (red dashed lines) splitting the mesentery. (**b**) The two intestinal 'halves' are then tubularised with each relying on half of the original mesenteric blood supply. (**c**, **d**) Continuity is restored by anastomosing (green and purple lines) and reincorporating the 'new' loop in an isoperistaltic manner

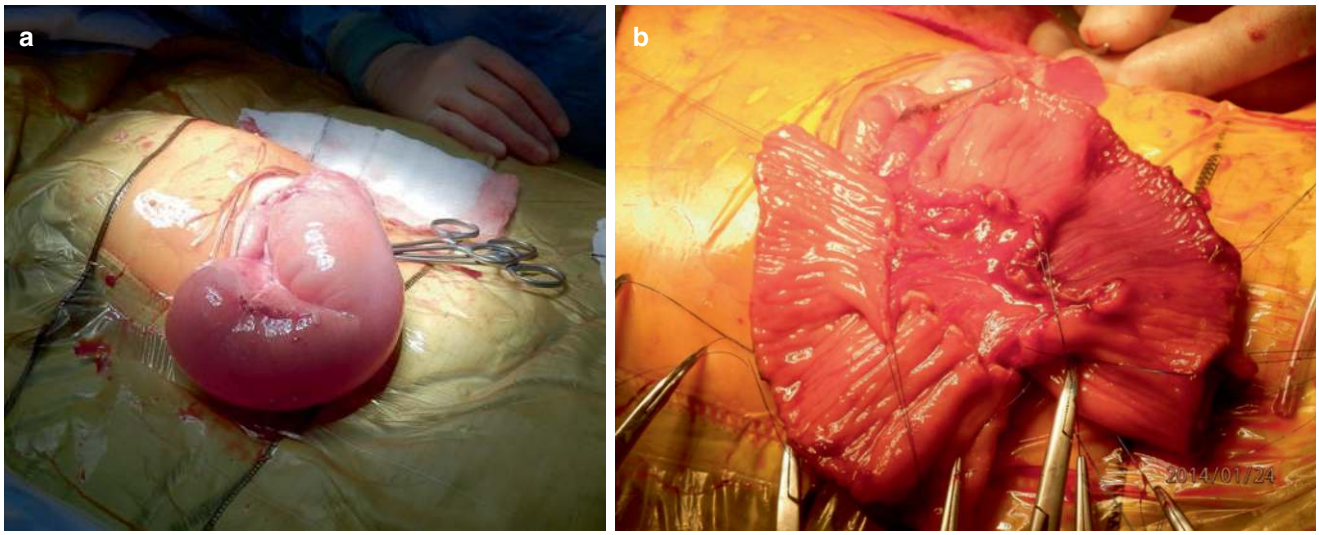

Fig. 5 LILT—operative picture after division of dilated jejunum. (**a**) Case of closed gastroschisis with grossly dilated jejunal atresia and an initial measured length of 20 cm. (**b**) Post-division of jejunum showing two independently vascularised intestinal strips prior to re-tubularisation

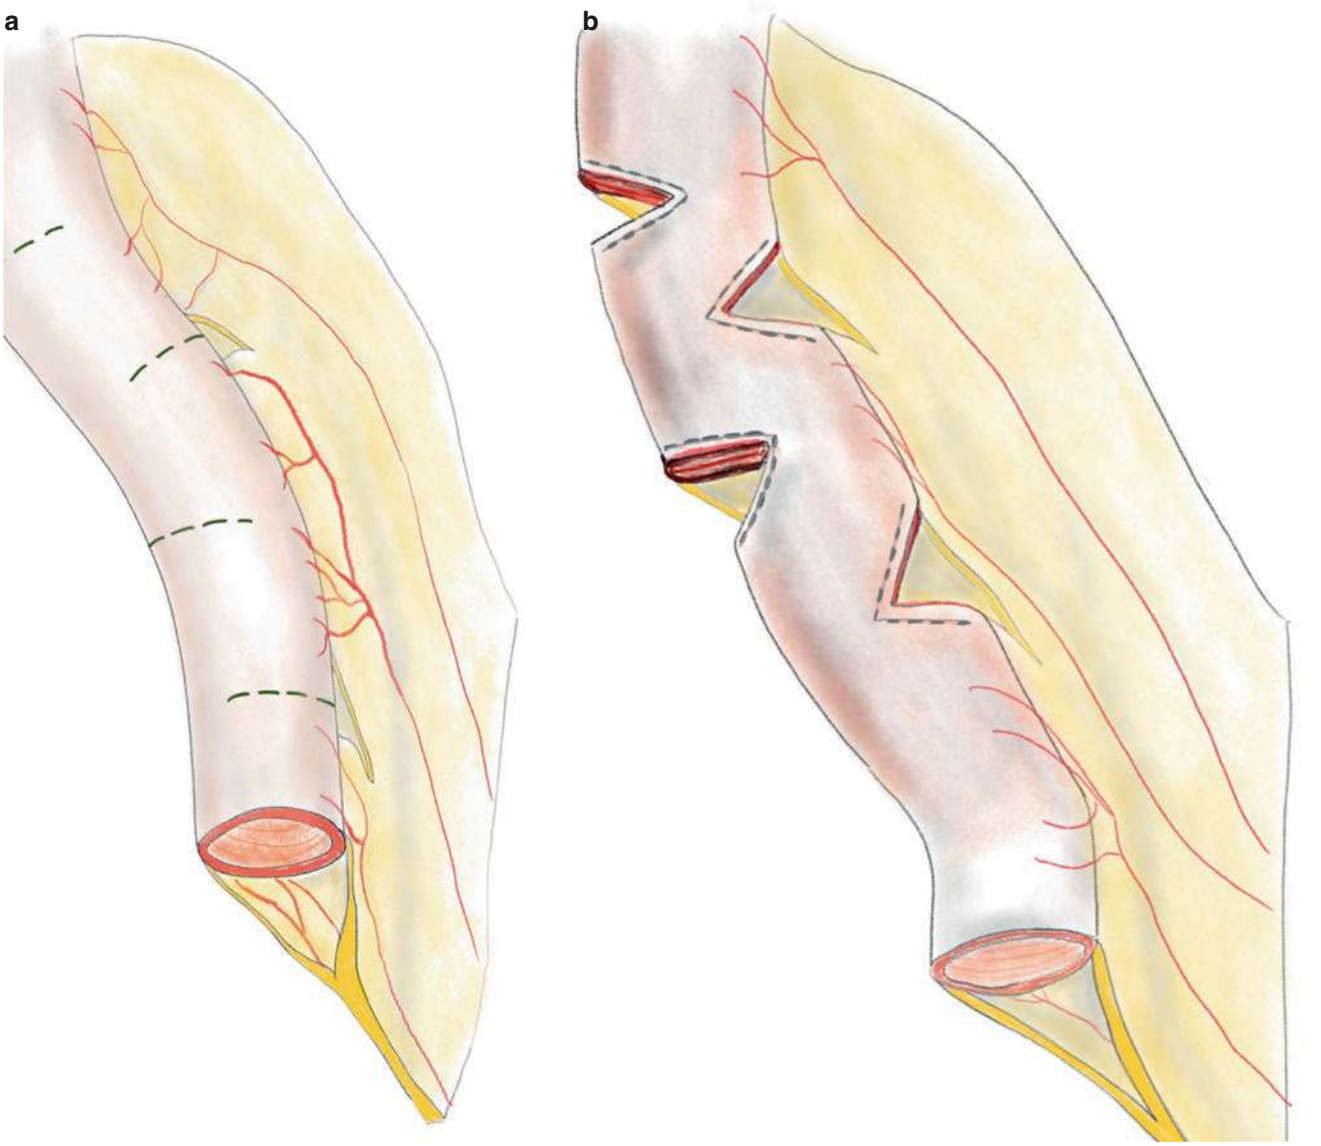

Fig. 6 Serial Transverse Enteroplasty (STEP). (**a**) Small mesenteric 'windows' are created so that a GIA stapler may be fired part way across the bowel diameter (dashed lines). (**b**) GIA firings are repeated at equal intervals and from alternate sides to create a zig-zag channel of about 1–2 cm diameter

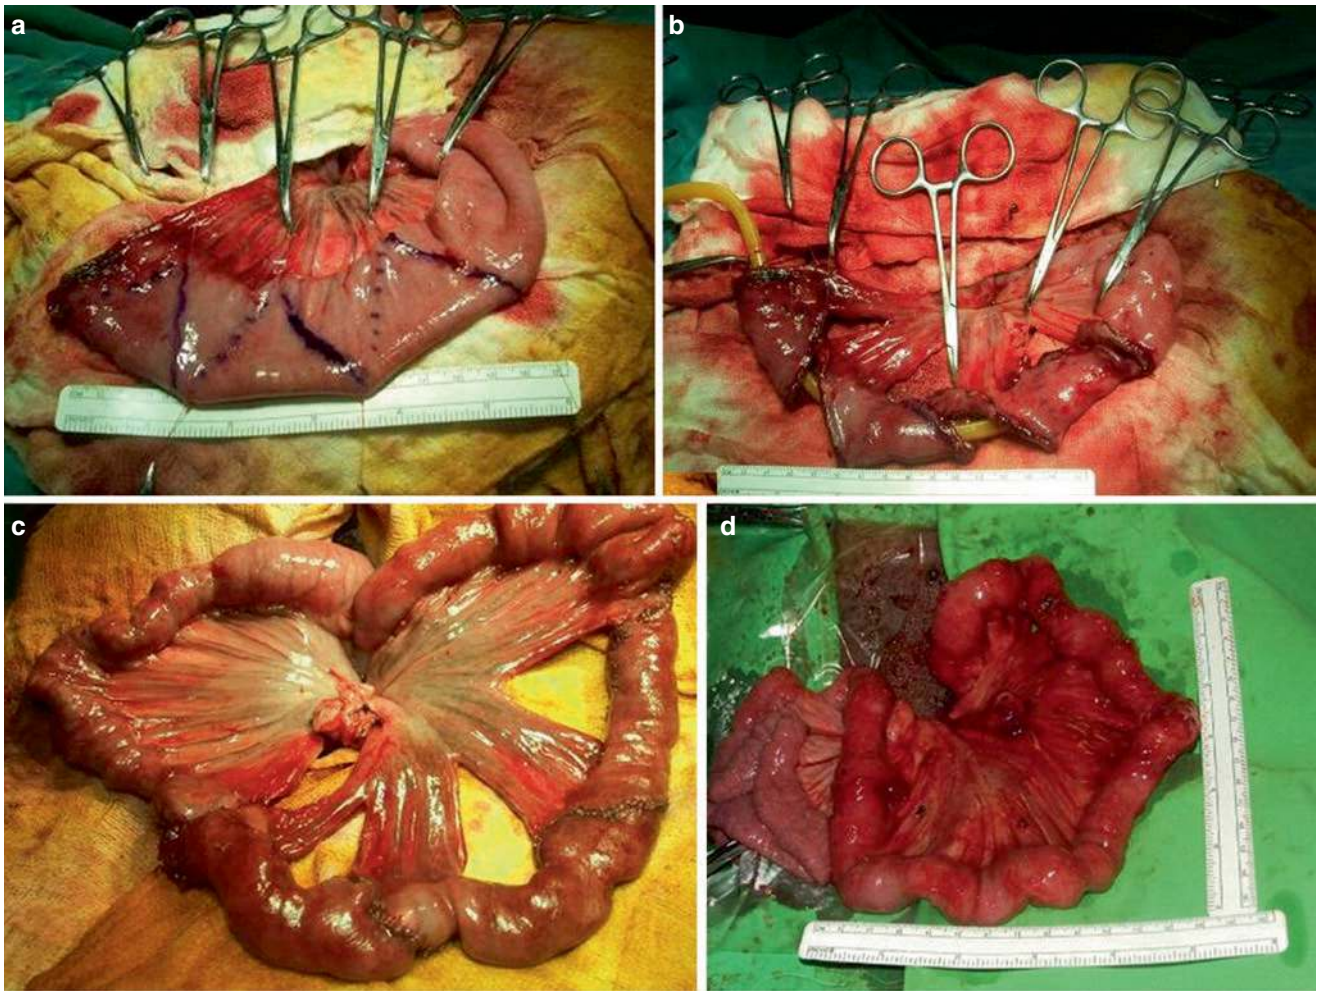

Fig. 7 Spiral Intestinal Longitudinal Intestinal and Tailoring (SILT): experimental model in minipigs. (**a**) Incision line marked on the dilated segment (dotted line: incision on the posterior wall). The scale is 15 cm. (**b**) After spiral incision. (**c**) End result of SILT.(**d**) Lengthened segment 5 weeks postoperatively is viable, with normal calibre and remains long. (Reprinted with permission from [50])

Table 1 Comparison of the Longitudinal Intestinal Lengthening Technique (LILT) and Serial Transverse Enteroplasty (STEP)

	LILT	STEP
First reported	1980	2003
Rate of successful PN weaning	70% (4–100%) at a mean of 10.3 months (5–21 months)	58.1% (20–100%) at a mean of 9.4 months (6–16 months)
Learning curve	Technically challenging requiring dissection of mesentery and long hand-sewn anastomoses	Undertaken with GIA stapler without disturbing mesenteric vessels
Limitations	Minimum of >20 cm of dilated bowel required Cannot be reapplied	Can be applied to any dilated bowel (including duodenum) though arguably of limited use Can be reapplied as ReSTEP
Complications	Re-dilatation, leak, stricture and necrosis	Re-dilatation, leak, stricture and bleeding
Reported mortality	30%[a]	14%

[a]The reported series of LILT are much older and reflect the limited options available for end-stage liver disease in previous eras

and anatomy. Ideally units undertaking AIR should be able to offer both procedures, but for those establishing an initial practice STEP would appear to be the more versatile, reproducible and straightforward procedure to adopt.

Controlled Intestinal Expansion

Actual enterocyte mucosal tissue expansion appears to be feasible, simply by increasing intraluminal pressure. This may be an exciting alternative pioneered in Manchester and Toronto for infants with ultra-short bowel due to closed gastroschisis or intestinal atresia and seemingly destined for life-time PN or intestinal transplant.

There are two methods which have been used to achieve what is effectively controlled proximal jejunal obstruction.

The Manchester method is to form a tube jejunostomy with a soft catheter (e.g. Malecot or Foley) constrained by purse-string sutures. This is then periodically obstructed over a period of time (e.g. 20–24 weeks) for progressively longer and longer periods to create proximal dilatation. This process—combined with ongoing distal refeeding—is termed the ‘controllable expansion recycle’ technique [55].

The Toronto approach entails the creation of a Stamm gastrostomy and a distal sigmoid colostomy at the initial laparotomy. Oral sham feeds are commenced post-operatively and the gastrostomy tube is intermittently clamped/unclamped to create proximal dilatation. When sufficient (>5 cm) dilatation is achieved a STEP is performed and intestinal continuity is restored [56].

Summary

Short bowel syndrome is the commonest cause of intestinal failure in infants and arises either as a result of congenital malformations such as small bowel atresia and gastroschisis or is acquired as a consequence of intestinal loss following acute pathology such as NEC or malrotation volvulus [57].

In the management of short bowel in childhood the paediatric surgeon is a key member of the MDT from the outset. Adopting a considered and structured approach to the initial surgical management of these infants can minimise the loss of intestinal mass, maximise the potential for enteral absorption and aid the creation of anatomy upon which future AIR is then feasible. When adequate adaption cannot be achieved by conservative means alone then the timely undertaking of AIR may deliver enteral autonomy or at least reduce the burden of PN.

Part III

Chronic (Long-Term) Intestinal Failure

Physiology and Problems of a Short Bowel

Jeremy M.D. Nightingale

Key Points

1. A short bowel occurs when there is an insufficient length of small intestine to absorb enough nutrition/fluid to maintain health/growth.
2. Due to large range of "normal" small intestinal length, it is important to refer to the remaining length of small bowel rather than the length resected.
3. There are two common types of patient with a short bowel. Those with jejunum anastomosed to colon (jejunum-colon or type 2) and patients with an end jejunostomy (type 1). A third less common group have had a predominantly jejunal resection [jejunum–ileum. (Type 3)], and have more than 10 cm of terminal ileum remaining, their problems are similar to the jejunum-colon patients.
4. Patients with a jejunostomy have high stomal losses of water and sodium and often have hypomagnesaemia. Fluid balance dominates their management.
5. Patients with a jejuno-colic anastomosis do not generally have fluid balance problems and the colon salvages energy from colonic fermentation. However they have a high prevalence of calcium oxalate renal stones.
6. All patient types have a high prevalence of calcium bilirubinate gallstones.
7. The absorption in patients with a preserved functioning colon improves with time; this does not occur in patients with a jejunostomy.

Background

In 1880, Koberle performed the first reported successful small intestinal resection of more than 200 cm on a 22-year-old girl with multiple intestinal strictures [1]. At the beginning of the twentieth century, a resection of more than 200 cm of small intestine, thought to be a third of the total small intestinal length, was referred to as an 'extensive' intestinal resection and was thought to be the maximum length of small intestine that could be removed and for the patient to survive [2]. In 1935, Haymond used the term 'massive' in preference to 'extensive' intestinal resection when he reviewed the literature of 257 patients, most of whom had had a resection for an intestinal volvulus (Table 1); he noted an overall survival of 67% [3].

In the 1960s, as an awareness developed that the outcome from an intestinal resection depended upon the length of small bowel remaining rather than the length resected, so the term 'short bowel syndrome' came into use. The syndrome was characterized by 'intractable diarrhoea with impaired absorption of fats, vitamins, and other nutrients, ultimately leading to malnutrition, anaemia, and continued weight loss' [4]. This description implies a slow chronic illness and is adequate to describe most patients who have a short bowel and retained functioning colon; it does not describe the acute fluid balance problems experienced by patients with a jejunostomy (end-jejunostomy syndrome). The first report of a patient surviving with a jejunostomy, 120 cm from the duodeno-jejunal flexure, was in 1963 [5].

Early work was on physiology first in animals after a large predominantly jejunal resection then work in man was initially in those with a jejunocolic anastomosis. Later work was with patients with a jejunostomy and a high output

stoma. The studies to understand the physiological changes in the 1990s were about motility and gastrointestinal hormones. Research since the millennium has concentrated on peptide growth factors, new hormones and the microbiome.

Length of Small Intestine

The length of the adult intestine, measured surgically, radiologically or at autopsy from the duodeno-jejunal flexure, ranges from about 275 to 1510 cm and tends to be shorter in women than in men (chapter "Normal Intestinal Anatomy and Physiology"). Congenital cases of a short bowel have been reported and are usually associated with malrotation of the gut [6, 7]. Patients who have a small intestinal length at or below the lower end of the normal range may develop the problems associated with a short bowel after relatively little small intestine has been removed. In a study of 11 patients with Crohn's disease and less than 200 cm small bowel remaining, the median original small bowel length was calculated from the lengths resected and remaining to be 240 cm (range 205–315 cm), indicating a short small bowel length before any resections [8]. A further study has confirmed that patients with Crohn's disease have a shorter total small intestinal length than controls (mean length at laparotomy in 279 Crohn's disease patients 460 cm vs. 564 cm in 77 non-inflammatory bowel disease patients) [9].

The large range of normal human small intestinal length means that it is more important to refer to the length of small bowel remaining rather than to the length removed. The term ultrashort bowel is occasionally used to refer to patients who have less than 20 or 30 cm small bowel remaining and are thus unlikely to absorb any macro or micronutrients.

Assessment of Residual Small Intestine

Anatomical Length

The remaining small bowel length is ideally assessed at surgery by measuring 10–30 cm segments of bowel along the antimesenteric border, taking great care not to over-stretch the bowel. If there is no surgical measurement available and radiographic films are available, the bowel can be measured using an opisometer, a device used for measuring distances on maps. It traces the long axis of the small bowel on a small bowel meal radiograph. This technique is relatively accurate if the total small intestinal length is less than 200 cm and if the entire small bowel is shown on one film [9, 10]. As most films are saved on a computer the small bowel length (on contrast follow through, computerized tomographic enterography [11] or magnetic resonance scans [12]) can be measured in short segments and give an a moderately accurate estimate of the remaining small bowel length. This is easier to estimate if the total small bowel length is less than 200–300 cm.

Functional Length

Citrulline is a non-essential amino acid that is almost exclusively synthesized in the enterocyte by pyrolline-5-carboxylase-synthase from glutamine. It is not derived from food or proteolysis and is not incorporated into body proteins. Some of the citrulline made by the enterocyte passes to the liver, where it is an important intermediate in the urea cycle (urea made from ammonia) and some passes into the systemic circulation. All the citrulline in the systemic circulation is derived from small intestinal enterocytes, thus plasma levels of citrulline are related to the length of the remaining functional small bowel (Fig. 1) [13–16].

Apolipoprotein AIV (Apo AIV) may be an equally effective marker of functional enterocyte mass; it is exclusively synthesized by enterocytes. Its concentration in plasma, like citrulline, mainly depends on production in the small intestine and is not affected by first-pass metabolism. Apo AIV is incorporated into the surface of nascent chylomicrons. Upon entering the blood circulation, it is rapidly dissociated from the chylomicrons and predominates in the plasma as a lipoprotein-free fraction. It shows no circadian rhythm and maintains stable physiological plasma levels. It has the advantage over citrulline of being easier to measure (smaller sample, simpler equipment and faster results) [17].

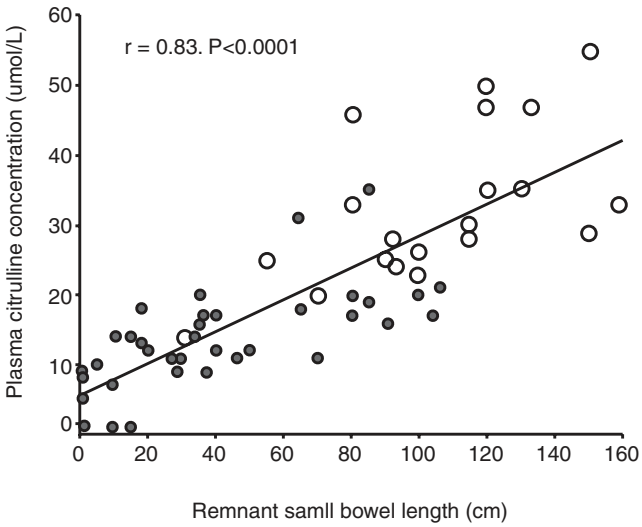

Fig. 1 Fasting plasma citrulline level and remaining small bowel length. (With permission [13])

Anatomical Considerations of Remaining Bowel

Ileum or Jejunum

A jejunal resection is better tolerated than an ileal resection. Ileal mucosa, in contrast to the jejunal mucosa, has tight intercellular junctions and thus can concentrate its contents. Gastrointestinal transit is naturally slower in the ileum than jejunum, so allowing more time for absorption [18, 19]. The terminal ileum absorbs vitamin B_{12} [20, 21] and bile salts. Ileum remaining after a small bowel resection can adapt in both structure and function to increase absorption [22–24], while the jejunum can only adapt functionally if some distal bowel remains (chapter "Intestinal Adaptation").

Ileocaecal Valve

It is traditionally considered that preservation of the ileocaecal valve is beneficial as it may slow transit and prevent reflux of colonic contents into the small bowel; however, studies of ileocaecal valve excision show no evidence that it slows transit, and small bowel peristalsis probably prevents reflux from the colon into the small bowel [18, 25] (chapter "Normal Intestinal Anatomy and Physiology").

Some reports suggest that conservation of the ileocaecal valve in children is beneficial in terms of survival and the need for parenteral nutrition [26, 27]; others show no such benefits [28, 29]. The reports proposing benefit of ileocaecal valve preservation in adults may reflect preservation of a significant length of terminal ileum.

Colon

Conservation of the colon is beneficial because it absorbs water, sodium [30–34], calcium [35] and short- and medium-chain fatty acids [36–38]; it also slows gastrointestinal transit [39], stimulates small intestinal hyperplasia [40] and its bacteria manufacture some amino acids and vitamins (e.g. vitamin K, biotin, folic acid and thiamine) which can then be absorbed in the colon. Patients with an entero-colic anastomosis may survive without parenteral support with a very short [41, 42] or even no remaining jejunum [43]. Patients with a preserved functioning colon rarely need regular water and sodium supplements [32–34]. In terms of the need for parenteral nutrients, preservation of at least half of the colon after a jejuno-ileal resection is equivalent to about 50 cm of small intestine [34].

Causes of a Short Bowel

The four most common reasons for patients to have less than 200 cm of small bowel are superior mesenteric artery thrombosis, Crohn's disease, irradiation damage and surgical complications [10, 34, 44] (Tables 2, 3 and 4). Resection of an ischaemic small intestine ultimately results in colonic pres-

ervation (75%) and affects an older age group (median age 57 years) [34]. Patients with Crohn's disease and jejunum in continuity with a functioning colon had undergone a median of 3 small intestinal resections (range 2–6) over a median of 14 years (range 0–29), compared with 4 resections (range 1–12) over a median of 11 years (range 1–26) in those with a jejunostomy [34]. The median time from irradiation to having a small intestinal length of less than 200 cm in 8 patients with irradiation damage (5 gynaecological cancers, 2 carcinomas of the colon and 1 seminoma) was 5 years (range 1–16) [34].

A short bowel occurs more commonly in women (67%) than in men [34, 45]; this may be because women start with a shorter length of small intestine than men.

The more recent causes of a short bowel in adults are derived from the reported aetiology of patients receiving parenteral support and additionally from those taking part in peptide growth hormone studies. There are no studies since 1992 of patients with a short bowel and not receiving HPS. The number of patients with a short bowel and Crohn's disease has reduced while the number following surgical resections, with mesenteric ischaemia and malignancy have all increased [46].

The causes of a short bowel arising in childhood and infancy usually result in colonic preservation. In infancy the causes include necrotizing enterocolitis, multiple jejuno-ileal atresia, gastroschisis, mid-gut volvulus and congenital [26–29, 46–49] (chapters "Peritoneal Adhesions and Encapsulating Peritoneal Sclerosis" and "Acid-Base Disturbances in Intestinal Failure"). In children trauma, post-operative complications, cancer and motility disorders dominate [46]. As the management and thus the survival of these children improves [27–29], they are being cared for as adults.

Types of Patient with a Short Bowel

There are three types of patient with a short bowel (Fig. 2):

1. *Jejunum–colon*. (Type 2) Patients in whom the ileum has been removed, often with the ileocaecal valve, to leave a jejuno-colic anastomosis (jejunum–colon); patients who have less than 10 cm of terminal ileum are included in this group.
2. *Jejunostomy*. (Type 1) Patients in whom some jejunum, the ileum and colon have been removed, so they are left with an end-jejunostomy.
3. *Jejunum–ileum*. (Type 3) Patients who have had a predominantly jejunal resection, and have more than 10 cm of terminal ileum and the colon remaining (jejuno-ileal) [10, 34, 50]. This last group is not common (2 of 86 patients [34]); since the residual ileum can adapt both structurally and functionally, these patients rarely have major problems and they are not specifically discussed in this chapter.

Patients with a jejunostomy can be classified according to the results of balance studies as net 'absorbers' or net 'secretors'. The 'absorbers' in general have more than 100 cm of residual jejunum and absorb more water and sodium from their diet than they take orally (usual daily jejunostomy output about 2 kg); they can therefore be managed with oral sodium and water supplements, and parenteral fluids are not needed. The 'secretors' usually have less than 100 cm residual jejunum and lose more water and sodium from their stoma than they take by mouth (the usual daily stomal output may be 4–8 kg). 'Secretors' cannot convert from negative to positive water and sodium balance by taking more orally, and so they need long-term parenteral supplements [51]. These requirements change very little with time [34]. The jejunostomy output from a net 'secretor' increases during the daytime in response to food and decreases at night; any drug therapy that aims to reduce the output is therefore given prior to food. The change from a net secretory state, in terms of water and sodium balance, to a net absorptive state occurs at a jejunal length of about 100 cm (chapter "Management of a High Output Stoma, Jejunotomy or Uncomplicated Enterocutaneous Fistula").

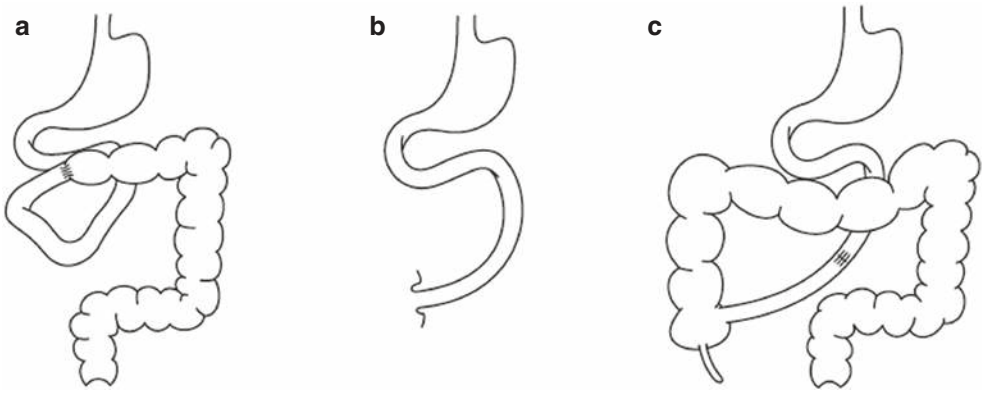

Fig. 2 The three types of patient with a short bowel. Patients with a jejuno-colic anastomosis or a jejunostomy are most commonly encountered. (**a**) Jejuno-colic anastomosis; (**b**) Jejunostomy; (**c**) Jejuno-ileal anastomosis

Bowel Length and Fluid/Nutritional Support

- *Jejunum–colon*. While it is possible for a patient with no remaining jejunum to survive without parenteral nutrition, quality of life is poor [42]. A patient with 100–200 cm of normally functioning jejunum in continuity with a functioning colon may need oral nutrient supplements for a few months but in the long-term would not be expected to need any supplements unless the remaining bowel was diseased. When the jejunal length is between 50 and 100 cm, some patients will need long-term parenteral nutrition (PN), if it is between 30 and 50 cm most will do so, and if it is less than 30 cm almost all patients will need PN [34, 50] (Fig. 3). Sometimes parenteral

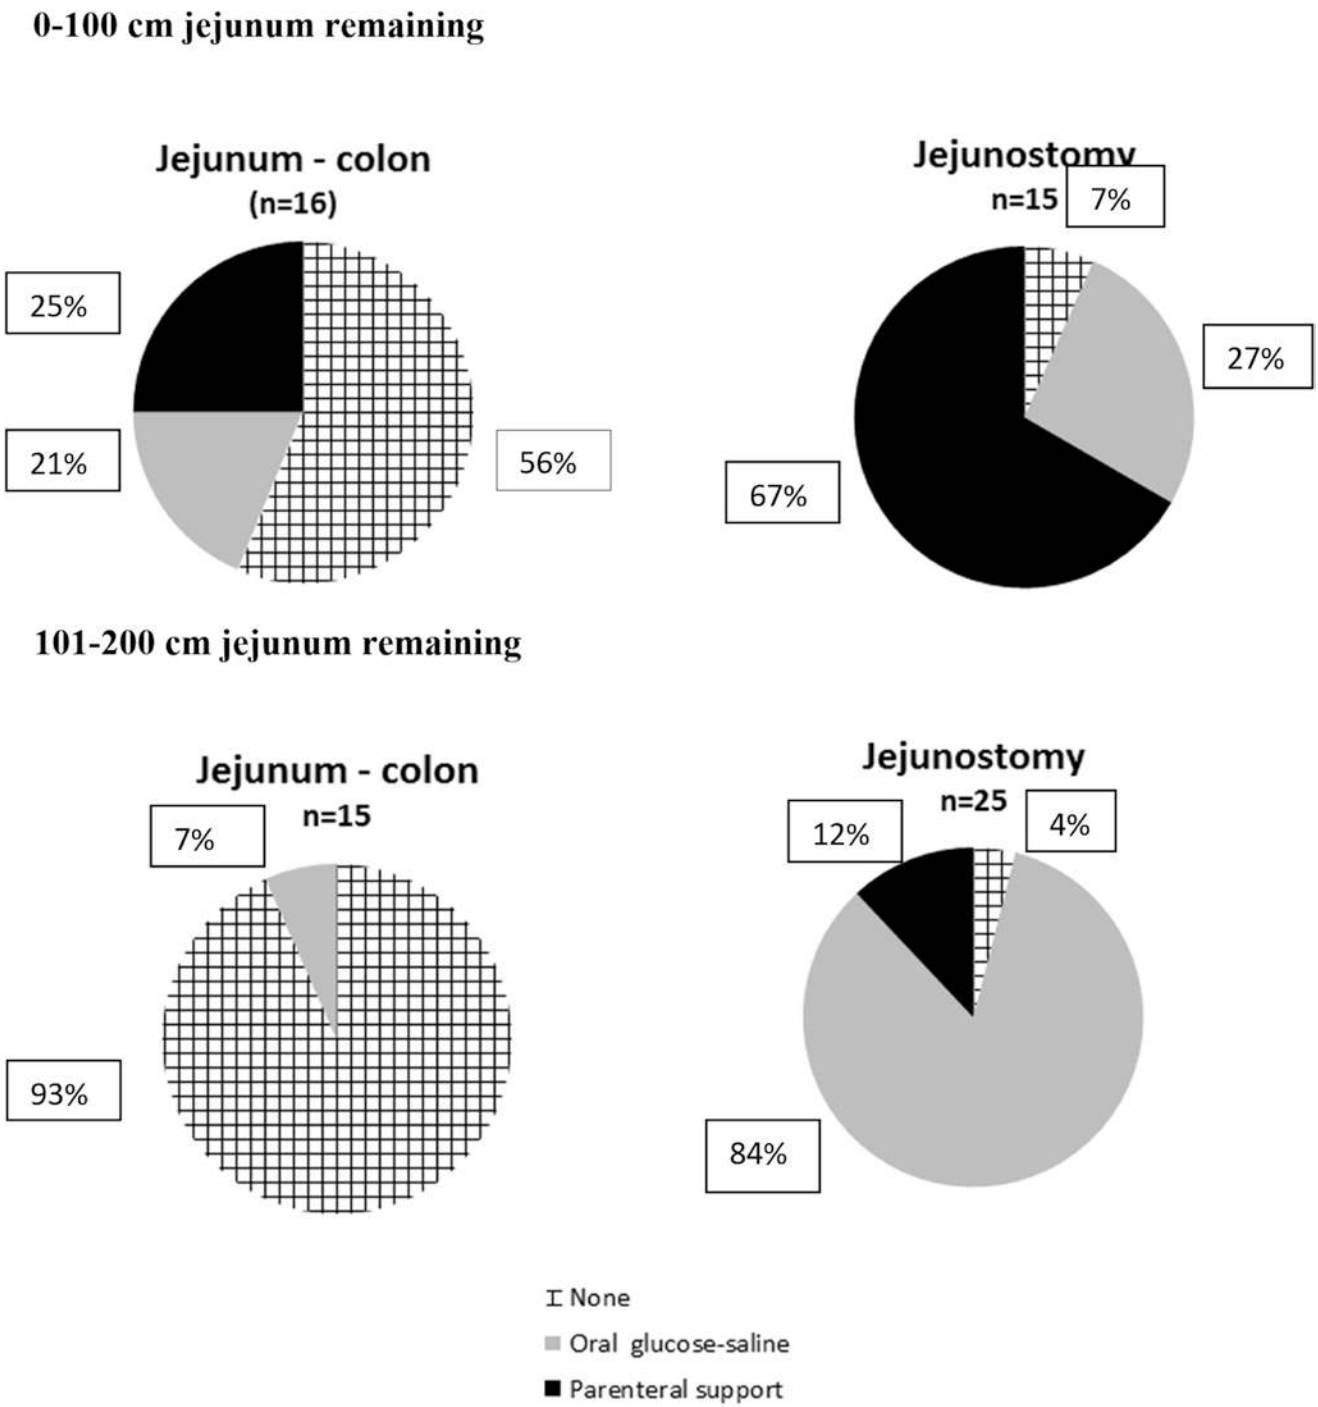

Fig. 3 Pie chart showing the parenteral and enteral sodium and water supplements given to 71 stable patients with less than 200 cm jejunum remaining. Few patients with a colon were receiving oral or parenteral sodium and water supplements, but almost all jejunostomy patients were receiving them [34]

nutrition is needed not to maintain nutritional status but to prevent the severe diarrhoea associated with eating.

- *Jejunostomy*. The survival of patients with a jejunostomy has improved since 1963 [5, 52]. If 100–200 cm normally functioning jejunum remains, oral sodium supplements (glucose–saline solution or sodium chloride tablets) are likely to be needed, often with oral nutrient solutions to which sodium chloride has been added [34, 50, 51, 53]. A patient with a jejunostomy and less than 100 cm jejunum remaining would be expected to need long-term parenteral saline. If less than 85 cm jejunum remains, long-term parenteral nutrition is likely to be required in addition to the saline. Patients usually need long-term parenteral nutrition when they absorb less than a third of their oral energy intake [51, 54].

Physiological Changes

Of the physiological changes observed after a small intestinal resection, some reflect normal and some altered physiology. Most experimental work in animals involves a predominantly jejunal resection (jejuno-ileal anastomosis); this has a better prognosis but is not a common situation in humans, in whom an ileal resection with or without a colectomy is most common.

Gastrointestinal Motility

Gastric Emptying

There are mechanisms (brakes) in the jejunum, ileum and colon that slow gastric emptying (chapter "Normal Intestinal Anatomy and Physiology"). In addition, events external to the bowel can affect gastric emptying; for example, malnutrition and many drugs (e.g. cyclizine and opiates) delay gastric emptying and parenteral nutrition delays the gastric emptying of solids [55]. Studies in animals have shown that gastric emptying of liquid is normal after a jejunal resection [56, 57].

- *Jejunum–colon*. Gastric emptying of liquids is normal in patients who have had a distal small intestinal resection that does not result in a short bowel [58]. Studies in which a dual isotope meal (liquid and solid components of the meal are labelled with different isotopes) has been given to patients with a jejuno-colic anastomosis have shown that some liquid leaves the stomach rapidly and travels quickly through the short length of remaining jejunum to reach the colon. In the colon, by a neural or hormonal mechanism, the liquid meal activates a colonic braking mechanism by which subsequent gastric emptying is slowed and overall measurements of liquid and solid gastric emptying are normal [39]. This colonic braking mechanism may be caused by the release of peptide YY from the colon [59] (Fig. 4). Infusions of peptide YY that achieve similar levels in normal subjects delay the gastric emptying of liquid [60].

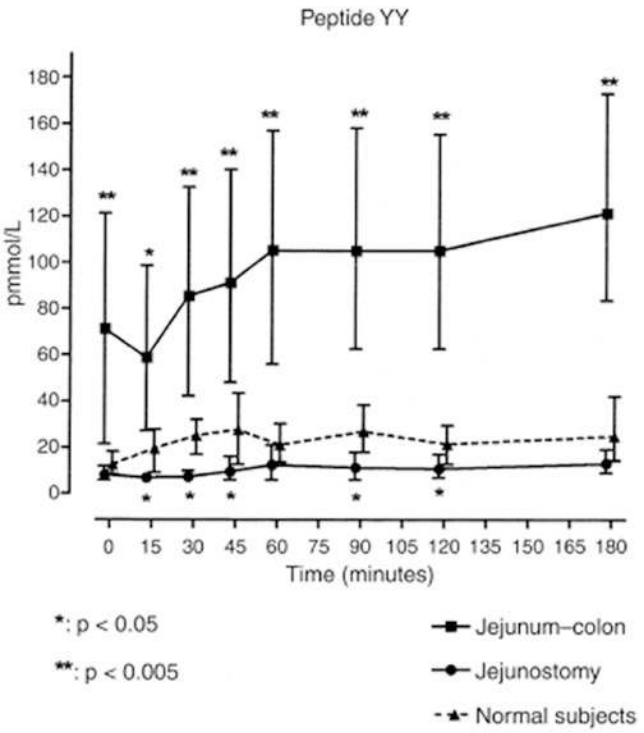

Fig. 4 Median peptide YY levels with interquartile range for 6 jejunum–colon patients, 7 jejunostomy patients and 12 normal subjects after a pancake and orange juice meal [59]

- *Jejunostomy*. The rate of gastric emptying of solids is normal in patients who do not have a short bowel but have had a proctocolectomy and distal ileal resection [61]. In patients with a jejunostomy, barium taken orally has been observed to pass rapidly into the jejunostomy bag. Dual radio-isotope studies have shown that the early rate of liquid gastric emptying is rapid and that this tends to correlate inversely with the remaining length of jejunum [39]. This is probably caused by the loss of cells secreting peptide YY in the terminal ileum and colon, and the consequent low plasma levels [59].

Small Bowel Transit

As there is normally faster transit of chyme through the jejunum than ileum [18, 19, 23, 61], it is not unexpected that small bowel transit has been shown to be fast after an ileal and slow after a jejunal resection [56, 57, 62].

- *Jejunum–colon*. The first part of a liquid meal travels rapidly from the stomach to the colon, reflecting both the

normal faster jejunal transit and the short distance it has to travel. The transit rate for solid is normal, however, suggesting that jejunal transit has been slowed by the colonic brake already activated by the prior arrival of some liquid in the colon. This effect may have been mediated by peptide YY.

- In the fasting state, in patients with a short bowel and a retained colon, the interdigestive migrating motor complex (MMC) occurs more frequently but for a shorter total time than in normal subjects, and phase 2 activity is of a shorter duration [63, 64]. The frequency and amplitude of jejunal contraction is unaffected [64].
- *Jejunostomy*. The rate of liquid and solid small bowel transit is rapid in patients with a jejunostomy. This may be due to low peptide YY levels. Six hours after a meal there is still some meal residue within the stomach, and this may result from a disorder of the MMC [39].

Gastrointestinal Secretions

Salivary Secretion

The volume of saliva produced at rest was significantly less in 7 jejunostomy patients (median 0.6 g/5 min, range 0.0–1.4) than in 13 normal subjects (median 2.2 g/5 min, range 0.9–8.7, $p < 0.005$). After stimulation of salivary flow by chewing paraffin wax for 5 min, the volume of saliva was significantly less in jejunostomy patients (median 4.6 g/5 min, range 2.2–8.2) than in normal subjects (median 9.7 g/5 min, range 7.0–20.5, $p < 0.005$). These observations are likely to reflect altered physiology, but a degree of dehydration was not excluded [65].

Gastric Secretion

In 1914, Stassoff [66] performed experiments on six dogs in which he demonstrated that if the distal half of the small intestine was removed, the chyme that emerged from a duodenal fistula was more liquid and had left the stomach more quickly than before the resection. Many studies in dogs with denervated Heidenhain pouches [67–82] and in some with innervated Pavlov pouches [76] have shown hypersecretion of gastric acid. In most studies, the colon has been retained, though in one a colectomy alone caused gastric acid hypersecretion [83]. The larger the intestinal resection, the greater is the postoperative gastric acid hypersecretion [70, 84]. The greatest rises in acid output are produced by jejunal rather than ileal resection [75, 81, 84] (with the exception of one study [72]) and by defunctioning bowel [69, 74] rather than resecting it. The increased secretion is prevented by antrectomy [74, 79, 81, 82] but not by a vagotomy and pyloroplasty [79, 82].

Fielding and Cooke showed an 8% incidence of peptic ulcer among 300 patients with Crohn's disease and they noted that resections of 60 cm or more of the small bowel caused an increase in basal and pentagastrin-stimulated acid output [85]. They related this increased gastric acid output to a previous terminal ileal resection rather than to active disease [86].

In humans, the survival of some patients with a very short bowel has been attributed to their previous gastric surgery [70, 87, 88]. The evidence for gastric acid hypersecretion in the long term in patients with a retained colon is not good. Miura et al. reported three of seven patients with a short gut and a retained colon who developed duodenal ulcers [89]. Windsor et al. described 19 patients in whom more than 300 cm of small intestine had been resected and noted in 8 patients large postoperative aspirates of gastric juice of more than 1.5 L daily which lasted for less than 14 days. The volume of aspirate did not correlate with the remaining length of small intestine. In 6 of the 19 patients the increased secretion was attributed to impaired liver function, which these researchers postulated might increase circulating histamine levels [78].

One patient with a jejunostomy 90 cm from the duodenojejunal flexure following surgery for Crohn's disease had an acidic (pH 1–6) jejunostomy output of 4.8 L daily that was reduced by gastric irradiation [72]. O'Keefe et al. showed normal pentagastrin-stimulated gastric acid secretion in nine patients with a jejunostomy (jejunal length 25–200 cm) more than a year after surgery [90].

High gastrin levels have been observed [59, 91, 92] and may result from a reduced length of small bowel being available to catabolize gastrin [93, 94]. However, gastrin may not be of major physiological importance as studies in the Rhesus monkey have shown that, 6 months after a distal small intestinal resection, basal and histamine-induced acid secretion are at their highest levels, yet serum gastrin levels have returned to normal [95]. Another reason for gastric acid hypersecretion may be the loss of a normal inhibitor of gastric acid secretion, such as neurotensin or peptide YY, from the distal small bowel/colon. In an extensive review in 1974, Buxton suggested that stasis in remaining bowel segments allowed bacterial colonization; these bacteria then either deconjugate bile salts or degrade 'protein' which directly or indirectly causes the release of gastrin or a gastrin-like hormone that causes increased gastric acid secretion [96].

Excess gastric acid in the duodenum, in addition to increasing the incidence of peptic ulceration, causes bile salt precipitation [97], reduced pancreatic enzyme function and increased jejunal motility; all of which impair nutrient absorption.

The evidence indicates that gastric acid hypersecretion, after a small intestinal resection, occurs in dogs with denervated gastric pouches and colons left in situ. It may be present for the first 2 weeks after a small bowel resection in humans, but there is no good evidence that it occurs in the

long term in patients with a short bowel with or without a colon, even though high gastrin levels are observed.

Pancreatico-biliary Secretions

If a person is undernourished [98], or if no food passes through the gut [99], pancreatic function is reduced. In seven well-nourished patients who had a mean small bowel resection of 164 cm (leaving colon) and were taking an oral diet, the post-prandial secretion of trypsin and bilirubin (measured by jejunal aspiration after a liquid meal) was the same as in normal healthy individuals [100]. However, another study in children showed reduced pancreatic volume and enzyme secretion, after an injection of secretin and cholecystokinin, in two of five patients; both of these had most of their colon remaining [101].

When more than 100 cm of terminal ileum has been resected the increased hepatic synthesis of bile salts cannot keep pace with the stool or stomal losses and thus fat malabsorption results [102]. The greatest lipid malabsorption (steatorrhoea) occurs in patients with a jejunostomy: partly because of a very reduced bile salt pool, partly due to rapid transit, and, in a few cases, due to bacterial overgrowth in the remaining bowel [103]. It has not been determined if changes occur in the volume of bile produced each day after an intestinal resection.

Gastrointestinal Hormones

There are differences in the systemic plasma gastrointestinal hormone profiles after a meal in patients with a short bowel compared to normal subjects. However, it is only as studies are performed in these patients, using the hormones, specific agonists or antagonists, that the physiological importance of the observations can be understood; until then the significance of many observations remains a matter for speculation.

Parenteral nutrition itself does not affect the gastrointestinal hormone response to food [104]. The levels of some plasma hormones (e.g. enteroglucagon, pancreatic polypeptide and somatostatin and gastric inhibitory polypeptide) before and after a meal in patients with a short bowel (with or without a colon) are the same as in normal subjects. Plasma levels of vasoactive intestinal peptide in patients with a colon were normal in one study [105], but high in another [106]. High plasma gastrin and cholecystokinin levels and low plasma neurotensin, GLP-1 and insulin levels occur in both types of patient. The plasma neurotensin levels correlate with the length of residual jejunum [59]. The high plasma cholecystokinin levels could cause satiety in some patients with a very short gut [59]. Ghrelin (the "hunger" hormone) levels have been found to be low in patients following a substantial resection (60–80% of total length) of small intestine [107].

There are differences between the two types of patient, the most significant ones being in the plasma levels of two hormones produced by the terminal ileum and colon, namely peptide YY [59, 105] (Fig. 3) and GLP-2 [108, 109] (Fig. 5). Peptide YY slows gastrointestinal transit and GLP-2 stimulates small bowel villus growth (chapter "Normal Intestinal Anatomy and Physiology"). Patients with a colon have high fasting plasma peptide YY and GLP-2 levels, and both hormone levels are low in patients with a jejunostomy [59, 108–110]. Low plasma peptide YY levels also occur in ileostomy patients who have had a colectomy [110]. High plasma motilin levels occur in patients with a jejunostomy, but this is unlikely to be of physiological importance as the highest levels occur in those with the longest lengths of jejunum remaining who do not have rapid intestinal transit [59].

Changes in Intestinal Microbiome

The faecal microbiome is becoming an increasingly researched and thus increasingly understood. Unabsorbed nutrients (especially polysaccharides) within the colon are metabolised by bacteria to form short chain fatty acids (chapter "Normal Intestinal Anatomy and Physiology") which in turn may enhance mineral absorption, promote enteroendocrine secretions, stimulate epithelial cell growth and differentiation in the small and large intestine and may also promote the motility across the ileocaecal junction [111]. Additionally the colonic microbiome manufactures (in addition to short chain fatty acids) some amino acids (especially when undernourished), micronutrients (e.g. vitamins: folate, K, biotin, thiamine, riboflavin and panthothenic acid). It may detoxify some chemicals and manufacture others that are important for messaging/that aid absorption and it may help regulate the immune system and promote intestinal adaptation [112].

The faecal bacteria composition is different from healthy individuals in that anaerobic bacteria are reduced (e.g. bacteroidetes). Firmicutes (includes the lactobacillus and chlostridium geni) are the most abundant phylum, Proteobacteria is second, followed by Bacteroidetes, and lastly by Actinobacteria (includes bifibacterium). The lactobacilli are the largest genus and are responsible for manufacturing L and D lactic acid which in some patients may accumulate in the stool. This may be promoted by lactate-consuming bacteria (Veillonellaceae, Bacteroidaceae, Sutterellaceae, and Acidaminococcacea) being under-represented [113, 114]. When the D isomer dominates then D-lactic acidosis can result. Healthy individuals do not accumulate faecal lactate as it is readily absorbed or metabolised by other commensal

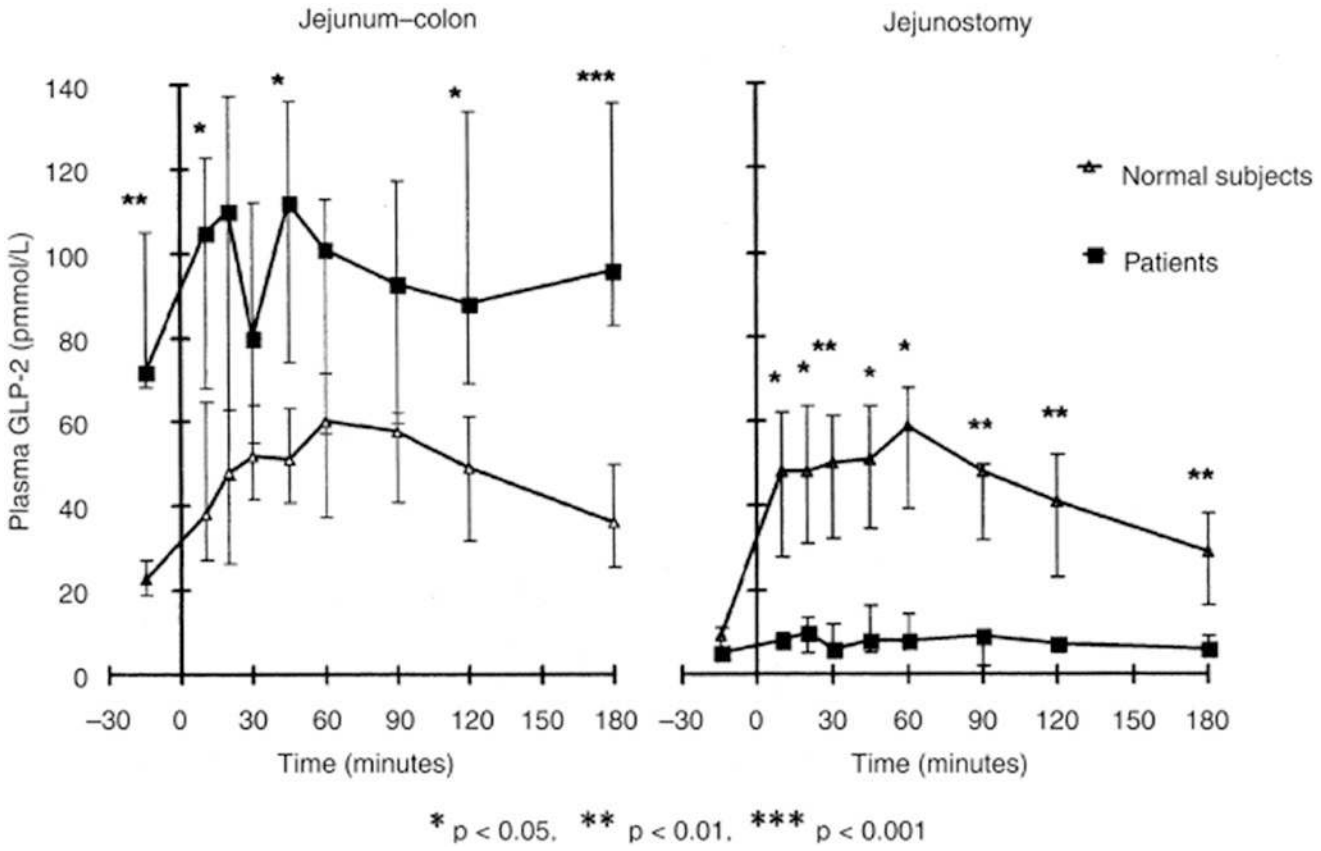

Fig. 5 Median GLP-2 levels with interquartile range in 7 jejunum–colon patients, 7 jejunostomy patients and 7 normal subjects after a continental breakfast [108, 109]. Courtesy of P. Jeppesen and P.B. Mortensen

bacteria or converted to other metabolites (e.g. SCFAs) [115]. It has been suggested that patients with jejuno-colonic anastomosis are stratified according to the presence or absence of lactate in their faeces [114].

A lack or reduction of the Gram-negative anaerobic bacterium *Oxalobacter formigenes* which both interacts with the *colonic mucosa* to induce active secretion of endogenously produced oxalate and also degrades oxalate in the intestinal tract may be partly responsible for the high prevalence of calcium oxalate renal stones in patients with a short bowel and a retained colon [116, 117] (chapter "Nephrolithiasis and Nephrocalcinosis").

The changes in bacterial content of patients with a jejunostomy or indeed an ileostomy are poorly investigated and due to a fast transit time may not be of major significance.

Changes in Absorption

In addition to absorption of nutrients, there are some specialist functions that are particular to the ileum. The ileum has the unique functions of absorbing vitamin B_{12} and bile salts. Vitamin B_{12} deficiency is likely to occur if more than 60 cm of terminal ileum has been resected [20, 62]. If more than 100 cm ileum has been removed, the enterohepatic circulation will be disrupted and diarrhoea is likely to be due to steatorrhoea [102]. If less than 100 cm has been resected, diarrhoea may result from unabsorbed deoxybile salts (secondary bile acids) causing colonic sodium and water secretion [102].

Clinical Problems and Their Treatment

The problems experienced by patients with a short bowel depend upon the type and length of remaining small bowel and the presence or absence of a functioning colon (Table 5). Most of these problems are dealt with in specific chapters and only a brief summary follows here.

Presentation

The presentation and long-term outcome from a resection can be predicted from knowledge of the remaining small bowel length and the presence or absence of a functioning colon. In both types of patient, treatment is aimed first at maintaining fluid balance. Nutritional supplements are usu-

Table 5 Problems of a short bowel

	Jejunum–colon	Jejunostomy
Presentation	Gradual, diarrhoea and undernutrition	Acute fluid losses
Water, sodium and magnesium depletion	Uncommon (in the long-term)	Common
Nutrient malabsorption	Common[a]	Very common
D(-) lactic acidosis	Occasionally	None
Renal stones (calcium oxalate)	25%	None
Gallstones (pigment)	45%	45%
Adaptation	Functional adaptation	No evidence
Social problems	Diarrhoea	High stomal output
		Dehydration
		Dependency on treatment

[a] Bacterial fermentation of carbohydrate salvages some energy, but D(-) lactic acidosis can occur if the diet is high in mono- and oligosaccharides

ally started 24–48 h after the surgery, to prevent loss of lean body mass. This may entail a period of parenteral nutrition, which is gradually reduced as the patient takes more food orally.

- *Jejunum–colon*. These patients are often deceptively well after the resection except for diarrhoea/steatorrhoea, but in the succeeding months they may lose weight and present as severely undernourished (classical 'short bowel syndrome').
- *Jejunostomy*. These patients have immediate problems after surgery due to the large volume of stomal output, which increases with food and drink. This high-volume output results in patients rapidly becoming depleted in water and sodium. Recognition of this high output means that clinicians are often aware that nutritional problems will follow; hence nutritional care is often addressed at a much earlier stage than in patients with a retained colon. Jejunostomy patients are highly dependent on treatments to compensate for water and sodium losses. If they miss their treatment for 1 day they are likely to become unwell from sodium and water depletion. Their requirements for water and sodium supplements change little with time (chapter "Intestinal Adaptation").

Undernutrition

Loss of muscle leads to weakness and early fatigue. Loss of body fat results in feeling cold, a gaunt facial appearance, dry and wrinkled skin, and dull hair. These features, together with a stooped posture, give an impression of premature ageing. Patients may dislike looking in the mirror and weighing themselves, and may avoid company because they are selfconscious about their wasted appearance. Apathy, depression and irritability associated with undernutrition may stop the patient from being motivated to recover (chapter "Consequences of undernutrition and dehydration"). Short bowel patients who can be maintained on an oral diet need to consume more energy than normal subjects because as much as 50% of the energy from the diet may be malabsorbed. Patients can achieve this by eating more high-energy food, having oral sip-feeds, or receiving high-energy enteral feeds at night through a nasogastric or gastrostomy tube. Once weight is regained, the daily energy requirements may decrease, especially in those with a retained colon. Only if these measures fail and the patient continues to lose weight, or fails to regain lost weight, is parenteral nutrition given. Even then, parenteral supplements may be needed for only a limited period of weeks or months, and thereafter oral supplements may be adequate.

In the long term, parenteral nutrition is needed if a patient absorbs less than one-third of the oral energy intake [51, 54], if there are high energy requirements and absorption is about 30–60%, or if increasing the oral/enteral nutrient intake causes a socially unacceptably large volume of stomal output or diarrhoea. In addition to consumption of a high-energy diet, the dietary advice given to the two types of patient is different (chapter "Dietary Treatment of Patients with a Short Bowel").

- *Jejunum–colon*. In order to increase energy absorption and to reduce the risk of renal stones, patients with a retained colon need a large total energy intake with a diet high in carbohydrate (polysaccharides) [37] but not increased in fat (long-chain triglycerides); the diet should also be low in oxalate. D(-) Lactic acidosis may occur if a diet is high in monosaccharides [118]. If oxalate is not reduced there is a 25% chance of the patient developing symptomatic calcium oxalate renal stones [34] (chapter "Nephrolithiasis and Nephrocalcinosis"). Long-term parenteral nutrition is likely to be needed if less than 50 cm jejunum remains [34].
- *Jejunostomy*. Jejunostomy patients need a diet high in energy. It does not matter whether this is as carbohydrate or lipid so long as the osmolality is kept low by using large molecules (polysaccharides, protein and triglycerides) [119, 120] and thus allowing extra sodium chloride to be added to give the meal/liquid feed a total sodium concentration of 90–120 mmol/L and an osmolality of about 300 mOsm/kg. An elemental diet has a high osmolality and little sodium and should therefore be avoided as it may increase water and sodium losses. A high-lipid diet may increase stomal calcium and magnesium losses (chapter "Dietary Treatment of Patients with a Short Bowel").

Water and Sodium Losses

Clinical Assessment/Monitoring

Deficiencies of water and sodium (most common in those without a retained colon) are common and result in a loss of extracellular fluid volume, hypotension and, if severe, prerenal failure. Daily body weight and an accurate fluid balance (to include stomal effluent) are essential measurements during the initial stages of management. Acute sodium and water deficiencies are detected by a rapid fall in body weight, postural hypotension, low urine volume and, if very severe, by a rising serum creatinine and urea. A useful guide to sodium depletion is measurement of sodium concentration in a random urine sample: lack of body sodium is suggested by a concentration of only 0–5 mmol/L. It is ideal, though not always possible, to achieve a daily urine volume of at least 800 mL with a sodium concentration greater than 20 mmol/L. In addition to relatively normal haematological and biochemical measurements, it is desirable (though again not always possible with oral medication) to have a plasma magnesium level greater than 0.6 mmol/L (chapter "Management of a High Output Stoma, Jejunotomy or Uncomplicated Enterocutaneous Fistula").

- *Jejunum–colon*. The colon has a large capacity to absorb sodium and water; thus patients with a short bowel and a preserved colon are rarely in negative water and sodium balance and rarely need water or sodium supplements [31, 34]. If sodium deficiency does develop, a glucose–saline drink can be sipped during the day, as for patients with a jejunostomy. Although the colon secretes potassium, a low serum potassium level is rare [34]. There is an exchange mechanism of chloride absorption/bicarbonate secretion in the colon; thus, if much sodium chloride is consumed, bicarbonate may be lost in the stools and give rise to a metabolic acidosis similar to that occurring in patients who have an ileo-conduit following a cystectomy.
- *Jejunostomy*. Patients with a jejunostomy have a large volume of stomal output that is greater after eating or drinking. Each litre of jejunostomy fluid contains about 100 mmol/L of sodium [51]. This high-volume output is mainly the result of loss of the normal daily secretions produced in response to food and drink (about 4 L/day) although gastric acid hypersecretion and rapid liquid gastric emptying and small bowel transit may contribute.

The effluent from a jejunostomy or ileostomy contains relatively little potassium (about 15 mmol/L) [32, 51]. Potassium balance is not often a problem, and net loss through the stoma occurs only when less than 50 cm jejunum remains [51]. A low serum potassium level may be caused by sodium depletion with secondary hyperaldosteronism and thus greater than normal urinary losses of potassium [32] or by magnesium depletion [121] (chapter "Dietary Treatment of Patients with a Short Bowel").

Treatment of Water and Sodium Depletion

Jejunostomy. Intravenous fluid is given initially while the patient takes no oral food or fluid. This will reduce the high output dramatically; food is then gradually reintroduced. Parenteral nutrition/saline is likely to be needed in the long term if less than 100 cm jejunum remains. Oral hypotonic fluids are restricted and a glucose–saline solution (sodium concentration 90–120 mmol/L) is given to sip during the day. Some clinicians suggest that liquid and solids be taken at different times although there is no published evidence that this reduces stool/stomal output [122]. Drugs that reduce gastrointestinal secretions or motility may be used; often both types of drug are administered. In general, patients who are net 'secretors' have the greatest reduction in their stomal output when drugs that predominantly reduce gastrointestinal secretions are given, for example omeprazole 40 mg daily, ranitidine 300 mg twice daily, cimetidine 200 mg every 6 h or 300 mg continuously over 6 h or, if there is insufficient gut to absorb these (less than 50 cm), subcutaneous or intravenous octreotide 50 μg twice a day. However, these treatments rarely completely alleviate the need for parenteral supplements. Patients who are net 'absorbers' have the greatest reduction when drugs that predominantly reduce gastrointestinal motility (e.g. loperamide 4 mg four times a day and codeine phosphate 60 mg four times a day) are given half an hour before food (chapter "Management of a High Output Stoma, Jejunotomy or Uncomplicated Enterocutaneous Fistula").

Magnesium and Other Micronutrients

The clinical syndrome of magnesium deficiency in man was described in 1960 [123, 124] and in the same year was reported as occurring after a massive intestinal resection [125]. It has subsequently been reported after jejuno-ileal bypass for obesity [126] and after ileal resections of more than 75 cm [127]. Its features include fatigue, depression, jerky and weak muscles, ataxia, athetoid movements, cardiac arrhythmias and, if severe, convulsions [123, 124, 128, 129]. Carpopedal spasm and positive Chvostek and Trousseau signs generally occur if there is a concomitant hypocalcaemia [124, 128, 130].

Low serum magnesium levels are more common in patients with a jejunostomy than in patients with a retained colon. Of short bowel patients who were not receiving parenteral nutrition, 11 of 27 (41%) of those with a colon were receiving magnesium or had low serum magnesium levels, compared with 19 of 28 (68%) with a jejunostomy [34].

Patients with a preserved colon require less magnesium and have higher serum values than those without a retained colon. This, together with reports that magnesium poisoning can occur after a magnesium sulphate enema, provides further evidence that the colon absorbs magnesium [131].

Most clinicians use a serum magnesium measurement of less than 0.6 mmol/L as their guide to magnesium depletion; however, urine, skeletal muscle, mononuclear cell or ionized magnesium levels [129] are more sensitive indicators.

There are several reasons for magnesium deficiency. Magnesium is normally absorbed by passive diffusion in the distal small bowel and colon. Bowel resections reduce the absorptive area and may increase stool losses [132]; however, this does not occur in an easily predictable manner and balance studies have shown that magnesium balance does not relate to the length of small bowel remaining [65]. The composition of the diet consumed may be another cause of stool losses of magnesium. Fatty acids, derived either from digestion of dietary fat or from bacterial fermentation of malabsorbed carbohydrate, combine with magnesium, calcium and zinc and prevent their absorption, increasing faecal or stomal losses [133]. A third reason, occurring particularly in patients with a jejunostomy, is stool/stomal loss of salt and water and the consequent secondary hyperaldosteronism. Aldosterone increases renal excretion of magnesium in rats and man and the faecal excretion of magnesium in rats [134, 135].

A low serum magnesium level reduces both the secretion and function of parathormone [136]. Thus parathormone cannot promote magnesium absorption in the ascending limb of the loop of Henle or activate renal 1α-hydroxylase to make 1,25-hydroxycholecalciferol. The failure to make 1,25-hydroxycholecalciferol results in reduced magnesium and calcium absorption from the gut [137]. Na^+/K^+-ATPase activity, which normally keeps potassium within a cell and sodium out, depends upon magnesium. When the serum magnesium level is low, activity of this enzyme is impaired. Potassium is therefore lost from cells and renal potassium excretion is increased, resulting overall in hypokalaemia. This hypokalaemia may not respond to the administration of oral or intravenous potassium, but does to magnesium supplementation [138].

The treatment of hypomagnesaemia is outlined in Table 6. Patient hydration and, thus, secondary hyperaldosteronism must first be corrected. Serum magnesium levels can usually be improved by oral supplements, however the data on magnesium absorption from different preparations are often derived from normal volunteer studies. Tablet dissolution and magnesium availability may be different in patients with a short bowel. Various magnesium salts have been given as oral treatment including magnesium sulphate, chloride, hydroxide, acetate, carbonate, gluconate, lactate, citrate, aspartate, pyroglutamate, oxide (magnesia) and diglycinate.

Table 6 Treatment of hypomagnesaemia

1. Correct water and sodium depletion (and thus secondary hyperaldosteronism)
2. Give oral magnesium preparation (e.g. 12 mmol magnesium oxide or 10 mmol magnesium aspartate at night)
3. Reduce lipid in diet
4. Give 1α-cholecalciferol (1–9 μg daily)
5. Give intravenous magnesium (occasionally subcutaneous or intramuscular magnesium sulphate)

Most magnesium salts are poorly absorbed and may worsen diarrhoea/stomal output. Magnesium acetate causes less diarrhoea than magnesium gluconate [139]. Magnesium oxide is commonly given and contains more elemental magnesium than the other salts. It is insoluble in water and alcohol but soluble in dilute acid. In the stomach it is converted to magnesium chloride. It is given as gelatine capsules of 4 mmol magnesium oxide (160 mg of MgO) to a total of 12–24 mmol daily or magnesium aspartate 10 mmol daily. Magnesium diglycinate (chelate) is absorbed as well as magnesium oxide as an intact dipeptide in the proximal jejunum and after an ileal resection it results in the passage of fewer stools than magnesium oxide [140]. Oral magnesium treatment is usually given at night when intestinal transit is assumed to be slowest and there is more time for absorption. This regimen does not appear to increase stomal or stool output. Magnesium may also be given as a topical spray [141]. A low-fat diet decreases stool/stomal magnesium losses, especially in patients with a retained colon [133]. If oral magnesium supplements, dietary advice and correction of water and sodium depletion do not bring the magnesium level into the normal range, oral 1α-hydroxycholecalciferol in a dose of 1–9 μg daily may improve magnesium balance [142, 143]. It may exert its effect by increasing both intestinal and renal magnesium absorption [143].

Magnesium can occasionally be given as a subcutaneous injection of 4 mmol magnesium sulphate every 2 or more days, but can cause skin ulceration. Intramuscular injection of 10 mmol/L is an alternative, but is painful. Regular intravenous infusions of 12 mmol or more can be given, usually in a litre of saline over 1–2 h, but can cause flushing.

Selenium

Patients receiving parenteral nutrition are commonly deficient in selenium [144–146] and need larger amounts of selenium than are required in the diet of normal subjects [146]. This suggests a loss of selenium from the gastrointestinal secretions. Patients with a jejunostomy also have a reduction in selenium absorption, the amount by which absorption is reduced correlating with residual jejunal length [147]. The kidney can conserve selenium but often not to a sufficient extent. Selenium deficiency is therefore common and may cause weak muscles, a tendency to infections, a dilated car-

diomyopathy and symptoms of hypothyroidism (it is a cofactor for the conversion of thyroxine to the more active triiodothyronine) [148].

Vitamin B_{12} Deficiency

Both groups of patients have had more than 60 cm of the terminal ileum removed and need long-term hydroxycobalamin injections, Traditionally 1 mg intra-muscularly every 3 months though may be longer depending on serum levels [20, 62].

Other Vitamin and Mineral Deficiencies

There may be impairment of absorption of the fat-soluble vitamins A, D, E and K and essential fatty acids. Essential fatty acid deficiency may be treated by rubbing sunflower oil into the skin [149]. Zinc deficiency is not common unless stool volumes are large, when zinc sulphate may be given (15–45 mg orally one to three times a day) [150]. In patients receiving parenteral nutrition the deficiencies depend on the regimen used, but deficiencies of iron, vitamin D and biotin [151–153] occurred with some regimens in the 1990s.

Diarrhoea (Jejunum–Colon Patients)

The oral intake determines the amount of stool passed. Diarrhoea may severely limit a patient's lifestyle; limiting food intake can reduce diarrhoea but may increase the problems of undernutrition. Rarely, a patient requires parenteral nutrition to allow him or her to eat less and so reduce the diarrhoea.

Diarrhoea may be treated with loperamide, 2–8 mg, given half an hour before food. Loperamide is usually given in preference to codeine phosphate (30–60 mg half an hour before food), as it is non-sedative and non-addictive; occasionally, however, both are needed. If tablets/capsules emerge unchanged in stool/stomal output, they can be crushed, opened, mixed with water or put on food. If less than 100 cm of terminal ileum has been resected, bile salt malabsorption may contribute to the diarrhoea. This may be helped by cholestyramine (or colesevelam) which has the additional advantage of reducing oxalate absorption but may be detrimental by reducing fat absorption and by further reducing the bile salt pool [102]. Gastric anti-secretory drugs may reduce diarrhoea shortly after surgery but are not usually effective in the long term.

Confusion

In addition to the many common general medical causes of confusion (e.g. hypoxia, hepatic, renal or cardiac failure, sepsis, hypoglycaemia, thiamine deficiency, alcohol or other drugs), other specific causes should be sought in a patient with a short bowel. Hypomagnesaemia may cause mild confusion. In patients with a preserved colon, severe confusion can result from D-lactic acidosis (in lactate accumulators), in which a metabolic acidosis with a high anion gap will be observed (chapter "Dietary Treatment of Patients with a Short Bowel"). Hyperammonaemia may cause confusion in both types of patients with a short bowel because ammonia cannot be detoxified. The small amount of intestine remaining cannot manufacture adequate citrulline to detoxify the ammonia created in the urea cycle. If there is concomitant renal impairment, the increase in blood ammonia causes a problem as the kidney will not be able to excrete the excess ammonia. Hyperammonaemia can be corrected by giving arginine (an intermediary in the urea cycle) [154, 155].

Drug Absorption

Drug absorption can be predicted from knowing the time to peak levels and the biopharmaceutical classification (chapter "Drug Absorption in the Short Bowel"). Omeprazole can be absorbed in the duodenum and upper jejunum; problems are likely to occur only if less than 50 cm jejunum remains. Warfarin [156] and thyroxine may need to be given orally in high doses. Loperamide circulates in the enterohepatic circulation, which is disrupted, and higher doses than usual may need to be given (chapter "Management of a High Output Stoma, Jejunotomy or Uncomplicated Enterocutaneous Fistula").

Adaptation

Intestinal adaptation (chapter "Intestinal Adaptation") is the process, following intestinal resection, that attempts restore total gut absorption of macronutrients, macrominerals and water to that occurring before the intestinal resection (chapter "Intestinal Adaptation").

In a classical paper in 1959, Pullan described three phases that related to the changing situations in patients after a 'massive intestinal resection' leaving a functioning colon in situ (i.e. 'short bowel syndrome') [157]. These changes reflect structural and functional adaptation.

- *Stage 1*. As intestinal motility returns in the first few days after the resection, profuse diarrhoea occurs and is maximal for the first 2–3 weeks. During this stage there may be large losses of fluid and electrolytes (up to 10 L/day). These losses have been attributed to gastric acid hypersecretion.

- Large volumes of saline (sometimes with magnesium) may be needed to maintain fluid balance, especially when the patient first starts to eat. A protein pump inhibitor or H_2 antagonist, loperamide and often codeine phosphate are empirically given. If the residual bowel length is less than 100 cm, parenteral nutrition may be started on the second postoperative day. Anal soreness and excoriations may be a problem. This phase ends as the diarrhoea lessens.
- *Stage 2*. The problem changes from that of fluid and electrolyte balance to that of progressive undernutrition requiring nutrition support. If untreated, the patient may rapidly lose weight and, despite a large oral energy intake, not absorb enough to maintain weight. Fat malabsorption is much more significant than that of carbohydrate and protein. Deficiencies of the fat-soluble vitamins A, D, E and K may occur, causing night blindness, bone pains, ataxia and bleeding respectively. Vitamin B and C deficiencies sometimes occur and cause glossitis, angular stomatitis, pellagra, psychotic changes and bleeding. Anaemia and hypoproteinaemia are rare after an uncomplicated resection.
- The patient may complain of abdominal cramps, distension and nausea. During this time the gastrointestinal transit rate slows, although a large volume of fatty stool is still passed. Carbohydrate and protein are better absorbed and a state of equilibrium is reached after 3–6 months.
- *Stage 3*. In the final stage relative equilibrium has been reached and minor adjustments are made. The dietary regimen tries to limit the lipid intake. Long-term parenteral nutrition is unlikely to be needed unless less than 50 cm jejunum remains. The beneficial effects of a proton pump inhibitor may have ceased by the end of the first year and the drug can be stopped.
- After a large resection of small intestine, improvement in absorption of macronutrients, macrominerals and water may occur by:
  - The patient eating more food than normal (hyperphagia);
  - The remaining bowel increasing in size and absorptive area (structural adaptation); and
  - Reduction in bowel transit rate to allow more time for absorption (functional adaptation).

An increased oral intake has been observed [158]. After a jejunal resection in animals, the ileal remnant undergoes structural changes which include elongation of villi, deepening of crypts, and an increase in the number of absorptive cells in a given length of villus. After a jejuno-ileal resection in man to leave a jejunocolic anastomosis, no structural adaptation (except possibly hyperplasia) has been demonstrated even though high GLP-2 levels are observed [109]. A degree of functional adaptation with slowing of liquid gastric emptying and solid small bowel transit has been demonstrated [39] and is likely to be caused by high peptide YY levels. Functional adaptation does occur, as demonstrated by the findings that there is a small reduction in faecal weight in the 3 months after a small bowel resection [159], and that there is increased jejunal absorption of water and sodium [160, 161], glucose [162] and calcium [163] with time. The intestinal calcium absorption may continue to increase for more than 2 years after a resection [163]. Restoring bowel continuity after a mesenteric infarction resulted in cessation of home parenteral nutrition in 77% within 5 years (Fig. 6) [164].

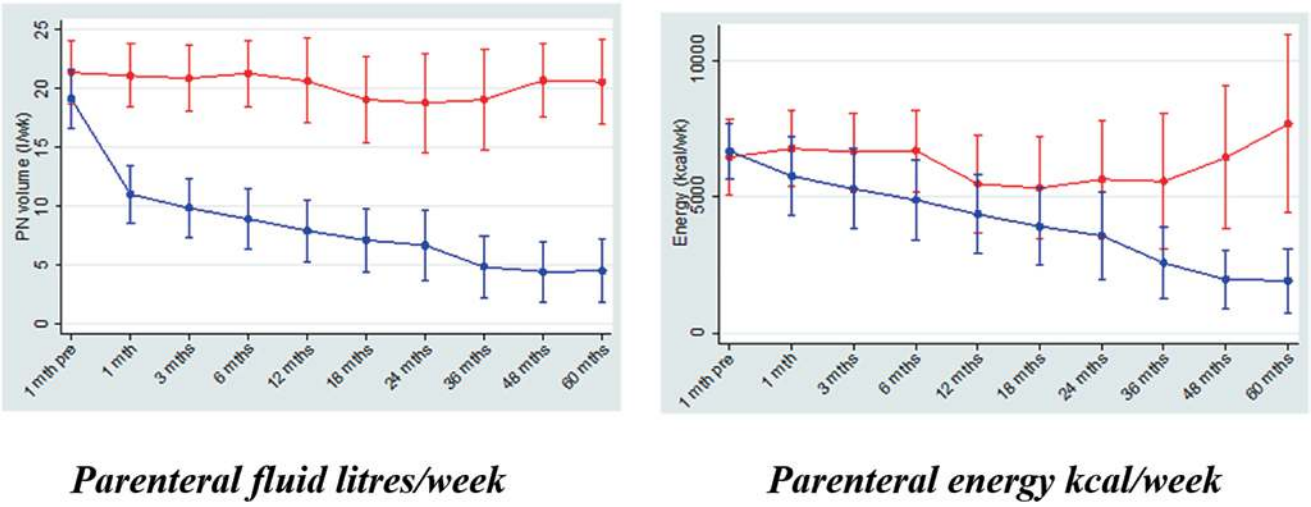

Fig. 6 Parenteral support after mesenteric infarction in patients with jejunostomy and in those following an anastomosis bringing the colon back into continuity [164]. Red top line Jejunostomy ($n = 29$) and lower blue line Jejunum-colon (re-anastomosis) ($n = 57$). There is a reduction in the need for parenteral fluid and nutrition in the 36 months (3 years) after the re-anastomosis

- Although adaptation occurs in the months after the creation of an ileostomy, there is no evidence for any structural [90] or functional [34, 165] adaptation at any time in patients with a jejunostomy.

Gallstones

Gallstones are common (45%) in both types of patient and are more common in men [34] (chapter "Gallstones in Intestinal Failure"). It was originally thought that gallstones in this circumstance resulted from deposition of cholesterol because of a depleted bile-salt pool. However, the gallstones tend to contain calcium bilirubinate. Such stones probably result from gallbladder stasis: biliary sludge develops and this subsequently forms calcium bilirubinate stones which often appear calcified on abdominal radiographs [166]. Calcium bilirubinate crystals within biliary sludge are more commonly found in men than in women [167]. Cholecystokinin injections have been used to prevent gallbladder stasis [168] and some units have advocated a prophylactic cholecystectomy [169, 170] (chapter "Gallstones in Intestinal Failure").

Social Problems

Most long-term patients with a short bowel have a body mass index within the normal range, and most are in full-time work or look after the home and family unaided [34]. Both groups of patients may have diarrhoea, which causes problems, especially if housing conditions are poor. In those with a colon the diarrhoea is malodorous and bulky due to steatorrhoea.

The effluent from a small-bowel stoma, unlike that from a colostomy, is not offensive. The large volume of fluid that emerges, however, may trouble the patient; sometimes 3 or more litres in 24 h may be passed from the stoma. The bag then has to be emptied frequently and, if it becomes overfull, the adhesive flange may separate from the skin with embarrassing leakage of fluid and with the likelihood of skin soreness.

Other and Future Treatments

New treatments are likely to be aimed at increasing the absorptive function of the remaining gut. Most are currently directed at inducing structural adaptation, for example GLP-1 or 2 analogues [171], epidermal growth factor [172, 173], colostrums or aminoguanidine [174]. Studies using growth hormone, glutamine and fibre have been disappointing [175–178]. Studies that use analogues of peptide YY have yet to be tried [179]. Cholylsarcosine is a synthetic bile acid resistant to bacterial deconjugation and dehydroxylation, that does not itself cause colonic secretion and thus diarrhoea, but does result in a variable improvement in fat and calcium absorption in patients with a short bowel, with or without a retained functioning colon [180, 181]. Attempts to replace colonic mucosa with small intestinal mucosa to increase absorption have not proved successful [182]. Tissue engineering to make small intestine over a scaffold (decellularized organ or synthetic biodegradable matrix) is difficult due to the complex structure of the small intestine (includes nerves, blood vessels, muscle and mucosa) and having to achieve a secretory, absorptive, propulsive and barrier function [183]. Another area of importance is the prevention of gallstones after an intestinal resection: trials using prophylactic antibiotics, ursodeoxycholic acid and cholecystokinin may be performed. An oral nutrient solution containing 100 mmol/L sodium and having an osmolality of 300 mOsm/kg has yet to be commercially manufactured as an ideal nutrient solution to give to patients with a jejunostomy or high-output ileostomy.

Small bowel transplantation is becoming more safe (chapter "Intestinal Transplantation") and the outcome in selected patients may be as good as that of prolonged parenteral nutrition though one set of problems may be changed for another (e.g. high output stoma, dependency on HPS for rejection/complications of immunosuppressive drugs).

Preventative Measures

Post-operative monitoring of Crohn's disease to ensure mucosal healing along with smoking cessation, immunosuppressive therapy (e.g. azathioprine, 6-mercaptopurine and methotrexate), and/or biological medication (e.g. anti-tumour necrosis factor antibodies) and balloon dilatation of strictures may reduce the need for repeated or major resections of Crohn's disease and thus the chance of developing a short bowel [184].

A small bowel embolus/venous infarction may be prevented by identification of risk factors such as atrial fibrillation, a poorly functioning myocardium, recent myocardial infarction, coagulation abnormalities or a period of hypotension. Anticoagulation therapy may be given to a patient in whom a potential source of emboli is identified. The diagnosis of a small bowel infarction can be difficult but needs to be made soon after the event. Clues to the diagnosis include the presence of the risk factors above, pain (usually of sudden onset and continuous), and usually a rise in the white cell count, amylase, phosphate, lactate and D-Dimers [185]. Ideally, contrast-enhanced computed tomography (CT) should be performed within 2–3 h of the onset of pain especially if a plain abdominal radiograph has shown no obvious abnormality [186]. If there is partial occlusive

obstruction to the mesenteric artery then percutaneous transluminal angioplasty or a surgical revascularization procedure can be performed (chapter "Mesenteric Ischaemia"). If clot is shown in the superior mesenteric artery or vein and bowel necrosis has not occurred, a bolus of a vasodilator (e.g. papaverine 60 mg or tolazoline 25 mg, phenoxybenzamine, adenosine triphosphate, glucagon or prostaglandin E) may be given into the superior mesenteric artery. If this is unsuccessful, surgery may be needed but papaverine can continue to be infused at a rate of 30–60 mg/h (1 mg/mL) [186]. Thrombolytic drugs, heparin and low molecular weight dextran may all be infused into the superior mesenteric artery or peripherally to try and halt and/or reverse the progression of the infarction or ischaemia. The outcome is best if there are no signs of peritonitis at the onset of treatment [186]. In addition nitrates, calcium antagonists or octreotide [187], may be given to try and reduce the chance of a small bowel infarction.

Experimentally, the most severe problems occur after ischaemic bowel is reperfused as the resultant toxins and cytokines can cause liver and multi-organ failure. Other drugs that may be of benefit include free-radical scavengers (e.g. superoxide dismutase, 5-aminosalicylate) or xanthine oxidase inhibitors (e.g. allopurinol) and antibiotics [188, 189]. Prostacyclin analogues may be useful when bowel is reperfused as they produce vasodilatation, reduce white cell and platelet aggregation and protect ischaemic tissues. If bowel is resected, a primary anastomosis is avoided and a temporary stoma created; often there is an elective re-exploration of the abdomen the following day and any further ischaemic bowel is resected [188, 190].

The techniques used to deliver abdominal radiotherapy have improved, with avoidance of the parallel opposed fields technique and the administration of glutamine and sucralfate (chapter "Pelvic Radiation Disease and the GI Tract"), so radiation damage may become uncommon.

Survival

The survival of patients with a short bowel is good, though there is only data on those requiring HPN in whom there is an over 50% survival at 10 years for non-malignant aetiologies [34, 45, 191–196] (chapter "Home Parenteral Support for Adults").

Chronic Small Bowel Dysfunction

Jeremy M.D. Nightingale and Peter Paine

Key Points

1. Patients with chronic small bowel dysmotility have predominantly a myopathy (usually dilated gut and classical chronic intestinal pseudo-obstruction (CIPO)), a neuropathy or idiopathic.
2. The patient's primary symptoms/problems are listed in order of importance to the physician and patient.
3. Contributing factors (e.g. drug therapy, psychosocial and quality of life issues) are evaluated.
4. Mechanical obstruction must be excluded (especially if dilated loops of bowel are noted) usually with a CT scan of the abdomen with oral contrast.
5. The patient's nutritional status is assessed and if poor, nutritional treatment is begun while taking into account/treating refeeding risks.
6. Tests to help establish a clinical diagnosis are performed when the patient is not taking any medications that affect gastrointestinal motility (e.g. opiods and cyslizine) and ideally when they have achieved a normal body mass index.
7. A definite diagnosis of dysmotility should not be given unless it is certain. Terms such as possible/probable or working diagnosis are preferred as a label of dysmotility is difficult to remove. As the clinical situation changes the diagnosis may be reconsidered.
8. A plan and treatment goals are agreed to help symptoms, nutritional status, psycho-social issues and quality of life. This should be with a multidisciplinary team (includes psychology and pain management specialists). All members of the team should give the same agreed information to the patient/family.
9. Surgical options may be considered. These include insertion of jejunal feeding tubes, venting stomas, a full thickness jejunal biopsy and selected bypasses/resections or rarely small bowel transplantation.
10. Opioids and intravenous cyclizine should be avoided.

Introduction

Chronic small intestinal dysmotility occurs when, for more than 6 months, there is a failure of coordinated intestinal propulsion, giving rise to the symptoms and signs of intestinal obstruction (colicky abdominal pain, nausea, vomiting usually with abdominal distension, and often a dilated bowel) in the absence of a mechanical cause [1–3]. It may be defined as severe when there is objective evidence of malnutrition, dehydration or electrolyte disturbance (e.g. BMI of less than 18.5 kg/m^2 or more than 10% unintentional weight loss in last 3 months) and thus clinically assisted nutrition and hydration (CANH) therapy may be needed. A classical obstructive picture with distended bowel is not always the case, especially if there is a neurological aetiology.

Normal gastrointestinal motility is determined by intestinal smooth muscle function which in turn is influenced by neural and humoral factors. A disorder of one or more of these systems can result in intestinal pseudo-obstruction [2]. Dysmotility may occur not only in the small bowel but also in other areas of the gastro-intestinal tract (e.g. oesophagus, stomach and colon) and their involvement may complicate diagnostic tests and treatments. There are many causes of acute or reversible/temporary intestinal dysmotility which include abdominal surgery, trauma, sepsis, metabolic (e.g. hypokalaemia) or endocrine problems (e.g. hypothyroidism); and there are other medical causes of abdominal pain (e.g. functional dyspepsia, irritiable bowel syndrome, centrally mediated abdominal pain, familial mediterranean fever, ischaemia, angio-oedema, abdominal migraine and

J. M.D. Nightingale (ed.), *Intestinal Failure*, https://doi.org/10.1007/978-3-031-22265-8_17

lead poisoning) which are not specifically discussed in this chapter but the clinician must be aware of them.

The diagnosis of these patients can be very difficult and may be empirical. Different diagnostic labels have been given to these patients based upon the diagnostic test used. Histology in an expert centre may be the most definitive but is often not available and indeed it may be inappropriate to obtain it due to associated risks and lack of specific therapy implications. Histology may show abnormalities but the extent they are due to malnutrition, previous surgery (including defunctioning bowel) or drug therapy is not clear. The clinical features, results of investigations (e.g. manometry) and histology may not all combine to indicate one specific diagnosis. Other factors that can give rise to the clinical picture or aggravate the condition are: unrecognised organic small bowel obstruction/the effects of previous abdominal surgery (including adhesions and neuropathic pain), drug usage (particularly opioids and drugs with anticholinergic effects), psychosocial problems including abnormal illness behaviour and malnutrition. In practice, all of these often play a part and contribute to the patient's presentation (Figs. 1 and 2). Untangling which of these factors gives rise to the dominant symptom can be challenging and needs the help of a multidisciplinary team that ideally consists of a gastroenterologist, gastrointestinal physiologist, gastrointestinal surgeon, pain team, psychiatrist/psychologist, rheumatologist (including a specialist in fatigue management), urologist, gynaecologist, neurologist, clinical biochemist, histopathologist, radiologist and nutritional support team.

If there is uncertainty about the diagnosis this should be clearly documented and only described as working (probable or possible) and the contributing factors to this should be stated on the patient's problem list (e.g. previous surgery, opioid or cyclizine use, psychosocial problems or undernutrition). A definitive diagnosis should only be given if there is a clear cause identified. It is very difficult to remove a diagnostic label once it has been given and a premature or erroneous organic diagnosis in those with predominantly psychosocial issues or abnormal illness behavior may make the management of contributing issues very difficult. A definite diagnosis although satisfying to have, rarely affects the patient's clinical management.

This document discusses the differential diagnoses, the medical and nutritional treatment of chronic small intestinal dysmotility, which result in malnutrition. In its most severe form patients with small bowel dysmotility may need long-term PN or even a small intestinal transplant, while in a milder form dietary adjustment may suffice.

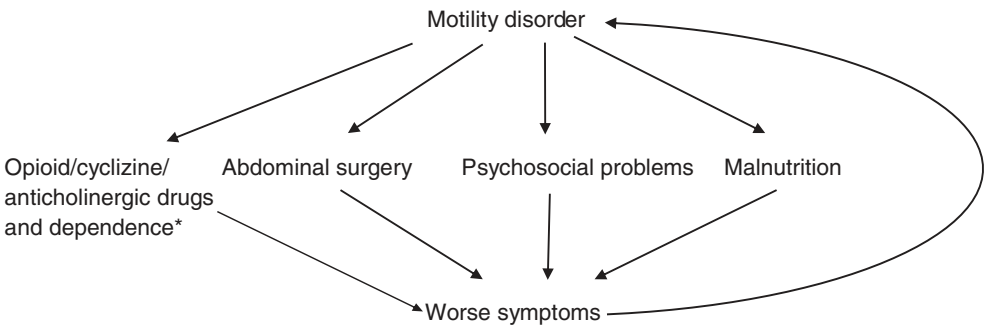

Fig. 1 Progression of dysmotility

*some other drugs can have similar problems (e.g. calcium channel blockers, antidepressants etc)

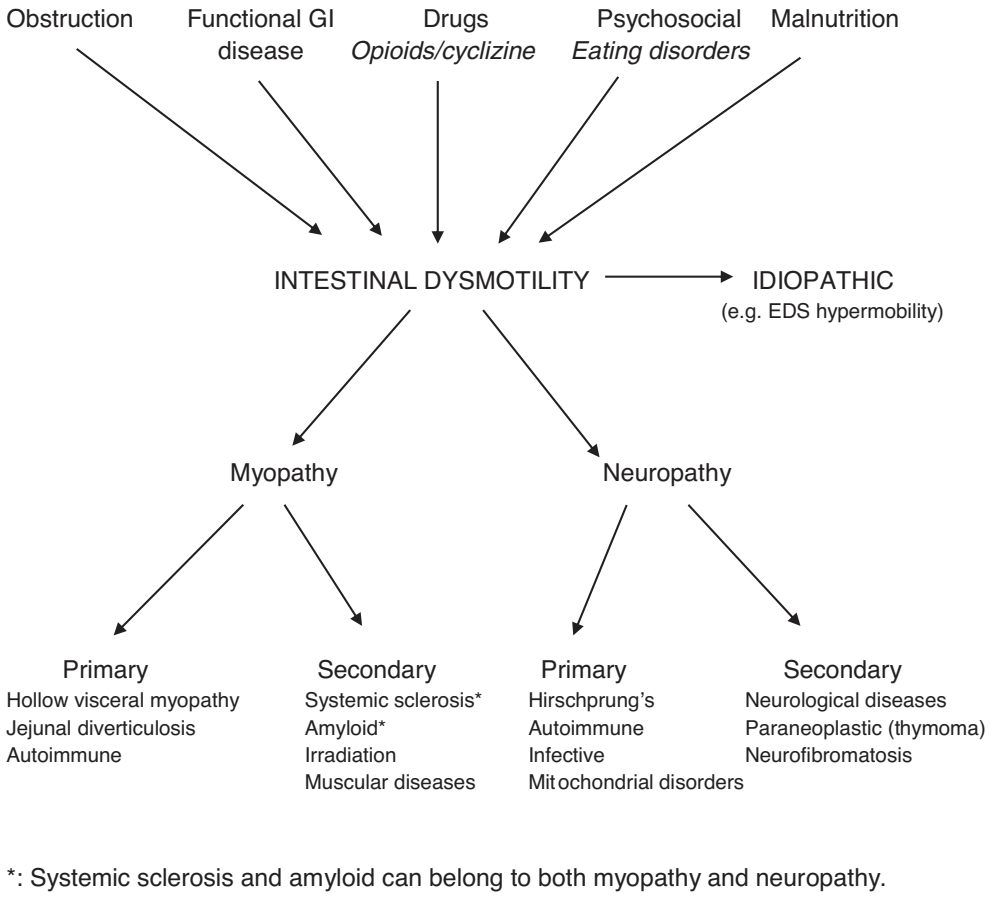

Fig. 2 Factors contributing/mimicking severe chronic intestinal dysmotility and its traditional classification

Conditions that Mimic or Can Contribute to the Presentation

A patient with suspected small bowel dysmotility will have had basal investigations to exclude other causes; these include inflammatory markers (CRP, albumin, platelets and faecal calprotectin) which, if normal, make active inflammatory bowel disease unlikely. These may be followed, as appropriate, with the use of endoscopies and cross-sectional imaging including with intravenous contrast to diagnose structural/mucosal diseases. Several other conditions may appear as severe chronic intestinal dysmotility but with no primary bowel pathology (Fig. 1). In one series the most frequent misdiagnoses for dysmotility were volvulus, megacolon and chronic constipation [4].

Organic Obstruction

A major problem, that is often not diagnosed, is a localised bowel obstruction as a result of adhesion formation. This may be suspected clinically when a patient has had a number of abdominal operations (with or without extensive adhesion division) [5]. A history of intermittent colicky abdominal pain with abdominal distention, loud bowel sounds, no bowel or stoma action and vomiting suggest this. A distal obstruction is suggested if the vomit is faeculent, while a more proximal one by green/yellow vomit. During an obstructive episode the bowel secretes more fluid and when the obstruction resolves diarrhoea follows (or a high stomal output). If a patient sticks to a low residue diet or even a liquid diet, the obstructive episodes may reduce or even be abolished. This approach, if successful, can be a useful supportive diagnostic test.

Radiologically the clue to an organic obstruction is the demonstration of a distinct transition point between dilated and normal sized bowel but this may not be apparent either because the obstruction has resolved or the bowel is fixed by adhesions and thus cannot dilate. It can be helpful to obtain an abdominal CT scan when the patient has an episode of severe pain. Contrast follow-through studies or MRI scans although useful when positive may not be tolerated in the acute setting and do not always demonstrate the obstruction. Unsuspected diagnoses may be revealed (e.g. small bowel volvulus from a band adhesion or an intussusception). Further clues to an organic obstruction are visible small bowel peristalsis, worse pain after prokinetic drugs or giant jejunal contractions on manometry [6, 7].

Multiple laparotomies themselves may result in secondary dysmotility, especially if the bowel becomes encased in fibrous tissue as can occur with sclerosing peritonitis. In addition upper gut surgery (e.g. a vagotomy, Whipple's resection, gastro-enterostomy, bariatric procedures or any bowel anastomosis) can result in secondary small bowel dysmotility [8].

Radiation damage can cause strictures and a localised obstruction and/or a generalised secondary dysmotility. Problems caused by radiation damage tend to be progressive over many years.

Opioid and Other Drug Effects on the Bowel

Opioid-induced bowel dysfunction (OBD) can result from both opioid withdrawal and chronic opioid usage and manifests with features of dysmotility (especially constipation) when pain is not the dominant issue. The narcotic bowel syndrome (NBS) may result from chronic usage and is defined as chronic, worsening or frequently occurring abdominal pain despite continued or escalating doses of narcotics in addition to dysmotility [9]. The opioid usage induces a hyperalgesic effect. It may be becoming more prevalent but it is often not recognised by clinicians [10, 11]. In addition to being acknowledged to occur in patients with gastrointestinal disease (functional or organic) it also occurs in patients with no pre-existing gastrointestinal problems who take high doses of the opioids for other painful conditions (e.g. joint problems or following surgery).

The components of therapy for NBS are recognition of the disorder, a trusting therapeutic relationship with the patient, replacement using neuropathic type pain drugs and controlled reduction in the opioid dose [12]. Specific drug treatments have been tried for OBD and NBS and include clonidine (to reduce withdrawal symptoms), and peripheral mu opioid antagonists (naldemidine, naloxone, methylnaltrexone, alvimopan) [13–15].

Opioids inhibit intestinal motility and so invalidate the tests of small bowel motility. They may also increase the risk of catheter-related blood stream infections (CRBSI) in patients on long term PN.

Survivors of cancer treatment may have bowel dysmotility which may be due to chemotherapy or opioid medication. Their management may require a wider MDT input.

Cyclizine is both an antihistamine and anti-cholinergic drug that acts as a centrally acting anti-emetic. There are many reports of it being taken for its euphoric effect which is most marked when taken intra-venously. In addition to causing addictive behaviour, it is of a low pH and so damages veins. It is not recommended for long-term use, especially in patients receiving PN [16].

Other drugs such as anti-cholinergics, anti-depressants, calcium channel blockers, chronic laxative abuse or some chemotherapeutic drugs (e.g. vincristine) may also cause reduced gut propulsion.

Functional Gastrointestinal Disorders

Many of the symptoms of small intestinal dysmotility are the same as for patients with other functional abdominal gastrointestinal disorders (e.g. irritable bowel syndrome, functional dyspepsia, cyclical vomiting, functional bloating/distension, functional constipation/diarrhea and centrally mediated disorders of gastrointestinal pain) [17].

The differentiation and overlap with these functional gastrointestinal disorders is difficult. They all may have genetic and psychosocial influences (early life trauma, life stresses, coping mechanisms, lack of social support etc.). In addition bacterial flora, inflammation, visceral sensation and motility may all contribute to the symptoms. In irritable bowel syndrome there may be an overlap with enteric neuropathy as increased lymphocytes have been observed in the jejunal myenteric plexus [18]. However, significant malnutrition is rarely a consequence of these disorders.

The treatment as for all dysmotility problems is to identify and treat the main symptoms. If weight loss has occurred nutritional support is given at the same time as therapies as for intestinal dysmotility. Significant caution should be exercised to avoid escalating to more invasive forms of nutrition support in patients with functional symptoms, especially in pain predominant presentations, in the absence of objective features (e.g. no biochemical disturbance or who having a normal body mass index). Escalation of invasive intervention in these patients risks causing iatrogenic problems, and in clinical practice does not appear to improve global function, quality of life or symptoms.

Psychological/Psychiatric Problems

Anorexia Nervosa

The American Psychiatric Association (APA) Diagnostic and Statistical Manual of Mental Disorders (DSM-5) stated in 2013 that to diagnose a person with Anorexia Nervosa they must display: (1) Persistent restriction of energy intake leading to significantly low body weight (in context of what is minimally expected for age, sex, developmental trajectory, and physical health). (2) Either an intense fear of gaining weight or of becoming fat, or persistent behaviour that interferes with weight gain (even though significantly low weight). (3) Disturbance in the way one's body weight or shape is experienced, undue influence of body shape and

weight on self-evaluation, or persistent lack of recognition of the seriousness of the current low body weight [19].

However the patients that present to gastroenterologists often do not have this typical presentation. Delayed gastric emptying, especially of solid, and delayed small and large bowel transit have been described in patients with anorexia nervosa [20–23]. There is a report of a patient having a mega-duodenum and no propagating migrating motor complexes (MMC) which both improved with an increased nutritional intake [24].

Avoidant/Restrictive Eating

Some patients who have had psychosocial problems in the past may have disordered gut motility partly due to a disordered eating pattern, undernutrition and the drug treatments which they received [25]. The Avoidant Restrictive Food Intake Disorder (DSM 5) is an increasingly recognized condition in patients with neurogastroenterology and malnutrition presentations and is best managed with a nutritional and psychological rehabilitation approach.

Psychiatric Disorders and Psychological Distress

Other major psychiatric disorders can be encountered, sometimes masquerading as or confounding a dysmotility diagnosis [26]. It is not uncommon for some of these patients to be referred to an Intestinal Failure (IF) unit. Psychological distress is common (Table 1) and so an MDT approach, including both clinical psychology and liaison psychiatry expertise is ideal.

Effect of Undernutrition on Gut Function

Malnutrition itself can impair gut function and cause malabsorption with mucosal atrophy, reduced gastric acid and pancreatic enzyme secretion and more bacterial colonization of the upper gut [27, 28]. The effects of undernutrition upon gut motility and histological appearance are uncertain.

There is a large literature on the superior mesenteric artery syndrome (Wilkie's syndrome) in which the third part of the duodenum is compressed between the superior mesenteric artery and the aorta (when the left renal vein is compressed it is referred to as 'nutcracker syndrome'). It is reported to be prevalent in patients who have suddenly lost weight and reported to improve when either the patient becomes better nourished or a duodeno-jejunostomy (bypass) is formed to avoid the obstruction. The symptoms attributed to this are post-prandial epigastric pain, nausea/vomiting and loss of weight [29–33]. Whether this is cause or consequence of malnutrition and whether it is a radiological rather than true clinical entity remains contentious and some clinicians dispute its existence and think it is over diagnosed. The risks of any surgery should be very carefully considered especially as the benefits of surgery are not always predictable or clear.

Table 1 Contributing psychological factors

• Delay in diagnosis
• Poor knowledge within the medical community
• No cure
• Pain and problems of analgesic drugs (including addiction)
• Anxiety, depression, somatisation, poor coping, sickness role
• Interaction with family, carers and job leading to low self-esteem/confidence/mood

Hypermobile Ehlers-Danlos Syndrome (EDS) (Joint Hypermobility Syndrome or Ehlers-Danlos Syndrome Hypermobility Type)

Hypermobile EDS with its gastrointestinal associations is difficult to classify as most patients with EDS do not have a dysmotility of the small bowel, but mainly visceral hypersensitivity. Its symptoms may mimic dysmotility (neuropathy) and the presence of EDS can contribute to dysmotility, usually if postural tachycardia syndrome (PoTS), or other associated factors such as opiates are present. According to the 2017 classification patients previously diagnosed with joint hypermobility syndrome and Ehlers-Danlos Syndrome-Hypermobility Type were reclassified as hypermobile Ehlers-Danlos Syndrome (hEDS) if they met the strict criteria or Hypermobile Spectrum Disorders (HSD) if they had many but not all of the characteristics of hEDS [34]. Patients with hEDS and HSD represent a third of patients referred to a tertiary neurogastroenterology clinic in the UK and these patients tended to be young, female with a poor quality of life [35]. hEDS/HSD is associated with a range of gut disorders (acid reflux, abdominal pain (especially typical is pain after eating or when any food arrives in the gut even from an enteral feed) and constipation) [36]. There is often autonomic dysregulation, particularly PoTS [37], chronic urinary retention due to a failure of the urethral sphincter to relax (Fowler's syndrome), and hypoglycaemia [35]. Mast cell activation disorder [37] is being increasingly reported (most commonly in those having PoTs) but is poorly defined and not often objectively confirmed. An increasing number of patients with joint hypermobility and gut dysmotility are being seen by nutrition support teams because of weight loss and malnutrition. This group seems especially sensitive to opioids and cyclizine both of which can exacerbate/mimic all of their symptoms [16]. It is currently unclear the degree to which the association of hypermobile EDS with gut symptoms encompasses specifically any greater degree of chronic small intestinal dysmotility, nor whether there are any different treatment approaches to patients without hypermobile EDS who have the same functional symptoms and it seems to be more prevalent in presenting to intestinal failure units

in the UK than the rest of Europe. The same cautions therefore should apply when considering escalating invasiveness of nutrition support in this group as to that of functional gastrointestinal disorders in general, especially if there is a pain predominant presentation. In Fig. 1 these patients have been inco-orporated into the idiopathic dysmotility group but may represent a mainly pain sensitivity problem rather than true dysmotility.

Pathophysiology

The propulsive failure of pseudo-obstruction is usually a consequence of either temporary dysfunction or irreversible damage to enteric neural networks (neuropathy), or less frequently, to disease of the effector system (myopathy). The pathophysiological basis of pseudo-obstruction is propulsive failure. In this context, the term 'motility' is confusing, because it refers to both transit and to the contractile activity of the gut. Clearly when there is reduced transit, there is, in one sense, 'reduced motility'. In the small bowel, however, the most common motor abnormality, in impaired propulsion, is an overall increase in the incidence of contractions; this can be regarded as 'increased motility'. The increased activity, probably due to a reduction in the inhibitory neural input, is obstructive rather than propulsive. This explains why 'prokinetic' drugs, which are designed to increase contractile activity, are usually ineffective in treating propulsive failure.

In the small bowel, the abnormal contractile activity results in distortion of the fasting migrating myoelectric complex (MMC) pattern. This is most easily seen during nocturnal sleep, when fasting activity is always present and consists largely, in health, of alternating sequences of quiescence and the 'migrating' contractions of phase III. In propulsive failure, the nocturnal motor quiescence is replaced by intermittent single or clustered contractions. Phase III episodes are prolonged in duration, and 'migrate' more slowly; phase III may even be altogether absent. In the colon, the high amplitude propagated contractions that usually occur 2–6 times daily are reduced in chronic constipation.

Classification of Chronic Small Intestinal Dysmotility

There are three major histopathological entities recognised—myopathies, neuropathies and mesenchymopathies depending respectively upon the predominant involvement of smooth muscle cells, enteric neurons or the interstitial cells of Cajal (ICC). Mesenchymopathies, which involve ICC, which are the gut pacemakers, are being recognised. The abnormalities described include a decreased ICC density, loss of processes and damaged intracellular cytoskeleton and organelles as revealed by immunohistochemical analysis and electron microscopy. It may be that abnormalities with the ICC are the primary event or may result from a neuropathy. In baby's, immaturity may result in delay in maturation of ICCs that can lead to the appearance of a reduction in these cells, so care needs to be taken with the histological diagnosis. (1) As conditions specifically falling into this category are few, this chapter will only discuss conditions traditionally classified as a myopathy of neuropathy. In general, a myopathy results in a dilated non propulsive gut and includes those termed chronic intestinal pseudo-obstruction (CIPO). A neuropathy more generally results in hypersensitivity and poorly co-ordinated bowel contactions (often increased) without bowel dilatation and is often referred to as enteric dysmotility (Fig. 2, Table 2).

It can be hard to determine if a condition is primarily a myopathy or neuropathy as some secondary conditions (e.g. systemic sclerosis, vasculitis or amyloid) may appear as

[a]Histology is generally inflammatory or degenerative

both. The end result of a neuropathy is often dysfunctional enteric muscle which occasionally can dilate, as in a myopathy. Overall a neuropathy (often a secondary one) is more common than a myopathy in causing small bowel dysmotility. The diagnosis can be difficult to define partly because the radiological, isotopic, manometric and histologic diagnoses may be different.

Myopathies

Primary myopathies most commonly occur in children and young adults and are often familial (genetic). Myopathies often have multivisceral involvement and thus a relatively high mortality. They may show reduced propulsive activity on manometry (Fig. 3b) and in the most severe form they are associated with massive gut dilatation (CIPO). Many predominantly affect the circular muscle (except hollow visceral myopathy). Primary myopathies are more common in children whereas secondary myopathies are more common in adults.

Primary Myopathies

Primary myopathies are due to abnormalities in enteric muscle (e.g. hollow visceral myopathy or autoimmune myopathy). There has been interest in reduced immunostaining of alpha-isoactin in jejunal circular muscle, observed in one [38] then 28 more patients (overall 24% of patients having full thickness jejunal biopsies) [39]. However it is not clear if this is the primary pathology or secondary to other factors (e.g. drugs, undernutrition or previous surgery) or a normal anatomical variant, and therefore not a specific finding [40]. Precise information as to the location of the biopsy—jejunum or ileum is essential for interpretation in this context.

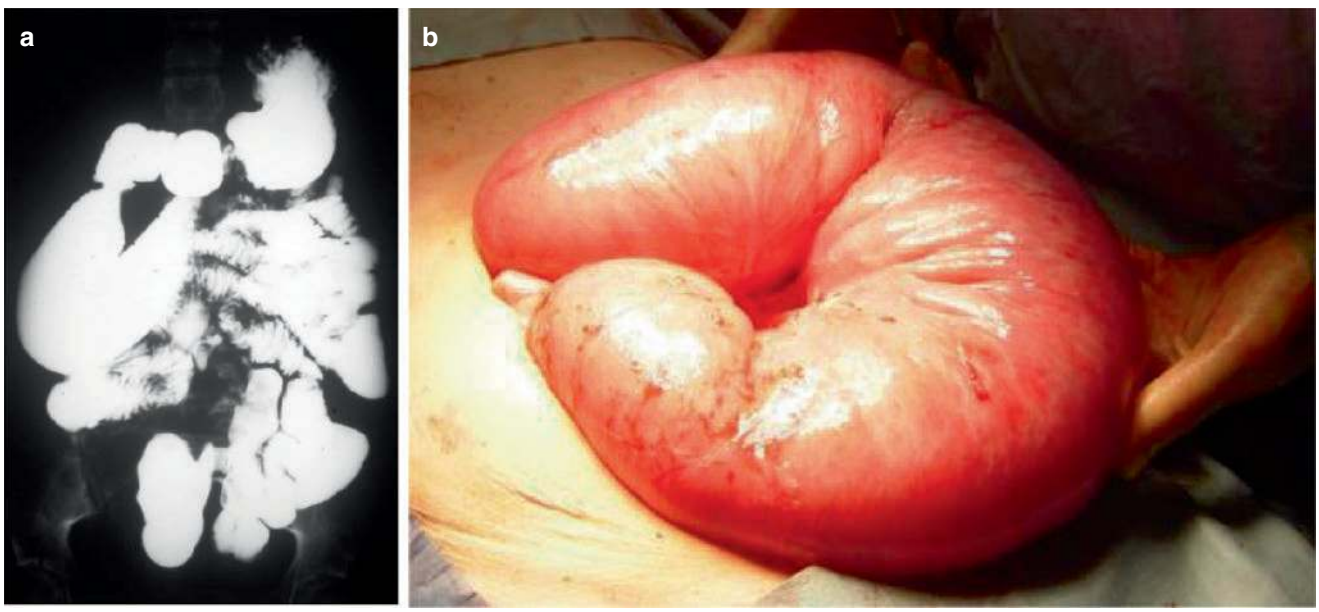

Fig. 3 (**a**) Plain abdominal radiograph of a patient with visceral myopathy. Note huge duodenal loop. Kindly supplied by M.A. Kamm. (**b**) Dilated small bowel in patient with visceral myopathy. Kindly supplied by N. Wyer

Familial

Hollow visceral myopathy is the best know example of a familial visceral myopathy. It is a rare congenital disorder that usually presents in the first or second decade of life and in addition to gross dilatation of the gastrointestinal tract (Fig. 3) (that often starts with a megaduodenum) there may also be associated dilatation of the urinary tract and associated frequent urinary tract infections [41–43]. The disease has been reported to follow an autosomal dominant mode of inheritance [44, 45]. In infants other features may include malrotation, pyloric stenosis and bladder atony. There is a loss of enteric smooth muscle with vacuolar degeneration and fibrosis [46]. The longitudinal muscle is predominantly affected. This may be due to the transformation of smooth muscle cells to collagen synthesizing myofibroblasts [47]. In one study of adult patients four of six patients had urinary tract involvement with dilatation of the ureters and/or incomplete bladder emptying [41].

Acquired-Autoimmune Myopathy

A few cases only of a lymphocytic enteric leiomyositis involving the smooth muscle cells have been reported [48–50]. Eosinophilic leiomyositis has also been reported, and in this context must prompt investigation for parasites, including dog hookworm.

Jejunal Diverticulosis

Diverticula in the jejunum usually result from congenital abnormalities or dysmotility (e.g. disordered high pressure bowel contractions) and may be associated with sub-clinical systemic sclerosis. Careful examination of any respected specimen should be carried out to examine the muscle and nerve layers of the bowel wall both in the region of the diverticula and adjacent bowel.

Secondary Myopathies

Secondary myopathies occur as part of a multi-system disease (e.g. systemic sclerosis, amyloid, chronic irradiation damage or muscular diseases) [51]. The problems of pseudo-obstruction are often only clinically apparent towards the end of the illness when nutritional support may be needed.

Systemic Sclerosis (Scleroderma) and Other Connective Tissue Disorders

Most patients with systemic sclerosis do get gastrointestinal involvement (Fig. 4) particularly of the oesophagus [52]. While the end result and main pathology is smooth muscle atrophy and gut wall fibrosis [53] it may start with microvasculature damage due to collagen deposits and inflammation which cause neural damage that progresses to muscle dysfunction and fibrosis. While systemic sclerosis patients with gross gastrointestinal involvement present in the terminal phase of the illness, this is not always the case and some present with the gastrointestinal involvement early in the disease without cutaneous involvement and the disease may not progress for many years. The clinical outcome in elderly scleroderma patients is the poorest of all adult onset dysmotility patients [54]. However, where indicated, long term PN can offer a safe and effective means of nutritional support in patients with severe small bowel involvement [55]. Other connective tissue and rheumatological disorders have been associated with dysmotility including SLE, RA and Stills disease [56, 57].

Fig. 4 Abdominal radiograph of a patient with progressive systemic sclerosis. Kindly supplied by E.A. Quigley

Amyloidosis

The primary type distribution may be associated with gut involvement. The most common underlying diagnosis is myeloma (often producing lambda chains). While classified as a myopathy it can also cause neurological damage and, like systemic sclerosis, may cause both a myopathy and a neuropathy. The rectum can be spared and so duodenal sampling should also be considered. Any full thickness biopsy

for motility investigation should also be examined for amyloidosis. Genetic testing is now readily available for the hereditary type of amyloidosis which may present more commonly in men and with peripheral neuropathy and cardiac as well as gut involvement.

Chronic Irradiation Damage

This usually occurs after pelvic irradiation for gynaecological cancers or genital-urinary cancers. The sigmoid and terminal ileal areas are often most involved. However, the whole small bowel can be involved giving rise to a pseudo-obstruction picture or as discrete areas of strictures. Surgery is very difficult and has a high risk of an enterocutaneous fistula(s) being created. Gut permeability, secretion, motility and blood supply can all be affected giving rise to any or all of the following: malabsorption, protein losing enteropathy, diarrhoea, perforation/fistulas, bleeding and obstruction. These problems can all occur months or years after more than 50 Gy irradiation has been given. The irradiation is more likely to give problems if a patient is already malnourished, has diabetes mellitus, hypertension or a vasculitis [58].

Muscular Diseases

Myopathies may occur associated with congenital muscular disorders (muscular dystrophies, myofibrillar myopathies (e.g. *Desmin myopathy*), hereditary inclusion body myopathies) but the muscle weakness (and often cardiac problems) dominates the clinical picture though gastrointestinal problems if sought are common. Metabolic storage disorders can have a myopathic process and occasionally can be treated with specific enzyme-replacement therapy [59].

Neuropathies

An enteric neuropathy may occur as a primary pathology (congenital, autoimmune or infective), secondary to a generalised neurological disorder, paraneoplastic process, metabolic disorder (e.g. diabetes) or drugs/toxins or as a developmental abnormality. Visceral neuropathy is less well reported in the literature than visceral myopathy. Visceral neuropathy is commonly acquired in adulthood or in old age and is associated with a high morbidity usually due to factors other than the neuropathy. Luminal dilatation is rarely seen except at the end stage of the disease.

Two forms of pathology are found either enteric neural *degeneration* (in the absence of inflammation) or *inflammatory* [60]. Degenerative neuropathies can result from mitochondrial dysfunction and the pathological findings include neuronal swelling, intranuclear inclusions, axonal degeneration and hypoganglionosis. The aetiology of many degenerative enteric neuropathies will remain idiopathic. Inflammatory neuropathies may include both plexitis and neuritis, and can be lymphocytic or less commonly eosinophilic, the former promoting autoimmune screening, the latter investigation for parasites.

Manometry may show intense but apparently uncoordinated motor activity with no propulsive contractions (Fig. 3c) and there may be no fasting MMC.

Primary Neuropathy

The enteric neuropathies can affect both the submucosal and myenteric plexuses, but the myenteric plexus is predominantly affected. The term visceral neuropathy is used for primary intrinsic enteric nervous damage.

Congenital/Familial/Developmental

Familial visceral neuropathies include Hirschprung's disease, mitochondrial cytopathies and Von Recklinghausen's disease. Hirschprung's disease can affect any part of the gut.

Mitochondrial disorders are relatively common if specifically sought. One study showed 19% of 80 adult patients labelled as CIPO to have this [61]. Mitochondrial cytopathies such as mitochondrial neurogastrointestinal encephalomyopathy (MNGIE) (the most common) (also referred to as Thymidine Phosphorylase Deficiency) is an autosomal recessive disorder characterised by severe gastrointestinal dysmotility (including bacterial overgrowth and lactic acidosis); cachexia, and neurological problems including leukoencephalopathy (96%), polyneuropathy (96%), ophthalmoplegia (91%) (with ptosis) and hearing loss (55%) [62, 63]. The disease is caused by mutations in the thymidine phosphorylase (TP) gene. Gastrointestinal dysmotility is the most prominent manifestation, with recurrent diarrhoea and symptoms of obstruction. Patients with MNGIE present between the first and third decade (mean age 18 years) [64] and usually have a much reduced life expectancy and tend to die in early adulthood (mean 37.6 years; range, 26–58 years). It, like all mitochondrial defects, can be tested for by plasma and urine thymidine deoxyuridine, white cell thymine phosphorylase, the Tymp gene, MR brain scanning and muscle biopsy.

Autoimmune

Auto-antibodies directed at enteric neurons, usually neuronal ion channels (e.g. voltage-gated potassium channels) can occur as a paraneoplastic phenomenon, when the anti-neuronal nuclear antibody (ANNA-1 or anti-Hu) is most commonly found, and antineuronal antibodies can occur in non-paraneoplastic motility disorders [65–67]. Other auto-antibodies associated with dysmotility include acetyl cholinesterase receptor antibody (AchR) (ganglionic, nicotinic and M3 type), antibodies against the voltage gated potassium

channel-complex (VGKC-complex), voltage gated calcium channel antibodies (VGCC), smooth muscle and gonadotropin-releasing hormone (GnRH) [57]. The pathogenetic role of auto-antibodies is currently however unclear. Coeliac disease has also been implicated in some cases of dysmotility.

Infective

Both herpes (Epstein-Barr virus and cytomegalovirus) [68] and polyoma viruses [John Cunningham (JC) virus] [69, 70] have had their DNA isolated in the myenteric plexuses of some patients with visceral neuropathy. They may be causative agents rather than innocent bystanders, but this has yet to be proven. Chagas' disease (South American trypanosomiasis) typically causes a megaesophagus and megacolon. Chagas' enteropathy is common and gives rise to dyspepsia, intestinal pseudo-obstruction with bacterial overgrowth [71]. Lyme disease and botulism have also been reported as reversible causes of dysmotility.

Secondary Neuropathy

The neuropathic process may affect the nerves external (extrinsic neuropathy) to the gut and so indirectly affect gut motility or may be part of a generalised illness. Indeed, most cases of visceral neuropathy are part of a generalized neurological disorder rather than a primary neuronal disorder of the gastrointestinal tract.

Generalised Neurological Disorders

Disorders of the parasympathetic or sympathetic nerves that innervate the gut (including autonomic system degeneration and the neurological effects of diabetes mellitus (most common) and other endocrine or metabolic disorders) can indirectly cause gut dysmotility. Brainstem lesions, spinal cord injury, multiple sclerosis, Parkinson's disease (basal ganglia calcification) and leukoencephalopathy can all affect gut motility [72, 73]. A lymphocytic leiomyositis and myenteric ganglionitis have been described in the ileum of children with cystic fibrosis and distal ileal obstruction [74]. Myotonic dystrophy, multiple sclerosis, Parkinson's disease and porphyria may all be associated with an enteric neuropathy.

Paraneoplastic

Small cell lung cancer, carcinoid tumours, neuroblastoma and thymoma with anti-neuronal nuclear antibodies have all been described to cause an enteral neuropathy. There is often a dense inflammatory infiltrate of lymphocytes and plasma cells affecting both plexuses but mainly the myenteric (myenteric ganglionitis). Anti-Hu neuronal antibody is characteristic [75]. Removal of a thymoma may result in resolution of the dysmotility and the patient gaining weight. CRMP 5 (CV2) and AchR auto-antibodies have also been associated with paraneoplastic dysmotility and should prompt a careful search for occult malignancy [57].

Drugs/Toxins

Vincristine is directly neurotoxic and causes a visceral neuropathy. Anticholinergics (e.g. phenothiazines and tricyclic anti-depressants) have been associated with severe dysmotility. A case series of 102 life-threatening episodes of clozapine-induced gastrointestinal dysmotility episodes were collated with some evidence for dose dependence [76]. A number of other drugs have been associated with severe dysmotility, which, in most cases, improves with stopping the drug or reducing the dose; these include baclofen, buserelin, clonidine, fludaribine, phenytoin and verapamil. Lead poisoning can be a rare reversible cause [57].

Idiopathic

In the majority of patients and in most centres, the precise aetiology of chronic severe intestinal dysmotility is not characterised histopathologically and remains based on the clinical presentation, physiological testing and exclusion of obstructive and mucosal disease. This in part reflects a low uptake of full thickness biopsies outside of the context of stoma formation or other surgical intervention. In selected populations of PN dependent patients with dysmotility, high rates of full thickness biopsies were associated with high rates of neuromuscular abnormalities of which 2/3 were primary and 1/3 secondary causes, although not all biopsies yielded a diagnosis. The threshold and acceptability of full thickness biopsy testing, especially as most will not lead to a change in management, has not currently achieved consensus. There also remain some unresolved issues for gastrointestinal neuromuscular pathology standardisation and interpretation [57]. For the near future therefore it is likely that the aetiology in the majority of dysmotility patients will remain idiopathic.

Physiological Consequences of Severe Small Intestinal Dysmotility

Impairment of Coordinated Gut Contractions and the Migrating Myoelectric Complex

If the migrating myoelectric complex (MMC) is impaired, then the small bowel will not be cleared of debris predisposing to gut stasis and bacterial overgrowth. With enteric neuropathies gut co-ordination is disrupted and the presence of chyme in the small bowel can cause severe painful non-propulsive large contractions. This is one of the causes of abdominal pain shortly after eating.

Gut Stasis

The failure of forward propulsion may also cause constipation, and this is often the first symptom. Gut stasis results in abdominal distension and if much fluid accumulates (oral intake and normal gut secretions) it may produce a large volume vomit. The vomit may be faeculent and contain food debris from several days previously.

Bacterial Overgrowth and Malabsorption

The combination of a dilated gut with reduced propulsion and ineffective MMC allows anaerobic bacteria to proliferate in stagnant loops of bowel. This bacterial overgrowth results in bile salts being deconjugated, less effective secondary bile acids (e.g. lithocolic acid) being made and pancreatic enzyme degradation occurs so that steatorrhoea and malnutrition may occur. Associated with steatorrhoea is malabsorption of the fat-soluble vitamins A and E (less so D and rarely K) with deficiency symptoms (night blindness, poor colour vision, dry flaky skin and ataxia). Vitamin B_{12} may be malabsorbed but both folic acid and vitamin K can be manufactured by the bacteria and so may give rise to high serum levels.

Occasionally the bacteria can manufacture D-lactic acid (normally L-isomer) giving rise to D-lactic acidosis (high anion gap acidosis) and other bacteria can manufacture ammonia which may appear in high levels in the blood.

Small intestinal bacterial over growth (SIBO) is when excess micro-organisms are present in the small intestine and lead to a malabsorption syndrome with occasionally a protein losing enteropathy. Subtotal villous atrophy may be found on histology. There are several endogenous mechanisms for preventing bacterial overgrowth: gastric acid secretion, intestinal motility, intact ileo-caecal valve, intestinal immunoglobulin secretion and bacteriostatic properties of pancreatic and biliary secretions. The aetiology of SIBO is usually complex, associated with disorders of these mechanisms. In some patients more than one factor may be involved.

There is currently no gold standard for diagnosis of SIBO and the commonly available methodologies (the culture of jejunal aspirates and a variety of breath tests) are limited by large variations in their performance and interpretation [77].

Problems of Undernutrition

Patients who rapidly lose more than 10% of their body weight frequently have demonstrable physiological changes which include, skeletal and cardiac muscle weakness, poor concentration and mental function including memory, prolonged sleeping, reduced sexual function, a low body temperature and a propensity to develop infections which are potentially severe [78]. In the gut, malabsorption with mucosal atrophy, reduced gastric acid and pancreatic enzyme secretion and more bacterial colonization of the upper gut can occur though the experimental backing for this is inferred from studies in patients with anorexia nervosa [20–24].

Clinical Features of Chronic Small Intestinal Dysmotility and Management Plan

History, Examination and Blood Tests

The clinical history and examination should determine if there are associated systemic neuromuscular, connective tissue, or endocrine diseases (muscular diseases, neurological disease, storage diseases, systemic sclerosis, diabetes mellitus, irradiation etc.) and thus if the myopathy or neuropathy is a primary or secondary disorder. Exploring the family history will detect some congenital diseases as will asking about foreign travel (Chagas disease). Examination especially includes the neuromuscular system and testing for joint hypermobility. Autonomic neuropathy should be considered if orthostatic, pupillary or sudomotor (sweating) dysfunction accompanies dysmotility. Simple clinical bed-side assessment of orthostatic pulse rate change (lying to standing) may identify PoTs.

Symptoms need to be listed in order of importance to the patient, and a record made of all the drugs currently taken or that have been taken for long periods (especially opioids and cyclizine).

A basic nutritional assessment will include measuring the patient's height and weight and asking their usual weight in health and their weight change over the last 2 weeks, 3 and 6 months. From these their body mass index and percentage weight loss can be calculated. In addition, they are asked about recent changes in their food intake.

The ideal logical sequence in the diagnosis of these patients is:

- The confirmation that there is abnormally impaired transit of luminal content
- The identification of the region of the bowel that is affected
- The identification of the propulsive abnormality
- The identification of specific pathology.

A management plan is made, including tests to help make the diagnosis (Table 3). Blood tests will include routine blood count, renal (including potassium and magnesium), liver, bone chemistry, thyroid function, glucose, myeloma screen, anti-tissue transglutaminase (for Coeliac disease). Nutritional measures if undernourished or steatorrhoea include vitamin

Table 3 Management plan for small intestinal dysmotility

1. Determine and order the primary symptoms
2. Exclude mechanical obstruction (CT abdomen with oral contrast)
3. Evaluate other contributing factors: drug therapy (e.g. opioids, cyclizine and anti-cholinergics), psychosocial (may need formal psychological/psychiatric assessment) and quality of life issues
4. Nutritional assessment (BMI, percentage weight loss and other anthropometric tests)
5. Start nutritional treatment if necessary and consider/treat refeeding risks
6. Perform specific blood tests to help establish aetiology and consider tests of autonomic function
(a) Screen for hypothyroidism, coeliac disease and diabetes.
(b) Chest X-ray (or CT/PET CT) for *thymoma or other neoplastic conditions* (e.g. small cell carcinoma of lung)
(c) Antibodies for scleroderma (anti-centromere, anti Sc170, anti M3R) and other connective tissue disorders (ANA, ANCA, anti DNA, anti SMA)
(d) Antibodies that may be associated with paraneoplastic diseases (mainly small cell carcinoma and thymoma). These include type 1 anti-neuronal nuclear antibody (ANNA-1 "anti Hu"), anti-collapsin response mediator protein 5 (anti CRMP-5 also known as anti CV2), ganglionic acetyl cholinesterase receptor antibody (AChR antibody) especially if autonomic dysfunction [49], and anti-voltage gated potassium channel (VGKC)-complex antibodies
(e) Test for *mitochondrial disorders* with plasma and urine thymidine and deoxyuridine, WBC thymine phosphorylase. If there is a high suspicion then test for the TYMP gene and also screen for related diseases (e.g. "MELAS" (mitochondrial encephalopathy with lactic acidosis and stroke-like episodes) with the m.3243A>G mutation). Muscle biopsy and sequencing of mitochondrial genome may be considered
7. Therapeutic plan/objectives of care to address patient's symptoms, nutritional status, psycho-social issues and quality of life
8. Try to establish a clinical diagnosis (or probable one). Perform physiologic assessment of the parts of the gastrointestinal (GI) tract that may be involved. These are done when nutritional status is near normal and the patient is off drugs likely to affect GI motility. Consider full thickness jejunal biopsy
9. Consider surgical options
10. Regular review and reconsider diagnosis as the clinical situation changes. Treat the predominant symptom/problem

A, E, D, INR, iron, ferritin. B_{12}, red blood cell folate, selenium, zinc and copper. Consideration is given to requesting auto-antibodies associated with connective tissue disorders and neoplasia (especially anti-neuronal antibodies) and tests for mitochondrial disorders.

In MNGIE (a mitochondrial disorder) direct evidence is provided by a plasma thymidine concentration greater than 3 μmol/L and a plasma deoxyuridine concentration greater than 5 μmol/L. Thymidine phosphorylase enzyme activity in leukocytes will be less than 10% of the control mean. Molecular genetic testing of TYMP, the gene encoding thymidine phosphorylase, detects mutations in affected individuals.

Rectal examination with an unprepared sigmoidoscopy will identify stool consistency and colour and permit biopsy for amyloid. Steatorrhoea will be detected, and constipation/diarrhoea confirmed. Basic tests of autonomic function include lying and standing systolic blood pressure and heart rate with electrocardiogram (ECG) confirmation.

Diagnosis made by radiology (contrast follow through, MRI and isotope studies), manometry and/or histology.

Myopathy

Symptoms include chronic abdominal pain, abdominal distension and bloating, early satiety, recurrent nausea and vomiting and alternating diarrhoea and constipation. Without treatment, weight loss and protein-energy malnutrition may ensue [78]. The symptoms in 28 patients with a probable enteric myopathy were abdominal pain (100%), distension (82%) nausea/vomiting (79%), constipation (61%) and diarrhoea (21%); weight loss occurred in 36%, 5 of whom were given parenteral support [39]. The vomiting may be faeculent and often of high-volume giving rise to a risk of pulmonary aspiration.

In hollow visceral myopathy (HVM) in addition to the features above patients have a very dilated small bowel. They may have urological complaints including bladder-emptying dysfunction [41–43]. Children with HVM may present at or before birth with hydronephrosis, megaureters and megacystis, or in the first year of life with constipation and episodes of intestinal pseudo-obstruction [41, 42]. The presence of digital arches on fingerprint, mitral valve prolapse, joint laxity and constipation before age 10 years all favour the diagnosis [72]. HVM may present at any age, but early adulthood is most common [44, 45].

Signs of autoimmune disease (arthropathy, Raynauds disease or proteinuria) may suggest a secondary myopathy, or the pseudo-obstructive syndrome associated with scleroderma may be declared by the cutaneous manifestations of this disease.

Neuropathy

Many of the features are the same as for a myopathy particularly with severe abdominal pain after food however abdominal distension is often absent and the plain abdominal radiograph may appear normal [79].

Radiological Tests

The diagnosis is usually first suspected after plain abdominal radiographs have shown a dilated small and large bowel. Once suspected, investigations aim to confirm that there is impaired transit of luminal contents, to identify the region of the bowel affected, ideally to identify the propulsive abnormality and to show a specific pathology [4]. Investigations help establish the presence of intestinal pseudo-obstruction and may delineate an underlying cause. In practice the diagnosis is often presumed after several laparotomies have excluded a physical obstruction, although computerised tomography/barium follow through/MR enterography

excluding a transition point in a diffusely distended small bowel suggests CIPO and may prevent unnecessary laparotomy. Computerised tomography (CT) may also help distinguish severe dysmotility from functional bloating due to abdomino-phrenic dysinergia [80]. Dynamic magnetic resonance imaging (MRI) of the small bowel is becoming increasingly helpful [81, 82] though is less established. MRI brain can be helpful in the diagnosis of MNGIE [55].

The measurement of whole gut time can be measured by serial X-rays of ingested radio-opaque markers (small lengths of barium-impregnated polyvinyl tubing).

Small bowel transit using a barium follow-through examination will usually give some indication of accelerated or delayed transit and a dilated duodenal loop (megaduodenum) may be one of the earliest signs of visceral myopathy [4]. In addition in HVM there may be oesophageal aperistalsis and variable dilatation of the small and large bowel.

Radioisotopic Investigations

Gastric emptying can be measured using gamma scintigraphy to obtain serial images of labelled solid (scrambled eggs, liver or pancake), semi-solid (thick soup) or liquid (orange juice) meals in the stomach. Gastric emptying measurements may be helpful in determining whether the stomach is involved in a generalised disorder of propulsion or a localised one (e.g. Chagas' disease). These isotopic meals can be extended to measuring the transit of the meal through the small bowel and if the isotope has a long half-life oro-caecal and colonic transit may be determined. Liquid meals may not clearly demonstrate an abnormality.

Endoscopic Tests

Jejunal aspirate for bacterial overgrowth is infrequently performed but usually by endoscopy (or fluoroscopy with jejunal intubation). A clinically significant overgrowth is when counts exceed 10^5/mL (usual is less than 10^4/mL). Common species include bacteroides, enterooccus and lactobacillus. But most of the bacteria likely to be relevant in causing symptoms cannot be cultured. Endoscopy also has a role in mucosal sampling and palliative venting. Capsule endoscopy examination can rarely give transit information but is seldom used due to the risk of the capsule being retained and some regard it as contraindicated.

Non-invasive Investigations of Gut Transit

Orocaecal transit can be measured using the rise in breath hydrogen due to the degradation of ingested polysaccharides (e.g. lactulose), in health this is caused by caecal bacteria fermenting the ingested agent but this is unhelpful if there is propulsive failure as small bowel bacterial overgrowth is common and is not a recommended test for this application [83, 84]. It is also unhelpful following a significant small bowel resection or if there is an enteric fistula.

Breath tests to diagnose bacterial overgrowth may be misleading and produce false negative results compared to culture of small bowel aspirate [77, 85]. This has in part been due to broad variations in how these tests are performed and interpreted. Recent work in the UK and US has taken place to develop evidence based consensus guidelines for breath testing in terms of dose of substrate (75 g glucose, 10 g of lactulose) and cut off values. In addition, whilst hydrogen only breath testing was previously used, modern testing protocols have incorporated the measurement of methane. Increased intestinal methane levels have been associated with delayed small bowel transit as measured by scintigraphy and therefore should be measured in patients with suspected small bowel dysmotility to improve the tests utility [85]. Other tests that may indicate bacterial overgrowth include raised urinary indicans, blood D-lactate or alcohol levels.

Manometry

Intraluminal pressure sensors incorporated into a catheter can detect the patterns of contractile events. For the diagnosis of pseudo-obstruction, the logical investigation is small bowel manometry. Small bowel motor activity was initially studied using multi-lumen perfused tube systems, with a pump and strain gauge transducers external to the patient [86]. This gave information on motor activity in the antrum and proximal duodenum, and detected abnormal motility [87] and some types of pseudo-obstruction [88, 89]. This technique required the patient to remain in a laboratory attached to a machine for more than 6 h and was not good at recording fasting, and postprandial activity (Fig. 5) [90].

An alternative is the wireless motility capsule (WMC) which is an ambulatory, minimally invasive diagnostic modality that allows continuous assessment of intraluminal pH, temperature, and pressure during its transit through the gastrointestinal tract. The technology allows for both measurement of transit times in multiple regions of the upper and lower gastrointestinal tract, as well as pressure profiles in the antro-duodenum. The standardised equipment and procedures in WMC allow the comparisons of data across multicenters. The role of the technology has been best established in the evaluation of a large number of healthy volunteers [91] and in patients with suspected gastroparesis and suspected chronic constipation. The worry with this is technique in these patients is that the capsule may remain in the bowel and not be passed. However, a paper in patients with Crohn's disease has shown that the same precautions used when considering patients for capsule endoscopy (i.e. clinical and radiological assessment and use of a patency capsule) can mitigate much of the risk in potential WMC patients [92].

Twenty-four hour ambulatory jejunal manometry [93] uses a catheter with built-in miniature strain gauge transducers [94] and records data to a solid-state digital recorder [95].

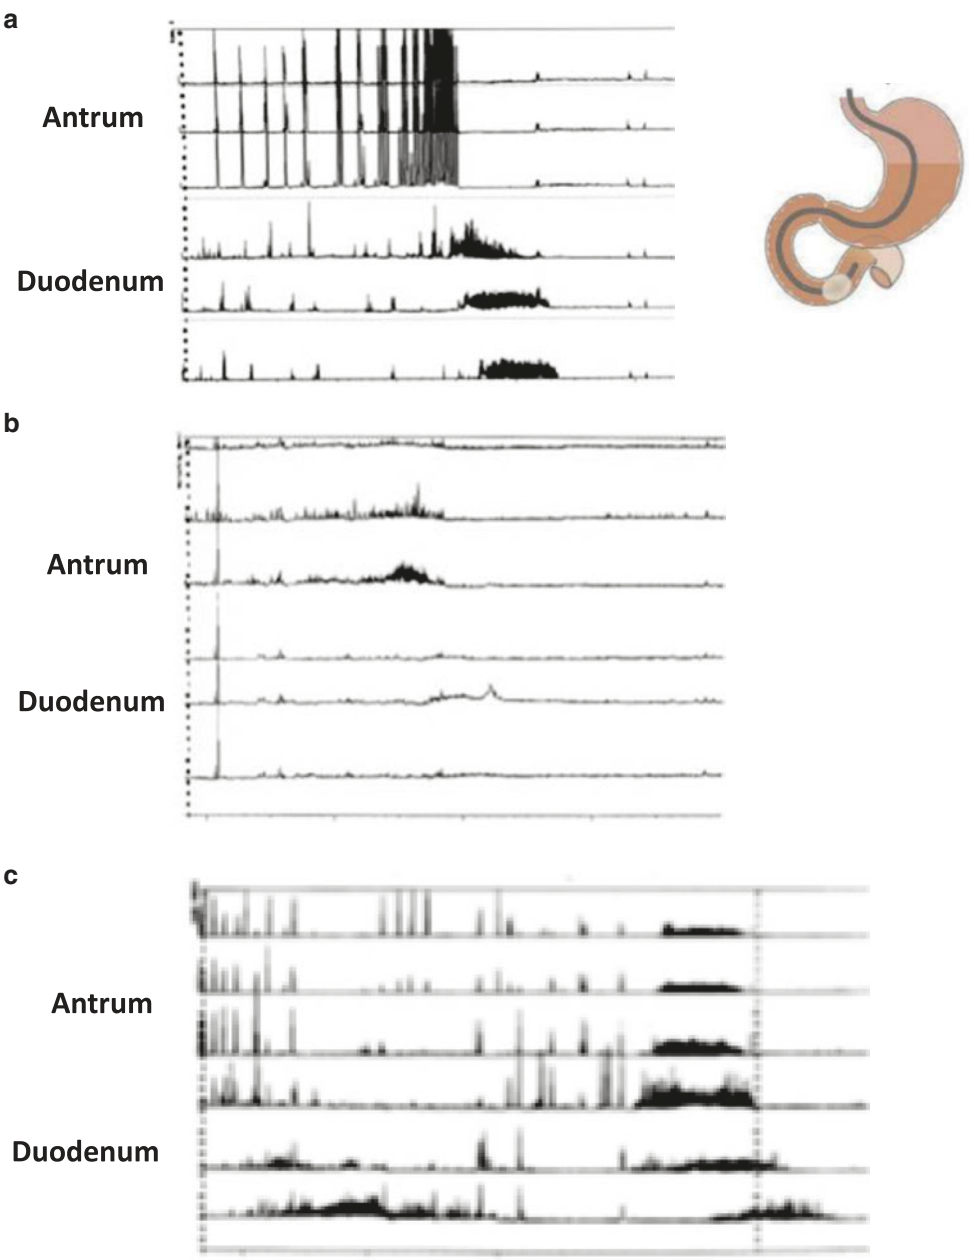

Fig. 5 (**a**) Fasting antro-duodenal motor activity from a control subject. Simultaneous recording of antral (top three channels) and duodenal (lower three channels) motor activity demonstrates the sequential phases of the Migrating Motor Complex (MMC). The sequence begins, on the left, with phase II, irregular activity, is followed by phase III a period of uninterrupted phasic activity which migrates along the intestine and finishes with phase I, motor quiescence. (**b**) Recording from a patient with a visceral myopathy, at a similar moment in an MMC cycle as in (**a**); in this instance, however, the amplitude of individual contractions in the antrum (top two channels) and the duodenum (bottom four channels) is markedly reduced through the organization of motor events is preserved. (**c**) Recording from a patient with a visceral neuropathy, again taken at a similar moment in the MMC cycle. The tracing features intense but apparently uncoordinated motor activity. In this example the phase III seen in the middle of the trace appears bi-directional in propagation and is not followed by the expected quiescence of phase I; the tracing also contains a phase III-like burst during what should be phase II and repeated bursts of intense contractile activity

The digital encoding of pressure data simplifies the analysis of continuous 24-h recordings by computer software [96, 97]. This technique has proved useful in several conditions [98, 99] including pseudo-obstruction. During nocturnal sleep normal stereotypic MMC activity is clearly evident [100] and in some patients with pseudo-obstruction the abnormal contractile activity of the small bowel results in distortion of the fasting MMC pattern. Manometry of patients with pseudo-obstruction can be difficult in the later stages of disease because the peristaltic activity required to propel a manometry catheter into position in the proximal jejunum is lacking, and endoscopic assistance may be needed. A patient with a neuropathy may have a normal diameter gut but it may be hyperactive with many uncoordinated and often strong contractions (bursts) [89].

The effect of any drugs the patient may be taking must be taken into account in interpreting any results (for example opioids, anticholinergics and cyclizine). Manometry does not always produce results that are clinically helpful [89].

Pathology and Histology

The biochemical testsrecommended are listed in Table 3. Adequate biopsy material is not often available and few laboratories have an experienced gastrointestinal neuropathologist. There also remain some additional pitfalls for collecting and analysing samples including sampling error, effects of

bowel handling, sparsity of normal data and specificity. Good histological samples are needed to make a firm diagnosis. Close liaison between surgeon and pathology laboratory is crucial so that a full thickness specimen of bowel is immediately processed. The samples should be divided; in an ideal situation some is snap-frozen in liquid nitrogen, and the main portion fixed for routine histology and electron microscopy, in practice the latter two may be the best option. The immediate processing of samples is important if a detailed examination of the nerves, ganglia and muscle tissue is to be carried out. Diagnosis of a neuropathy may be difficult in conventionally oriented and stained sections of gut, and whole mount plexus assessment is a research tool. The most important element is to ensure that enough sections and material is examined, in a centre with experience of dysmotility.

A full thickness jejunal biopsy is usually taken laparoscopically and is often helpful diagnostically but the procedure in centres without much experience can be unhelpful and have a significant risk. Published data from centres with expertise suggest a median operating time of 50 min, conversion rate to open operation 2% and length of stay 1 day with an 8% readmission rate for obstructive symptoms [101]. In myopathies the diagnosis may be established. A neuropathy in general shows either degenerative changes or inflammation.

All full thickness biopsies should be stained with Congo red stains to look for the presence of amyloid. As full thickness jejunal biopsies may not change the clinical management and are associated with risks, they are often performed when a laparotomy does not find an organic cause of obstruction or when the patient happens to be undergoing surgery for another reason (e.g. a jejunal tube placement) [102].

MNGIE can be diagnosed with a skeletal muscle biopsy in addition to the blood and genetic testing.

Treatments

The drug treatments for intestinal dysmotility are shown in Table 4. Most of the drugs are commonly used to treat milder forms of the symptoms. Treatment is occasionally directed at the underlying condition but more often is targeted at a specific symptom.

Underlying Condition

An underlying disease may need to be treated (e.g. connective tissue disorder, enteric myositis, neoplastic disease or myotonic dystrophy). Diabetic control should be very good and may necessitate an insulin pump. Electrolyte, mineral or endocrine abnormalities should be prevented and treated when detected.

Immunosuppressive treatment has a small evidence base restricted to case series or reports. Prednisolone and cyclosporin have been reported to be of particular benefit in autoimmune myopathy [103]. There is a case report of an improvement with initially prednisolone 1 mg/kg and azathioprine 2 mg/kg/day then subsequently the prednisolone was replaced with budesonide 9 mg/day [50].

Table 4 Drug therapies for intestinal dysmotility

Laxatives (after adequate fluid in diet)	
Osmotic	Macrogols (PEG), lactulose, magnesium salts
Stimulant	Anthraquinone group (senna and dantron), bisacodyl, sodium picosulfate, docusate sodium, phosphate enema, glycerol suppository parasympathomimetics—bethanechol, neostigmine, pyridostigmine $5HT_4$ receptor agonists—prucalopride
Bulk forming	Unprocessed wheat bran, methylcellulose, ispaghula, and sterculia
Faecal softeners/ lubricants	Liquid paraffin, arachis oil (ground-nut oil, peanut oil) enemas
Peripheral opioid-receptor antagonists	Methylnaltrexone, naldemidine
Secretagoges	Linaclotide, tenapanor[a]
Antispasmodics	
Antimuscarinics	Tertiary amine—dicycloverine hydrochloride
	Quaternary ammonium compounds—propantheline bromide, hyoscine butylbromide
Direct smooth muscle relaxant	Alverine, mebeverine, and peppermint oil
Prokinetics	
Dopamine receptor 2 antagonists	Metoclopramide, domperidone
Macrolides	Erythromycin
Antidiarrhoeal drugs	Loperamide, codeine phosphate, diphenoxylate
Anti-emetics	D_2 receptor antagonists (see above)
	Cyclizine, ondansetron, romosetron[a]
Analgesics	Tricyclic antidepressant (low dose)—amitriptyline
	Selective serotonin reuptake inhibitor
	SNRI (duloxetine)
	Gabapentin
	Pregabalin
	Antispasmodic drugs
	Opioids (low dose)
Antibiotics for bacterial overgrowth	Amoxycillin-claevulinic acid
	Ciprofloxacin
	Metronidazole, tinidazole
	Cephalosporin
	Tetracycline, doxycycline
	Non-absorbable antibiotics—rifaxamin, neomycin

[a]Not licensed in the UK

There must always be awareness that organic obstruction can be missed as a diagnosis and if a prokinetic drug [104] makes pain worse then an organic obstruction must be considered. Similarly, a successful trial of a low fibre or liquid diet suggests an organic obstruction.

Some metabolic storage disorders can be treated with specific enzyme-replacement therapy [59].

Specific Drug Treatments of Symptoms

No treatment is ideal and even though some help to correct physiological abnormalities, they may not affect the patient's symptoms. Drug therapy [105] can be difficult and often drugs with conflicting actions are used (prokinetic for constipation and anticholinergic for colicky pain). Essentially the drug therapy is targeted at the symptom perceived as most important by the patient (Table 4).

Prokinetic treatments are used to try and improve the dysmotility itself and can return some of the measured abnormalities towards normal. They may especially help with vomiting and constipation. Prokinetic drugs are generally not used after a bowel anastomosis. Some of the previously used prokinetic drugs have been withdrawn or can only be used with extreme caution. They include domperidone and metoclopramide (D_2 dopamine receptors antagonists) which stimulate gastric emptying and small intestinal transit, and enhance the strength of oesophageal sphincter contraction. Metoclopramide also increases the release of acetylcholine from some enteric nerves. Domperidone is a selective antagonist of peripheral D_2 dopamine receptors, which does not have the acetyl-choline like effect of metoclopramide. *National Patient Safety Agency* (NPSA) alerts have been issued for Domperidone that highlighted problems with prolonged QTc therefore long-term use should be subject to QTc monitoring. The extra-pyramidal side-effects of metoclopramide (especially in children) and the potentially irreversible tardive dyskinesia in the elderly, together with no evidence of consistent benefit in gastroparesis, caused the European Medicines Agency's Committee to recommend that metoclopramide is not used in the long-term [106]. Cisapride, a 5-HT_4 agonist, enhances acetylcholine release in the myenteric plexus without having anti-dopaminergic effects and may have been of particular benefit if MMCs were present on small intestinal manometry. In a 6 week double-blind, placebo-controlled trial in 26 patients, cisapride helped abdominal pain, improved solid gastric emptying and the MMC [104]. Unfortunately, due to an increased risk of fatal cardiac arrhythmias (probably relating to a prolonged QT interval) in patients taking other medications or suffering from underlying conditions known to increase the risk of cardiac arrhythmias, cisapride was withdrawn. Tegaserod, a 5-HT_4 receptor partial agonist, increased stool frequency in IBS [107, 108] and improved the symptoms in functional dyspepsia [109] but was withdrawn due to an increased risk of heart attacks or strokes.

Prucalopride, a high affinity selective $5HT_4$ receptor agonist has been used for constipation and appears not to have the cardiac risks of cisapride or tegaserod as it does not affect the QT interval. This is by having no significant action on the 5-$HT_{1B/D}$ and on the cardiac human ether-a-go-go K+ channels [110].

Erythromycin, a motilin agonist, is potentially useful [111] if there are absent or impaired antroduodenal migrating complexes but is subject to tachyphylaxis. Doses of 900 mg/day have been recommended [112]. Azithromycin may be more effective for small bowel dysmotility [113].

A somatostatin analogue (octreotide), is given by a relatively painful subcutaneous injection, may be dramatically beneficial, especially in systemic sclerosis when other treatments have failed [114–116]. It can improve vomiting and pain, partly because octreotide (in normal subjects) reduces the perception of volume distension due to inhibition of sensory afferent pathways [114]. Octreotide may cause low amplitude MMC's to return [116]. Octreotide may have a beneficial effect when erythromycin has been unsuccessful; its effect (50–100 μg once or twice a day) is apparent within 48 h and lasts for more than 2 years. It may be more effective when combined with erythromycin [117].

The parasympathomimetics bethanechol, distigmine, neostigmine, and pyridostigmine enhance parasympathetic activity in the gut and increase intestinal motility. They are rarely used because of both their gastro-intestinal and cardiovascular side effects (diarrhoea and severe bradycardia). Pyridostigmine has however been shown to help refractory constipation (including in diabetes) and was well tolerated using a stepped dosing regimen [118, 119].

Naloxone 1.6 mg given subcutaneously each day, or methylnaltrexone subcutaneously alternate days may be beneficial in blocking dysmotility effects of opioids or in improving motility through blocking endogenous opioids [120].

Constipation

Constipation may be a problem in early stages, but is rarely present when IF occurs. In the early stages of these diseases' constipation may be managed by diet ensuring that it includes an adequate intake of fibre and fluid. Bulk forming laxatives such as unprocessed wheat bran (or oat bran), taken with food or fruit juice are effective and methylcellulose (which is also a faecal softener), ispaghula, and sterculia are useful in patients who cannot tolerate bran.

Osmotic laxatives [macrogols (polyethylene glycol), lactulose, or magnesium salts] increase the amount of water in the large bowel, either by drawing fluid from the body into the bowel or by retaining the fluid that was adminis-

tered. Macrogols are inert polymers of ethylene glycol (PEG) which sequester fluid in the bowel. Lactulose is a semi-synthetic disaccharide, which is not absorbed from the gastro-intestinal tract. It produces osmotic diarrhoea of low pH and prevents the proliferation of ammonia-producing organisms. Magnesium salts are useful where rapid bowel evacuation is required. Sodium salts should be avoided as they may give rise to sodium and water retention.

If there is an inadequate response to an osmotic laxative, a *stimulant laxative* can be added. Stimulant laxatives increase intestinal motility and often cause abdominal cramp; they should be avoided in intestinal obstruction. Excessive use of stimulant laxatives can cause diarrhoea and hypokalaemia. The anthraquinone laxatives (senna, dantron, cascara) are converted in the intestine to active sennosides, which may function by stimulating the myenteric plexus in the colon and by inhibiting colonic water absorption. Their principal effect is in the descending and sigmoid colon. Their effect is largely local and depends upon sufficient intestinal motility to present them to the colon for bacterial degradation to their active form. Sennosides, with prolonged use, had been thought to damage the intestine muscle and or myenteric neurons but there is no clinical or animal evidence to support this [121, 122]. Poorly absorbed diphenylmethane derivatives (bisacodyl, phenolphthalein, sodium picosulfate) stimulate sensory nerves in the proximal colon and increase sodium and water movement into the colonic lumen. Castor oil can have a place with its principal effect on small bowel fluid secretion. Docusate sodium probably acts both as a stimulant and as a softening agent.

Dantron, cascara and castor oil are rarely used, dantron because of potential carcinogenicity.

$5HT_4$ receptor agonists (Prucalopride) are selective serotonin $5HT_4$ receptor agonists with prokinetic properties. Prucalopride is licensed for the treatment of chronic constipation, when other laxatives have failed to provide an adequate response. Headache and gastro-intestinal symptoms (including abdominal pain, nausea, and diarrhoea) are the most frequent but rare side-effects. The side-effects generally occur at the start of treatment and are usually transient. It has the potential to be a useful prokinetic drug now that cicapride and tegaserod have largely been withdrawn. Linaclotide (a 14-amino acid peptide) which acts in the intestinal lumen on guanylate cyclase-C (GC-C) so generating cyclic guanosine monophosphate (cGMP), which stimulates chloride secretion, resulting in increased luminal fluid secretion and an acceleration of intestinal transit. It also may have some visceral analgesic activity.

Methylnaltrexone is a peripherally acting mu-opioid-receptor antagonist that is licensed for the treatment of opioid-induced constipation in patients receiving palliative care, when response to other laxatives is inadequate; it should be used as an adjunct to existing laxative therapy. Methylnaltrexone does not alter the central analgesic effect of opioids. Naloxegol and naldemidine are oral agents and have the same properties.

Faecal softeners (Liquid paraffin), the traditional lubricant, has potential disadvantages of minimal efficacy (hence usually used in combination with other agents) and safety issues (aspiration of paraffin or, perianal burning). Bulk laxatives and non-ionic surfactant 'wetting' agents (docusate sodium) also have softening properties. Enemas containing arachis oil (ground-nut oil, peanut oil) lubricate and soften impacted faeces and promote a bowel movement. Dioctyl sulfosuccinate, an anionic detergent, can be used to break down hard stools.

Stimulant suppositories (glycerol) or enemas (phosphate) may also be effective though are often less acceptable to the patient. Glycerol suppositories act as a rectal stimulant by virtue of the mildly irritant action of glycerol. Constipation may need regular enemas initially using low volume phosphate preparations progressing to high volume saline washouts or trans-anal irrigation systems.

Treatment of faecal impaction may need a manual evacuation under anaesthetic if disimpaction does not occur after oral and rectal treatment, or if there is a megarectum. The outcome of colectomy +/− ileorectal anastomosis is poor for these patients and best avoided. Sometimes a defunctioning loop ileostomy, which is reversible, may be performed before considering a total colectomy.

Pain

Pain is often poorly correlated with motor events (chapter "Chronic Abdominal Pain"). A simple measure such as reducing fibre in the diet can reduce abdominal distension by reducing bacterial fermentation and the production of gases. Low FODMAP diets may also have a role but are restrictive in nature and should not be used in an already malnourished individual. Peppermint oil may also help.

Anti-muscarinics that are used for gastro-intestinal smooth muscle spasm include the tertiary amine dicycloverine hydrochloride and the quaternary ammonium compounds propantheline bromide and hyoscine butylbromide. The quaternary ammonium compounds are less lipid soluble than atropine and are less likely to cross the blood–brain barrier; they are also less well absorbed from the gastro-intestinal tract. Dicycloverine hydrochloride has a much less marked anti-muscarinic action than atropine and may also have some direct action on smooth muscle. Hyoscine butylbromide is advocated as a gastro-intestinal antispasmodic and is commonly tried, but it is poorly absorbed, therefore intramuscular preparations may be more effective and can be used in the long-term at home [123].

Direct relaxants of intestinal smooth muscle (alverine citrate, mebeverine, and peppermint oil) that may relieve

pain in irritable bowel syndrome are commonly tried and have no serious adverse effects.

Persistent abdominal pain may be a major problem and its mechanism may include central nervous system sensitisation making it very difficult to treat. Features of neuropathic pain should be sought and managed with neuropathic agents. Opioid induced hyperalgesia as part of the narcotic bowel syndrome can also develop and needs appropriate management by opioid reduction and withdrawal. If other analgesics prove ineffective opioids and their derivatives may be cautiously tried though they themselves have pro-absorptive/antisecretory effects and cause slowing of intestinal transit. Some opioids, such as tapentadol, may have a better dysmotility side effect profile. Targinact® (oxycodone and naloxone combined) is marketed as a way of giving analgesia without causing constipation. A small amount of naloxone crosses the blood brain barrier to block the dependence action of oxycodone though when first used may precipitate some withdrawal symptoms from the previous opioid like drug. Naloxegol is a PEGylated naloxone formulation not combined with opioid and therefore should not cross the blood-brain barrier, owing to the PEGylation, to minimise withdrawal side effects.

Oral liquid preparations may be used but sublingual or transdermal buprenorphine or fentanyl has the advantage of bypassing the abnormal gut function. It may be of value to give a patient a "pain holiday" in hospital during which sedation and continuous subcutaneous opiates, or even epidural anaesthesia, may reduce the pain threshold so allowing a reduction in maintenance analgesic dosage. Escalation beyond a low dose of opioid is likely to be ineffective in managing chronic pain and is associated with unacceptable risks, including catheter related blood stream infections, and should be de-escalated or discontinued if the chronic pain persists, even if no other effective pain medication is available [124].

There is a growing appreciation for the role in abdominal pain management of the gut-brain neuromodulators, frequently used in neuropathic pain management [125]. These include a tricyclic agent which can be used at sub-antidepressant doses for abdominal pain or discomfort in patients who have not responded to laxatives, loperamide, or antispasmodics. Low doses of a tricyclic antidepressant are used (e.g. amitriptyline, initially 5–10 mg each night, increased if necessary in steps of 10 mg at intervals of at least 2 weeks to max. 30–50 mg each night). A selective serotonin reuptake inhibitor (SSRI) may be considered in those who do not respond to a tricyclic antidepressant but they are considered to be less effective analgesics than the serotonin-norepinephrine reuptake inhibitors (SNRIs), of which duloxetine is the first choice [126]. The role of gabapentin and pregabalin is well established for chronic neuropathic pain, and there is emerging evidence that the use of combination gut-brain neuromodulators from more than one class is more effective than monotherapy although gabapentin and pregabalin are classed as controlled drugs in some countries including the UK [125, 127]. SNRI and SSRI classes however should not be combined due to risks of serotonin syndrome.

Vomiting

Now that domperidone and metoclopramide are no longer used in the long-term and as cyclizine can cause psychological dependence and addictive behaviour [16], the 5-HT_3 antagonists like ondansetron are most commonly used but can result in constipation.

If a naso-gastric draining tube helps symptoms, then a venting gastrostomy (ideally over 20 *French gauge* (FG)) usually inserted endoscopically (though may also be done radiologically or surgically) may reduce vomiting by decompressing the stomach. The difficulty is having a large enough gastrostomy tube to allow all debris from the stomach to drain. Sometimes a tube can be inserted into the small bowel if very dilated to decompress it. These venting ostomies are often successful but are associated with many complications such as leakage and infection (often with candida) and generally need to be changed more regularly than a feeding ostomy.

Diarrhoea: Bacterial Overgrowth and Bile Salt Malabsorption

Antidiarrhoeal drugs such as loperamide, diphenoxylate, or rarely codeine phosphate are very occasionally used for symptomatic benefit. Opioids with a central action, such as codeine, are not the first choice because of the risk of dependence and sedation.

Steatorrhea may be secondary to an overgrowth of anaerobic bacteria in the motionless dilated loops of bowel.

As the disease progresses bacterial overgrowth can result in diarrhoea. This can be reduced with oral amoxycillin-claevulinic acid combination, metronidazole/tinidazole, cephalosporin, tetracycline (doxycycline), ciprofloxacin, cotrimoxazole, or non-absorbable antibiotics such as rifaximin or neomycin. Rifaxamin is often the first choice if it is on the local drug formulary. These may be used as necessary or in repeated courses every 2–6 weeks often rotating (sometimes with a 1–2 week period of no antibiotic) to another antibiotic for a similar period of time before repeating. If metronidazole is used in the long-term, the patient must be warned to stop if they develop numbness or tingling in their feet as an early sign of reversible peripheral neuropathy and be used at the lowest dose possible. Ciprofloxacin use longer term can cause tendonitis and rupture and again low dose and vigilance are required. The risk of resistant organisms, including *Clostridioides difficile*, should also be considered. There is no data currently about the use of probiotics.

Bacterial overgrowth is virtually inevitable and can cause cachexia without necessarily causing diarrhoea, thus antibiotics, as suggested above, may be needed.

Bile salt malabsorption may occur and respond, if tolerated, to bile salt sequestrants (cholestyramine and colesevelam). It is most likely if terminal ileum has been resected or if there are large areas of fluid filled dilated bowel.

Octreotide occasionally used for its effects in reducing secretions and slowing gastrointestinal motility, has also been used in refractory SIBO.

Bloating/Distension

Bloating and distension are common symptoms and not easy to treat. Reducing gas forming microbes (e.g. those producing CO_2, methane and hydrogen sulphide) with a low fibre diet or an antibiotic (rifaxamin), giving simethicone or peppermint oil or reducing visceral hypersensitivity (antidepressants) or constipation may help along with increasing physical exercise [126].

Neuromodulation (Pacemakers)

There is some limited evidence for Gastric electrical stimulation (gastric pacing) to improve vomiting symptoms where gastroparesis is prominent and small bowel function relatively intact [128–130]. Patients with diabetic gastroparesis respond best and in general responders tend to have more severe vomiting. Patients with idiopathic gastroparesis have a potentially higher rate of poor response to gastric electrical stimulation [131]. Non-invasive vagal nerve stimulation has shown some promise both for improving gastro-duodenal motility and reducing pain sensitivity [132].

The dorsal column pathways are involved in the transmission of visceral pelvic pain. Spinal cord stimulation suppresses the visceral response to colon distension in an animal model and therefore may be an effective therapy for chronic pelvic pain of visceral origin. There has been success reported in one study of 35 patients in whom the catheter tip was situated at T5 position for a median of 9 days (range 4–14) [133], the Cochrane database concludes that more studies are needed [134].

Sacral nerve stimulation (SNS) uses electrical stimulation applied to the sacral nerves, eliciting a physiological effect on the lower bowel, anal sphincter and pelvic floor and has shown some success in treating faecal incontinence and constipation [135–137]. A Cochrane review concluded that from three studies there was "very limited evidence that sacral nerve stimulation can improve continence in selected people with faecal incontinence, and reduce symptoms in selected people with constipation" and larger "good quality randomised crossover trials are needed" [138]. There is no evidence that SNS helps any of the symptoms in patients with chronic intestinal pseudo-obstruction.

Small intestinal electrical stimulation is at an experimental stage.

Nutritional Support

Nutritional assessment and support is an important aspect of management. With appropriate therapy, many patients with chronic intestinal pseudo-obstruction manage to maintain their nutritional status through the oral/enteral route, without the need for parenteral support.

Dietary Adjustments/Fluid Management

Gastric motility may be far less deranged for liquids than for solids with the result that many patients tolerate liquid feeds better than solid meals. Sometimes frequent small meals with a low-fat, low-fibre and liquid nutritional supplements may be helpful.

If the patient has a stoma and a short bowel, fluid restriction, a sipped glucose saline solution, use of loperamide sometimes in high dose (occasionally with the addition of codeine phosphate) will reduce the risks of dehydration, sodium and magnesium depletion. If a high net secretory output occurs, a proton pump inhibitor (or occasionally octreotide) may be needed [139].

Post-feeding orthostatic symptoms in partial autonomic failure may respond to dietary adjustments and drugs such as fludrocortisone, midodrine and octreotide.

Vitamin/Mineral Deficiencies

Care is needed to ensure that micronutrient deficiencies particularly of iron, vitamin B_{12} and the fat-soluble vitamins, especially vitamin A, D and E, do not occur. Magnesium deficiency is common especially if a high output stoma. Magnesium oxide may cause less osmotic effects than other preparations but is expensive.

Bone mineral density is important to address and should be assessed with dual energy X-ray absorptiometry (DEXA) scanning in those with malnutrition. For patients who cannot take oral measures to improve bone density then parenteral bisphosphonates such as zoledronate should be considered.

Enteral Nutrition

Enteral nutrition is preferred if the gut is accessible and absorbing. In carefully selected patients, feeding jejunostomy with or without decompression (venting) gastrostomy may be tried. A percutaneous endoscopic or radiological gastro-jejunostomy is preferred to a direct jeunostomy where possible as direct jejunostomy tubes are more subject to leakage, retention, pain and skin problems and the gastro-

jejunostomies can achieve both post-pyloric feeding and venting with generally easier endoscopic placement whereas direct jejunal tubes will often need to placed surgically. Invasive enteral tube insertion should be preceded where possible by a trial of naso-enteral tube feeding to ensure absorption and tolerance prior to running the risks of mortality and morbidity associated with invasive tube placement.

If liquid enteral feeds are given, any excess can be aspirated by enteric tube or gastrostomy before the start of the next meal to ensure that excess volumes do not accumulate in the stomach. Gastrostomies can be used, therefore, to aspirate liquid gastric contents (decompression of venting gastrostomy) as well as a conduit for feeding, particularly when there is a need to bypass a malfunctioning oesophagus and or stomach. Pulmonary aspiration of large volume vomits is a very serious complication that may be difficult to prevent. A low antral site for gastro-jejunal tube placement is preferred to optimise drainage/venting and stability of the jejunal extension.

Parenteral Support

Long term parenteral support (PS) should be reserved for patients with significant malnutrition or electrolyte disturbance who cannot tolerate enteral nutrition. Complications associated with total PS include infections, sepsis, and cholestatic hepatic dysfunction.

If safe nutritional status cannot be maintained through the oral and enteral route, then home parenteral support (HPS) may be required. These patients, when receiving HPS, have more problems than do patients with a short bowel [102]. They particularly have a higher incidence of catheter-related blood stream infection (CRBSI), septicaemia and venous thrombosis. The reasons for this are not entirely clear. Procoagulation states sometimes exist, and it is possible that there is increased bacterial translocation from the gut. Opioid medication (which at high doses suppresses some aspects of immune function) and/or cyclizine increase the risk of CRBSI partly as the care taken by the patient in the management of their infusions at home [140], due to cognitive effects, is reduced. The use of feeding lines to administer any drug is to be strongly discouraged because of the risk of catheter infection. Such patients test the capabilities of the best-organized nutrition teams to the full and should be managed in centres with a large experience [141]. Vigilance for psychopathology and ongoing involvement of psychology and liaison psychiatry should be offered. There may be a benefit from the mutual support patients can give to each other in these situations, although patients with significant psychopathology can have a detrimental effect on others.

Howard et al. [142] have emphasized that clinical outcome on home parenteral feeding, like mortality risk, is to a large extent a reflection of the underlying condition. While about 70% of patients with Crohn's disease or ischaemic bowel conditions are fully rehabilitated after the first year on HPN, only a third of those with chronic intestinal dysmotility are similarly rehabilitated and it is most likely if the gut is not dilated [98]. Weaning from HPN is less likely when the diagnosis is idiopathic dysmotility [95, 102] and when the post-absorptive plasma citrulline is lower than 20 mmol/L [143] Impairment of strength and of wellbeing as a result of undernutrition and fluid and electrolyte imbalance will be corrected by HPN but if the patient continues to experience vomiting, diarrhoea or abdominal pain from the underlying condition quality of life will remain suboptimal. The annual risk of catheter-related sepsis among HPN patients is consistently around 0.5 per 1000 catheter days but tend to be higher among those with chronic pseudo-obstruction especially if they remain on opioid analgesia [102, 144]; by contrast, patients with systemic sclerosis who may tend to have lower opioid requirements, have lower catheter infection rates [145].

Over half those with pseudo-obstruction receiving HPN will be alive at 10 years [146].

Surgical Options

Surgery is to be avoided in this group of patients who are at high risk of iatrogenic injury; however judicious palliative surgical intervention [resection, bypass (Fig. 6) or stoma formation] can improve symptoms and quality of life [147, 148]. If constipation is difficult to manage and high-volume saline washouts are needed then colectomy with ileorectal anastomosis or ileostomy may be necessary but diarrhoea or continuing episodes of obstruction may remain a problem. Adhesiolysis in the absence of a clear focal obstruction carries a high risk of severe complications and morbidity with ultimately more adhesion recurrence and worsening pain. Often urology input is needed to help with neuromuscular disorders of the urinary tract (dilated ureters and bladder) and may need to insert stents and/or a supra-pubic catheter. Especially in women there may be fertility problems due to dilated non-functioning fallopian tubes. Often the pains experienced result in gynaecological referrals.

Bypass Surgery and Enteric Resections

There are several reports of surgery in adults to help patients with pseudo-obstruction though the clear separation into those with a myopathy and those with a neuropathy is not always made [89, 147]. After diagnostic laparotomy, bypass operations (gastroenterostomy, duodeno-jejunostomy and jejuno-enterostomy) can be performed in adults to reduce vomiting if there is dilated gut. If gastric surgery is being performed, a vagotomy must be avoided, as this will further retard gastrointestinal transit. Many have an ileostomy [54, 89] often to treat constipation and some develop a short

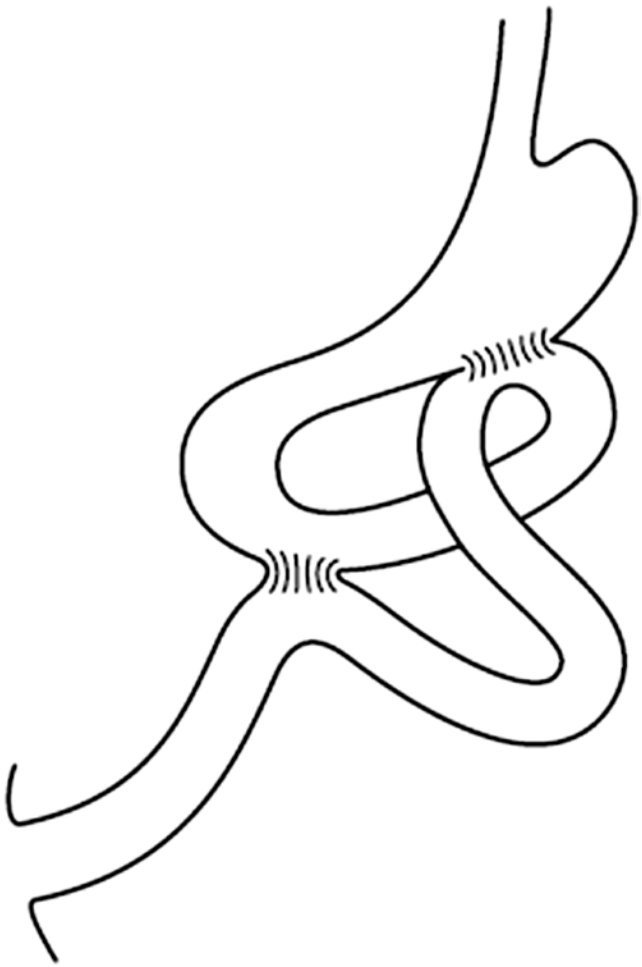

Fig. 6 Drainage procedures (gastro-jejunostomy, duodenojejunostomy, and ileostomy) occasionally performed in patients with visceral myopathy (after P. Hawley, St Mark's Hospital, London)

bowel from multiple resections. The reports of success are variable and any undertaking of surgery needs to be a multidisciplinary decision and based upon each individual patient. Outcome is poorer in patients with evidence of small bowel dysmotility who undergo colectomy.

Small Intestinal Transplantation

Dysmotility is a rare indication for intestinal transplant in adults with dysmotility needing HPN but since the outcomes of HPN are currently better, transplantation should be reserved for those who develop complications related to PN including IF associated liver disease, central vein thrombosis with reduced venous access, and recurrent catheter-related blood stream infections [139, 148, 149]. If other organs are damaged a multivisceral transplantation may be considered. The role of small bowel transplantation solely to improve quality of life by ceasing PN is somewhat contentious, but as worldwide experience of transplantation increases with corresponding improvements in survival rates, the indications for transplantation may broaden in the future. It is vital that all patients considered for transplantation are reviewed by an experienced multidisciplinary team with expertise in IF, and a transplant centre [150]. Pain is not an indication for a transplant.

Psychosocial Treatments

Psychological support from nurses, physicians, and psychologists is important. Vigilance needs to be maintained for the presence of psychopathology even in patients with a strong suspicion of gastrointestinal neuromuscular disorder. In one case series, six patients diagnosed initially with IF had significant psychopathology requiring specialised psychiatric unit treatment [23]. In addition to psychological distress including anxiety and depression; other psychological problems encountered can include somatisation disorder, personality disorders, substance misuse and disordered eating. Dysmotility disorders can also be associated with a risk of self-harm including suicide. Clinical psychology and liaison psychiatry provide overlapping but complimentary approaches and ideally a multi-disciplinary team involving both specialties should be available.

Outcomes

Outcome can vary from minor symptoms consistent with irritable bowel syndrome to problems resulting in home parenteral feeding, opioid analgesics and frequent hospital admissions. Causes of death in these patients include pulmonary aspiration, pulmonary embolism, cardiac failure and suicide. Cardiac failure may be the terminal event in hollow visceral myopathy. The relationship between "megaduodenum" and upper gastrointestinal tract cancer seems tenuous if it exists. Death will often be related to the underlying condition—obviously so in the case of pseudo-obstruction occurring as a paraneoplastic phenomenon, and also particularly in the degenerative neuropathies, collagen vascular disorders and infiltrative conditions such as amyloid. Amiot et al. reported 51 patients with CIPO who required HPN, representing 26-years of experience and found that surgery was required in 84% of patients and survival probability was 94%, 78%, 75% and 68% at 1, 5, 10 and 15 years respectively [54]. Higher mortality was associated with systemic sclerosis. 20-year experience of HPN from the Mayo clinic found that the survival for motility patients was second worse only to cancer, due to the progression of the underlying disease, which was similar in data from United Kingdom St Mark's hospital. Recently published data from the Salford IF Unit have demonstrated worse outcomes for patients with a CIPO than non-CIPO dysmotility phenotype [140]. However,

it would appear that there is room for improved outcomes in this challenging patient population by cost-effective investment in tertiary multi-disciplinary provision.

Conclusions

Most cases of intestinal dysmotility will be without a clear diagnosis and thus labelled as idiopathic. Addressing the patient's primary symptoms and treating malnutrition are the keys to management.

Pelvic Radiation Disease and the Gastrointestinal Tract

Darren Fernandes and Jervoise Andreyev

Key Points

1. Radiotherapy to a pelvic tumour causes a spectrum of disorders within and outside the GI tract which should be considered a progressive condition with a defined pathology which has recently been termed pelvic radiation disease (PRD)
2. Simple "trigger" questions can be used to alert any clinician to the fact that significant PRD may be occurring and the patient needs specialist help
3. Large numbers of survivors of cancer suffer from PRD which is often not acknowledged or recognised by health care workers
4. Following published checklists and treatment algorithms are efficient and inexpensive at ameliorating the GI symptoms of PRD and much more effective than relying on "clinical intuition" or experience
5. The underlying ischaemia and fibrosis which develops in the tissues exposed to radiotherapy means that endoscopic and surgical approaches which work in inflammatory or malignant tissues are potentially hazardous in patients with PRD
6. The progressive ischaemic and fibrotic pathological changes which are the basis for PRD offer opportunities to halt or reverse the changes of radiotherapy and clinical trials to assess the effectiveness of many agents which might do this are a priority
7. Identifying an objective biomarker of progressive radiation change is a key step in radiation research

Why Patients Develop Symptoms

Most patients starting pelvic radiotherapy will have normal gastrointestinal function apart from possible local tumour effects. During radiotherapy, normal tissues that surround the tumour will be exposed to some radiation. The rectum and sigmoid are in close physical proximity to the area being treated and are at particular risk. The caecum is relatively immobile and may too receive a significant dose. The transverse colon and small bowel frequently loop down into the pelvis, putting them at risk, so too is the proximal small bowel and pancreas especially when para-aortic nodes are irradiated [1]. The presence of abdominal adhesions may increase the risk to normally mobile bowel loops. Other factors related to the risk of toxicity are outlined in Table 1.

Almost all data on development of radiation injury at a molecular level are derived from animal models. However, animal models represent poorly what happens in humans for many reasons limiting clinical relevance of the results. Indeed, adequate animal models for many aspects of late radiation enteropathy have not yet been developed.

It was once thought that the radiation dose was entirely responsible for the damage that may develop but increasingly, patient related factors are understood to be important. The gastrointestinal immune system, the enteric nervous system and the intestinal microvasculature play key roles in

Table 1 Factors significantly associated with the development of Radiation Pelvic Disease

Therapy-related factors
Radiation dose
Volume of bowel irradiated
Time-dose-fractionation parameters
Concomitant chemotherapy or biological therapy
Patient-related factors
Diabetes mellitus
Tobacco smoking
HIV disease
Inflammatory bowel disease
Collagen vascular disease
Previous pelvic or abdominal surgery
Pelvic inflammatory disease
Low BMI
Colonic microbiota
Genetic polymorphisms

the development of radiation enteropathy [2]. Emerging data increasingly suggest that the 100 trillion bacteria in the gut lumen, tenfold the number of cells in the human body, are also crucial determinants of radiation enteropathy severity [3].

In the past, radiation injury was classified as "early" or "late" depending on the timing of its clinical expression that was founded on two different, but not mutually exclusive, mechanistic models of injury—the "target cell" and "vascular injury" models [4].

However, the recognition that delayed radiation injury might develop clinically in the wake of severe acute injury was recognised by Bourne et al. [5] and Peters et al. [6] who subsequently coined the term "consequential late effects". In 2001, in a very important paper, a new terminology for classifying healthy tissue radiation responses was described [4]. In this paper, Denham and Hauer-Jensen classified lesions producing radiation injury into three interacting categories: cytocidal effects, indirect effects and functional effects.

Cytocidal effects relate to the phenomena characterised by the "target cell" model, where rapidly proliferating cells give rise to early pathology and more slowly proliferating target cells show delayed effects [7]. Hence, the time between irradiation and manifestation of injury depends on target cell characteristics (radiation sensitivity, repair capacity, proliferation rate, etc.) and tissue organisation. In rapid renewal tissues, such as the gastrointestinal epithelium, injury manifests itself clinically within days of first radiation exposure, when cells in the "differentiated" cellular compartment are no longer replaced by cells from the progenitor compartments. These tissues have been dubbed "early-reacting tissues". Cellular turn over, however, is much slower in connective tissues and organs that are composed of cells capable of re-entering the cell cycle. Radiation injury may therefore be expressed months or even years after exposure if cell death occurs when cellular division is attempted, and these tissues are said to be "late reacting" [4].

"Indirect" effects are reactive phenomena that occur in response to radiation-induced injury in other cells or tissues, and include phenomena such as parenchymal cell depletion secondary to vascular damage, the "bystander" effect and tissue reactions to vasoactive, procoagulant, and inflammatory mediators, including cytokines, growth factors and chemokines [4].

"Functional" effects from non-lethal effects on different intra- and extracellular molecules and changes in gene expression in irradiated cells lead, for example, to direct inactivation of anticoagulant molecules, activation of latent growth factors and activation of proteases. They include phenomena such as the inhibition of cellular replicative ability and accelerated senescence that lead to decreased tissue vitality [4].

Tissue injury after radiation therapy can therefore occur either quickly or after a prolonged period of time and these processes can clinically present as [8]:

1. Damage to specific neurological, enzyme based and muscular functions (and probably also local hormonal and immunological regulation) of the gastrointestinal tract
2. Acute inflammatory processes and chronic cytokine activation
3. Development of chronic ischaemia within the gastrointestinal wall, surrounding stroma and mesenteries
4. Progressive fibrosis within the gastrointestinal wall, surrounding stroma and mesenteries
5. Changes in preexisting conditions or the development of new conditions unrelated to radiotherapy, which also cause symptoms indistinguishable from those arising as a result of radiotherapy.

Epidemiology of Radiation Damage to Gut

Over 17,000 men and women are treated with pelvic radiotherapy in the UK annually and an estimated one million worldwide. While oncologists frequently report that 10–15% develop moderate or severe GI toxicity, patient focused research suggests that up to 50% depending on the site treated develop permanent gastrointestinal symptoms interfering with daily activity [9, 10]. It can be difficult to define exactly when symptoms start to affect quality of life and why some people seek help for specific gastrointestinal symptoms when others do not. Prospective studies using comprehensive, validated methodology concentrating on bowel toxicity with adequate follow-up are very few. It is frequently claimed that modern techniques of radiotherapy for pelvic malignancy have substantially reduced acute toxicity but as yet there are few randomized controlled trial data to support this assertion and almost no long term high quality follow up data.

Examples of the weakness and variability in the reported data can be quickly exemplified by from a number of studies. In one prospective study in which about two-thirds of patients had prostate cancer and most of the rest had gynaecological cancer, 2-year follow-up was only available in 57%. Of these, only 12% reported bowel problems moderately affecting daily activity [11]**.** In the Swedish Rectal Cancer Trial which helped establish short course preoperative (5 × 5 Gy) radiotherapy as an important therapeutic modality, meaningful follow up data were obtained from 77% of the 92% of survivors followed for more than 5 years. This showed that 30% of the irradiated group had a significantly impaired social life because of bowel dysfunction, compared with 10% of the surgery-alone group [12]. In a third prospective

study, a small subset of surviving patients who had undergone adjuvant radiotherapy after surgery for rectal cancer were questioned and investigated in detail and compared with a small subgroup of patients randomised to surgery alone. Bowel frequency (80% vs 23%), loose or liquid stools (60% vs 23%), faecal incontinence (60% vs 8%) and the need to wear a pad more often (47% vs 0%) were all significantly more frequent in the radiotherapy patients [13]. A large recent study confirms the continuing adverse health related quality of life outcomes in patients with colorectal cancer, 16% of survivors without a stoma reported having no control of their bowels, with a further 17% reporting moderate problems. With regards to sexual matters, 15.9% of respondents reported experiencing severe difficulties with patients with rectal cancer reporting a higher percentage (25.1%) and 15.4% reported severe urinary problems [14].

What does seem clear from these and other patient-centred studies, of all the symptoms that can arise after pelvic radiotherapy, new bowel symptoms seem to have the greatest effect on quality of life [15]. Studies that have assessed 'symptoms causing moderate or severe distress' or whether their symptoms prevent them doing things on a regular basis in patients suggest that if radiotherapy was part of their treatment approximately half of all patients treated for rectal cancer, one-third of bladder and gynaecological patients and one in five of all patients treated for prostate cancer are left with significant gastrointestinal symptoms [16]. While the risk of bias in some of these studies from patients lost to follow up or because the studies are retrospective must be acknowledged, however, consistent data suggest that unrecognised toxicity causes a significant burden and is an important unmet need for large numbers of patients.

Is Bowel Morbidity Adequately Documented?

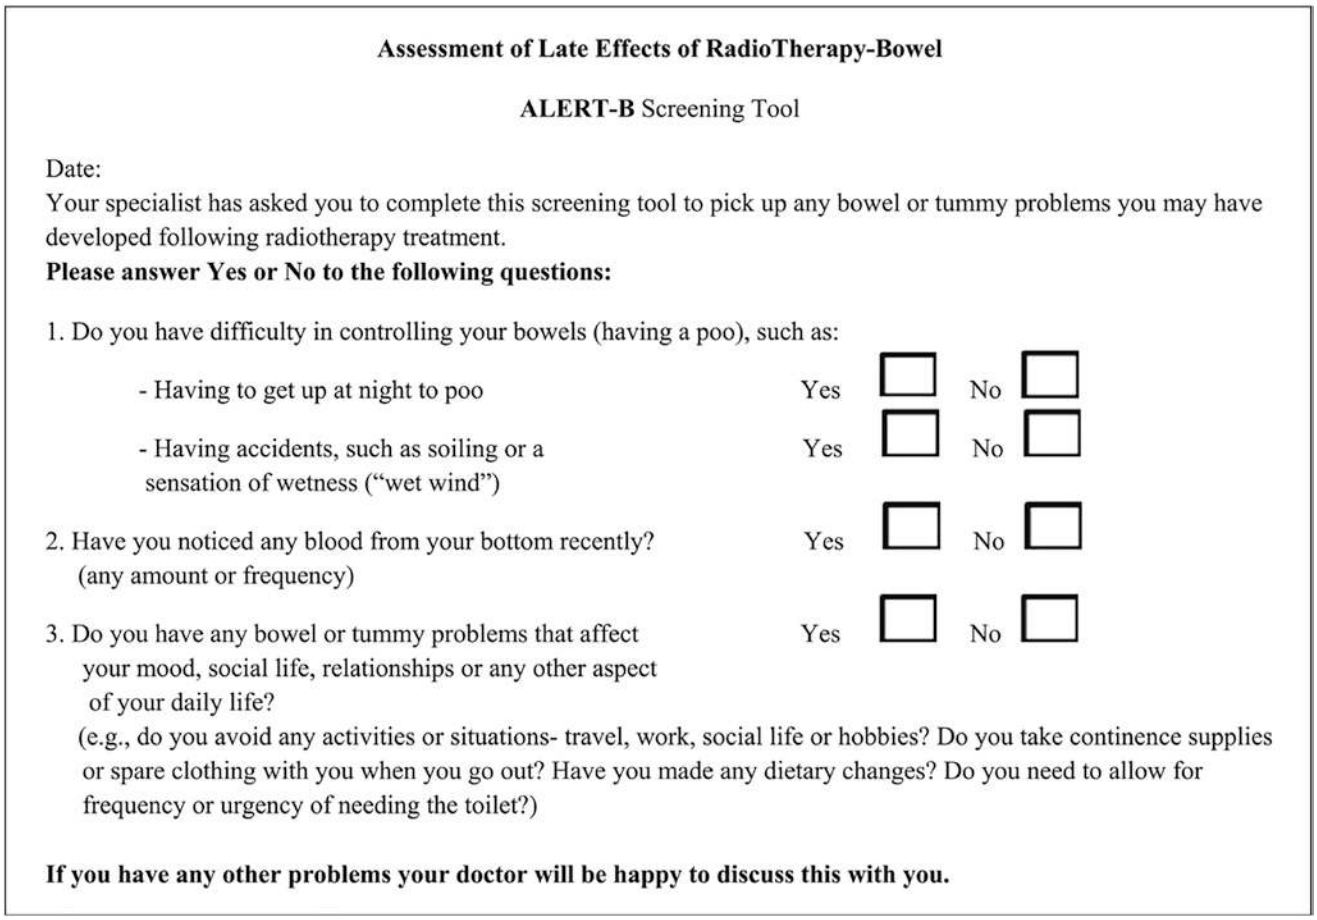
The frequent under-reporting of chronic bowel symptoms that occur after radiotherapy raises concerns as to the assessment and recognition of late effects in clinical practice and the potential value of "trigger" questions to identify those running into significant difficulty (see Fig. 1). Symptoms can occur months to years after radiotherapy and many clinicians from primary to tertiary care often fail to consider and are unfamiliar with the spectrum of late radiotherapy effects.

Simple "trigger" questions have been described in a paper endorsed by all GI professional bodies in the UK that any clinician could use to help identify patient in need of specialist help [17]. These have been validated in a subsequent study and the ALERT B can be a useful tool used in any patient waiting room (Fig. 1) [18]. However, a raised awareness of the potential problems that can be experienced by everyone who comes into contact with a patient previously treated for cancer is required if we are to make significant progress with helping patients with consequences of cancer therapy [19].

There are extensive data which tell us which symptoms impact patient's most [20]. Yet, when Chen et al. assessed rectal cancer specialists' understanding of which bowel dysfunction symptoms truly matter to patients after sphincter-preserving treatment, they found that there was considerable discrepancy between the specialist's perspective and patient experience. For example, specialists tended to overestimate the impact of incontinence for liquid stool and frequent bowel movements, while underestimating the impact of urgency and clustering [21].

The lack of incidence data may be as a consequence of lack of information how best to assess and define abnormal bowel problems and the somewhat subjective nature of chronic symptoms. A retrospective study by Tom et al. 2017 demonstrated this [22] when they examined and compared patient and clinician reports of acute gastrointestinal toxicity during chemoradiation therapy and found discrepancies in reported symptoms. Going forwards, there needs to be better measurement of toxicity not just within research but also in clinical practice during follow-up visits. Furthermore, which scoring systems and tools should be used to document and score the late effects of radiotherapy and how best to measure bowel effects objectively needs to be assessed.

The scoring systems that have been used include the Radiation Therapy Oncology Group (RTOG) score, Late Effects Normal Tissue-Subjective, Objective, Management (LENT-SOM) scales and Common Terminology Criteria for Adverse Events (CTCAE). However, these are not only insensitive measures of the patient experience and frequently underestimate the amount of toxicity suffered but also cannot explain clinical outcomes [23, 24]. We have routinely augmented our standard medical assessment with a modified Gastrointestinal Symptom Rating Scale that patients complete at each clinic visit, along with a Bristol Stool Chart [25]. This helps focus the consultation on all of the patient's GI issues. In addition, offering all new patients a holistic needs assessment questionnaire pays dividends. In addition to their GI problems, 80% of these patients report moderate or severe bother from fatigue, 45% from urinary problems, 36% from nutritional issues, 35% from sexual issues, 11% from emotional concerns and 2% from dermatological issues. So whilst the focus is on gastrointestinal and nutritional issues, these other areas cannot be ignored and require thoughtful management strategies [26] albeit often by a different specialist in a different service setting.



Assessment of Late Effects of RadioTherapy-Bowel

ALERT-B Screening Tool

Date:

Your specialist has asked you to complete this screening tool to pick up any bowel or tummy problems you may have developed following radiotherapy treatment.

Please answer Yes or No to the following questions:

1. Do you have difficulty in controlling your bowels (having a poo), such as:

- Having to get up at night to poo — Yes ☐ No ☐
- Having accidents, such as soiling or a sensation of wetness ("wet wind") — Yes ☐ No ☐

2. Have you noticed any blood from your bottom recently? (any amount or frequency) — Yes ☐ No ☐

3. Do you have any bowel or tummy problems that affect your mood, social life, relationships or any other aspect of your daily life? — Yes ☐ No ☐

(e.g., do you avoid any activities or situations- travel, work, social life or hobbies? Do you take continence supplies or spare clothing with you when you go out? Have you made any dietary changes? Do you need to allow for frequency or urgency of needing the toilet?)

If you have any other problems your doctor will be happy to discuss this with you.

Fig. 1 The ALERT-B questionnaire for screening for significant GI toxicity after previous pelvic irradiation [18]

Diagnosis and Management

Men presenting to a gastroenterology clinic after radiotherapy frequently have a median of 11 symptoms (range 1–16) while women have a median of 12 symptoms (range 4–16). Presenting with a cluster of "typical symptoms of radiation toxicity" has been shown to be highly unreliable at predicting the underlying cause. These clusters can be present before radiation and are aggravated by, or amplify, the inflammatory symptoms that occur during radiation as well as being related to the more permanent injuries that present after radiotherapy [27]. Furthermore, it is difficult even for experienced clinicians to predict how symptom clusters relate to bowel pathology. This was shown in a recent prospective study that assessed experienced clinicians' predictions of possible diagnoses for patients presenting with troublesome gastrointestinal symptoms compared to the actual diagnoses made following comprehensive investigation following a checklist. While 168 actual diagnoses were identified, only 92 were predicted and of those only 24% matched the diagnoses made. The majority of patients had multiple causes contributing to their symptoms and none of the participating clinicians predicted the correct combination of diagnoses [28] (Table 2).

Table 2 Clinicians prediction of commonly suspected causes of changes in gastrointestinal function following cancer based on clinical acumen have poor sensitivity and specificity [28]

Contributing GI pathology	Sensitivity (95% CI)	Specificity (95% CI)
Small intestinal bacterial overgrowth	67% (41–86%)	48% (29–67%)
Bile acid malabsorption	50% (21–79%)	86% (70–95%)
Pancreatic insufficiency	22% (3–60%)	87% (72–96%)

The lack of accuracy of empirical treatment without adequate investigation perhaps explains why so many of these patients continue to be highly symptomatic after gastroenterological intervention. An alternative approach, which has been shown in both randomised trials and in cohort studies to be highly effective, is to use a detailed checklist to investigate these patients and when the investigations are abnormal instigate treatment following a management algorithm sys-

tematically. Indeed, patients can be significantly helped and need only a median of six investigations and three clinic visits [8, 29–31] and this costs approximately £1563 [32]. The benefit of this approach has been confirmed by others [31]. The ORBIT trial also showed, in an era when there are huge numbers of affected patients, is that a nurse can be trained to manage the patients following checklists and algorithm and, with adequate gastroenterology support, can obtain outcomes similar to those obtained by a senior gastroenterologist in most cases. This algorithm is now freely available to clinicians [33].

Physiological Model of Symptoms

The real conceptual advance in the treatment of patients with complex GI symptoms however, comes from the understanding that the aetiology of GI symptoms depends not on pathological change, but rather depends on physiological change (Fig. 2).

It is this realisation that symptoms are caused not by pathological changes *per se*, but by 'changes in the normal physiology' of the GI tract, that has allowed the management of complex symptoms to be effective.

Initial Assessment

The first step towards diagnosing and formulating a management plan that will improve patients' symptoms is to take an accurate history. This needs to elicit:

- What was bowel function like before the cancer emerged?
- How have the symptoms changed over time?
- Are key features indicative of reversible underlying pathology present, for example:
  - Steatorrhoea
    - Is there an oily film in the lavatory water?
    - Is the stool ever pale/putty-like/foul smelling/difficult to flush/floating?
    - Has there been rapid weight loss?
  - Nocturnal waking to defaecate
  - Symptoms suggestive of recurrent cancer or a new primary?
- Is there a consistent impact of a specific component of diet on their symptoms, especially:
  - Fibre: how much are they eating—too much/too little?
  - Fat: does this promote type 6–7 stool/steatorrhoea?
  - Lactose-containing foods?
  - Gluten-containing foods?
  - Alcohol intake?
  - Caffeine intake
- Is there an association between the start of specific medication or increase in its dose and their symptoms—for example, metformin, proton pump inhibitor, α-blockers?
- What individual symptoms are present. We particularly favour the use of sensitive symptom questionnaires which patients can fill in before their clinic appointment and help everyone understand which issues are important [25]. Each symptom may have a different physiological cause and so understanding in detail which symptoms are present help us identify what tests need to be arranged.

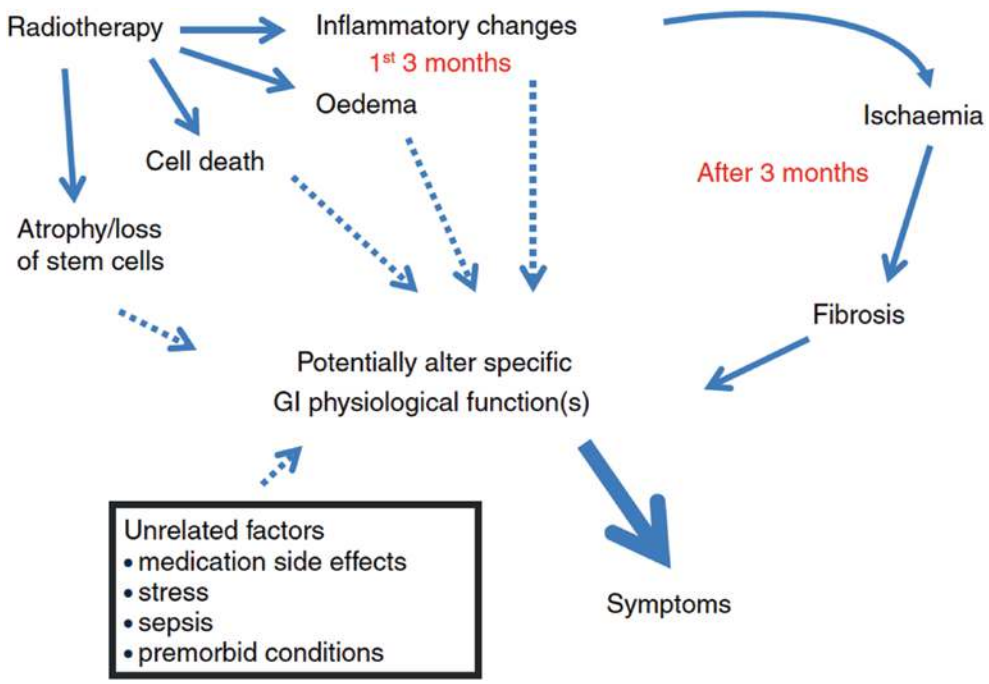


Fig. 2 Physiological model of symptom aetiology [34]

Loose Stool or Diarrhoea

This common symptom may be due to multiple causes. The frequency of these causes during and after radiotherapy as far as they have been reported is shown in Table 3 and then the more important causes are discussed in more detail below.

Small Bowel Bacterial Overgrowth

Radiotherapy has a direct effect on small bowel motility. This change in motility in turn predisposes to bacterial overgrowth and in some patients episodic pseudo-obstruction [16]**.** Small-bowel bacterial overgrowth occurs in 25% of patients [35] during the acute phase of radiotherapy. In the chronic setting, motility changes caused by radiotherapy are the main cause of such overgrowth [36]—particularly that of gram-negative bacilli, which in 4–45% patients may cause a wide variety of gastrointestinal symptoms [9, 36–38]. Three studies [9, 37, 38] suggest that in 8–15% of patients with diarrhoea, the diarrhoea is caused by bacterial overgrowth and improves after antibiotic treatment.

Reliable diagnosis of bacterial overgrowth is difficult and better diagnostic tests using modern molecular techniques are urgently required. Currently available diagnostic techniques include breath tests—breath tests which just look for expired hydrogen levels and do not measure methane will miss 25% of patients with bacterial overgrowth—direct culture of small-bowel contents which is particularly helpful for defining bacterial sensitivity to specific antibiotics, or determination of bile acid products in the blood. Some patients have low vitamin B12 levels or modestly raided CRP—<15—which normalise once bacteria are eradicated from the small bowel [39].

Optimal strategies for the management of bacterial overgrowth are not defined. Appropriate antibiotics to which the specific bacteria are sensitive, used for 1–2 weeks may abolish symptoms within a few days of starting treatment. However, symptoms can recur any time after antibiotics are stopped—from a few days to many years later—because the underlying cause of bacterial overgrowth has not gone away. If symptoms return, retreatment with antibiotics might help. In patients with recurrent symptoms, use of antibiotics for a few days every month, or continually at the lowest effective dose, might be effective [1].

Table 3 Causes for diarrhea during and after radiotherapy. It is not unusual especially after radiotherapy for several causes to coexist. Therefore, empirical treatment is rarely effective as it is difficult to guess the cause(s) accurately. This list does not include other common reasons such as excess fibre which is often poorly tolerated after radiotherapy, excess caffeine or alcohol. Clearly many of the causes in this list can be cured with simple interventions if they are diagnosed accurately

	During radiotherapy	After radiotherapy
Lactose intolerance	50%	5–7%
Other disaccharide malabsorption	Not known	Yes but frequency unknown
Bile acid malabsorption	50%	1–83%
Small bowel bacterial overgrowth	25%	8–45%
Large bowel strictures	–	3–15%
Pancreatic insufficiency	Not known	Yes but frequency unknown
Rapid transit	100%	Yes but frequency unknown
Viral infection	Not known	Not known
Clostridium difficile	Not known	Not known
Cancer relapse	–	4–10%
Drug related (non chemotherapy)	10%	5%
New GI neoplasia	–	10%
New onset IBD		2%
Other	Not known	5%

Bile Acid Malabsorption

Up to half of patients who develop diarrhoea acutely during radiotherapy will have bile acid malabsorption [40] because of a direct effect on the mechanisms of bile reabsorption; accelerated transit that reduces bile absorption [41, 42]; or colon damage that exacerbates symptoms [43]. After radiotherapy, a chronic reduction in bile acid absorption is common [44, 45] but does not cause symptoms in most patients [40, 46, 47]. Bile acid malabsorption can cause a variety of symptoms. Intermittent or constant loose stool is universal but patients may also develop abdominal cramps, frequency and/or urgency of defaecation, nocturnal defaecation or incontinence. The development of bile acid malabsorption should be considered in all patients who have episodes of loose (type 6) or liquid (type 7 stool as per the Bristol stool chart) and if these patients are subjected to a Selenium homocholic acid taurocholate (SeHCAT) scan, consistent data suggest that approximately 50% have developed the condition across a wide range of diseases (see Fig. 3) [48].

The gold standard for measurement of bile acid malabsorption is the SeHCAT (selenium 75 homo-cholic acid conjugated with taurine) scan. Bile acid is secreted in response to dietary intake of fat, so reducing dietary fat intake, can be a useful therapeutic approach in patients with mild malabsorption. Regular use of antidiarrhoeal drugs such as loperamide or codeine phosphate [49], especially if taken 30–60 min before eating, may improve symptoms. Most patients however require bile acid sequestrants which

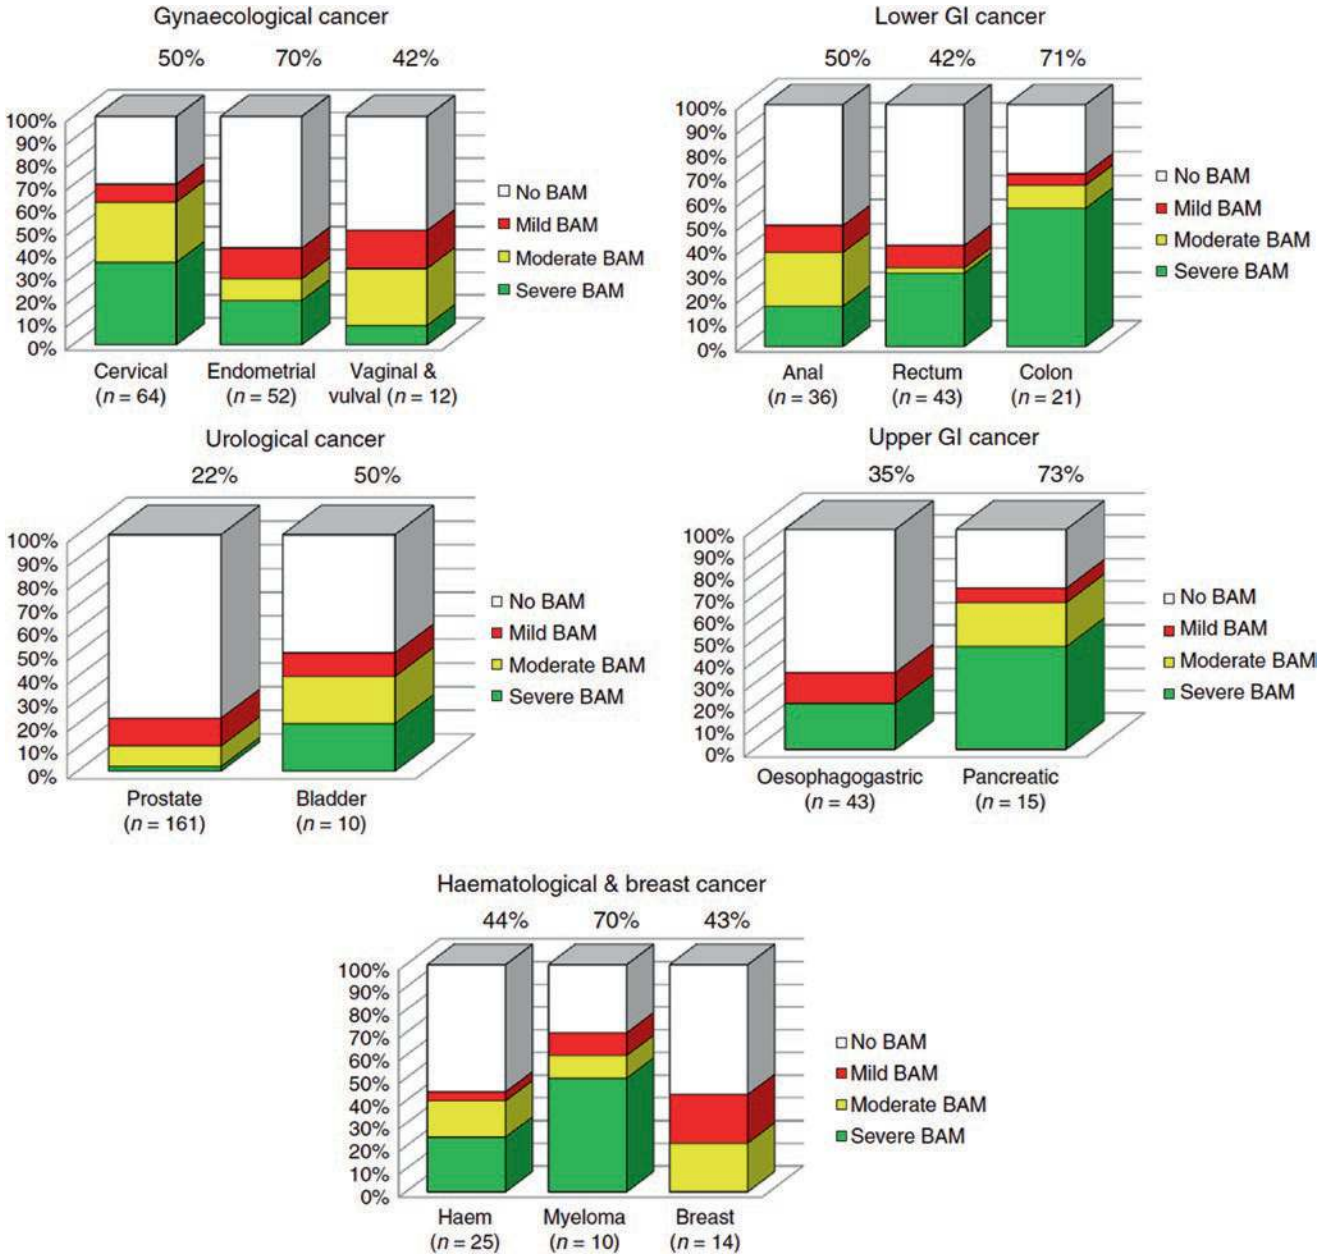

Fig. 3 Taken from Phillips et al [48] showing the frequency and severity of bile acid malabsorption (BAM) in 506 patients undergoing a SeHCAT scan. Not all had been treated with pelvic radiotherapy

have been shown to be beneficial in several series [37, 46, 49–52]. Most of these data are for use of colestyramine. However, many people cannot tolerate bile-binding resins. An effective and well-tolerated alternative is colesevelam [53]. As a last resort a diet where medium-chain triglycerides replace most of the fat can be tried [54] though this diet is unpalatable and is rarely required. A logical therapeutic approach which has been shown to be highly beneficial is described in Fig. 4.

Carbohydrate Malabsorption

De-novo lactose malabsorption occurs in 50% of patients by the fourth week of pelvic radiotherapy [53]. The severity of malabsorption correlates with the length of small bowel irradiated [55]. New-onset lactose malabsorption persists in about 5% of patients and frequently causes diarrhoea [44, 56]. If lactose malabsorption occurs, it is likely that malabsorption of other disaccharides also occurs. No studies have

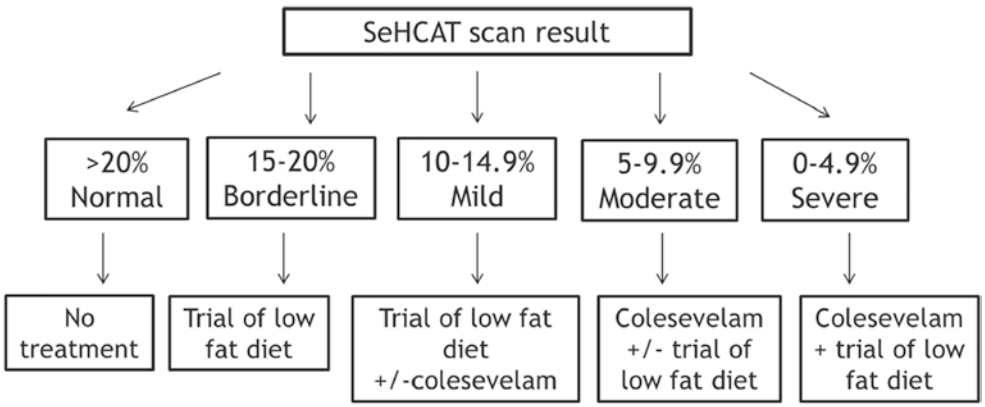

Fig. 4 Taken from Gupta A et al [30] suggesting a therapeutic approach to bile acid malabsorption based on the SeHCAT scan value

investigated this systematically although clinical experience suggests that malabsorption of other sugars does sometimes occurs. Clinical experience suggests that many patients who believe they have lactose intolerance, in fact have developed bile acid malabsorption and their symptoms arise from the fat found in milk containing products rather than from the lactose.

Investigation for carbohydrate malabsorption can include stool chromatography, oral-tolerance tests that measure blood or breath responses, use of isotope-labelled carbohydrate, direct biopsy proof of enzyme deficiency or empirical trials of diet. Dietary advice to avoid the unabsorbed sugars, which could include one or more of lactose, fructose, sucrose and starches is needed and should be given by a qualified dietician because diets can be complex and lactose avoidance changes calcium intake, which might affect bone health a potential problem in people who have had radiotherapy and are known to suffer from an increased risk of bone fracture [1].

Risk of Second Cancers

Endoscopic surveillance should probably be discussed with all patients 5 years after radiotherapy and probably should be continued long term. Large studies have concluded that after radiotherapy there is a significant risk of secondary colon cancer and rectal cancer [57]; rectal (but not colon) cancer [58–60]; or either rectal cancer or colon cancer but only in parts of the gastrointestinal tract that were included in the radiation field [61] and that risk increases over time.

Steatorrhoea

Steatorrhoea is loose stool caused by the presence of excessive undigested fat (i.e., >0.3 g per kg a day). It causes unpleasant symptoms of frequency of defaecation, urgency, faecal incontinence, perianal irritation, and severe, socially debilitating flatulence. Patients with substantial fat malabsorption especially when it occurs together with small bowel bacterial overgrowth can develop severe abdominal cramps and vomiting, which can sometimes be mistaken for acute obstruction.

In a patient who has had pelvic radiotherapy, steatorrhoea is commonly caused by bile acid malabsorption or bacterial overgrowth. More rarely, it is caused by chronic pancreatic insufficiency or by the little-recognised disorder of free fatty-acid malabsorption. Very rarely it may be due to Addison's disease, thyrotoxicosis, the development of a hormone secreting neuroendocrine tumour, intestinal lymphangiectasia or very extensive new onset small bowel inflammatory disease.

Steatorrhoea needs to be diagnosed by direct questioning—is the stool pale, extremely offensive, with a tendency to float and difficult to flush away? Of most usefulness, patients sometimes describe a frequent oily film on the surface of the lavatory water.

It is now almost impossible to obtain laboratory quantification of stool fat levels [1] so these should not be requested.

Radiation-Induced Pancreatic Insufficiency

The pancreas is thought to be fairly radio-resistant. However, chronic pancreatic insufficiency can develop after pancreatic irradiation [9, 62–68]. The pancreas frequently appears completely normal on magnetic resonance cholangiopancreatography, even in the presence of severe radiotherapy-induced pancreatic insufficiency. Invasive tests of pancreatic function are rarely justified. Faecal elastase levels may be artificially lowered in patients with undiagnosed coeliac disease or small intestinal bacterial overgrowth (SIBO) but SIBO is often present in patients with pancreatic insufficiency and is not an uncommon reason why patients do not tolerate pancreatic supplements. If SIBO is eradicated then pancreatic supplements, if tried again, will usually be tolerated.

Free-Fatty-Acid Malabsorption

Malabsorption of free fatty acids occasionally occurs after small-bowel irradiation [69] and may be related to the development of lymphangectasia [70] (which rarely, is the only cause of steatorrhoea). A low-fat diet (i.e., 20–30 g a day), or occasionally a diet rich in medium-chain triglycerides, is needed in addition to optimum treatment of other causes of steatorrhoea.

Faecal Incontinence, Urgency, Tenesmus, Mucus Discharge, and Frequency of Defaecation

Of all gastrointestinal symptoms that can occur after radiotherapy, urgency of defaceation and faecal incontinence causes the greatest distress [71–73]; however, it is the most difficult symptom for patients to discuss.

Changes in stool consistency, reduced rectal volume, psychological issues, inflammation, or neoplasia in the lower gastrointestinal tract might increase the frequency of defaecation. In all patients with these symptoms, rectal examination with assessment of anal tone and flexible sigmoidoscopy is the minimum investigation needed. In patients with frequency of defaecation or changes in stool consistency, a full blood screen is appropriate. Local rectal or sigmoid pathology, such as a mucus-secreting tubulovillous adenoma or carcinoma, might cause faecal incontinence, and flexible sigmoidoscopy will exclude new onset inflammation of the lower GI tract unrelated to pelvic radiotherapy (which occurs in about 2% of patients in one series) [9]. Endoanal ultrasonography might define sphincter defects (e.g., after childbirth or those caused by radiotherapy).

A retrospective study [74] that evaluated the management of patients with faecal incontinence after pelvic radiotherapy found that the use of phenylephrine gel benefited three quarters of all patients with incontinence that had not responded to other treatments.

As these symptoms are commonly characterised by muscle spasm, several treatments exist that might help, including use of correct positioning on the lavatory, pelvic floor exercises, biofeedback, correct use of anti-diarrhoeal drugs, non-fermented stool- bulking agents (e.g., sterculia), and low doses of antidepressants. Surgery to divert the faecal flow and stoma formation might have a role in the few patients who have substantial loss of rectal volume and who have not responded to other interventions [1]. There have been suggestions that sacral nerve stimulators may be of use for faecal incontinence but this very expensive device should be implanted only with great caution into tissues made ischaemic after radiotherapy because of the high risk of complications and definitely only after all the other causes for faecal incontinence after radiotherapy—especially when there is diarrhea or steatorrhoea - have been excluded.

Rectal Bleeding

The natural history of radiation-induced bleeding after conformal radiotherapy is that it starts to be clinically apparent 6–12 months after radiotherapy, may get worse over the next 5 years or so and then slowly improve over the next 5–10 years. Some newer radiotherapy techniques may lead to a more prolonged time to recovery and cessation of all bleeding. The likelihood of bleeding is closely related to the dose of radiotherapy delivered to the anterior rectal wall. Up to half of all patients have some rectal bleeding after pelvic radiotherapy [75–77], for many it will be trivial but it is reported to impair quality of life in up to 6% of patients [78]. Incidence of transfusion-dependent bleeding is 1–5% of patients [78, 79].

The mucosal lesion that typically is associated with radiation-induced bleeding is angiectasia, which are a response to radiation-induced ischaemia. All patients, within weeks to months after treatment, develop endothelial dysfunction, with subsequent vascular sclerosis and wall fibrosis [80]. This can lead to narrowing or thrombosis of small arteries and arterioles, progressive ischaemia to the supplied tissues, and consequent neo-angiogenesis [81, 82]. Intermittent bleeding can frequently follow from these fragile new vessels which it on the surface of the mucosa.

All patients with any rectal bleeding should be offered assessment with at least flexible sigmoidoscopy; proctoscopy and rigid sigmoidoscopy are inadequate. Colonoscopy can be reserved for those with symptoms or signs that suggest pathological changes to the proximal colon [83]. There is no role for routine biopsy of typical radiation change and in patients who have undergone brachytherapy there is a significant risk of fistula formation after endoscopically guided biopsy of the anterior rectal wall. Lower GI endoscopy can be more difficult after previous radiotherapy and we recommend that only experienced endoscopists should assess these patients and that clinicians should consider routinely using either a paediatric colonoscope in this population or even a gastroscope rather than a normal colonoscope to reduce the risk of perforation around fixed loops in the sigmoid.

Several series have suggested that the nature of bleeding does not discriminate between the different causes and that radiotherapy is not the cause of rectal bleeding in 25–60% of patients [1]. For patients with severe bleeding, anticoagulants or antiplatelet therapies should be discontinued or reduced, if possible. Patients should be advised to maintain regular bowel habits and we often prescribe non fermentable stool bulking agents (we favour the use of sterculia above all other preparations) when needed to avoid addi-

tional trauma to the rectal mucosa from hard stool. For patients with trivial bleeding not causing anaemia or interfering with daily activities, once serious underlying pathology has been ruled out, should be reassured that they need no treatment [84].

Endoscopy

Endoscopy is frequently the first treatment option considered for patients with rectal bleeding. However, there have been only a very few controlled studies to evaluate its safety and efficacy in these patients and these rarely report symptom severity adequately so it is difficult to assess whether the intervention was required. Overall, based on retrospective and uncontrolled prospective studies, endoscopic treatment seems to be effective for about 80% of cases; the specific treatment given usually depends on the endoscopist's preference and expertise [85, 86]. However, when we worked in a specialist centre we were referred a steady flow of patients with serious complications of the endoscopic intervention; either perforation or non-healing ulceration. This is unsurprising as there is significant risk of non-healing after the use of a thermal therapy such as argon plasma in ischaemic tissue. While argon plasma and formalin therapy in small randomized controlled studies [87, 88] seem equally effective in reducing rectal bleeding our preference is to avoid argon plasma if at all possible and, if there is no ulceration present, use the technique of intra-rectal formalin instillation described by Cullen et al. [89].

Thermal Coagulation

If thermal coagulation therapy is used, it should only be performed by experienced endoscopists because of the frequency of serious procedure-related side effects [90–93]. Thermal coagulation therapy destroys bleeding vessels but also potentially the mucosa and submucosa. It therefore can lead to ulceration, which sometimes is associated with increased bleeding, chronic pain and slow healing (or no healing at all), and subsequent rectal stricture and loss of function. Prospective studies showed that as many as 50% of patients develop rectal ulcers after treatment [94]. Therefore, it is reasonable to propose reducing argon flow rates (≤2 L/min) and wattage (≤40 watt), with precise application, to try to reduce the number of complications [91].

Recently, the technique of Radiofrequency Ablation has been proposed as an effective solution for bleeding radiation proctopathy. It cannot be recommended until there are published data showing it is safe.

Formalin

Formalin solutions of 4–10% are applied directly to the mucosa, where they cauterize tissue and seal fragile neovasculature to prevent further bleeding. However, studies published on the effects of this approach are of poor quality, and important outcomes, including the risk of serious complications, are not well defined [95].

Endoscopic cryoablation and radiofrequency ablation have been proposed as alternative treatments and have shown initial promising results. However, results from only a few pilot, uncontrolled studies have been published [96, 97]. Additional well-performed studies are needed before the effects of endoscopic cryoablation can be recommended.

Nonendoscopic Therapies

Medicine

Patients with radiation-induced injuries have minimal amounts of inflammation, although pelvic radiation disease is frequently called *radiation proctitis*. This misleading term results in inappropriate treatment, such as with anti-inflammatory agents (steroids and 5-aminosalicylic acids), being frequently proposed as first-line treatment for pelvic radiation disease [98]. A systematic review of randomised and nonrandomised, prospective, comparative trials clearly show that these agents have no beneficial effects for patients with radiation toxicity [99]. At the moment, only 2 treatments have been shown (in small, non–placebo controlled, randomized trials) to be effective therapies for chronic radiation-induced telangiectasias: a 4-week course of oral metronidazole [100] and sucralfate enemas [101].

Antibiotics

Antibiotics have been used to treat patients with radiation-induced bleeding. Metronidazole kills anaerobic and microaerophilic bacteria, which contribute to hypoxia; it also can act as an immunomodulator. However, it is not clear how this antibiotic might reduce bleeding. Cavcic et al. [99] performed a study of 60 patients with radiation-induced rectal bleeding and diarrhea who were given either the combination of metronidazole (3 × 400 mg/day orally), mesalazine and betamethasone, or the combination of mesalazine and betamethasone. After 12 months of follow-up evaluation, they observed significant reductions in the incidence of rectal bleeding, ulceration, and diarrhoea in the metronidazole group. We belive that these findings indicate that improved

bowel function may have been seen as a result of effective treatment of small-bowel bacterial overgrowth and as a result of this improved bowel function, this is why bleeding was reduced.

Sucralfate Enema

A Cochrane review [101] has summarised the evidence for treatment of rectal bleeding from radiotherapy. Sucralfate enemas (2 g sucralfate suspension made-up with 30–50 mL water in a bladder syringe injected twice a day via a lubricated foley catheter passed through the anus into the rectum) are often effective but need often to be continued long term. It should be noted that systematic review suggests that corticosteroid or mesalazine enemas are ineffective for treating bleeding from radiation proctopathy.

Hyperbaric Oxygen

Hyperbaric oxygen therapy provides the best evidence that radiotherapy morbidity can be modified. This therapy seems to stimulate angiogenesis, fibroplasia, and tissue restructuring through an increase in oxygen gradients in ischaemic tissues. A systematic review [102] has summarised the efficacy of hyperbaric oxygen in the management of radiation-induced bleeding and other symptoms. These data (none of which are randomised and much of which are retrospective) are encouraging, but they lack consistency in scoring of symptoms and response criteria. Two randomized controlled trials have been published—one showed benefit [103]. Our own trial did not although in patients with bleeding possibly there was a trend to improvement [104]. Our own view is that there is a definite role for hyperbaric oxygen in patients with severe rectal ulceration but further studies are needed especially as hyperbaric oxygen is expensive and has a low risk of side-effects, including the theoretical risk of promoting the growth of occult metastases [1].

Surgery

A final treatment option is surgery to defunction or resect the bleeding area. However, these procedures have high morbidity. In view of the potential of all interventions to cause substantial harm to patients who may already have major problems, there is an urgent need for carefully designed multicentre randomised trials to assess the management of post-radiotherapy bleeding [1].

A clinical algorithm [17] for treating problematic radiation bleeding is shown in Table 4.

Table 4 Suggested steps for managing GI bleeding after pelvic radiotherapy

Step 1: Investigate with flexible endoscopy to determine the cause of the bleeding
Step 2: Optimise bowel function and stool consistency which may reduce the amount of bleeding
Step 3: If bleeding is not affecting quality of life (eg, staining clothes, causing anaemia, interfering with daily activities), reassure and do nothing further
Step 4: If bleeding affects quality of life, stop/reduce anticoagulants if possible and, if very severe, start sucralfate enemas
Step 5: Discuss definitive treatment to ablate the telangiectasia with the patient; options include:
(a) Hyperbaric oxygen therapy
(b) Argon plasma coagulation
(c) Formalin therapy

Preventing Radiation Injury: Future Perspectives

As yet, no objective biomarkers of radiation-induced toxicity exist; their discovery should be a very high research priority. The need for these markers has intensified due to the growing number of cancer survivors at risk for developing toxicity from cancer therapies and would allow us to select patients for trials of therapies to reduce that risk of toxicity [105].

A second priority is to develop treatments that are safe, easily administered and effective at reducing or eliminating adverse health effects to individuals from radiation exposure.

A number of radiation countermeasures are currently under investigation; however, these must undergo further trials before being approved for use on humans. Importantly, protective or mitigating agents can only be considered for clinical use if they do not hamper the anti-tumour effect of the radiotherapy treatment [102]. With regard to efficacy, it is crucial that both the effects on acute and late intestinal radiation injury are assessed as both agents that reduce acute and late injury are needed in order to improve the quality of life of patients [106].

Somatostatin Analogues

Radiation exposure causes breakdown of the intestinal epithelial barrier due to a decrease in intestinal crypt/stem cell proliferation and inadequate cell supplies to compensate for continuous enterocyte loss. As a result, sub epithelial tissues may be exposed to intraluminal pancreatic enzymes that subsequently aggravate the injury by initiating auto-digestion of the intestine and the induction of inflammatory processes [107, 108]. Strategies to reduce exogenous pancreatic

secretion, like pharmacological inhibition with somatostatin analogues, have been shown effective in reducing intestinal radiation toxicity in animals [109, 110]. Human studies investigating the effect of octreotide on post-irradiation diarrhoea in patients being treated for rectal or anal cancer have had mixed results [111, 112]. This might, in part, be because of the limited volume of small intestine in the radiation field, the site at which somatostatin analogues are expected to exert their effect.

The recently developed somatostatin analogue SOM230 (Pasireotide) may be more effective in reducing radiation injury than octreotide. It has a more favourable pharmacokinetic profile and broader receptor affinity. It was also found to reduce radiation toxicity when started up to 48 h after exposure [113]. Studies are now needed to determine the safety and potential efficacy of SOM230 in abdominal and pelvic radiotherapy.

Growth Factors and Growth Factor-Like Agents

The use of growth factors and growth factor-like agents to improve post-irradiation intestinal epithelial recovery has been researched over the past several years. Glucagon-like peptide 2 as well as keratinocyte and fibroblast growth factors has been shown to ameliorate post-irradiation intestinal injury in various animal models [114–119]. Moreover, recombinant human epidermal growth factor as well as R-spondin 1, an intestinal stem cell growth factor, has been shown to reduce apoptosis and improve recovery of the intestinal villi [120, 121]. Growth factor-like agents have also been be used to reduce radiation injury. For example, the growth factor-like lipid mediator lysophosphatidic acid (LPA) was shown to reduce post-irradiation intestinal apoptosis through the LPA receptor 2 subtype [122].

Going forwards, it is important that these agents do not affect radiation-induced tumour cell kill, tumour growth or other malignant tumour properties. In the animal studies performed, this did not appear to be the case. However, further research is needed to confirm these results and if they are shown to be effective, serious discussions are required to make them an affordable option.

Agents Acting on the Toll-Like Receptor 5 Pathway

Toll-like receptors (TLR) are an important component of the intestinal innate immunity. Activation of TLRs by commensal microflora is essential for the protection against intestinal injury and in the regulation of epithelial repair [123, 124]. Activation of TLRs reduces the sensitivity of enterocytes to radiation-induced apoptosis. The bacterial protein flagellin is a natural agonist of toll-like receptor 5 (TLR5). Both flagellin and the less toxic synthetic flagellin derivate CBLB502 have been shown to be potent radioprotectors in mice and non-human primates [125, 126].

Pretreatment with Toll-like receptor 5 agonist prevents radiation-induced apoptosis of intestinal epithelial cells and subsequent injury [126, 127]. A concern regarding the use of TLR5 receptor agonist is the possible induction of systemic inflammation [128]. Further research is thus needed to determine the safety and efficacy of the above mentioned agents before they can be used clinically to prevent intestinal radiation injury.

Endothelial Protectants

It is thought that post-irradiation, endothelial apoptosis contributes to intestinal stem cell dysfunction and mucosal injury [129]. Treatments that reduce radiation-induced microvascular endothelial cell apoptosis may therefore be able to prevent intestinal radiation injury [129]. The sphingolipid, ceramide, has been shown to play a crucial role in radiation-induced endothelial apoptosis. Radiation exposure can cause hydrolysis of cell membrane sphingomyelin by acid sphingomyelase which results in the formation of ceramide. Ceramide then initiates the apoptotic process via the mitochondrial system [130]. Bonnaud et al. showed that inhibition of post-irradiation ceramide production promotes post-irradiation endothelial survival and ameliorates intestinal injury in mice [131]. In addition, as well as reducing endothelial apoptosis, endothelial function may be improved post-irradiation with agents like 3-hydroxy-3-methylglutaryl-CoA (MHG-CoA) reductase inhibitors that have been shown to reduce intestinal radiation injury in animal models [132, 133].

γ-Tocotrienol

Another group of promising new agents targeted at reducing intestinal radiation injury are Vitamin E analogues or so called tocols that are powerful antioxidants with favourable toxicity profiles. Hence, they have strong potential to be developed as radioprotectants. γ-Tocotrienol may be so effective in reducing intestinal radiation injury because tocotrienols accumulate in the small intestine and colon to a higher level than tocopherols supplemented in the same concentration [134]. Other properties that may contribute to the powerful radioprotective effects of γ-tocotrienol are its ability to concentrate in endothelial cells to levels that are 30–50 fold greater compared to α-tocopherol and to inhibit the enzyme MHG-CoA reductase [135, 136].

At present, little is known about the effects of γ-tocotrienol on tumour cells during radiotherapy. γ-Tocotrienol may sensitise tumour cells to radiation exposure and chemotherapeutic agents [137, 138], however, further studies are needed to confirm that it does not protect tumour cells against radiation. With regard to the safety of γ-tocotrienol in human beings, studies from other fields have shown that γ-tocotrienol supplementation is well tolerated in human subjects [139, 140]. We have just completed a randomised double blind trial of tocotrienol combined with pentoxifylline and its utility in treating established radiation injury not responsive to other modalities. The results should be available soon.

Pentoxifylline +/− Vitamin E

Pentoxifylline is a methylxanthine derivative originally developed for the treatment of regional microcirculation disorders and shown to have anti-inflammatory and immunomodulatory properties. Consistent with animal data, the majority of studies published from the use of pentoxifylline in humans to treat radiation-induced fibrosis including some randomised trials have reported improvement. The total number of enrolled patients in these studies is 336 and looking through these studies gives an impression that pentoxifylline is more effective when used in combination with vitamin E but that any benefits achieved may take many months to become apparent. There is a pressing need for appropriately powered randomised studies, which should be double-blind placebo-controlled in view of the subjective nature of most clinical endpoints to confirm these encouraging findings.

Interleukin-11 (IL-11, Oprelvekin)

IL-11 is a multifunctional cytokine of the interleukin-6 (IL-6) family. It stimulates maturation of megakaryocytes and has anti-inflammatory properties as well as cytoprotective effects on gastrointestinal crypt cells [102]. Administration of IL-11 improves crypt survival and reduces GI mucosal injury after total-body irradiation in mice [141]. It also protects the clonogenic stem cells in murine small-intestinal crypts from impairment of their reproductive capacity by radiation [142]. Although IL-11 is well-tolerated in animals, significant adverse effects including fluid retention, multisystem organ failure and pleural effusion have limited its clinical use in humans.

OrbeShield®/Beclomethasone 17,21-Dipropionate (BDP)

BDP is a potent, topically-active corticosteroid currently under development as an orally-administered radiation countermeasure for GI-acute radiation syndrome (GI-ARS) [143]. It offers potent anti-inflammatory effects with minimal toxicity compared with other systemic corticosteroids. BDP showed significant survival benefit in a canine model of GI sub-syndrome [143]. In this model, canines received total body irradiation (TBI), followed by autologous BM administration and supportive care. This was coupled to experimental treatments with either the test agent or placebo. The study suggested that BDP can reduce inflammation of tissues of the GI mucosa after irradiation and can improve survival, even when treatment is initiated as late as 24 h post-irradiation [144].

Myeloid Progenitor Cells (MPC)

MPC can improve the survival of mice after exposure to high doses of radiation. It has been evaluated for use as a bridging therapy for radiation injuries and to mitigate the effects of lethal doses of ^{60}Co γ-irradiation and X-rays in different strains of mice [145]. Results from studies have demonstrated that cryopreserved allogeneic MPC significantly improved survival in strains of mice irradiated with lethal doses of ^{60}Co γ-radiation (CD2F1, 9.2 Gy) and X-ray exposures (BALB/c, 9 Gy) that are known to cause ARS in hematopoietic tissues [135]. The survival benefit was MPC-dose-dependent and significant even when MPC administration was delayed up to 7 day's post-irradiation. Additionally, MPC administration decreased deaths from ARS at radiation doses up to 15 Gy (^{60}Co γ-radiation, CD2F1 mice). Exposure levels of such magnitude can cause mice to succumb to multi-organ failure. Even at doses of up to 14 Gy ^{60}Co γ-radiation, MPC administration could be delayed up to 5 days in CD2F1 mice and still provide significant benefit to 30-day survival.

In addition, MPC also improves the structural integrity of GI tissue after irradiaton. This has been observed in a study that looked into the structural integrity of the GI tract of mice who had received MPC treatment after doses of radiation capable of causing GI injury and found that it improves the structural integrity of GI tissue and inhibits bacterial translocation from the GI tract [146]. These results give support to the administration of MPC as a bridging therapy for GI tissue. However, as promising as these studies are, further work

with extended observational periods are needed in order to investigate whether any potentially late-arising pathologies stem from graft versus host disease.

Enterade®/Amino Acid-Based Oral Rehydration Solution

Enterade® is an amino acid-based oral rehydration solution recently developed by researchers at the University of Florida. Studies in irradiated mice have shown that specific combinations of amino acids increase Na^+ absorption via amino acids-coupled Na + absorption while there is no stimulation of Cl^- secretion and, therefore, fluid secretion [147]. In addition, Enterade® led to tightening of the mucosal barrier, increased crypt count and villus length in intestinal tissue. The animal data are highly suggestive that Enterade® is an effective radiation mucosal protectant [147]. Publications subsequently suggest that it is palatable and safe and so the results of ongoing interventional human studies are eagerly awaited.

Human Microbiome

Recent research has shown how the gut microbiota interacts with the host to promote homoeostasis. These mechanisms could be important in our understanding of the gastrointestinal symptoms that are seen after pelvic radiotherapy. A study of 231 patients showed that 12% of microbial metabolic pathways were changed in patients with inflammatory bowel disease compared with only a 2% change in the microbial genera profile [148], with a shift towards a phenotype that allows the microbiota to cope with oxidative stress. Thus, dysbiosis associated with intestinal inflammation promotes a selection of bacteria capable of withstanding a highly oxidative environment, also present after radiotherapy [3].

Additionally, anaerobic bacteria convert primary bile acids into secondary bile acids. Secondary bile acids are anti-inflammatory and inhibit TNFα, interleukin 1α, interleukin 1β, and interleukin 6 through the bile acid specific receptor, TGR5. In inflammatory bowel disease, dysbiosis modifies this balance as it decreases the production of secondary bile acids, creating a proinflammatory environment [149]. Similar imbalances in the microbiota produced after intestinal radiation have been observed [150], suggesting that this mechanism could also be of importance in pelvic radiation disease.

Propionate, butyrate, and acetate are short-chain fatty acids with anti-inflammatory properties, suppressing proinflammatory cytokines such as NFκB, TNFα, interleukin 1a, or interleukin 6 [151, 152]. Butyrate also has a role in maintaining the stability of the intestinal epithelial barrier [153]. The microbiota plays a role in determining the availability and production of these molecules. Fibrolytic bacteria degrade large polysaccharides into smaller carbohydrates, which are then fermented into short-chain fatty acids [154, 155]. The *Roseburia* genus is an acetate consumer and butyrate producer, whereas *Phascolarctobacterium* is a propionate producer; they are both reduced in inflammatory bowel disease. *Faecalibacterium prausnitzii* is a major butyrate producer and is reduced in Crohn's disease [155]. These effects are clinically relevant in inflammatory bowel disease [155] and in acute radiation proctitis [156], and could also be relevant in pelvic radiation disease.

Thus, being able to characterise the gut microbiota and research its role further may allow the development of genomic and metabolomic profiles for risk assessment of patients and enable manipulation of the intestinal flora for prevention and treatment of pelvic radiation disease [3].

The development of next-generation sequencing technologies and metabolic phenotyping could make stratification of patients at risk of radiotherapy-induced gastrointestinal toxicity a realistic possibility. This is further supported by studies of common bacterial traits in patients with radiation-induced gastrointestinal symptoms [157]. A recent pilot study used an electronic nose and field asymmetrical ion mobility spectrometry to detect selected metabolites in the stool of 23 patients before and 4 weeks after pelvic radiotherapy, with promising results in risk prediction [158]. It is attractive to attribute this difference to changes in the microbiota. Nevertheless, these results should be carefully interpreted because at present faecal metabolomes do not stratify populations according to their gut bacteria [159].

Finally faecal microbiota transplantation has recently been reintroduced as a treatment for *Clostridium difficile*-induced colitis and evidence of its benefit is steadily growing [160]. It has not been tried in the context of radiation intestinal toxicity; however, its clinical potential seems exciting because it could be an inexpensive, potentially effective radiation-response modifier, possibly allowing for increases in the therapeutic index of pelvic radiotherapy [3].

Overall, the potential of the microbiota as a risk assessment and treatment instrument for radiation-induced gut toxicity seems promising. If confirmed, this could be an important step forward in oncology, allowing for inexpensive, patient-tailored treatment to modulate toxicity.

Problems After Gastric Surgery

Alastair Forbes and Alistair McIntyre

Key Points

1. Gastric surgery is most commonly a result of surgery for cancer (usually gastric) or as a result of complications of peptic ulceration (bleeding or perforation).
2. The anatomy and thus physiology must be understood following gastric surgery (e.g. how much of which part of the stomach was removed, how do pancreatico-biliary secretions enter the system etc.).
3. Malnutrition results from reduced intake (partly due to early satiety), poor gastric secretion/mixing and sieving functions, reduced pancreatic secretions (maldigestion) and dysmotility (fast gut transit due to neural disruption) all of which contribute to malabsorption. Most patients are chronically underweight.
4. General malnutrition and/or specific deficiencies (e.g. iron, B_{12}, folate, fat soluble vitamins (especially vit D), thiamine, pyridoxine and copper) may result.
5. Early and late dumping syndrome, small bowel bacterial overgrowth, post vagotomy diarrhoea, bile salt malabsorption and osteoporosis may occur. In addition there is an increased risk of gastric cancer.
6. These patients need long-term follow up for general/specific nutritional monitoring/giving appropriate supplements, treating fast transit (high dose loperamide or octreotide), small intestinal bacterial overgrowth (SIBO) (rotating antibiotics), bile salt malabsorption (cholestyramine) and monitoring for osteopenia/osteoporosis and gastric cancer.

Introduction and Background

Gastric surgery is very rarely a cause of intestinal failure. Only when there have been substantial operative complications or when gastric surgery is combined with some other insult to gastrointestinal integrity is intestinal failure at all likely to occur. However, although surgery for gastric pathology is now less often performed than in earlier decades, these combinations of multiple morbidity are seen and form a small but important part of intestinal failure practice. Additionally, the inclusion of gastric interventions in most bariatric procedures (chapter "Surgery for Obesity and Its Consequences") reinforces the value of an understanding of the consequences of disturbing the functions of this organ.

Operations have been performed on the stomach to treat cancer and peptic ulcer disease since Billroth's first partial gastrectomy in 1881. These operations initially disrupted normal gastrointestinal physiology to a very marked degree. As surgical techniques developed, mobility and mortality were reduced but some patients nonetheless developed major post-operative problems which were considered part of a post-gastrectomy syndrome. These problems can be attributed to alterations in gastric, intestinal and pancreatic physiology, and may result directly or indirectly in malabsorption and other nutritional deficiencies.

Elective surgery for peptic ulcer disease has become much less common because of a reduced incidence of ulcers and improved medical therapy with acid suppression and eradication of *Helicobacter pylori*. Emergency surgery for complications such as bleeding and perforation is still required but rarely necessitates gastrectomy; consequently there are few lasting effects on gastrointestinal physiology. By contrast there is a continued and increasing need for gastric resection for malignancy, particularly in the west, with the increasing recognition of early and potentially curable cancers.

Undernutrition Following Gastric Surgery

Post-gastrectomy syndromes comprise a wide spectrum of conditions, many of which are associated with adverse nutritional consequences. Reduced intake and malabsorption both contribute to weight loss and are often seen together in affected patients.

Inadequate nutritional intake can result from early satiety due to a small volume gastric remnant and/or its lack of compliance. Operations which alter gastric motor function without an adequate drainage procedure being performed lead to delayed gastric emptying, which also leads to post-prandial fullness and early satiety. Alterations in gastric motility resulting in inadequate mixing, combined with surgically induced reduction of acid, pepsin and intrinsic factor secretion, contribute to a varying degree to subsequent malabsorption of the food that has been consumed.

It is common for gastric surgery to be followed by suboptimal pancreatic function given that pancreatic exocrine function is determined in part by an intact enteroendocrine system, and because procedures that create an afferent loop separate pancreatic secretions from the immediate outflow from the remaining stomach (or the oesophagus when a total gastrectomy has been performed) (see below), thus reducing their ability to contribute to digestion.

The gut hormone responses to food clearly differ substantially from those in normal individuals, the secretion profiles for insulin, glucagon-like peptide 1 and cholecystokinin all being significantly different after a liquid challenge in gastrectomised patients [1].

The function of the proximal small bowel may be compromised by rapid transit, limiting the time available for absorption of nutrients, and further if bacterial overgrowth occurs (see below). Nonetheless mucosal absorptive capacity appears to remain within normal limits in most cases.

Patients may dramatically reduce their intake of food in attempts to avoid post-prandial symptoms and especially so if they are affected by the dumping syndrome or diarrhoea (see below). Other patients may select an inappropriate diet, with large and insufficiently masticated particles of food, nutrients with especially high osmolality or simply excessive volumes. As well as contributing to unpleasant sensations of excess satiety these may also contribute to intestinal digestive malfunction.

There is no doubt that impaired quality of life is strongly associated with malnutrition and weight loss [2, 3], but it is more difficult to determine whether this is a causal relationship and if so in which direction the cause operates!

Direct Effects of Gastric Surgery

The disruption to physiological processes depends on the operation performed and also on the individual's response to that surgery. Many different procedures are or have been performed on the stomach (Figs. 1 and 2) and their pathological consequences are determined by the anatomical and physiological changes caused.

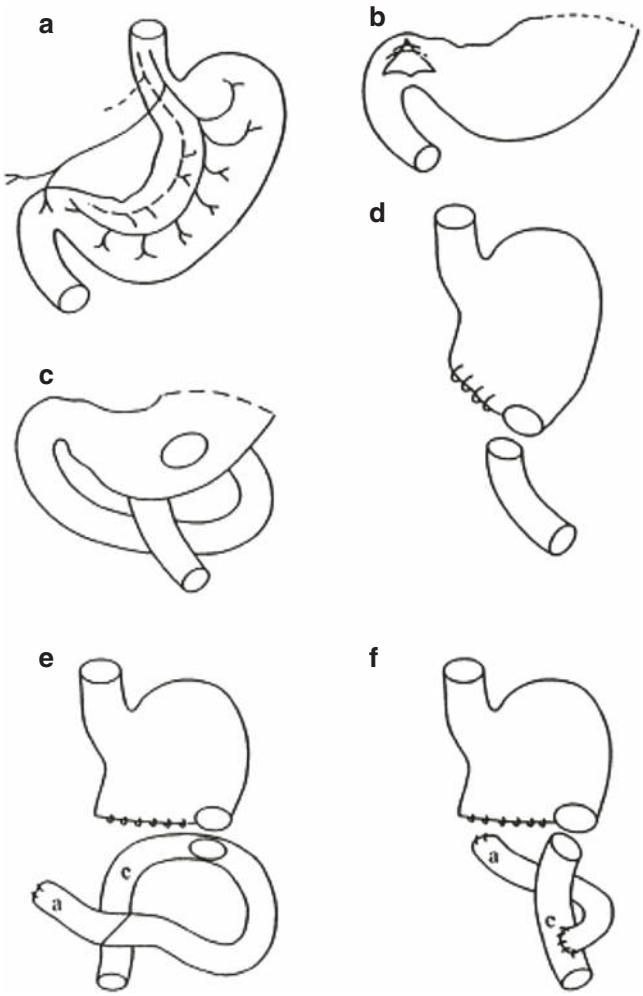

Fig. 1 Types of gastric surgery done for peptic ulceration. (**a**) The vagus nerve which supplies the stomach may be divided proximally (a truncal vagotomy), or more distally (selective or highly selective vagotomy). (**b**) Pyloroplasty (frequently used with truncal vagotomy to prevent delay in gastric emptying). (**c**) Gastroenterostomy (which enhances emptying by bypassing the pylorus). (**d**) Billroth I partial gastrectomy. (**e**) Billroth II (or Polya) gastrectomy with afferent (a) and efferent (e) small intestinal limbs. (**f**) Roux-en-Y reconstruction with afferent (a) and efferent (e) small intestinal limbs

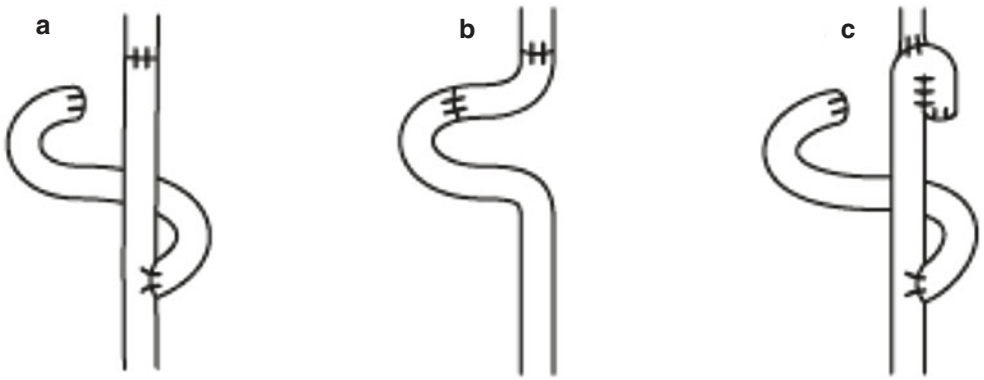

Fig. 2 Types of total gastrectomy. (**a**) Roux-en-Y oesophago-jejunostomy. (**b**) Interposition of jejunal, ileal or colonic loop. (**c**) Small bowel pouch and Roux-en-Y oesophago-jejunostomy

In broad terms the greater the magnitude of resection the greater the nutritional consequences, and (for example) near-total gastrectomy gives some protection compared to total gastrectomy, with less severe and less persistent objective markers of malabsorption than in the patients receiving the more radical surgery and without oncological hazard [4].

Vagotomy reduces acid secretion by interrupting the vagal simulation of the gastric parietal cells. When this is a highly selective procedure there is essentially no other effect, but a truncal vagotomy not only cuts acid secretion but also profoundly impairs gastric motor function and compliance, delays gastric emptying (but see below), and compromises pancreatic function.

Partial gastrectomy reduces the physical size of the stomach, and, depending on the site removed, will reduce acid secretion to a greater or lesser degree. The normal mixing and sieving functions will be impaired.

Drainage procedures such as pyloroplasty and forms of gastroenterostomy were introduced to overcome delayed gastric emptying caused by vagotomy or partial gastrectomy, but paradoxically can also be the main cause of precipitate gastric emptying, dumping syndrome and rapid intestinal transit (see below).

Reconstructional surgery to permit continuity of the gut for biliary and pancreatic secretions such as the Roux-en-Y procedure yields an afferent loop which can itself be responsible for additional physiological disturbance.

Gastric surgery may also be responsible for uncontrolled gastro-oesophageal reflux (which will often be alkaline) and places the patient at increased risk of malignancy in the gastric remnant as well as at risk of the full gamut of post-operative complications common to all abdominal surgery.

Weight Loss and Dietary Restriction

Loss of weight after gastric resection is so common as to be considered an expectation; even with optimal nutritional support the weight lost may be substantial. The magnitude to be expected with best practice remains difficult to predict as the various studies performed have had heterogeneous criteria for entry, type of surgery and nutritional intervention. This position is often aggravated by omission of baseline weight (many studies start using pre-operative weight which, from the nature of the diseases concerned, is generally lower than the patient's weight in health), and by a lack of appropriate control populations. As an example, one study claimed to show avoidance of weight loss but did not take account of the normal gradual increase in weight during middle-age nor the fact that the "baseline" weight was that immediately before the surgery [5]. Overall more than 50% of patients are and remain underweight indefinitely after gastric surgery [6, 7].

In general, patients with no symptoms after eating eat normally, while those with symptoms almost universally respond to this by eating less roughly in proportion to the severity of those symptoms. Weight loss indeed correlates strongly with reduced food intake [7–9] and also with the speed of orocaecal transit [10, 11].

Patients who are underweight after partial gastrectomy typically eat less than half the macronutrient intake of normal controls or those who have managed to maintain their weight after surgery [12]. In those who can be encouraged, and are able, to consume normal amounts of food, some weight gain can be expected. A major study of patients after various forms of cancer surgery accordingly confirmed that even as early as 3 months after operation differences in nutritional intake can be overcome, but showed that those with more invasive procedures did indeed have more persisting weight loss [13].

Other factors contributing to weight loss are however almost certainly important, including dysfunctionally exaggerated satiety (Table 1). The normal response to relative starvation (eating more) appears blunted in patients who have undergone partial gastrectomy.

The routine use of oral nutritional supplements has its advocates, and there is good evidence in support of this and other forms of artificial nutrition at the time of surgery for gastric cancer (e.g. [14, 15]) but evidence in favour of longer-term support is lacking, problems with compliance perhaps

Table 1 Nutritional effects of gastric resection

Reduced food intake
Maldigestion
Impaired gastric sieving
Impaired gastric secretion (acid and enzymes)
Malabsorption
Impaired gastric secretion
Impaired pancreatic secretion
Impaired intestinal secretion
Blind loops and bacterial overgrowth
Specific deficiencies (e.g. thiamine, vitamin B12)
Early and late dumping syndromes
Motility disorders affecting gastric emptying and intestinal transit

confounding possible benefit [16]. An educational approach taken in this regard may pay dividends [17].

Gastric Emptying

Disturbance of the stomach's normal role in processing food, so as to be suitable for transfer to the duodenum and optimal digestion thereafter, contributes to post-operative malabsorption. In health the stomach regulates the entry of nutrients into the duodenum in quantity, particle size, and nutritional content, titrating efflux against osmolality and energy load in such a way that proximal small intestinal function is facilitated and absorption maximised [18].

Gastric emptying is thus not a single simple process, and although (for example) vagotomy is generally considered to delay emptying it is also a potential cause of rapid emptying with precipitate "dumping" of nutrients into the small intestine [19]. Indeed liquids empty abnormally rapidly following vagotomy, with or without pyloroplasty, as well after all forms of gastric resection and reconstruction [20]. The emptying of solid food following gastric surgery is much more variable—the initial phase often results in rapid emptying of some solids, but after 30–60 min emptying of solids may become very slow or continue at rapid rates depending on the individual as well as on the procedure that has been performed. Following truncal vagotomy, even with pyloroplasty, emptying of solids is delayed [21] whilst emptying is abnormally rapid after essentially all forms of gastrectomy [20].

Many patients describe particular problems with fatty foods and most dramatically so when oils (liquid fats) are ingested. This is probably because their rapid gastric efflux overwhelms the digestive abilities of the pancreas, which is attuned to relatively slow exposure to fats after meals, given the usual sequence of solids leaving the stomach in which fats follow carbohydrate and protein. The absorptive capacity of the proximal small intestine can be exceeded for other nutrients also, and if the more distal intestine is insufficient in length or function to accommodate this then significant malabsorption may arise.

The study of gastric emptying using a two-phase (liquid and solid) double radio-isotopic method can provide objective evidence of the nature and rate of gastric emptying, but its clinical usefulness is limited given the variable response to interventions even when these are based on information specific to the patient concerned.

Gastric Sieving

The normal stomach yields duodenal access to liquids and—through the process known as gastric sieving—of particles only less than 1 mm in size [21]. This process is self-evidently greatly compromised by the more major gastric resections and those with a substantial enterotomy, but vagotomy with antrectomy or pyloroplasty can also disrupt the process and allow entry of larger particles into the small bowel following meals [22, 23]; only following proximal/selective vagotomy alone does normal gastric sieving appear to be preserved post-operatively [23].

In one small study (n = 9) vagotomy and antrectomy permitted the emptying of abnormally large meat particles into the small intestine, to the extent that 37% of the meat left the stomach while still more than 1 mm in size [22]. The effect on gastric emptying was however quite variable since two of the nine patients had normal sieving (<2% of the particles reaching the small intestine >1 mm) whilst in the worst affected patients 75% of particles were >2 mm in size. In a similar small study of patients after vagotomy and pyloroplasty two of seven patients had abnormal sieving [23].

Larger particles have a lower surface to mass ratio, and when these are presented to the small intestine their hydrolysis, overall digestion and absorption are slower than is normal [24, 25]. In a controlled experiment on dogs with Billroth I gastrectomies absorption of ^{14}C triolein from margarine in the liquid phase was—as in controls—almost complete by the mid-gut. However when the ^{14}C triolein was incorporated in steak and liver more than double the amount (50% vs 20%) was recovered unabsorbed in the mid small intestine in the gastrectomised animals. This was attributed to a failure of gastric sieving and to a shielding of fat from the digestive processes given the observation of many meat particles exceeding 0.5 mm in diameter, whereas fewer than 2% of particles were larger than 0.5 mm in the controls [24, 25]. There are no directly comparable studies in man, but investigation of iron absorption strongly suggests a similar phenomenon.

Under normal circumstances the absorption of radiolabelled iron from solid phase dietary muscle myoglobin is only minimally less than its absorption from an aqueous solution. However after Billroth I or Billroth II gastrectomy there is a markedly reduced absorption of iron from the solid phase [26]. It is thought that this reflects the failure of mixing

and sieving by the stomach, and the premature delivery of oversized iron-containing particles to the small bowel.

The Small Intestine After Gastric Surgery

Although there is some involvement of the small bowel in many gastric procedures—from the simple gastrojejunostomy to more complex multi-loop reconstructions—the general observation is that the small intestine remains normal macroscopically and histologically. At a cellular level the absorption of salt, water, soluble iron, glucose and fatty acids can all be shown to be normal [27].

Nonetheless intestinal factors contribute to post-gastrectomy malabsorption, mainly as a result of excessively rapid transit and a reduced time available for intraluminal digestion and absorption. When the intestine itself is normal this rarely presents a major nutritional challenge given generally high levels of reserve capacity [28], but if there is intestinal disease or if there has been small bowel resection then problems may be profound.

Pancreatic Function

The roles of the pancreas are closely aligned with those of the stomach, so it is to be expected that gastric surgery compromises its normal function to some extent. Selective proximal vagotomy appears to have no impact, but all gastric resections and drainage procedures reduce pancreatic exocrine function, typically by 30–50% from normal [22, 23], and a reduction of up to 70% has been reported after truncal vagotomy and pyloroplasty.

Direct study of pancreatic secretion is now rarely done and reference data are relatively aged, but robust evidence nonetheless exists for reduction in output of trypsin, chymotrypsin and amylase in response to secretin-cerulein stimulation. There is parallel perturbation of pancreatic endocrine function. Baseline and post-prandial levels of pancreatic polypeptide and gastrin are low, whilst meal-stimulated cholecystokinin is significantly increased [29], and abnormal glucose tolerance tests are common.

These reductions in pancreatic function are compounded by the loss of synchronous delivery of pancreatic secretions (and bile) as food enters the upper small intestine. The combined effect is of slower digestion of all macronutrients and especially of fat. The normal negative feedback loop that inhibits gastric emptying is also disrupted following many gastric surgical procedures adding to the problems, especially in the earlier phases of digestion.

Following all of the procedures in which the normal flow of nutrients across the outflow from the pancreas is disrupted (e.g. Billroth II gastrectomy and the Roux-en-Y reconstructions) pancreatic secretions are to some degree sequestered in the afferent loop of the small intestine and mix with the oesophagogastric effluent relatively late [10, 20].

The mechanisms that lead to pancreatic enzymes leaving the afferent loop are not fully elucidated, but are thought to depend on a combination of passive filling and overflow with some degree of active post-prandial motor function. It is probable that in most patients the reduction in pancreatic enzyme secretion is less important than the loss of synchronous timing of peak enzyme contact with food, as overt fat malabsorption can still be demonstrated in patients with more conservative procedures (such as Billroth I gastrectomy) where the total integral post-cibal pancreatic enzyme secretion is less affected. Maldigestion is most marked in the early phases after eating when there would normally be the most pronounced peak of enzyme secretion [20].

These observations have led to a range of suggested interventions to improve maldigestion and malabsorption of pancreatic origin after gastric surgery. Patients are usually advised to reduce the ingestion of oils and to take pancreatic enzyme supplements with meals. While these measures can be expected to ameliorate the pancreatic dysfunction [10, 30], the former restriction may add to the overall nutritional deficit. A small controlled trial of pancreatic enzymes after surgery for gastric cancer showed modest improvements in quality of life and a range of nutritional measures when compared with standard dietary advice alone [31]. When pancreatic enzymes are given it is important to prescribe preparations which do not depend on an acidic pH in order to release their contents.

More imaginatively (although as yet without convincing data) it is suggested that asynchrony is overcome by recommending that gastrectomised patients with an afferent pancreatobiliary loop should ingest a small quantity of fat or oil 60 min before ingestion of a meal [32]. This is intended to stimulate pancreatic secretion and to fill the afferent loop thus "priming" the system for the meal that is about to be ingested.

Overall Effects of Gastric Surgery on Absorption of Nutrients

Protein

Western diets generally yield protein intakes well in excess of requirements. Although some malabsorption of protein is demonstrable, along with azotorrhoea (protein in the stool), in patients who have undergone total or subtotal gastrectomy, it is not generally a clinical problem after gastric surgery.

Carbohydrates

Carbohydrate malabsorption is more of a problem. It is difficult to quantify accurately but it contributes to postoperative malnutrition, and also to a series of symptoms increasingly familiar to those exploring FODMAP intolerance in patients with irritable bowel syndrome and other functional disorders. The FODMAPs are Fermentable Oligosaccharides, Disaccharides, Monosaccharides, and Polyols, and comprise a group of poorly absorbed short-chain carbohydrates. These are the most likely to be malabsorbed after gastric surgery, but to their number will be added lactose and longer chain molecules including starch [33]. Absorption of the FODMAPs and other carbohydrates by the small intestine is compromised here predominantly through the effects of excessively rapid intestinal transit.

Malabsorption of sugars can be precipitated in completely healthy subjects if the ingested dose exceeds a threshold dictated by the speed of intestinal transit [34], so the gastrectomised patient can be seen always to be vulnerable. Flatulence, bloating, cramps and diarrhoea can all result and subclinical lactose intolerance may be unmasked [35]. Rarely, even glucose may be malabsorbed [36].

Fats

Clinical fat malabsorption with steatorrhoea does not occur following vagotomy alone [37] and is seldom present in patients following vagotomy and pyloroplasty or Billroth I gastrectomies [30]. Under normal circumstances less than 6% of ingested fat is lost in the faeces, but following Billroth II gastrectomy or vagotomy with gastroenterostomy, levels in the region of 8% are found. Following total gastrectomy 15–20% of dietary fat is typically malassimilated [10, 30]. This correlates quite tightly with deficiency of the fat soluble vitamins and especially of vitamin D (see below).

Micronutrients

Vitamin D in bone disease and deficiencies of haematinics in contributing to the anaemia seen after gastric surgery are considered below, but there is also evidence for specific deficiency of thiamine in more than 25% of patients even after relatively conservative surgery such as the gastric sleeve [38]. These patients also show frequent deficiencies in copper and pyridoxine [39] and while the bariatric population may be at particular risk there is no reason to be confident that these could not occur after surgery for other indications.

In Combination

Although nitrogen balance is not especially compromised after gastric resection it is clear that the many deleterious effects on digestion and absorption of carbohydrates and fats contribute to a global tendency to malnutrition. However neither weight loss, nutritional status nor changes in body composition correlate well with any individual component of the malfunctioning physiology [9].

Bacterial Overgrowth

Gastric acid normally makes an important contribution to the relative sterility of the proximal small intestine so it is to be expected that procedures which diminish or eliminate acid secretion will sometimes be complicated by small bowel bacterial overgrowth (SBBO). Bacterial counts of $>10^4$ colony forming units/ml are generally considered abnormal and counts of above 10^6 to be diagnostic. Diagnostic levels are found in patients after all types of gastrectomy [40, 41]. When there is a partially defunctioned/blind loop more than 50% of patients will be affected, and only with selective vagotomy do rates remain below 10% (British Society of Gastroenterology (BSG) Guidelines, accessible via https://www.bsg.org.uk/resource/guidelines-for-the-investigation-of-chronic-diarrhoea-in-adults%2D%2Dbritish-society-of-gastroenterology%2D%2D3rd-edition.html). The presence of bacteria (which are usually of the types considered colonic/faecal) does not correlate closely with clinical manifestations however and in at least one study colonisation was equally common in those with and without symptoms [41].

Clinical features attributed to SBBO include bloating and diarrhoea and/or steatorrhoea together with evidence of malabsorption particularly of vitamin B12. Investigation is troublesome as, apart from direct culture of small bowel aspirates, the available tests have very considerable false positive and false negative rates, not least because of the underlying rapid intestinal transit (BSG Guidelines: https://www.bsg.org.uk/resource/guidelines-for-the-investigation-of-chronic-diarrhoea-in-adults%2D%2Dbritish-society-of-gastroenterology%2D%2D3rd-edition.html). SBBO is therefore often a clinical impression and one which may be subjected to a diagnostic trial of antibiotic therapy, although this too can result in some misinterpretation through the possibility of a placebo effect in one direction or the choice of an antibiotic to which there is already resistance in the other.

Dumping Syndrome

Dumping syndrome has come to be considered the archetypal symptomatic complication of gastric surgery. First reported by Hertz in 1913 [42] and given its name by Mix in 1922 [43], early dumping is characterised by weakness, faintness or syncope, palpitations, pallor, sweating, nausea and vomiting, colicky abdominal pain and diarrhoea, one or more of which occurs typically 20–30 min after eating. In some patients features may arise sooner but it is rare for these symptoms to begin much later. Dumping is a direct consequence of excessively rapid gastric emptying (particularly of the liquid phase) with resultant delivery of hypertonic fluid into the duodenum. The ensuing reduction in vascular volume combined with stimulation and dilatation of the duodenum cause a marked neurohumoral response, not necessarily with hypoglycaemia. Vasoactive intestinal peptide, serotonin, neurotensin, enteroglucagon, peptide YY and kinins are all implicated [44, 45]. Their vasomotor effects are responsible for most of the distressing symptoms.

The so-called late dumping syndrome occurs at least an hour after eating. Also responsible for faintness, palpitations, perspiration and confusion, this is a consequence of the rapid transit of food causing excessive release of gastric inhibitory peptide and insulin which results in reactive hypoglycaemia [46, 47].

The dumping syndromes can be a major contributing cause to malnutrition if their effects are sufficient to deter the patient from eating. Relatively small, frequent meals should be encouraged with an emphasis on foods of low glycaemic index. Monosaccharide-based drinks in particular should be avoided. Measures to slow gastric emptying with pectin, glucomannan, acarbose or loperamide can be helpful in some patients [47].

Somatostatin acts as a natural counterweight to the gastrointestinal neurohumoral response, and its longer-acting analogues octreotide and lanreotide can slow gastric emptying of liquids and solids, slow orocaecal transit, and reduce the plasma levels of several of the implicated hormones. In patients where simpler (and cheaper) measures have failed, octreotide (50–100 μg) given subcutaneously about 30 min before meals is often effective in control of dumping symptoms [47]; monthly injections of lanreotide may have a similar effect.

Post-vagotomy Diarrhoea

Diarrhoea is common after truncal vagotomy. Depending on the definition it occurs in 2% [48] to 53% of patients [49]. In a study of 102 patients studied a mean of 13 years after vagotomy and pyloroplasty, 53% had diarrhoea compared to 7% of a control group. In 11% the diarrhoea was continual, and a further 22% of patients had at least one episode of diarrhoea each week [49]. In 8% of patients the diarrhoea had been a serious problem because of sudden and unpredictable onset, sufficient at times to lead to incontinence.

The diarrhoea in this syndrome appears to be related to the truncal vagotomy and not to whether patients have had a pyloroplasty or a gastroenterostomy. The pathogenesis rests on rapid gastric emptying and rapid upper gastrointestinal transit which results in reduced digestion and absorption in the small intestine and delivery of an osmotic load to the colon (confirmed by intubation studies [50]). Transit can be so fast that it even overwhelms the gut's ability to absorb glucose [36, 50]. On glucose/hydrogen breath testing there is a rapid rise in breath hydrogen coinciding with delivery to the caecum at a mean transit time of 25 min. There may also be may a contribution from the cathartic action of bile acids reaching the colon. A controlled study demonstrated higher total bile acids in the faeces (in particular chenodeoxycholic acid), in patients with post-vagotomy diarrhoea than in controls [51]. Results from patients who had undergone a vagotomy but did not have diarrhoea lay between those from these two groups. Nonetheless, in affected patients, avoidance of food to reduce symptoms is more commonly the reason for weight loss than malabsorption. Vagotomised patients fortunate enough to avoid post-vagotomy diarrhoea are thought to have particularly efficient colonic salvage [28].

Treatment of post-vagotomy diarrhoea is predominantly with the use of antimotility agents. In one study codeine phosphate (60 mg) and loperamide (12–24 mg) delayed transit by 58 min and 63 min respectively, and improved symptoms dramatically in most patients [36]. It is key to give such drugs in sufficient dose and at least 30 min before a meal, since ingestion immediately prior to or with food may even aggravate dumping.

Treatment with Lomotil (diphenoxylate hydrochloride and atropine sulphate) reduced stool frequency to a significant degree, but did not prove useful in the prophylaxis of the more severe attacks of diarrhoea [52]. In an attempt to reduce the rapid efflux of food from the stomach to the small bowel, McKelvey *et al* reduced the liquid content of meals. Low fluid meals gave complete control of diarrhoea in two patients, and improved the diarrhoea in 12 patients, (less frequency: $n = 12$; less urgency: $n = 9$), only 4 failing to respond [19]. In patients with more resistant diarrhoea, however, such manipulation of meal content is less successful. Some patients will also respond to bile salt binding agents such as colestyramine [51, 53, 54] and there is a good case for SeHCAT scanning in gastrectomised patients with diarrhoea (BSG Guidelines: https://www.bsg.org.uk/resource/guidelines-for-the-investigation-of-chronic-diarrhoea-in-adults%2D%2Dbritish-society-of-gastroenterology%2D%2D3rd-edition.html).

Anaemia Following Gastric Surgery

Anaemia is common after gastric surgery. Although the reported incidence after resection ranges from 3% to 77%, in most series the frequency is around 30% [55–57]. Anaemia is more common following operations for gastric ulcer (e.g. 30%) than duodenal ulcer (e.g. 9%) [58, 59], and patients with Billroth II anastomoses are affected more commonly than those with a Billroth I anastomosis [55, 58, 60]. After uncomplicated gastroenterostomy anaemia (generally iron-deficient) is more unusual, and vagotomy and pyloroplasty alone are rarely followed by anaemia [18, 19].

Deficiencies of iron and B_{12} make approximately equal contributions to the incidence of anaemia following partial gastrectomy, with folate deficiency being less common [60]. The relative contributions are typified by Shafer et al.'s study of 142 male patients an average of 8.3 years after surgery, 33 of whom had Billroth I and 109 Billroth II gastrectomies [61]. Anaemia was present in 69 of the 142 patients, 32% of whom were found to have predominant iron deficiency, 42% vitamin B_{12} deficiency, and 25% folate deficiency. In 23% of the anaemic patients there was isolated iron deficiency, in 20% isolated B_{12} deficiency and in 9% isolated folate deficiency; mixed deficiencies were present in the remaining 48%.

Following total gastrectomy a similar frequency and spectrum of anaemia is found. Anaemia is present in about half of cases, with evidence of iron deficiency in half of these, the precise figures tending to increase the longer patients survive following surgery [62].

Iron Deficiency

Iron deficiency thus occurs in 30–50% of patients following partial gastrectomy and is the main cause of about 50% of post-operative anaemia [60]. The causes of iron deficiency are multifactorial. Dietary deficiency may contribute but is not found uniformly [59]. Chronic faecal blood loss, as measured by chromium-labelled red cell studies, is typically 3.2–6.5 ml/day and surely contributes to the anaemia [63]. It has been suggested that there is an inability to up-regulate absorption in the iron-deficient state [64]. Reduced acid secretion from the operated stomach reduces the absorption of inorganic iron, and there may be a contribution from high mucosal cell turnover. Rapid intestinal transit through the upper gut and/or bypass of the duodenum, which is the preferential site for iron absorption, almost certainly also contributes [65]. Replacement with oral iron is usually sufficient treatment when iron deficiency is found, provided other causes have been adequately excluded (see below).

Vitamin B_{12} Deficiency

The incidence of overt vitamin B_{12} deficiency following gastric resection is typically in excess of 15% [55, 59]. In one series of 351 patients with Billroth II anastomoses, 36% of patients had low (20%) or borderline low (16%) B_{12} levels [66], though other authors using more subtle measures such as red cell B_{12} and the presence of hypersegmented neutrophils suggest that minor deficiency may be present in 68–l00% of patients [60]. The prevalence of B_{12} deficiency increases with time from surgery. These figures are of course despite the well-recognised risks of B_{12} malabsorption and reflect a failure to use prophylactic treatment.

Lack of intrinsic factor contributes to the deficiency in about half of affected patients [59, 66], though elective assessment of B_{12} absorption shortly after surgery suggests it is usually normal at that stage [67]. The explanation may lie in that, although pure B_{12} absorption is normal when measured by conventional absorption tests, such as the Schilling test [68], the abnormal emptying of food particles from the stomach and their subsequent impaired digestion may reduce B_{12} availability from a normal diet [69].

It is unclear how much bacterial overgrowth in the small intestine contributes to B_{12} deficiency, but some bacteria certainly have the ability to compete for dietary B_{12}. In some patients with a Billroth II anastomosis, treatment with a broad-spectrum antibiotic has been shown to correct B_{12} deficiency. Similarly pancreatic insufficiency is a compounding factor in patients with Billroth II anastomoses and may too reduce the absorption of B_{12}. The relative contributions of these causes remain uncertain, but regular treatment with parenteral B_{12}—usually 1 mg im every 3 months—is safe and highly reliable and should be the preferred method when B_{12} deficiency is identified or strongly predicted.

Folate Deficiency

Although dietary inadequacy is common and serum folate levels are often a little low after gastric resection [59], resultant anaemia is relatively rare, being the main cause in no more than about 5% of patients [58]. It should nonetheless be sought in any patient who is anaemic. Oral replacement should be given orally when levels are low and also for short-term prophylactic cover in patients receiving iron or vitamin B_{12} for deficiencies of these haematinics to prevent the unmasking of borderline folate deficiency during the rapid haemopoiesis induced with treatment.

Metabolic Bone Disease

Metabolic bone disease—both osteoporosis and osteomalacia—are commonly reported after gastric surgery with an incidence of up to 25% [30]. When specifically sought, bone pain and tenderness are reported by 6 times as many patients as age-matched controls [70]. Serum calcium levels are also lower in patients (though usually within the normal range), associated with demonstrable reduction in calcium absorption [71]. Similarly, inorganic phosphate levels are low in 5% of patients and serum alkaline phosphatase tends to be elevated. Radiological evidence of osteopenia can be found in 24% (controls 4%).

It has been suggested that vitamin D and calcium loss may be proportional to loss of faecal fat, which would be consistent with the general observation that bone disease affects patients following total gastrectomy and Billroth II rather than Billroth I partial gastrectomy [70]. Dietary deficiency of vitamin D may contribute. In the bariatric population where there is a pre-operative tendency to secondary hyperparathyroidism the prevalence of this condition doubles post-operatively—again with a frequency related to the magnitude of the operative procedure [72].

It is reasonable to advise a higher than normal intake of vitamin D and calcium prophylactically after gastric resection. Regular (e.g. alternate year) monitoring of bone density should be considered. Those with overt bone disease should be managed actively with higher dose oral vitamin D and a low threshold for its parenteral administration if the serum level of hydroxy-vitamin D does not respond. In osteoporosis consideration of bisphosphonates will also often necessitate parenteral dosing given the poor absorption and frequent oesophageal toxicity of these drugs when given by mouth. Nonetheless, despite the frequency of metabolic bone disease after gastric surgery there is surprisingly little evidence of increases in fracture rates.

Other Complications of Gastric Surgery

Patients who have undergone gastric surgery remain at risk of the usual hazards of previous abdominal surgery such as incisional hernia and adhesions, which may occasionally lead to additional complications and thus a route to intestinal failure through the need for further surgery and the risk of short bowel syndrome.

Systemic infection is also more common in the post-gastrectomy patient indicating a general level of depressed immunity which is probably distinct from malnutrition and independent of underlying malignancy [73]. There are also more specific late complications of gastric surgery which warrant attention and in many cases formal endoscopic surveillance.

Anastomotic ulcers are most often seen in patients whose surgery was for peptic ulcer, and with modern medical management of ulcer disease these patients are becoming rare, but these can be responsible for significant overt upper gastrointestinal bleeding as well as for more subtle presentations with iron deficiency anaemia. Endoscopic detection (and sometimes therapy) in combination with proton pump inhibitors and eradication of residual *H. pylori* is usually sufficient, but revisional surgery with its attendant risks is occasionally required.

Neoplasia in the Residual Stomach

There is a definite increase in the risk of gastric carcinoma in the partially resected stomach, a risk which will normally be sufficient to justify long-term endoscopic surveillance. New symptoms, including late deterioration from a nutritional point of view, between procedures should also prompt consideration of this possibility.

Failure to Regain Weight Lost in the Absence of any Overt Explanation

The great majority of patients loses weight after gastric resection, and although some younger patients can make good this loss over a year or so, most patients will never regain their premorbid weight. There does not seem to be a single or reversible explanation for this and it is now becoming conventional to think of it as a form of sarcopenia. Progress in the management of sarcopenia in general may yield specific new interventions, but it is probable that a combination of optimized nutrition with a physical exercise programme offers the current best chance of success.

Summary

Subtotal and total gastrectomy frequently lead to symptoms resulting in a change in eating habit and more rarely result in malnutrition which reflects maldigestion, malabsorption and motility problems. The resultant malnutrition may be global, affecting all nutrient groups, or limited to specific nutritional deficiencies such as of lipid soluble elements or individual vitamins. Established intestinal failure is most unusual unless there have also been major post-operative complications. Less invasive gastric surgery is also associated with nutritional problems, but at lower levels of frequency and severity.

The causes of malnutrition are often multifactorial and a knowledge of the likely problems and an understanding of the pathophysiological mechanisms help to organize the approach for the individual patient. A combination of dietary changes, drug therapy to slow transit or bind bile salts, or supplementation with enzymes and addition of dietary supplements, usually leads to successful control of the problem. Nonetheless, most patients remain underweight in the long-term.

Surgery for Obesity and Its Consequences

Cynthia-Michelle Borg and Jean Deguara

Key Points

1. Bariatric surgery is performed in patients suffering from obesity when non-surgical techniques have been unsuccessful and the BMI is greater than 40 kg/m^2 (or 35–40 kg/m^2 if obesity complications).
2. Laparoscopic sleeve gastrectomy and Roux-en-Y gastric bypass are the most commonly performed bariatric operations.
3. Patients with abdominal pain and vomiting at any time after a Roux-en-Y gastric bypass may have an internal (mesenteric) hernia and should be urgently investigated and treated (to prevent bowel resections due to ischaemia).
4. Patients should have lifelong annual follow up with regular blood tests depending on the operation and local guidelines.
5. Cholelithiasis is common and if suspected confirmed by ultrasound.
6. Some of these patients may present to IF/HPN centres due to weight loss (especially if small bowel has been resected due to ischaemia) or if an enterocutaneous fistula(s).

Introduction

Obesity is a chronic, progressive and complex disease. It is defined as an excessive accumulation of body fat that can impact the health or the wellbeing of an individual. A body mass index (BMI) of 30 kg/m^2 or more is often used to define obesity.

In 2016, the World Health Organization (WHO) estimated that 13% of adults (18 years and over) worldwide suffered from obesity [1]. The Health Survey for England in 2018 reported that 26% of men and 29% of women were obese, with 2% of men and 4% of women suffering from morbid obesity (BMI of 40 or more) [2].

Obesity is associated with numerous medical complications, worse quality of life and a shorter life expectancy [3]. In particular, excess body weight is associated with metabolic problems including type 2 diabetes (T2D), non-alcoholic steatohepatitis (NASH) as well as cardiovascular disease and some types of cancers. Central weight distribution with a waist circumference of more than 80 cm in women and 94 cm in men puts the individual at higher risk of development of cardio-metabolic complications [4].

Mechanical problems like obstructive sleep apnoea and musculoskeletal issues are also common in patients suffering from obesity. They may also experience higher levels of depression, anxiety and low self-esteem.

Weight loss has been shown to improve cardio-metabolic problems associated with obesity as well as increase the life expectancy. A 10 kg weight loss has been found to be associated with a 10 mmHg fall in systolic blood pressure, a 20 mmHg fall in diastolic blood pressure, 10% lowering of the total cholesterol and improvement in the lipid profile. A fall of 30–50% in fasting blood glucose and improvement in HbA_{1c} are also observed with weight loss [5].

The regulation of food intake and body weight is complex with signals from body fat, the gut and the pancreas to the hypothalamus and the brainstem together with signals from the higher reward centres.

The ideal weight loss management should improve the health, wellbeing and life expectancy of the individual, prevent obesity related complications, be safe and lead to sustained weight loss. Although, lifestyle measures that involve dietary restrictions may initially be associated with good weight loss, long-term weight regain is common [6].

Bariatric surgery leads to significant, sustained weight loss with improved medical issues and survival [7]. This is

J. M.D. Nightingale (ed.), *Intestinal Failure*, https://doi.org/10.1007/978-3-031-22265-8_20

because surgery not only induces a decrease in food intake but is also associated with changes in signals from the GI tract leading to increased satiety and fullness, decreased hunger sensation and changes in taste and smell [8].

Adequate patient preparation, proper choice of the primary procedure and long-term follow-up are very important. The criteria and indications for the use of bariatric surgery have been extensively debated in the surgical literature and in conferences. Most bariatric multidisciplinary teams use the guidelines published by the National Institute for Health in the USA [9] or by the National Institute of Clinical Excellence in the UK [10].

In its 2014 guidelines, NICE advises that patients undergoing bariatric surgery should have tried all appropriate, available non-surgical measures for weight reduction but failed to achieve or maintain clinically beneficial weight loss. They should have a BMI of 40 kg/m^2 or more, or between 35–40 kg/m^2 with obesity related co-morbidities. Patients with a BMI of 30–34.9 kg/m^2 who have recent-onset T2D should also be offered an assessment for bariatric/metabolic surgery. A slightly lower BMI may also be considered in patients with T2D of Asian family origin. Patients require multidisciplinary team management and should be fit for general anaesthesia and surgery. Pre-operatively, medical or psychological contraindications need to be excluded and patients are required to understand the need for long-term post-operative follow-up [10].

The number of bariatric surgery operations being performed has increased over time. The International Federation for the Surgery of Obesity and Metabolic Disorders (IFSO) Global registry collates data from around the world. In its latest publication, the most commonly performed primary operation was the sleeve gastrectomy (46.0%) followed by the Roux-en-Y gastric bypass (38.2%), the one anastomosis gastric bypass (7.6%) and gastric banding (5.0%) [11]. Bariatric surgery has evolved over the years.

Bariatric and Metabolic Procedures

Historic Operations: Jejuno-Ileal and Jejuno-Colic Bypass

The concept of surgery for severe obesity was introduced in the 1950s. The first reported case in the literature was an end-to-end jejuno-ileal bypass (JIB) in 1954 [12]. It aimed to induce weight loss by malabsorption. Jejuno-colic bypass (JCB) was also performed with the proximal 15 cm of the jejunum being joined to the mid-transverse colon [13]. In 1969, Payne et al. reported the results of 11 patients who had JCB. These patients had developed uncontrollable diarrhoea with associated dehydration and electrolyte imbalance. The authors thus advised against such procedures recommending JIB as an alternative [14]. Several variations, in terms of limb lengths and the faith of the bypassed small bowel, were described. JIB, though associated with excellent weight loss and improvement of hyperlipidaemia, was itself found to be associated with a multitude of serious complications. These included hypoalbuminaemia and deficiency of calcium, fat-soluble vitamins and vitamin B12 resulting in osteoporosis, osteomalacia, night blindness, anaemia and peripheral neuropathy [14]. Diarrhoea and electrolyte imbalance were also common. Migratory polyarthralgias, cholelithiasis, liver cirrhosis and liver failure developed in some patients [15]. Other long-term complications included renal disease secondary to hyperoxaluria with the development of oxalate stones and interstitial oxalate deposition potentially leading to renal failure [16]. The bypassed small bowel segment was also prone to various problems including intussusception and small intestinal bacterial overgrowth (SIBO). As a result of these serious complications, JIB was abandoned by the 1970s and most patients had their procedure reversed, with or without another metabolic/bariatric operation being performed concurrently. There are still, however, some patients living well with this operation. Most bariatric surgeons will advise close, lifelong follow-up in this patient group to detect complications early and most would offer reversal of the surgery should these arise.

Operations Involving the Stomach Only

Gastroplasty

Gastroplasty involved the partitioning of the stomach creating a small proximal pouch, which communicated with the distal and larger portion of the stomach via a restrictive channel. The most popular variety, developed by Mason [17], used a vertical segment of stomach along the lesser curve for the pouch (Fig. 1) and was thus called a vertical banded gastroplasty (VBG). The volume of the pouch was standardized to 14 mL at the time of surgery and a polypropylene band was placed around the lower end of the pouch to prevent dilatation. The band's circumference was standardized and fixed at 5 cm. Different variations of this procedure exist [17]. VBG was sometimes complicated with stomal stenosis and gastro-oesophageal reflux (GORD) symptoms. It had inferior long term weight loss when compared to RYGB often due to the formation of gastro-gastric fistulas between the two partitioned parts of the stomach thereby negating the restrictive effect. Since the development of adjustable gastric banding, VBG is obsolete although again, there are some patients still living with this operation.

Gastric Banding

Adjustable gastric banding involves the laparoscopic positioning of a silicone band around the upper part of the stom-

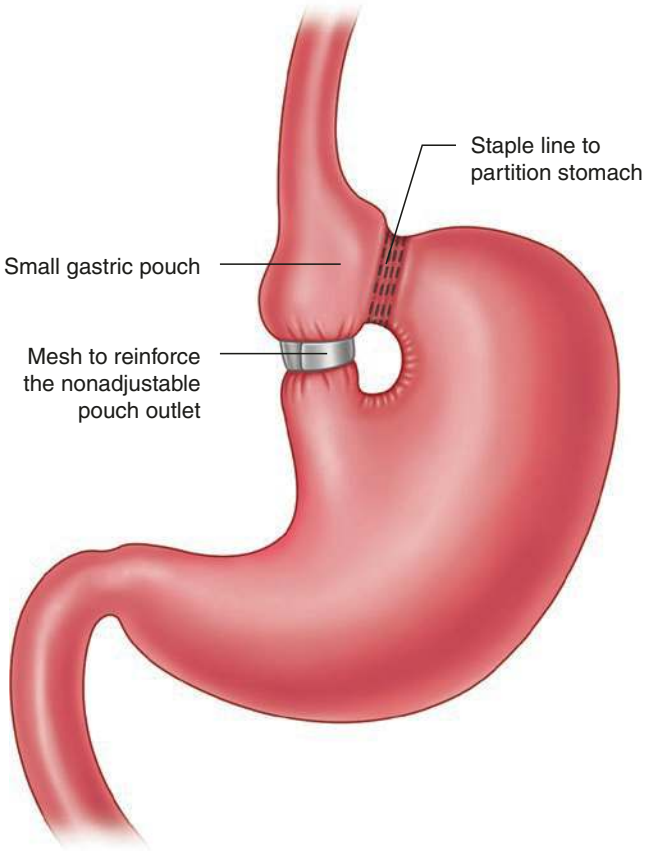

Fig. 1 Vertical banded gastroplasty VBG

ach (Fig. 2) creating a small proximal gastric pouch that is usually calibrated to have a capacity of 15–20 mL. The undersurface of the band has an inflatable inner cuff, which is connected by a tube to a subcutaneous port. The size of the pouch outlet can be adjusted by varying the volume of fluid in the band through the port using a non-coring needle. The amount of fluid is adjusted until the patient is in the 'green zone'—when weight loss is achieved by inducing an early feeling of satiety after eating smaller amounts of food than before the surgery.

While band insertion is safe and can often be performed as a daycase procedure, long-term complications like band erosion, slippage and pouch and oesophageal dilatation can occur. Between 30–40% of patients who undergo banding will require revision surgery by 7 years post-op [18]. Weight loss with GB is usually slower and lower than after RYGB and the SG. Results may vary from centre to centre depending on patient selection and the intensity of follow-up.

Sleeve Gastrectomy

Sleeve gastrectomy SG (Fig. 3) involves the excision of most of the greater curve of the stomach and the fundus using surgical staplers, with the remaining stomach having a tube like appearance with a reduced volume (usually less than 100 mL). The diameter of this tube is standardized by using an orogastric bougie which may vary in size from centre to centre [19]. Besides being a restrictive operation, sleeve gastrectomy has also been found to be associated with acceleration in gastric motility [20] and changes in gut hormones [8, 21]. Although initially intended as the first step before RYGB or duodenal switch (DS) operation in patients with very severe central obesity [22], sleeve gastrectomy is increasing being offered as a single stage bariatric procedure. It is currently the commonest primary bariatric procedure performed worldwide [11].

Most surgeons would regard the presence of Barrett's oesophagus as a contraindication for SG. Post-operative complications may include staple line bleeding, leaks, twists and strictures. Long-term issues with post-operative GORD may require lifelong medication or revision surgery.

Gastric Plication

Laparoscopic gastric plication is the infolding of the greater curvature to reduce stomach volume using running sutures. While cheaper than LSG, the long-term results and the durability of the operation are uncertain and most surgeons would regard it as investigational [23].

Operations Involving the Stomach and Small Bowel

Roux-en-Y Gastric Bypass (RYGB)

The RYGB has, for many years, been regarded as the gold standard bariatric operation (Fig. 4). It was first described in 1967 by Mason et al. [24], with the first laparoscopic procedure performed in 1994 [25]. It involves the creation of a small stomach pouch (based on the lesser curvature). A cut Roux loop of jejunum (the alimentary limb) is joined to the pouch to allow food to bypass the larger, distal part of the stomach, the duodenum and the first part of the small bowel (the biliopancreatic limb). The alimentary and biliopancreatic limb are anastomosed to allow intestinal continuation and mixing of food and digestive enzymes digestion occurs in the common channel. The standard length of the alimentary limb is usually around 100–150 cm with the biliary limb being 60–100 cm although some surgeons may use longer limbs especially in patients with a BMI of 50 kg/m^2 or more [26]. The small gastric pouch restricts the amount of food that can be eaten while bypassing of the duodenum induces changes in gut and pancreatic hormone secretion leading to metabolic and hormonal changes that are associated reduced appetite and an increased feeling of satiety and fullness.

Fig. 2 Gastric banding

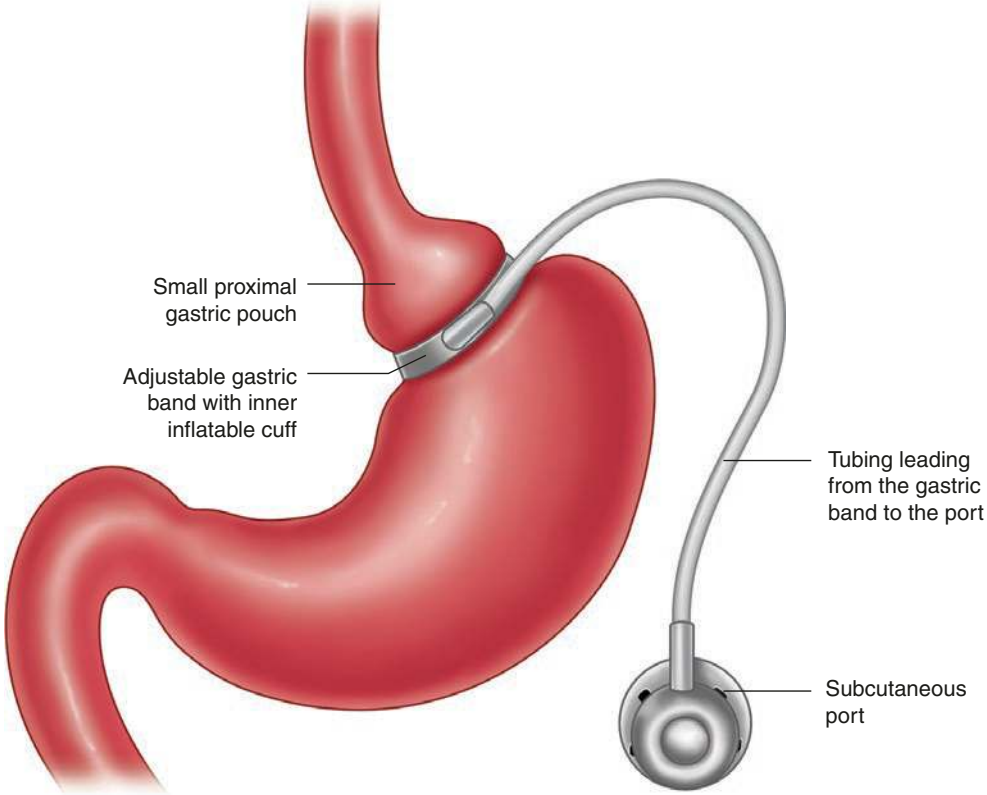

Fig. 3 Sleeve gastrectomy SG

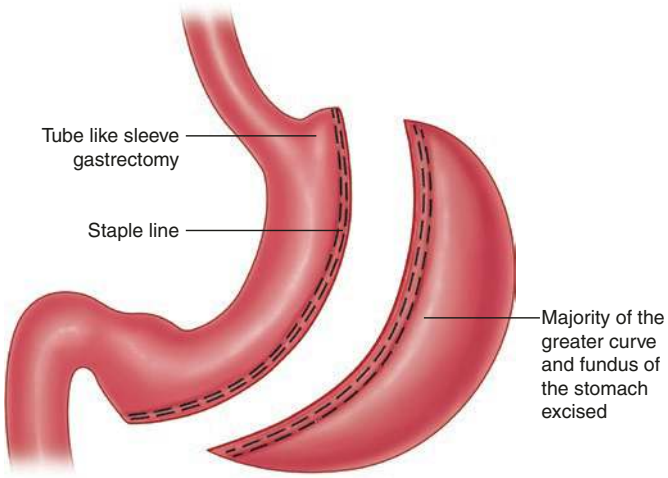

There are also changes in gut microbiota, bile acid levels and composition and intestinal motility [8].

Contra-indications for RYGB include small bowel disease such as adhesions or Crohn's disease as well as conditions that require access to the stomach (eg in areas or families with high incidence of gastric cancers), the duodenum and biliary tree. Complications of RYGB may include bleeding, anastomotic leak, anastomotic ulceration and strictures, dumping syndrome, internal herniation and mineral and vitamin deficiency.

One Anastomosis Gastric Bypass (OAGB)

The OAGB was first described by Rutledge in 2001 [27]. It is also known as the single anastomosis or the mini-gastric bypass. A long tube-like proximal pouch of stomach is created from the lesser curvature side. Intestinal continuity is re-established by connecting the gastric pouch to a loop of jejunum bypassing up to 100–250 cm of the proximal jejunum (biliopancreatic limb). As it has one less anastomosis, OAGB has a shorter operating time when compared to RYGB.

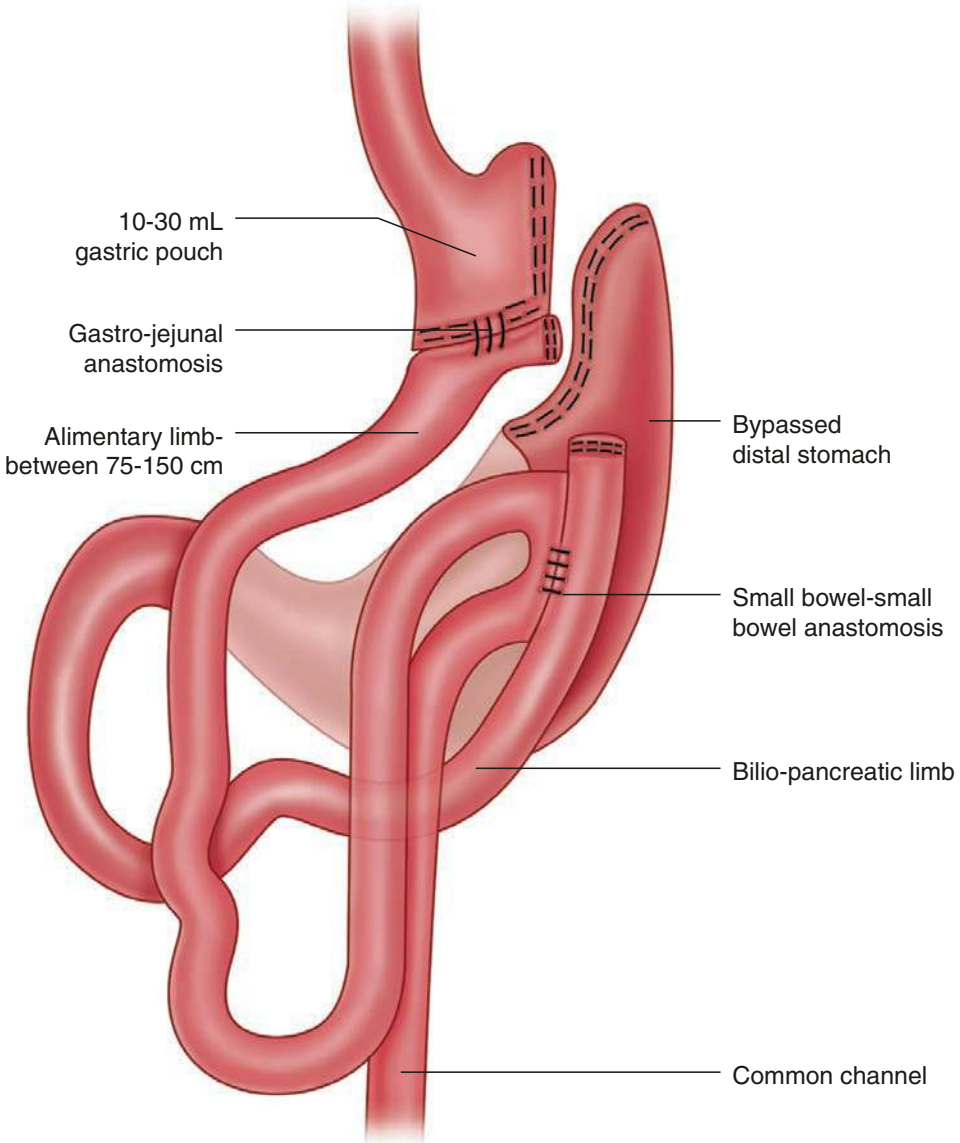

Fig. 4 Roux-en-Y gastric bypass RYGB

Long-term data shows that the OAGB using biliopancreatic limbs of over 150 cm may result in a slightly better weight loss and better resolution of diabetes than the RYGB [28]. Some surgeons believe that long-term, OAGB has a lower risk for internal herniation than the RYGB. The recent YOMEGA trial has been however showed that OAGB with a 200 cm small bowel biliopancreatic limb has more malabsorptive complications when compared to RYGB [29]. Bile reflux into the stomach with gastritis and oesophagitis is common and may adversely affect the patients' quality of life [30]. The long-term effects of this are uncertain.

Other Operations

The bilio-pancreatic diversion (BPD) (Fig. 5) was described by Scopinaro [31] and involved the creation of a 200–500 mL gastric pouch and a distal two-thirds gastrectomy. Intestinal continuity was achieved by the formation of a gastro-ileostomy 250 cm proximal to the ileocaecal valve. The biliopancreatic limb was then anastomosed to the alimentary limb creating a common channel, which originally was described as around 50 cm. Most surgeons increased the length of the common channel to at least 100 cm in an attempt to limit the malabsorptive symptoms. BPD is more technically demanding than other bariatric procedures and carries the morbidity of a partial gastrectomy. It has been reported to have the best results in terms of weight loss and resolution of T2DM [32]. It can result in significant malabsorptive complications and patients undergoing this procedure require strict compliance, close follow-up and long-term nutritional supplementation [33].

Variations of BPD include the duodenal switch (DS) as described by Hess [34]. This involves a sleeve gastrectomy with preservation of the pylorus (Fig. 6). Like the BPD, DS is technically challenging and may lead to protein, mineral

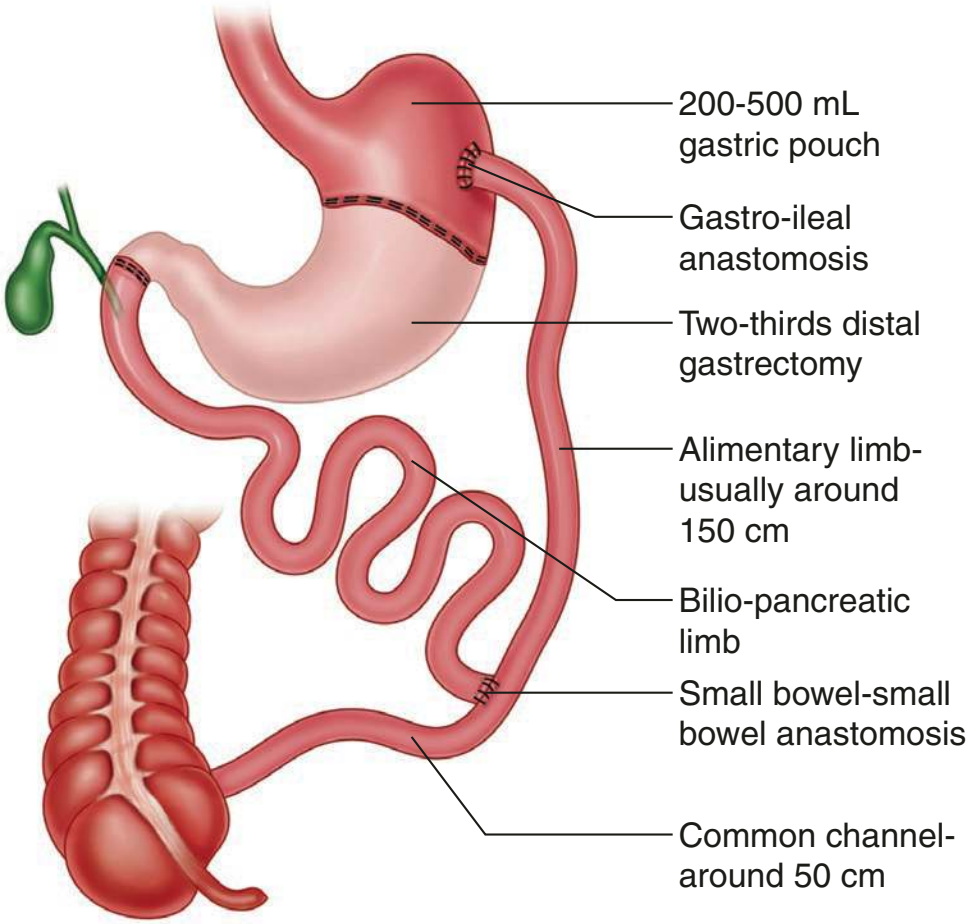

Fig. 5 Biliopancreatic diversion BPD

and vitamin deficiency. A further recent modification of DS, the single anastomosis duodenal-ileal bypass with sleeve gastrectomy SADI-S (also known as the one anastomosis duodenal switch), utilizes a single anastomosis. It was first described Sanchez-Pernaute et al. and anastomoses the duodenum directly to an omega loop of ileum 200–300 cm proximal to the ileo-caecal valve, eliminating the need for the Roux-en-Y jejunal-ileal anastomosis [35]. Such an operation may play a role in the management of patients who have a BMI of over 60 or for those with weight regain or poor weight loss after SG in the future. Both IFSO [36] and American Society for Metabolic and Bariatric Surgery (ASMBS) [37] have highlighted the lack of long-term data about SADI-S at this stage.

Endoscopic Bariatric and Metabolic Therapies

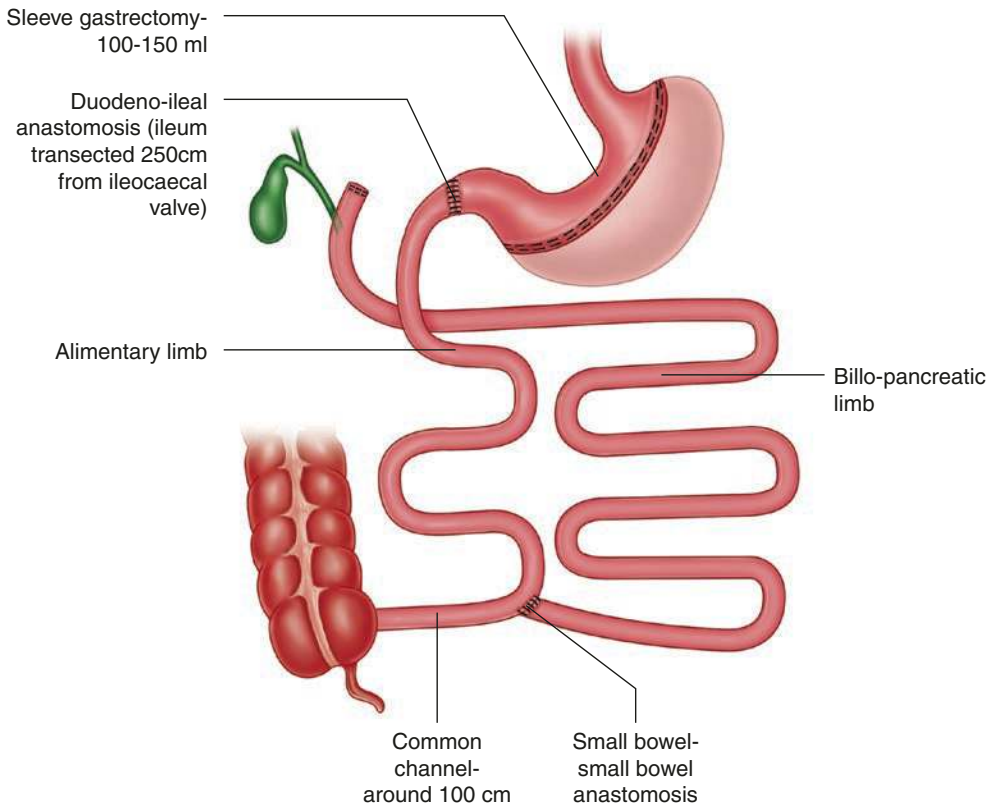
Endoscopic bariatric and metabolic therapies (EBMT) are a relatively new modality in the management of obesity. They are important, alternative treatment options for patients suffering with obesity but who have relatively low BMIs and those who are not keen to undergo surgery. They may also be used as a bridge to surgery in patients with severe obesity. They are generally divided into gastric and small bowel procedures.

The gastric therapies include intragastric balloons, the gastric aspiration system and endoscopic sleeve gastroplasty (ESG).

The intragastric balloon (IGB) is a space-occupying device. Several different types of IGBs are licensed for use including ones that are liquid or air filled, some that require endoscopic insertion and removal (usually made of soft silicone), others that do not need endoscopic removal as they disintegrate after 16 weeks and others that are swallowable. Most of the soft silicone balloons require endoscopic removal after 12 months. While they can be replaced by a new IGB, they are not a durable, long-term solution for severe obesity [38]. They however do result in modest weight loss and improvement in quality of life whilst in situ.

Contraindications to IGB placement include a history of gastrointestinal surgery and large hiatal hernia. Nausea is a common side-effect especially early on after IGB insertion. Although most patients will improve with time and antiemetics, some IGBs need to be removed early due to intolerance. The Brazilian Intragastric Balloon Consensus

Fig. 6 Duodenal switch DS



Statement reported on their experience of over 40,000 IGB implantations in 2018 and showed that that implantation is safe and effective [39]. The most common complications in this large series were hyperinflation, deflation, migration and ulceration [39]. Gastric perforation and small bowel obstruction secondary to migrated IGB are rare.

Gastric aspiration therapy involves the insertion of a gastrostomy tube (A-tube). Together with a siphon assembly, it allows the patient to aspirate gastric contents 20 min after eating. Aspiration usually takes about 10 min and reportedly removes approximately 30% of ingested calories. It is licensed for used in patients with a BMI of between 35–55 kg/m^2 in the setting of a multidisciplinary program to adjust eating behavior. In motivated and compliant patients, it has safe and durable weight loss [40]. Skin irritation around the stoma site is common. Persistent gastric fistula requiring surgical closure may occur once the A-tube is removed.

Endoscopic sleeve gastroplasty (ESG) attempts to reduce the volume of the stomach, recreating the gastric plication using a transoral endoscopic suturing platform. It is mostly used in patients with BMI 35.0–39.9 but it may be play a role in patients who are unfit for laparoscopic surgery. The technique results in short and medium term weight loss but long-term data regarding durability is lacking [38].

The duodenum and proximal jejunum have been recognized as a key metabolic signaling center. The EndoBarrier duodenal-jejunal bypass liner (DJBL) was developed to avoid contact of food with the mucosal lining of the duodenum and proximal jejunum. The device consists of a ring that anchors on the duodenal bulb connected to a 60 cm Teflon liner that covers the mucosal surface of the duodenum and proximal jejunum. It has a modest weight loss effect but has been shown to ameliorate T2D control whilst the device is in place [41]. It is not currently in clinical use due to a high incidence of adverse effects especially liver abscesses reported during a US pivotal trial.

Duodenal mucosal resurfacing involves circumferential mucosal lifting followed by hydrothermal ablation of duodenal mucosa. It has been showed to improve glycaemic control in patients with suboptimally controlled T2D [42]. The mechanism of how and why this happen is uncertain. Whether the effect will be sustained in the medium and long term is also unknown. Adverse effects are common, most are mild but duodenal stenosis may occur.

Consequences of Bariatric Surgery

Early Post-operative Complications

Laparoscopic bariatric surgery is safe and effective. In the UK, the in-hospital mortality rate is around 0.061% with the 30-day mortality being reported at 0.13% by Hospital Episode Statistics (HES) [43]. Although early complications often represent to the bariatric centres where the surgery was performed, awareness of such presentations by other clinicians is important especially due to the rise in bariatric tourism. Early complications may include leakage or bleeding from anastomosis and staple lines, venous thromboembolism and chest, wound and urinary infections.

Patients suffering from morbid obesity may not present with typical signs of sepsis and peritonism and a high index of suspicion is required. Tachycardia and tachypnoea may be the only features in this patient group.

Bleeding occurs in less than 1% of cases [44] and may be intra-luminal, presenting with meleana and haematemesis, or intra-peritoneal. Most patients settle with close monitoring and conservative management with or without blood products. Some however may need endoscopy or re-laparoscopy if unstable or having increased transfusion requirements.

Leaks may occur from anastomosis sites, from staple lines or from iatrogenic bowel injuries. With improvement in staple line technology and operative techniques, the risk of leaks continues to decrease and the incidence is currently quoted as less than 0.5% [44]. Leaks usually present between day 5–10 post-operatively. Abdominal pain may not be a feature with patients presenting with fever, shoulder tip pain and non-specific symptoms instead. A high index of suspicion and early investigation with contrast imaging or a re-laparoscopy is essential to avoid deterioration and long-term consequences.

Venous thromboembolism (VTE) was found to have a significant effect on readmission and mortality post-bariatric surgery [44]. Longer operations, past history of VTE and blood transfusion have been found to increase the risk of VTE [45]. Most surgeons encourage the peri-operative use of thromboembolic deterrent stockings, intermittent pneumatic compression intra-op, early mobilization, prophylactic anticoagulation and patient education for early recognition.

Portomesenteric and splenic vein thrombosis (PVT) is a rare yet occasionally catastrophic complication of bariatric surgery. PVT is a well-recognized complication of upper GI surgery including fundoplication and gastric resection. It may also occur within the first month after bariatric surgery especially after SG. Risk factors include recent oral contraceptive use, smoking, a history of malignancy, T2D and a history of pro-thrombotic genetic tendencies including Protein C and S deficiency and Prothrombin 20210 mutation [46, 47]. The use of high intraperitoneal pressure during laparoscopy may also play a role. Patients often present with non-specific abdominal pain. CT scan with intravenous contrast is often diagnostic. Most patients can be treated non-operatively with anticoagulation but some may require surgery if they develop bowel necrosis. Such patients may end up with massive small bowel resection and subsequent short-bowel syndrome. In the literature a mortality rate of about 4% is described with PVT.

Medium/Late Gastrointestinal Complications

Vomiting

Nausea and vomiting are common in the first few months after surgery and often settle as patients get used to their new eating habits. Patients may be unable to progress to a solid diet and persist on a liquid or soft diet. Common pitfalls include eating too fast, not chewing the food thoroughly and mixed food and water. If these symptoms persist, investigation of the post-operative anatomy with upper GI endoscopy and/or contrast studies is important to exclude strictures especially at the site of gastro-jejunal anastomosis or any other intra-operative mishap eg Roux-en-O reconstruction [48].

Sometimes with SG a functional twist can arise in the body of the sleeve. Although there is no anatomical obstruction on endoscopy, this may often be demonstrated with a contrast study. Other causes on nausea and vomiting including pregnancy need to also be excluded. Acute presentations with vomiting will require exclusion of acute band slippage in patients with gastric bands and internal hernias in patients with operations who involved small bowel anastomosis. Expeditious investigation and treatment are important to avoid ischaemia.

Empirical intra-venous thiamine replacement is important in patients with persistent vomiting to avoid precipitation of Wernicke's encephalopathy [49].

Gastro-oesophageal Reflux

Several studies have shown a higher incidence of GORD in patients who are overweight compared to the general population [50]. The Bristol Helicobacter project reported that patients who suffer from obesity are up to three times more likely to suffer from heartburn or regurgitation [51]. These patients are also at higher risk of developing GORD complications including erosive oesophagitis [52], Barrett's oesophagus and oesophageal and junctional adenocarcinoma than their lean counterparts [53]. Central obesity rather than BMI itself is closely associated with these complications. The pathophysiology of this may include increased intra-abdominal and intra-gastric pressure, reduced oesophageal

clearance, increased transient relaxations of lower oesophageal sphincter (LOS) and abnormal gastro-oesophageal junction anatomy with shorter, hypotensive LOS and increased incidence of hiatal hernia [54]. Increased mucosal sensitivity, larger gastric capacity, dietary habits and higher levels of leptin, interleukin 6 and TNF and lower levels of adiponectin may also be involved [55]. Non-surgical weight loss has been associated with a decrease in GORD symptoms in several studies [50, 56].

Pre-operative upper GI endoscopy is recommended prior to bariatric surgery [57] but not universally performed. A recent systematic review noted that only 7.6% of OGDs performed prior to bariatric surgery [58] lead to a change in the operative management. However over a third of patients undergoing bariatric surgery have abnormal OGD findings [57] and endoscopy often helps to establish appropriate operation planning, consent and follow-up. Most surgeons would consider repairing the hiatus if there is a significant hiatus hernia or opt for a RYGB, which has long been hailed as the best operation for patients with obesity and GORD [59]. De novo GORD may occur after surgery especially after gastric banding, SG [60] and OAGB [61] while the same operations can improve GORD in patients with pre-operative symptoms [55, 60, 62]. Studies are often difficult to interpret and compare due to different operative techniques including management of the hiatus, length of follow-up, medication use and how GORD was defined (symptoms, questionnaires, endoscopy, biopsies, pH studies). The topic of reflux and its potential consequences are hotly debated in bariatric surgical conferences and in the literature [63] and are not the remit of this chapter.

If patients with a history of bariatric surgery develop dysphagia or worsening reflux, 2-week wait or expedited endoscopy should be arranged. Some surgeons offer routine OGD every 2–3 years after SG and OAGB [57], as poor correlation between GORD symptoms, degree of oesophagitis and the development of Barrett's oesophagus has been shown, but this is no means the norm. Most patients who develop GORD can usually be managed with lifestyle modification and proton pump inhibitors (PPIs) although a small proportion may require revision surgery.

Anastomotic Complications: Ulceration, Stenosis, Perforation

Operations involving anastomosis of the stomach and small bowel like the RYGB and the OAGB may be complicated by ulceration, stenosis or perforation at or near the joint (marginal ulceration). Reduced blood flow and tension at the anastomosis site may play a role. Other risk factors include smoking, chronic NSAID use, a large proximal gastric pouch, the presence of a gastro-gastric fistula and Helicobacter pylori. Bile reflux may play a role in marginal and gastric ulceration after OAGB.

Patients with ulcers may be asymptomatic or may present with nausea, vomiting, epigastric pain and rapid weight loss. They may also present with anaemia due to chronic bleeding. Diagnosis is usually made with an upper GI endoscopy. Ulcers may be complicated by stricture formation. While these often respond to endoscopic dilatation, iatrogenic perforation and recurrence are not uncommon. Ulcer perforation may occur spontaneously and often require laparoscopy, washout and an omental patch repair.

Marginal ulceration may occur in 0.6–16% of patients with RYGB [64]. Most surgeons recommend PPIs for the first 3 months post-op to try and prevent this complication. PPIs, together with sucralfate, form the mainstay of treatment together with management of other risk factors including smoking cessation therapy. Up to a third of patients with recurrent or refractory ulceration after RYGB may need revision surgery.

Ulceration in OAGB may occur in up to 10% of patients and may be particularly difficult to treat as it is often the consequence of bile reflux. In these cases, conversion to traditional RYGB configuration is usually beneficial [65].

Dumping

Dumping syndrome has been reported with several bariatric operations but especially with the RYGB and SG [66]. It is often thought to be secondary to rapid post-prandial gastric emptying and is characterised by gastrointestinal and vasomotor symptoms. The clinical presentation is variable and symptoms are divided into early and late. Early dumping symptoms usually occur within 1 h after a meal and include abdominal pain, loose stools, nausea, vomiting and bloating. Patients can also present with vasomotor symptoms such as fatigue, tachycardia and facial flushing. The mechanisms underlying early dumping may involve the osmotic effects of food in the jejunum, gut hormone release and autonomic neural responses [67].

Late dumping symptoms (1–3 h postprandial) relate to hypoglycaemia and include perspiration, palpitations, hunger, fatigue, tremor and confusion [67]. In one study of 450 patients who had undergone RYGB or SG, over a third reported symptoms suggestive of postprandial hypoglycaemia [68]. Spontaneous plasma levels of glucose <2.8 mmol/L (50 mg/dL) are indicative of late dumping syndrome. Late dumping and the associated hypoglycaemia is thought to be secondary to an exaggerated GLP-1 response.

Most patients with symptoms of dumping are reviewed by a multidisciplinary team including the bariatric surgeon, physician and dietician. Dietary changes are usually successful in most patients. Rapidly absorbable carbohydrates should be eliminated from the diet to prevent symptoms of late dumping syndrome. They should be advised to eat a diet consisting of foods high in fibre and rich in protein, eaten slowly and chewed well. Some patients therefore find symp-

toms of dumping, a timely reminder that they may be eating 'the wrong types of food'.

In patients whose symptoms persist despite dietary manipulation, Acarbose and somatostatin analogues may be used. If conservative management fails, further endoscopic or surgical techniques may be offered to attempt to slow down the passage of food from the stomach into the small bowel [69].

Cholelithiasis

Gallstone disease can be found in 10–20% of general population. Out of these about 20% will develop symptoms including biliary colic, acute cholecystitis and gallstone pancreatitis. A eightfold rise in incidence has been documented in patients with BMI equal of more than 40 kg/m^2 [70]. Rapid weight loss induces gallbladder stasis and changes in bile composition with supersaturation of bile with cholesterol and raised concentrations of mucin [71]. These changes may result in the formation of biliary sludge and gallstones. Bariatric surgery is associated with a predisposition for further development of cholelithiasis in over 35% of patients [72]. Cholelithiasis is more common in the patients who have lost most weight [73].

Ursodeoxycholic acid (UDCA) is a secondary bile acid—a by-product of intestinal bacteria, which helps reduce the rate of cholesterol absorption in intestines, resulting in decreased cholesterol saturation of bile and gallstone incidence. UDCA has some side-effects such as diarrhoea, loose and pale stools, and pruritis which may decrease patient compliance to treatment. Prophylactic use of urseodeoxycolic acid for at least the first 6 months post-operatively has been shown to decrease the incidence of gallstone formation [73] and lower the risk of requiring an urgent cholecystectomy [74].

In the laparoscopic era, most surgeons would not advocate concomitant prophylactic cholecystectomy for normal gallbladders or for patients with asymptomatic gallstones.

Mineral, Vitamin and Protein Deficiency

Patients with severe and complex obesity often have nutritional deficiencies. The most common ones include low levels of vitamin D, iron, folate and B12 [75]. The dietician plays a crucial role in the care of patients prior to bariatric surgery as they would undertake a detailed nutritional and dietary assessment and help in patient education. Patients are also routinely screened for mineral and vitamin levels and for anaemia as part of their pre-operative preparation. It is important that such deficiencies are corrected prior to bariatric surgery as this will limit the intake and absorption of such supplements.

With patient education, protein malnutrition is uncommon post-operatively after gastric bands and SG. It is also unusual with the gastric bypass unless technical issues like strictures are present. Protein malnutrition is more common with OAGB, BPD, DS and SADI. These patients require between 60–120 g of protein per day to maintain their lean body mass. If malnutrition is suspected, patients should be admitted to hospital for investigation, mineral and vitamin supplementation and feeding (enteral/parenteral). Patients with protein malnutrition should be assumed to have accompanying mineral and vitamin deficiency until proven otherwise.

Most bariatric centers recommend that their patients should stay on lifelong mineral and vitamin supplementation due to a reduction in oral intake with food and reduced intestinal absorption. The dosage of these may vary depending on the operation, the patient's dietary habits (eg vegetarians) and in women with heavy periods. Routine blood tests to check levels are also very important. These usually include a full blood count, ferritin, folate, Vitamin B12, Vitamin D and calcium at 3, 6, 12 months post-operatively and then at least annually after that. Vitamin A, E and K1 should also be monitored after BPD and DS and may also be required after OAGB. Zinc, copper and selenium levels may be required if oral intake is poor, patients are loosing wait rapidly or have unexplained anaemia, neuropathy, cardiomyopathy, or diarrhea. The recent BOMSS updated guidelines should be consulted for more information about monitoring and nutrient replacement after bariatric surgery [76].

Intestinal Failure in Childhood

Olivier Goulet and Cécile Lambe

Key Points

1. Pediatric IF is commonly due to congenital or neonatal intestinal diseases or malformations.
2. Three groups of patients are identified: those with a reduced intestinal length (short bowel syndrome), abnormal intestinal mucosal development, or severe intestinal dysmotility.
3. At birth, term-neonates have a SB length of approximately 250 cm and their intestines lengthen substantially during the first year of life.
4. IF associated liver disease (IFALD) (mainly cholestatic picture in children) develops frequently at an early age, especially in premature infants in whom liver immaturity, frequent sepsis and necrotizing enterocolitis (NEC) increase liver inflammation and severe damage. In older children it is associated with a dilated bowel with bacterial overgrowth.
5. Phytosterols contained in soybean oil are associated with IFALD progression and their exclusion from lipid bags may be beneficial in children receiving PN.
6. The major indications for HPN are SBS secondary to necrotizing enterocolitis, midgut volvulus, gastroschisis, long segment Hirschsprung Disease and intestinal atresia. Other conditions are congenital enteropathies, chronic intestinal pseudo-obstruction.

Introduction

Intestinal failure (IF) is defined as a critical reduction of the gut mass or its function below the minimum needed to absorb nutrients and fluids required for adequate growth in children and weight maintenance in adults [1]. As a matter of fact, severe IF, results in the need for parenteral nutrition (PN). IF may be reversible or irreversible, depending on a number of factors such as the underlying disease and also on the treatment used to develop or restore intestinal capacity. Severe and even irreversible IF in children is very challenging. IF conditions being rare, there is not enough data to provide the scientific foundation needed to form treatment guidelines or for the creation of gold-standards for the care of such very specific patients. However, guidelines for PN may provide basic knowledge for the management of those complex patients [2, 3]. In clinical practice intestinal sufficiency may be indirectly measured by the level of PN required for normal or catch up growth [4]. Others indicators such as residual bowel length measured at last surgery and serum citrulline, though helpful, have not proven to be always reliable prognostic factors in children with short bowel syndrome (SBS) [5–7]. Therefore, PN requirements or PN dependency index (PNDI) remain the best measure of the degree of intestinal sufficiency in this setting [8].

Due to technical refinements and steady advances in the development of highly sophisticated nutrient solutions consisting of optimal combinations of macronutrients and micronutrients, PN plays an important role in patient management [2, 3]. PN has become a safe and efficient feeding technique. However, IF that requires long-term PN may be associated with various complications including catheter related blood stream infections (CRBSIs), growth failure, metabolic disorders, and bone disease [9]. Cholestatic liver disease (CLD) was rapidly identified as one of the limitations of long term IF management while CLD related factors are mostly related to IF rather PN supporting the wording "Intestinal Failure Associated Liver Disease" (IFALD) [10–13]. Severe liver disease may lead to the so-called "nutri-

J. M.D. Nightingale (ed.), *Intestinal Failure*, https://doi.org/10.1007/978-3-031-22265-8_21

tional failure" which is considered as a major indication for intestinal transplantation or combined liver-intestinal transplantation [9].

Causes of Intestinal Failure

In industrialized countries pediatric IF is most commonly due to congenital or neonatal intestinal diseases or malformations that can be divided into three groups (Table 1): (a) IF with a reduced intestinal length and consequently reduced absorptive surface, such as in SBS or extensive aganglionosis (Long segment Hirschsprung disease); (b) IF related to an abnormal development of the intestinal mucosa such as congenital diseases of enterocyte development (CDED); (c) IF with intact length but with extensive motility dysfunction such as pediatric intestinal pseudo-obstruction syndromes (PIPOS).

Table 1 Causes of intestinal failure

Short bowel syndrome
• **Prenatal disease**
– Intestinal atresia
– Apple peel syndrome
– Gastroschisis
• **Post-natal disease**
– Necrotizing enterocolitis
– Mid gut volvulus
– Vascular thrombosis
– Tumor
– Traumatism
Congenital enteropathy
• Microvillous inclusion disease/microvillous atrophy
• Intestinal epithelial dysplasia/tufting enteropathy
• Syndromic diarrhea/trico-hepato-enteric syndrome
Neuromuscular intestinal disease
• Chronic intestinal pseudoobstruction syndrome
– Neuropathy
– Myopathy
– Mesenchymopathy
• **Long segment Hirschsprung disease/total or subtotal aganglionosis**

The Short Bowel Syndrome

Definition and Etiology

SBS is characterized by a compromised bowel absorptive capacity due to a severely reduced mucosal surface resulting in malabsorption with subsequent diarrhea, water-electrolytes imbalance, and malnutrition. SBS is the leading cause of pediatric IF, usually following extensive surgical resection leaving the SB length below a critical value for adequate nutritional supply [9]. Exact measurement of the remnant intestine remains difficult even with the help of radiographic assessment [14]. At birth, term-neonates have a SB length of approximately 250 cm and their intestines lengthen substantially during the first year of life [15]. Preterm infants have a greater potential for bowel growth since their intestines lengthen substantially during the last trimester of gestation [16].

The cut-off length for SBS is related to a number of factors. In general, SBS occurs after a massive resection leaving less than 40 cm of viable small bowel. A residual bowel length of only 15–40 cm has been associated with bowel adaptation, intestinal autonomy and PN weaning, but, most of the time, unfortunately with littleinformation regarding the long-term growth and the final stature [17–26]. Numerous factors determine SBS prognosis: the underlying diagnosis, the type of segments preserved, the presence of the ileo-caecal valve (ICV) and the colon, a long-term stoma *versus* a primary anastomosis, the number of surgical procedures, as well as the age of the patient at the time of surgery [17–26]. Classification of SBS in three type is helpful for the understanding of different outcomes (Fig. 1). Other factors are relevant to the development of SBS such as the functionality of the residual bowel, especially the motility disorders [24].

In children the conditions most commonly leading to extensive small bowel resections are necrotizing enterocolitis (NEC), midgut volvulus, gastroschisis, intestinal atresia and extensive aganglionosis (eg: long segment Hirschsprung disease, the last one leading to SBS without a functioning colon (SBS type 1) (Table 1 and Fig. 1).

Management of SBS

Bowel adaptation after small intestinal resection is a physiological process resulting in bowel lengthening and villous hyperplasia (Fig. 2) [27]. The management of SBS patients aims at promoting this physiological process by using as much as possible the GI tract especially by oral feeding (OF) which is more physiological than enteral tube feeding (ETF) [27]. ETF early in life, has been shown to promote oral feeding disorders [28].

PN itself aims in promoting normal somatic growth during the time bridge for achieving full intestinal autonomy. PN should not be stopped until adequate intake and growth can be achieved with only OF and/or ETF.

The optimal strategy for enteral feeding, OF *versus* ETF and continuous *versus* bolus, remains debated [27]. OF allows the maintenance of sucking and swallowing functions along with the psychological interest and enjoyment associated with eating, thus helping to prevent eating disorders. It is important to point that OF promotes the release of epidermal growth factor (EGF) from salivary glands and increases GI secretion of trophic factors [29]. Sialoadenectomy in animals significantly attenuates ileal villus height, total protein and DNA content after small

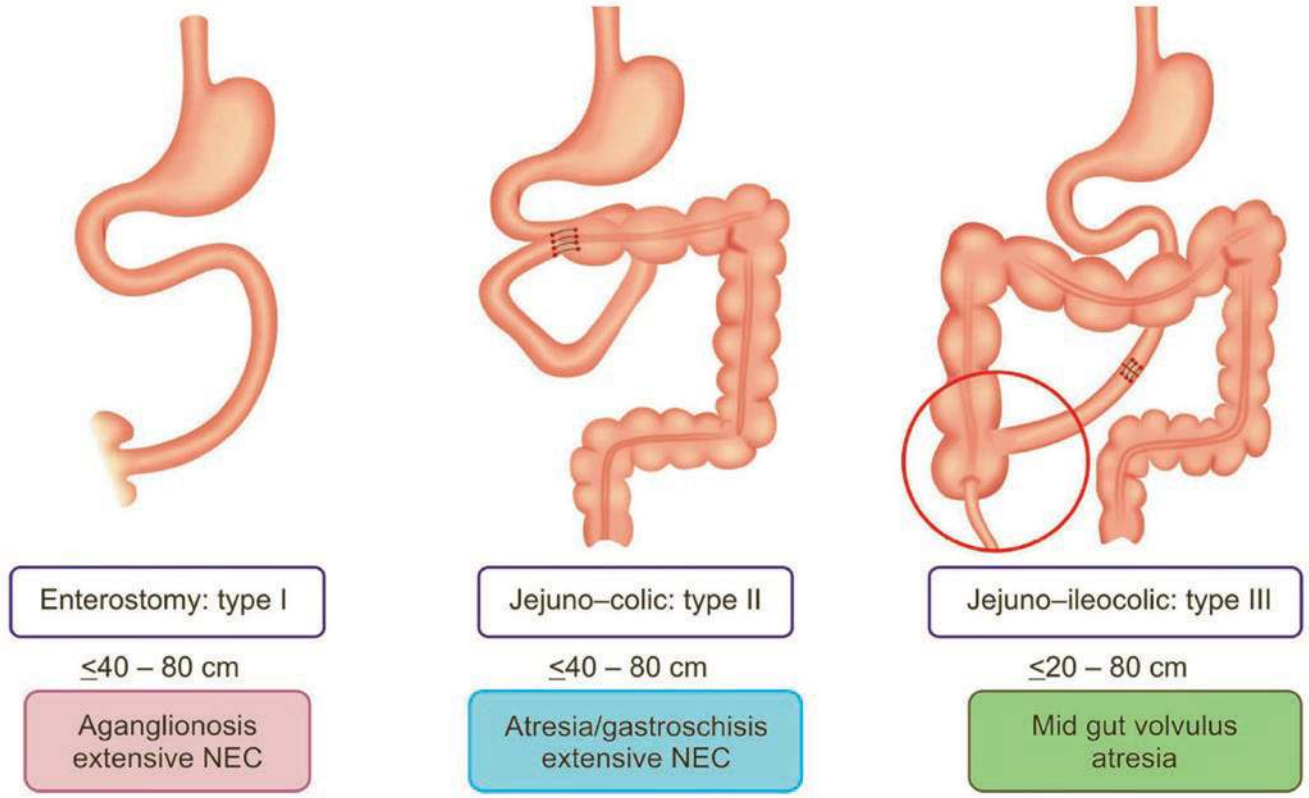

Fig. 1 Classification of short bowel syndrome (SBS) according to anatomy of the remnant intestine and different causes of intestinal resection

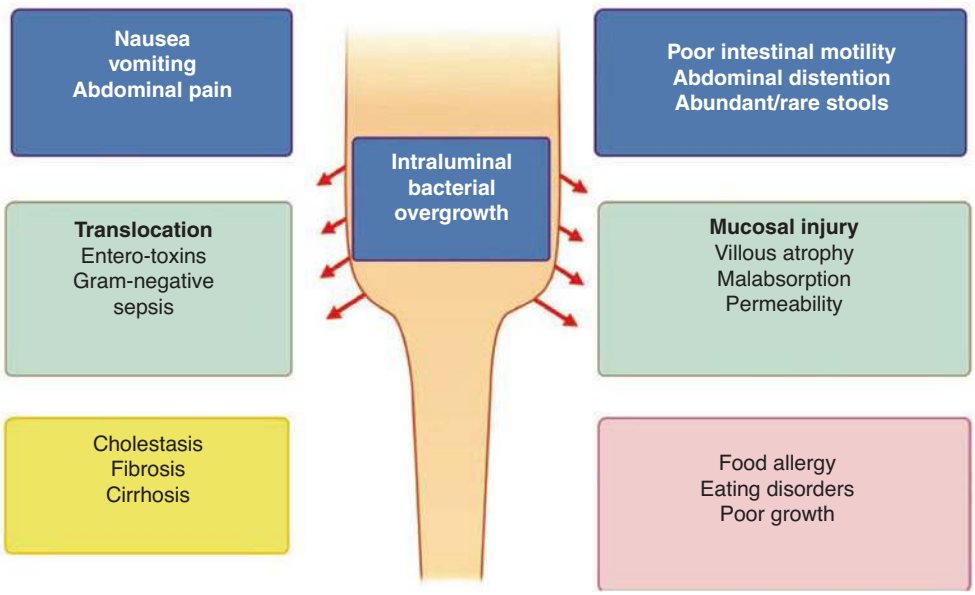

Fig. 2 Consequences of over-feeding a dilated and poorly motile intestine leading to intestinal stasis, small intestinal bacterial overgrowth (SIBO), mucosal injury, bacterial translocation, portal inflammation, cholestasis and fibrosis

bowel resection that is reversed by the administration of both systemic and oral EGF [30]. Moreover, the stimulation of hormones released by the GI tract promotes adaptation whereas alternating fasting and feeding periods along with cyclical PN avoid permanent release of insulin and excessive fat synthesis and deposition (steatosis, fat body mass).

Enteral - preferentially oral - feeding must be started as soon as possible after surgery. Breast feeding should be encouraged [31]. Human milk (HM) contains a number of factors supporting the developing neonate's intestinal microbiota and immune system including human milk oligosaccharides (HMOs), nucleotides, immunoglobulin A, and leucocytes [32–34]. HM also contains glutamine and growth

factors, such as EGF, which promote bowel adaptation [32]. Interestingly, polymeric diets containing whole protein, lactose, and long chain triglycerides (LCT), are not usually used while extensively hydrolyzed formulae (EHF) are preferred. The latter have the advantages of containing short peptides, better absorbed than free amino acids, as well as medium-chain triglycerides (MCT) [27]. Amino acid based formulas (AABF) are generally used in the treatment of food allergies or in case of milk protein hydrolyzate intolerance [35]. True food allergies have been rarely documented in children with SBS [36]. Andorsky reported less intestinal allergy by using AABF, without clearly defining the criteria for the diagnosis of allergy [18]. Two retrospective studies reported that the use of an AABF was associated with earlier weaning off PN and also a reduced rate of allergies [37, 38]. However, the very small sample sizes and the lack of control groups in these studies do not support the recommendation of using AABF in SBS patients. Moreover, commercially available AABF contain lower levels of MCT than EHF.

Feeds should be increased gradually as tolerated. Tolerance is evaluated by measuring stool number and volume and by the observation of vomiting, irritability and abdominal as well as intestinal distension. Many factors can affect stool volume in SBS, including the length of the residual intestinal segment and the type of segment (the more proximal the resection the larger the fluid and sodium losses), the mucosal and endoluminal variables (residual enzymatic activity and absorptive capacity, bacterial overgrowth). Forced continuous ETF may worsen fluid, minerals and nutrients malabsorption and may result in severe perianal skin lesions. Bile salts malabsorption may be suspected in children without ICV and/or colon, presenting with high stool volume and perianal injury that can be improved by using cholestyramine. Fluid losses in these patients are often accompanied by sodium and zinc losses with subsequent risks of severe depletion; supplements should therefore be provided.

The Many Faces of Intestinal Microbiota in Short Bowel Syndrome

Colonic Bacterial Metabolism

The Trophic Role of the Colon

When preserved, the colon, by hosting the largest part of intestinal microbiota plays a predominant role in the physiological adaptation of the intestine after large small intestinal resection. Colon is capable of reducing loss of energy and producing trophic factors [39, 40]. In animal models, supplementation of an elemental diet with pectin, which is fermented to short chain fatty acids (SCFAs) in the colon, improved adaptation of the small intestine and colon in SBS [41]. In piglets, the supplementation of PN with SCFAs or their intra-caecal infusion reduced mucosal atrophy and intestinal immune dysfunction following massive small bowel resection [42].

In addition to their local effects, systemic SCFAs, in animal studies, can affect the motility of both the stomach and the ileum through neuroendocrine mechanisms, probably through the expression of enteroglucagon family peptides and peptide YY [43]. Furthermore, both systemic and enteral SCFAs exert a trophic effect on the jejunum by increasing mucosal mass, DNA and villus height [44]. Since SCFAs are the preferred energy source for colonocytes, in patients with SBS the colon becomes an important organ for calories salvage. Unabsorbed carbohydrates are metabolized by the intestinal microbiota to SCFAs [40]. In turn, SCFAs may be considered as trophic factors directly by developing colon mucosa trophicity [45] or by promoting the release of GLP-2 [42].

Restoration of intestinal continuity, such as an anastomosis of the small intestine to the colon, should be done whenever possible. With improved colonic water and electrolyte absorption, PN can then be discontinued or at least decreased. In addition, anastomosis enables colonic fermentation of unabsorbed carbohydrates from the small intestine to occur, being an important source of energy assimilation. In spite of small intestine malabsorption in patients with SBS, both hyperphagia and adaptation of the remaining colon improve patient outcomes. A study evaluated morphology, proliferation status and transporters' expression level in the epithelium of the remaining colon of SBS adult patients compared to controls [45]. It seems that in hyperphagic SBS patients with severe malabsorption, adaptive colonic changes include an increased absorptive surface with an unchanged proliferative/apoptotic ratio and well-preserved absorption NHE2, NHE3 and PepT1 transporters mRNA levels [46]. As mentioned before, the preservation of the colon and its associated microbiota is essential for energy salvage, in reducing the need for PN and in improving the outcome of SBS patients. Bacteriological analysis based on culture-dependent methods has found that the microbiota of SBS patients is mainly composed of Lactobacilli, but neither qualitative nor quantitative information is available regarding the other main bacterial groups [47]. Few data have been reported in pediatric SBS but have mostly shown low intestinal microbiota diversity and dysbiosis [48, 49].

Colonic Hypermetabolism and D-Lactic Acidosis

Clinical manifestations such as abdominal distension, bloating and nausea - due to colonic microbiological hypermetabolism - may impair daily life and should be monitored. They are the consequences of the intestinal malabsorption

leading to huge load of undigested CHO reaching the colon. This condition may be worsened by hyperphagia or aggressive tube-feeding. One rare complication of colonic hypermetabolism, which is clearly different from small intestinal bacterial overgrowth (SIBO), is D-lactic acidosis.

D-lactic acidosis, also referred to as D-lactate encephalopathy, is a rare neurologic syndrome that occurs in individuals with SBS or following jejuno-ileal bypass surgery [50, 51]. Fortunately, this complication is very rare. Symptoms typically present after the ingestion of high-carbohydrate feedings. Neurologic symptoms include altered mental status, slurred speech and ataxia, with patients often appearing drunk. Onset of neurologic symptoms is accompanied by metabolic acidosis and elevation of D-lactate plasma concentration. L-lactate concentration, which is reflected by serum lactate concentration is normal. Thiamine deficiency should be excluded [52].

When present, *Lactobacilli* and other bacteria, including *Clostridium perfringens* and *Streptococcus bovis*, ferment unabsorbed carbohydrate to D-lactic acid, which cannot be metabolized by D-lactate dehydrogenase so it accumulates in the blood and may cause neurological symptoms. These organisms may proliferate in an acidic environment that may be promoted by the metabolism of unabsorbed carbohydrates to SCFAs. The mechanism for the symptoms with the high anion gap acidosis is unknown. They have been attributed to D-lactate, but it is unclear if this is the cause or whether other factors are responsible [45]. Treatments described in case reports have included nothing (with spontaneous resolution after reducing enteral feeding), oral metronidazole, neomycin, vancomycin, (for 10–14 days) and avoidance of "refined" carbohydrates [53, 54]. Probiotics, prebiotics and synbiotics have been used but without clear efficacy [55, 56].

Finally, one should consider the intestinal microbiota as a major factor for achieving intestinal adaptation and should be always respected and not be destroyed by unnecessary and/or inappropriate use of oral antibiotics worsening the so called SBS related intestinal dysbiosis [48, 49].

Small Intestinal Bacterial Overgrowth

Cholestatic liver disease (CLD) has been shown to be more frequent in the SBS patients than in any other IF conditions [57]. Out of 175 neonates with abdominal pathology requiring surgery, the patients with SBS (n = 40) suffered significantly more morbidity than the group without SBS in all categories of investigation (surgical complications, septic events, CRS, PN weaning delay, liver disease, and duration of hospitalization). The case fatality rate was 37.5% in patients with SBS versus 13.3% in patients without SBS (P = 0.001). Most of the deaths were caused by liver failure or sepsis and occurred within 1 year from the date of surgery. More recently, the US IF consortium reported a large cohort involving 272 infants [58]. Overall, they have a gestational age of 34 weeks and birth weight of 2.1 kg (range: 1.2–2.7 kg) and were followed up for 25.7 months (range: 11.2–40.9 months). Residual small bowel length in 144 patients was 41 cm (range: 25.0–65.5 cm). Diagnoses were NEC (26%), gastroschisis (16%), atresia (10%), volvulus (9%), combinations of these diagnoses (17%), long segment Hirschsprung disease (LSHD) (4%), and other single or multiple diagnoses (18%). Prescribed medications included oral antibiotics (76%), H2 blockers (69%), and proton pump inhibitors (57%). Enteral feeding approaches varied among centers; 19% of the cohort received human milk. The cohort experienced 8.9 new catheter-related blood stream infections per 1000 catheter days. The cumulative incidences for enteral autonomy, death, and intestinal transplantation were 47%, 27%, and 26%, respectively. Enteral autonomy continued into the fifth year after study entry. Interestingly, Finnish pediatric surgeons reported a link between bowel dilatation, sepsis and cholestatic liver disease [59].

It is generally accepted that continuous ETF offers the advantages of optimal digestion and absorption rate [31]. However, continuous infusion changes the intestinal motility pattern by missing fasting period [60]. Significant dysmotility - impairing intestinal bacterial clearance - leads to small intestinal bacterial overgrowth (SIBO) with subsequent Gram-negative sepsis. SIBO and cholestasis are common especially in patients without ICV and those having abnormal motility (eg: intestinal atresia, gastroschisis, NEC). Aggressive continuous ETF is often attempted for mimicking "hyperphagia" with the aim of weaning the child off PN that is thought to be the cause of liver injury. These patients present with dilated loops of bowel containing residual non-absorbed nutrients. This strategy results in increasing SIBO that can cause mucosal inflammation and increased permeability leading to sensitization and allergy as well as bacterial translocation, sepsis and cholestasis [9, 58, 61, 62] (Fig. 2). In addition, aggressive ETF may also result in such a overloaded gut syndrome with abdominal discomfort, intestinal distension and loss of self-regulation of intake leading to eating disorders.

Factors that link infection to cholestasis are either cytokines (mainly TNFα, IL-1β, IL-6) or microbial TLR2 or TLR4 agonists [63]. Liver targets primarily include hepatocytes, but also extend to Küpfer cells, cholangiocytes, endothelial cells, and stellate cells. There are no direct studies of bile flow in humans given endotoxin, but there is sufficient indirect evidence to link endotoxin and endotoxin-induced cytokines, to cholestasis. During severe sepsis, including septic shock, hyperbilirubinemia is usually a central clinical finding, often out of proportion to typically

mild elevations in serum transaminase. Interestingly, TNFα administered in humans has shown significant hyperbilirubinemia, further supporting a link between cytokines and cholestasis [64].

Peri-Anastomotic Ulcerations

Peri-anastomotic ulcerations (PAU) is a rare but severe complication after intestinal resection and anastomosis. It is described mostly in children [65, 66]. The main symptom is bleeding, leading to iron-deficiency anemia, which is life threatening. A series of 11 patients (7 boys) with PAU after an intestinal resection and anastomosis in infancy was reported [65]. The study focuses on predictive factors, medical and surgical treatment options, and long-term outcomes [65]. The diagnosis of PAU was often delayed for several years. No predictive factor (including the primary disease, the length of the remnant bowel, and the loss of the ileocaecal valve) could be identified. Numerous treatment options, including antibiotics, probiotics (*Saccharomyces boulardii*) and anti-inflammatory drugs, proved to be ineffective to induce prolonged remission. Even after surgical resection, relapses were observed in 5/7 children. The mechanism leading to PAU remains unknown. Another series reported 14 cases revealed by severe anemia, diarrhea, abdominal pain and growth failure in average 11.5 years after surgery [66]. Ulcerations were most often multiple (n = 11), located on the upper part of ileocolonic anastomoses (n = 12) and difficult to treat. No granulomas were seen but lymphoid follicules were frequent. In addition, either ASCA or ANCA were positive in 4/9 tested patients and 8/11 genotyped patients exhibited a NOD2 mutation ($P < 0.0002$ when compared to French healthy controls). A recent multicenter study involved 51 patients (29 boys) identified from 19 centers in 8 countries [67] Most patients were followed after necrotizing enterocolitis (n = 20) or Hirschsprung disease (n = 11). The anastomosis was performed at a median age (interquartile range) of 6 [1–23] months, and first symptoms occurred 39 [22–106] months after surgery. Anemia was the most prevalent symptom followed by diarrhea, abdominal pain, bloating, and failure to thrive. Hypoalbuminemia, elevated CRP, and fecal calprotectin were observed. Deep ulcerations were found in 59% of patients usually proximally to the anastomosis (68%). During a median follow-up of 40 [19–67] months, treatments reported to be the most effective included exclusive enteral nutrition (31/35, 88%), redo anastomosis (18/22, 82%), and alternate antibiotic treatment (37/64, 58%). Unfortunately, persistence of symptoms, failure to thrive, and abnormal laboratory tests at last follow-up in most of patients show the burden of PAU lacking optimal therapy and incomplete understanding of the pathophysiology.

Non-transplant Strategies for Enhancing Intestinal Capacity

Autologous Bowel Reconstruction

Surgical approaches aimed at maximising gastrointestinal digestive and absorptive function are crucial to the management of SBS. These include stoma closure and restoration of bowel continuity together with resection of strictures and closure of fistula. There are situations where surgical interventions aimed at reducing stasis in very dilated bowel, possibly decreasing SIBO (with its negative effects on digestion, absorption and a factor of IFALD) in the process and increasing contact time between luminal nutrients and mucosa might improve overall absorption. Indeed, these procedures aim not only to enhance the intestinal length and reduce the diameter of the distended intestinal loop with subsequent reduction of SIBO. The most common procedures are Longitudinal Intestinal Lengthening and Tapering (LILT) developed by Bianchi in Manchester, UK [68] and Serial Transverse Enteroplasty (STEP) developed by Kim et al. and mostly used in North America [69] (Fig. 3a, b).

The precise indications and the potential benefits of these procedures remain a matter of debate [70, 71]. Classical conditions and indications for bowel-lengthening surgery include the presence of a large intestinal diameter (>3–4 cm) for at least 20 cm of small bowel and a minimum total bowel length of 40 cm.

LILT involves longitudinal splitting of the small bowel remnant along its mesenteric and anti-mesenteric border, ending up with two tubes of bowel of identical length each with their own blood supply which are then joined together [68]. The advantages of the LILT procedure (Fig. 3a) include the conservation of the normal orientation of the muscular fibers allowing more physiological peristaltic contraction, and the possibility to further perform a STEP procedure on the operated segments. The disadvantages are the risk of vascular complications during surgery making LILT more technically demanding as compared to the STEP procedure [68, 69]. However, results after STEP and re-STEP procedure are not as performant as expected [72–75].

The STEP procedure involves the use of a surgical stapler applied sequentially from alternating and opposite directions to the dilated loop, in a transverse, partially overlapping fashion creating a zigzag–like channel of approximately 2–2.5 cm in diameter (Fig. 3b). This operation has the great advantage of being simple and reproducible. STEP is a more recent and less complex technique [69]; unlike LILT, no anastomosis is needed, and the mesenteric blood supply is not put at risk. If the bowel re-dilates, a further STEP procedure can be undertaken. Unfortunately, there are no surgical techniques that can reliably increase small bowel surface area, and by so doing rapidly achieve more than the background process of gut adaptation.

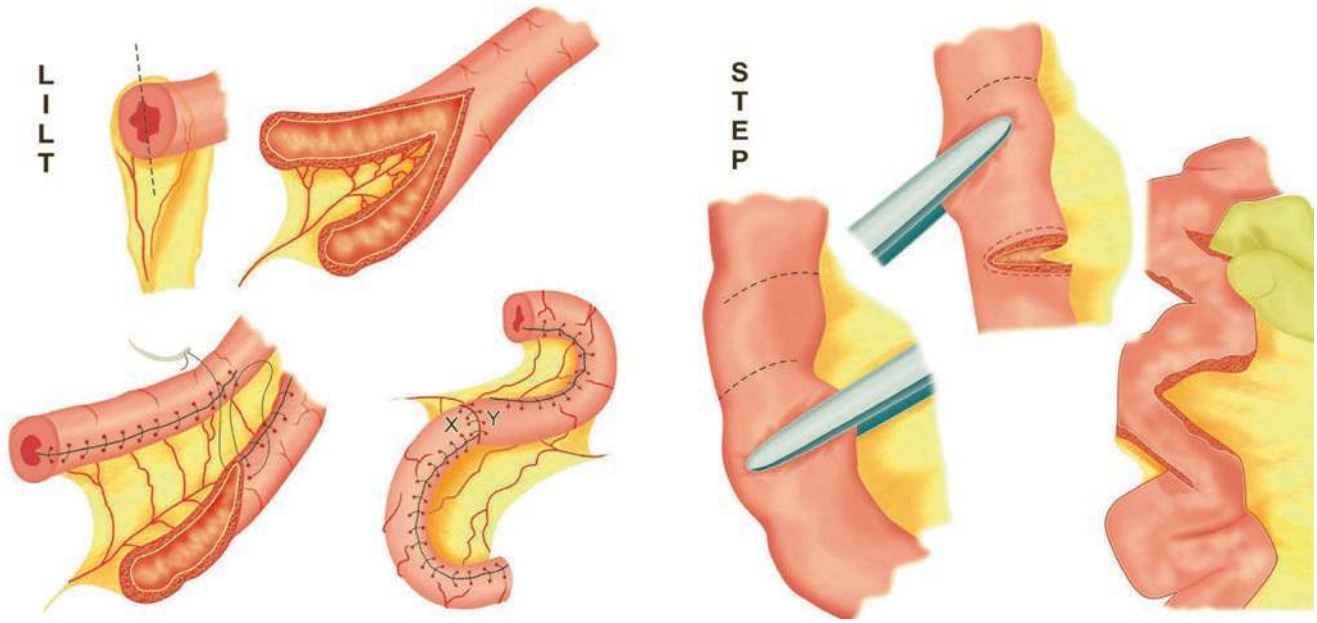

Fig. 3 The longitudinal intestinal lengthening and tailoring (LILT) procedure and the serial transverse enteroplasty (STEP) procedure

Plasma citrulline is a marker of small bowel enterocyte mass [5–7]. A 5-year follow-up cohort study after STEP confirms the efficiency of this procedure. Interestingly, both D-xylose - a marker of carbohydrate absorption and mucosal integrity - and plasma citrulline - a marker of small bowel enterocyte mass -increased significantly postoperatively [76]. This suggests that STEP procedure by reducing SIBO, restores small intestinal mucosa integrity and improves villous size within the first weeks following the procedure. However recent data showed no adaptive mucosal hyperplasia or muscular alterations occurred between first and repeat STEP [75]. This suggest that persistent inflammation and lacking mucosal growth may contribute to continuing bowel dysfunction in SBS children, who require repeat STEP procedure, especially after removal of the ileocecal valve.

A more recent described procedure is the spiral intestinal lengthening and tailoring, which consists of a spiral incision of the intestinal wall and in the elongation longitudinally of the intestine by sliding one flap over the other [77]. The final intestinal lengthening is strictly dependent on a series of parameters, some of which are defined by the surgeon.

The gut overload syndrome may be defined as the association of dilated intestinal loops, abdominal discomfort, SIBO, cholestasis and failure to thrive in a SBS patient who is partially or totally enterally fed. Surgical bowel-tapering with or without lengthening should be considered in such setting whatever the patient is PN-dependent or not.

Hormonal Therapy and Other Adaptive Treatments

Hormonal therapy is promising in the management of infants with SBS. The role of recombinant human growth hormone (rhGH) alone or in combination with glutamine has been investigated. Inconsistent results have been reported in adults receiving rhGH, with reported side effects [78]. A few studies of rhGH alone or in combination with glutamine have been carried out in PN dependent children with SBS [79–81]. Despite some decrease in PN requirements during treatment these trials showed little benefit on body composition and mucosal absorption in the long-term [79–81].

Glucagon-like peptide 2 (GLP-2) is produced by the L-cells of the terminal ileum in response to luminal nutrients and has a trophic effect on the intestine, promoting absorption and adaptation [81]. GLP-2 has been shown to increase the surface area of the gut mucosa, up-regulate nutrient absorption, improve gut-barrier function, increase intestinal blood flow and decrease bone resorption [81]. Patients with low levels of GLP-2 following the resection of the terminal ileum and/or the ileo-caecal valve improved intestinal absorption and nutritional status after treatment with GLP-2 [82]. A 12-week, open-label study, enrolled SBS PN dependent patients aged 1–17 years [83]. It has been concluded that Teduglutide (GLP-2 analogue) was well tolerated at 0.025 or 0.05 mg/kg/day and was associated with trends toward reductions in PN requirements and advancements in enteral feeding. The above pilot study validated the recommended dose of Teduglutide to be used as 0.05 mg/kg per

day. However, study limitations included its short-term, open-label design, small sample size and heterogeneity of both patients and management because of the multicenter study. An other 24-week, open-label study, has been reported [84]. A 24-week, phase III trial included 59 patients with 2 randomized, double-blind teduglutide dose groups and a non-blinded standard of care (SOC) arm was used; patients received 0.025 mg/kg or 0.05 mg/kg teduglutide once daily: (0.025 mg/kg, n = 24; 0.05 mg/kg, n = 26; SOC, n = 9) [84]. Safety end points included treatment-emergent adverse events (TEAEs) and growth parameters. The primary efficacy/pharmacodynamic end point was the number of patients who achieved a ≥ 20% reduction in parenteral support (PS) from baseline at week 24. TEAEs were reported by 98% and 100% of patients in the teduglutide and SOC groups, respectively. The most common TEAEs in the teduglutide-treated groups were pyrexia and vomiting. The primary end point was achieved by 13 (54.2%), 18 (69.2%), and 1 (11.1%) patients who received 0.025 mg/kg teduglutide, 0.05 mg/kg teduglutide, and SOC, respectively ($P < 0.05$ vs SOC). Both 0.025-mg/kg and 0.05-mg/kg teduglutide groups showed clinically significant reductions in PS volume ($P < 0.05$ vs SOC), PS calories, days per week and hours per day of PS infusions, and increases in enteral nutrition and plasma citrulline at week 24 compared with baseline. Two (8.3%, 0.025 mg/kg teduglutide) and 3 patients (11.5%, 0.05 mg/kg teduglutide) achieved enteral autonomy. In a monocenter open trial of 48 weeks treatment with teduglutide (0.05 mg/kg/day) currently under submission, we report a PN weaning rate in 8 patients (32%) a significant increased of citrulline plasma levels ($p < 0.001$) ($p < 0.001$) and a significant decrease of the PN dependency index ($p < 0.0001$).

Monocenter trials are required for addressing recommendations and extend the use of GLP-2 analog (eg: Teduglutide Revestive®) at a dose of 0.05 mg/kg/d. Oral insulin has been shown to be beneficial in animal models and might be assessed very soon in infants and children [85]. Other relevant treatments associated with a trophic effect on the bowel mucosa such as short chain fatty acids may be beneficial in children with SBS [82]. Finally, there is also interest in the use of other trophic factors such as epidermal growth factor (EGF) and insulin-like growth factor-1 (IGF-1) in children with IF and SBS [83].

Outcome of SBS and Long-Term Growth

Mortality decreased during the last decade especially following the implementation of the so called "intestinal rehabilitation centres" (IRC) [86–90]. Multidisciplinary management, improved prevention of sepsis by performing autologous bowel reconstruction [68], by preventing catheter related blood stream infections (CRBSIs) with taurolidine or ethanol lock procedures [91, 92], by using the last generation of lipid emulsions [11] [see below]. In the mean time, the rate of intestinal transplantation decreased with these measures [93].

Some studies have been reported, involving the long-term growth and nutrition status of children with neonatal SBS after weaning off PN [22, 94–96]. Improved care of patients with SBS significantly achieved more optimal weight gain for age compared with decade 1980 [94]. However, the final genetic target size is not always achieved while some deficiencies may be evidenced [95, 96]. Indeed, children with SBS are still at risk for different nutrient malabsorption even after weaning off PN for a long time. They may develop such an "overloaded gut syndrome" with failure to thrive requiring, for some, PN to be restarted. Therefore, they need long-term, regular monitoring and intensive nutritional care to prevent various nutrient deficiencies. Too early PN weaning may be responsible for both "overloaded gut syndrome" and failure to thrive.

Neuro-Muscular Intestinal Diseases

Intestinal motility is under the control of the enteric nervous system that is functionally independent from the central nervous system and is therefore efficient even in completely disconnected bowel loops, such as intestinal transplants. Normal motility is achieved through the transmission of the signals from the enteric nervous system to the enteric smooth muscle generating healthy peristaltic waves. Therefore, neuromuscular intestinal disease (NMID) may derive from either enteric nerve or muscle dysfunction. Severe gastrointestinal conditions classified among the NMID lead to intestinal failure: extensive Hirschsprung Disease and chronic intestinal pseudo-obstruction syndrome (CIPOs).

Hirschsprung Disease

Total or subtotal intestinal aganglionosis (TIA) leaving the child with less than 50 cm normally innervated small intestine below the ligament of Treitz (LOT) is a rare condition. It may be considered as a SBS type 1. Appropriate management strategies are not well established. Surgery is performed as a simple jejunostomy below the LOT with or without or short-segment longitudinal myomectomy [97–99].

Nutritional management includes cyclic PN (home-PN) associated with oral feeding for reducing the risk of liver disease and promoting oral skills [8]. Continuous attention is needed in the daily long-term management of these unstable infants and children with a permanent risk of dehydration and subsequent complications such as hypercalcemia, renal

failure. ITx is undertaken according to the occurrence of complications (water-electrolytes disorders, CRC, and IFALD) and/or the wish of parents for another quality of life. In 12 patients with TIA, it was reported an outcome rate of 62.5% in the LITx group and 75% in the ITx group, both with half colon grafting [100]. All the surviving patients were fully weaned from total PN, after a median of 57 days. Pull through of the colon allograft was carried out in all patients. Fecal continence is normal in all but one of the surviving children. When graft is tolerated on the long-term, growth is normal and quality of life is improved [101, 102]. A monocenter survey included 25 patients born between 2000 and 2015 were followed for a median of 10.9 years [103]. Fifteen patients had less than 80 cm of ganglionic small bowel (SB) with a median of 20 cm. Ten patients had more than 80 cm of ganglionic SB with a median of 115 cm. The median PN duration was significantly shorter for patients with more than 80 cm: 0.9 *versus* 7.5 years in those with less than 80 cm ($P < 0.001$). No patient with less than 80 cm was weaned off PN, except 1 who underwent ITx. Ten patients with less than 80 cm develop enterocolitis on the excluded segment, leading to emergency entero-colectomy in 5. Liver disease was more frequent in patients with less than 80 cm (11 vs 0). Three patients required combined liver-ITx; 2 underwent an isolated ITx. The more severe complication was enterocolitis. Liver disease compromised long-term survival without transplantation. Both complications should be prevented by early diversion and enterectomy of the whole aganglionic segment. Follow-up in or together with a multidisciplinary IRC is mandatory.

Chronic Intestinal Pseudobstruction

Chronic intestinal pseudo-obstruction syndrome (CIPOS) is a condition considered as the most severe disorders of gut motility. CIPOS continue to be very challenging despite recent progress in the understanding of its pathophysiology, resulting in a high levels of morbidity and mortality. Major contributors to the disappointing lack of progress in paediatric CIPOS include a dearth of clarity and uniformity across all aspects of clinical care from definition and diagnosis to management.

CIPOS is a descriptive term pooling together several disorders of the enteric muscles or nerves [104]. Thus it may have heterogeneous features but has a similar phenotype characterized by recurrent bouts of intestinal obstruction without demonstrable mechanical occlusion. CIPOs are the cause of approximately 15% of all pediatric cases of IF [9]. Repeated surgical procedures can negatively affect the course of the disease [105].

CIPOs may be due to several diseases that can be either congenital or acquired. The most severe forms are usually congenital and present shortly after birth with episodes of intestinal obstruction. CIPOs have been conventionally divided into two groups, according to the pathogenesis of dysmotility: neuropathies and myopathies. The former is due to the involvement of the enteric nervous system and the latter is due to the dysfunction of intestinal muscles. CIPOs due to muscle dysfunction are rare but seem to be more severe. Urinary tract disorders such as megacystis and megaureter can be associated both with neuro and myopathies causing CIPOs. These should be managed by experienced urologists although, surprisingly, they may be better tolerated than other more common obstructive urinary tract disorders [106].

Diagnosis

The diagnosis of CIPOs is based on clinical and radiological analysis. Tools helpful to assess a severe motility disorder include radiological and histological evaluations and, if feasible, gastrointestinal manometry [104]. However, intestinal manometry is not highly contributive for either the diagnosis of CIPO or its treatment. CIPOs management is mainly based on clinical and radiological features. In CIPOs a plain abdominal x-ray typically shows air-fluid levels and dilatation of the bowel loops. Contrast studies, such as the barium small bowel follow-through study, are helpful to rule out mechanical obstruction, but may not reveal motility abnormalities. The presence of a systemic autoimmune disease as well as severe infections and endocrinopathies suggests an acquired form of CIPOs that sometimes can be managed by treating the underlying illness. Congenital forms of CIPOs can be misdiagnosed as Hirschsprung Disease, even resulting in surgery. However, surgical biopsies reveal normal enteric ganglia. In these cases, bowel resections should be avoided [105]. When CIPO is strongly suspected laparoscopic full-thickness biopsies may support the diagnosis with a minimally invasive procedure. Nevertheless, histological hallmarks are scant and the sample should be evaluated in referral centers by expert pathologists who have experience in similar cases and access to specific immunohistochemistry and electron microscopy allowing the recognition of immune-mediated conditions, congenital neuromuscular disorders and mitochondrial cytopathies [107].

Genetics of CIPOS is complex and partially known [104, 108]. Most patients do not show familial recurrence (sporadic cases) but syndromic autosomal-dominant, autosomal-recessive and X-linked forms have been described. In particular, an X-linked locus has been mapped to the Xq28 region. Although both familial and sporadic CIPOs have been widely reported, so far only a few genes have been identified as responsible for syndromic CIPO: the thymidine phosphorylase gene (*TP*, also known as endothelial cell growth factor-1, *ECGF1*), the DNA polymerase-γ gene (*POLG*) and *SOX10*.

Management

Management is based on a multidisciplinary intervention by medical, surgical and allied professionals. Children with CIPOs almost invariably require some surgical intervention. The major barriers to food progression in patients with inefficient propulsive strength are the natural GI tract bottlenecks: the pylorus and the ileo-cecal valve. These can cause a functional occlusion of the gastric outlet or small bowel clogging, which can be easily resolved by the formation of a gastrostomy (or jejunostomy) and an ileostomy respectively. The formation of a stoma can improve the quality of life and reduce symptoms in up to 50% of children with CIPOs [105]. It is sometimes possible to localize the segments of the bowel the most responsible for the dysmotility symptoms: in such cases a loop resection can improve the intestinal transit and allow enteral feeding and a return to a more normal life. Near total small bowel resection has been proposed as treatment of CIPOs in some cases [109].

Due to the heterogeneity of the syndrome, a key issue is to adapt the treatment/management to each individual patient according to age at onset, severity, and the outcome of surgical procedures such as a primary ileostomy. These children need to maintain the ability and the pleasure to eat normal food and this can be permitted by taking small and frequent meals with liquids or, in more severe cases, by using the gastrostomy as a venting device; the known benefits of delivering enteral feeding in children with IF make it mandatory to attempt intermittent gastrostomy closure and gastric or gastro-duodenal low-fiber feeding [110].

Only a few medications have been shown to improve gastrointestinal motility in patients with an intact enteric nervous system. Erythromycin at low or full antibiotic doses may improve gastric emptying in children with CIPOs and gastroparesis [111]. Several other drugs with a demonstrated effect on gastric motility, such as the serotoninergic agents cisapride and tegaserod, have been withdrawn from the market because of the occurrence of rare but severe cardiac adverse events including arrhythmias, heart attacks and strokes. Colonic acute pseudo-obstruction can be managed successfully by the infusion of the anticholinergic drug neostigmine, but this drug has not been tested on a long-term regimen.

Children with CIPOs may experience small bowel bacterial overgrowth and can thus occasionally benefit from a course of antibiotics such as metronidazole, aminoglycosides or cotrimoxazole. These drugs should be prescribed only in case of clinical symptoms rather than regularly, in order to avoid the emergence of bacterial resistance.

A French multicenter study including 105 children, 18 with prenatal diagnosis and 80 younger than 12 months of age at onset, showed that early age at presentation, PN dependency and the number of surgical procedures were associated with a poor prognosis [112]. In the most severe forms of CIPOs children end up with an ileostomy, a gastrostomy with almost permanent aspiration due to gastroparesis, frequent bowel obstructions, and total PN dependency. Patients with such a poor quality of life may benefit from transplantation that should include the stomach (i.e. modified multivisceral transplantation) [113].

Congenital Enteropathies

Congenital diseases of enterocyte development (CDED) are a group of rare disorders causing IF in early infancy. Children with these disorders have usually neonatal onset of severe diarrhea that requires PN support [114].

The etiology includes defects in nutrient-electrolyte absorption and disorders of enterocyte differentiation and polarization [115, 116]. Clinically it is important to differentiate protracted from intractable diarrhea of infancy (IDI) - the latter being irreversible. Figure 4 proposes a simple algorithm to approach newborns and infants with severe diarrhea.

Microvillous Inclusion Disease

The most common causes of IDI are microvillus inclusion disease (MVID, also known as microvillus atrophy), congenital tufting enteropathy (CTE, also known as intestinal epithelial dysplasia), syndromic or phenotypic diarrhea, and autoimmune enteropathy. The latter is not considered to be intractable unless all available treatments fail. Several genes responsible for these disorders have been identified by studies based on genome-wide analysis of polymorphisms, adding new tools for the diagnosis of intractable diarrhea of infancy [116].

The first described form of MVID was related to MYO5B mutation [117, 118]. Severe watery diarrhea develops in the first few days after birth and can rapidly reach a total fecal output of 200–300 ml/kg of body weight per day. Diarrhea does not stop during fasting and causes life-threatening electrolyte and acid-base imbalances, rapid and severe dehydration and hypovolemic shock. Children with MVID are usually dependent on continuous PN infusion not allowing for cyclic PN. Some patients have associated disorders involving biliary acids metabolism and some develop liver disease leading liver failure within the first few years of life [117, 118]. Currently, the survival rate for these children is around 70%, including those patients (up to half) who received intestinal or liver-intestinal graft [119, 120].

The second gene in which MVID causing mutations were identified is STX3 [121, 122]. Patients were reported with

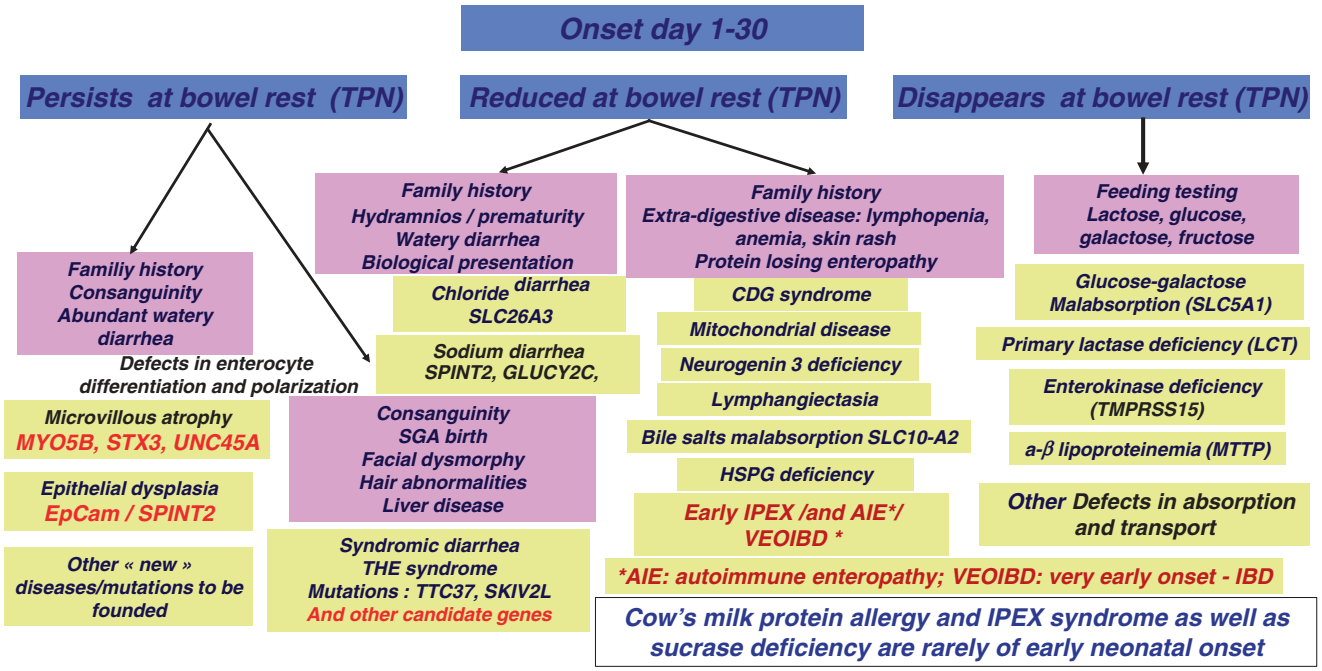

Fig. 4 Clinical approach of early onset severe diarrhoea

nonsense mutations resulting in truncations of the apically targeted N-ethylmaleimide-sensitive factor attachment protein receptor (SNARE) protein syntaxin3. No genotype-phenotype correlation with respect to *MYO5B* and *STX3*-related MVID has been reported so far, due to the small number of patients with *STX3* mutations. Genetic counseling can be performed for this autosomal recessive disorder when mutations in *MYO5B*, *STX3* are identified. An international registry has been set up [122].

UNC45A belongs to the UCS protein family (UNC-45/CRO1/She4p). *C. elegans* unc-45 was first described after a screening for mutations causing motility disorders (UNC stands for uncoordinated) [76]. The UNC-45 protein has three recognizable domains: an N-terminal tetratricopeptide repeat (TRP) domain (115 amino acids), a central domain of 400 amino acids, and a C-terminal UCS domain (400 amino acids). The TPR domain participates in protein-protein interactions, especially with Hsp70 and Hsp90 HSP90AA1. The role of the central domain remains unclear, while the C-terminal UCS domain is critical for myosin binding [77]. Whether or not variants located within specific domains of UNC45A lead to different functional outcomes is still unknown. UNC45A appears to be ubiquitously expressed and has been postulated to be involved in cytoskeletal functions, such as cell division or exocytosis [78]. Data are consistent with the multi-organ defects observed in children, as well as the structural pathology in the gut in a zebrafish mutants [79]. However, other features of the protein are not reflected in the phenotype seen in humans.

Congenital Tufting Enteropathy

Neonates with congenital tufting enteropathy (CTE) develop a severe neonatal diarrhea persisting at bowel rest [123]. Often there is a family history of consanguinity and neonatal deaths related to severe diarrhea and dehydration. Indeed CTE has been found to be associated with mutations in the genes encoding for epithelial cell adhesion molecule (EpCAM and Spint2) [124]. There are reported clusters of cases in the Arabic Gulf area [125]. Infants with CTE typically experience a worsening of diarrhea during continuous ETF even when given extensively hydrolyzed or amino acid-based formula, resulting in failure to thrive and protein-energy malnutrition. Diarrhea is usually less severe than in children with MVID; some patients may be weaned from PN. Nevertheless, most remain PN dependent and sometimes require ITx [123]. Expert histological review of duodenal biopsies is the key to making the diagnosis of this severe cause of IF. The so-called Congenital Sodium Diarrhea (CSD) has been reported as related to SPINT2 mutations [126]. Clinical presentation associated extra-intestinal disorders and histological features suggest a link between CTE and CSD [127]. Thirteen patients presenting with IF, and TE histology were retrospectively reviewed for up to 30 years [128]. It was concluded that IED cases have >92% chance of long-term survival and >50% chance of enteral autonomy by/in early adult life and 75% by 25 years. Patients with IED managed on PN at home by an IF rehabilitation service should avoid intestinal transplant [128].

THE Syndromic Diarrhea/Trichohepatoenteric Syndrome (SD/THE)

It is a rare and multi-system genetic disorder [129, 130]. This disorder is characterized by life-threatening diarrhea starting within the first 6 months of life, wooly and poorly-pigmented hair, facial dysmorphism including prominent forehead and cheeks and hypertelorism, hypopigmentation, cardiac defects, immunodeficiency, and liver disease. It includes extensive hepatic fibrosis and cirrhosis, affecting about half of patients. SD/THE is caused by mutation in *SKIV2L* or in *TTC37*, two genes encoding subunits of the putative human SKI complex involved in RNA degradation [130]. There are currently no specific biochemical profiles in these patients although a functional T-cell immune deficiency with defective antibody production has been reported [131]. Microscopic analysis of the hair shows twisted hair (pili torti), aniso- and poikilotrichosis, and trichorrhexis nodosa. Histopathological analysis of small intestine biopsies shows non-specific villous atrophy with low or no mononuclear cell infiltration of the lamina propria and no specific histological abnormalities involving the epithelium. Early management consists of total PN. Some infants have a milder phenotype requiring partial PN or only enteral feeding. Prognosis of this syndrome is poor but most patients now survive and some patients may be weaned off PN at adolescence. Even treated patients have a short stature and often a mental retardation [130]. Other severe persistent diarrhea causing chronic IF, with or without extra-digestive manifestations, have been described with genetic molecular biology based diagnosis [132, 133].

Deletion of the Percc1 Gene

Eight patients from seven families (2 consanguineous) of common ethno-geographic origin with IDI were recently reported [133]. They presented an early onset severe diarrhea (7–21 days) with mild villous atrophy and variable PN dependency. Deletions of a sequence termed intestine-critical region (ICR) on chromosome 16 were identified. Transgenic mouse reporter assays showed that the ICR contains a regulatory sequence that activates transcription during development of the gastrointestinal system. Targeted deletion of the ICR in mice caused symptoms recapitulating the human condition. Transcriptome analysis uncovered an unannotated open reading frame (Percc1) flanking the regulatory sequence whose expression was lost in the developing gut of ICR knockout animals. Targeted deletion of the Percc1 gene in mice causes phenotypes similar to those observed upon ICR deletion in mice and patients, whereas an ICR-driven Percc1 transgene was sufficient to rescue the phenotypes found in ICR knockout mice. The molecular, cellular, and physiological phenotypes observed in human patients and engineered mice indicate that PERCC1 is required for normal development of EECs and normal entero-endocrine hormone secretion.

Intestinal Failure Associated Liver Disease

Many peoples continue to talk about PN-related liver disease suggesting that PN is the cause of liver disease. Nowadays IF should be considered as the main cause of cholestatic liver disease. The most appropriate wording should be intestinal failure associated (or related) liver disease (IFALD) [10]. It is probably the most important complication affecting children with IF on long-term PN. The prevalence of the disorder is unknown because there is no established definition of liver disease in this setting and it is unclear as to whether IFALD should be diagnosed on the basis of clinical, biological or histological criteria. Indeed, there are insufficient data on the degree and type of liver involvement in patients with long term PN.

Causes and Mechanisms of IFALD

The main factors contributing to liver injury in these patients are recurrent catheter related sepsis, *p*rematurity and low birth weight, lack of enteral feeding, disruption of enterohepatic biliary acid cycle *(proximal stoma, ileal resection),* intestinal stasis and SIBO *(obstruction, dysmotility, lack of ileo-caecal valve, over-tube feeding…).* Table 2 reports the IF and PN related factors causing liver injury.

It should be stressed that the most important factors leading to IFALD are those related to individual patient characteristics and, importantly, the episodes of catheter related blood stream infections (CRBSIs) or SIBO [134–136] An important role in this process is played by liver inflammation caused by extra-hepatic infections in which microbial products brought to the liver through the blood stream, either directly or through production of cytokines, lead to alterations of bile flow. The inflammation associated with these changes may cause rapid fibrosis and eventually biliary cirrhosis with end-stage liver disease [136–140].

IFALD develops frequently at very early ages, especially in premature infants in whom liver immaturity, frequent sepsis and necrotizing enterocolitis (NEC) facilitate liver inflammation and severe damages. At this young age PN is most often administered continuously over 24 h and CRBSIs is common. High risk situations for developing liver disease are summarized in Table 3. The combination of those factors makes the onset of cholestatic liver disease likely. The current use of taurolidine lock procedure decreased dramatically the rate of CRBSIs [141].

Table 2 Factors causing liver disease

Patient and intestinal failure related factors
• **Prematurity and low birth weight**
• **Lack of enteral feeding**
– *Total parenteral nutrition*
• **Dysruption of entero-hepatic biliary acid cycle**
– *Proximal stoma, ileal resection*
• **Intestinal stasis and bacterial overgrowth**
– *Obstruction, dysmotility, lack of ileo-caecal valve, over-tube feeding*
Parenteral nutrition related factors
• **Duration of PN**
• **Recurrent catheter related sepsis**
• **Unadapted protein energy delivery**
– Excessive or unadapted amino acid intake
– Continuous versus cyclic infusion
– Excessive glucose intake
– Unappropriate use of lipid emulsion
Phytosterols
Lipoperoxidation
Excess of omega-6 fatty acids
Essential fatty acid deficiency
• **Potential toxic components of PN**
Iron
Aluminium
Chromium
Manganese
• **Deficiencies**
Taurine
Chlorine

Table 3 High risk situations for developing liver disease

• Premature and young infants
• NEC or gastroschisis ± atresia
• Protracted bowel rest/intestinal stasis
• Bacterial overgrowth/gram negative sepsis
• Recurrent catheter-related sepsis
• Unadapted and/or continuous PN

The combination of these factors makes cholestatic liver disease likely

Intravenous Lipid Emulsions and Liver Disease

Frequently cited observational studies suggested a link between intravenous lipid emulsions (ILE) and liver disease [142, 143]. It has been reported that the improvement of cholestasis depends also on maintaining an appropriate protein/energy ratio in PN, achieving cyclic rather than continuous PN infusion, using medium-chain triglycerides (MCT) based lLE and adding α-tocopherol in ILE [144].

IFALD is a multifactorial disease in which the use of soybean oil-based ILE in PN may represent the major culprit [145]. Several factors should be taken into consideration when choosing an ILE for parenteral use: the content in essential fatty acids (EFAs), the ratio of ω-6/ω-3, the polyunsaturated fatty acid (PUFAs) content, the amount of medium chain triglycerides (MCTs), the quantity of α-tocopherol and phytosterols [146]. The probable detrimental effect (pro-inflammatory) of ω-6 FAs on liver function is provided by studies that showed fat emulsions based on pure fish oil (containing ω-3 FAs) being successful as rescue therapy in pediatric patients with SBS affected by severe liver disease. The infusion of exclusively ω-3 FAs ultimately changed the management of these patients since it allowed the reduction of intake of pro-inflammatory ω-6 and phytosterols while increasing the amounts of alpha-tocopherol, a powerful antioxidant agent [146].

The evidence gathered on the beneficial effects of fish-oil in these patients has led to its use in clinical practice. However, two different approaches have been developed in North America as compared to Europe. In North America, following the paper by Gura et al. or Cowles et al., a pure fish oil based lipid emulsion (Omegaven®) has been promoted and has been, until recently was the unique emulsion to be available on the market [147–149]. In Europe it has become early possible to use a composite lipid emulsion containing a mixture of soybean oil (30%), coconut oil (30%), olive oil (25%) and fish oil (15%) (SMOF-lipid®). Both ILEs contain 200 mg/L of alpha-tocopherol. Clayton compared the level of phytosterols in plasma of healthy subjects, patients with mild hepatic dysfunction and those with severe dysfunction who received soybean oil emulsion - rich in sterols, and found a link between liver damage and phytosterols plasma levels [150]. Phytosterols contained in soybean oil have been found to be associated with liver disease progression and their exclusion from ILE may also be beneficial in children on PN [151].

Regarding the presence of tocopherol in lipid emulsions, one should emphasize that there are different preparations of tocopherol: alpha-tocopherol is the form with far greater antioxidant activity [152]. While soybean oil emulsions contain a high amount of gamma-tocopherol (which has 25% of the antioxidant power as compared to alpha-tocopherol), lipids based on fish oil are rich of the most powerful antioxidant vitamin E, alpha-tocopherol [153]. To ensure a proper antioxidant power in lipid preparations it is advisable to add 0.5 mg of alpha-tocopherol per gram of PUFAs.

Some concerns have been raised on providing fish oil as the sole source of lipids over a long period of time. Pure fish oil provides less essential ω-6 fatty acids than that currently recommended in infants and young children. Furthermore, Omegaven® (pure fish oil) can only be given at lower infusion rates compared to SMOF-lipid®). Omegaven® may not be able to provide enough calories to sustain growth. Thus, the combination of several types of oil by mixing soybean oil (rich in ω-6 FAs), coconut oil (rich in MCTs), olive oil (rich in MUFAs) and fish oil (rich in ω-3 FAs) appears to promote better growth while limiting hepatic toxicity [145]. A ran-

domized, double-blind, controlled trial on 60 preterm babies stratified by body weight has analyzed a set of parameters (clinical data, laboratory data, fatty acids in plasma and red blood cells, plasma levels of alpha-tocopherol and-phospholipids) after infusion of PN with SMOF-lipid® or soybean oil based emulsion [154]. The SMOF-lipid® emulsion increased the content of eicosapentaenoic EPA and docosahexaenoic (DHA) acids and reduced the ω-6 / ω-3 ratio, improving also liver function tests).

Another study evaluated the long-term effects of the lipid mixture SMOF-lipid® versus a soybean oil based preparation in pediatric patients on home PN [155]. This randomized, double blind study involved 28 children who received more than 4 infusions of PN per week for 4 consecutive weeks. The infusion was administered in 12–14 h overnight. At the end of the study no differences between biochemical and nutritional outcomes were recorded, but there was a clear association between the use of SMOF-lipid® and a significant decrease of bilirubin levels, that conversely increased in the soybean oil based group.

A confirmation of these findings comes from the study of Muhammed et al. who examined the effect of the switch from a soybean based lipid emulsion to SMOF-lipid® in 17 children with cholestasis [156]. The subjects were assigned to a treatment group receiving SMOF-lipid® and a group receiving soy based lipids. Over a period of 6 months the use of SMOF-lipid® was associated with a marked statistically significant reduction in the levels of bilirubin when compared with the soy based lipid group [156].

Finally, recent studies have emphasized the "superiority" of fish-oil derived lipid emulsions as a major advance for the management of patients on long-term PN. Preparations with pure fish oil are effective in decreasing cholestasis but their use as the sole source of lipids may not meet essential fatty acids requirements especially in the long-term [145]. Nevertheless, while some randomized controlled trials have demonstrated the beneficial effect of SMOF-lipid® versus soy-based lipid emulsion, no studies have compared SMOF-lipid® to Omegaven® in these patients The last ESPGHAN/ESPEN guidelines make the following recommandations [157]: As part of measures to reverse IFALD in paediatric patients, a discontinuation of Soy based ILE, a reduction of other ILE dosage and/or the use of composite ILE with FO, should be considered along with the treatment and management of other risk factors (LoE 2þ, RG B, strong recommendation for).

R 4.19 The use of pure FO ILE is not recommended for general use in paediatric patients but may be used for short-term rescue treatment in patients with progression to severe IFALD, based on case reports. (LoE 3e4, GPP, conditional recommendation for, strong consensus).

A recent study of the long-term use of the composite ILE SMOF-lipid® at a dose of 1.5–2 g/kg/day for more than 2 years, concluded that the Long-term use of the composite fish oil based ILE was well tolerated in home PN-dependent children. The RBC-FA profile alterations were consistent with the ω-3 PUFA-enriched composition of this emulsion without evidence of essential FA deficiency [158].

Long Term Management of Intestinal Failure

Home Parenteral Nutrition

Long-term PN administration is best achieved at home. Home PN, first used in the early 1980s, allows for full nutritional support of children and adults with temporary or permanent IF at home [8, 94, 159, 160]. Survival of children receiving prolonged PN depends mainly on the underlying diagnosis and has increased dramatically during the last three decades; nevertheless complications such as CRBSIs, IFALD and loss of venous access can seriously challenge the clinical stability of patients with IF [8, 94, 159–165].

The expertise required to prescribe PN both at home and in the hospital usually comes from a dedicated hospital-based nutritional team who has a thorough knowledge of energy expenditure, nutrients and trace-elements requirements by age, appropriate central catheter handling, and awareness of the risk and complications of long-term PN. Home PN must be tailored to the single patient and its family, always maintaining the goal of counteracting the deleterious aspects of intestinal failure. Official guidelines and position statements on central catheter handling and PN prescription have been published [135].

One of the largest cohort from a single center has been recently reported [8]. It involves 251 children referred to the Paris-Necker Intestinal Rehabilitation Center and discharged on HPN between January first 2000 and December 31st 2013. In this survey, 217 children (86%) had a primary digestive diseases (PDD). The mean age at HPN onset was 0.7 ± 0.3 year with a mean duration of 1.9 ± 0.4 years. The major indication for HPN was SBS (59%) secondary to midgut volvulus (16.7%), necrotizing enterocolitis (12.3%), gastroschisis (12%), extensive Hirschsprung Disease (10%) and intestinal atresia (6.4%). Other PDD were congenital enteropathies (10%), CIPOS, (9.1%) and Inflammatory Bowel Diseases (IBD, 5.1%). At the end of the study period, 56% of children were weaned off HPN, 8% had intestinal transplantation and 9.6% of children died - most of them had immune deficiency. The major complications of HPN were catheter-related blood stream infections (CRBSI, 1.7 per 1000 days of catheter) and IFALD, 51 children, (20% of the cohort). Children with congenital enteropathies had the highest rates of IFALD (44% of the sub-group). Children on HPN in this cohort have a shorter HPN duration to weaning, lower death rate and longer interval to catheter replacement than other

studies. One of the most important advances for long term PN dependent patients has been the onset of antiseptic catheter locking [92, 166].

The European data on the long-term management of IF on HPN need to be compared with other continent, especially North America. Several papers from the US, report "intestinal rehabilitation centers" including early management of intestinal failure (IF), especially short bowel syndrome in both neonatalogy and surgical wards, with the aim of the earliest PN weaning [87, 88, 167–170]. Some patients get severe complications and become candidates for ITx. Some others fail to be weaned off PN and are discharged on home-PN when suitable. The organization and follow-up of home PN is supposed to be shared between paediatric gastroenterology-nutrition teams and home care-giver companies according to the local facilities. Unfortunately, there is almost no report in the literature about the prevalence and results of paediatric home PN programs making a comparison with North-America management almost impossible. One of the reasons is linked to the organization and the management of IF. In France, patients suffering from IF, especially those with SBS, are managed by specialized medico-surgical departments, including paediatric surgeons and paediatric gastroenterologists-nutritionists or neonatology units. The decision of discharging the child on home PN and the follow-up are fully dependent on paediatric gastroenterology and nutrition teams. The French network is organized regionally. Patients are referred to the closest of the 7 reference centres for HPN. The world largest cross-sectional study included all children enrolled in any of the 7 French HPN certified centres from January 1st, 2014 to December 31st, 2019 [165]. The number of patients increased by 43.6% between 2014 and 2019. According to the year of follow up, the indications for HPN were short bowel syndrome (SBS) (42.3–46.6%), congenital enteropathies (CE) (18.5–22.8%), chronic intestinal pseudo-obstruction syndrome (CIPOS) (13.0–16.3%), long segment Hirschsprung's disease (LSHD) (9.7–13.3%), Crohn's disease (CD) (1.6–2.6%) and other non-primary digestive diseases (NPDD) such as immune deficiency, cancer or metabolic disease (4.0–9.2%). The median age at discharge on HPN decreased from 11.7 months in 2014 to 8.3 months in 2019 ($p < .001$). By December 31st, 2019, 44.8% of children had left the HPN program after a median duration ranging between 39.9 and 66.4 months. Among these patients, 192 (74.2%) were weaned off PN (94.7% SBS), 41 (15.8%) were transferred to adult centers for CIPOS (42%), SBS (31%) or CE (27%), 21 died (8.1%) - mostly in relation to cancer or immune deficiency - and 5 were transplanted (1.9%): 4 underwent combined liver-intestine transplantation for LSHD (n = 2), SBS, CE and one multivisceral Tx for CIPOS. The use of a composite fish-oil based ILE increased from 67.4% in 2014 to 88.3% in 2019 ($p < 0.001$). With the use of taurolidine lock procedure (TLP) the rate of CRBSIs dropped from 1.04 CRSBIs per 1000 days HPN in 2014 to 0.61 in 2019 ($p < 0.001$) while in meantime, the percentage of children receiving TLP increased from 29.4% to 63.0% ($p < 0.001$). The prevalence of cholestasis (conjugated bilirubin ≥20 μmol/l) was low and stable between 4.1 and 5.9% of children during the study period.

Intestinal Rehabilitation Centers and Multidisciplinary Team

Paediatric IF is a multifaceted condition requiring the competent contributions of several medical and allied health professionals both for inpatient and outpatient care. Therefore, the formation of a multidisciplinary team is crucial to achieve optimal results [165, 167–170].

The IF team should ideally include staff specialised in surgery, neonatalogy, gastroenterology and nutrition, a paediatric dietician and nurses experienced in central venous catheters handling and parenteral nutrition infusion. Special consideration should be given to the link between the hospital team and the home care team. Fostering coordination of surgical, medical, and nutritional management is mandatory to provide high quality, integrated care of patients with IF, thus improving remarkably the survival of these patients [8]. The three most important issues in the management of children with IF include:

1. A good and early link between primary care givers and intestinal failure programs.
2. The presence in the program of both intestinal rehabilitation and intestinal transplantation expertise.
3. The participation in the network of the organisations providing home PN bags.

Collaborative strategies must be developed in order to reduce mortality and morbidity in patients with IF, especially for those who are referred for permanent IF or intestinal transplantation [144].

Intestinal Transplantation

Although a large percentage of children with IF can survive with long-term PN, a proportion of patients develop life-threatening complications such as severe septic episodes (CRBSIs and/or SIBO related), fluid and electrolytes imbalance with renal disease, loss of venous access for PN and end stage liver disease. In these patients, nutrition has failed both in the enteral and the parenteral routes. These patients are considered to have "nutritional failure" [9, 144, 171]. They should be referred for intestinal transplantation (ITx). Successful ITx were first reported in the late 1980s and pro-

posed for the treatment of patients affected by irreversible intestinal failure [172, 173]. In 2001 the American Society of Transplantation defined irreversible liver disease, exhaustion of central venous access sites, and recurrence of life-threatening situations (recurrent sepsis or dehydration) as indications to consider ITx for patients with IF [174]. Despite important surgical and medical advances in the transplant techniques, reported long term patients' and grafts' survival rates remains around 50% at 5 years for children [175]. As an example, from a series of children with ultra-SBS referred to our institution some of them underwent ITx for nutritional failure while the others were maintained on HPN. With 5 years follow up, all children on HPN (100%) survived while those who have died anyway from nutritional failure survived in only 60% of cases [26]. This suggests that ITx has been a life saving procedure for 60%.

There is probably a different threshold for ITx on both sides of the Atlantic Ocean. The European approach is more inclined to support long-term home PN, which is cost-effective and provides a better quality of life, rather than to refer a child for ITx. Support for this view comes from Pironi et al. who have performed a 3-year prospective study including both adults and children on long-term PN for IF [176]. They compared 'non-candidates' for ITx (no indications nor contraindications), with 'candidates' who had an indication according to the USA Medicare and Medicaid Services definitions, and a high risk of death or morbidity according to the American Society of Transplantation position paper [177, 178]. The results showed that only patients with nutritional failure due to IFALD or major catheter complications had an increased risk of death on home PN, thus supporting its use as the primary treatment for IF. Those results were confirmed by another 3 years prospective follow-up study on potential paediatric candidates to ITx in Japan [179]. Bilirubin levels >100 μmol/l seem to negatively impact on post ITx survival. It is an important observation that a quarter of patients referred to an IF multidisciplinary team for ITx work up for irreversible IFALD, eventually reversed their cholestasis with an appropriate nutritional management [144].

Therefore it was suggested that ITx should be used only as a life-saving procedure. Although experienced transplantation centers have suggested that the role of ITx should be expanded to a pre-emptive/rehabilitative procedure applicable to all patients with irreversible IF, the recent findings have shown that home PN is the treatment of choice for IF in adults as well as in children. An early referral to IRC is essential to prevent or optimize the long-term management of IFALD. Central venous-catheter-related major complications might be indications for a pre-emptive ITx in selected patients. As a matter of fact, "nutritional failure" should be regarded mostly or even only as a clear indication to ITx [9].

In certain patients with other major organ failure in addition to SBS-IF, both long-term home PN and ITx may prolong suffering without improving quality of life. In such cases a wide-ranging ethical discussion should be performed to establish the best course of further treatment for the individual child. If home PN and ITx are not considered in the child's best interests it is important to involve a symptom care/palliative care team and if necessary make an end of life care plan [180].

Isolated liver Tx has been performed for IFALD in patients with SBS. Taha et al. reported a group of children with SBS and IFALD who have the potential for adaptation in the residual bowel underwent isolated LTx [181, 182]. The prognosis remains poor after this procedure, 8 survivors out of 14 [181]. This procedure should be avoided by preventing liver disease. If performed, it should be exercised with extreme caution. These children need careful assessment before isolated LTx and close follow-up with an experienced multidisciplinary team to monitor nutritional outcomes and may need consideration for transplant or non-transplant surgery in the long term (Fig. 5).

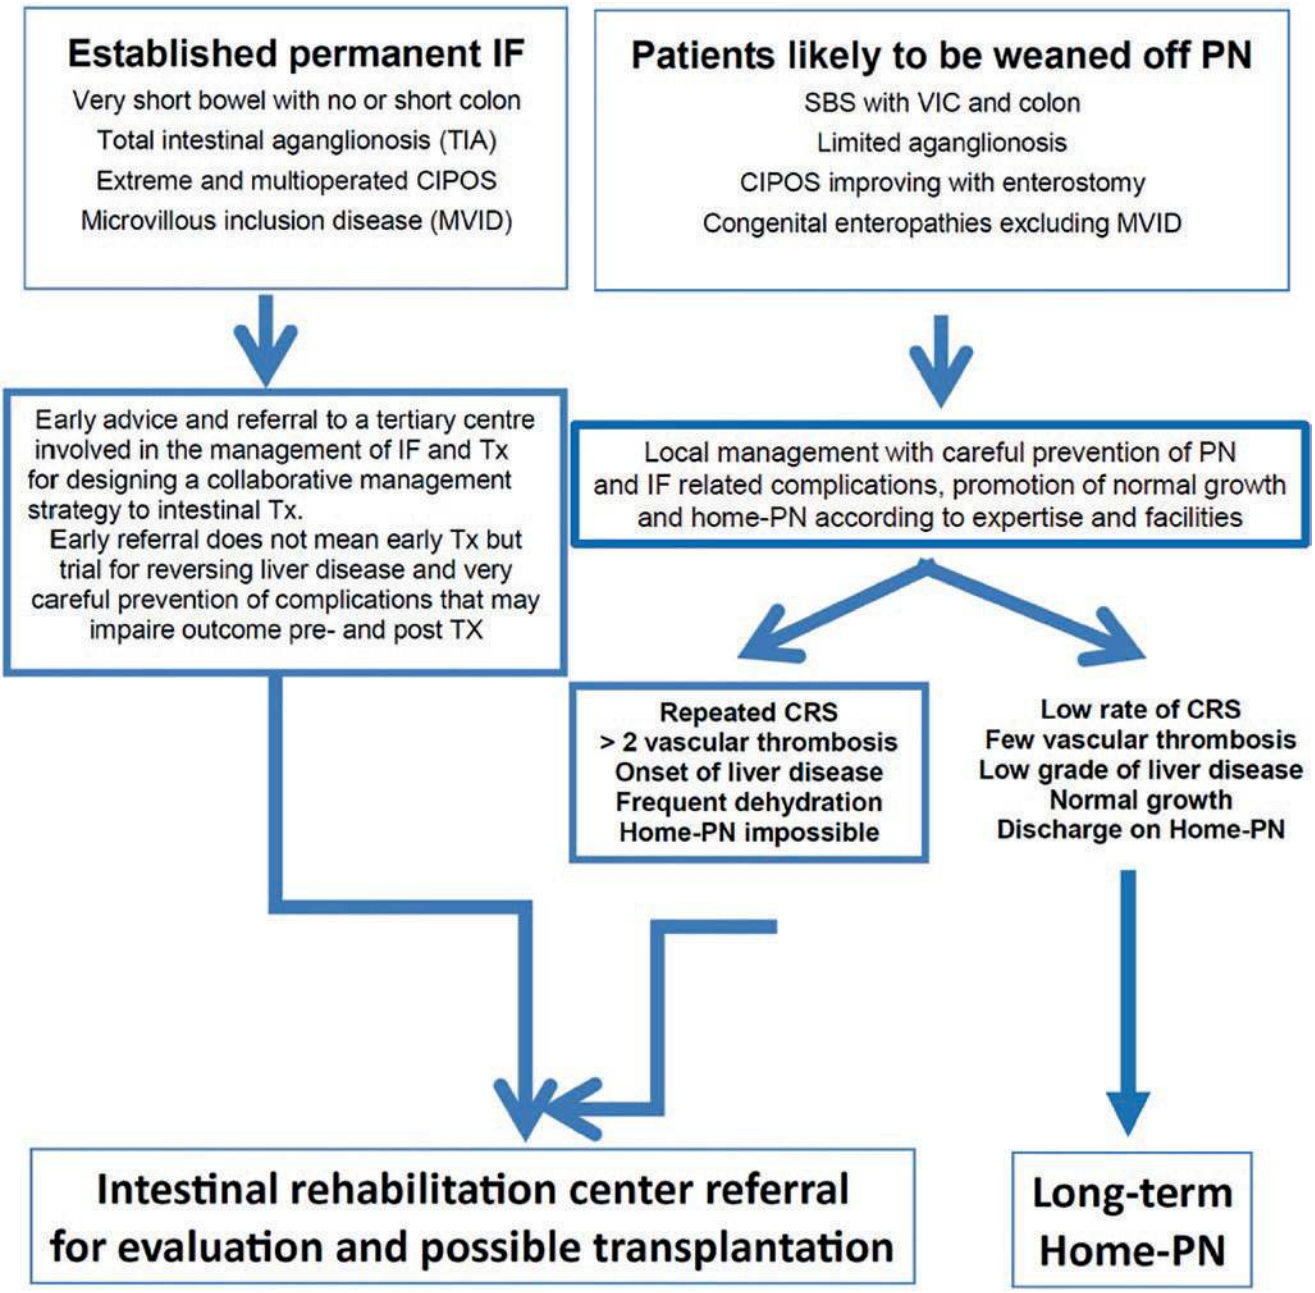

Fig. 5 Algorithm for managing intestinal failure from referral to possible intestinal transplantation

Conclusion

Intestinal failure requires specialized and individualized medical therapy that includes surgery, medical equipment, nutritional products, and standard nursing care. Intestinal rehabilitation programs provide such complex care with the goal of achieving enteral autonomy and oral feeding with or without intestinal transplantation. The treatment of permanent IF has made remarkable strides in the past decades. The establishment of multi-disciplinary intestinal rehabilitation programs at leading centers has improved the survival of children with IF while the morbidity associated with both IF and PN has significantly decreased. These programs almost all include neonatalogists, pediatric surgeons, pediatric gastroenterologists, specialized nurses, and dietitians; many also include a variety of other medical and allied medical specialists, providing integrated interdisciplinary care.

Recent advances in the knowledge of factors implicated in PN and IF complications and improvements in the medi-

cal and surgical management of SBS result in better outcomes for these patients. Isolated liver Tx for SBS patients who have the potential of bowel adaptation should be no longer required. It is interesting to note that the most recent International Intestinal Transplantation Registry report showed early evidence of a world-wide trend of reduction in the number of pediatric ITx. This might be explained by at least four factors:

- the provision of guidelines and training
- the development of intestinal rehabilitation centers with increasing IF expertise
- the enlarged use of non-transplant surgery
- the better prevention of IFALD, with fish oil based lipid emulsions playing a role
- the improved prevention of catheter related sepsis by using taurolidine or ethanol locks
- the onset of hormonal treatment for SBS

The combined and coordinated talents and skills of multiple types of health care practitioners have the potential to ameliorate the impact of intestinal failure and improve health outcomes and quality of life.

Major efforts are needed to improve the outcome of ITx that will likely remain part of the armamentarium required to prolong the survival of children with life-threatening complications of IF. Nevertheless the European experience has led to support a more conservative approach more inclined to home PN, limiting referrals for ITx only to children with nutritional failure.

Part IV

Consequences of Intestinal Failure

Consequences of Undernutrition and Dehydration

Pete Turner, Simon Alison, and Jeremy M.D. Nightingale

Key Points

1. Undernutrition is common in all patient groups and affects all body systems.
2. Undernutrition adversely affects all disease processes resulting in longer hospital admissions with increased nursing dependency, higher morbidity and mortality.
3. Severe malnutrition impairs thermoregulation so that patients with a severe sepsis may not be identified.
4. Albumin is generally not a marker of nutritional status.
5. Patients who have been obese can have a high body mass index (BMI) yet be severely undernourished (sarcopenic obesity).
6. With no food (oral intake) but with water a healthy adult may be expected to live 2 months. This time is reduced in the presence of sepsis/inflammation.
7. With no water intake (oral, enteral or intravenous) an adult may be expected to survive for up to 2 weeks. This depends upon activity, ambient temperature and fluid losses.

Introduction

The European Society of Enteral and Parenteral Nutrition (European Society of Clinical Nutrition and Metabolism) (ESPEN) have stated that the terms undernutrition and malnutrition can be considered synonymous and can be defined as 'a state resulting from lack of intake or uptake of nutrition that leads to altered body composition (decreased fat free mass) and body cell mass leading to diminished physical and mental function, and clinical outcome from disease' [1]. Gastrointestinal disease gives rise to undernutrition by reduction of appetite, oral intake, digestion and/or absorption, and increased metabolic demands.

The physical and mental consequences of starvation and undernutrition have been known since ancient times. An ancient Egyptian royal tomb of more than 2000 years BC bears the inscription:

> *I am mourning on my high throne for the vast misfortune, because the Nile flood in my time has not come for seven years! Light is the grain; there is lack of crops and of all kinds of food. Each man has become a thief to his neighbours. They desire to hasten and cannot walk. The child cries, the youth creeps along as does the old man; their souls are bowed down, their legs are bent together and drag along the ground and their hands rest in their bosoms. The counsel of the great ones in the court is but emptiness. Torn open are the chests of provisions, but instead of contents there is air. Everything is exhausted.*

During the twentieth century, a number of studies of normal and obese individuals undergoing prolonged starvation, [2, 3] of populations under famine conditions, [4] and of patients suffering from disease-related undernutrition, [5] have given us a clearer picture of the relationship between weight loss or, more particularly, loss of body cell mass and deteriorating mental and physical function. The relationship between structure and function is not always linear [6] with some functions beginning to deteriorate early in the process of starvation, whereas others are relatively unimpaired until later. In some cases there may be a threshold above, which function is largely maintained but below which it falls rapidly [7]. Much depends upon the initial nutritional state of the subject and also on the rate at which tissue is lost [8]. Total starvation may have different effects from partial starvation, and there may also be a process of adaptation to chronically low intakes, as seen among the lean subsistence farmers of Asia. The relative proportions of energy and protein deficiency, the development of single or multiple deficiencies of minerals, trace elements and vitamins, and the

presence of disease may all modify the consequences of partial starvation.

This chapter mainly outlines the consequences of disease-related undernutrition consequent upon intestinal failure, with supportive and relevant evidence from other studies of starvation. Much data about the consequences of undernutrition come from paediatric reports from developing countries and from work on young people with anorexia nervosa. The chapter also summarises the consequences of dehydration which are known to most clinicians but for which there are few publications to reference.

Survival

Hunger strikes have occurred since Roman times, and the suffragettes brought this method of protest to public attention in Britain in the early twentieth century. Mahatma Gandhi fasted at least 14 times but never for more than 21 days. The most striking example of total starvation in previously healthy young men without disease was provided by the 30 Irish Republican Army (IRA) hunger strikers of Northern Ireland [8]. In 60–70 days, they lost 38% of their body weight and one-third of them had died, allowing us to conclude that, in the absence of disease, previously normally nourished adults may survive weight loss of 35%, or approximately 60 days of total starvation (Fig. 1). Beyond this point mortality rises steeply. This time point is considerably reduced if a patient has already lost weight or has underlying sepsis or malignancy. One of the hunger strikers, who was suffering from a gunshot wound, survived for only 45 days, emphasizing the cumulative effect of illness and starvation. Studley in 1936 showed that if patients had lost more than

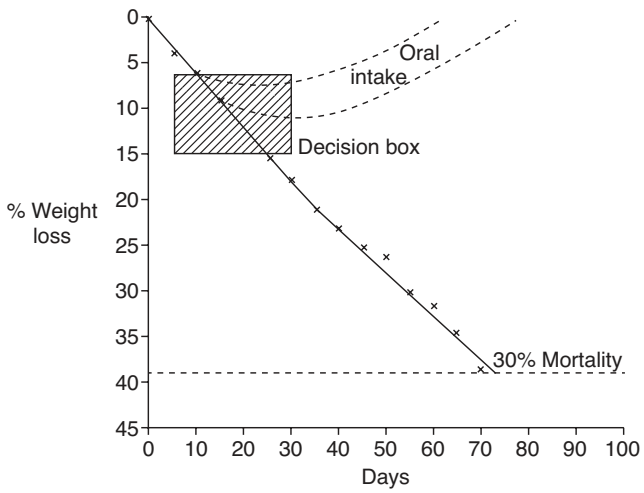

Fig. 1 Percentage weight loss and days after starting to starve. The decision box indicates the time when an oral intake will lead to a rapid recovery

20% of their body weight prior to surgery for peptic ulcers, they had a 33% mortality compared with 4% if less than 20% body weight had been lost [9].

Children are even more vulnerable because of the demands of growth and development and, during infancy, because of their high metabolic rate in relation to body size and high surface to volume ratio. The survival of a totally starved neonate may be no more than a few days. Studies among undernourished Asian children by Pelletier et al. suggested that their odds of dying from disease and undernutrition increased by a compound rate of more than 7% for each percentage point deterioration in weight for age [10]. There was also an exponentially increasing probability of morbidity as weight fell below 80% of normal for age.

The protective effect of obesity is illustrated by reports of survival by fat adults undergoing periods of starvation of 130–382 days [3]. This protective effect is not only due to greater fuel reserves, but also to the lower daily losses of nitrogen in relation to lean mass, implying a metabolic control mechanism. Whether obesity is similarly protective in the presence of intercurrent illness is unclear.

The extraordinary studies carried out by the Jewish physicians in the Warsaw ghetto in 1942 gives us further insight [4]. Most of the inhabitants had been on 800 kcal a day or less for many months and at the point where they were studied had already lost between 20% and 50% of their pre-war weight and weighed between 30 and 40 kg. One woman, for example, with a height of 1.52 m weighed 24 kg, giving a body mass index (BMI) of 10.3 kg/m^2. Many were suffering from intercurrent infections and most died within 3 weeks of the studies, although there were clearly some variations in the ability to survive starvation. A review suggests that the lower limit of BMI compatible with survival is approximately 10 kg/m^2 in women and 12 kg/m^2 in men [11]. These observations have important implications for clinical work. The MEED guidelines suggest admitting anyone with a BMI of less than 13 kg/m^2 [12]. It is not uncommon to be referred patients for nutritional support who have lost 20–35% of their body weight and in whom not only function but also survival is at stake. It can also be argued that, if parenteral nutrition is required for a total of 60 days or more because of continuing gastrointestinal dysfunction, such treatment is life-saving in the same sense that dialysis is life-saving in renal failure and ventilation in respiratory failure. The difference between these situations is not one of principle but of time-scale.

Undernutrition in Intestinal Failure

Undernutrition in intestinal failure (IF) can be considered as disease related malnutrition that occurs not only due to reduced intake/loss of appetite but through malabsorption, high GI losses, multiple surgical procedures, immobilisa-

tion and sepsis/inflammation all of which result in a loss of body mass. This is classified by ESPEN as 'disease related malnutrition with inflammation' [1]. A further subcategory 'chronic disease related malnutrition with inflammation' is considered synonymous with cachexia and can include that caused by inflammatory bowel diseases [1]. In this a less severe inflammatory response (CRP ≤40 mg/L) due to the disease itself over a prolonged period can lead to significant muscle wasting. A detailed nutritional assessment taking into account the degree and cause of inflammation is imperative for successful management of malnutrition in IF. In the presence of sepsis/inflammation nutritional status may not improve despite adequate energy being given. A study of 1950 medical patients found that those with a CRP level <100 mg/L did not respond well to nutrition support in terms of improvements in 30 day mortality or functional measures, whereas those with moderate (CRP 10–100 mg/mL) or low inflammation (CRP <10 mg/L) did [13]. This phenomenon forms a key part of the SNAP (Sepsis, Nutrition, Anatomy, Plan) principle of treating IF (chapter "Acute Surgical Intestinal Failure. Sepsis and Enterocutaneous Fistula(s)").

Due to malabsorption and high GI losses, IF patients are at a high risk of multiple micronutrient deficiencies. These have been demonstrated in paediatric studies and are likely to occur in adults. A study of long term paediatric IF patients having undergone transition from PN to oral nutrition demonstrated a high incidence of vitamin, mineral and trace element deficiencies, despite most (101 of the 138) children studied being on micronutrient supplements (Table 1) [14].

Zinc and copper are excreted in bile and deficiencies can therefore easily occur in patients with high output fistulas and stomas. Their levels should be interpreted with caution in acutely unwell patients; zinc is a negative acute phase reactant being bound to albumin and copper a positive one being bound to caeruloplasmin [15].

Table 1 Micronutrient deficiencies in children with IF [14]

Micronutrient	Deficiency %	p-value
Vitamin A	19.1	0.046
Vitamin B12	12.4	0.41
Vitamin D	30.1	0.56
Vitamin E	6.2	<0.001
Folate	0	1
Copper	7.7	0.14
Iron	61	0.003
Selenium	4.3	0.26
Magnesium	10.9	0.71
Phosphorus	8.8	0.88
Zinc	22.9	0.73
Anaemia	43.2	<0.001
Iron deficiency anaemia	29	0.21

Consequences of Undernutrition

General

A clear description of undernutrition/starvation comes from data in Western Holland in 1945. Complaints were of backache, aching legs, tingling of fingers and toes, periods of diarrhoea, nocturnal urinary frequency. Superficial haemorrhages, on skin on the back of the hands and on the face, hunger oedema, cyanosis of the skin of the extremities and rarely gangrene of the toes. A low temperature down to 35 °C was recorded, the heart rate was usually slow at 40 beats per min, the systolic blood pressure was down to 80 mmHg. There was often a red tender tip of tongue. The reflexes were normal, the urine testing showed no albumin, acetone or glucose. Anaemia was common (Hb 110 g/L) as was a leucopenia. Osteoporosis and kyphoscoliosis of the upper spine was observed [16].

Observations from hunger strikers state that they feel faint and dizzy. They learn to stand up very slowly and may become bed bound. Bradycardia and drop in blood pressure occur after even relatively short fasting. Orthostatic hypotension is present by about day 20 and may be disabling. Weakness and light headedness are common. Although thyroxine concentrations are maintained in fasting, triiodothyronine is converted rapidly to an inactive metabolite, thus reducing effective thyroid function. This will lead to weakness and a sensation of feeling cold. Abdominal pain has been described in around three quarters of hunger strikers [17–19].

Undernourished patients in hospital require high-dependency nursing, having an increased hospital stay with an increased morbidity and mortality compared with patients of normal weight having similar underlying clinical problems [20–24]. The consequences of undernutrition are summarised in Table 2.

Biochemical

In uncomplicated starvation, hepatic gluceonogenesis maintains blood glucose for use by the brain, blood cells and renal medulla. Muscle, some neural tissue, adrenal cortex and adipose tissue switch from using glucose to using fatty acids and ketones, derived from lipolysis, for energy. Muscle supplies alanine, glycine and lactate for hepatic gluceonogenesis, and glutamine as a source of energy to intestinal and lymphoid tissue. The glycogen reserves are rapidly utilised (6 h–3 days). As there is no carbohydrate for energy insulin levels fall and glucagon levels rise. The increased plasma glucagon levels (like GLP-1) induce a naturesis and thus weight loss. Energy starts (day 3 onwards) to be derived mainly from lipid via ketones. The sodium/potassium pump fails. Whole body phosphate, potassium and magnesium fall.

Table 2 Consequences of undernutrition

System with reduced function	Consequence
Psychological/neurological	Apathy/depression/anxiety/psychosis
Depletion of water soluble vitamins e.g. thiamine	Increased sleep time
	Reduced recent memory
	Loss of appetite
Muscle	Weakness, impaired rehabilitation
Skeletal	Chest infections
	Pressure sores
	DVT/pulmonary emboli
Cardiac	Bradycardia/low BP/orthostatic hypotension
	Cardiac failure, Cardiac atrophy
	Long QT interval, T wave abnormalities, sudden death
Gastrointestinal	Parotid hypertrophy, reduced gastric acid and pancreatic enzymes Mucosal atrophy with inflammatory infiltrate Gastric dilatation and slow gastric emptying, colonic stony Bacterial overgrowth/change in microbiota Increased translocation
	Reduced gut associated lymphoid tissue
	Reduced colonic sodium and water absorption Diarrhoea
	Sepsis/multi-organ failure
Liver	Steatosis, abnormal nuclear receptor PPARalpha signaling, synthetic function reduced (e.g. conjugated bile acids, complement proteins and albumin)
Endocrine (low sex, thyroid and growth hormones)	Poor growth
	Delayed puberty
	Amenorrhoea
	Infertility
	Osteopaenia/osteoporosis
Thermoregulation	Hypothermia
Repair mechanisms	Slow wound healing
	Pressure sores
Immune	Reduced lymphocyte count
	Infections
Fluid and electrolytes	Oedema
Metabolic	Low creatinine, urea, glucose, phosphate and potassium Faecal alpha 1 antitrypsin increased
Haematological	Anaemia, neutropaenia, thrombocytopaenia
Bone	Osteopaenia/osteoporosis

In the presence of sepsis, lipolysis is impaired and a further increase in muscle protein catabolism occurs. Protein is initially protected (making up only about 10% of the energy source) but in the latter stages, when fat stores have been exhausted there is catastrophic protein catabolism including from cardiac muscle and ultimately death [19].

Psychological and Neurological

Apathy/Depression

The mental changes associated with starvation, noted by the ancient Egyptians, were a striking feature of the studies carried out by the Warsaw physicians [4]. They reported: 'The most striking psychiatric finding is the prevalence of depression, even in young people. There is complete apathy, lack of interest, poor thinking, and even incoherence.'

In his introduction to the *Biology of Human Starvation*, [2] Sir Jack Drummond wrote of the famine in Holland in 1945:

> *Two impressions dominated: firstly the immense importance of the psychological aspects of inanition; secondly the comparative simplicity of the nutritional and biochemical problem. One of the curious and rather disconcerting psychological manifestations of starvation, seen repeatedly in Western Europe, was the unresponsive and uncooperative attitude of those to whom relief was brought. It disappeared without trace when calorie intakes rose above 1500 to 1800 a day…. An outstanding impression gained in Western Holland in 1945 was the importance and significance of the psychological consequences of food shortage…. From the grumbling and grousing that are inevitably provoked when the energy intake is deficient to the extent of 15–20%, to the apathy and dissolution of higher human qualities that come with severe starvation, there is a wide variety of psychological reactions to hunger, many of which are almost of themselves diagnostic of the level of calorie intake.*

In their study of normal young male volunteers undergoing semi-starvation for 24 weeks, Ancel Keys and his colleagues described not only the diminished physical powers which were associated with a loss of up to 23% of the body weight during that time, but also a rise in a depression score of 30% [2, 25]. This was slow to recover during the process of re-feeding. Indeed it took up to 4 months to return to normal. Similar observations have been made in prisoner of war camps, during the Russian famine of 1918–1921, among undernourished children in the Indian subcontinent and in Africa.

It is important to remember that patients suffering from disease-related undernutrition are often apathetic, depressed and awkward. These difficulties soon dissolve with appropriate nutritional care. The fatigue, which follows illness, may also be prolonged by undernutrition.

Intellectual Performance/Sleep

Intellectual performance changes little though short-term memory is reduced and sleep-time increased [2, 11, 26].

Appetite

Undernutrition causes a reduction in appetite. A vicious circle is thereby created which needs to be broken if normal oral intake is to be resumed. After 1–2 weeks of overnight nasogastric tube feeding, the appetite may be restored so that voluntary oral intake by day is increased [26]. This is sometimes very striking in some cases of inflammatory bowel disease. Once a certain weight has been reached, the appetite appears to be self-perpetuating and nutritional support may be discontinued. Interestingly it has been demonstrated that patients undoing upper gastrointestinal surgery such as oesophagectomy may have decreased appetite similar to that seen following bariatric surgery, mediated by enhanced release of satiety hormones [27].

Skeletal Muscle Function

Protein/energy malnutrition is characterized by muscle wasting with particular loss of the Type II fast-twitch fibres, which are prevalent in the respiratory muscles, including the diaphragm [28–33]. The poor function of skeletal muscle in the chest increases the risk of developing chest infections [34] including tuberculosis, and the resulting reduction in mobility increases the risk of deep venous thrombosis, pulmonary emboli and pressure sores [33–37].

In a study of ten patients with various gastrointestinal disorders, Lopez et al. [28] measured the function of the adductor pollicis muscle by electrical stimulation of the ulnar nerve and found that undernutrition resulted in increased muscle fatiguability and an altered pattern of muscle contraction and relaxation, all of which were reversible by nutritional supplementation. In a study of five morbidly obese female subjects, on a 400 kcal/day carbohydrate diet, Russell et al. [29, 30] showed similar changes in muscle function, significant reductions in muscle enzymes and a change in muscle histochemistry with type II fibre atrophy. Comparing the effect of undernutrition with the effects of surgery and sepsis, Brough et al. [31] found abnormal muscle function consequent upon sepsis, but the changes were easily distinguishable from subjects taking an inadequate diet. They found no effect on muscle function following trauma, surgery or steroid administration. They also showed that, following the initiation of parenteral nutritional support, there was a rapid initial improvement in muscle function within days, which occurred before any change in anthropometric variables or plasma proteins. Hill found similar changes in undernourished patients with inflammatory bowel disease [5, 6]. Measuring whole body protein by neutron activation techniques, he showed that a 20% reduction in total body protein, reflecting lean mass, was associated with little change in respiratory muscle strength, but beyond this there was a steep deterioration.

Over the first 5 days of nutritional support, both grip strength and peak expiratory flow rate rose from a mean of 65–75% of normal [5, 6]. This was followed by a much more gradual and sustained improvement over the ensuing weeks as body composition was restored. This again illustrates the two-phase response to refeeding. The first is associated with a rapid improvement in cellular function and the second with the much more gradual process of the restoration of body cell mass. Muscle function may also be seriously impaired with single or multiple electrolyte, mineral or micronutrient deficiencies, conditions that are not uncommon in patients with gastrointestinal disease. Hypokalaemia may be responsible for muscle weakness or even paralysis; selenium deficiency causes impairment of both myocardial and skeletal muscle function. Deficiencies of magnesium and of calcium decrease peristalsis but increase skeletal neuromuscular excitability and may cause fits.

Respiratory

Undernutrition impairs respiratory function, chiefly through its effect on respiratory muscles, impairing ventilation and the ability to cough and clear secretions [38–44]. It also reduces respiratory response to hypoxia [45, 46] and the ability to wean from ventilators [43]. In contrast, nutritional support improves ventilatory function and has facilitated weaning from ventilators. Respiratory complications of surgery, trauma or acute illness are one of the major consequences of under-nutrition. The terminal event in progressive starvation is nearly always bronchopneumonia [16].

One corollary of weak respiratory muscles is the inability to cope with the additional respiratory demands imposed by excessive caloric feeding, particularly of carbohydrate. Such patients may be rendered breathless by carbohydrate loads in

excess of 5 mg/kg/min or total energy intakes in excess of 40 kcal/kg/day, owing to increased oxygen consumption and CO_2 production [47, 48].

Cardiovascular and Sympathetic Nervous System

The Warsaw studies of advanced starvation [4] showed that this was associated with lower systolic and diastolic blood pressures at rest and in response to exercise. Bennett et al. showed that starvation, with sodium supplementation, for 48 h in healthy men was associated with a small drop in supine blood pressure, but after 10 min standing, there was a fall in systolic blood pressure of 15 mmHg with no change in the non-starved controls [49]. There is a reduction in heart rate, blood pressure and cardiac muscle mass; although this reduction in cardiac muscle is considerably less than that of skeletal muscle, it could predispose to cardiac failure [50, 51]. A prolonged QT interval may lead to ventricular arrhythmias [52]. The long QT interval is a function that takes the longest to recover on refeeding. Patients who have a postural fall in BP greater than 20 mmHg (or syncope), a bradycardia less than 40 bpm, and or a long QT internal are at risk of sudden death [12].

As sympathetic nervous system function is a major determinant of metabolic rate and as its function is reduced in undernourished patients, it is not surprising to find a markedly reduced resting metabolic expenditure in these patients. This must be borne in mind when estimating the nutritional requirements of depleted patients.

Gastrointestinal

The effects of undernutrition upon the gastrointestinal tract are complex and depend upon its severity. The Warsaw studies [4] demonstrated, in patients with more than 30% weight loss, an impairment of gastric acid secretion. Lack of luminal nutrition during parenteral nutrition, in studies on normal subjects or associated with undernutrition, may result in villous atrophy, impaired small bowel mucosal function and increased intestinal permeability [53–56]. Gut mucosal atrophy may be responsible for mucosal barrier dysfunction and bacterial translocation which may gives rise to an endotoxaemia, which with immune impairment, in turn may contribute to multi-organ failure [57]. The addition of antibiotics to therapeutic regimens for uncomplicated severe acute malnutrition in children is associated with a significant improvement in recovery and mortality rates [58]. The colon can be affected, losing its ability to reabsorb water and electrolytes, so diarrhoea may result [59, 60]. There may be altered intestinal flora with migration of bacteria proximally into the small bowel, thereby exacerbating malabsorption [61].

These changes may be seen during parenteral feeding when there is a lack of oral/enteral intake, or in segments of bowel that have been by-passed. The introduction of food, by the oral or enteral route, reverses these changes and accelerates adaptation of a retained ileum in patients with a short bowel. Particular substrates may be important. Soluble fibre and prebiotics such fructo-oligosaccharides, giving rise to short-chain fatty acids, may enhance both small and large bowel mucosal growth and function. Glutamine is an essential fuel for the mucosal epithelium and may enhance the protective effect of the gut-associated lymphatic tissue.

Pancreatic function has been studied in undernourished infants and in adults, and been shown to be impaired. Winter and colleagues [62–64] studied a series of patients with a mean BMI of 13.6 kg/m^2 before treatment and 16.5 kg/m^2 after nutritional support. They found that before treatment, pancreatic protein synthesis and enzyme production was reduced, so that 70% of gastric and pancreatic secretion was lost with consequent impairment of xylose and fat absorption. All parameters were restored towards normal by refeeding. They confirmed findings of impaired gastric acid secretion, as well as pancreatic amylase and trypsin secretion.

Malnutrition-related enteropathy is well described though can be difficult to differentiate from environmental enteric dysfunction (EED) ("tropical sprue"). It is characterised by villous atrophy, crypt hyperplasia, loss of tight junctions, and an influx of inflammatory cells into the intestinal mucosa [65]. This is why care must be taken in interpreting small bowel biopsies (usually to determine if there is an enteric myopathy or neuropathy) in the presence of severe malnutrition.

Gastric emptying for liquid and solid is delayed in undernourished patients with anorexia nervosa [66, 67]. Gastric dilatation, peptic ulcer, acid reflux and colonic atony leading to constipation have been reported.

Malnourished patients with Crohn's have a worse disease progression than those who are normally nourished and indeed feeding and increasing the weight of malnourished patients with Crohn's disease reduces the inflammation [68].

The microbiota of malnourished children change to being less diverse and there being an increased relative abundance of pathogenic genera within the phylum Proteobacteria (*Enterobacter, Escherichia, Klebsiella,* and *Shigella*), and a decreased relative abundance of genera containing beneficial bacteria (*Bifidobacterium, Butyrivibrio, Faecalibacterium, Lactobacillus*, and *Roseburia*) [69].

Immunological

In undernutrition, many aspects of immune function, particularly of cell-mediated immunity, are impaired and increased susceptibility to infection is well documented in adults, [4,

70–73] children [74, 75] and the elderly [76]. Conversely, one of the consistent features of positive trials of nutritional support is a reduction in postoperative and other infections [74–80]. Much of the tissue involved in immune responses lies in the gastrointestinal tract and the gut-associated lymphatic tissue. The provision of luminal nutrients and special substrates such as glutamine may have their beneficial effects partly through providing essential nutrients to this tissue. It is important, however, not to over-simplify the situation, since the relationship between nutritional status and immune competence is a complex one and may vary according to the clinical condition and the nutritional deficiencies involved. As well as protein-energy undernutrition, mineral and micronutrient deficiencies may also impair immunity. Good et al. [73] for example, found zinc to be an important factor for the maintenance of cell-mediated immunity.

Immune competence, as measured by delayed cutaneous hypersensitivity (DCH), is affected by severe protein-energy malnutrition. While it is true that immune competence as measured by DCH is reduced in protein-energy malnutrition, several diseases [53] and drugs influence this measurement making it a poor predictor of protein-energy malnutrition in sick patients. The following factors non-specifically alter DCH in the absence of protein-energy malnutrition:

1. Infections (viral, bacterial and granulomatous)
2. Uraemia, cirrhosis, hepatitis, trauma, burns and haemorrhage
3. Steroids, immunosupressants, cimetidine, warfarin and perhaps aspirin
4. General anaesthesia and surgery.

Hence in the critically sick patient many factors can alter DCH and render it valueless in assessing the state of nutrition. Meakins et al. [54] have shown that simply draining an abscess can reverse anergy. Immunity is therefore neither a specific indicator of protein-energy malnutrition nor is it easily studied [55].

Thermoregulation

The Warsaw physicians observed lower than normal body temperatures in their patients, as well as failure to develop a fever in response to typhoid or tuberculosis [3]. Similar changes may be seen among the undernourished and the elderly in routine hospital practice. Bastow et al. [81] observed low core temperatures in winter (<36 °C) among elderly women admitted with fractured femur, whose anthropometric indices were more than two standard deviations below the reference range. In contrast, the normally nourished fractured femur patients had core temperatures in excess of 36 °C on admission. When undernourished individuals were put in a cooling suit, Fellows et al. [82] found normal vasoconstriction but no increase in thermogenesis in response to the challenge. Mansell et al. [83] showed, in younger subjects, that the thermogenic response to cooling was restored when body composition was returned to normal by nutritional support. They also showed [84] that the vasoconstrictor response to cooling was impaired in normal subjects who fasted for 48 h. Both short-term starvation and weight loss, therefore, impair thermoregulation but by different mechanisms.

In adults, with a temperature of 34–36 °C: they will feel cold and will move around more, but may become withdrawn or aggressive. At a temperature of 33–34 °C: they may stagger and become confused and drowsy, but strangely the patient may feel warm and remove clothes. At a temperature of 26–32 °C, coma may occur and at less than 26 °C death may occur (sometimes after ventricular fibrillation) [12].

Thus undernourished patients are prone to hypothermia and the recognition of sepsis/fever may be difficult as their temperature tends to be lower than normal.

Wound Healing

The metabolic response to injury in which energy and substrates are mobilized from within the body to meet the demands of illness and injury must have a survival value to have evolved at all. The paradox is that, when taken to extremes, it may threaten survival. One of the crucial features of the response is the mobilization of nitrogen from muscle to meet metabolic requirements. This feature was blunted in traumatized rats that had previously been exposed to a low protein diet [85].

There is an impairment of wound healing [86–92]. Windsor et al. [86] showed, in man, that a low preoperative food intake impaired wound healing. Haydock and Hill [87] also documented impaired wound healing in undernourished surgical patients and further observed that this can occur with quite modest degrees of undernutrition. Pressure sores are also more likely to develop in undernourished patients and are slower to heal [88]. Nutritional support may contribute to more rapid healing. An adequate supply of minerals and micronutrients is necessary for wound healing, including vitamins A, B, C, D, E and K [89]. Zinc is a cofactor for collagen formation, [89] and zinc deficiency has been associated with failed wound healing which is restored to normal by zinc supplementation [90, 91].

Endocrine and Bone

Anorexia nervosa with a BMI below 17 kg/m^2 is characterized by amenorrhoea with subdued hypothalamic function

and secondary effects upon the pituitary and the ovaries or testes. Exactly the same changes are seen in patients who are cachectic as a result of gastrointestinal disease. Low sex and growth hormone coupled with increased cortisol and glucagon levels reduce muscle mass, strength and energy, as well as reducing bone density. We have observed a young patient with Crohn's disease to have a bone density three standard deviations below the mean for his age and a low serum testosterone. These were both restored to normal within 2 years, once his chronic state of undernutrition had been adequately treated. Protein/energy malnutrition may also affect bone structure; osteoporosis is characteristically more prevalent in the undernourished. Malabsorption of fat-soluble vitamins may result in vitamin D deficiency and osteomalacia.

Growth and Development

Undernutrition in childhood leads to reduced growth velocity which may be restored by nutritional intervention. However, prolonged undernutrition permanently impairs achievement of genetic potential for height, which cannot be recovered even with optimal nutrition [93, 94]. Puberty is also delayed since the pituitary gonadal axis fails to function normally and it is a common experience to find impaired growth and development among adolescents with severe gastrointestinal disease and malabsorption.

Fluid and Electrolytes

Starvation and subsequent refeeding have profound effects on fluid and electrolyte balances. Intracellular concentrations of key ions such as sodium and potassium are maintained by cell membrane pumps. Since cell membrane pumps are activated by insulin and account for approximately a third of resting energy expenditure [95], there is likely to be a significant reduction in their activity during starvation which is responsible for depletion of intracellular ions such as potassium, magnesium and phosphate. 98% of body potassium is intracellular [96] and starvation can lead to a significant reduction in whole body potassium that is not reflected in plasma levels which may remain normal [97].

Oedema has been observed during refeeding [4, 98] and may partially be due to reactivation of cell membrane pumps leading to a loss of accumulated sodium and water from cells, with subsequent failure to excrete this load due to the effects of insulin and potassium depletion on the kidney [99]. Since sodium excretion more or less ceases in refeeding [100] it has been recommended that sodium provision be restricted to <1 mmol/kg and fluid to around 20 mL/kg/day, [101] especially as malnourished patients who may have cardiac atrophy and risk of cardiac failure [102]. Extreme caution should be taken when providing electrolytes or medicines in 0.9% saline as the sodium load and constriction of renal arteries caused by hyperchloraemia increase the risk fluid overload and oedema [103, 104]. Bowel oedema may lead to ileus and poor healing of anastomoses and fistulae [104, 105]. However since IF patients may have high GI losses of fluid, sodium, chloride, potassium and magnesium, a careful daily assessment of fluid and electrolyte requirements is imperative to ensure the correct composition of maintenance fluids and those used to replace GI losses [106].

Resistant oedema can be encountered in acutely unwell IF patients and unusual causes such as beri beri may need to be excluded. A slightly negative sodium and fluid balance should be the target with provision of adequate potassium [107]. Whole body potassium depletion can lead difficultly in excreting sodium if there is insufficient potassium to exchange in the kidney, thus ensuring patients get adequate amounts is imperative and at least maintenance amounts should be given even if plasma levels are normal [106, 107]. Strict fluid balance recording is essential and is important to take into account the effect of fluid balance, including GI losses, on body weight and its use for nutritional assessment.

Albumin

In the past a low serum albumin has been considered a marker of malnutrition. Although oedema is often seen in hospitalised malnourished patients it is a common misconception that this is due to starvation or low protein intake leading to hypoalbuminaemia [107]. Starvation does not cause hypoalbuminaemia, [108, 109] a point illustrated by patients with anorexia nervosa who may have a very low BMI but neither low albumin nor oedema [110, 111].

The concentration of serum albumin represents the net summation of many events—albumin synthesis, albumin degradation, albumin losses from the body, exchange between intra- and extravascular albumin compartments, and the volume in which albumin is distributed. Albumin is highly water-soluble and resides in the extracellular space. The total body pool of albumin in a normal 70 kg man is about 300 g (3.5–5.3 g/kg). Approximately one-third of the total pool constitutes the intravascular compartment and two-thirds the extravascular compartment [112]. The concentration of albumin in blood is greater than that in lymph or other extracellular fluids, and the ratio of intravascular to extravascular albumin concentration varies from tissue to tissue. Within 30 min of initiating albumin synthesis, the hepatocyte secretes albumin into the bloodstream [113]. Once albumin is released into plasma, its half-life is 20 days. During steady state conditions ~14 g of albumin (200 mg/kg) are produced and degraded daily. Thus, each day about 5% of the total albumin pool is degraded and replaced by newly synthesized albumin. Equilibration of albumin in the intra-

vascular compartment is rapid and occurs within minutes after albumin enters the bloodstream. Equilibration between intra- and extravascular albumin occurs more slowly. Every hour about 5% of the plasma albumin pool exchanges with extravascular albumin so that the total plasma albumin mass exchanges with extravascular albumin each day. Because the rate of equilibration varies among tissues complete equilibration may take 7–10 days.

Protein-calorie malnutrition causes a decrease in the rate of albumin synthesis because adequate nutrient intake is important for polysomal aggregation and maintenance of cellular RNA levels needed for protein synthesis. Within 24 h of fasting, the rate of albumin synthesis decreases markedly [114]. However, a short-term reduction in albumin synthesis has little impact on albumin levels because of a large pool size, compensatory decrease in the rate of degradation, a transfer of extravascular albumin to the intravascular compartment and an increase in colonic urea salvage [115]. Indeed, plasma albumin concentration may actually increase during short-term fasting largely because of contraction of intravascular water [116].

Prolonged protein-calorie restriction induced experimentally in human volunteers [2] or observed clinically in patients with anorexia nervosa [111] causes marked reductions in body weight but little change in plasma albumin concentration. A protein-deficient diet with adequate calories in elderly persons causes a decrease in lean body mass and muscle function without a change in plasma albumin concentration [117].

Hospitalized patients may have low levels of plasma albumin for several reasons. Inflammatory disorders cause a decrease in albumin synthesis, [118] an increase in albumin degradation, [119] and an increase in albumin transcapillary losses [120]. Gastrointestinal and some cardiac diseases increase albumin losses through the gut, while renal diseases may cause considerable albuminuria. Wounds, burns and peritonitis cause major losses from the injured surface and in certain circumstances an increase in albumin losses through the gut, kidneys, or damaged tissues. Because the exchange between intra-and extravascular albumin is so large, even small changes in the percentage of exchange can cause significant changes in plasma albumin levels. The normal rate of albumin exchange between intra- and extravascular compartments is more than ten times the rate of albumin synthesis or degradation. During serious illness vascular permeability increases dramatically. Albumin losses from plasma to the extravascular space were increased twofold in patients with cancer cachexia and threefold in patients with septic shock. Plasma albumin levels will not increase in stressed patients until the inflammatory stress remits and is not affected by nutritional intake. For example, albumin levels fail to increase in patients with cancer after 21 days of intensive nutritional therapy [121] and in nursing home patients after enteral feeding through a gastrostomy [122]. Rapid drops in plasma levels can be seen in sick individuals due to the inflammatory response leading to increased vascular permeability and loss of albumin to the extravascular compartment [108, 109]. In hospital excessive provision of high sodium and chloride IV fluids may contribute to this. Lobo et al found that the rapid IV infusion of 2000 mL 0.9 saline led to a 20% drop in serum albumin that did not recover over the 6 h study period (indeed it took 2 weeks to return to normal), with the authors concluding that this was not only due to dilution but to increased loss of albumin to the extravascular compartment [123].

While a very poor nutritional marker, albumin is a good marker of disease severity, and moves inversely as the as the acute phase reactants (e.g. CRP) rise [124]. In a recent Malaysian IF study, low BMI and serum albumin and correlated with poor healing of enterocutaneous fistulae and increased mortality [125]. It is also a good marker of saline excess.

Prealbumin

Prealbumin is a transport protein for thyroid hormones and exists in the circulation as a retinol-binding–prealbumin complex [126]. The turnover rate of this protein is rapid with a half-life of 2–3 days. It is synthesized by the liver and is catabolized partly in the kidneys. Protein-energy malnutrition reduces the levels of prealbumin and refeeding restores levels [127]. However, prealbumin levels fall without protein-energy malnutrition in infections [128, 129] and in response to cytokine [130] and hormone infusion [131]. Renal failure increases [132] while liver failure may cause decreased levels. Although, prealbumin is responsive to nutritional changes it is influenced by several disease-related factors making it unreliable as an index of nutritional status in patients.

Serum Cholesterol

Low levels are seen in undernourished patients. However, very low levels are seen in patients with liver disease, renal disease and malabsorption. In addition, low levels correlate with mortality [133, 134].

Refeeding

Functional improvements in cell function occurs long before any gain in tissue mass. Muscle function may improve rapidly (15% over the first 5 days) with refeeding, but the restoration of muscle mass, unlike that of adipose tissue, is very slow [2, 8]. Functional improvements should be seen as the initial goal of nutrition support, with restoration of body

composition a longer term aim that can be achieved once inflammatory issues have been treated (chapter "Refeeding Problems").

Under Hydration/Dehydration

Most of the human body (65%) is water which is needed for almost every physiological process. These include regulating body temperature (through sweating and breathing), aiding digestion (through secretions), lubrication/moistening functions and helping eliminate waste products/toxins. When exercising in a hot environment, the human body can lose 1.5–3 L of water every hour from sweating. Another 0.2–1.5 L can be lost as moisture in exhaled breath, depending on the humidity of the surrounding air.

Survival with Dehydration

Survival is often quoted as 2 weeks but will vary according to ambient temperature, degree of activity, illness/losses (including sepsis) (sweating). In a previously healthy adult, death follows the loss of 12–15 L of body water. In the very young, the very old, or the debilitated, death occurs at a lower level of dehydration. As it is unethical to perform experiments on normal subjects going without water, the only information about survival time can be gained from newspaper reports of survival times after people are trapped or buried alive without water. From this it appears that it is possible to survive without food and drink for 8–21 days [135, 136].

Symptoms and Signs of Dehydration

Initially with mild dehydration a person feels thirsty (occurs when cells have lost about 1% of their intracellular water), and has a dry mouth (may not be the case in the elderly). They may complain of sluggishness, lack of energy, difficulty swallowing, stiff joints, cramps, headache, dizziness, syncope and confusion.

The signs of dehydration include dry wrinkled skin, sunken eyes often with a dark ring around them, dry mucus membranes, a tachycardia, postural fall in systolic blood pressure. Urine output may be low but as long as more than 30 mL per hour the kidneys can excrete nitrogenous and non-nitrogenous molecules. If however 8% of the total body water has been lost (about 4 L) then the blood urea and creatinine are likely to rise. Blood viscosity also increases. As dehydration progresses sweating stops and body temperature rises, as blood pressure reduces due to low blood volume cardiogenic shock may occur. Because of their relatively larger skin surface-to-volume ratio, children are especially susceptible to rapid overheating and dehydration.

Refeeding Problems

Aminda De Silva and Jeremy M.D. Nightingale

Key Points

1. Refeeding syndrome (RFS) describes the adverse clinical and biochemical problems that may result from feeding severely malnourished patients via any route, be it oral, enteral or parenteral.
2. Clinicians need to be aware of it and assume most malnourished patients are at risk.
3. Hypophosphataemia is the most commonly used marker of refeeding syndrome and it commonly occurs when artificial nutritional support is started (especially with carhohydrate) and can rarely cause death. Hypomagnesaemia, hypokalaemia and hypo (or hyper) glycaemia may also occur.
4. More enterally fed patients have refeeding hypophosphataemia than those given parenteral nutrition.
5. Sodium and water retention is common as the cell membrane sodium/potassium pump reactivates and can lead to oedema and cardiac failure.
6. Confusion can be due to thiamine deficiency (Wernicke's encephalopathy) which if untreated may lead to a permanent loss of short term memory (Korsakoff psychosis)
7. United Kingdom NICE guidelines are are helpful but not a reliable predictor of high risk patients. Low magnesium or Insulin like growth factor-1 (IGF-1) may improve them.
8. When feeding malnourished patients carbohydrate must be introduced slowly (non-protein energy usually 50% carbohydrate and 50% lipid). Additional phophate, B vitamins, potassium and magnesium may be given before starting and when feeding commences. Little or occasionally no sodium is given.
9. Nutritional support to the high risk patient should start at no more than 50% of estimated needs for the first 24–48 h.
10. Monitor phosphate, potassium and magnesium regularly (especially after the first feed).
11. Hypothermia and low blood glucose are often an indication of co-existing sepsis and must be treated.
12. These patients should be cared for by healthcare professionals with skills, training and knowledge about nutritional requirements and nutritional support.

Definition

There are wide variations in what is defined as refeeding syndrome (RFS) [1]; hence in this chapter the phrase "refeeding problems" is mostly used. RFS is a potentially fatal condition commonly characterised by rapid changes in fluid and electrolyte balance leading to problems of cardiac arrthymias, cardiac and respiratory failure. There are also a wide variety of other manifestations that can occur, including hidden sepsis, acute fatty liver, endocrine & haematological abnormalities along with acute thiamine deficiency (which can lead to Wernike's syndrome and possibly Korsakoff's psychosis) and other neurological syndromes such as delirium and centropontine myelinolysis.

RFS is thus best described as the adverse clinical and biochemical problems that can result from feeding malnourished patients via any route, be it oral, enteral or parenteral.

History

The first records of the problems of refeeding come from when towns/cities were surrounded and the inhabitants starved into surrendering. In AD 70 after the Seige of Jerusalem by the Romans, written about by Flavius Josephus: "they all on the sudden overfilled those bodies that were before empty, and so burst asunder, excepting such only as

were skillful enough to restrain their appetites, and by degrees took in their food", "death was observed in those who overindulged but not in those who restrained their appetite" [2], Then in AD 543 after the Siege of Naples by the Ostrogoths, Totila "exhibited a considerable humanity." "He knew that if an abundance of food were at once supplied, the famished inhabitants would gorge themselves to death. He posted sentinels at the gates and in the harbour and allowed no one to leave the city. Then he dealt out small rations, gradually increasing the quantity every day until the people had recovered their strength" [3].

While many associate the problems of refeeding with the Second World War, the scientific literature for this is sparse. There are reports stating that "Untold thousands of the liberated starved prisoners from the Nazi concentration camps died immediately after liberation, after having been given some food by well-meaning soldiers. According to an oral testimony a woman died after eating just a few sugar packets." The three scientific papers that relate to the second world war are from the Leningrad siege of 1940 [4], freed Japanese prisoners of war [5] and from when the Netherlands was liberated towards the end of the Second World War (1944–1945) [6]. The information from the Lenningrad siege is surprisingly scarce; in the 2 years following the siege of Leningrad there were a high number of hospital admissions for hypertension (BP > 140/90), oedema and cardiac failure. The observations in 1945 of 24 Japanese prisoners of war who typically weighed 35 kg having lost 30% of their body weight in the preceeding 6 months reported that an intervention of a diet containing approximately 3500 kcal/day was made and it was observed that 5 of the 24 died. However they all had a serum albumin of less than 20 g/L, indicating that there were other medical issues in addition to simple malnutrition (e.g. infection or inflammation). It was observed that an attack of malaria made their oedema worse. The large informative publication from when the Netherlands was liberated towards the end of the Second World war (1944–1945) reported that deaths in severely malnourished people occurred in 3 ways; Firstly suddenly shortly after admission. Secondly after seeming to recover then a low blood pressure and tachycardia occurred with death within 1 h. Thirdly a slow death preceded by coma taking days. While there is much haematological and biochemical detail regular phosphate/magnesium measurements were not made. The overall death rate was 10% and it was noted that "obstinate diarrhoea" had a particularly poor prognosis. Many of the subjects had increased pigmentation though the cause was not clear.

Towards the end of the second world war (19 November 1944 to 20 December 1945) Ancel Keys performed studies upon 36 men (22–33 years) who were all conscientious objectors at the University of Minnesota, USA [7]. They were put on a semi-starvation diet for 24 weeks (1560 kcal/day) and during this time they had to walk 22 miles per week. and on this they lost more than 25% of their body weight. No deaths occurred on refeeding with 4 regimens (400, 800, 1200, 1600 kcal more than in semi-starvation).

Evidence for RFS in Clinical Practice

The lack of a uniform definition of RFS hampers all studies. The evidence of refeeding problems from oral, enteral and parenteral feeding is poor. Two patients (1 anorexia nervosa, 1 alcohol excess) were described as having a low phosphate after oral refeeding [8]. A low phosphate was observed in a study of 25 post-operative patients [9]. With parenteral nutrition 3 patients are described with paraesthesia, weakness seizures 4–5 days after starting and a low serum phosphate was observed [10]. The paper that brought attention to the problems of refeeding was entitled "Death resulting from overzealous total parenteral nutrition" [11] in which 2 deaths were described associated with hypophosphataemia; yet both were being given large amounts of intravenous glucose (500 and 700 g glucose in 24 h). Hypophosphatemic respiratory failure has been described in patients given post-operative total parenteral nutrition [12].

The UK NCEPOD report of 2010 showed that 60% (455/877) of patients given parenteral nutrition were at risk of refeeding problems with hypophosphataemia occurring in 18%. Hypokalaemia, hypomagnesaemia and hyperglycaemia were also common [13].

A retrospective study by Zeki et al. showed that a phosphate fall to less than 0.6 mmol/l occurred in 36/168 21% fed nasogastrically and 23/153 8% fed parenterally within a week of starting feeding [14]. Rio et al. using more strict criteria ($K^+ < 2.5$, $P < 0.32$, $Mg < 0.5$ mmol/l, oedema/circulatory fluid overload or disturbance to organ function) showed only 3/243 patients met these criteria within 15 days of starting to feed though 6% had a phosphate less than 0.5 mmol/l on day 3 [15].

Pathophysiology and Biochemistry of Refeeding

Biochemistry of Starvation

With reduced glucose levels resulting from starvation, insulin secretion drops and glucagon levels increase, resulting in higher glycogenolysis to generate energy from carbohydrate sources. However as starvation continues glycogen stores become depleted, typically within 6 h to 3 days, then the body shifts to using fat and eventually muscle to produce energy resulting in a high production of ketone bodies which are in turn used for energy instead of glucose.

Other changes include reducing basal metabolic rate and down-regulating energy consuming processes. This includes down-regulating the activity of ATP pumps such as the sodium/potassium ATP-pump. Down-regulation of these pumps results in changes of electrolyte handling causing leakage of mainly-intracellular cations such as potassium, magnesium and phosphate into the circulation where they are lost in urine. Down-regulation of cell membrane Na^+/K^+-ATP pump also allows sodium and water to leak into cells.

Despite poor dietary intake of electrolytes, serum levels of these cations during starvation could remain normal during starvation (or could even be high if there is a degree of renal failure) as these electrolytes move from the intracellular to the extracellular space [16], so measuring electrolyte levels as a one off investigation at this point gives littles or no useful information to the risk of refeeding syndrome occurring.

Severe starvation may lead to hepatic steatosis through various mechanisms. Protein deficiency can result in decreased apolipoprotein synthesis, leading to decreased very low density lipoprotein (VLDL) synthesis and inhibited VLDL transport. Reduced VLDL transport plays a significant role in lipid accumulation in the liver during starvation [17].

Biochemical Changes of Refeeding

Two key events happen on feeding glucose to patients who have been starving (Fig. 1).

Insulin levels increase which drives glucose and phosphate into cells. This leads to an increased uptake of glucose, phosphate and thiamine (needed for glycolysis and thus ATP manufacture). As a result, serum levels of phosphate along with other cations such as potassium, magnesium, calcium may fall, as will thiamine. Thiamine is a co-factor in many metabolic processes including its essential role in cerebral energy utilization, it will already be depleted in starvation so refeeding with glucose will result in rapid depletion of the already low stores of thiamine [18].

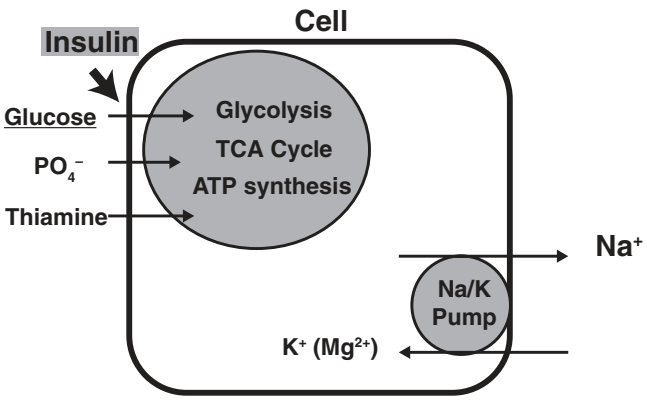

Fig. 1 Diagragm to show key events in RFS

Secondly the cell membrane sodium/potassium pump starts actively pumping sodium out of the cell and taking potassium and magnesium into the cell thus furthering the deficit in circulating electrolytes. In addition to this insulin stimulates sodium reabsorption from the distal nephron [19]. Water and sodium efflux into circulation also results and may result in fluid overload and heart failure [20]. This combination of a sudden fluid load into the circulation in to a system where the heart (like all other muscles) has been weakened and atrophied due to starvation, along with low circulating electrolytes (causing a propensity to cardiac arrhythmias) can easily lead to pulmonary oedema or signs of heart failure and potentially death (Fig. 2) [20].

Clinical Manifestations of Refeeding

Hypophosphataemia

This is often considered the hallmark feature of the refeeding "syndrome" (Table 1) though there are many other reasons for hypophosphataemia than just refeeding syndrome (Table 2). Within the cell phosphate is vital for many cellular pathways including glycolysis and the decarboxcylic acid cycle. Hypophosphataemia results in reduced ATP so many metabolic pathways are slowed/stopped. The low phosphate also reduces the levels of 2,3-diphosphoglycerate so causing the RBCs to be less able to give up oxygen (shifting the oxygen dissociation curve to the right). Hypophosphataemia is common in the critically ill but may not be associated with adverse outcomes [22]. The normal adult range of phosphate is 0.8–1.5 mmol/l. About 3% of patients admitted to hospital will have a phosphate below 0.85 mmol/l. Blood levels below 0.32 mmol/l are considered severe in the literature.

Thiamine Deficiency

The body stores of thiamine (vitamin B1) are sufficient for up to 7 days. It is a co-factor in aerobic glucose consumption. In thiamine deficiency, a combined enzyme defect results in aerobic metabolism impairment and isufficient ATP generation. Furthermore, pyruvate is converted into lactate, resulting in hyperlactaemia and lactic acidosis. As thiamine dependent metabolic pathways are present in almost all human cells, deficiency can affect many organ systems. It can also exacerbate the hypmagnesaemia, hypokalaemia and hypophosphataemia associated with increased renal losses due to oxidative stress that has damaged the renal tubules [23]. Thiamine deficiency can lead to the development of Wernicke's encephalopathy which is a triad of encephalopathy, ataxia and ocular dysfunction (nystagmus). Other features include hypothermia, peripheral neuropathy and heart failure [18]. Wernicke's encephalopathy can progress to the

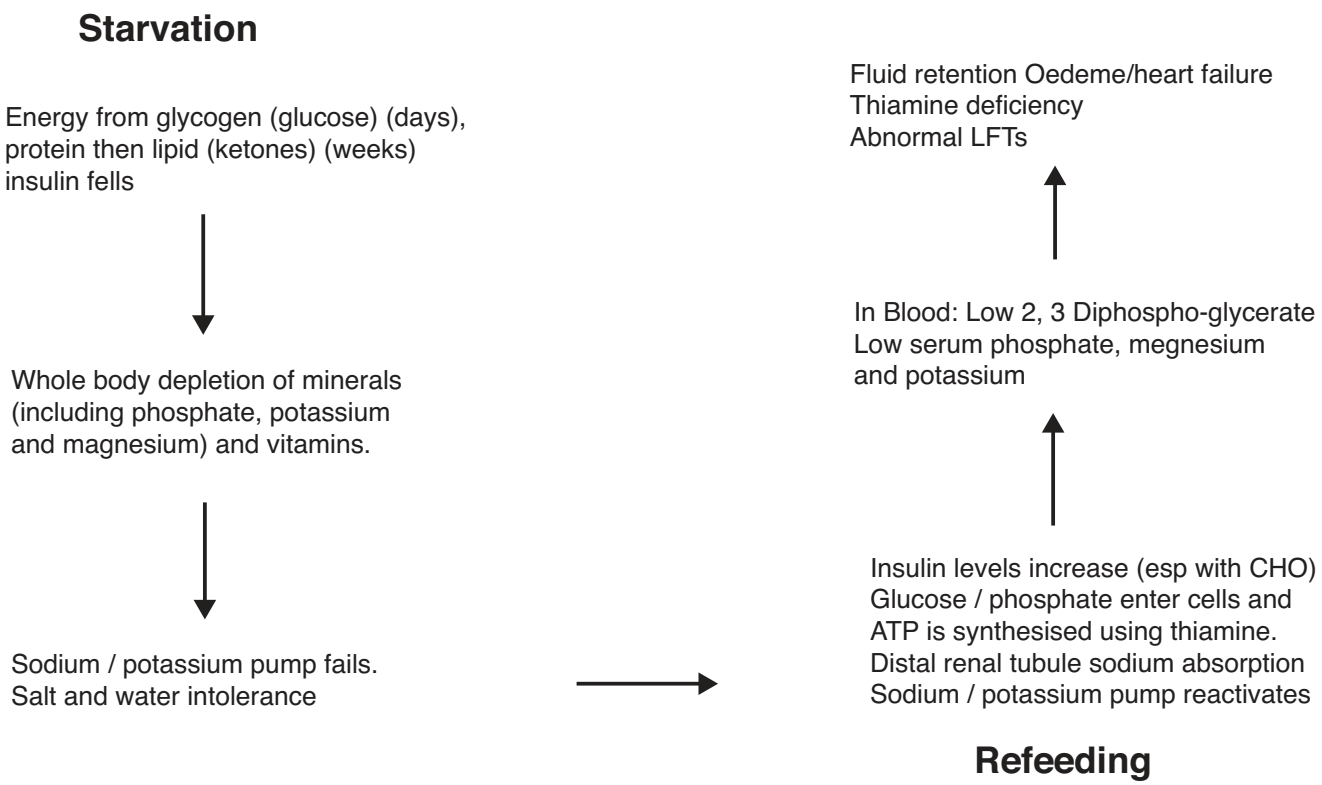

Fig. 2 Diagram summarising events in RFS. Based upon [21]

Table 1 Effects of hypophosphatemia

Muscular	Weakness (diaphragm), respiratory failure
	Rhabdomyolysis
Cardiac	Biventricular failure, low blood pressure
	Arrhythmias, sudden death
Haematological	Low and dysfunctional white blood cells, red blood cells and platelets
	Haemolysis
Neurological	Weakness, lower motor neurone type paralysis (loss of reflexes)
	Cranial nerve palsies
	Confusion, ataxia, tremors, fits, coma
Hepatic	Dysfunction (esp alcohol excess)

Table 2 Causes of hypophosphataemia other than refeeding

Sepsis
Post op/trauma/burns
Recovery from acidosis (e.g. diabetic ketoacidosis)
Alcohol withdrawal
Insulin (±glucose) treatment
Drugs—chemotherapy, diuretics, biphosphonates, phosphate binding antacids
Renal dialysis/transplantation
Hyperparathyroidism
Respiratory alkalosis

irreversible Korsakoff's syndrome which is an amnesic syndrome consisting of retrograde and antegrade amnesia (short term memory loss) but preservation of long-term memory. A substantial percentage of patients suffer from confabulation. Patients with Korsakoff syndrome often lack insight into their problem.

Return of Activity to the Cell Membrane Sodium/Potassium Pump

As the cell membrane sodium/potassium (Na^+/K^+) pump returns to activity the osmotically active sodium enters the interstitial space and circulation so giving rise to oedema and occasionally cardiac failure. This effect is compounded by insulin causing sodium retention in the kidney [19], dysregulation of anti-diuretic hormone and aldosterone secretion, and the addition of carbohydrate into the diet which leads to a rapid decrease in renal excretion of sodium and water [19]. This sudden fluid flux into the circulation and the inability to excrete it, particularly in the presence of a heart that may well be functioning less well in the context of poor nutrition, along with the possibility of low circulating elctrolytes giving a predisposition to cardiac arrhythmia, can lead to oedema, left ventricular failure and hypertension. Thus, the first clinical manifestions of refeeding problems may be a raised pulse and respiratory rate. In patients with low BMIs, one would often expect a sinus bradycardia, so even a pulse of above 60 beats/min might indicate a relative tachycardia and should alert the clinician to a potential problem.

Hypokalaemia

Potassium is the main intracellular cation. Depletion in starvation and malnutrition is mainly driven by low intake and/or excessive losses (e.g. hyperemesis). Serum potassium levels may remain normal in starvation because of movement of potassium along chemical gradients to the extracellular space. Insulin is important in stimulation of potassium influx into cells through the cell membrane Na^+/K^+-ATP pump. With initiation of nutrition the resulting increased secretion of insulin precipitates potassium influx into cells causing a fall in serum potassium levels. Hypokalaemia can cause muscle weakness including the respiratory muscles, atrial and ventricular arrhythmias (QT prolongation), atrioventricular block, a U wave on the electocardiogram and can cause/prolong an ileus.

Hypomagnesaimia

Magnesium is a predominantly intracellular cation. Deficiency in malnutrition and starvation stem from poor intake and redistribution. Upon refeeding, magnesium moves into cells with resultant drop of serum levels. While clinicians usually treat low serum magnesium levels patients with high stomal outputs are often seen with very low levels and apparently no symptoms or signs. The literature suggests that hypomagnesaemia alone (in the absence of hypocalcaemia) may cause a tremor, poor memory and precipitate arrhythmias in susceptible patients [24].

Moderate Abnormalities of Liver Function

Liver enzyme abnormalities are commonly found both in periods of starvation as well as during the refeeding phase. Excess glucose administered in the early phase of refeeding, particularly after prolonged periods of starvation leads to lipogenesis, again as a result of insulin stimulation. Deposition of fatty acids and triglycerides (hypertriglyceridaemia may occur) in the liver can lead to an acute fatty liver often being detected through raised liver transaminases. Moderate abnormalities of liver function (e.g. alanine transaminase up to 10 times the upper limit of the normal range) should not delay feeding [25].

Other Metabolic/Clinical Abnormalities

Both hyperglycaemia or hypoglycaemia can occur. Glucose intake after a period starvation, can suppress gluconeogenesis through the release of insulin. Excessive administration of glucose can therefore lead to hyperglycaemia and its sequelae including osmotic diuresis, dehydration, metabolic acidosis and ketoacidosis. Conversely, hypoglycaemia can also occur, particularly in the presence of sepsis [26]. This may relate to depleted glycogen stores, impaired gluconeogenesis and increased peripheral glucose utilization. Hypoglycaemia must be detected and corrected quickly as if prolonged can lead to perminant cerebral damage. Symptoms of bloating / constipation have been reported [25].

Infection

Hypothermia and low blood glucose are often an indication of sepsis and these must be urgently treated. Studies have documented significantly elevated rates of infection and leukopenia among hospitalized patients with anorexia nervosa [27]. In a case series of 14 patients, two patients developed occult sepsis that proved fatal, in one case despite of ITU treatment. Two patients in the same series had severe leukopenia with WBC of less than 0.5×10^9/l [28]. While infection and sepsis are not classical presentations of refeeding syndrome, it is important to monitor for these during the initial period of refeeding as patients with significant malnutrition are at higher risk of developing severe infections. These patients often don't develop the usual signs of sepsis (eg pyrexia, neutrophilia or increased CRP). In fact, their temperatures often fall, and blood sugars can be high or low. The combination of low BMI, hypoglycaemia and hypothermia is often termed the deadly triad and is a marker for severe infection and should always trigger consideration of antibacterial treatment [21].

Who Is at Risk of Refeeding Problems

Not only gastroenterological patients who have become severely malnourished often with IF or pancreatic disease are at risk of refeeding problems; but also patients with anorexia nervosa, classic kwashiorkor/marasmus, prolonged fasting (greater than 7–10 days including hunger strikers), some critical care patients, elderly patients (particularly those who are depressed), patients with cancer and those who are post bariatric surgery [29, 30]. It is especially common to find patients who look obese (BMI within the normal range) but who have lost much of their muscle mass (sarcopenic obesity) due to a poor intake of food and/or an inflammatory process (e.g. sepsis, surgery etc) and thus become relatively immobile and so are at a high risk of hospital acquired complications (e.g. sepsis, DVT etc).

How to Detect a Patient at Risk of Refeeding Problems

The current United Kingdom (UK) guidelines for nutrition support [29] identify criteria as risk factors for developing refeeding syndrome (Table 3). These criteria are not always reliable in predicting RFS as an accurate history regarding weight and recent nutritional intake may not be available. Moreover, the sensitivity of NICE guidelines (i.e. the proportion of those who developed refeeding hypophosphataemia who were correctly identified) was poor; scoring just 0.5 for enteral nutrition and 0.38 for parenteral nutrition but the specificity was better 0.76 for nasogastric tube feeding and

Table 3 UK NICE risk factors for developing refeeding problems [29]

One or more of the following
• BMI <16 kg/m^2
• Unintentional weight loss >15% within last 3–6 months
• Little or no nutritional intake for more than 10 days
• Low potassium, magnesium or phosphate prior to feeding
Two or more of the following
• BMI <18.5 kg/m^2
• Unintentional weight loss >10% within last 3–6 months
• Little or no nutritional intake for more than 5 days
• A history of alcohol abuse or drugs including insulin, chemotherapy, antacids or diuretics

0.73 for parental nutrition [14]. There are a variety of other risk factors identified in other studies that have identified those at risk of refeeding syndrome including, age, higher nutritional intake during feeding and nutritional risk feeding score >3 [1] however there are no data on their sensitivity or specificity. A baseline low serum Mg^{2+} was a predictor in one study [15]. Refeeding Index (a score generated from baseline insulin-like growth factor and leptin) has been proposed as a useful biochemical marker for predicting those at risk of RFS [31]. A study in 2015 has shown that using highly sensitive baseline IGF-1 alone is an objective, sensitive and specific biochemical marker in identifying patients who are at high risk of developing refeeding hypophosphataemia in patients starting parenteral nutrition (a ≥30% drop in PO_4 during the first 36-h of PN administration) [32].

Why Is Refeeding Hypophosphataemia More Common with Oral/Enteral Feeding Than with Parenteral Feeding?

Zeki et al. showed that the occurance of refeeding hypophotaemia in adult patients fed enterally vs those fed parenterally was more common in those fed enterally (21 vs 8%, $p < 0.05$) [14]. The reason for the more significant fall in phosphate after enteral rather than intravenous feeding was not due to more phosphate being in the parenteral feed rather than the enteral one (both had about 20–30 mmol). It does not relate to a difference in the lipid or carhohydrate amount in enteral and parenteral feeds (generally the lipid and carbohydrate energy were the same). The main reason is likely to relate enteral feeding stimulating a greater insulin secretion than parenteral feeding and so the mechanism that drives refeeding hypophospahtaemia is amplified. This "incretin effect" was first recognised in the 1960s and describes the descibes the greater insulin secretion after a patient is given the same amount of glucoses orally as intravenously [33]. This response has subsequently been related to the release of two upper gut peptide hornones gastroinsulinotropic peptide (GIP) and glucagon-like peptide 1 (GLP-1) which both act to increase/exaggerate insulin secretion from the pancreatic islet β cells. It is for this same reason that hyperglycaemia is more common with parenteral than enteral feeding. Refeeding problems must be considered very seriously when starting enteral feeding.

Treatment of Patients at Risk of Refeeding Problems

Circulatory volume (dehydration) should be restored and fluid balance monitored. Hypothermia and sepsis must be treated [34]. In the acute phase cardiac monitoring is advised. It is also recommended for inpatients with cardiac manifestations and/or ECG changes secondary to hypokalaemia, patients with a QTc >450 ns or where intravenous correction of potassium is needed at a rate of more than 10 mmol/h is deemed necessary [21].

There is varied opinion about giving vitamins/minerals (including phosphate) before starting to give feeding. It can be argued that without the necessary energy to switch the celluar homestatic mechanisms back on, thereby enabling them to move vitamins/minerals (including phosphate) from the circulation to the intracellular compartment, there is a concern that any administered may simply be excreted via the kidneys. This argument is especially around phosphate and pre treating with it. Most institutions would give supplementation prior to feeding if serum electrolyte levels are low or low normal before feeding.

Energy

When the UK NICE guidelines were published there were no good quality trials to enable evidence based management protocols to be developed so reliance was upon expert opinion (Level D evidence considered a Good Practice Point) [29]. It suggested that people who had eaten little or nothing for more than 5 days should have nutrition support introduced at no more than 50% of requirements for the first 2 days; that the prescription for people at high risk of developing refeeding problems could be giving nutritional support at a maximum of 10 kcal/kg/day, increasing levels slowly to meet or exceed full needs by 4–7 days. It even controversially went on to suggest using only 5 kcal/kg/day in extreme cases (for example, BMI less than 14 kg/m^2 or a negligible intake for more than 15 days). A survey in 2008 showed 39% felt the guidance was appropriate and 36% felt it was too cautious [30].

Subsequent to this there have been two trials in intensive care units to show that a hypocaloric diet given to patients with refeeding hypophosphataemia in ITU do have a better survival than in those fed without restriction [35, 36]. Most nutrition support teams in UK do give reduced amounts of energy and gradually increase the energy to requirements

over 4–7 days. The Parenteral and Enteral Nutrition Group (PENG) which is a specialist group within the British Dietetic Association now recommends 10–20 kcal/kg feeding for the severely malnourished [37]. Some however, are bolder and start the parenteral feed to meet the requirements of the BMI and after taking into account the protein energy, give the lipid and carbohydrate energy as half each.

Refeeding of adolescents with anorexia nervosa at 1200 kcal/day versus 500 kcal/day resulted in improved weight gain but no other adverse effect, including on QTc interval [38]. Within 48 h of feeding commencing, 28% of high calorie and 11% of low calorie developed hypophosphataemia but in the absence of other electrolyte abnormality

Phosphate Replacement

Most authorities suggest that in patients with mild to moderate hypophosphataemia (phosphate above >0.32 mmol/dl) oral replacement should be initiated unless there are concerns about absorption from the gastrointestinal tract. However in RFS, it could be argued that in the context of multiple electrolyte disturbances, a lower threshold for starting intravenous correction should be employed and most advocate IV replacement for patients at high risk of RFS at PO4 levels of <0.6 mmol.

Intravenous phosphate supplements could be in the form of monbasic potassium phosphate or the more-widely used phosphate infusion, Polyfusor. Electrolytes need to be closely monitored as the latter contains significant amounts of sodium and potassium. One litre of Polyfusor contains 100 mmol of PO_4^{3-}, 162 mmol of sodium and 19 mmol of potassium. Excessive doses should also be avoided as they can result in hypocalcaemia and metastatic calcification. The BNF defines maximal dose as 500 µml/kg. Maximal dose is 50 mmol/24 h i.e. 500 ml of polyfuser [39]. We would advocate smaller infusions of 10–20 mmol phosphate i.e. 100–200 ml of polyfuser repeated if necessary to reduce the risk of metastatic calcification. The UK NICE guidelines suggest the likely requirement for potassium is 0.3–0.6 mmol/kg/day.

A study showed 36.8% of critically ill, mechanically ventilated patients developed hypophosphataemia and those fed at 50% target rate had improved 6 month outcomes [36].

There is no doubt that phosphate must be administered concurrently with a low rate feeding.

Thiamine, Other Vitamins and Trace Elements

It is crucial that thiamine supplementation is started prior to and continued during nutrition support and glucose administration. Oral thiamine can be given at a dose of 200–300 mg daily. One to two tablets of vitamin B co strong can be given three times a day. A daily intravenous vitamin B preparation such as Pabrinex can be given intravenously (usually for 3–5 days) in addition to oral multivitamin supplements. A balanced multivitamin/trace element supplement once daily for 10 days is recommended by UK NICE guidelines [29]. If signs of Wernicke's encephalopathy are present the B vitamins need to be given intravenously.

Electrolytes (Potassium and Magnesium)

Severely abnormal blood electrolytes (e.g. phosphate, potassium or magnesium are corrected prior to feeding. A drop of serum potassium by 1 mmol/L is equivalent to a total deficit of approximately 200–400 mmol. Mild asymptomatic hypokalaemia is ideally be corrected orally with potassium chloride used to provide up to 50 mmol/day. However, many patients suffer from gastrointestinal side effects that limit compliance [39]. Intravenous potassium can be used to treat significant hypokalaemia with potassium levels less than 3.0 mmol/l. Intravenous infusion with potassium chloride concentration of 40 mmol/l are used when using peripheral veins [39]. This can be administered at a rate of 10–20 mmol/h. Higher concentrations of intravenous potassium delivered into a central vein can be used with close cardiac monitoring after specialist advice. Some authorities accept up to 40 mmol/dl administered into a large central vein. The UK NICE quideline recommends providing oral, enteral or intravenous supplements of potassium with the likely requirements being 2–4 mmol/kg/day [29].

About 80% of plasma magnesium is filtered through glomeruli. 20% is reabsorbed by the proximal tubules and about 80% is reabsorbed by Loop of Henle, a process influenced by the plasma concentration of magnesium. Intravenous infusion of magnesium will result in a transient increase in magnesium levels and consequently renal wasting of a substantial proportion of that magnesium. So, in more severe hypomagnesaemia where higher magnesium supplements are required, these should be administered over longer hours to avoid sudden increases in magnesium levels [39]. In mild hypomagnesaemia 4–8 mmol of magnesium sulphate can be given over 1–2 h [39]. Oral formulas like magnesium glycerophosphate, oxide or aspartate can be used to prevent recurrence of the deficit. The UK NICE quideline recommends providing oral, enteral or intravenous supplements of magnesium with the likely requirements being 0.2 mmol/kg/day intravenous, 0.4 mmol/kg/day orally [29].

Fluid

Should problems with fluid overload occur an 'ABC' approach to resuscitation should be taken and transfer to ICU should be considered. If absolutely necessary, diuretics may be required but may have the effect of lowering circulating electrolytes further. If this occurs, central access should be sought and administration of concentrated electrolytes in ICU may be appropriate. The feed should be slowed further whilst these issues are being managed. Sodium administration at first is very reduced. Patients at high risk of refeeding prob-

lems should receive about 20 ml fluid/kg and <1 mmol/kg sodium. Sodium excretion is limited in refeeding and excess provision combined with that liberated from cells can lead to circulatory overload (heart failure and severe oedema) which is dangerous in combination with cardiac atrophy from malnutrition / arrhythmias from electrolyte imbalances. Extreme caution should be observed when giving electrolytes in 0.9% NaCl (154 mmol Na/l) due to the risk of sodium and fluid overload and if using 5% dextrose the energy content needs to be taken into consideration (200 kcal/l). Ideally electrolytes should be added to the PN bag and oral preparations in water should be used where possible for oral and enteral tube feeding. However it is important to remember that intestinal failure patients may need additional sodium and fluid to replace gastrointestinal losses from stomas/ fistulas.

Conclusion

Refeeding problems are common however are less likely to occur if patients are identified as at risk and if precautions are taken (14 vs 46%) [13]. Electrolyte (especially hypophosphataemis), sodium and water and thiamine deficiency are common and can be life threatening/life changing so need to be prevented and treated. The "Start low, go slow" approach-for energy provision recommended by UK NICE guidelines may risk underfeeding which is linked to poor weight gain and the risk of the underlying clinical condition deteriorating leading to organ dysfunction, poor wound healing, increased rates of infection and prolonged hospitalisation [29]. In this review we have advocated an equally cautious start to energy provision but would highlight the importance of a more rapid increase in energy, particularly during the first couple of days, linked to careful blood monitoring and electrolyte/vitamin provision. Experienced healthcare workers should manage these patients [40–43].

Intestinal Failure Associated Liver Disease

Sue V. Beath and Alan L. Buchman

Key Points

1. Intestinal failure-associated liver disease (IFALD) is a stand-alone disease that may have multiple aetiologies, but develops exclusively in patients with dysfunctional gastrointestinal tracts, namely short bowel syndrome, intestinal dysmotility and various malabsorptive disorders.
2. Paediatric patients often present with cholestatic liver function tests (LFTs).
3. In acute intestinal failure abnormal liver function is most commonly due to sepsis, drug therapy or pre-existing liver disease, rather than due to the parenteral nutrition.
4. An excess of any of the macronutrient components of parenteral nutrition (PN) can cause abnormal LFTs. In particular first-generation, soya bean-based lipid preparations are associated abnormal liver function.
5. An excess of copper, manganese, or aluminium and deficiencies of choline, taurine, carnitine or essential fatty acids may all cause abnormal LFTs.
6. Treatment involves treating sepsis, reviewing medication and parenteral nutrition prescription, maximising oral/enteral feeding, giving cyclical PN and changing bile composition (e.g. ursodeoxycholic acid (URSO)).
7. Bacterial overgrowth should be evaluated and treated with antibiotics and small bowel dilation sub-acute obstruction should be actively managed by a multidisciplinary team (MDT) which includes gastrointestinal surgeons.
8. Severe IFALD-associated liver failure is an indication for small bowel transplantation.

Introduction

Intestinal Failure-Associated Liver Disease (IFALD), formerly known as parenteral nutrition-associated liver disease (PNALD) develops in a significant percentage of patients who cannot maintain nutritional autonomy and thereby require the infusion of parenteral nutrients. It must be recognized that the assimilation of nutrients when delivered to the body intravenously differ, at least for some nutrients, when they are consumed via the oral or enteral route [1] The bypassing of the enterohepatic circulation and associated homeostatic mechanisms, combined with different presentations of nutrients across the sinusoids explains the tendency to hepatic steatosis in patients who are committed to extended periods of PN [2, 3].

The History of IFALD, Epidemiology and Outcome

First recognized in 1971 in an infant [4], for many years IFALD was described as one cause for non-alcoholic steatohepatitis (NASH) [5]. Although NASH has many aetiologies, IFALD is an unrelated disease with different pathophysiology, histology, and outcomes [6]. Transient biochemical abnormalities in hepatic aminotransferases and alkaline phosphatase have been reported in over 90% of adults within 1–6 weeks of starting parenteral nutrition [7]. These reports, however, came from an era of overfeeding wherein excess carbohydrate energy was often provided to patients (often >50 kcal/kg/day) [8]. With longer term use (home parenteral nutrition) Aspartate aminotransferase (AST) and alkaline phosphatase (ALP) become progressively more elevated [9]. It should be recognized however, that biochemical indices of liver injury provide little information with regards to hepatic function and specifically, serum aminotransferase concentrations are often insensitive and nonspecific indicators of hepatic histopathology [10]. This is equally true of IFALD in children [11, 12].

J. M.D. Nightingale (ed.), *Intestinal Failure*, https://doi.org/10.1007/978-3-031-22265-8_24

The frequency of clinically-significant IFALD remains substantial, but is much less when compared to the 1980s [13]. In the Cavicchi study of adults, at least two of three enzymes (ALT, AST or alkaline phosphatase) were elevated in 55% of patients at 2 years, 64% at 4 years, and 72% at 6 years in a group of 90 (57 with histologic data) patients that had received home parenteral nutrition (HPN) [13]. However, modern cohorts differ from this historic group in which half the patients developed clinically significant liver disease; when defined by a serum total bilirubin concentration exceeding 60 μmol/L (3.5 mg/dl) for at least one month, the presence of ascites, hepatic encephalopathy, variceal haemorrhage, a serum factor V concentration less than 50% or portal fibrosis or cirrhosis on biopsy, the percentage of patients was 26% at 2 years, 39% at 4 years, 50% at 6 years and 53% at 8 years.

In adults, the elevation of serum bilirubin is an ominous sign, with a mean lifespan of only 10.8 months following this observation and death in all once the total serum bilirubin concentration exceeded 61 ± 20 μmol/L (3.6 ± 1.2 mg/dl) for 6–12 months [14]. IFALD is the complication in patients with intestinal failure with the greatest risk of death [15], and impending hepatic failure is the most common indication for isolated small bowel transplantation [16]. Chan et al. reported 15% of their 42 adult patients that received long-term PN at the Beth Israel Deaconess program in Boston developed IFALD that progressed to end stage liver disease; all died shortly thereafter [14]. Should the liver fail, a combined liver-small bowel transplant is necessary given that continued malabsorption will result in continued hepatic insult. Timely isolated intestinal transplant carried out before end stage liver disease has developed has lead to the reversal of IFALD [17–19].

Children, especially pre-term infants are particularly susceptible to IFALD [20]. A study which recruited pre-term babies born between 28 weeks gestation and 37 weeks week found that lower gestational age (<34 weeks) was associated with higher serum bilirubin and that episodes of sepsis were on average responsible for 30% increase in serum bilirubin [21]. Physiologically babies are less robust because the immaturity of liver canalicular membranes reduced glutathione reserves and dependency on exogenous taurine, choline [2, 20, 22]. Fifty percent of children become jaundiced (bilirubin in excess of 70 μmol/L) at some point during the administration of PN [23]. In addition to immature homeostatic mechanisms, infants and children are exposed to relatively higher toxic impact of intravenous nutrition intakes because of the greater calories requirement per kg to account for growth requirement. As in adults the development of persistent jaundice was associated with mortality, and in the early phase of intestinal transplantation in the 1990s approximately twice as many children as adults were transplanted for end stage IFALD, despite the difficulties in finding size matched donors for young recipients typically weighing 10–20 kg.

The improved awareness of IFALD and willingness to ameliorate risk factors such as over provision of nutrients and a more active approach to supplemental enteral nutrition has led to a reduction in severe IFALD in children and adults the past three decades [24, 25].

Definitions

Intestinal failure is defined as a condition where an individual is unable to absorb sufficient nutrients and/or fluid to maintain nutritional autonomy. The European Society of Enteral and Parenteral Nutrition (European Society of Clinical Nutrition and Metabolism) (ESPEN) has defined intestinal failure as "the reduction of gut function below the minimum necessary for the absorption of macronutrients and/or water and electrolytes, such that intravenous supplementation is required to maintain health and/or growth" [26]. The International Small Bowel Transplant Association (ISBTA), now known as the Intestinal Rehabilitation and Transplant Association (IRTA), a subdivision of The Transplantation Society, has defined IFALD as "a persistent elevation of liver enzymes, alkaline phosphatase and γ-glutamyl transferase 1.5 times the upper limit reference range which persist for more than or equal to 6 months in adults and more than or equal to 6 weeks in children" [27]. This definition of IFALD includes pragmatic definitions of severity—clinically described as mild/early IFALD; moderate IFALD; advanced/end stage IFALD. And acknowledges that IFALD is a disease with a spectrum of responses by the liver to a variety of biological provocations including: abnormal route of nutrient administration causing greater glucose uptake (PN versus EN) [3]; excess nutrient provision [13, 28]; bacterial overgrowth; systemic sepsis, especially originating from the bowel [29, 30].

Histopathology

Steatocholestasis (combination of steatosis and cholestasis) is the hallmark of IFALD, and a histologic finding that differentiates it from non-alcoholic fatty liver disease (NAFLD), which includes non-alcoholic steatohepatitis (NASH) [6], although steatosis tends to predominate in most adults. Steatosis generally develops initially as macrosteatosis in zone 1 (periportal) (Fig. 1). Microvesicular steatosis is seen in the majority of adults, and in some patients a combination of both macro- and microsteatosis is observed [13] (Fig. 2). Steatohepatitis is uncommon and is rare in the absence of cholestasis [13, 31]. Therefore, although IFALD is a unique liver disease unto itself, in children it is often

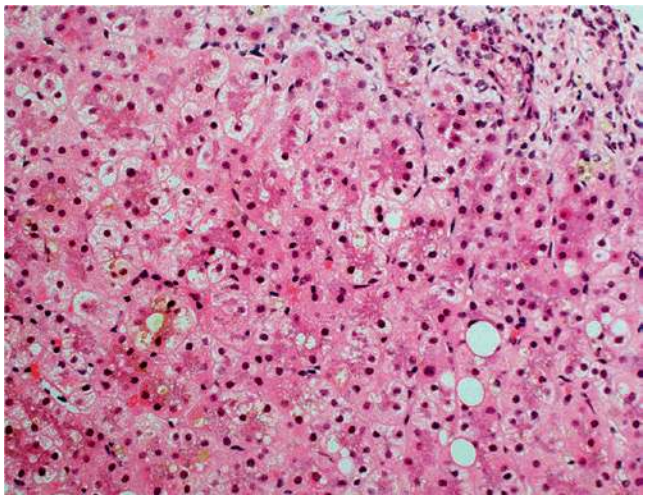

Fig. 1 Macrosteatosis with steatosis (steatocholestasis) in zone 1 (periportal)

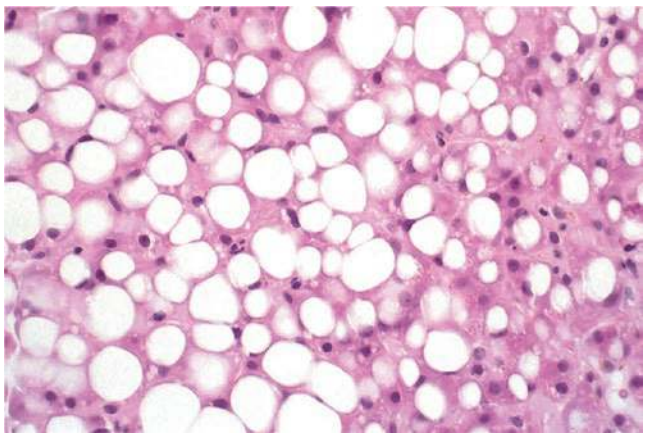

Fig. 2 Macro-and microsteatosis

noted to resemble numerous other diseases such as extra hepatic biliary atresia, α1anti-trypsin deficiency, or cystic fibrosis, and thus careful clinical pathological correlation is required. It is to be noted cholestasis may be evident biochemically (1.5× the normal upper value for at least 2 of 3 livers tests including alkaline phosphatase, conjugated bilirubin and γ-glutamyl transferase as defined by Cavicchi et al. or the ISBTA [13, 27]. Other histologic findings may include features of biliary obstruction with portal inflammation, edema and ductular proliferation, although ductopenia (the absence of bile ducts in >50% of portal tracts) may also occur uncommonly [6] (Fig. 3), this is important as it illustrates how IFALD can mimic other diseases histologically. Fibrosis begins with portal expansion and may progress to cirrhosis, often in a characteristic "jig-saw" pattern) although hepatic failure may occur prior to development of cirrhosis (Fig. 4).

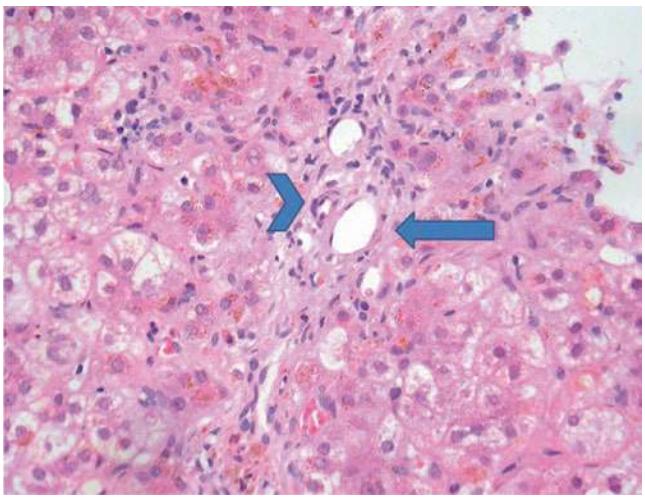

Fig. 3 Ductopenia (the absence of bile ducts in >50% of portal tracts) found in a 4 months old baby who has been on parenteral nutrition since being born prematurely. Slide H&E × 200. Arrow head = artery, arrow = vein branch, but no accompanying bile duct. Kindly supplied Dr. Rachel M. Brown Consultant Histopathologist Queen Elizabeth Hospital Birmingham, UK

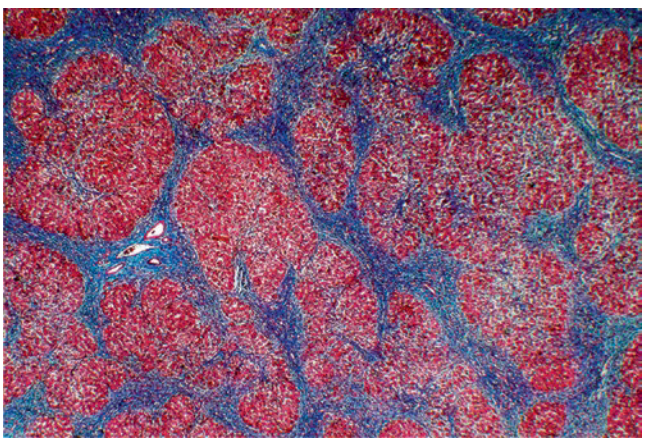

Fig. 4 Fibrosis begins with portal expansion and may progress to cirrhosis, often in a characteristic "jig-saw" pattern)

In young children, cholestasis dominates the histopathology, with steatosis being relatively inconspicuous [32, 33]. A peri-cellular pattern of fibrosis is often seen in early cases of IFALD in children along with Mallory-Denk bodies which are often seen with toxic insults. The combination of perivenular and portal fibrosis is especially characteristic of IFALD [31]. Although cirrhosis is not common in IFALD, when it occurs there is a risk of hepatocellular carcinoma development [34]. Ischaemic hepatitis has also been reported in an acute case of intestinal failure caused by mid-gut volvulus and septic shock—this child developed rapidly progressive liver disease but did well after combined liver and bowel transplant [35].

Pathophysiology of IFALD in Adults

Adult patients with the least functional residual intestine and thereby the most significant nutrient malabsorption and most dependent on PN are at the greatest risk for development of IFALD [36]. Normally, upon ingestion of food, nutrient digestion begins in the mouth and continue into the stomach and small bowel, with absorption in those organs with transport to the liver via the portal vein. When nutrients are intravenously infused, they are infused directly into the vena cava at the cardiocaval junction. After passing through the heart, the nutrient-enriched blood eventually makes its way to the liver via the hepatic artery. As such, first pass metabolism is effectively bypassed. In 1972 Stegink and Den Besten showed that orally-administered methionine was metabolized via the hepatic transulfuration pathway to cystine [1]. Choline is a product of the same hepatic pathway, which is incompletely functional when presented with intravenously-infused substrate, resulting in deficient choline biosynthesis [37–39]. As a result of impaired methionine metabolism, plasma methionine concentrations ranges from high normal or elevated in patients that receive PN [37, 40, 41]. In such circumstances, choline deficiency develops in patients fed intravenously because there is minimal choline supplied in PN (chiefly via lipids) and hepatic biosynthesis is impaired. Plasma free choline concentration is decreased below normal in 85–90% of PN patients, and negatively correlates with serum hepatic aminotransferase concentrations and the degree of hepatic steatosis [42, 43]. Steatosis develops due to decreased very low-density lipoprotein (VLDL) synthesis and a subsequent reduction in transport of triglycerides from hepatocytes; choline is required for VLDL biosynthesis. Small, but placebo-controlled studies have shown IFALD can be improved or ameliorated with choline supplementation in adults [42, 44]. Animal data have suggested choline also improves bile flow [45], which is decreased during PN infusion [46–48], and thereby reduce cholestasis as noted by a fall in the serum alkaline phosphatase [44]. Choline deficiency may be necessary for the development of IFALD, but not sufficient. A second "hit" such as lipid peroxidation [49, 50], or the presence of endotoxin may be required [51].

There are however a myriad of other proposed etiologies for IFALD in adults (Table 1), some of have not been substantiated by investigational studies (carnitine deficiency), but others clearly contribute (carbohydrate overfeeding, essential fatty acid deficiency, generalized malnutrition, lipid overload), Others proposed etiologies have little human or animal data currently (glutamine, taurine and bile salt deficiencies, bacterial overgrowth and endotoxin, aluminum and bile salt toxicities).

Both severe protein undernutrition [52], and essential fatty acid deficiency (EFAD) [53–56] have been associated with the development of hepatic steatosis. The undernutrition presumably would be corrected with PN although a minimum of 2–4% of total energy must be supplied as linoleic fatty acid via lipid emulsion to prevent development of EFAD. Like choline, carnitine is also a product of the hepatic transsulfuration pathway and blood concentrations are decreased in patients that receive PN, although not to the level generally seen in congenital carnitine deficiency [41, 57, 58]; Carnitine supplementation however has not been useful in the treatment of IFALD [59].

Table 1 Factors associated with the development of IFALD

Malnutrition	Excessive dextrose calories
Essential fatty acid deficiency	Excessive omega-6 fatty acids
Glutamine deficiency	Toxic effects of protein hydrolysates
Choline deficiency	Carnitine deficiency
Taurine deficiency	Differential metabolism of intravenously-infused nutrients
Hyperglycemia	Increased portal insulin: glucagon ratio
Bacterial overgrowth	Bacterial endotoxin
Bile salt deficiency	Toxic bile salts
Lithocholic acid toxicity	Aluminum and heavy metal toxicity

Nutrient toxicity has also been implicated in the development of IFALD. These include dextrose overfeeding (>50 kcal/kg/day), which leads to an increase in the portal insulin: glucagon ratio [60]. Mitochondrial carnitine acyltransferase is then inhibited and thereby fatty acid oxidation impaired since it is the rate-limiting step [61]. Hepatic acetyl-coenzyme A is increased and acetyl-coenzyme A carboxylase is induced, which stimulates hepatic fatty acid synthesis [62]. Case reports indicate lipid overload (>2.5–3.0 g/kg/day also causes severe cholestasis and even death [63, 64]. It has been suggested that phyotosterols (plant sterols) present in soyabean based lipid infusions may decrease bile secretion and contribute to cholesatasis [65]. What remains unclear is whether the increase in serum phytosterols is a result of impaired hepatic function or a cause of impaired hepatic function. There is limited data for the treatment of IFALD in adults short of intravenous lipid reduction (to a maximum of 1 g/kg/day) [13], and even here there is no prospectively-controlled data to support this practice. Two single retrospective case reports suggest some potential value of the use of a fish oil-based lipid emulsion in adults with IFALD [66, 67].

Manganese toxicity has been described in association with hepatic abnormalities during PN in case reports [68–70] although it is not clear whether these heavy metals, which are eliminated in bile, accumulate in the liver because of cholestasis, or whether they directly contribute to the exacerbation of IFALD. There is concern that the amount of manganese in PN is excessive [71], although there is no data currently that the dose of copper typically provided causes liver disease outside of the presence of IFALD or other liver disease.

Pathophysiology of IFALD in Children

As in adults, the abnormal route of administration whereby nutrients reach the hepatic sinusoial bed via the hepatic artery rather than the portal vein must adversly affect the liver—but observations have focused more on the effect on the canalicular membrane and the liver's capacity to take up glucose from PN solutions in the absence of enteral feeds [2, 3]. The role of choline in restoring bile flow and reducing steatosis has not been proven in children, although choline concentrations in blood are low [38]. However, taurine may be important in reducing serum bilirubin: in a study of 236 premature infants with NEC—those who were supplemented with taurine had a significant reduction of peak bilirubin (70 μmol/L versus 140 μmol/L) [72]. Vitamin E has been shown to protect against liver injury when given pre-operatively to adults undergoing partial hepatectomy for tumour surgery [73], and the positive effects on liver biochemistry of the multisource lipid emulsion SMOFlipid (SMOFlipid™ Fresenius-Kabi, Uppsala, Sweden) reported by Goulet et al. [74] may in fact be a function of vitamin E which was found to be significantly increased in the SMOFlipid 20% when compared to Intralipid 20%, although definitive studies in IFALD are lacking.

The role of fish oils which contain relatively greater ratio of omega 3 lipids to omega 6 lipid (either multisource oils or Omegaven, Frenius-Kabi, Bad Homburg, Germany) in long term PN has been debated vigorously for two decades and opinion remains divided as to whether the the omega 3 lipids have a protective effect on sinusoidal/cholangiocyte function or whether a reduction in the pro-inflammatory omega 6 lipids is the key. An important caveat to the claims around the value of the mulitsource lipid SMOF (Fresenius-Kabi, Bad Homburg, Germany; contains soya oil; medium chain fatty acids; olive oil and fish oil) is that although many studies have demonstrated a an improvement in serum bilirubin concentration, improvement has not generally been seen in alkaline phosphatase and improvement is variable for hepatic aminotransferases [11]. More importantly, the long term outcomes are unknown and there are publications calling attention to the development of fibrosis and cirrhosis despite the use of this lipid emulsion in children who have normal or close to normal hepatic aminotransferases [11–13]. This lack of concordance between hepatic aminotransferases tests and liver histology is of concern and shows that improved means of monitoring and detecting IFALD are needed (see later section).

Perhaps because of the obvious immaturity of organ function (liver and intestine) of infants and children, the concept of toxic stress (excess calories/hypertonic glucose/phytosterols/w6 fats) as an important driver of IFALD has gained particular traction in the paediatric literature [33]. This, combined with deficiency of protective factors (vitamin E, taurine and choline) and amplification by endogenous factors such as abdominal sepsis especially NEC and VAP-1 released by inflammed bowel [29, 30], and the role of bacterial overgrowth have resulted in IFALD being regarded as a multi-stage condition requiring multiple triggers [75–77]. See Fig. 5 processes leading to steatosis and fibrosis.

There is increasing acknowledgement of role of bacterial overgrowth especially in dilated and/or, obstructed bowel. Hukkinen et al. [78] reported a relationship between degree of dilatation of bowel and blood stream infections. The small bowel diammeter (sbd) was standardised to vertebral height (vh) and a ratio of sbd to vh was derived: ratio of >2.71 predicted PN dependency. Dilatation of the bowel also correlated with: increased faecal calprotectin; serum bilirubin; and gamma glutamyl transferase (GGT); pre-albumin and inversely correlated with citrulline [78]. Patients with dilated bowel were also more likely to demonstrate abnormal liver histology (i.e. increased portal inflammation and cholestastis).

The importance of the intestinal microbiome in a wide range of diseases is well described and has led to the notion that a "fibrogenic microbiome" exists [76, 77]. Rifaximin was found in rodent study to significantly reduce portal pressure, fibrosis, and angiogenesis and a follow up study in TLR4 mutant mice confirmed that the effect of rifaximin was dependent on lipolysachharide acting via the TLR4 pathway [77]. In a study of 21 children with intestinal failure the loss of bacterial diversity in the colon and an overabundence of Lactobacilli, Proteobacteria, and Actinobacteria correlated with steatosis and fibrosis, which was noted to be a stronger association with steatosis than duration of PN or bowel length [75]. These studies point to the loss of barrier function as being the key link between abnormal bowel; bacterial overgrowth, the "fibrogenic microbiome" and the development of IFALD in children [79] and adults [80]. There are only few human studies published as yet but this is an expanding field and the excellent review of the literature by Cahova et al. [81] is a good source of further information.

It is appreciated that the Gut-Liver axis is fundamental to health with many examples of the impact of disease in the bowel leading to liver dysfunction (e.g. inflammatory bowel disease and autoimmune hepatitis) and the most obvious example in intestinal failure is the adverse impact of necrotising enterocolitis on the liver [20]. Disruption to the enterohepatic circulation is inevitable in short bowel syndrome especially if the distal ileum is affected as this is the region of the bowel which contains cell surface active transporter channels for the re-absorption of bile acids. Furthermore reduced bowel mass leads to less ileal fibroblast growth factor-19 (FGF-19) [81, 82] and, since FGF-19 activates the nuclear transcription factor frasenoid X (FXR) in hepato-

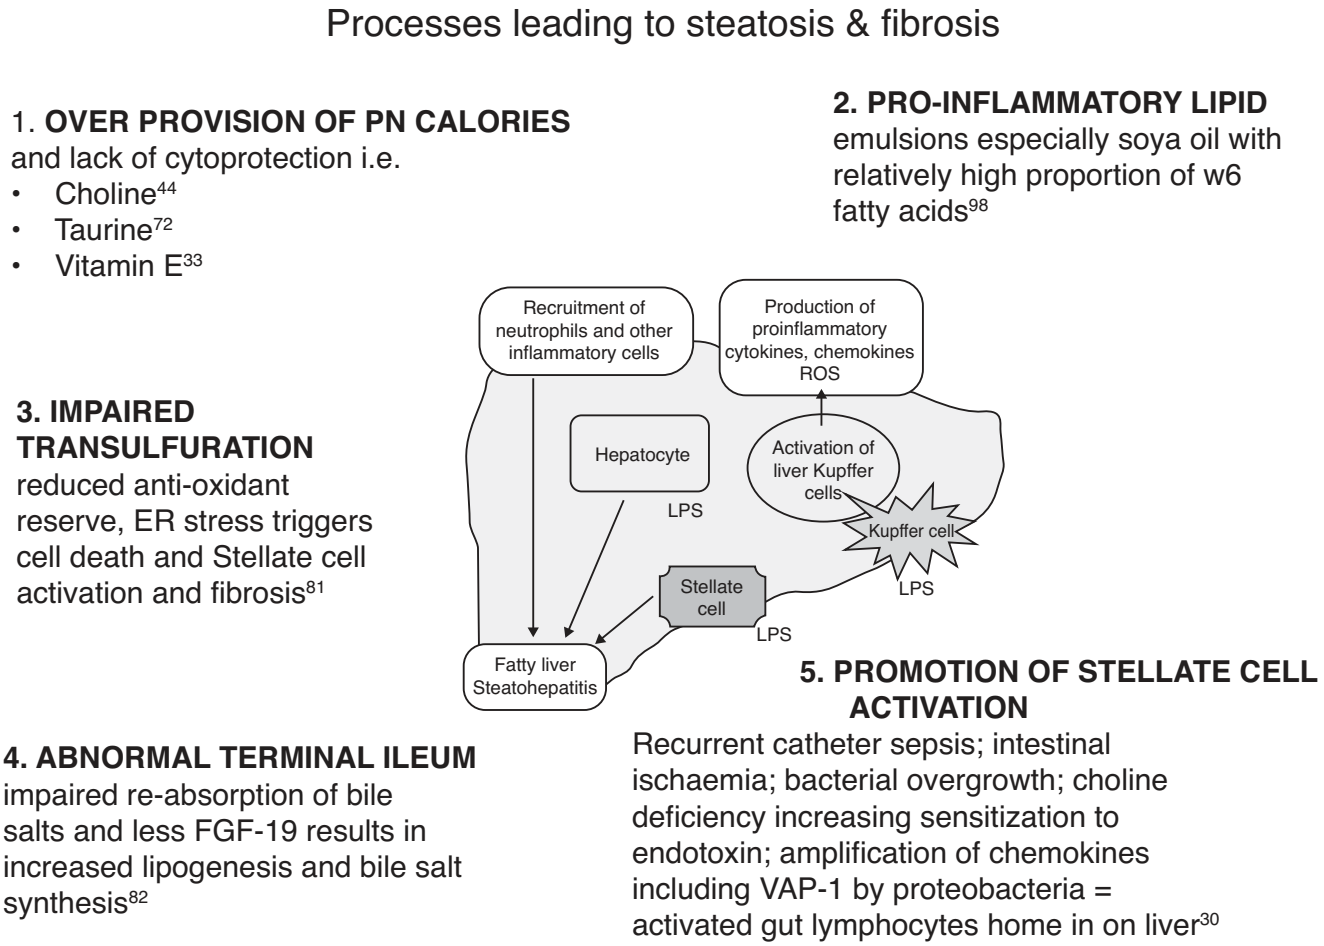

Fig. 5 Processes leading to steatosis and fibrosis in IFALD

cytes, a lack of FXR ensues. The lack of FXR in short bowel syndrome permits excess lipogenesis and bile salt synthesis [83, 84] and this leads on to the observed development of steatosis and fibrosis reported in IFALD [85]. See Fig. 6 liver-gut axis in IFALD. However, recent investigation suggests the residual bowel ina model of short bowel syndrome in fetal pigs is unable to respond to FXR activation, casting doubt for FXR as a treatment for IFALD [86].

Detecting IFALD

The monitoring of patients on PN is routine and rightly includes measures of anthropometry and biochemical stability. Normal liver function and transaminases do not necessarily correlate with a healthy liver as is clear from reports of hepatic fibrosis and cirrhosis in adults and children with normal LFTs [10–12]. In addition, the haemodynamics of the splanchnic circulatory system are different in intestinal failure: typically lower portal blood flow ensues, and this may result in lesser varices and trivial ascites except in advanced cases. This means that fibrosis and cirrhosis can be easily overlooked. However, regular abdominal ultrasound every 6–12 months may be valuable [87]: changes in hepatic parenchyma reflectivity and the size of spleen may give early warning of steatosis and fibrosis. Biliary sludge and obstruction to the biliary tree may also be detected prior to frank jaundice. See Fig. 7—impacted gall stones in a young adult with gastroschisis who required PN for first 12 months of life.

In addition to spleen size on ultrasonography, hypersplenism may be tracked by regular measurements of the platelet count [88], but it is often unclear whether thrombocytopaenia it is acting as a surrogate marker for portal hypertension or inflammation, or both.

Specific tests for IFALD are not available—detection depends on the exclusion of primary liver pathologies (e.g. heterozygote or homozygous alpha 1 antitrypsin deficiency; thyroid disease; viral hepatitis; autoimmune disease) and a baseline abdominal ultrasound, CT or MR, which are especially useful for the detection of steatosis, which may be diffuse. Liver biopsy is not usually necessary in mild IFALD, except when staging of liver disease is helpful or where there is persisting diagnostic uncertainty. Other less invasive tests

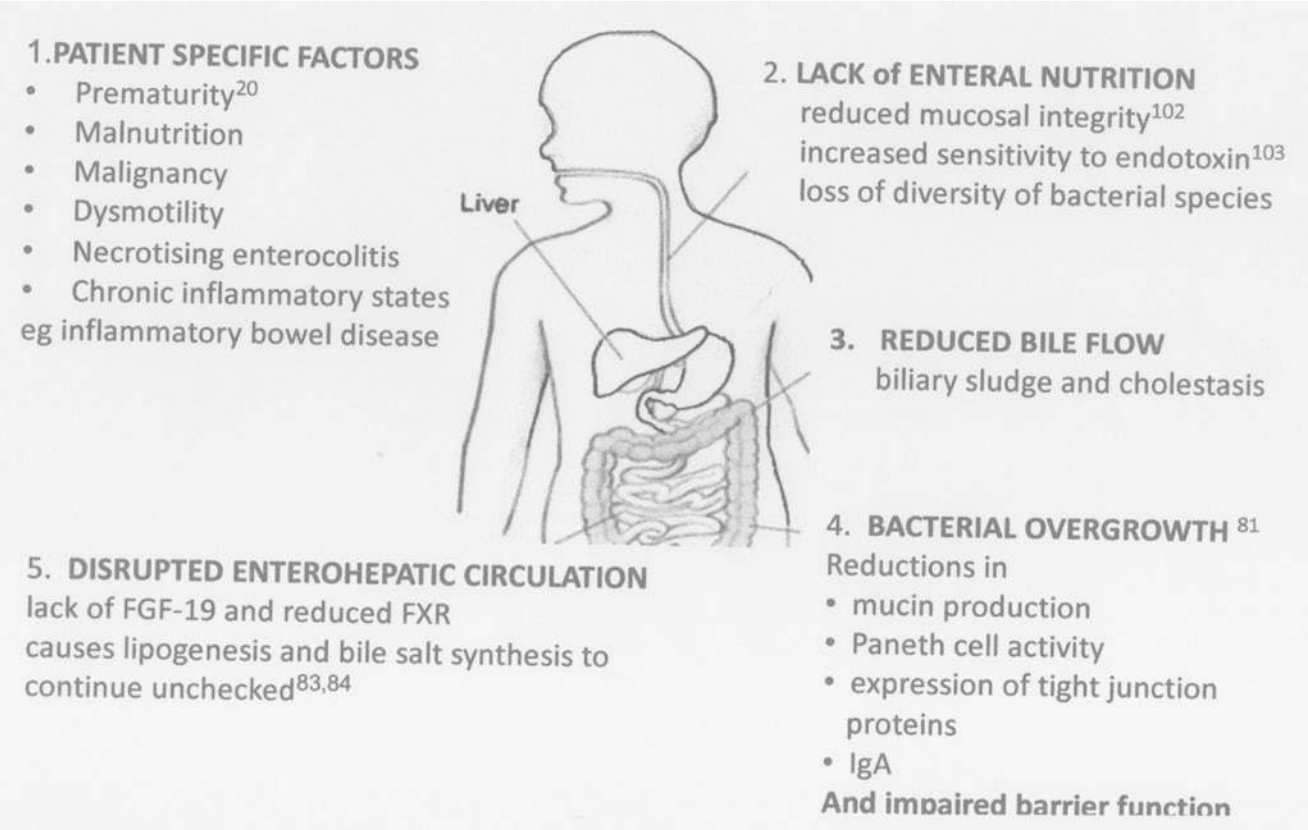

Fig. 6 Liver–Gut axis in IFALD

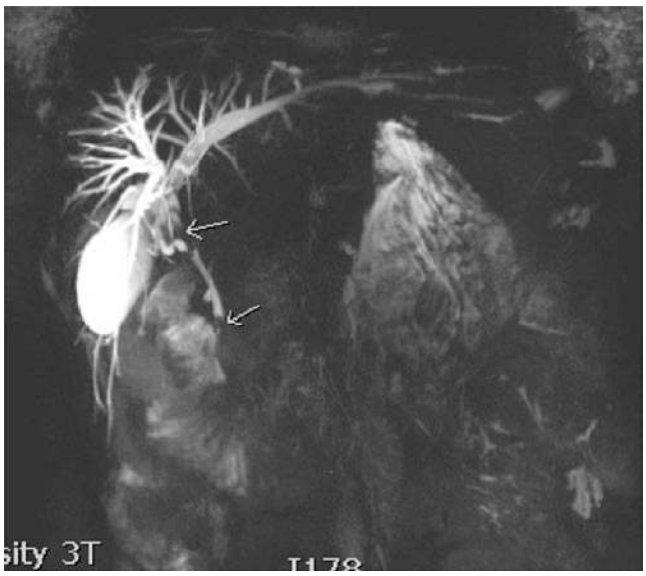

Fig. 7 Illustration of biliary disease in a child with short bowel syndrome—MRCP arrows show areas of filling defect caused by bilary sludge and impacted gall stone

such as the AST to platelet ratio (APRI) score have been used to predict cholestasis in children but doe not correlate with fibrosis. Hukkinen et al. in a retrospective study [89] reported on 57 children who receive PN ≥3 months and found raised AST and bilirubin levels were found in 51%, splenomegaly in 26%, and oesophageal varices in 3.5%. All the children had at least one liver biopsy and histological fibrosis was present in 61% (Metavir stage F1; 27%, F2; 26%, F3-4; 9%), cholestasis and steatosis was noted in a quarter. This group found that transient elastography was superior to APRI in predicting fibrosis Metavir F2 0.73 (95% CI 0.59–0.88). However, in adults, elastography appears to correlate better with cholestasis then it does with fibrosis [90].

Other non-invasive tests include: serum markers of collagen synthesis (cytokeratin 18 fragment levels, hyaluronic acid, matrix metalloproteinase [75]; and [13 C] methionine breath test [91]). Duro et al. found that intravenous. administration of the stable isotope [C]-Met was straight forward and, in five patients who were studied serially, the [C]-Met breath sampling reflected changing paediatric end stage liver disease (PELD) scores [91]. These tests are very interesting and may provide a more dynamic measure of liver dysfunction in IFALD than other measures, but the number of patients studied is small and not yet validated with long term outcomes. See Fig. 8 algorithm to evaluate abnormal liver function in children and adults with intestinal failure.

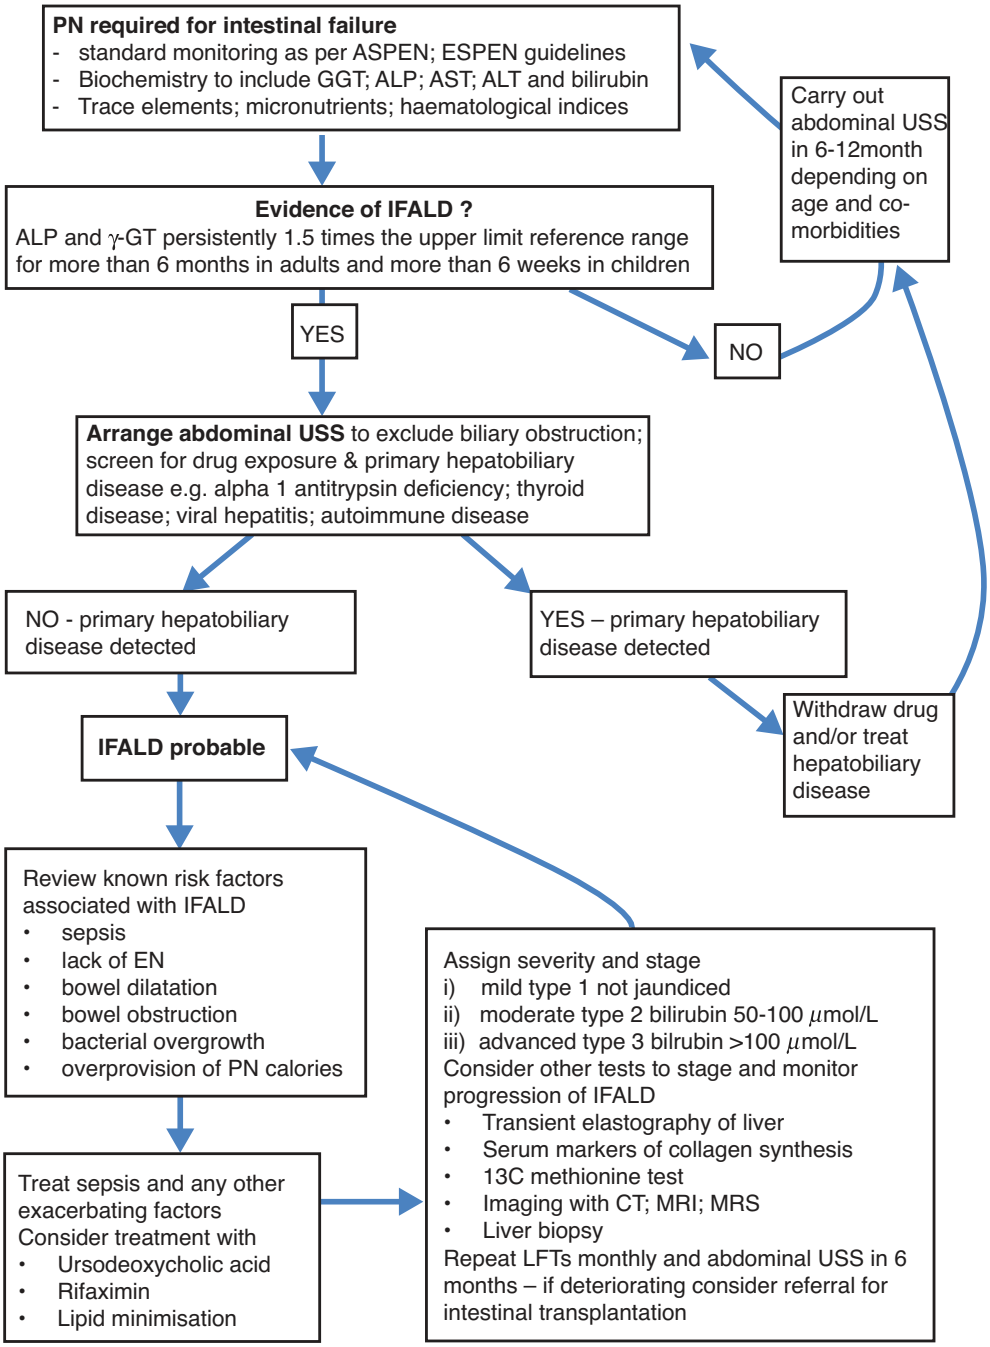

Fig. 8 Algorithm for detecting IFALD

Managing IFALD in Children and Adults

The management of IFALD in children and adults has common principles which include scrupulous attention to the PN prescription which should avoid excess calories in the form of carbohydrates [8] and minimisation of lipids [13, 92–94]. There is long history of the use of substrates with cytoprotective properties e.g. choline [42, 44] and taurine [72] and and more recently the role of vitamin E which is added in high concentrations in newer lipids to prevent peri-oxidation, but may have a cytoprotective role equal to the use of fish oils [33, 73, 74].

Lipid management strategies is a term which covers a huge range of approaches to mitigate the the pro-inflammtory nature of soyabean oil and its role in IFALD. The term includes: reduction or removal altogether of soya oil lipid infusions (usually for limited periods only in order to avoid development of essential fatty acid deficiency); the use of mixed source lipid emulsions containing another of lipids

added to Soya oil lipid such olive oil (Clinolipid®, Baxter Healthcare Corporation, Deerfield, IL) or medium chain triglyceride (Lipofundin® MCT/LCT; B Braun, Mesungen, Germany), and multisource lipid emulsions containing soyabean oil; medium chain triglyeride (from coconut oil); olive oil and fish oil (SMOFlipid™ Fresenius-Kabi, Uppsala, Sweden). Omegaven (Frenius-Kabi, Bad Homburg, Germany) is also used especially in the United states of America—this last lipid consists entirely of fish oil as a 10% emulsion. There are some significant claims for SMOF and Omegaven but although cholestasis improves, there are reports that these lipid sources do not arrest the development of fibrosis [11, 12, 95–97]. Whilst most agree that lipids can contribute to the pro-infammatory signal coming from the bowel or septic states, there is no clear agreement about which type of lipid, if any, is best for prevent hepatic deterioration in patients on long term PN [97]. A pragmatic approach is to substitute at least half the soya bean oil with any other [33, 98].

Enteral feeding in short bowel syndrome should be promoted and started as soon as possible as it may improve function of the residual bowel and is associated with beneficial effects on gut permeability [99]. A study of patients in critical care randomly allocated to recive either EN or TPN found that permeability was increased in both groups initially compared to controls, but only in the EN group did the recovery of lactulose relative to rhannose start to fall, suggesting that mucosal integrity is better maintained by the institution of EN [100] although the clinical ramifications of this observation are unknown. The hypothesis that excluding EN and relying on TPN can adversely affect response to endotoxin was tested in small group of human volunteers who were given either TPN or EN and then challenged with endotoxin—the TPN group had an exaggerated physiological response with twice as much tumor necrosis factor detected and significantly increased serum lactate and C-reactive protein [101].

It is not certain what component of EN, if any specific component(s), is beneficial in improving the mucosal integrity of stressed GI tracts: it could be the role of nutrients in the bowel acting locally on the mucosa, or EN may be influencing the microbiome. The lack of EN is associated with a loss of diversity of bacterial species combied with overabundance of Lactobacilli, Proteobacteria, and Actinobacteria is linked with reduced mucin production by Goblet cells; reduced Paneth cell activity; reduced expression of proteins associated with tight junctions and reduced IgA - all of which contribute to reduced intestinal epithelia barrier function [81]. The microbiome in children with IFALD and short bowel has been reported to show less diversity than in healthy children although it is not clear whether this directly leads to liver disease or whether it is and epiphenomenon of the short bowel syndrome causing an abnormal microbiome [75]. Overabundance of Lactobacilli and decreased abundance of Ruminococcus has also been reported in children with short bowel syndrome and increased bowel frequency [102].

Ursodeoxycholic acid may be helpful in preventing biliary sludge gall stones especially in babies with low enteral intake. In a prospective, double-blind, placebo-controlled study of ursodeoxycholic acid in preterm infants, fecal fat excretion decreased and achievement of full enteral feeding was slightly earlier in the UDCA group, but these differences did not quite reach significance, although the gamma-glutamyl transferase activity was significantly lower in the UDCA treated group for the duration of the study [103]. A smaller study in very low birth weight babies showed some benefits of ursodeoxycholic acid: the group given ursodeoxycholic acid had a shorter period of jaundice than the control group [104]. However, there is no prospective data to support the role of ursodeoxycholic acid in adults.

Multidisciplinary nutrition support teams faciliate monitoring (as per algorithm in Fig. 8) and staff training [105] in the care of feeding catheters, and are well established approaches for minimising liver disease in intestinal failure [106]. Dedicated multidisciplinary expert teams not only improve staff training but the increasing prevalance of such teams is thought to be behind the overall improvements in long term outcomes of intestinal failure and the reduction in IFALD [25]. These teams allow timely management of dilated/obstructed/bowel with tapering surgery [78, 107]. Dedicated vascular access teams have been shown to have good long term results for vessel patency [108] and are especially important for children and adults who may need PN for years.

The relationship between induction of inflamatory states by sepsis especially the role of endotoxin and other products of gram negative bacteria is well known and thus attempts to minimise infection from the bowel and/or catheter related blood stream infections (CRBSI) are now part of the management of IFALD. Octenisan skin washes have been shown to reduce CRBSI [109] and a study of 200 adult patients the use of taurolidine line locks was associated with a five-fold reduction in the incidence of CRBSI [110].

Intestinal Transplantation for IFALD

Patients who demonstrate signs of worsening liver disease despite the measures above should be considered for isolated intestinal transplantation before irreresible liver disease supervenes. But the timing of referral can be difficult as depending on liver function tests alone can provide false re-assurance. Regular liaison with an intestinal transplant centre and professional collaborations are key to identifying that point where a patient could benefit from an isolated small bowel transplant [27, 98]. This topic has been reviewed recently [99] and based on reports that sustained but mild hyperbilirubinaemia can be reversed once enteral feeding is re-established after successful small bowel trans-

plant [19], the following criteria based on degree of hepatic fibrosis and markers of portal hypertension/hypersplenism are proposed: (1) Total plasma bilirubin <100–120 mmol/L. (2) Minimal hepatosplenomegaly. (3) Platelet count >150,000 × 10^9/L. (4) Stage 1 or 2 fibrosis on biopsy. Once patients are listed for isolated intestine transplant, it is important they are re-evaluated if they wait longer than a few months for a donor, and especially after any septic episode given the likelihood of progression of IFALD. Combined liver-small bowel transplantation should not be necessary if isolated intestinal transplantation is performed at an appropriate time.

Acid-Base Disturbances

Barry J. M. Jones

Key Points

1. Acid-base disturbances (ABD) should be expected from the changes to anatomy and physiology in Intestinal Failure, even when the gastrointestinal tract is intact. They may be exacerbated by intravenous nutrition or saline, oral rehydration solutions, acid suppressing treatments, urinary diversion, thiamine and phosphate deficiencies, refeeding syndrome, L- or D-lactic acidosis and renal or respiratory disease.
2. Serum bicarbonate and chloride should be regularly measured in intestinal failure (IF) patients and the serum anion gap calculated as recommended by international guidelines. Blood gas measurements are occasionally needed to give further information.
3. Metabolic high anion gap acidosis occurs with renal failure, ketosis, L-lactic acidosis, thiamine deficiency and D-lactic acidosis. Coexistent impaired renal function is the most important contributory factor, tolerance of which is further impaired by respiratory disease.
4. Metabolic hyperchloraemic acidosis with a normal anion gap is common and due to bowel bicarbonate loss, sodium chloride infusions (or oral rehydration solutions) and acid suppression therapy (also urinary diversion and phosphate deficiency).
5. Metabolic alkalosis reflects loss of acid through vomiting, and/or potassium and magnesium deficiencies (often consequent upon diuretics, hypovolaemia and hyperaldosteronism) and is associated with cardiac, intestinal, muscular and neurological symptoms.
6. Respiratory acidosis results from excessive glucose infusion, particularly if respiratory disease is present.
7. Chronic acidosis leads to bone mineral loss resulting in osteoporosis.
8. Acetate (which is metabolisable) may replace chloride in parenteral nutrition (PN) infusions to reduce acidosis. Rehydration solutions not based on sodium chloride should be considered in intestinal failure patients at risk of acidosis. Additionally stopping a patients proton pump inhibitor (PPI)H_2 antagonist may also reduce acidosis.
9. Patients with a short bowel and a functioning colon in continuity may develop a high anion gap acidosis due to D-lactate (worse if thiamine deficiency and/or liver disease); this may cause profound cerebellar signs, behavioural changes and coma.
10. Patients with a jejunostomy may develop chronic renal failure from dehydration. If dialysed they should not have fluid removed (no weight loss), with additional fluid being given at the time (weight gain).
11. Muscle cramps during PN infusion are an enigma but possibly relate to acute acid-base changes or electrolyte fluxes across cell membranes. Slower infusion rates appear to relieve symptoms.

Introduction

Survival of our species depends upon maintenance of the "milieu interieur" within boundaries permitting normal metabolism. Mammals including humans have evolved to be able to cope with the production within their bodies of highly acidic and alkaline fluids without detriment to local structures or the wider metabolic balance of the body—an extraordinary and finely balanced feat of evolution. It takes very little to disturb this equilibrium yet the body is able to compensate for most of such disturbances—provided that those compensatory mechanisms are intact and the demands upon them are not excessive. The function of the gastrointestinal system depends upon the interactions between its anatomy and physiology. The gastrointestinal tract has been likened to "a sleeping bear" with regard to acid-base homeostasis [1]. It should not be surprising that disturbed anatomy leads to dis-

J. M.D. Nightingale (ed.), *Intestinal Failure*, https://doi.org/10.1007/978-3-031-22265-8_25

ordered physiology. *In the context of intestinal failure, the gut should be considered a critical part of the acid-base metabolic system* [1]. Hitherto, the contributions of acid-base disturbances (ABD) to the complications associated with intestinal failure have not received the attention they deserve compared to other major organ failures.

The purpose of this chapter is to aid understanding, detection, treatment and avoidance of ABD in intestinal failure (IF), especially in patients with a short bowel (SB). ABD can cause profound short and long term consequences in these most complex patients.

The major contributors to acid base equilibrium are the kidneys, lungs and buffering systems within the extracellular fluids including blood and the intracellular compartment. The metabolic and excretory roles of the liver should not be forgotten with regard to metabolism of ketones, lactate, amino acids and other potentially acid substances with onward transport via blood or bile. The roles of the kidneys and lungs in the overall control of acid-base balance (ABB) are well known but the role of the gut is not. Unlike the kidneys and lungs, the gut has no role in normal acid-base homeostasis and under normal conditions, the fluxes of acid and alkali within the gut do not lead to metabolic stresses on the buffering systems or the final arbiters of acid–base balance—the kidneys and lungs. However, in patients with a SB and other causes of IF, this is not so as ABB can become severely imbalanced. The patient then becomes precariously dependent on renal and respiratory function which are often insufficient to maintain homeostasis leading to ABD. Other causes of disturbed ABB include urinary diversion to the gut, abnormal intraluminal fermentation and specific nutritional deficiencies. Parenteral nutrition and hydration with saline are major contributors to acid load. Treatment with acid suppressing agents may also prove critical in leading to metabolic acidosis. The common scenario of inadequate fluid balance places IF patients at great risk of ABD—either metabolic acidosis or alkalosis.

To adequately consider acid-base disturbances in the human suffering from intestinal failure, and in particular patients with a SB, we must first observe the main influences on acid-base balance under normal physiological conditions.

Normal Acid-Base Balance

Large amounts of H^+ and HCO_3^- traverse the gut epithelia daily and facilitate digestion and absorption of nutrients and water. When normal, only 40 mmol HCO_3^- are lost in the stool which does not stress acid-base homeostasis [1]. To the daily production of intrinsic acid production by cellular metabolism and digestion of diet, must be added the impact of fluxes of acid and alkali associated with gastric, hepatobiliary, pancreatic and ileocolonic function. Acid base equilibrium is maintained and finely controlled within the body principally by buffering systems. These include the ubiquitous carbonic anhydrase and plasma proteins such as albumin. Any net excess of acid (H^+) or alkali (HCO_3^-) from cellular metabolism must then be dealt with by the homeostatic functions of the kidneys, lungs and liver.

The production of 2 l of gastric fluid containing hydrochloric acid (HCl) in the stomach to a pH of 1–3 [1] means that a corresponding amount of alkali is left behind during the synthesis of gastric acid. There is potential for major acid-base disequilibrium if acid secretion is interrupted or absent in IF/SB and if corresponding bicarbonate production elsewhere in the gut is lost through diarrhoea or a stoma.

The buffering effect of diet, the dilution effect of oral fluid intake and alkaline saliva reduce the acidity of gastric contents which then come into contact with alkaline secretions from the duodenal ampulla. This leads to a rise in luminal pH to 6 [2] in the proximal jejunum and an average pH over the small bowel of 7 [3]. Small bowel intraluminal bicarbonate rapidly disappears [4] partly due to an active transport system but also with a rise in pCO_2 [5]. This reflects carbonic anhydrase activity in the mucosa with fluxes of hydrogen ions across the mucosa [5]. The overall impact of acid and alkaline fluxes across the length of the gut are probably neutral under normal circumstances but not so when IF is present.

The production of bicarbonate by the pancreas, hepatobiliary system and salivary glands is also a potential metabolic strain leaving behind net acid. The volume of these fluids is approximately 2.5 l/day [1] but the pH of 7.6–8.6 is not equivalent to that of gastric acid pH. Thus there must be a net residuum of acid in the gut at the level of the duodenal ampulla and proximal jejunum with a corresponding level of alkali (bicarbonate) in the extra—alimentary compartments of blood/extracellular fluids. Under normal conditions, this extraluminal excess is dealt with in the distal duodenum and jejunum by buffer systems including carbonic anhydrase and plasma proteins, notably albumin. Intraluminal pH falls again to 5.7 in the caecum but rises towards 6–7 in the rectum. Any intraluminal excess of acid is normally removed by ileal and colonic exchange of intraluminal chloride for bicarbonate [1, 4, 5]. Further influences on acid-base balance occur in the colon from the formation and absorption of acetate and other short chain fatty acids (SCFA) which are metabolised with consumption of hydrogen ions to bicarbonate, thus reducing the impact of ileocolonic secretion of bicarbonate [6].

Assuming normal buffering capacity, any net imbalances of H^+ or HCO_3^- are easily dealt with in the bowel mucosa or vascular compartments and any residual excesses of H^+ or HCO_3^- are dealt with by normal respiratory and renal function along with the usual products of cellular metabolism.

Normality also assumes normal body stores of potassium, magnesium, sodium and water and normal urinary drainage via bladder, none of which may apply in IF/SB.

Armed with an understanding of normal acid base balance and gut physiology, it should be possible to predict ABD when IF/SB is present [1] but each individual differs with regard to the quantitative impact of losses of bowel and qualitative function of the remaining bowel, as well as day to day fluid balance, oral dietary and fluid intake and renal function. The impact of dehydration on renal function and aldosterone secretion on both renal and gut function must also be factored in as well as potassium and magnesium deficiencies.

Physiology of Acid-Base Balance in IF/SB patients

The metabolic stresses of dehydration, lactic acidosis, ketoacidosis, renal impairment and infusion of acid PN regimes or "normal saline" are a challenge to the otherwise normal patient. In IF, these challenges are amplified by the metabolic stresses associated with reduced bowel length and function.

These metabolic stresses caused by IF/SB are predictable and have considerable consequences. Even when normal compensatory mechanisms are intact, ABD may occur in IF/SB [7]. ABD does not only occur in patients with a SB, but in other causes of IF in which the gut remains structurally intact but functionally incompetent, as in dysmotility syndromes in which vomiting may predominate [7]. In addition, urinary diversion to colon or ileum, and loss of gastric acid production (acid suppressing drugs, achlorhydria, gastric or vagal surgery, radiation or vomiting) may influence ABB.

To the above causes must be added the impact of the nutritional support required for treatment of IF/SB, whether it be enteral or parenteral [8]. Parenteral nutrition (PN) [9] and some enteral nutrition (EN) solutions are acid. Elemental or semi-elemental diets are usually acid and are the types of EN often used in borderline intestinal failure. So called "normal saline" is itself an acid promoting infusion [10] and saline is often the mainstay of replacing intestinal losses in "net secretors" [11]. The influence of oral rehydration solutions should also be considered [12, 13]. All IF/SB patients are as much at risk of the causes of ABD as normal patients plus those causes related to the disturbed physiology associated with IF/SB.

Net alimentary losses of acid or bicarbonate pose metabolic stresses leading to metabolic acidosis or alkalosis unless compensatory mechanisms are intact and sufficient to cope [1].

Negative water balance may cause either metabolic acidosis or alkalosis or a mixture of both linked by renal impairment [1]. Normally stable long term HPN patients can develop ABD with acute changes in hydration as a result of hot weather, intercurrent infections or increases in stomal losses, and hydration may be precarious even with full supportive measures [11].

To these disturbances can be added other causes such as D-lactic acidosis, sepsis related L-acidosis, hepatic causes (thiamine efficiency), phosphate deficiency and the metabolic impact of refeeding syndrome, potassium and magnesium deficiencies.

The scene is therefore set for extreme disturbances of the metabolic norms enjoyed by healthy individuals. These problems will be discussed further below.

Detection of ABD

Although simple in principal, ABD often goes unnoticed or undetected in IF. There are several reasons for this.

1. The possibility of acid-base disturbance is not considered as part of normal monitoring.
2. Arterial blood gas analysis is not routine in chronic IF patients and regarded as painful by many patients. Blood pH may be normal but not reflective of underlying ABD if compensatory mechanisms are functioning adequately. Thus metabolic acidosis may be masked by respiratory compensation but careful inspection of all of the blood gas parameters including pCO_2 and bicarbonate should elicit the true picture. This is especially important in high anion gap acidosis due to L- or D-lactic acidosis.
3. Many units do not monitor venous bicarbonate and chloride levels as part of a routine electrolyte profile. The reasons for this failure may lie in economic pressures to reduce laboratory costs incurred with assays with low overall utility due to low rates of abnormality detection. In IF, this can lead to chronic failure to detect metabolic acidosis and alkalosis with serious consequences for the individual patient in terms of bone disease, intestinal function or cardiac abnormalities. Until recently, neither textbooks nor national and international guidelines included recommendations to monitor ABD using bicarbonate and chloride estimations [6] so IF/HPN units did not monitor these parameters. ESPEN and ASPEN have now issued such guidance (see below).
4. Calculation of the serum and urinary anion gaps (SAG and UAG) is not routine.
5. An increased anion gap should lead to measurement of L- and D-lactate. D-lactic acidosis should be suspected in the presence of an increased anion gap and normal L-lactate in any patient with colon in continuity with residual small bowel [14].

6. Compensatory or mixed metabolic acidosis and alkalosis may mask underlying ABD [15].
7. Serum potassium levels are often not indicative of total body potassium and may be normal even in the presence of total body K^+ deficiency. Raised bicarbonate levels with a normal potassium may indicate metabolic alkalosis due to potassium deficiency. K^+ deficiency often accompanies magnesium deficiency so the presence of metabolic alkalosis as indicated by a high bicarbonate will highlight the need for potassium supplementation as well as magnesium [16].
8. The acid pH of PN solutions should be made clear on the labelling of PN bags [9].

Anion Gap and Types of Metabolic Acidosis

Metabolic acidosis can be subdivided according to the presence or absence of a serum anion gap (SAG) [17, 18], also now known as Strong Ion Difference or SID. Calculation of serum anion gap differs from centre to centre with differing normal ranges. Two methods are commonly used;

$$\left[Na^+ + K^+\right] - \left[Cl^- + HCO_3^-\right] = \text{Serum anion gap} > 20\,\text{mmol/l} = \text{positive abnormal anion gap}$$

$$Na^+ - \left[Cl^- + HCO_3^-\right] = \text{Serum anion gap} > 15\,\text{mmol/l} = \text{positive abnormal anion gap}$$

Calculation of Urinary anion gap (UAG) excludes bicarbonate [19];

$$\left[Na^+ + K^+\right] - Cl^- = \text{UAG} > 5\,\text{mmol/l} = \text{positive gap}, < 5\,\text{mmol/l} = \text{negative UAG}$$

Normal Serum Anion Gap (Non gap) Acidosis: Table 1

Hyperchloraemic acidosis is associated with a normal anion gap as bicarbonate levels fall reciprocally as chloride rises. Causes fall into 3 main groups which can be distinguished by use of the UAG [18]:

Loss of base (bicarbonate) via the gut: negative UAG of −27 ± 10 mmol/l

Loss of base via kidneys/reduction in ammonium excretion as in Renal tubular acidosis: positive UAG of >5 mmol/l

Infusion of acid solutions such as parenteral nutrition or acidosis inducing solutions such as sodium chloride: positive UAG.

High Serum Anion Gap Acidosis: Table 2

A high SAG is caused by accumulation of unmeasured anions [17, 18].

L-lactic or D-lactic acidosis patients have a high SAG due to accumulation of lactate as do ketoacidotic and renal failure patients.

Renal control of acid excretion depends on excretion of hydrions via ammonium ions (NH_4^+) and phosphates together with bicarbonate reclaim. Renal tubular acidosis should be suspected if a normal serum anion gap acidosis is detected with hyperchloraemia, low serum bicarbonate and hypokalaemia. An increased UAG with normal SAG indicates decreased ammonium excretion due to renal tubular acidosis [19]. A negative UAG with normal SAG indicates increased ammonium excretion due to extra renal causes such as gut bicarbonate losses together with potassium [19]. Interestingly, renal ammonium excretion is derived from tubular metabolism of glutamine [20], an amino acid which is often depleted in malnutrition and which is not routinely added to PN solutions in chronic IF.

To make matters more complicated, combined metabolic acidosis and metabolic alkalosis can occur simultaneously [15]. For example, excessive bicarbonate losses from a jejunostomy lead to metabolic acidosis but the combination of gut potassium losses and hyperaldosteronism due to the vascular contraction lead to metabolic alkalosis. The interpretation of such complex metabolic situations [15] is beyond the scope of this chapter but use of the "delta gap" [21] can help explain the presence of mixed ABD.

One of the principle mechanisms for controlling acid-base equilibrium is the buffering system of blood and extra cellular fluid. The major extracellular buffer is serum albumin. In low albumin states, during the early phase of treatment of IF, or during intercurrent illness, interpretation of SAG requires adjustment for the low albumin which may mask high SAG [22]. Such patients are also more likely to be susceptible to acidosis induced by endogenous or extraneous sources of acid or bicarbonate loss.

Table 1 Non anion gap acidosis; hyperchloraemic metabolic acidosis

Cause	Mechanism	Comments
Diarrhoea	Loss of bicarbonate and Na^+	Worse with gastroenteritis
Stomal losses	Loss of bicarbonate	Net secretors most at risk
Urinary diversion	Ileocolonic exchange of chloride for bicarbonate	More likely with colonic diversion and continent pouch than ileal conduit
Oral rehydration solutions	High chloride content. Lack of bicarbonate or citrate.	Bicarbonate or citrate based ORS may prevent acidosis
Normal saline and sodium chloride in PN solutions	Causes greater changes in ECF chloride than Na^+. Cl^- is not a buffer	Most common iatrogenic cause of Metabolic acidosis in critical care
PN/HPN	Amino acids and acid pH for stability. NaCl content	Acetate preferable to HCl and NaCl
PPI/achlorhydria/gastric resection/vagotomy	Loss of H^+ secretion into gut	PPI used to suppress fluid losses in SB
Phosphate deficiency	Reduced H^+ elimination from tubules with chloride retention	Phosphate is a major factor in renal H^+ excretion
Refeeding syndrome	Hypophosphataemia	May occur after intercurrent illness

Table 2 High anion gap metabolic acidosis

Cause	Mechanism	Comment
Renal impairment/failure	Retention of acidic ions, sulphate, chloride	Respiratory compensation may be inadequate.
L-lactic acidosis	Sepsis	Worse in liver disease, thiamine deficiency
Ketosis	Diabetic or starvation	Associated with renal acidosis due to dehydration
D-lactic acidosis	Colonic fermentation. Poor metabolic capacity for D-lactate	Colon continuity required but possible in dysmotility syndromes due to small bowel bacterial overgrowth
Vitamin B1 deficiency	L-lactate accumulation	Worse if hepatic dysfunction
Drugs	Ethanol, methanol, salicylates	Rare in IF

Acid-Base Disturbances in Intestinal Failure

ABD, particularly metabolic acidosis, has long been recognised as a complication of PN and saline infusion in hospital and critical care units [10]. The now obsolete practice of hyperalimentation led not only to uraemia and dehydration but to metabolic and respiratory acidosis [23, 24]. There is little to be found in the literature on ABD during long term management of IF with HPN [7]. In the context of IF with or without PN, respiratory alkalosis is the only ABD not to be represented, except as part of the acute compensatory response to metabolic acidosis or sepsis. Metabolic acidosis and alkalosis, and respiratory alkalosis occur frequently enough for every clinician involved in managing IF/HPN to be fully aware of how to avoid, detect and treat such problems [7]. No one patient with IF is the same as another in view of the wide variation in underlying causation, complications and anatomical impact of loss of intestinal length or function, together with concomitant renal or respiratory impairment. Intercurrent illness leading to sudden loss of circulating volume, dehydration, sepsis, respiratory or renal failure can lead to rapid deterioration with acute acidosis or even alkalosis. IF patients are at particular risk of being unable to respond to metabolic stresses caused by acute illness such as gastroenteritis [7] as the compensatory processes are already under duress before the addition of further stress.

Metabolic Acidosis in IF

Historically, metabolic acidosis was a well recognised cause of acidosis and confusion in the early days of PN [25]. Fructose and ethanol were both used as main energy sources until superseded by glucose and lipid sources and interest in ABD seems to have waned. However, metabolic acidosis is still a significant complication of PN in IF patients [7, 26–28]. In the experience of one UK HPN centre with apparently stable Type 3 IF patients on HPN, normal anion gap acidosis is more common than positive anion gap acidosis due to D-lactic acidosis [7]. In the acutely ill IF patient, perhaps admitted with negative fluid balance due to excessive intestinal losses, L-lactic acidosis should be considered as the result of underlying sepsis, especially line related or intra-abdominal. Measurement of serum lactate and arterial blood gases should be part of the investigation of such patients who may have both hyperchloraemic acidosis and high anion gap acidosis. In IF patients with underlying renal impairment or diabetes mellitus, lactic acidosis or ketoacidosis with a high anion gap may be compounded by hyperchloraemic acidosis due to excessive bicarbonate losses and/or replacement therapy with normal saline. Arterial blood gases AND serum chloride and bicarbonate should be measured and resuscitation with solutions other than sodium chloride considered, including sodium bicarbonate [29]. In those with a SB but some colon in continuity, D-lactic acidosis should be considered if confusion, cerebellar signs and a high serum SAG are detected [14]. The high SAG is associ-

ated with low plasma pH although compensatory respiratory alkalosis may mask the low pH. A low bicarbonate and pCO_2 but normal chloride would be characteristic.

The commonest cause of metabolic acidosis in IF is hyperchloraemic acidosis with low bicarbonate and normal SAG [7] and elevated potassium [1]. Bicarbonate losses from the gut, failure of gastric acid secretion, sodium chloride infusion or PN are the most likely causes. High serum potassium levels accompany acidosis due to displacement of K^+ from cells and impaired renal function [1]. However, concomitant renal impairment due to excessive losses of fluid from the gut (high stoma/diarrhoea) may lead to a combination of hyperchloraemic acidosis and high SAG acidosis due to retention of anions usually excreted via the kidneys (L-lactate, sulphate, phosphate, ketones) [8, 30].

Since both negative fluid balance and sepsis are common in patients with a SB and replacement fluids most usually include "normal saline", the above scenario is common.

Oral Treatments in IF

Patients with <1200 ml stomal losses/day can usually maintain sodium balance by adding salt (sodium chloride - NaCl) to their food at the table [11]. With increased stomal losses of 1200–2000 ml, salt capsules (NaCl) or glucose—saline solutions may permit sodium balance to be maintained except when ambient temperatures are high. Many require an oral rehydration solution (ORS) of which the commonest in use is based on the World Health Organisation (WHO) cholera solution without the potassium chloride. This contains NaCl 60 mmol/L $NaHCO_3$ (or citrate) 30 mmol/L and glucose 110 mmol/L. This reflects the high concentration of sodium lost from jejunostomies. Sodium losses from short jejunostomies average 88 mmol/l but rise with longer residual jejunum and terminal ileal stoma sodium losses rise to 140 mmol/L [11]. Colostomy losses can be closer to plasma levels but the lower volumes lost mean that this is less of a problem. In the human jejunum, sodium balance breaks even at 90 mmol/L [31, 32] but solutions containing much higher concentrations of NaCl (136 mmol/L) have been used [33]. Use of high sodium chloride concentrations in ORS may therefore exacerbate metabolic acidosis [8, 12, 13] especially if a solution without bicarbonate or citrate is used (NaCl 120 mmol, glucose 44 mmol/L) [34].

The potential for acidosis or alkalosis to occur in patients receiving ORS [12, 13] may be exacerbated by the high chloride, low bicarbonate content (acidosis) or absent potassium (alkalosis). Oral sodium bicarbonate or citrate based solutions can be used to treat hyperchloraemic metabolic acidosis [35]. Again, this emphasises that monitoring for ABD should be conducted in such IF patients.

Enteral Feeds

There is no data on the occurrence of ABD in patients with borderline SB who can be managed using oral supplements or enteral feeds. However, it should be noted that some enteral feeds are themselves acidic, particularly peptide based feeds. Since the degree of intestinal failure and the intensity of treatment are only moderate in the absence of parenteral nutrition, serious episodes of ABD are unlikely but sub clinical ABD may be present nevertheless.

However, when oral measures fail to maintain fluid and sodium balance, intravenous 0.9% saline 1–2 L/day is often used [11], perhaps supplemented with magnesium [11] or potassium. Such patients are at risk of saline induced acidosis.

Metabolic Acidosis Caused by Infusion Fluids

Parenteral nutrition solutions must be titrated to a pH at which the constituents can remain stable under conditions of storage and usage. This is typically 5–5.5 but pH as low as 4.36 has been used [9]. Thus the interaction between amino acids and glucose (the Maillard reaction) and the stability of calcium salts and lipids depends on an acid pH achieved by use of hydrochloric acid (non metabolisable) or acetate (metabolisable), both of which are added to PN bags during their preparation [9, 27]. Evidence suggests that titratable acidity due to non-metabolisable acid (hydrochloric acid) rather than metabolisable acid (acetate) is the principal cause of acidosis associated with PN infusions [9, 36]. When IF patients already have a tendency to metabolic acidosis due to bicarbonate losses, infusion of hydrions with chloride may precipitate acute or chronic acidosis, particularly if renal impairment is present. Metabolism of acetate involves consumption of hydrions hence the improvement seen in acidosis when this acid is used to acidify PN solutions [28].

PN solutions are also formulated with sodium chloride in sufficient quantities to prevent dehydration and sodium depletion in those unable to maintain hydration due to a SB. Once infused, sodium chloride also induces metabolic acidosis although it is not itself acidic, nor does it contribute to the acid pH of PN solutions [10].

Lessons from critical care and surgery provide a background for changes in the management of IF patients requiring fluid resuscitation. Normal saline solutions have been implicated in metabolic acidosis during treatment of critically ill patients with a variety of diagnoses [29, 37] and by inference, also contribute to the acidosis seen in IF patients on PN or during resuscitation when hypovolaemic. More importantly, saline has been shown to increase mortality in critical care whereas use of balanced salt solutions improved both metabolic acidosis [38] and mortality [39]. Chloride based crystalloids may not be the most appropriate solutions for rehydration, especially when other causes of metabolic

acidosis such as stomal bicarbonate loss or renal impairment are present [29, 40].

Since NaCl solutions are neutral, it is important to understand why NaCl causes or exacerbates acidosis. The *concentration* of Na Cl in solution is not the reason—any concentration may precipitate acidosis because it is the *imbalance between ECF concentrations of* Cl^- *and* Na^+ which provokes acidosis. Unlike bicarbonate, chloride does not act as a buffer. The equimolar concentrations of Na^+ and Cl^- in infusion solutions lead to further imbalances between Na^+ and Cl^- in the blood and ECF as a whole. Thus so called normal saline 0.9% contains 154 mmol/l of Na^+ and Cl^-. Blood and ECF contain Na^+ at 140 mmol/and Cl^- at 100–110 mmol/l. Although the concentration of Na^+ and Cl^- both exceed the ECF concentrations and therefore increase the concentrations of Na^+ and Cl^- they do so to different degrees. Chloride pairs with H^+ to form hydrochloric acid, and sodium pairs with OH^- and HCO_3^- to form base but less so as the increment in sodium is less than for chloride.

When sodium chloride is present in more dilute solutions as in PN, it is again the influence of the imbalance between ECF Na^+ and Cl^- which determines the final balance between Na^+ and Cl^- which still contributes towards acidosis but less so than with normal saline. It follows that the greater the concentration of saline added to PN solutions, the greater effect on acidosis. In those who need large quantities of sodium to replace gut losses which usually include bicarbonate, use of chloride exacerbates the tendency to acidosis. Hence the use of sodium acetate to replace not only HCl but sodium chloride in PN solutions [28]. This permits a reduction in chloride infusion and each acetate molecule consumes one H^+ during its metabolism in vivo [26]. Use of acetate therefore achieves 2 aims—the reduction in chloride infusion and a reduction in the non-metabolisable acid load of the PN solution required for stability purposes as described earlier. The burden on buffering capacity and renal or respiratory compensation on infusion of PN can therefore be offset by use of acetate. It has been suggested that when renal impairment is present chloride based PN solutions should be avoided [28].

This strategy has been shown to improve measures of acid-base balance in a retrospective study [28] and a prospective randomised controlled study [9].

The use of acetate does not come without some adverse consequences. Acetate has been shown to inhibit osteoblast activity [41] thus offsetting some of the benefits of avoiding acidosis although acidosis itself also inhibits osteoblasts and enhances osteoclast activity.

The amino acid content of PN solutions may also contribute to acidosis as a result of sulphur containing amino acids such as methionine and cysteine, and cationic amino acids such as arginine, lysine and histidine, metabolism of which may contribute to ABD. Sulphates are excreted by the renal tubules in exchange for chloride and oxidation of cationic amino acids generates hydrions thus contributing to hyperchloraemic acidosis [8].

Loss of Gastric Acid Production: Effect on Acidosis

The integrated acid-base functions of the gut depend on production of acid and bicarbonate as already discussed. If acid is not produced, bicarbonate is not generated in the gastric mucosa to balance the acid produced during secretion of bicarbonate from liver and pancreas. If bicarbonate losses occur due to SB from a high stoma, acidosis may occur even if gastric acid production is normal but if gastric acid production fails for any reason, acidosis is promoted further. In the presence of achlorhydria (due to gastritis or pernicious anaemia), gastric surgery (complete or partial gastrectomy, vagotomy) or drug inhibition of gastric secretions (H_2 receptor antagonists, PPI or somatostatin analogues), acidosis is likely to occur if bicarbonate losses are high. If renal compensation fails, acidosis is inevitable. Omeprazole has been used clinically to correct metabolic alkalosis [42]. There is anecdotal evidence that PPI induce metabolic acidosis in SB/IF and that withdrawal of the drug leads to correction of metabolic acidosis [7]. Since PPIs are used to reduce stomal fluid losses in IF [11, 43], and since those losses themselves predispose to acidosis, any patient on a PPI should have appropriate monitoring to detect onset of acidosis.

Urinary Diversion to Colon or Ileum

Urinary diversion to the ileum or colon can both lead to metabolic acidosis which is more common in those with uretero-colonic diversions (50% or more) than with uretero-ileal (2–20%) [44]. The tendency to acidosis does not prevent the occurrence of alkalosis from other causes [7]. Deficiencies of potassium and magnesium leading to alkalosis may also occur. The impact on bone metabolism has also been highlighted, partly as a result of the sub clinical acidosis which routinely accompanies urinary diversion [44]. This appears to decline over time [45].

The colonic exchange of chloride for bicarbonate and slower transit explain the occurrence of acidosis with urinary diversion to the colon. Clinical presentation may be influenced by hyperammonaemic encephalopathy [46, 47]. If acidosis occurs with an ileal conduit, stenosis or obstruction of the conduit should be considered [48].

Thiamine Deficiency

Acidosis caused by thiamine deficiency is a well recognised feature of alcoholics presenting with withdrawal symptoms and Wernicke–Korsakoff syndrome. High anion gap acidosis requiring thiamine treatment has also been described during parenteral nutrition [49]. Thiamine is essential to the correct functioning of the Krebs cycle and metabolism of lactic acid to pyruvate and alpha keto butyrate which then enter the Krebs cycle. L-lactic acid accumulates in the absence of this vitamin cofactor, particularly in septic and critically ill patients [50]. Malnourished patients including those with IF are at risk of this complication if thiamine is not included in their nutritional regime. The practice of feeding patients with incomplete "off the shelf" nutritional regimes, particularly PN can precipitate acute metabolic acidosis and should be discouraged. Indeed the metabolic consequences of providing an incomplete regime containing no vitamins, trace elements, phosphate or potassium can be a catastrophic form of refeeding syndrome. PN should never be administered in such form and the use of PN solutions as an emergency out of hours by inexperienced clinicians should be avoided. Thiamine deficiency has also been shown to precipitate L-lactic acidosis even in the absence of liver dysfunction in ICU patients [50]. Many IF patients have liver disease consequent upon the long-term use of PN and a SB. Although less frequent now, especially in children with the introduction of newer lipid sources and prevention of line sepsis, liver disease is not uncommon in IF so avoidance of L-lactic acidosis is important. Thiamine deficiency may also precipitate D-lactic acidosis as discussed below [50].

Hypophosphataemia

Failure to provide adequate phosphate in PN solutions to the malnourished (for example–anorexia nervosa) or acutely sick IF patient can precipitate metabolic acidosis, acute psychiatric disturbances and muscle dysfunction [8]. Phosphate is required as part of the renal elimination of hydrogen ions together with the bicarbonate and ammonia systems. Renal tubular excretion of H^+ is impaired in phosphate deficiency and therefore predisposes to acidosis. At tissue level, phosphate deficiency impairs oxygen release and leads to lactic acid accumulation [8]. These problems are most commonly found in the refeeding syndrome and when incomplete PN solutions are used "off the shelf".

D-lactic Acidosis

This is a rare but serious complication of SB with colon in line, occurring in <5% [6] but more commonly in jejuno–ileal bypass for obesity. It is possible that dysmotility syndromes may also be complicated by D-lactic acidosis from small bowel bacterial overgrowth [51, 52]. It may be acute, subacute or recurrent. It is characterised by confusion, ataxia, slurred speech, ophthalmoplegia, nystagmus and behavioural disturbances such as aggression. In severe cases, stupor may progress to coma. The exact pathophysiology is unclear. Messing [6] states that only a few mmols of D-lactate are required to cause cerebellar signs and pseudo-ebriety or drunkenness. However, D-lactate levels do not correlate with symptoms and administration of D-lactate to the levels seen in D-lactic acidosis or above does not cause symptoms [53, 54]. To further confuse the picture, the syndrome can occur in the absence of acidosis [6] and could be due to other products of colonic metabolism such as mercaptans, aldehydes, amines and alcohols acting as false neurotransmitters [55]. It was thought that no enzyme capable of metabolizing D-lactate existed in humans but it is now known that humans do have an enzyme capable of metabolising D-lactate to pyruvate (D-2-hydroxy acid dehydrogenase) in liver and kidney [56] and that most D-lactate is excreted via the kidneys. The enzyme is inhibited by low blood pH. Similarly, in the gut, a low pH favours greater D-lactate production.

Diagnosis requires low pH, hypocapnia, an increased serum anion gap with low bicarbonate, elevated D-lactate and normal L-lactate [56].

Symptoms appear after ingestion of carbohydrate loads including those in enteral tube feeds, particularly monosaccharides or disaccharides including sucrose and lactose. Pickles, yoghourt, sour milk, tomatoes, apples, beer and wine should be avoided as they contain D-lactate. Colonic bacteria are required to metabolise these sugars to produce the syndrome [54].

B1 deficiency may also provoke D-lactic acidosis [51] as may broad spectrum antibiotics [57]. Changes to colonic flora with a reduction in gram-negative anaerobes and an increase in gram-positive anaerobes, especially Lactobacillus, Eubacterium and Bifidobacterium [58] lead to an increase in D-lactate [59].

Treatment Options in D-lactic Acidosis

Initial: Rehydrate and give IV bicarbonate with nil by mouth for 24 h. Haemodialysis has been used in serious cases.

Prevention of future attacks: include nil by mouth with introduction of enteral diet under supervision avoiding mono and oligo saccharides and rapidly digestible glucose polymers in favour of slow digesting complex starches [56, 60]. Since medium chain triglycerides may also provoke D-lactic acidosis they should be omitted from the oral intake [61].

Antibiotics such as metronidazole, neomycin or vancomycin may improve symptoms presumably by suppressing colonic flora but rifaxamin has proved most effective [14, 56].

Recently, faecal transplant has been used to treat D-Lactic acidosis successfully [62, 63].

Probiotics containing B Breve (Yakult®) or L Casei (Shirota®) producing L-lactate not D-lactate may help reset the microbiome after a course of antibiotics but care should be taken when choosing a probiotic containing lactobacillus as some may precipitate D-lactic acidosis [64].

The role of oral rehydration solutions containing bicarbonate to prevent recurrence by raising intestinal pH or moderating the systemic acidosis is unclear.

Metabolic Alkalosis: Table 3

This is typically associated with potassium deficiency and hypochloraemia, often compounded by magnesium deficiency, especially if intestinal losses are great as in net secretors. Hyperaldosteronism, as in chronically underfilled patients, leads to increased renal potassium wastage and also causes increased colonic potassium excretion [65]. Without replenishment of magnesium, potassium levels will remain low with consequent muscle weakness, cardiac arrhythmias and ileus, the latter compounding potassium and acid losses through vomiting. Metabolic alkalosis should be regarded as a surrogate for total body deficiency of potassium, hence the importance of monitoring bicarbonate levels as well as potassium. Mortality associated with severe alkalosis is high [65].

The main causes of metabolic alkalosis are:

- Vomiting or drainage of gastric contents (by NGT or drainage PEG) leading to loss of HCL. This scenario may occur in patients on palliative PN for small bowel obstruction due to cancer if palliative gastric drainage is utilised. IF due to dysmotility of the gut leads to recurrent vomiting of either gastric or small bowel contents or both. If gastroparesis predominates, metabolic alkalosis may occur due to loss of gastric acid and increased aldosterone activity leading to a low serum potassium. Cimetidine has been used successfully to treat severe metabolic alkalosis in gastric hypersecretion in patients with a SB [66]. Omeprazole may be protective [42].

Table 3 Metabolic alkalosis

Cause	Mechanism	Comment
Loss of K+	Diarrhoea, vomiting, stomal losses, diuretics	May be resistant if low magnesium too
Loss of Mg++	Stomal losses; Vit D deficiency	May require vitamin D to replete stores
ORS solutions	Potassium free ORS	Taste and compliance a problem
Contraction alkalosis	Hyper aldosteronism. renal and intestinal chloride loss	Now called chloride depletion alkalosis
Refeeding syndrome	Hypokalaemia	May be masked by acidosis

- Vomiting of small bowel contents leading to losses of potassium and sodium with secondary hyperaldosteronism and further potassium losses from the kidneys and gut. Spironolactone may have a role as an aldosterone antagonist in severe cases [65].
- Activation of the renin—angiotensin—aldosterone system by reduction in plasma volume/dehydration leading to loss of potassium from kidneys and gut—so called constriction alkalosis (see below).
- Hypokalaemia leads to alkalosis as hydrogen ions enter cells to replace lost potassium, leaving bicarbonate in the ECF. Any cause of hypokalaemia may lead to alkalosis including use of loop and thiazide diuretics leading to tubular losses of potassium and magnesium. These diuretics also promote alkalosis through renal chloride excretion [65]
- Loss of sodium chloride in sweat as in cystic fibrotics or hot climates leading to contraction alkalosis.
- Magnesium losses occur in stomal effluent in SB independent of the length of residual small bowel, together with potassium losses. Aldosterone increases both potassium and magnesium losses from the kidneys. Since magnesium deficiency inhibits Na^+/K^+/ATPase leading to K^+ loss from cells and excretion via the kidneys, potassium deficiency is resistant to repletion until magnesium stores have been repleted [16] but this can only be achieved if underfilling due to dehydration and sodium depletion are corrected first, thereby removing the influence of aldosterone. Magnesium deficiency quickly leads to a 25% reduction in total body stores of potassium [67]. Potassium deficiency cannot be remedied without repletion of magnesium stores [16] which are best assessed using 24 h urinary excretion studies. Care should be taken to monitor magnesium levels during octreotide therapy. Magnesium repletion may require oral 1 alpha-hydroxycholecalciferol treatment [68].
- Inadequate replacement of potassium, often due to misleading serum K^+ levels, is exacerbated by infusion of glucose (as in refeeding syndrome) and more so if insulin is given too. As cells return to an anabolic phase, K^+ requirements increase so adequate replacement is essential if metabolic alkalosis is to be avoided.
- Contraction alkalosis or chloride depletion alkalosis?
- This term reflects the contraction of the vascular compartment caused by fluid losses insufficient to reduce glomerular filtration but adequate to stimulate the renin—angiotensin—aldosterone secretion system. Renal tubular exchange of potassium for sodium leads to potassium deficiency and alkalosis. Aldosterone also has a role in sodium and potassium exchange in the small bowel and colon, promoting alkalosis. Chronically fluid depleted patients can thereby develop metabolic alkalosis. This can even be enough to overwhelm the tendency to metabolic

acidosis associated with ureteric diversion in our experience [7].

However, more recent publications have challenged the concept of contraction alkalosis [65, 69] emphasising the role of chloride repletion in hypochloraemic alkalosis but this is beyond the scope of this article.

Respiratory Acidosis

It has long been recognised that infusions of glucose lead to an increase in CO_2 production with concomitant increases in respiratory excretion. If respiratory function is normal, this does not present a problem and CO_2 is exhaled sufficiently. When respiratory reserve is impaired due to pulmonary infection, trauma or underlying disease, CO_2 can accumulate to cause respiratory acidosis [23, 24, 70]. If other causes of metabolic acidosis are present, infusion of glucose may impose a rise in total body CO_2 which contributes to an overall fall in pH due to a combination of metabolic acidosis and respiratory acidosis, leaving the kidneys as the sole means of readjusting pH. Since the use of glucose is essential in PN solutions, it follows that avoidance of metabolic causes of acidosis are essential if compensatory mechanisms are not to be overwhelmed, particularly because many causes of metabolic acidosis impact upon renal function (loss of intestinal fluid, vomiting, sepsis).

Respiratory Alkalosis

This is never chronic in IF but can occur acutely as part of the response to sepsis or haemorrhage. Hyperventilation together with confusion and a low pCO_2 should alert the clinician to the possibility of line sepsis or intraabdominal causes.

Drug Therapy During IF

Potassium sparing diuretics have been implicated in precipitating metabolic hyperchloraemic acidosis during PN [71] by opposing renal aldosterone response and impairing tubular function. Intracellular transfer of potassium leads to loss of intracellular hydrions to the ECF [71]. The carbonic anhydrase inhibitor, acetazolamide, has been used to treat alkalosis and may cause acidosis by inducing renal bicarbonate secretion [72].

The role of acid suppressing agents has already been discussed above.

Octreotide and other somatostatin analogues may in theory affect ABB by influencing gastric or pancreatic secretions and there a few reports of metabolic acidosis in patients on octreotide [73] with pancreatic fistula but no evidence that octreotide is either causal or therapeutic.

Cholestyramine used to treat bile acid related diarrhoea in patients with resected ileum has also caused metabolic hyperchloraemic acidosis [74].

Consequences of ABD

These may be life threatening or lead to chronic morbidity.

Metabolic Acidosis

Short term metabolic acidosis due to lactic acidosis is better understood than hyperchloraemic non gap acidosis or chronic metabolic acidosis. Metabolic acidosis impacts upon cardiac function with hyperventilation, arrhythmias, vasodilatation, and hypotension and may also increase inflammation and impair immune responses [75]. Hyperkalaemia is common and potentially fatal [1]. Some studies have shown that high anion gap acidosis adversely affects mortality whereas non gap acidosis does not [10]. Other studies have shown increased mortality with non-gap hyperchloraemic acidosis [10, 37, 38]. Many studies have shown increased mortality with the use of normal saline as a resuscitative fluid compared to solutions with lower chloride content [10, 37, 38] and others have shown improved acid-base parameters with alternatives to 0.9% saline solutions [29].

It should be clear that prevention of metabolic acidosis is of paramount importance and that modification of PN, intravenous and oral rehydration solutions offers the best opportunity to do so. The treatment of acute severe acidosis is beyond the remit of this chapter.

Acidosis and Metabolic Bone Disease

In the context of chronic IF on HPN, the long term effect of acidosis on bone metabolism cannot be ignored. The impact of chronic metabolic acidosis on bone metabolism and the benefits to muscles, bones and growth with treatment of acidosis have long been recognised in renal failure [76–78]. Acidosis increases bone resorption by increasing osteoclast and decreasing osteoblast activity [79, 80]. Acidosis also impairs renal vitamin D activation. Mobilisation of bone calcium leads to nephrocalcinosis and nephrolithiasis.

Although acidosis has not featured strongly in texts or guidelines until recently, the importance of treating acidosis to prevent metabolic bone disease in IF during HPN has been highlighted [13, 41].

Metabolic acidosis is considered to be an important contributor to metabolic bone disease in chronic renal failure. Improvements in bone metabolism follow treatment of acidosis [81]. Impaired bone metabolism has also been documented in D-lactic acidosis [82], treatment of which improves bone metabolism. Subclinical acidosis is most likely to contribute to long term bone disease, hence the importance of monitoring acid-base balance and preventing acidosis by incorporating acetate in PN formulations. Pironi [41] advises 160 mmol/day of acetate to avoid acidosis and maintain bicarbonate within normal range.

Metabolic Alkalosis

Clinical features are those of hypokalaemia, low magnesium and the decrease in ionised calcium caused by alkalosis itself. With increasing pH, ionised calcium increasingly binds to albumen leading to further falls in ionised calcium and tetany. Convulsions, muscular irritability and cramps or tetany, paraesthesia, psychosis and coma may occur. Cardiac arrhythmias, gastroparesis or paralytic Ileus reflect hypokalaemia. Mortality is high in severe cases [65].

Alkalosis may also affect bone metabolism when associated with low magnesium stores which reduce parathormone secretion and renal activation of vitamin D [83].

Incidence of ABD

Little has been published on ABD in IF on HPN. This author's group described their experience in a small UK referral centre for Type 3 IF and HPN [7]. Of 39 patients, there were 11 episodes of ABD in 10 patients (25%). In 5/11 episodes, the presentation was after many years on HPN with severe ABD and renal impairment as a prominent feature. The remaining 6 episodes were subclinical detected on routine screening and only 1 of these had renal impairment.

Symptomatic hyperchloraemic acidosis (e.g. lethargy, rapid breathing, confusion) was present in 3/5 severe presentations. Jejunostomy was present in 2 and jejunocolonic anastomosis in one. All had impaired renal function, 2 were on a PPI and all were taking modified WHO oral rehydration solutions without potassium. Withdrawal of PPI in one case led to improvement in the acidosis. None had D-lactic acidosis. Interestingly, 2 had a raised anion gap but both had elevated serum creatinine. Smoking related chronic obstructive airways disease was present in one case with Crohn's disease.

There were 2 severe symptomatic metabolic alkaloses, one of which had also suffered from severe metabolic acidosis which resolved on withdrawal of PPI and supplementary IV saline infusions at home. On this occasion, she suffered acute delusional psychosis. Both cases had hypochloraemia, hypokalaemia, hypomagnesaemia and elevated creatinine suggesting contraction alkalosis and hyperaldosteronism. Neither were taking a PPI. Both had high stomas but one had urinary diversion to an ileal conduit.

There were 6 cases of subclinical metabolic acidosis, none of which had a raised anion gap or detectable D-lactate. All were detected on implementation of routine monitoring of serum bicarbonate and chloride for ABD. The PN formulations were altered to include sodium acetate instead of sodium chloride and the incidence of metabolic acidosis declined. There was no colon in continuity in 6/9 acidotic patients. One case had a dysmotility syndrome due to scleroderma with the entire gastrointestinal tract intact.

Refeeding Syndrome Scenarios Leading to ABD

Instigating nutritional support in the malnourished or metabolically challenged patient without attention to providing adequate amounts of all essential nutrients can lead to a refeeding syndrome. Typically, provision of energy sources creates demands for other basic nutrients and exposes deficiency states if those nutrients are in short supply. This applies particularly to potassium, phosphate, thiamine, zinc and selenium. Acidosis may result if insufficient thiamine or phosphate are provided [8, 49–52] as in a case on HPN [84]. Stable HPN patients could be exposed to this risk after intercurrent illness such as line sepsis or surgery when the catabolic phase gives way to the anabolic recovery phase.

Vitamin B1 thiamine deficiency is well recognised, particularly in alcoholics with the onset of Wernicke–Korsakov syndrome. The associated acidosis may contribute to the overall malaise of this condition but if acidosis is detected in such patients, B1 deficiency should be suspected and treated urgently.

Phosphate deficiency is seen at its worst in anorexia nervosa. The contribution of acidosis is unclear but impaired oxygen release at tissue level due to 2,3-diphosphoglycerate deficiency and ATP in red blood cells probably explains the symptoms of confusion, seizures, muscle weakness, paraesthesia, hyperventilation and coma [8].

Cramps During PN Infusions

Muscle cramps occurring during HPN infusions represent the commonest side effect of HPN according to a multicentre report [85] from the UK. These cramps should be distinguished from the tetanic cramps associated with calcium or magnesium deficiencies which occur independent of PN infusions. The cause of PN related muscle cramps is unclear

but some theoretical possibilities can be entertained on the basis that PN solutions are acid (pH 4.4) and contain sodium at lower concentrations than in blood and extracellular fluid.

One particular observation stands out to direct investigation into this problem. It is generally agreed that reduction in flow rates of PN infusions either reduces the intensity and duration of cramps but may help avoid them altogether [86]. This would suggest that it is the rate of infusion of fluid and some constituent or property of that PN which causes the cramps. There is no clear evidence that quinine reduces the cramps although this treatment is often deployed.

The suggestion that some cases may prove to be due to sodium deficiency does not explain why symptoms occur during infusion of sodium. Similarly, one would expect cramps due to underlying calcium, magnesium or phosphate deficiencies to be corrected during infusion of PN solutions. Some other cause must explain these cramps. On the other hand, infusion of 3 l PN solution over 12 h may cause dilution of serum sodium or other electrolytes sufficient to trigger cramps. However, increasing the sodium content of HPN solutions does not improve the cramps in this author's experience.

Transport of ions across muscle cell membranes during glucose and amino acid infusions could create temporary ionic transmembrane gradients as in the refeeding syndrome but no evidence exists to support this theory.

The infusion of large volumes of PN solutions with an acid pH may alter acid—base balance sufficiently for polarisation of muscle membranes to be affected adversely, thus triggering cramps. To this theory may be added the dilutional effect of infusing solutions with sodium concentrations well below those of serum and extracellular fluid bathing nerve membranes. A sudden drop in sodium concentration coupled with a transient but rapid fall in pH of extracellular fluids could precipitate cramps. However, this theory requires further investigation. Meanwhile, reduction in flow rate of PN solutions is the most effective treatment, albeit at the expense of time online. Patients are willing to accept this trade off if they can avoid the extremely painful cramps associated with their PN in my experience. This is a subject requiring further investigation.

Guidelines and ABD

Until recent iterations of ASPEN and ESPEN guidelines, acid-base disturbances were not highlighted. However, the latest ASPEN recommendations and ESPEN guidelines now include clear advice on detection of ABD.

ASPEN Recommendations 2014

These recommendations state [87] that safe PN should start with a clear understanding of acid-base equilibrium and that monitoring the major electrolytes involved in nutritional metabolism and fluid homeostasis, blood glucose concentrations and acid-base balance is important. They state categorically that laboratory testing should include measures of acid-base balance.

ESPEN Guidelines 2016

Recommendation 19 [13] recommends regular monitoring of acid-base status in patients on long term HPN (serum chloride and bicarbonate) because both metabolic acidosis and alkalosis can occur. The guidance also states that chloride and bicarbonate levels should be monitored frequently until stable.

Renal Impairment in IF

Renal impairment in patients with intestinal failure is most commonly due to chronic dehydration in patients with a jejunostomy and due to oxalosis in patients with a jejunum in continuity with a functioning colon (chapter "Nephrolithiasis and Nephrocalcinosis"). In addition parenteral chloride may cause renal vasoconstriction so further impairing renal function [88].

Acute renal impairment due to hypovolaemia can often be treated with intravenous fluids but if a patient is allowed to be chronically dehydrated (often an insidious process) then permanent renal dysfunction will ensure. Persisting dehydration is a reason for starting or increasing parenteral support.

Patients with acute kidney injury secondary to a high output from a small bowel stoma may need dialysis (if acidotic or hyperkalaemic), however during dialysis fluid must not be removed, in fact they must continue to be rehydrated and ideally gain 1–4 kg in weight depending upon how dehydrated they are at the commencement of dialysis. If an already dehydrated patient is dialysed and fluid removed their kidney injury may become irreversible.

If a patient is prone to acute kidney injury due to dehydration then it is important to avoid or closely monitor them if they take a potassium containing rehydration solution (e.g. dioralyte®). While omeprazole and loperamide are relatively safe in patients with renal impairment the dose of codeine phosphate which has active renally excreted metabolites, must be reduced.

Gallstones in Intestinal Failure

Jeremy M.D. Nightingale and Mattias Soop

Key Points

1. Gallstones are more common in patients with intestinal failure (IF) 38% at 20 years of parenteral nutrition at home. They are also common in patients with a short bowel (21% over 10 years).
2. Most (76%) patients receiving home parenteral nutrition (PN) with gallstones develop complications.
3. Gallstone formation may relate to a high-calorie and/or lipid parenteral nutrition, a lack of oral intake, an ileal resection or disease, and certain medications (anticholinergics, opioids or octreotide).
4. Supersaturation of bile, nucleation, crystallization and reduced gall bladder contractility are the key factors that contribute to gallstone formation. In IF patients biliary stasis is most relevant and leads to gall bladder sludge and the formation of gallstones containing calcium bilirubinate.
5. Medical therapy is rarely used to prevent or dissolve gallstones in IF patients due to unpredictable absorption of medication and a lack of proven benefit.
6. Gallstones might be prevented changing the bile composition directly (e.g. ursodeoxycholic acid) or indirectly by increasing gut transit (e.g. cisapride) or changing the bowel flora (e.g. metronidazole).
7. Prevention could also be by maintaining regular gall bladder contraction with oral diet, cholecystokinin injections, rapid amino acid infusions, non-steroidal anti-inflammatory drugs (NSAID's) and avoiding octreotide.
8. Cholecystectomy is recommended if there are gallstones present and surgery is being performed for another reason.
9. Prophylactic cholecystectomy and/or sphincterotomy are not recommended if there are no gallstones.

Introduction

Gallstones (stones in the gallbladder or biliary ducts or both) are a major public health issue and are present in 10–15% of adults in the Western world and are overall more common in women [1]. Of those with gallstones (mainly cholesterol ones) about 25% will develop symptoms, in particular women [2]. Gallstones are of three main types: cholesterol stones, comprising about 75% of stones; pigment stones; and mixed. While pigment stones may predominate in patients with intestinal failure (IF), all types of stones can occur [3]. Gallstones may cause severe and life-endangering complications from cholecystitis (typically large stones >10 mm), biliary colic, obstructive jaundice (often multiple stones), pancreatitis (small stones), bowel obstruction (a large stone which passes from the gallbladder through a choledocho-duodenal fistula into the small bowel, where it may cause obstruction in the duodenum or terminal ileum) and rarely gallbladder cancer or a cholangiocarcinoma. Generally, gallstones greater than 1–1.5 cm and of a high number are most likely to cause symptoms.

(a) *Cholesterol gallstones* are composed of cholesterol, mucin, bile pigments, calcium salts and other compounds. The pathogenetic factors for cholesterol gallstones include a genetic background, female, older age, sedentary life style, high fat diet, lack of fibre, pregnancy (high number of childbirths), hormone replacement therapy. Insulin resistance, as occurs with obesity, metabolic syndrome and type 2 diabetes is a common aetiological component. A further contribution may be from factors within the gallbladder: hepatic hypersecretion of cholesterol, supersaturation of bile (precipitation of cholesterol

Fig. 1 Pigment type gallstone of 1 cm from a patient with a short bowel

crystals), a sluggish gallbladder, mucin and inflammatory changes in the gallbladder. Factors outside the gallbladder include slowing intestinal motility, increased intestinal absorption of cholesterol, and altered gut microbiota [4, 5].

In patients with IF (having PN or with a short bowel) however, the predominant type of gallstones found are pigment stones. Cholesterol may also play a part in gallstone formation in this group.

(b) Pigment gallstones (Fig. 1) are composed of calcium bilirubinate and are classically associated with haemolytic anaemia but do occur in other circumstances. In North India, where obesity is common, gallstones are primarily (>80%) cholesterol stones whereas in south India where most are vegetarian (less spices and fat) and non-obese, most (>60%) are pigment stones [1]. Liver disease (non-alcoholic fatty liver disease and cirrhosis) are also associated with pigment gallstones. Patients with cirrhosis have an incidence of 2–5% per year (most common if an alcoholic aetiology, a more severe cirrhosis and a longer duration of cirrhosis), which is four times that of the general population [5].

Epidemiology of Gallstones in Intestinal Failure

Gallstones are prevalent in patients with acute or chronic intestinal failure, and in chronic illnesses such as Crohn's disease, after intestinal resections and with the long-term use of parenteral nutrition (PN). Increased rates of cholelithiasis and cholecystitis have been shown also following trauma, burns, truncal vagotomy and pregnancy.

Inflammatory Bowel Disease

There is an increased prevalence of gallstones (25%) (detected by cholecystography and ultrasonography) in patients with Crohn's ileitis or ileo-colitis [6–9] and these occur with equal frequency in men and women [8, 10]. These stones often appear calcified on a plain abdominal radiograph [7]. Gallstones are more common in patients with ileitis than in those with ileo-colitis or colitis [11] and the likelihood may increase with the length of bowel resected [10], the duration of disease, previous surgery and the age of the patient [8, 12].

Patients with loss of functioning distal ileum due to disease or surgical excision have a disruption to the normal enterohepatic circulation of bile salts. It was estimated that the frequency of gallstones in patients with an ileal resection greater than 50 cm in length was 33%, compared to 17% in those who had undergone a lesser resection [10]. However, some studies suggest that the likelihood of gallstone formation is not related to the site of disease or resection but to the duration of disease and previous surgery [12].

Patients with ulcerative colitis (without operation) have on average a 7–14% prevalence of gallstones, marginally more than controls [9, 12, 13]. The risk of stones is higher after a panproctocolectomy and ileostomy formation [6, 14]. A large series of patients (180) who had an ileostomy following a panproctocolectomy showed gallstones in 24–25%, (three times the incidence that might have been expected in a population of this age and sex distribution), it was higher if more than 10 cm terminal ileum had been removed [15].

Short Bowel

Work at St Mark's Hospital showed that 17/27 (63%) men and 15/47 (32%) women with less than 200 cm small bowel remaining had either had a cholecystectomy or were found to have gall stones on an ultrasound examination. This study included subjects who were nutritionally autonomous and subjects who required parenteral nutrition (PN). There was no difference between those with a colon in continuity (15 (44%)) and those with a jejunostomy (17 (43%)) [16]. Another study showed that 72 of 345 patients (21%) who had a total small bowel length less than 104 cm (19% had a jejunostomy) developed gallstones over a 10 year period. PN dependence (34% of patients) and a very short length of

remaining jejunum were independent risk factors. 39% developed symptoms (23/28 (82%) acute cholecystitis/cholangitis and 5/28 (18%) acute pancreatitis) [15].

Parenteral Nutrition

Anecdotal reports in the 1970s suggested that PN might be associated with an increased incidence of both acalculous cholecystitis and cholelithiasis [17]. There were also descriptions of massively dilated gallbladders in patients receiving PN [18]. Later studies confirmed the association between PN and gallstone formation. In one study of patients receiving PN for a minimum of 3 months, 23% developed gallbladder disease after commencement of PN [19]. There was a 40% incidence of gallbladder disease in this group receiving PN, which is significantly greater than that in Crohn's disease or ileal resection patients not receiving PN. The same researchers also found that the risk of development of gallstones whilst on PN was greater in patients of less than 30 years old and in patients whose ileal resection had been performed less than 15 years previously. Research on a population of children on PN showed that 43% of children on long-term PN (mean duration 20 months) developed gallstones [20].

Subsequent studies also showed that long-term parenteral nutrition in both adults and children is commonly associated with gallstones (40%) [19–25], which in patients with a short bowel are often symptomatic [24]. Acalculous cholecystitis may occur but is less common [17, 23]. Gallstones were more common in men than women in one study [22].

Patients receiving PN frequently develop sludge and may go on to develop gallstones [21]. Dray et al. prospectively followed adult patients with a gallbladder in situ receiving HPN and 45/119 (38%) developed gallstones and/or biliary sludge (14 sludge alone), the probability of developing them was 21% at 1 year and 39% at 2 years. Eight of the 45 developed biliary complications. It was estimated that the incidence of biliary complications was 5% at 1 year and 10% at 2 years. No or negligible oral intake was associated with the development of gallstones. There was no difference in incidence between the sexes in this study [26].

Appleton showed that 17/63 (27%) of patients with no previous gallstones developed them over a median of 11 years of HPN. The cumulative incidence was 21% at 10 years, 38% at 20 years and 47% at 30 years. No less than thirteen of the 17 (76%) had symptoms (4 biliary colic, 4 acute pancreatitis, 2 common bile duct (CBD) stones, 1 cholangitis, 1 empyema/abscess) and 10 of these required surgical or endoscopic interventions. Increased energy content and the provision of lipid were predictors for cholelithiasis [27]. The authors concluded that complications from gallstones were so common that en-passent cholecystectomy is warranted when gallstones are present; in other words, during abdominal surgery for other reasons, the gallbladder should be removed if safe [27].

Biliary Sludge in PN and Crohn's Disease

Biliary sludge formation is an important stage in gallstone development and is associated with PN. Messing et al. reported a progressive increase in the incidence of biliary sludge from 6% after 3 weeks of PN to 50% between 4 and 6 weeks, and reaching 100% in patients receiving intravenous nutritional therapy for more than 6 weeks [21]. Sludge appears to precede gallstone formation; gallstones were then noted in six of 14 patients who developed sludge, while none of the patients without sludge developed gallstones. Interestingly, five of seven patients who earlier had sludge or gallstones were found to be free of both after a short period of oral refeeding [21].

There are considerably less data available on the prevalence of sludge in Crohn's disease itself without the concomitant use of PN but reduced gallbladder contractility, which predisposes to biliary sludge, has been demonstrated especially in those who have undergone ileal resection [28].

Biliary sludge also commonly develops rapidly in patients on an intensive care unit. Some of these patients had a previously recognized risk factor such as abdominal surgery or PN but neurosurgical procedures were also associated with sludge formation [29].

Pathogenesis of Gallstone Disease

Supersaturation of bile, nucleation and crystallisation, and reduced gall bladder contractility are the traditional factors that produce "lithogenic bile". In patients with IF the stones, while containing some cholesterol, are mainly of pigment type composed of calcium bilirubinate. The stones develop within biliary sludge, which has formed due to gallbladder stasis often due to a period of no or reduced oral intake. Biliary sludge contains calcium bilirubinate or unconjugated bilirubin, cholesterol monohydrate crystals and increased amounts of mucin glycoproteins [30]. Biliary sludge may disappear spontaneously but frequently evolves into gallstones [31]. Sludge may persist or recur in 50% of cases and gallstones may form in up to 14% of affected subjects over 3 years [25]. Calcium bilirubinate crystals, within biliary sludge, are more commonly found in men than women [32].

Supersaturation of Bile

While pigment stones are most common, cholesterol supersaturation is well researched and may occur and contribute to the genesis of gallstones [3]. Cholesterol is secreted into the bile canalicular lumina and subsequently taken up by biliary lipid vesicles with a cholesterol: phospholipid ratio of 0.34: 0.38, but the ratio is higher in lithogenic bile [33, 34]. Cholesterol, lecithin (the most abundant biliary phospholipid) and bile salts aggregate to produce mixed micelles and

vesicles in bile, in which the hydrophilic portions of these lipids are located peripherally with the hydrophobic portions orientated centrally in a hydrophobic domain, thus permitting lipid solubility in an aqueous environment [35]. Cholesterol solubility in bile has been defined using a triangular coordinate map comprising cholesterol, bile salts and phospholipids [36, 37]. Bile supersaturated with cholesterol may be a result of increased cholesterol secretion or decreased phospholipid or bile salt secretion. Cholesterol-rich vesicles play an important part in the formation of cholesterol crystals [38].

Nucleation and Crystallization

Bile contains both anti-nucleating and pronucleating factors, the balance of which is important in determining the likelihood of gallstone formation. Apolipoprotein A-1 and A-2, and a glycoprotein (120 kDa), all found in human bile, have been identified as anti-nucleating factors [39]. Pro-nucleating factors include both mucin glycoproteins [40] and non-mucin glycoproteins [41]. Mucin is thought to play a significant role in crystallization of cholesterol. The evidence for this comes from three main sources. First, mucin glycoproteins have been found in the matrix of cholesterol gallstones [42]. Second, mucin hypersecretion precedes crystallization of cholesterol in animal models [43] and probably humans [44]. Third, mucin has been shown to promote crystal nucleation in cholesterol supersaturated bile *in vitro*. Mucin may act as a nidus for crystal aggregation by entrapping cholesterol crystals or calcium bilirubin on non-glycosylated hydrophobic domains of the peptide chain of the mucin glycoprotein molecule [45].

In addition to mucin, several other non-mucin pronucleating factors have been identified *in vitro* such as amino peptidase N, a low-density lipoprotein particle, and haptoglobins.

Crystal growth in bile follows nucleation. Cholesterol monohydrate crystals are composed of bilayers of cholesterol bonded to a water layer. Rapid growth occurs as these crystals pack side-by-side in their long axis, resulting in plate-like monohydrate crystals. Cholesterol also precipitates in other forms such as helical, tubular and filamentous forms of non-hydrated cholesterol [46].

Gallbladder Contractility

As well as cholesterol supersaturation and mucin hypersecretion, reduced gallbladder contractility appears crucially important in cholelithiasis by allowing the cholesterol crystals entrapped in mucin to grow to a sufficient size to allow them to remain in the gallbladder. Early cholesterol crystals are likely to develop into macroscopic stones only if formed in the mucus layer adherent to the epithelium in gallbladders with reduced contractility.

It would appear that all three requirements—cholesterol/calcium bilirubinate supersaturation, increased nucleation rate mediated by mucin hypersecretion, and reduced gallbladder contractility—occurring simultaneously allow cholelithiasis to occur (the "triple defect of gallstone formation").

Pigment stones have been shown to be largely composed of calcium bilirubinate and other calcium salts. Less is known about the process of pigment stone formation than about cholesterol gallstones, but biliary stasis appears to play a major role. Unconjugated bilirubin concentration is higher in gallbladder bile in patients with pigment gallstones than in controls and it is likely that unconjugated bilirubin forms gallstones by precipitation in a similar fashion to that of cholesterol [47].

Biliary Sludge

Biliary sludge may be an important intermediate factor in the formation of gallstones [45]. Sludge was initially identified by ultrasonography as low amplitude echoes without acoustic shadowing which layered in the most dependent portion of the gallbladder [48] (Fig. 2). Biliary sludge is an amorphous precipitant of mucin glycoproteins, bile pigment granules (calcium bilirubinate), cholesterol crystals, small stones, protein and lipids. An ever-present constituent of biliary sludge in humans is calcium bilirubinate or unconjugated bilirubin. Cholesterol monohydrate crystals and a marked increase in the amount of mucin are found in biliary sludge [45]. They also noted that the cholesterol and phospholipid concentration in bile from sludge-forming patients was no different to that of normal controls and gallstone patients [45].

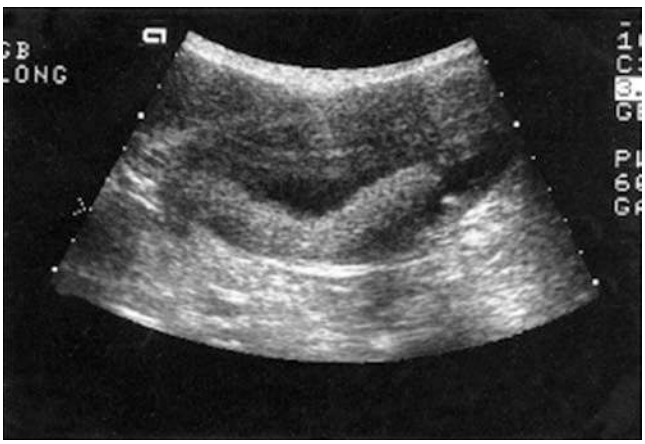

Fig. 2 Ultrasound image of the gallbladder in longitudinal section showing layering of sludge without acoustic shadowing (courtesy of Professor M. J. Lee, Radiology Department, Beaumont Hospital, Dublin 9)

Several possible factors leading to biliary sludge formation are cited in the literature including biliary stasis (due to no or little oral intake), use of total parenteral nutrition, mucin hypersecretion, bile infection and acute illness. A definite association between development of biliary sludge and gallbladder stasis has been noted especially in patients receiving total PN with no oral intake [24].

The exact mechanism of sludge formation has not yet been elucidated but one theory is that decreased gallbladder contractility leads to bile becoming progressively more concentrated due to water absorption and the cholesterol vesicular carriers becoming enriched in cholesterol content and depleted of lecithin and other phospholipids. Crystals of cholesterol are thus formed, and calcium salts (especially bilirubinate) precipitate secondary to stasis as well. Thus, sludge may form. Prolonged stasis and further growth may lead to the development of gallstones [49]. Biliary sludge may disappear spontaneously or have a fluctuating course but it frequently evolves into gallstones [50]. It would appear that sludge may persist or recur in at least 50% of cases and that gallstones may form in up to 14% of affected subjects over 3 years [51]. Biliary sludge always represents a pathological process and cholecystitis is common [52].

Intestinal Microbiota

Bile acids are cholesterol-derived molecules that can be modified by the gut microbiota and can act as signaling molecules to regulate metabolic and physiological processes. The gut microbiota releases many enzymes that can modify the bile acids such as bile salt hydrolases (7α-dehydroxylase, and hydroxysteroid dehydrogenase). These enzymes can change the gut microbiota composition, and thus alter the bile acids (more secondary bile acids) and so predispose to gallstone formation. A slower gut transit time also allows more secondary bile acids to be manufactured.

Pathogenesis of Gallstones in Intestinal Failure

Gallstones in IF patients may occur due to ileal disease/resection, fasting, PN, surgery, rapid weight loss or drug treatments (Fig. 3). Bacterial overgrowth may have a role.

Surgery, weight loss and parenteral nutrition may all involve prolonged fasting. The main drugs that are causative are anticholinergic agents, opioid analgesics or octreotide. Other factors may include poor cholecystokinin secretion and less physical activity.

Ileal Disease/Resection

While disruption of the enterohepatic circulation and consequent loss of bile salts should lead to an increase in cholesterol saturation (relates to concentrations of cholesterol, bile salts and phospholipids); this was the case in some studies of patients with "ileal dysfunction or resection" [53, 54] but not in others [53]. A reduced amount of deoxycholic acid and an increased amount of ursodeoxycholic acid are found in the bile of patients with ileal Crohn's disease [54, 55]. Bilirubin concentrations are two- to threefold higher in patients with ileal disease compared to those with no ileal disease [54, 55] while phosphatidylcholine levels are not different [54]. The majority of patients (children and adults) who undergo ileal resection and require long-term PN develop pigment gallstones [56]. Of note, some researchers have found normal or even low cholesterol saturation of bile after resection of ileum [55]. In patients with Crohn's disease gallbladder contractility is reduced after a fatty meal [31, 57], which may contribute to the formation of biliary stasis. The fasting gallbladder volume is decreased and fasting plasma cholecystokinin levels are surprisingly increased in patients with Crohn's disease of the large bowel and patients after an ileocecal resection) [58].

Much data suggests that ileal resection results in alteration of bilirubin rather than cholesterol metabolism so resulting in pigment gallstone formation (Table 1). Ileal resection

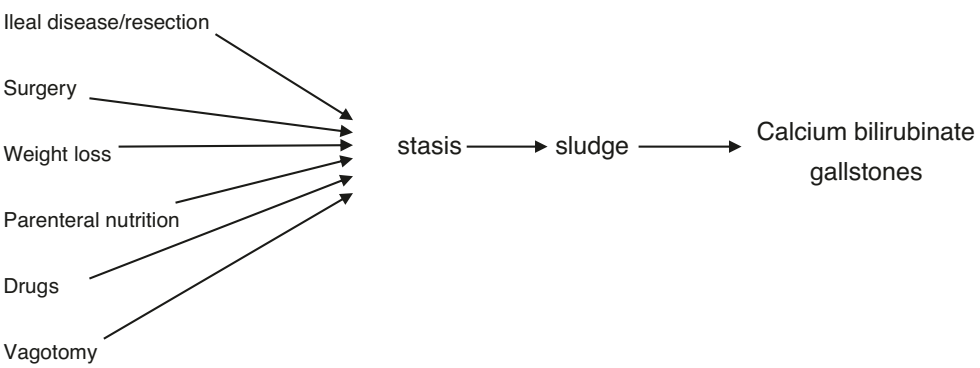

Fig. 3 Pathogenesis of gallstones in patients with intestinal failure

Table 1 Gallstones in Crohn's disease: disturbance of cholesterol or bilirubin metabolism?

Researchers	Year	Subjects	Main findings
Dowling RH, Bell GD, White J [53]	1972	Patients with Crohn's disease	Increased cholesterol saturation index
Dowling RH, Mack E, Small DM [59]	1971	Rhesus monkey's ileal resection	Cholesterol supersaturation Lithogenic bile model
Kelly TR, Klein RL, Woodford JW [60]	1972	Prairie dog's ileal resection	Increased cholesterol/ phospholipid ratio
Pitt HA, Lewinski MA, Muller EL, Porter-Fink V, Den Besten L [61]	1984	Prairie dog's Ileal resection	Pigment gallstones Increased bilirubin concentration in bile
Brink MA, Slors FM, Keulemans YCA, et al. [62]	1999	Patients with Crohn's disease or ileal resection	Increased bilirubin levels in bile, probably secondary to enhanced colonic uptake of bilirubin

in the prairie dog led to the development of pigment gallstones in 44% of animals compared to none in the control group [61]. Calcium bilirubinate crystals were found in up to 94% of animals who underwent ileal resection and in none of the control groups. It was noted that calcium and total bilirubin concentrations in bile were significantly greater in ileal-resected animals.

Data from patients with ileal resection receiving TPN have shown that there is a predisposition to development of pigment gallstones. Analysis of stones from adults and children who have had significant ileal resection necessitating long-term parenteral nutrition shows that pigment rather than cholesterol stones form in the majority of these patients [56].

Research in humans has shown that there is a three- to tenfold increase in bilirubin levels (unconjugated and conjugated) in gallbladder bile in patients with ileal disease and/or resection for Crohn's disease compared to patients with ulcerative colitis or Crohn's colitis [62]. Biliary bilirubin concentrations correlated positively with the anatomic length of resection and duration of ileal disease. This shows that there is an increase in the enterohepatic cycling of bilirubin secondary to enhanced uptake of bilirubin in the colon. This may explain the increased risk of pigment gallstone formation in patients with terminal ileal Crohn's disease and after an ileal resection.

There are several proposed mechanisms for reduced gallbladder contractility in Crohn's patients. Reduction in intestinal release of cholecystokinin or other peptides due to proximal small bowel disease may be a factor [63]. The number of argentaffin cells in colonic mucosa in patients with ulcerative colitis is reduced [64]. Reduction in levels of peptide YY concentration in the colonic mucosa of patients with ulcerative colitis and Crohn's disease has also been demonstrated [65]. Thus, changes in peptide secretion by small and large bowel may occur in Crohn's disease and may influence gallbladder contractility.

In contrast to the increased prevalence of gallstones in women compared to men in the general population, female sex does not seem to be a risk factor for gallstones in Crohn's disease [10]. In fact, some data suggest a higher prevalence of gallstones in men receiving PN compared to women [22]. Men with a short bowel with or without a retained colon have a much higher prevalence of gallstones than women [16].

A diagnosis of CD, intestinal surgery, prolonged NSAID use, disease activity and duration and bowel stenosis have been associated with cholecystonephrolithiasis in IBD [66].

Fasting and Parenteral Nutrition

Patients who have a reduced or absent oral intake (e.g. if having total PN) may experience long periods when food-stimulated intestinal hormone secretion (e.g. cholecystokinin) is not activated. Cholecystokinin secretion in response to a meal is significantly decreased in short bowel patients [67]. This may result in gallbladder stasis and the rapid formation of biliary sludge [21, 50, 68]. As reviewed above, the incidence of biliary sludge rapidly increases from 6% at three weeks of TPN to 50% between four and six weeks, and 100% after 6 weeks [21]. The sludge gradually disappears when oral refeeding is begun [21]. Gallstones will have started to become apparent by 4 months [21]. Bile is not supersaturated consequent on TPN [69], but bile flow is impaired [70] and gallbladder emptying during both continuous and cyclic infusions is reduced [71]. A medium/long chain triglyceride mixture in a PN regimen may be more likely to cause biliary sludge than one of long chain triglycerides alone [67]. In children on PN, cholelithiasis may be associated with a massively dilated gallbladder [18].

Bile flow is impaired when PN is given [70]. Current evidence suggests that bile is not supersaturated as a consequence of PN [69], but that prolonged stasis may be the key pathogenetic mechanism for increased cholelithiasis. The evidence for the dominant role of stasis in this scenario comes from several sources. Gallbladder contractility measured by ultrasound is reduced in patients receiving parenteral feeding [71]. The cholesterol saturation index in bile in prairie dogs receiving PN is not increased but gallbladder stasis is noted [72].

Improved radiological imaging has lent itself to the investigation of gallbladder disease. Radionuclide imaging of the gallbladder revealed biliary tract abnormalities in 92% of patients who received PN [73]. Ultrasonographic measurements of gallbladder motility during use of PN showed that, while maximal gallbladder volume was similar in PN patients and controls, gallbladder emptying was significantly reduced in parenterally fed patients during both continuous and cyclic infusion [71].

The mechanism underlying impaired gallbladder contractility in patients receiving PN is unclear. In one animal model using cholesterol-fed ground squirrels, agents which bypassed receptors and their subsequent interactions with calcium channels in the sarcolemma can restore gallbladder contractility in gallstone disease [74]. This suggested that bile saturated with cholesterol causes excessive integration of cholesterol into the sarcolemma, thus changing its functional characteristics. The primary smooth muscle defect in this animal model would appear to involve the sarcolemmal membrane, rather than the intracellular signal transduction pathways or contractile apparatus [73].

The finding of biliary sludge and potential for gallstone formation during PN has also been documented during fasting after surgery. Ultrasound studies have provided evidence of the relationship between prolonged periods of fasting and gallbladder sludge formation in patients who have undergone gastrointestinal surgery [68].

Is gallbladder Stasis Alone Sufficient to Cause Gallbladder Disease in Patients Receiving PN?

In untreated coeliac disease, the gallbladder enlarges, contractility after a fatty meal is reduced and biliary sludge may occur [75, 76]. Reduced gallbladder contractility in response to a fatty meal has been noted in coeliac disease. This defect appears to correlate well with decreased cholecystokinin secretion [77]. Furthermore, gallbladder emptying improves after successful treatment with a gluten-free diet [77]. However, no increase in the prevalence of cholelithiasis has been found in patients with coeliac disease despite impaired gallbladder contractility. Thus, factors other than gallbladder stasis may be important in the development of gallstones but the lack of enteric stimulation of bile flow and impaired gallbladder contractility secondary to the absence of significant oral intake may be the primary factors in biliary sludge and gallstone development during PN use.

Type of Feed

In adults those receiving parenteral lipid were at greatest risk of stones [27]. In children on PN there was a higher prevalence of sludge on pure soya lipid. Predictors for sludge in these children were young age at PN, lack of enteral feed, and a motility disorder with stoma [78].

Surgery

Major abdominal (not involving the biliary system) [79], cardiac valve replacement surgery [80] and a period in an intensive care therapy [29] all predispose to gallstone development with an equal sex incidence. This is again likely to be due to bowel rest causing biliary stasis, biliary sludge and the formation of gallstones.

Many factors appear to influence development of gallstones in patients with inflammatory bowel disease who undergo surgery, including gender, episodes of fasting, TPN and the type of surgery involved. Particular operations such as ileal resection, which interfere with the enterohepatic bile salt cycle, are more likely to lead to gallstone formation. Major abdominal surgery itself (not involving the biliary system) also appears to accelerate gallstone development in some patients. Indeed, in one retrospective study of gallstone formation after major abdominal surgery, surgery and age were the only statistically significant independent predictors of gallstone development during follow-up [79].

The possible mechanisms responsible for gallstone formation in patients who have undergone major abdominal surgery outside the biliary tract. Lee et al. found that sludge preceded gallstone formation in six of 14 sludge-forming patients receiving TPN [51]. Gallbladder stasis and bowel rest were felt to be important factors in sludge development. Patients on intensive care units (who undergo periods of fasting) are predisposed to sludge development.

Harrison et al. found that patients who underwent valve replacement surgery for rheumatic heart disease had a gallstone prevalence of 39% compared to 12% in a matched control population [80]. No difference in the degree of haemolysis between the two groups was detected; undermining the suggestion that excess haemolysis might be the cause of increased cholelithiasis in the surgical group.

This finding has important practical and financial implications, and identification of patients at risk for development of gallstones postoperatively might encourage the use of prophylactic measures such as earlier enteral feeding or administration of cholecystokinin.

Rapid Weight Loss

Cholesterol gallstones are common (40%) in morbidly obese patients and this figure increases with a diet causing rapid weight loss or after weight reducing surgery [81]. 38% of patients undergoing gastric by-pass surgery developed gallstones and a further 12% developed gallbladder sludge [82] and these formed during the time of maximal weight loss. Reduced gallbladder motility is likely to be the most important factor but cholesterol saturation also increases [82]. A significant increase in the gallbladder volume occurred in obese patients taking a low-energy, low-fat diet after 10 days [83], and could be secondary to minimal cholecystokinin secretion or to excess secretion of pancreatic polypeptide or somatostatin (gallbladder wall relaxants).

The proposed factors involved in gallstone formation during weight loss include impaired gallbladder motility and modifications in biliary nucleation. Twenty-one obese patients were placed on a low-calorie, low-fat diet for weight

reduction purposes [83]. A significant increase in the gallbladder volume after 10 days ingestion of this diet was noted, and was attributed to poor gallbladder contractility secondary to minimal stimulation of cholecystokinin secretion or to excess secretion of gallbladder wall relaxants such as pancreatic polypeptide or somatostatin [84, 85].

Drug Treatments

The use of narcotics [86] and anti-cholinergics [87] both of which reduce gallbladder contractility, in patients receiving PN has led to an increase in gallbladder disease. Narcotics, by reducing bile flow through the sphincter of Oddi, encourage gallbladder stasis, and anti-cholinergics have been shown to antagonize the protective effect of sphincterotomy on gallstone formation—both lending strong support to the idea of gallbladder stasis playing the most important role in gallstone formation. Loperamide inhibits gallbladder contraction in healthy subjects at daily doses of 16 mg [88] and inhibits pancreatic and biliary secretions in patients with a short bowel at 6 mg daily [89].

Octreotide, a long-acting somatostatin analogue often used in the treatment of a high output jejunostomy, increases the risk of cholelithiasis [87]. It reduces post-prandial gallbladder contractility [90] secondary (more lithogenic) bile acids are formed by intestinal bacteria [91] and it inhibits cholecystokinin secretion.

Cholecystectomy and Sphincterotomy

As several risk factors have been identified for cholelithiasis in patients with a short bowel, namely ileal resection (especially if fewer than 120 cm of intestinal remnant is left), resection of the ileo-colonic junction, long-term PN and the presence of Crohn's disease itself, a role for prophylactic cholecystectomy in patients with a short bowel has been suggested [92]. In patients with a short bowel, cholelithiasis is usually symptomatic, often complicated by inflammation or bile duct stones, and is associated with a significant morbidity and mortality postoperatively.

The cumulative incidence for cholecystectomy in patients with Crohn's disease after an ileal resection was 0.5% at 1 year, 2.4% at 5 years, 4.6% at 10 years, and 10.3% after 20 years with a higher rate in women, and higher than in the general population [93]. Prophylactic cholecystectomy should be considered when an abdominal procedure is being done in patients with IF and gallstones [27]. The rationale for performing such an en-passent cholecystectomy is the markedly increased incidence of complications to gallstones in IF (76% in one study) [27]. Cholecystectomy is not without problems; however, as a postoperative bile leak may interfere with the healing of any new intestinal anastomosis. Longer-term, it may shorten gut transit time (mainly by accelerating colonic transit) and so increase dependency on PN. These sequelae which may be due to a change in bile acid composition (more diarrheogenic secondary bile acids) develop early and persist for at least 4 years [94]. Furthermore, some data suggest that patients who have a short bowel and a cholecystectomy may be more prone to liver fibrosis/cirrhosis [95].

Medical Prevention and Dissolution Therapies

There are many therapies that may prevent cholesterol gallstones (Table 2). It is more difficult for pigment stones. The studies/reports suggest that cholesterol gallstones can be prevented by giving statins, ezetimibe, w3 polyunsaturated fatty acids, liraglutide and many herbal, complementary or alternative medicines [1]. Dietary factors that may prevent the development of cholesterol gallstones include a vegetarian diet, polyunsaturated or monounsaturated fat, fiber, and caffeine. In the past direct contact dissolution of cholesterol stones was done by infusing methyltertbutylether via a cannula into the biliary tree. Experimentally calcium bilirubinate stones can be dissolved in a mixture of glycerol octanoate and EDTA [96], but no practical method of dissolving them have been used in human clinical trials.

The role of medical treatments for gallstones has diminished, but may on occasions, be considered an alternative to cholecystectomy in those patients who are not suitable for surgery. The main medical treatment for gallstones, used alone or in combination with extracorporeal shockwave lithotripsy, is an oral bile salt (originally chenodeoxycholic acid then subsequently ursodeoxycholic acid).

Changing Bile Composition

Ursodeoxycholic Acid

Ursodeoxycholic acid (UDCA) and chenodeoxycholic acid may, in addition to being used to help cholestatic IFALD, have roles in both prevention and dissolution of gallstones in patients with intestinal failure. Chenodeoxycholic acid was

Table 2 Prevention of gallstones and biliary sludge

Cholecystectomy and/or sphincterotomy	
Change bile composition	
• Directly	Ursodeoxycholic acid
• Indirectly	
– Change intestinal microflora	Antibiotics (Metronidazole)
– Increase gut transit	Prokinetics (Cisapride)
Prevent biliary stasis (promote gallbladder emptying)	
• Enteral feed	
• Cholecystokinin	
• Rapid amino acid infusions	
• NSAID's	
• Avoid octreotide	

used first but due to a dose-dependent increase in aminotransferases, an increase in serum low-density lipoprotein cholesterol and the development of bile salt-induced diarrhoea, it was superseded by ursodeoxycholic acid (urso stands for bear from which it is derived) and has been successfully used for patients to dissolve gallstones.

UDCA decreases biliary cholesterol saturation by 40–60% (i.e. makes cholesterol more soluble and less able to crystalize), by inhibition of cholesterol absorption in the intestine, reducing cholesterol secretion into bile and reducing the concentration of several crystallization-promoting factors (for example, amino-peptidase N, haptoglobin and some immunoglobulins) [97–99]. In addition UDCA decreases the toxicity of bile acids which can damage cell membranes and cause cholestasis [100].

UDCA is most effective in patients with good gallbladder function (and a patent cystic duct) who have few small non-radio-opaque cholesterol stones (<10–20 cm in size). UDCA has been used successfully to reduce the number of episodes of pancreatitis due to microscopic gallstones or biliary sludge [100]. The bile salt therapy may be required for more than 6 months. The problem of UDCA is that there is a high recurrence rate of gallstones of 30–50% at 5 years and 50–70% at 12 years, after successful treatment [101].

UDCA has not been studied in IF patients in whom there may be major problems with absorption.

Increase Gut Transit or Change Intestinal Microflora

Slow intestinal transit results in more primary bile acids being converted by bacteria to the more lithogenic secondary bile acids. Cisapride increases gastrointestinal transit rate (reversing any changes of octreotide treatment) and changes bile composition [91]. Thus it or another prokinetic drug could be useful in preventing gallstones in patients with intestinal failure due to small bowel dysfunction.

Metronidazole, by suppressing anaerobic intestinal organisms, reduced the rise in liver enzymes associated with parenteral nutrition in Crohn's disease [102]. This may be another simple way of reducing the chance of developing gallstones.

Prevent Biliary Stasis (Promote Gallbladder Emptying)

Oral Diet, Cholecystokinin, Rapid Amino Acid Infusions

As discussed cholestasis is an important contributor to the formation of gallstones and in part may be due to a lack of oral intake and thus reduced cholecystokinin which stimulates gallbladder contraction. cholecystokinin levels are low after a meal in patients with a short bowel and receiving PN [63]. Thus an oral diet and cholecystokinin injections could be a good preventative option in patients having PN with no or little oral intake. In prairie dogs, daily injections of cholecystokinin [30], or sphincterotomy [31], prevented gallstone formation. Data from human studies suggest that use of cholecystokinin in patients receiving TPN stimulates gallbladder emptying and prevents stasis and subsequent sludge formation [32, 72]. The prophylactic use of cholecystokinin in adult patients receiving total (no oral intake) PN, especially those with an ileal resection in whom the incidence of gallstone formation is increased may be beneficial. In children of whom 10% develop mostly asymptomatic gallstones while having total PN, cholecystokinin-octapeptide prophylaxis did not prevent the PN-associated gallstones forming. In addition, URDA did not dissolve gallstones, once identified [103].

The use of rapid infusion of amino acids [104–106] for example 125 mL of an aminoacid mixture (Synthamin 14 without electrolytes) over 5 min (2.1 g/min) produced a 64% reduction in gallbladder volume within 30 min [105]. A rapid infusion prevents the formation of biliary sludge [106].

Aspirin and Non-steroidal Anti-inflammatory Drugs

Studies involving the cholesterol-fed prairie dog showed that use of high-dose aspirin prevented gallstone recurrence after successful dissolution therapy. A decrease in mucin glycoprotein involved in nucleation was found and, as aspirin is an inhibitor of prostaglandin formation, it was suggested that secretion of mucin might be prostaglandin-mediated [107]. However, research in the same model showed that, at therapeutic doses, non-steroidal anti-inflammatory drugs (NSAIDs) had minimal effect on the production of mucin by the gallbladder [108].

NSAIDs may prevent gallstone formation by a prokinetic effect on the gallbladder. In a human study, subjects with gallstone disease given therapeutic doses of indomethacin had increased post-prandial gallbladder emptying [109]. This effect was not seen in healthy control subjects. The concentration of various eicosanoids in the gallbladder wall changes with bile cholesterol supersaturation and chronic inflammation and it may be that inhibitors of prostaglandin formation such as NSAIDs promote the production of prokinetic leukotrienes or prostaglandins in diseased but not in healthy gallbladders.

Nephrolithiasis and Nephrocalcinosis

Charles R. V. Tomson and Matthew Bultitude

Key Points

- Urate stones are common in patients with an ileostomy and are prevented/treated by making the urine alkaline.
- Calcium oxalate stones are common after an ileal resection/disease providing the colon is functional and in continuity. They can cause renal colic and/or end stage renal disease (ESRD) by causing nephrolithiasis and/or nephrocalcinosis which are both associated with inflammation.
- Calcium oxalate stones are prevented with a high fluid intake, low oxalate diet, calcium supplements (to bind oxalate in the gut), preventing hypomagnesaemia, acidosis (associated with low citrate) and pyridoxine deficiency. Cholestyramine and a reduced fat intake may be beneficial.
- Renal colic is common. Patients should have urine dipstick ± culture, serum creatinine, calcium and urate. A computerized tomography (CT) scan of the kidneys, ureters and bladder (CT KUB) is the recommended investigation due to high sensitivity and specificity.
- Septic obstructed kidney is a medical emergency and should prompt immediate drainage with ureteric stent or nephrostomy tube.
- For renal stones, treatment options are surveillance, shockwave lithotripsy, flexible ureteroscopy or percutaneous nephrolithotomy. Choice will depend on patient choice, surgical expertise, size and location of the stone.

Introduction

Kidney stone formation, nephrocalcinosis, and resultant chronic kidney disease are well-recognised complications of several forms of gut disease (Fig. 1). However, these are relatively rare, and late, complications of gut disease, so most physicians providing care for patients with gut disease lack experience in managing these complications. Conversely, gut disease contributes only a small fraction of the caseload managed by most nephrologists or urologists. There are no randomized controlled trials informing the management of these complications. Absence of evidence for the benefit of treatment is not the same of evidence of absence of benefit,

Fig. 1 Plain abdominal radiograph of a patient who had undergone extensive small bowel resection in 1985 as a result of spontaneous mesenteric thrombosis complicating the lupus anticoagulant syndrome. Stone formation was first reported in 1988, since when the patient had passed hundreds of calcium oxalate stones. Three months prior to this radiograph being taken he was admitted with acute renal failure, septicaemia and pyonephrosis as a result of obstruction by stones. Urinary oxalate was >1.0 mmol/day, but fell to 0.3 mmol/day on a synthetic oxalate-free diet

however: patients developing these complications therefore require specialized management. Such treatment, albeit based on limited evidence, can undoubtedly be successful in changing the course of disease and preventing life-changing complications.

History and Epidemiology

The first reports suggesting an increased risk of kidney stones amongst patients with inflammatory bowel disease were published in the 1960s [1–10]. Both uric acid and calcium oxalate stones appeared to be more prevalent than expected. A landmark study in 1972 was the first to demonstrate hyperoxaluria in patients with ileal resection, bacterial overgrowth, sprue, and other conditions characterized by fat malabsorption [11]. It has subsequently become clear that patients with ileostomies are at increased risk particularly of uric acid stones; patients with malabsorption and an intact colon are at particularly high risk of calcium oxalate stones. The introduction of jejunoileal bypass for obesity was soon followed by recognition that this form of surgically induced intestinal disease was also associated with a significantly increased risk of stone disease [12–15].

Later reports have focused not only on kidney stone formation but also on biopsy-proven oxalate nephropathy causing progressive kidney failure amongst patients with Crohn's disease and other causes of enteric hyperoxaluria [14, 16–20].

The precise frequency of these complications is difficult to determine, as the risks of stone formation and oxalate nephropathy vary with the severity and type of the underlying gut disease and with length of follow-up. Amongst patients with Crohn's disease, urolithiasis is more common amongst patients who have undergone surgery compared to those undergoing medical management. Most early reports were single-centre case reports or series, with no denominator. Recent systematic literature reviews have summarized these reports [21–24], giving estimated life-time risks for urolithiasis of 9–18% in patients with inflammatory bowel disease: the risks are higher with increasing age, with Crohn's disease compared to ulcerative colitis [25], and with ileal resection, particularly of the distal ileum [25]. Colonic preservation is associated with an increased risk of stones [26]. Urolithiasis in children with inflammatory bowel disease is rare, but does occur [27, 28]. Patients with ileal pouch after total colectomy remain at risk [29], although there are no controlled comparisons of stone frequency with pouch compared to ileostomy. Amongst patients with ulcerative colitis, total colectomy is associated with markedly increased risk of stone disease [6, 10, 30].

Possibly the best prospectively collected information comes from the Swiss National Inflammatory Bowel Disease Cohort Study. Kidney stones were reported in 4.6% of patients with Crohn's disease and 3.0% of patients with Ulcerative Colitis, over a median disease duration of 12.8 and 11.2 years respectively. In multivariate analysis, male gender, higher disease activity, intestinal surgery, use of non-steroidal anti-inflammatory drugs and reduced physical activity were independent predictors of kidney stone disease. Similar risk factors were reported for gallstones; patients with gallstones had a relative risk of 4.87 (95% CI 2.8–8.0) for kidney stones [31].

No large-scale study of the epidemiology of kidney stones has identified the proportion of episodes that are attributable to intestinal disease. This proportion is probably very small, given the high and increasing frequency of kidney stone disease in the general population [32, 33].

Similarly, the proportion of incident end-stage kidney failure caused by complications of intestinal disease is also very small, although such cases do exist [19, 34]. The best attempt to quantify the risk comes from a national registry study in South Korea, in which 38,812 patients with inflammatory bowel disease were matched 3:1 with people from the general population. Over a mean follow-up period of 4.9 years, end-stage kidney disease (ESKD) was detected in 79 patients with inflammatory bowel disease (0.2%) compared to 0.1% of controls; this was driven by an increased risk of ESKD amongst patients with Crohn's disease (adjusted hazard ratio 6.33, 95% CI 2.75–14.56) with no increased risk in Ulcerative colitis (adjusted hazard ratio 2.01, 95% CI 0.9–4.51) [35].

Pathophysiology

The pathophysiology of kidney stone formation in general has been discussed in detail elsewhere [36, 37].

Calcium oxalate is highly insoluble, with a solubility of around 7 mg/L at 37 °C in simple solution. However, urine is an extremely complex solution, containing inhibitors and promoters of crystallization. For instance, citrate and pyrophosphate form soluble complexes with calcium, thus decreasing calcium availability; magnesium forms a soluble complex with oxalate; and Tamm-Horsfall glycoprotein and other glycosaminoglycans inhibit one or several phases of calcium oxalate stone formation. Even though normal urine is supersaturated with respect to calcium oxalate, calcium oxalate crystals do not normally form in free solution, but rather by deposition on existing surfaces, such as tubular casts, sodium urate or uric acid crystals, or cell debris [38].

Uric acid is a weak acid, with a pK of 5.75. Undissociated uric acid is highly insoluble, with a solubility limit of 100 mg/L, whereas urate salts are very much more soluble (e.g. 1200 mg/L of urate at pH 6.5). Urine pH is therefore the main determinant of uric acid solubility; the most important risk factors for uric acid stone formation are therefore high urine concentration and acid urine (Fig. 2). Total uric acid

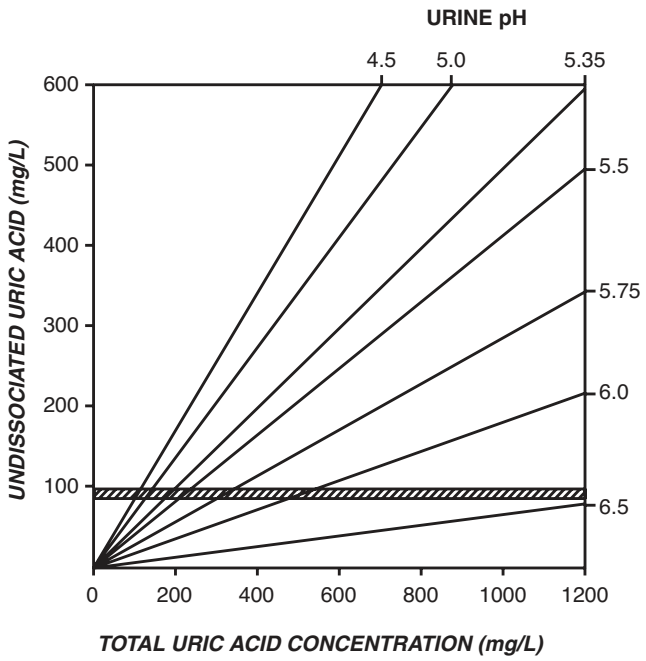

Fig. 2 Relationship between urine pH and solubility of uric acid. Redrawn with permission [100]

excretion is often normal in patients with uric acid stones, although increased production of uric acid as a result of increased purine catabolism can cause stone formation [39].

Patients with intestinal disease are at increased risk both of calcium oxalate stones and oxalate nephropathy, and of uric acid kidney stones. Although the two conditions share some risk factors, most importantly reduced urine volume and flow rate, calcium oxalate stones are largely caused by enteric hyperoxaluria, and uric acid stones by excessive urine acidity due to alkali loss in ileostomy effluent.

Influence of Dietary Calcium Intake on Oxalate Bioavailability

Epidemiological studies in men [40] and women [41] have shown that a high dietary calcium intake reduces the risk of developing renal stones. Other studies have also showed that variations in urinary calcium excretion are poorly, if at all predictive of stone recurrence, whereas the risk of recurrence appears to increase exponentially as urinary oxalate excretion increases [42]. The explanation for this paradoxical relationship between calcium intake and stone risk is twofold.

1. Studies *in vitro* and computerized iterative calculation of activity products show that the risk of calcium oxalate crystallization in urine is little affected by variations in urine total calcium concentration (as a result of the formation of soluble complexes which decreases calcium availability) but increases linearly with increasing oxalate concentration [43]. Thus, changes in urinary oxalate concentration are very much more important as a risk factor for stone formation than changes in urinary calcium concentration.
2. Oxalate is only absorbed from the gut in ionized form. Excess calcium in the gut lumen thus decreases oxalate bio-availability by the formation of insoluble calcium oxalate. Several studies have confirmed that, independent of other factors, urinary oxalate excretion decreases with increasing dietary calcium intake [43, 44], and, conversely, that dietary calcium restriction increases absorption of dietary oxalate, resulting in an increase in the probability of stone formation [45]. Similarly, administration of sodium cellulose phosphate (which decreases gut absorption of calcium) results in an increase in urinary oxalate excretion [46]. Increased intestinal absorption of calcium, as in vitamin D treatment and 'absorptive hypercalciuria' may also increase stone risk not so much because of the resulting increase in urinary calcium concentration but because of the resulting hyperabsorption of oxalate.

Enteric Hyperoxaluria

The major factor causing stone formation and kidney damage in gut disease is hyperoxaluria [47]. Enteric hyperoxaluria has now been reported in a wide range of conditions that alter oxalate bioavailability in the colon, including

- Ileal resection [11, 48]
- Jejuno-ileal bypass [18, 49, 50]
- Coeliac disease [51]
- High-dose oral phosphate supplementation [52]
- Intestinal lymphangiectasia [53]
- Roux-en-Y gastric bypass [19, 54, 55]
- Orlistat therapy [56, 57]
- Chronic pancreatitis [58]

It has been known since the 1970s that enteric hyperoxaluria is due to excessive absorption of dietary oxalate in the colon [48, 59–65]. Two major mechanisms account for this. Firstly, unabsorbed fatty acids form soaps with calcium in the gut lumen. This reduces the amount of calcium in the gut lumen that is available to bind to oxalate, thus increasing oxalate bioavailability. Secondly, unabsorbed bile acids increase colonic permeability to oxalate [66]. High-dose chenodeoxycholic acid for gallstone dissolution is associated with increased absorption of radiolabelled oxalate [67]. Absorption of oxalate after a test meal correlated so well with fat malabsorption that some investigators suggested that it should be used as a diagnostic test for steatorrhoea [68, 69] although this test did not prove reliable [70].

Figure 3 summarises current understanding of the pathogenesis of enteric hyperoxaluria, although the prominence given to the possible contribution of vitamin B6 deficiency to hyperoxaluria is, as discussed below, speculative at best.

Since the 1970s, our understanding of the mechanisms of oxalate transport in the colon has advanced considerably. It is now known that an active oxalate transporter, SLC26A6, is responsible for oxalate secretion into the gut lumen [71, 72]. Oxalate absorption has long been thought to be passive and paracellular [73] although more recently it has been suggested that SLC26A3 also mediates oxalate absorption [74]. Pro-inflammatory cytokines inhibit SLC26A6-mediated oxalate secretion, resulting in increased urinary oxalate excretion: this is one mechanism by which obesity increases the risk of calcium oxalate stones [75]. A case report in a patient with subclinical coeliac disease and oxalate nephropathy suggested reduced SLC26A6 expression as a contributor to hyperoxaluria [76]. SLC26A6 is also an inhibitor of the succinate transporter NaDC1, and reduced activity results in reduced urinary citrate and an increase in serum succinate—which may cause renin-dependent hypertension [77].

Pathogenesis of Oxalate Nephropathy

It was previously thought that hyperoxaluria caused kidney damage solely by causing obstructive nephropathy, resulting from tubular or ureteric obstruction by calcium oxalate kidney stones. While this may well play a role, it is now clear that calcium oxalate crystals cause parenchymal damage largely by activating an innate inflammatory pathway, the nucleotide-binding domain leucine-rich repeat inflammasome 3 (also called NALP3, NLRP3, or cyropyrin) [78–81]. In future, these findings might lead to new therapeutic options to prevent the progressive kidney failure that can complicate enteric hyperoxaluria.

Mechanisms of Stone Formation

Careful histopathological work has shown that the mechanism by which kidney stones form in patients with bypass surgery differs from that in 'idiopathic' kidney stone formers. Inner medullary collecting duct crystals, comprising calcium oxalate and hydroxyapatite, have been described in bypass patients but not in patients with idiopathic calcium oxalate stone disease [82]; whereas patients with ileostomies form interstitial hydroxyapatite deposits (known as Randall's plaques) and inner medullary collecting duct crystals made of hydroxyapatite and uric acid salts [83]. In patients with gut resection, deposits in the inner medullary collecting duct uniformly contain hydroxyapatite, with a minority also containing calcium oxalate, with abundant Randall's plaque [84].

Hypocitraturia

Citrate is the most important inhibitor of calcium oxalate crystallization in the urine; hypocitraturia is therefore a major risk factor for kidney stone formation [85, 86].

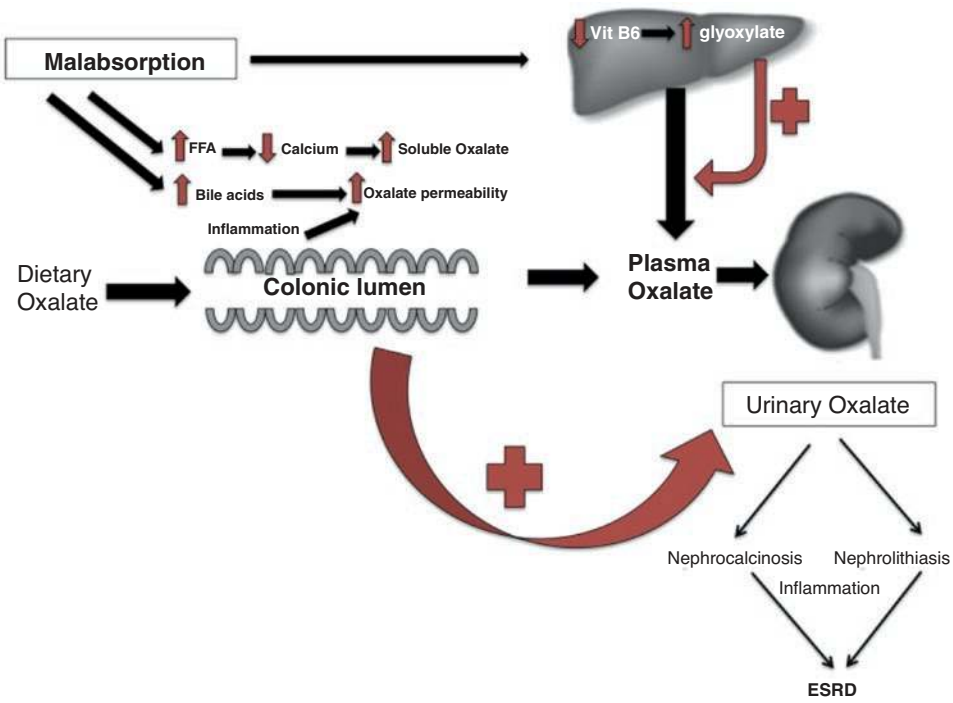

Fig. 3 Pathogenesis of enteric hyperoxaluria. From Nazzal et al. [34], with permission

Hypocitraturia is usually defined as urine citrate excretion <1.67 mmol/24 h; average daily excretion in healthy individuals is around 3.12 mmol/24 h [87]. Systemic acidosis is an important cause of hypocitraturia, but the amount of citrate filtered at the glomerulus is also a determinant. Hypocitraturia is common in patients with malabsorption and is due both to reduced filtered load and acidosis [88].

Low Urine pH

Highly acidic urine favours the formation of calcium oxalate and uric acid stones, and is common in patients with various forms of gastrointestinal disease, including those with ileostomy [47, 50, 89].

Low Urine Volume

Low urine volume results not only in increased concentration of stone components but also causes reduced flow rate, which increases the risk that crystals will agglomerate and adhere to the urothelium. Low urine volume is a common finding in many forms of gastrointestinal disease and results from excessive fluid loss in the gut [47, 50, 90].

Low Urine Magnesium

Along with citrate, magnesium is an important inhibitor of calcium oxalate crystal formation. Hypomagnesuria in gastrointestinal disease is caused by malabsorption of magnesium [50, 91], which can be exacerbated by long-term use of Proton Pump Inhibitors [92].

Effect of the Gut Microbiome

Our previous understanding, in which oxalate absorption was a passive process governed by oxalate intake and colonic 'permeability' to oxalate, has now been superseded as knowledge has grown. We now understand that the gut microbiome plays a crucial role in determining the amount of oxalate absorbed from the gut. Several organisms metabolise oxalate in the colon. In particular, the presence or absence of *Oxalobacter formigenes*, a normal anaerobic colonic commensal, helps to determine overall oxalate burden. This organism metabolises oxalate to carbon dioxide. Antibiotics can reduce both oxalate-degrading capacity and colonic carriage of the organism [93]. In the general population, exposure to antibiotics is associated with an increased risk of kidney stone formation [94, 95]. Absence of *Oxalobacter formigenes* in the gut microbiome is associated with higher urine oxalate excretion and an increased risk of recurrent stone formation in patients without gut disease [96]. In animal models, the organism promotes oxalate secretion into the colonic lumen [97]. However, numerous other gut organisms, including some species symbiotically linked to *Oxalobacter formigenes* but without a direct role in oxalate breakdown, can affect oxalate metabolism in the gut [98].

Vitamin Malabsorption

In health, most of the oxalate excreted in the urine comes from the liver, where oxalate is a metabolic end-product of amino-acid metabolism. Pyridoxine is a co-factor for alanine: glyoxylate aminotransferase, the enzyme that is defective in type 1 primary hyperoxaluria. Reduced enzyme activity results in accumulation of glyoxalate and subsequent overproduction of oxalate. High-dose pyridoxine can sometimes ameliorate hyperoxaluria in primary hyperoxaluria type 1, depending on genotype [99]. Pyridoxine deficiency caused by malabsorption could in theory contribute to hyperoxaluria in patients with intestinal disease [34], but this remains speculative: no study has demonstrated an association between pyridoxine status and endogenous oxalate production or urine oxalate excretion in patients with malabsorption, nor are there even case reports showing that pyridoxine supplementation reduces oxalate excretion in patients with enteric hyperoxaluria.

Uric Acid Kidney Stones Complicating Ileostomy

The major risk factor for the formation of uric acid stones is urine acidity (Fig. 2) [39, 100]. Urine uric acid concentration plays a lesser role. Although diet plays some part in determining urine acidity (ingestion of animal-derived protein being the major contributor to fixed acid excretion), the major cause of highly acidic urine is excessive gastrointestinal loss of bicarbonate—most commonly as the result of an ileostomy. This is combined with a chronic state of salt and water depletion causing reduced urine flow and increased urine concentration [4, 7, 90, 101]. These abnormalities are further exacerbated in patients with short gut.

Although less directly relevant in a chapter on intestinal failure, it is also noteworthy that obesity is strongly associated with an increased risk of uric acid stones, due to an ill-understood defect in urine buffering capacity that occurs in the presence of obesity and insulin resistance [102–104].

Dietary Sources of Oxalate

Restriction of dietary oxalate intake is clearly part of a logical approach to treatment of enteric hyperoxaluria. It should be obvious that advising patients to avoid a few very high oxalate foods (e.g. spinach, rhubarb, beetroot), that are infrequent components of most diets, is unlikely to have much effect on daily oxalate excretion: most dietary oxalate is ingested in commonly-used foods with moderate or high oxalate content: wheat bran is a good example.

Assessment of the oxalate content of food is complex, as oxalate content can vary within individual foods from cultivar to cultivar and from season to season, as can the proportion held as the calcium salt *versus* the soluble salts (predominantly potassium oxalate)—the soluble salts have much greater bioavailability. Boiling foods removes some soluble oxalate. Oxalate content also varies within foods—for instance, in whole grains oxalate is concentrated in the bran fraction, so refined flour contains less oxalate than unrefined flour, and bran products contain high amounts of oxalate. Preparation and cooking methods, and the calcium content of the food, further add to variability in bioavailability of dietary oxalate [105]. This variability probably explains the wide variation in publicly available sources of advice on dietary oxalate [106], and cannot easily be resolved (Table 1).

N.B. As discussed, both oxalate content and bioavailability are highly variable and can depend on the cultivar, the method of cultivation, the season of harvest, and the precise part of the plant used. Different sources give widely different values for oxalate content of the same foodstuff: this may relate to differences in assay method. Oxalate content may also change during processing. Some soluble oxalate (e.g. sodium oxalate) can be removed by cooking in water, but this will clearly depend on cooking time and volume of water. Bioavailability depends on what the food is ingested with: a large dollop of cream on a bowl of raspberries may well substantially reduce the amount of oxalate absorbed, as would milk taken with breakfast cereals derived from wheat bran. Many sources provide data on oxalate content of named brands, e.g. of breakfast cereals commonly sold in North America: these are of limited utility elsewhere. Oxalate content is often measured in mg/100 g, but can also be expressed per serving size: black pepper, for instance, has an oxalate content of >3000 mg/100 g, but the amounts used in cooking make this of very limited relevance.

Acute Oxalate Nephropathy

Acute oxalate nephropathy is increasingly recognized as a cause of acute kidney injury that can, if left untreated, progress to cause end-stage kidney failure. This syndrome is most

Table 1 High oxalate foods. Compiled from numerous sources, including: case reports of acute oxalate nephropathy (see text). United States Department of Agriculture Agriculture Handbook 8-11, 1984: https://www.ars.usda.gov/northeast-area/beltsville-md-bhnrc/beltsville-human-nutrition-research-center/nutrient-data-laboratory/docs/oxalic-acid-content-of-selected-vegetables/—the data from this table are also available sorted by oxalate content at http://www.petsnails.co.uk/documents/oxalates.html; a table previously published by the Oxalosis and Hyperoxaluria foundation, www.ohf.org but no longer available on their website; dietary advice from the University of Chicago, which provides detailed advice on food oxalate content, including how to translate this into practice http://kidneystones.uchicago.edu/how-to-eat-a-low-oxalate-diet/; data compiled by the Harvard TH Chan School of Public Health https://regepi.bwh.harvard.edu/health/Oxalate/files (this also provides advice on interpretation of the data, a table of low-oxalate alternatives to high-oxalate foods and other resources for dietitians); a website www.oxalate.org compiled by a patient from seven sources, not all of which remain available

Very high oxalate foods: to be avoided completely
Star fruit[a] (*Averrhoa carambola*)
Irumban pili[a] (*Averrhoa bilimbi)*
Rhubarb[a]
Peanuts[a]
Iced tea[a]
Chaga mushrooms[a]
Spinach[a]
Green ‘smoothies’ (depends on raw ingredients)[a]
Almonds
Amaranth seeds and leaves
Bamboo shoots
Beetroot and beet leaves
Black tea
Bran flakes
Brown rice and brown rice flour
Buckwheat groats, flour, and leaf
Bulghur wheat
Cassava
Chard
Chives
Cocoa powder
Corn grits
Cornmeal
Fava beans
Haricot beans (“Navy beans” in US parlance)
Millet
Miso soup
Okra
Parsley
Poppyseed
Potatoes, baked with skin
Purslane
Rice bran
Sesame seeds
Soya flour and other soy products
Sorrel
Tahini
Wheat bran
High oxalate foods
Nuts
Cashew nuts

Table 1 (continued)

	Hazelnuts
	Peanut butter
	Pecan nuts
Vegetables and legumes	
	Beans—fava, red kidney, refried
	Carrots (raw)
	Celery (raw)
	Collard greens
	Okra
	Parsnip
	Mustard greens
	Potatoes—fried or chipped
	Swede (Rutabaga)
	Sweet potatoes—baked
	Tomato paste
	Turnip
	Yams
Breads, pasta, rice	
	French toast
	Lasagna
	Rice bran
	Spaghetti
Fruit and juice	
	Avocado
	Dates
	Grapefruit
	Kiwi fruit
	Orange
	Pineapple
	Raspberries
Breads, grains, and breakfast cereals	
	Bagels
	Bran flakes
	Cornmeal
	Couscous
	French toast
	Millet

[a] Implicated in case reports of acute oxalate nephropathy

commonly recognized after excessive ingestion of a dietary source of oxalate. Substances responsible include the following:

- Star fruit (Averrhoa carambola) [107–109]—ingestion can also cause chronic oxalate nephropathy [110]
- Irumban puli (Averrhoa bilimbi), used in a traditional remedy in Kerala [111]
- Rhubarb [112]
- Peanuts [113]
- Iced tea [114]
- Massive Ascorbic acid intake [115–117]
- Green smoothies [118, 119]
- Chaga mushrooms [120]

If dietary oxalate is excessive enough, this can occur without intestinal disease, but it is reasonable to assume that the presence of intestinal disease greatly increases the risk at any given level of oxalate intake, as demonstrated in a number of reports [121, 122]. These foods and food supplements should therefore be avoided in all patients at risk of enteric hyperoxaluria.

Dietetic Advice for Patients with Enteric Hyperoxaluria

Notwithstanding the variability in oxalate content and bioavailability discussed above, and the fact that studies of oxalate bioavailability have largely been performed in normal subjects rather than in patients with enteric hyperoxaluria, it remains reasonable to equip patients with advice on which foods to avoid entirely, which foods should be used with care, and which foods are likely to be 'safe' with respect to the risk of stone formation and oxalate nephropathy. Such advice should be given by a dietitian: ideally all services providing care for patients with enteric hyperoxaluria should have a dietitian who is knowledgeable in this area. Table 1 contains an initial guide to the oxalate content of food. A comprehensive list, compiled by a patient from a variety of sources, can be found at www.oxalate.org.

Investigation

Biochemistry

Patients with intestinal disease who develop symptomatic renal colic, are found to have asymptomatic kidney stones on imaging, or who develop unexplained acute or chronic kidney disease, should all be offered further investigation with a view to treatment. Biochemical evaluation should include the following

- Full biochemical profile (including eGFR, calcium, magnesium, bicarbonate, urate)
- Spot urine pH (ideally using a pH meter, as these are more accurate than urine dipsticks)
- 24 h urine for volume, creatinine, sodium, calcium, magnesium, citrate, and oxalate (all these analyses can be performed on a single 24 h urine collection: most laboratories recommend acidification of the sample to prevent *in vitro* changes, including 'in vitro oxalogenesis' from oxalate precursors)

The purpose of including 24 h urine creatinine is to allow assessment of the completeness of urine collection. This is particularly useful when comparing repeated 24 h urine collections over time: barring significant changes in muscle mass, creatinine excretion remains constant over time within

an individual. So if a given patient returns a 24 h urine collection containing around 10 mmol of creatinine on several measurements but then returns one containing only 5 mmol, it is safe to conclude that the latest collection is incomplete; similarly, if the latest collection contains 15 mmol, it is reasonable to conclude that the patient continued the collection for more than 24 h.

Amongst patients who cannot reliably collect a 24 h urine collection (children, for instance), the use of analyate: creatinine ratios is a reasonable 'second best' for assessment of urine chemistry. These ratios rely on the assumption that the excretion of both analytes remains constant over 24 h; and that an 'average' adult excretes around 10 mmol of creatinine per 24 h. An oxalate: creatinine ratio of 0.07 mmol/mmol, for instance, would suggest a 24 h urine oxalate of 0.07 × 10 = 0.7 mmol—significantly higher than the upper limit of normal of around 0.45 mmol/24 h. Creatinine and albumin excretion show little diurnal variation (hence the widespread use of albumin: creatinine ratios to quantitate albuminuria, for instance in diabetic kidney disease) but this is less true of urine calcium, magnesium, citrate, or oxalate, and 24 h creatinine excretion may be substantially less than 10mmol in many patients with intestinal disease—so these ratios should be interpreted with caution [123].

Because of differences in assay performance, the laboratory reference range should be used to interpret results. Normal adults 24 h oxalate excretion is typically <460 μmol/24 h; patients with enteric hyperoxaluria may excrete up to 1500 μmol/L, depending on the severity of the intestinal disease.

Measurement of plasma oxalate concentration (only performed in a few specialized laboratories) is not helpful in most patients, as plasma oxalate remains close to normal (e.g. <5 μmol/L) in patients with normal glomerular filtration rate even in the presence of enteric or primary hyperoxaluria. However, as GFR declines below 45 ml/min/1.73 m^2, plasma oxalate rises, even in the absence of increased oxalate load, often to concentrations of around 20–30 μmol/L. In parallel, 24 h oxalate excretion may fall (as calcium oxalate crystals are deposited in the body), so measurement of 24 h urine oxalate in a patient with advanced kidney failure may give a misleadingly 'normal' result [124]. In this situation, measurement of plasma oxalate may be helpful. Kidney failure of any cause will result in hyperoxalaemia; in patients receiving modern dialysis plasma oxalate concentrations are usually around 30 μmol/L [125, 126]. Concentrations significantly higher than this—e.g. >50 μmol/L—should prompt further investigation for primary or enteric hyperoxaluria. In less advanced chronic kidney disease, plasma oxalate concentration rises as GFR falls; at a given GFR, plasma oxalate is lower in patients with no disorder of oxalate metabolism, higher in patients with enteric hyperoxaluria, and higher still in patients with primary hyperoxaluria [127].

Differential Diagnosis

The primary hyperoxalurias (type 1, type 2, and type 3) are autosomal recessively inherited disorders of hepatic amino-acid metabolism that result in hyperoxaluria. Phenotype is variable in each type, but in general, type 1 has a more severe phenotype (earlier onset, higher oxalate excretion) than type 2, and type 3 is milder still; a subgroup of type 1 patients respond to high-dose pyridoxine [128]. Testing for known pathogenic mutations is now the best way to confirm a diagnosis.

Kidney Biopsy

Patients with suspected oxalate nephropathy may present with slowly progressive chronic kidney disease (CKD) or with an acute deterioration in kidney function, often on a background of stable or slowly progressive CKD. Urinalysis is often negative for blood and protein. A high index of clinical suspicion is required, as patients with CKD who have negative urinalysis are often assumed to have non-specific 'hypertensive nephrosclerosis'—a pattern of kidney damage for which there is no treatment other than optimization of cardiovascular risk factors. In a patient with intestinal disease likely to cause enteric hyperoxaluria, however, this assumption would be dangerous. Urine microscopy in patients with oxalate nephropathy can demonstrate calcium oxalate crystals, but the sensitivity and specificity of this finding is unknown. Kidney biopsy is the definitive test, and carries a low risk when undertaken by an experienced operator [129]; these risks can easily be justified by the possibility that the results will alter management in a patient with intestinal disease and unexplained chronic or acute kidney disease. Kidney biopsy is also indicated when mesalazine-induced nephropathy—another condition causing CKD with negative urinalysis and normal ultrasound appearances—is a possible differential diagnosis [23, 130].

Treatment

High Fluid Intake

The most rational, and certainly the safest, treatment to reduce the risk of stone formation in patients who have had an ileal resection or have ileal disease is to increase water intake, and thus to make the urine more dilute, reducing supersaturation with respect to calcium, oxalate and any other potential constituents of urinary tract stones. Ideally, water intake should also be increased at night, when decreased urine flow and increased urine concentration may increase the risk of stone formation, although fluid intake should also be increased at meal-times to compensate for

transient hyperoxaluria due to absorption of dietary oxalate. However, it is remarkably difficult to persuade patients with normal intestinal function to increase fluid intake to ensure a daily urine volume of >3 l. Drug therapy with the vasopressin antagonist Tolvaptan has been proposed [131, 132], but is extremely expensive.

In patients with short bowel and a retained colon, who may be even more reluctant to increase fluid intake, efforts should also be directed to minimizing gastrointestinal fluid losses, with drugs that reduce motility and/or secretions. In patients with an ileostomy or jejunostomy who have problems of renal stones, a glucose–electrolyte solution should be encouraged (chapter "Management of a High Output Stoma, Jejunotomy or Uncomplicated Enterocutaneous Fistula") or slow release sodium supplements (as chloride or bicarbonate). If receiving parenteral nutrition good hydration must be achieved and consideration given to reducing the acidity of the solution infused (if urate stones).

Treatment of Enteric Hyperoxaluria

The aim of treatment should be to prevent episodes of symptomatic kidney stone; to prevent obstructive nephropathy and resultant CKD from clinically silent obstructing kidney stones; and to prevent acute and chronic oxalate nephropathy. These risks vary from patient to patient, depending on the severity of the gut disease and on other variables including habitual diet and fluid intake. The extent to which patients will agree to additional treatment (including the drug treatments listed above, a high fluid intake, and significant dietary restrictions) will require shared decision-making based on the value placed on avoidance of long-term complications compared to the perceived burden of treatment—which, in the case of patients with intestinal failure, is likely to be in addition to an already significant burden (Table 2).

Ideally, all patients at risk of complications of enteric hyperoxaluria should achieve a high urine volume (e.g. >2.5 L per 24 h), urine oxalate excretion <300 μmol/24 h, urine citrate excretion >3.0 mmol/24 h. Hypercalciuria (e.g. urine calcium >6.5 mmol/24 h) should be avoided, but is seldom seen in patients with enteric disease.

Bile Acid Sequestrants

In the seminal paper describing enteric hyperoxaluria in 1972, Smith et al. reported that urinary oxalate excretion was normalized by Cholestyramine [11], but subsequent reports have cast doubt on the utility of bile acid sequestrants [67, 133] and this may well vary with the severity of bile salt malabsorption in the individual patient. Given that bile acid sequestrants can improve diarrhoea (and thus improve urine output) they remain a logical part of the treatment strategy for patients with enteric hyperoxaluria.

Table 2 Available measures to decrease risk of calcium oxalate stone formation in patients with a short small bowel in continuity with the colon. N.B. none of these therapies have been proven to prevent stone recurrence in trials: all recommendations are based on pathophysiological reasoning

1. Maintain a high flow of dilute urine by maximizing fluid absorption
2. Low oxalate diet
3. Calcium supplements with meals; consider sevelamer, lanthanum, aluminium as alternatives
4. Bile acid sequestrants, particularly if there are other indications
5. Citrate supplements (particularly if hypocitraturic)
6. Magnesium supplementation (but avoid diarrhoea)
7. Oral oxalate decarboxylase, if current trials prove successful
8. Biotherapy: oxalobacter formigenes

Restriction of Dietary Oxalate Intake

The early descriptions of enteric hyperoxaluria included convincing proof that a low-oxalate diet could normalize urine oxalate excretion, at least in the short term [59], but provision of a low oxalate diet for the purpose of this demonstration required a synthetic diet. Provision of such a diet can prove that hyperoxaluria is enteric in origin (Fig. 4). The extent to which dietary restriction of natural foods results in reduction of oxalate excretion has never been adequately tested. One short-term study in 9 patients with mild enteric hyperoxaluria after bariatric surgery suggested that a low oxalate (70–80 mg/day), moderate protein, normal calcium diet had negligible effect on urinary oxalate but did reduce calcium oxalate supersaturation by increasing urine volume, citrate and pH [134]. It is logical to advise patients with enteric hyperoxaluria to restrict intake of very high and high oxalate foods, but long-term studies are required.

Oxalate 'Binders' to Reduce Bio-availability of Dietary Oxalate

Calcium Salts

Although it may seem counter-intuitive to administer calcium salts to reduce the risk of formation of calcium oxalate stones, this is the treatment strategy for which there is the best evidence in enteric hyperoxaluria. There is extensive evidence in the general population that a low calcium diet is associated with a higher risk of kidney stone disease [40, 41, 135, 136], and good experimental evidence that absorption of oxalate from the diet is inversely related to dietary calcium [137, 138]. Amongst patients with idiopathic hypercalciuria, a randomized controlled trial showed a higher risk of recurrent stone formation with a low calcium diet [139]. In patients with enteric hyperoxaluria, short-term studies have

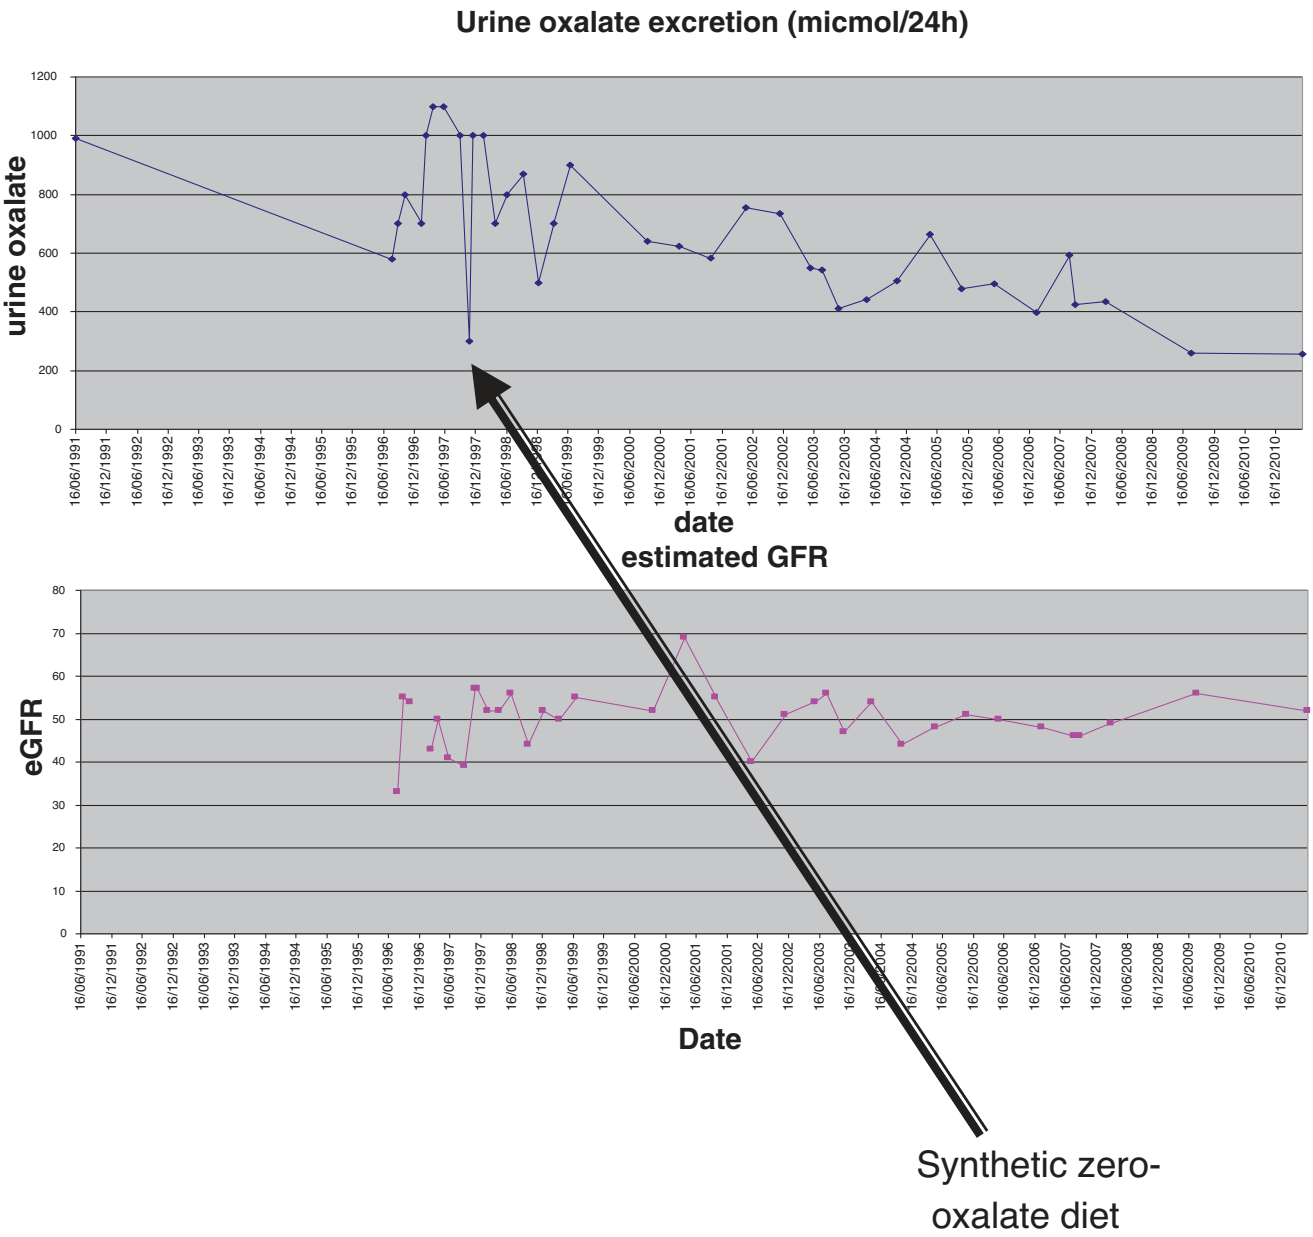

Fig. 4 Repeated measurements of urine oxalate in the patient whose radiograph is shown in Fig. 1, including measurements on a synthetic zero-oxalate diet

demonstrated a reduction in oxalate excretion with calcium supplements given with meals [67, 140–143]. The optimal dose probably varies between patients depending on the severity of the fatty acid malabsorption and on the calcium and oxalate content of the diet.

Aluminium Salts

Limited data suggest that aluminium hydroxide, administered with food, will reduce oxalate bioavailability [142, 144]. The use of aluminium salts to reduce phosphate absorption from the gut in patients with chronic kidney disease is now thought inadvisable because of the theoretical risk of aluminium intoxication (even though direct transfer of aluminium from dialysate water into the bloodstream is the dominant mechanism); the relative risk and benefit of using aluminium salts to reduce oxalate absorption in patients with enteric hyperoxaluria has never been studied.

Lanthanum Carbonate

Lanthanum carbonate is now widely used as phosphate binder for patients with chronic kidney disease, and has in vitro affinity for oxalate that exceeds that of calcium and aluminium [142]. Lanthanum reduces oxalate absorption in animal models [145], and although there are no published reports of its use in human enteric hyperoxaluria, it would be a logical drug to try if other treatments fail.

Sevelamer

Sevelamer, another drug licensed for treatment of hyperphosphataemia in chronic kidney disease, reduces urine oxalate excretion (although less effectively than calcium carbonate) in patients with chronic kidney disease [146] but was found to have disappointing effects in one small study of patients with enteric hyperoxaluria [147].

Magnesium

Magnesium is an inhibitor of calcium oxalate crystallization, so maintaining a high urine magnesium is likely to reduce the risk of stone formation. Magnesium also binds oxalate in the gut, reducing its bioavailability. Many patients with malabsorption are also hypomagnesaemic. Proton pump inhibitors can cause magnesium malabsorption [92] and should be avoided if possible. Magnesium supplements, given with meals to maximize the effect on oxalate bioavailability, should be given unless these prove to exacerbate diarrhoea.

Citrate Supplementation

Citrate supplementation has a proven role in reduction of stone recurrence rates amongst the general population of stone formers [148, 149]. Urine citrate excretion can be increased by dietary changes including drinking real lemonade [150] and increased intake of fruit and vegetables [87] but the effects of these dietary changes on oxalate excretion would need careful study in patients with enteric hyperoxaluria. Potassium calcium citrate supplementation has been shown to reduce the lithogenicity of urine in patients with enteric hyperoxaluria complicating bariatric surgery [151] but there are no long-term data on stone recurrence rate. Nevertheless, pharmacological treatment of hypocitraturia with citrate supplements is logical and usually well tolerated, and is an important therapeutic option amongst patients with enteric hyperoxaluria.

Thiazide-Type Diuretics

In the general population of stone-formers, treatment with thiazide-type diuretics, which decrease urine calcium excretion (and also probably preserve bone strength) has been shown to be effective in reducing stone recurrence rate [152]. However, their utility in patients with enteric hyperoxaluria, most of whom are hypocalciuric, is uncertain.

Biotherapy

The discovery (discussed above) that *Oxalobacter formigenes* regulates oxalate bioavailability in the colon by metabolizing luminal oxalate led to early studies in adults [153] and infants [154] with primary hyperoxaluria in which *Oxalobacter formigenes* was administed as frozen paste or enteric-coated capsules, resulting in time-limited reduction in urinary oxalate; however, faecal recovery of the organism dropped directly after cessation of administration of the biotherapy [153]. However, a small randomized controlled trial failed to show benefit, although this negative result could partly have been due to inaccurate 24 h urine collections [155]. Biotherapy with lactobacilli has also been studied, with positive preliminary results in patients with enteric hyperoxaluria [156] and after an oral load of oxalate [157] but negative results in stone-formers with mild hyperoxaluria and no gastrointestinal disease [158–160].

Enzyme Therapy

An attractive alternative to biotherapy is to deliver oxalate-degrading enzymes to the colon, where degradation of oxalate in the gut lumen will reduce the amount of oxalate available for absorption, and stimulate oxalate transport from the systemic circulation to the gut lumen [161]. A proof of principle study in human volunteers ingesting a high-oxalate, low-calcium diet demonstrated that oral capsules containing oxalate decarboxylase (Reloxaliase: Allena Pharmaceuticals) caused a significant reduction in urine oxalate, but did not fully correct the increase in oxalate excretion caused by the intervention diet [162]. At the time of writing, trials with this product are under way in patients with primary and enteric hyperoxaluria [163]. If it proves possible to prevent absorption of a dietary oxalate load by enzymatic digestion to CO_2 with a tolerable tablet burden, this treatment could revolutionise the treatment of enteric hyperoxaluria.

Prevention of Inflammation Caused by Crystalline Calcium Oxalate

In an animal model, N-acetyl cysteine ameliorated experimental oxalate nephropathy caused by star fruit ingestion [164]. The relevance of this finding for human oxalate nephropathy remains uncertain.

Reduction of Hepatic Synthesis of Oxalate

Although increased hepatic production of oxalate is not known to be a significant contributor to hyperoxaluria in intestinal disease, reduction of hepatic oxalate production would still be expected to ameliorate hyperoxaluria. Oxalate is produced in the liver from glyoxylate by the action of lactate dehydrogenase isoenzyme 5 (LDH5). The antiepileptic drug Stiripentol (used in a rare form of epilepsy, Dravet syn-

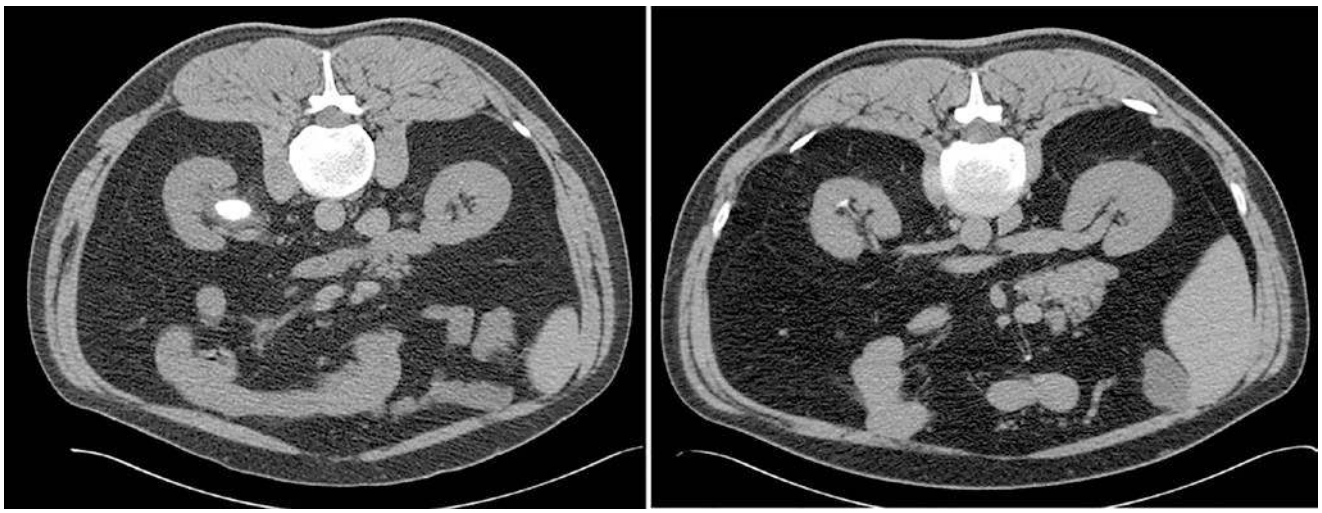

Fig. 5 Dissolution of a large uric acid kidney stone with potassium citrate in a patient with an ileostomy following urine alkalinisation

drome) inhibits neuronal LDH5, and has recently been shown to inhibit hepatic LDH5 as well, reducing hepatic oxalate production and alleviating experimental hyperoxaluria in experimental animals. Children with Dravet syndrome treated with Stiripentol had lower oxalate excretion than children with cystinuria, and Stiripentol caused a significant reduction in oxalate excretion in one child with primary hyperoxaluria [165].

Treatment of Kidney Failure: Dialysis and Kidney Transplantation

If oxalate nephropathy caused by enteric hyperoxaluria continues for long enough, end-stage kidney disease can result, necessitating renal replacement therapy with dialysis or kidney transplantation. As kidney function declines, oxalate load exceeds the capacity of the kidney to excrete oxalate, and plasma oxalate concentration rises, causing calcium oxalate supersaturation. When kidney failure complicates type 1 primary hyperoxaluria, kidney failure can result in a devastating syndrome of systemic oxalosis, caused by deposition of calcium oxalate in tissues including the eyes, blood vessels, heart and cardiac conducting system, peripheral nerves, and bones [126, 166]. Standard dialysis may be insufficient to prevent or reverse this syndrome. Patients with severe enteric hyperoxaluria are at risk of similar complications [167–169], although only a small number of such cases have been reported, probably because hyperoxaluria is usually less marked in enteric disease compared to type 1 primary hyperoxaluria. Kidney transplantation can be complicated by early oxalate nephropathy caused by mobilization of calcium oxalate deposits; for this reason, it is vital to ensure a high urine flow, high urine citrate, and to continue dialysis (to control hyperoxalaemia) until graft function is well established [170].

Treatment of Uric Acid Stones Complicating Ileostomy

Prevention of recurrent uric acid stones in patients with hypovolaemia and acid urine is highly rewarding. Regular alkali supplementation sufficient to achieve a urine pH of 7 or greater can result in complete dissolution of existing stones (Fig. 5) and prevents recurrent stone formation [171, 172]. Currently available alkalinizing agents are sodium bicarbonate (either in tablet form, or as baking powder, which can be dissolved in fruit juice to improve palatability) and potassium citrate (either in liquid, effervescent or tablet form: availability varies e.g. in the UK, tablets are not licensed for use, are available on an individual patient basis only and are prohibitively expensive). Some experts caution that sodium bicarbonate can increase calcium excretion, and thus increase the risk of calcium stones: this concern is probably misplaced, as sodium bicarbonate does not have the same effect on urine calcium excretion as sodium chloride [173]. Equipping patients with urine dipsticks and advice on how to titrate the dose of alkali to achieve a fasting urine pH of >7 can be an effective treatment strategy, depending on the activation and health literacy of the patient.

Surgical Aspects of Kidney Stones

Renal Colic

Renal colic is the term used to describe the pain experienced from obstruction of the ureter and should more correctly be termed ureteric colic. It can be one of the worst pains ever experienced and is caused by obstruction and spasm of the ureter. Pain classically starts suddenly and radiates to the flank, groin and testes or labia majora. It is an important teaching

point that although the pain is often assumed to be from stone (or stone passage), any acute obstruction of the ureter will cause the same symptoms so other causes are sloughed renal papilla or clot from a bleeding transitional cell carcinoma. All patients should have a urine dipstick (±urine culture) as well as blood tests for renal function, calcium and urate [174].

Non-contrast CT KUB (Fig. 6) is the recommended imaging of choice for patients presenting with renal colic [175] due to its high sensitivity and specificity and has almost completely replaced intravenous urogram (IVU) in most countries. Low dose protocols can be implemented to limit the radiation dose. Ultrasound is an alternative as an initial screening tool with the benefit of avoiding ionizing radiation although often patients will still require a CT in the situation of acute flank pain. It may be particularly useful in children and young adults [176] when an alternative diagnosis is more likely e.g. young female patients.

Patients usually require urgent pain relief. Non-steroidal anti-inflammatory medication (NSAID) should be offered first line [175, 176] along with intravenous paracetamol [176]. Opiates should be used as second line treatment for refractory pain. NSAID's have been shown in numerous trials to have better analgesic efficacy than opioids and avoid the side-effect profile of opiate medication [175]. There is no role for anti-spasmodic medication.

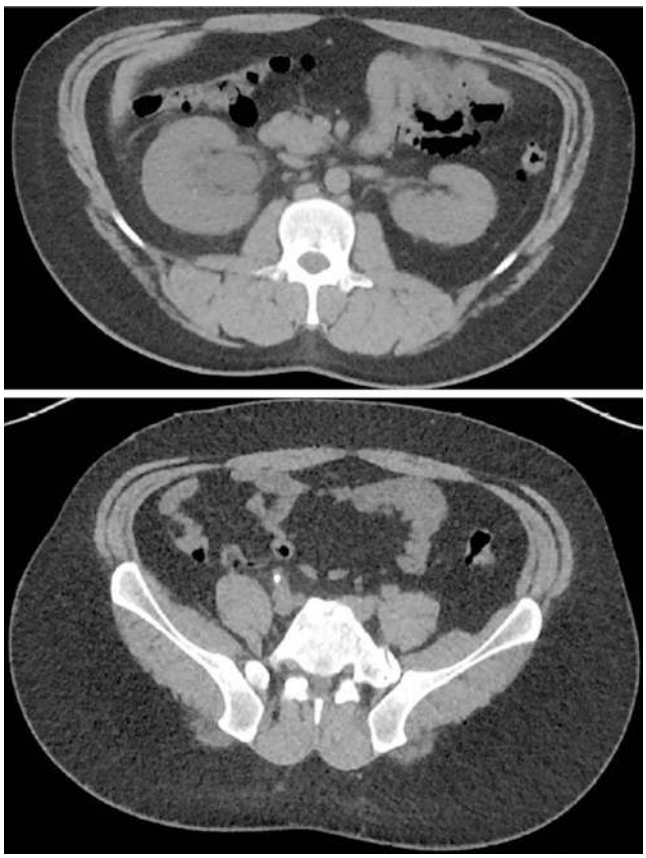

Fig. 6 Two axial slices of a CT scan of a patient with renal colic demonstrating hydronephrosis, mild perinephric stranding (top image) and a mid-ureteric stone (lower image). Ultrasound alone would have shown hydronephrosis but would not have seen the stone in that location

Management will depend on the clinical situation and will depend on numerous factors including presence of a normal contralateral kidney, renal function, evidence of infection/sepsis, size and location of the stone. Urgent surgical intervention is recommended in four situations: presence of an infected obstructed kidney, obstruction of a solitary kidney, bilateral obstruction or if there is uncontrolled pain [174]. An infected obstructed kidney is a surgical emergency as patients can become seriously unwell with sepsis and can be a cause of mortality. Patients should be treated with broad spectrum intravenous antibiotics, fluid resuscitation and urgent decompression of the kidney. This can be with either percutaneous nephrostomy or ureteric stent placement [177] and choice will depend on local preference and availability, stone characteristics and patient factors (obesity, coagulopathy, previous reconstruction etc.). Decompression should take place as soon as possible and treatment to the stone itself should not be attempted due to the risk of worsening the sepsis.

If the patient is well with normal renal function, no sepsis, normal contralateral kidney and controlled pain then often they can be managed conservatively and given chance to pass the stone spontaneously. Medical expulsive therapy (MET), mainly with alpha blockers, have been used to aid stone passage. However a number of high quality randomized trials have questioned the benefit of MET in recent years [178] although at the time of writing many guidelines continue to recommend the use of MET [175, 176] because of the cheap cost and favourable safety profile. The most benefit is likely for larger distal ureteric stones 5–10 mm in size [175]. Stones that fail to pass should be offered surgical treatment with either shockwave lithotripsy or ureteroscopy. Stones that are unlikely to pass e.g. large upper ureteric stones should be offered early intervention.

Stones in the Kidney

When stones form in the kidney they are often asymptomatic and are a common incidental finding on other imaging as it is estimated to be found in 8–10% of screened populations [179]. Thus it is important to realise that not all stones need treatment and small asymptomatic stones may be suitable for observation [175]. However patients with metabolic causes, such as those caused by intestinal disease, would be at higher risk of complications (stone growth, infection, colic) and should be carefully monitored if conservative treatment is chosen.

Stones in the kidney can cause a range of symptoms including discomfort, haematuria and infection. The presence of symptoms, stone growth, local obstruction, patient preference, social situation (e.g. a frequent traveler) would all be indications for intervention [176].

Fig. 7 A modern shockwave lithotripter

Stone Dissolution Therapy

Realistically only uric acid stones can be dissolved by medical management. The stone type maybe known from previous stone analyses or can be judged from radio-lucency (pure uric acid stones are not seen on plain KUB X-ray); stone density (Hounsfield Units of uric acid stones tend to be low) or surmised by body habitus (obesity), raised serum urate levels and/ or history of gout.

If there is a high suspicion of a uric acid stone then and there is no immediate need for surgery (e.g. obstruction) then attempt can be made to dissolve the stone by raising the pH of the urine with either sodium bicarbonate or potassium citrate. Regular pH monitoring should be undertaken to ensure that adequate levels (pH > 7) are reliably reached [175]. Regular imaging, often with ultrasound, should take place to track dissolution. Whilst sometimes disappointing, oral chemolysis can sometimes give spectacular results with dissolution of even complete staghorn stones.

Extracorporeal Shockwave Lithotripsy (ESWL)

ESWL (Fig. 7) was introduced in the early 1980s and revolutionised the treatment of urinary stones at the time [180]. Prior to this relatively few other options were available and open surgery was often required even for relatively small stones. The principal of the non-invasive treatment is that shockwaves are generated and targeted using either ultrasound or X-ray localization to the stone with the aim of fragmenting into smaller pieces which pass spontaneously. The first machines required general anaesthesia and hoisting into a water bath but modern machines typically require only oral analgesia or sedation with a thin water film as coupling

medium. The procedure is often performed by trained technicians/radiographers.

Unfortunately not all stones fragment with ESWL and making sensible choices improves stone-free rates. Consideration needs to be given to patient habitus as obesity makes targeting the stone more difficult with longer skin-to-stone distances and attenuation of the shockwaves. In addition large stone burdens significantly increases the risk of complications with ureteric fragments causing a steinstrasse (literally a stone-street of stone fragments in the ureter). Anatomy is important because success rates for stones in the lower pole of the kidney are lower as the fragments sit there are don't drain and lead to stone recurrence [175]. Thus assessment can be made of the angle and depth of the lower pole calyces [181]. Consensus guidelines suggest stones up to 2 cm can be offered ESWL in the renal pelvis, mid or upper pole and up to 1 cm in the lower pole [175]. Many urologists are likely to take into consideration other factors such as stone density and skin-to-stone distance. Certainly, if the stone does not respond in 2–3 treatments then alternative treatments should be offered. Complication rates are lower for ESWL compared with more invasive treatments and often patients will choose this as an initial treatment option.

Contraindications are bleeding diathesis, pregnancy, untreated urinary infection, distal obstruction, significant hypertension and proximity to abdominal aortic aneurysm [181]. Complications include haematuria, perinephric haematoma, renal colic. Previous concerns that it might cause development of diabetes have not been substantiated in large population based studies [182].

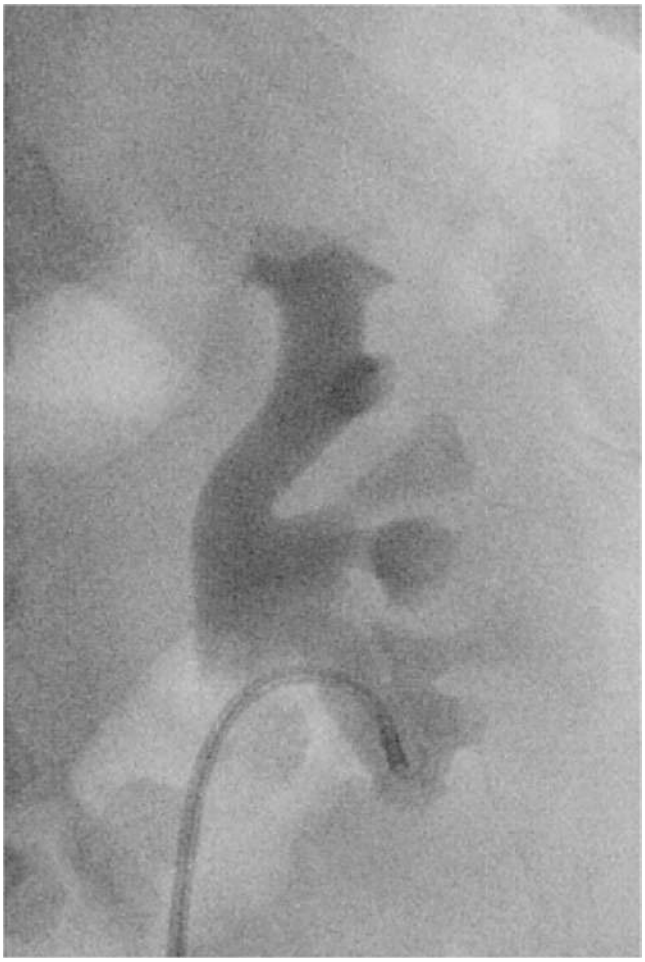

Fig. 8 An image intensifier image from the operating theatre with contrast opacifying the collecting system and a flexible ureteroscope (passed from the urethra and through the bladder) deflected into the lower pole

Uretero-renoscopy

Ureteroscopy can either be with a semi-rigid instrument—commonly called rigid ureteroscopy (rURS) or with a flexible fibre-optic instrument—flexible ureteroscopy (fURS) (Fig. 8), also known as retrograde intrarenal surgery (RIRS).

rURS is typically used to access stones in the lower, mid or upper ureter, while fURS is also used to access the upper ureter and the pelvi-calyceal system of the kidney. Advances in technology since the 1980s with smaller instruments and wider availability of wires, baskets and the holmium laser has made ureteroscopy a popular choice for all ureteric stones and renal stones up to 2 cm in size. Recent advances have seen the wider use of digital and disposable instruments.

Ureteroscopy requires general or spinal anaesthesia and is performed via the urethra. A guidewire is placed in the kidney and then followed with the ureteroscope. If small, a stone can be removed with a nitinol basket but usually it will be fragmented using the Holmium laser into dust and tiny fragments. Often a ureteric stent is left afterwards to ensure drainage of the kidney, allow oedema to settle and dilate the ureter to facilitate passage of the stone debris. Ureteric stents lead to a lot of the morbidity associated with ureteroscopy with 80% of people finding a reduction in quality of life [183].

Percutaneous Nephrolithotomy (PCNL)

The other major advance in the treatment of stone disease was PCNL with the first report in 1976 [184]. This became popularized in the 1980s around the world and is the mainstay of treatment for larger renal stones (Fig. 9a, b). Historically the procedure was performed in the prone position with ultrasound and fluoroscopy used to gain access to the kidney with a needle and guidewire. This tract was then dilated to 26–30 Fr to allow endoscopy, stone fragmentation and retrieval. Even the largest of staghorn stones can often be removed via a single tract.

More recently the supine position has become more popular and miniaturisation of instruments as small as 4.8Fr used for the procedure. Commonly mini-PCNL (11–20 Fr) is used for medium sized stones with larger tracts reserved for larger

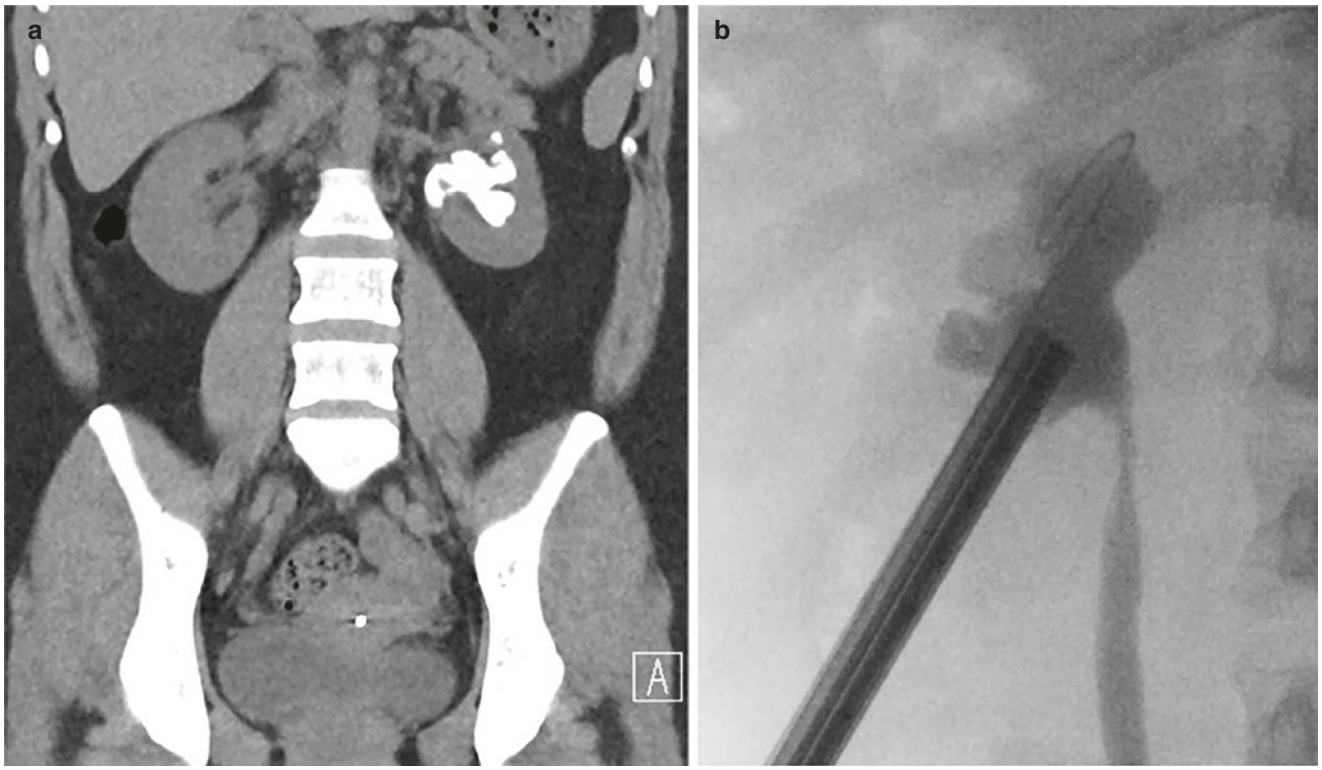

Fig. 9 (**a**) Complex staghorn stone of the left kidney. (**b**) Intraoperative Image intensifier image during PCNL showing the nephroscope (and guidewire). The stone has been cleared and contrast outlines the pelvicalyceal system

stone burdens [184]. Guidelines would suggest that stones >2 cm are best treated with PCNL [175], however miniaturisation has led to mini-PCNL taking on smaller stone burdens and a clear overlap in stone size indication with fURS. Patients are commonly left with a small bore nephrostomy afterwards with the benefit of avoiding an internal JJ stent. Ongoing trials are examining the best treatment modality for lower pole stones 1–2 cm in size.

One of the advantages of the supine position has been the advent of combining both fURS and PCNL simultaneously—endoscopic combined intra-renal surgery (ECIRS). This potentially offers the best of both worlds with the ability to retrieve large stone burdens via the PCNL tract, whilst access all the calyceal system with the fURS. Stones can potentially be moved to the PCNL surgeon—so called 'pass the parcel'.

PCNL is the most invasive of the procedures described in this chapter. Common risks include bleeding with risk of transfusion up to 7% [175] although this is commonly much lower. Other risks include fever, sepsis, injury to other organs (bowel, liver, spleen, pleura). A risk of 1:1000 of needing nephrectomy is often quoted if bleeding is uncontrolled. It is likely these risks are reduced with miniaturised techniques.

Choice of Treatment

When deciding on the choice of treatment consideration has to be given to size and location of the stone(s), anatomy of the kidney, stone type (if known), hardness of the stone (can be judged from previous surgery or by measuring the Hounsfield Units of the stone), patient preference and surgical experience. Careful patient counselling is required given the obvious differences between the treatments to ensure patient expectations are met whilst giving the best chance of stone clearance. For smaller renal stones <1 cm often ESWL will be offered 1st line with fURS as 2nd line treatment. For stones 1–2 cm, all 3 options are reasonable, and choice will depend on stone and anatomical characteristics as well as surgical opinion and patient choice. For stones >2 cm PCNL should be the 1st line treatment. Stone location and anatomy are important considerations e.g. a 15 mm stone in the lower pole of the kidney may be offered different treatment options to a 15 mm stone in the upper pole.

For patients with intestinal disease where recurrence risk is high then ensuring complete stone clearance is important and thus more invasive treatments may be considered, although this must be traded off against the high risk of needing repeat interventions in the future for recurrent stone formation. Ultimately careful review of these patients by a stone specialist taking into account patient choice is important to make the correct decisions.

Follow-up

Regardless of treatment choice, all patients with intestinal disease should have a thorough metabolic evaluation to mini-

mize risk of further stone formation. Follow-up for future stone formation should be undertaken. Usually this will be with periodic ultrasound and/or plain KUB X-ray (remembering uric acid stones are not seen on plain X-ray) although the timings of this will depend on the frequency of previous stones and anticipated risk going forwards.

Bone and Joint Disease

Loris Pironi and Anna Simona Sasdelli

Key Points

1. A metabolic bone disease (MBD) characterized by osteopenia, osteoporosis or osteomalacia may affect 40–100% of patients on home parenteral nutrition (HPN) for chronic intestinal failure. Fifty percent will have osteopenia/osteomalacia when parenteral nutrition (PN) starts.
2. Osteopenia occurs in 13–57% and osteoporosis in 18–44% of patients receiving long-term HPN. It is more common in those who were young when starting PN and in those with a low body mass index (BMI). Many (35%) have bone pain.
3. The common reasons for bone mineral loss are general causes or underlying disease rather than intestinal failure (IF)/HPN. These include: older age/female, reduced physical activity, low sunlight exposure, smoking/alcohol, chronic inflammation and medication (e.g. corticosteroids, long-term anticoagulation).
4. Vitamin D deficiency is common in those not having daily PN with Vit D supplementation.
5. PN composition can affect the calcium loss in the urine. Excessive sodium should be avoided and the amino acid content kept to less than 2 g/kg/day. At least 7.5 mmol calcium and 30 mmol phosphorus daily promotes their net retention.
6. A Dual-energy-X-ray absorptiometry (DEXA) measurement is made from the lumbar spine representing trabecular bone, and at the femoral neck representing cortical bone. The result of DEXA is expressed as a number of standard deviations from mean bone mineral density. Two scores are given that relating to young adults (T-score) and that relating to age and sex-matched healthy subjects (Z-score). A T-score between −1 and −2.5 SD is osteopenia and lower than −2.5 SD is osteoporosis.
7. DEXA is recommended at yearly intervals. Biochemical measurements of serum concentrations and 24 h urinary excretion of minerals (calcium, phosphate and magnesium) are made every 4 months and the measurement of serum parathormone (PTH) and 25-hydroxivitamin D every year. Vitamin K is assessed indirectly every 4 months with the international normalised ratio (INR).
8. Treatment of osteopenia/osteoporosis includes life style changes (stop smoking, little alcohol, more exercise and some sunlight exposure). Adequate vit D, calcium and magnesium intake is ensured and if necessary biphosphate infusions are given (being aware of the rare complication of osteonecrosis of the jaw) or denosumab.
9. As there is a loss of the diurnal parathormone rhythm with nocturnal PN, daytime PN may be considered.
10. Chronic hypomagnesemia in patients with a short bowel may result in symptomatic chondrocalcinosis.

Introduction

The adult skeleton is composed by trabecular or cancellous bone and by cortical bone. The trabecular bone appears as filaments that form the internal structure of the bones and gives the bone its compressive strength. The cortical bone is located around the circumference of bone and consists of thick and densely packed layers of mineralized collagen. On an annual basis, about 4% of cortical bone and 28% of trabecular bone undergo to remodeling (or bone turnover), that is required to repair and reinforce bone to compensate for the mechanical stress placed on the skeleton. Remodeling consists of the balanced activity of skeletal destruction (or bone resorption) by osteoclasts and skeletal reconstruction (or bone formation) by osteoblasts. Skeletal remodeling is regulated by numerous factors, including parathyroid hormone (PTH), vitamin D, and serum calcium, magnesium, and phosphorus concentrations [1–3].

Nygaard L, 2017	148	32%	57%

A metabolic bone disease (MBD) characterized by osteopenia, osteoporosis (Fig. 1) or osteomalacia may affect the 40–100% of patients on home parenteral nutrition (HPN) for chronic intestinal failure (CIF) [1, 4, 5] (Table 1).

Osteomalacia is characterized by defective mineralization and increased osteoid, which is the unmineralized bone matrix. Osteopenia is a state of low bone mass due to a decrease in bone mineralization that precedes the state of osteoporosis, characterized by a loss of bone mass due to an equal reduction in bone mineral and bone matrix [1–3].

The prevalence of MBD in patients with CIF was evaluated in a European multicentre survey [4] by dual-energy-X-ray absorptiometry (DEXA) at lumbar spine and femoral neck. This cross-sectional study showed that 43% of patients had osteopenia and 41% had osteoporosis. Associations between bone mineral density (BMD) and age at diagnosis of intestinal failure (lower BMD in younger patients), with body mass index (higher BMD with higher BMI) [6] and age at starting HPN (lower BMD in younger patients) [7] have been reported. Only the study by Raman et al. [8], reported a significant negative association between BMD and duration of HPN.

Actually, the real incidence of MBD during HPN is unknown. Indeed, a MBD frequently affect patients with intestinal insufficiency, who never underwent HPN [9] and a MBD is frequently present before the beginning of the HPN program [10]. Furthermore, as reported by longitudinal studies, long-term HPN is not necessarily associated with a worsening of bone health; in some cases an improvement on BMD may occur [7, 11–15].

Clinical Features

The main features of MBD in long term HPN may be asymptomatic osteopenia, bone pain localized mainly at spine and lower joints or bone fractures occurring with no or minimal trauma. The ESPEN prevalence study [4] showed that the lowest values of BMD were associated with bone pain in 35% of patients (mainly at spine, knee, hip, ankle, feet and hands) and with bone fractures in 10% (spine, rib and hip). Moreover, the patients' physical rehabilitation status may be negatively affected by MBD [16, 17].

Histology

The presence of either osteomalacia [13, 18–21] or osteoporosis [13, 19, 20, 22, 23] have been reported by histomorphometric studies. A low bone formation rate [2, 13, 18–22], as well as increased bone turnover [19, 23] or defective mineralization [18] were shown in most of the patients by the analysis of the dynamic histomorphometric indices.

HPN-associated MBD seems to be characterized by low bone turnover. The only one follow up observation performed by bone histology reported that most of the patients had a hyperkinetic bone turnover at the first assessment, evolving to a low bone formation rate 6–12 months later [18]. Data consistent with the early results by bone histomorphometry were reported by an observation using a bone formation marker serum osteocalcin (OC) (a hydroxyapatite-binding protein made by osteoblasts, odontoblasts, and hypertrophic chondrocytes which constitutes 15% of the non-collagenous bone matrix) and a bone resorption marker urinary pyridinium cross links; together they provide markers of bone turnover [24].

Pathogenesis

In patients on HPN, MBD is mainly due to general factors, like aging, postmenopausal status, alcohol and tobacco abuse, and to factors related to the patient's underlying disease (disease-associated MBD). However, accelerated bone loss has been reported during the HPN (HPN-associated MBD), raising the question of a specific role of HPN-related factors [11, 12, 25].

Disease-associated MBD has a multifactorial pathogenesis [1]. Some risk factors may be related to life-style changes, such as reduced physical activity and low sunlight exposure. Intestinal malabsorption of calcium, magnesium and vitamin D, calcium losses in the gut lumen, chronic inflammation and drugs, such as corticosteroids, immunosuppressive, loop diuretics, long-term anticoagulation with heparin or warfarin, are other disease-related factors. Chronic inflammation causes both increased bone resorption and decreased bone formation due to cytokines such as Tumour Necrosis Factor (TNF), Interluekin-1 (IL-1), Interleukin-6 (IL-6) and to Prostaglandin E2. In patients with a short bowel, the metabolic acidosis due to intestinal losses of bicarbonate or to D-lactic acidosis can activate the bone buffering systems may be directly affected by calcium and phosphorus resorption and can impair the metabolism of vitamin D.

There are several hypothesis about the HPN-related factors. In the seventies, aluminium overload due to aluminium contamination of the amino acid solutions deriving from caseine hydrolysis was demonstrated to be associated with high serum concentration and urinary excretion of aluminium, positive aluminium staining in bone, low serum concentrations of PTH and of 1,25 dihydroxyvitamin D and hypercalciuria, and an histologic feature of osteomalacia [21, 26, 27]. The reversal of this feature was observed by replacing casein hydrolysate with crystalline amino acid solutions, containing negligible quantities of aluminium [28]. Aluminium impairs bone mineralization by deposition at the mineralization zone of bone and by reduces the secretion of PTH, whose physiologic activity is to stimulate bone formation. The enzymatic conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D by the specific renal enzyme is also blocked by aluminium, thus directly inhibiting proliferation of osteoblasts [26]. Caseine hydrolysate solutions are no longer produced now-a-days, but other nutrient solutions, such as phosphate salts, calcium gluconate, vitamins and trace metals still may be contaminated with aluminium [26]. It may be possible to observe mild increase of serum aluminium concentrations, without an association with positive aluminium staining in bone histology [22].

Also vitamin D deficiency or toxicity may be related to MBD. Vitamin D increases intestinal absorption of calcium, phosphorus and magnesium, and enhances renal tubular calcium resorption. In bone, vitamin D induces osteoclast formation and bone resorption that indirectly promote bone mineralization via maintenance of extracellular calcium and phosphorus concentrations in a supersaturated state. Osteomalacia in adults and rickets in children are the consequences of vitamin D deficiency. Furthermore, the development of the giant osteoclast, as well as the regulation of the immune system, and of several cell functions, are significantly improved by vitamin D [29].

Most of adult patients on HPN (77–100%), who were receiving IV multivitamin supplementation including for each infusion day the recommended amount of 200 IU vitamin D3 (cholecalciferol), have been reported to have either vitamin D insufficiency or deficiency, diagnosed by serum concentration of 25-hydroxivitamin D <30 or <20 ng/mL, respectively [30, 31] (Table 2). When reading these results, however, it should be kept in mind the 25-hydroxivitamin D serum concentration behaviour as a negative inflammatory index. Therefore, the serum concentrations of inflammatory

Table 2 Vitamin D status in patients with intestinal failure or intestinal insufficiency, according to serum 25OH-vitamin D concentration (lower limit)

Author, year	Patients n.	Vit D insufficiency	Vit. D deficiency
Goodman WG, 2000	6, on HPN for CIF		100% (<50 nmol/L)
Compher C, 2007	8, on HPN for CIF		100% (<20 ng/mL)
Corey B, 2009	35, on HPN for CIF		77% (<30 ng/mL)
Thomson T, 2011	22, on HPN for CIF	27% (20–30 ng/mL)	68% (<20 ng/mL)
Kumar PR, 2012	15, on HPN for CIF	33% (27.5–75 nmol/L)	0 (≤27.5 nmol/L)
Ellegard L, 2013	106, on HPN for CIF		67% (<50 nmol/L)
Nygaard L, 2017	96, on HPN for CIF	28% (25–50 nmol/L)	14% (<25 nmol/L)
Nygaard L, 2017	71, intestinal insufficiency (no HPN)	31% (25–50 nmol/L)	17% (<25 nmol/L)

indices, such as C-reactive protein, should be considered when interpreting 25-hydroxivitamin D serum concentrations [32].

A higher risk of vitamin D deficiency was reported for those patients who did not receive daily administration of HPN [31]; moreover, during transition from HPN to enteral nutrition an increased risk has been observed [33]. High doses of oral vitamin D failed to achieve appropriate 25-hydroxivitamin D serum levels in patients with short bowel syndrome, either receiving HPN [34] or not [10].

According to a few studies from the same research group, the hypothesis of vitamin D-poisoning has been advanced. It seemed that the PTH secretion may be impaired by the daily intravenous infusion of 25-hydroxivitamin D amounts equal to the RDA for adult healthy people. Consequently, despite normal serum 25 hydroxyvitamin D concentrations, PTH physiologic effects like bone mineralization and 1,25-dihydroxyvitamin D synthesis might not occur. An increase of BMD together with the normalization of PTH and 1,25-dihydroxyvitamin D were observed after vitamin D withdrawal [25, 35]. These findings haven't been confirmed by any studies in the last decade.

Patients on HPN show frequently high urinary calcium excretion [13, 18, 19, 21–23]. The urinary excretion of electrolytes before (diurnal, 12 h) and during (nocturnal, 12 h) parenteral nutrition was measured by Boncompain-Gerard et al. [36] in 16 patients. Compared with diurnal urine, a significant increase in urine volume and excretion of urea, creatinine, sodium, magnesium, and phosphate but not potassium was observed in nocturnal urine. Referring to 24-h calciuria, 7 patients had normal values whereas 9 had hypercalciuria. Although the calcium supply was identical, only the hypercalciuric patients had diurnal hypercalciuria, whereas both had excessive nocturnal calciuria. In patients with normocalciuria BMD was slightly, although not significantly, higher, but in all patients, BMD had a significant correlation with calciuria. A positive correlation between renal calcium loss and the amount of infused amino acids, glucose, sodium and calcium with the parenteral nutrition solution has been shown by several cross-sectional studies [12]. Contrarily, other studies reported a negative correlation between urinary calcium and intravenous phosphate load, appearing to enhance calcium reabsorption by the renal tubules, independently of PTH actions [37–39]. Bone calcium reabsorption can be induced by metabolic acidosis, due to titratable acids produced by the metabolism of neutral and sulphur-containing amino acid [1, 12]. Finally, according to the study of Wood [40], cyclic infusion more than continuous infusions seem to be associated with a greater calciuria. Hypercalciuria during HPN may be related to both increased glomerular filtration rate (i.v. fluids, amino acids, calcium and sodium, metabolic acidosis) and decreased reabsorption by the renal tubules (excessive i.v. amino acids, glucose and calcium and low i.v. phosphate) [12]. According to some human studies [41] and an investigation on a nonhuman primate model, a reduction of renal calcium losses may occur during HPN adaptation [42].

It has also been hypothesized that the balance of the effect of PTH on bone between resorption and formation might be altered in the direction of resorption by parenteral nutrition [43]. According to Goodman et al. [20], the regularity of PTH secretion together with moderate but persistent elevations in serum PTH concentrations would be increased by long-term HPN. Consequently, the PTH-related peptide receptor expression might be lowered and the response to physiological blood concentrations of PTH in target tissues might be diminished. Bone formation and turnover and the renal calcium resorption would be both reduced.

HPN-associated MBD might also be related to deficiency or toxicity of micronutrients known to interfere with bone metabolism [1, 19, 23]. In patients with SBS receiving HPN a positive correlation between serum fluoride concentrations and lumbar BMD, but no correlation with femoral neck BMD, have been observed [44]. This data reflect the action of this electrolyte on trabecular bone formation, increasing cancellous bone density, but having no effect on cortical bone density. However, as some studies describe, the risk of fluoride toxicity must also be considered: actually an increased risk for bone fractures has been associated with high amounts of fluoride in drinking water. Other factors involved in bone formation are osteocalcin, matrix Gla protein (a small vitamin K-dependent protein, that is the most powerful natural occurring known inhibitor of calcification in humans), and protein S, which is also a vitamin K-dependent protein. HPN patients supplemented with vitamin K seemed to have a trend toward a better hip BMD compared with patients without supplementation, as described by Aljarallah et al. [45]. There are no studies investigating the role of boron, silicon and copper deficiency in MBD as well as the potential toxicity from other micronutrients, like vitamin A, cadmium, strontium and vanadium, in patients on HPN [46].

Finally, according to a limited number of human studies and a large number of animal investigations, low BMD during HPN administration is the result of a chronic inflammatory condition characterized by increased circulating concentrations of pro-inflammatory cytokines, such as TNF-αand IL-6, which stimulate osteoclast activity. Both the lack of significant small intestinal mass (as in short bowel syndrome) or the absence of small intestine stimulation (as in dysmotility syndromes), as well as the components within the PN solution, like lipid emulsions rich in omega-6, may lead to this chronic inflammation. Another suggestion is that the immune system interacts with the catheter as a foreign body, leading to inflammation [47].

Table 3 Instrumental and biochemical parameters for the diagnosis and follow up of metabolic bone disease in patients on home parenteral nutrition for chronic intestinal failure due to benign disease (frequency of assessment)

• Bone mineral density by dual-energy-X-ray absorptiometry (DEXA) (at starting HPN, then yearly)
• Serum and urinary Ca, Mg and P (every 4 months; additional measurement according to the clinical feature)
• Serum 25-hydroxyvitamin D, PTH and markers of bone turnover (yearly; additional measurement according to the clinical feature)
• Serum 1,25-dihydroxyvitamin D (in case of suspected vitamin D toxicity)
• Serum aluminium and other micronutrients (according to the clinical suspicion)
• Bone biopsy (with/without) double tetracycline labelling (if doubtful diagnosis between osteomalacia and osteoporosis)

Diagnosis and Follow Up (Table 3)

The guidelines for CIF of the European Society of Enteral and Parenteral Nutrition (European Society of Clinical Nutrition and Metabolism) (ESPEN) [48] recommend that for routine purposes both diagnosis and monitoring of MBD is based on a combination of bone densitometry scanning (Dual-Energy X-ray Absorptiometry, DEXA) and biochemistry. DEXA is used for the definition of the degree of MBD at starting HPN and its evolution during the treatment, whereas biochemical parameters are important for the assessment of bone turnover and the investigation of the potential pathogenetic mechanism (Table 1). DEXA assessment is usually made at lumbar spine, representing trabecular bone, and/or at hip, with femoral neck, representing cortical bone. The result of DEXA is expressed as a number of standard deviations from mean BMD value of young adult reference mean (T-score) and of age and sex-matched healthy subjects (Z-score). The severity of MBD as osteopenia or osteoporosis has been defined by the WHO Study Group [49] on the basis of the T-score value. The relative risk of any fracture has been estimated to be 1.4–1.6 for every decrease in BMD of 1 SD below the BMD Z-score [2]. Also in HPN patients the predictive value of the BMD for the assessment of fracture risk has been suggested [4]. DEXA measures BMD independently of the presence of osteomalacia or osteoporosis; bone histology is mandatory when a differential diagnosis is needed. For BMD monitoring, DEXA is recommended at yearly interval and biochemical assessment, serum concentrations and 24 h urinary excretion of minerals (Ca, P, Mg) every 4 months and the measurement of serum PTH and 25-hydroxivitamin D every year.

Prevention and Treatment (Table 4)

The potential pathogenetic mechanisms determine the prevention and treatment of MBD. The ESPEN guidelines [48] recommend that general risk factors for developing osteoporosis be promptly addressed, as well as factors with a possible negative impact on bone health, i.e. chronic inflammation, infections, drugs and other relevant factors related to the underlying disease, in all patients on long-term HPN.

Table 4 Prevention and treatment of metabolic bone disease in patients on home parenteral nutrition for chronic intestinal failure due to benign disease

General and life-style recommendations
• Regular low impact physical exercise program
• Regular and adequate sunlight exposure (UVB radiation from a tanning bed or other UVB emitting device might be considered)
• Maintain protein-calorie nutritional status
• Diet rich in dairy food (depending on the underlying intestinal functions)
• Avoid cigarette smoking and limit alcohol intake
• Estrogen replacement therapy in perimenopausal and postmenopausal period (depending on the underlying risk for vein thrombosis)
Correction of the underlying disease-related factors
• Treatment of chronic inflammation
• Limitation of bone damaging drugs
• Prevention and treatment of metabolic acidosis
• Oral calcium supplementation (500–1000 mg bid)
• Oral magnesium supplementation (Mg oxide 12–24 mmol/day)
Parenteral nutrition-related factors
• Fluids: as required to maintain fluid balance
• Infusion rate: slowing the infusion rate may decrease hypercalciuria
• Sodium: as required for maintain Na balance; excess urinary Na may induce hypercalciuria
• Minerals (Ca, P, Mg): as required of maintain balance; Ca/P ratio to be adjusted to precent hypercalciuria as well as formation of calcium-phosphate crystals in the admixture
• Acetate: as required to maintain normal serum bicarbonate
Amino acids: balance between requirement for protein synthesis and to avoid amino acid induced hypercalciuria
• Vitamin D: daily iv with multivitamin vials, 220 IU of cholecalciferol or 200 IU of ergocalcipherol; PN infusion <7 day/week: add oral or im vitamin D supplementation as required
• Vit K supplementation: as required to maintain normal prothrombin time
• Aluminium contamination of the PN admixture: <25 μg/L
Drug therapy (published protocols)
• Biphosphonates: clodronate, 1500 mg iv every 3 months; pamidronate, 30–60 mg im/monthly or 90 mg iv every 3–6 months
• Denosumanb: 60 mg sc/yearly

Research and treatment of the general and underlying disease related factors is absolutely important. HPN associated MBD can be prevented by the optimisation of the parenteral solution. Aluminium contamination should be less than 25 μg/L [26]. The amounts of minerals should aim to maintain the normal serum concentrations and 24-h urinary excretions. The Ca/P ratio in the solution should be always carefully observed, although, the optimal ratio cannot always be achieved due to problems of stability in the solution. It has been observed that supplying at least 15 mEq calcium and 30 mmol phosphorus on a daily basis can promote retention of these elements [37]. Berkelhammer et al.

[39], reported a positive calcium balance giving 12 mEq of calcium and 45 mmol of phosphate; according to other studies the phosphate amount should be 33–42 mmol [38]. Thus, to achieve a positive calcium balance it seems to be required a Ca/P ratio ranging from 1 mEq of calcium to 1 or 2 mmol of phosphate. However, chronic excess of phosphorus can lead to bone loss as a result of secondary hyperparathyroidism. Amino acids and sodium should not be added in amounts greater than losses [12]. The recommended intravenous vitamin D for adults is 200 IU/day [1]. In some patients, hypercalciuria may be reduced by slowing the infusion rate [12].

The ESPEN guidelines recommend as the primary step for treatment of metabolic bone disease to optimize the program for parenteral nutrition with the required supplements of vitamin D, calcium and phosphate. Further, medical treatment may be useful to increase bone mineral density and lower fracture risk. Recently, the American Society for Parenteral and Enteral Nutrition (ASPEN) has expressed concern as to whether the daily dose of 200 IU/day in the current PN products is adequate to maintain normal serum concentrations of 25-hydroxivitamin D in most patients requiring long-term PN [50]. Oral or intramuscular vitamin D supplementation, as well as exposure to sunlight or UVB emitting device could be required [29, 51]. Bisphosphonates provided intravenously at regular intervals (Clodronate, Pamidronate, or Zolindronic acid), may support bone mineral health in patients with osteopenia.

An ESPEN survey on the current practice of MBD management in patients on HPN for CIF reported that zolidronate, alendronate pamidronate and clodronate were the most common used [52]. So far, there are only one randomised controlled study and a few prospective observations about the use of biphosphonates in patients on HPN. The study of Haderslev et al. [53] showed that intravenous clodronate could decrease the urinary excretion of markers of bone resorption and maintain BMD at lumbar spine in patients on HPN after 12 months, but has no significant effect in increasing BMD. Improvement of BMD at both spine and hip has been observed with the use of intravenous pamidronate [8, 54]. The case-report reported normalized BMD after 18 months in a patient on HPN for short bowel syndrome with osteoporosis, treated with the subcutaneous administration of the recombinant PTH, teriparatide [55]. Another case report suggests that BMD may be also improved by growth hormone used to treat short bowel syndrome [56]. A recent study reported an improvement of BMD assessed by DEXA in patients on long-term HPN, after 12 months of treatment with denosumab, a fully human monoclonal antibody that inhibits bone resorption by neutralizing receptor activator of NF-κB ligand (RANKL) (a mediator for osteoclast formation and function) [57].

Joint Diseases and Enterophatic Arthritis

Two case reports described patients with chronic hypomagnesemia induced by SBS who developed symptomatic chondrocalcinosis due to deposition of calcium pyrophosphate dihydrate (CPPD) crystals in hyaline and fibrous cartilage [58, 59]. Magnesium deficiency in SBS is the consequences of intestinal malabsorption, increased renal losses and inadequate supplementation. Malabsorption is due to the loss of bowel absorptive area, especially ileum and proximal colon, to low 1,25-hydroxy-vitamin D levels leading to abnormal jejunal Mg absorption and to Mg bounding by fatty acids derived from both high dietary fat intake (long-chain triglycerides) and bacterial fermentation of malabsorbed carbohydrates. In patients with dehydration, increased renal losses of Mg result from hyperaldosteronism. Oral supplementation of Mg may cause intestinal motility and diarrhoea, which can further compromise adequate Mg absorption.

Magnesium is a cofactor for alkaline phosphatases, an enzyme playing a key role in converting inorganic pyrophosphates to orthophosphate. Moreover, Mg increases the solubility of CPPD crystals in vitro. Thus, hypomagnesemia could facilitate intra-articular elevation of extracellular inorganic pyrophosphate and/or reduced saturation product of CPPD, thus favouring crystal nucleation of CPPD. The clinical presentation of chondrocalcinosis is characterized by acute or chronic arthritis (attacks of pseudogout, typically in knees and ankles). The diagnosis relies on radiological finding of thin linear calcification of the cartilage. CPPD crystals can be identified by polarizing light microscopy. The prevalence of CPPD increases with age (10–15% for people in the 6 and 7 decades of age), whereas in younger individuals several disease can cause CPPD deposition disease, such as hemochromatosis, hyperparathyroidism, hyperparathyroidism, hypomagnesemia or hypophosphatemia [60]. The treatment of CPPD in SBS patients consists in the correction of Mg deficiency by parenteral supplementation of Mg associated with correction of vitamin D deficiency, administration of opioids to slow bowel transit, and colchicine as a long-term therapy instead of steroids, when required [59].

The underlying disease of patients with CIF may complicate with enteropathic arthritis or enteroarthritis (EA). In 8–36% of patients who underwent intestinal bypass surgery for obesity, polyarthralgia and sometimes arthritis has been reported to occur weeks or years following surgery, as a postoperative complication of this technique. Arthritis affected knee, wrist, ankle, shoulder and finger joints [61].

Inflammatory bowel disease (IBD) represents a good model for the pathological events that may predispose to the development of EA. EA may be diagnosed before, simultaneously or after the diagnosis of IBD, with a prevalence ranging between 17% and 39%. The main clinical features

are peripheral arthritis (women, 25–45 years old, asymmetric mono-oligoarthritis mostly in lower limbs, episodic and recurrent, frequent exacerbations) and axial arthritis (men, strongly association with HLA B27, early onset, and independent from IBD) [62]. The pathogenesis of EA has not been completely clarified; current hypotheses provide a possible relationship between inflammation of the gut mucosa and arthritis, supposing an aberrant migration of intestinal lymphocytes in genetically predisposed subjects. Other potential risk factors for EA are active bowel disease, family history of IBD and cigarette smoking. Other gastrointestinal diseases potentially developing EA are Whipple's disease and celiac disease [62]. Currently, "gold standard" criteria are not yet available. The diagnosis of EA is generally established on the basis of medical history and physical examination, according to the European Spondyloarthropathy Study Group (ESSG) criteria. In established disease, these clinical criteria have a sensitivity of 86% and a specificity of 87% and can be applicable without radiological examination and laboratory testing [62]. The treatment of EA requires different pharmacological therapies for both intestinal and joint disease. Corticosteroids are recommended for patients with mild exacerbations; cyclic intra-articular injections of steroids might have also beneficial effects. Sulfasalazine and 5-aminosalicylic acid can reduce mild peripheral arthritis, particularly in patients with ulcerative colitis, but have no effect on the evolution of joint damage; conversely, methotrexate, azathioprine, cyclosporine, and leflunomide can lead to a reduction of joint symptoms as well as laboratory parameters of disease activity [63]. The anti-TNFα, especially infliximab and adalimumab, are widely used to treat EA for their efficacy on both axial and peripheral symptoms of EA, especially in patients with Crohn's disease; Etanercept, instead, seems to be effective only to control joint symptoms but not the intestinal ones. Other non-pharmacological therapies for the treatment of EA might be probiotics, rest and physiokinesitherapy [64].

Intestinal Adaptation

Julie Bines, Jason Yap, Kelly Tappenden,
and Jeremy M.D. Nightingale

Key Points

1. Intestinal adaptation involves behavioural (hyperphagia), structural (morphological or anatomical) and functional changes.
2. Due to the practical and ethical challenges in conducting clinical studies following massive small bowel resection current understanding of the adaptive response has mainly been derived from animal models. Animal studies usually involve a jejunal resection and rarely a jejunostomy, whereas in man an ileal ± colon resection is more common.
3. Patients with a jejunostomy show no jejunal structural or functional adaptation over time.
4. Patients with a jejunum in continuity with a colon usually undergo a functional adaptive response that may continue to occur for 2–3 years. There may be a degree of structural adaptation. The colon also adapts both structurally and functionally.
5. The mediators for adaptive changes include nutrition, intestinal secretions (especially pancreaticobiliary), gastrointestinal hormones and peptide growth factors (e.g. growth hormone, (GH), Insulin like growth factor-1 (IGF-1), glucagon-like peptide-2 (GLP-2), epidermal growth factor (EGF), peptide YY) and the gut microbiome.
6. Pharmacological approaches may be used to promote adaptation by enhancing intestinal growth and/or function; these include fibre (pectin), glutamine, short chain fatty acids (SCFAs), long-chain fatty acids (LCFAs), GH, glutamine, EGF, GLP-1 and 2 analogues and aminoguanidine.
7. Surgical approaches to resolve mechanical barriers and enhance gut function are aimed at optimising the gut environment and facilitate the adaptative response.

Introduction

Intestinal adaptation is a physiological response following intestinal resection aimed at restoring the digestive and absorptive capacity of the remaining bowel to meet metabolic and growth requirements. Following intestinal resection, a number of mechanisms also contribute to malabsorption; such as gastric acid hypersecretion, impaired motility with rapid transit of intestinal content, bacterial overgrowth and excess water secretion when presented with an osmotic load [1]. The severity of malabsorption is influenced by the primary indication for intestinal resection, the residual length and segment of the remnant intestine [2]. For example, resection of the peptide YY producing distal ileum and proximal colon compromises the inhibitory function known as the "ileal and colonic brakes" that would normally delay gastric emptying, slow small intestine transit time and influence early satiety [3–6].

In an effort to compensate for the malabsorption due to the loss of intestinal length; altered diet a) and slowing of intestinal transit in occurs. The stomach and colon contribute to absorptive function that normally would be performed

J. M.D. Nightingale (ed.), *Intestinal Failure*, https://doi.org/10.1007/978-3-031-22265-8_29

by the small intestine [7]. The remaining small intestine undergoes adaptation changes to recover absorptive and functional capacity. Intestinal adaptation involves a broad range of changes, including changes in behaviour (hyperphagia), morphologic (structural and ultrastructural) and functional changes in the residual bowel [8]. Evolving knowledge of the molecular mechanisms involved in regulating the adaptive response provides the opportunity to identify targets and novel therapies to stimulate and enhance the adaptive response.

Due to the practical and ethical challenges in conducting clinical studies following massive small bowel resection, current understanding of the physiology of the adaptive response has mainly been derived from animal models. Studies in rodent models have been used extensively for studies describing intestinal adaptation whereas the large animal models, such as the porcine model are considered to more accurately reflect human gastrointestinal physiology and nutrition. Differences in the age and maturation stage at time of resection may impact elements of the adaptive response and studies from neonatal and growing animals may more accurately reflect the response in infants and children.

Hyperphagia

An early clinical feature of adaptation is an increase in food intake (hyperphagia) that occurs in compensation for the macronutrient malabsorption. Hyperphagia is reported in 70% of adult SBS patients and is defined as an oral intake >1.5 times their resting energy requirements. Hyperphagia may indirectly contribute to the morphological and functional adaptation of the remnant bowel through the provision of luminal nutrients. The development of hyperphagia in SBS patients, particularly after colonic continuity is re-established (by re-anastomosis), is considered a good prognostic indicator. The mechanism controlling hyperphagia is not well understood. In rodents jejuno-colonic anastomosis has been associated with elevated levels of serum ghrelin and peptide YY [9]. Ghrelin promotes appetite while PYY suppresses it. In addition, the hypothalamic mRNA levels of orexigenic Neuropeptide Y (NPY) and Agouti-related peptide (AgRP) were noted to be markedly elevated following jejuno-colonic anastomosis in rodents, suggesting that the gut-brain axis is involved in intestinal adaptation. Similar serum changes of serum ghrelin and peptide YY were confirmed in humans with a jejuno-colonic anastomosis; and there was also a failure to suppress post-prandial ghrelin secretion [9].

Historically, weight loss to reduce nutritional requirement was hypothesized to be a compensatory mechanism following massive intestinal resection. With the widespread availability of parenteral nutrition support in patients with intestinal failure, weight loss post-surgical resection is no longer considered an acceptable clinical outcome.

Morphologic Adaptation

Stassoff is credited as being the first person to report small bowel 'hypertrophy' and increased absorption in the remaining small intestine of dogs after a large resection of small intestine [10]. After a predominantly jejunal resection in animals (some ileum and colon left intact), there is structural adaptation with dilatation and elongation of the remaining intestine (compensatory hypertrophy), and the villi become longer, crypts deepen and the cell number over a given length of villus increases (epithelial hyperplasia) [11–14], but the size of the enterocytes do not change. These changes are much more marked in an ileal compared to a jejunal remnant [12, 13].

The morphologic features of the adaptive response involve all layers of the bowel wall, including muscular hypertrophy (increased bowel diameter and thickness, increase in length), mucosal hyperplasia (increased cell proliferation resulting in deepening crypts and lengthening of the villi) and angiogenesis (new blood vessel development) (Fig. 1) [15]. There is also an increase in cellular DNA, RNA and protein content [16]. Early crypt proliferation is regulated by IFRD1 (Tis7) which is a transcriptional co-regulator that alters the transcription of target genes (including *cyclin D1* and hedgehog signalling pathway genes including *Gli1, Hhip, Gli2*) through interaction with the mSin3B complex and histone deacetylases [16, 17]. In Tis7−/− mice undergoing mid-small bowel resection, crypt cell proliferation was reduced at 72 h and this was associated with inhibition in the expression of the target genes [17]. Inhibition of expression of hedgehog signalling commences soon after resection and is maintained for up to 2 weeks following 50% small bowel resection in mice [18].

Morphologic adaptation commences 24–48 h after resection in mice with colon in continuity and is characterized by a rapid expansion of putative enterocyte stem cells at 48–72 h that continues for up to 7 days before returning to baseline by 6 weeks [19]. Concurrent with the expansion of the putative stem cell population in the crypts, gut epithelial secretory cells, including goblet cell and Paneth cell proliferation, continue for up to 28 days post-resection [20, 21]. Interestingly, the rate of enterocyte apoptosis is modestly increased and thought to maintain the crypt-villus axis in the presence of an increased enterocyte proliferation [22]. The colon also undergoes morphological and functional adaptation following small intestinal resection. In a mouse model of 60% jejunal ileal resection, colonic adaptation was observed with a twofold increase in colonic mass and crypt depth. These changes were observed despite the absence of enteral nutrition, indicating non-nutritive factors influence colonic adaptation [23]. In the piglet model, early and late features of the

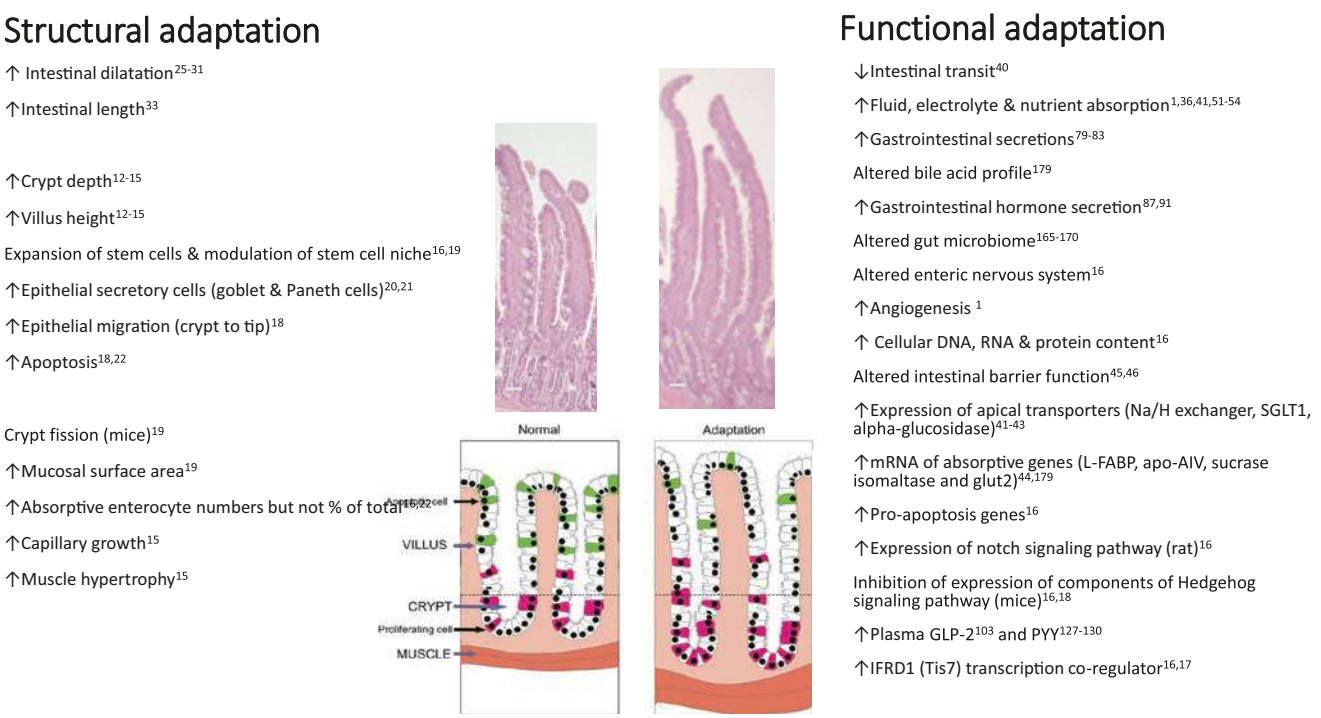

Fig. 1 Features of the adaptive response

adaptive response in the colon were reported, with early changes of increase enterocyte numbers and late changes of increase cell proliferation. Goblet cell and enteroendocrine cell numbers were continuously elevated at all time points of adaptation. Increased nutrient complexity enhanced colonic adaptation in this model [24].

In humans, various case reports have described dilatation of the stomach, duodenum, jejunum, ileum and colon after a massive small bowel resection [25–31]. However, there is a risk that some reports may reflect bowel dilatation proximal to an anastomotic stricture and not morphological adaptation. An increase in bowel length was reported in one case [25]; whereas another case report, with a carefully documented set of observations described over the 5 years from the original resection, demonstrated no change in residual bowel length [32]. This patient had a mesenteric infarction requiring resection leaving 105 cm of small intestine (95 cm jejunum and 10 cm terminal ileum) and a functioning colon remaining in situ. She subsequently had four caesarean sections over 5 years; on each occasion bowel length and diameter was measured [32]. There is also limited clinical data on the microscopic features of adaptation following resection, with the majority of data derived from paediatric studies. In 33 premature infants who underwent small intestinal resection for necrotising enterocolitis (NEC), there was a 32% and 22% increase in villus and crypt depth respectively from baseline, recorded at the time of small bowel stoma closure at a mean 74 days (range 61–90 days) after primary resection [33]. The change in villus height (in mainly ileum) correlated with length of small bowel resected. Similar observations have been observed in adults with enterocyte hyperplasia of 70–75% increase in villus height 2 years after jejuno-ileal bypass surgery in comparison to controls [34].

Colonic adaptation following small bowel resection in humans is poorly documented. Joly et al. studied the colon of 12 adult hyperphagic patients with jejuno-colonic SBS [35]. In patients with SBS compared to controls, the crypt depth and the number of cells per crypt were 35% and 22% higher respectively, resulting in increased absorptive surface [35]. There was no change to the apoptosis/proliferation ratio per crypt. This is the first convincing human study of colonic adaptation in SBS.

Patients with Jejunum–Colonic Anastomosis or Jejunostomy

In small and large animal models, adaptation in the duodenum and jejunum proximal to the site of a large small bowel resection has been observed, supporting a possible role for circulating growth factors in the adaptative response [1]. However, there is little data from human studies to suggest there is significant morphological adaptation in the jejunum of patients with residual jejunum anastomosed to a functioning colon. Two reports of jejunal biopsies from four patients with jejunum anastomosed to colon showed epithelial hyperplasia [36, 37], and a larger study of ten patients showed, not hyperplasia, but atrophy in most patients [38]. There is a lack of data on the impact of a proximal jejunal end-stoma on the adaptive response in animal models due to the practical challenges. No structural features of adaptation have been

observed in biopsies from the distal duodenal mucosa in patients with an established jejunostomy [39].

Functional Adaptation

The remaining intestine may also undergo adaptive changes to increase absorptive capacity of fluid, electrolyte and nutrients. A key measure of functional adaptation is an increase in the absorption of macro- and/or micro-nutrients over a given length of bowel that occurs over time or when compared with normal subjects. Functional adaptation may occur as a result of structural changes (such as an increase in enterocytes or enteroendocrine cells), a slowing of transit time or a range of intracellular events (e.g. increased transport and/or enzyme activity) (Fig. 1) [40]. However these changes are site specific and there is no clinical evidence that remaining jejunum acquires any of the specialized transport functions of the ileum (e.g. vitamin B_{12} or bile salt absorption).

The expression of over 60 proteins have been reported to change in response to massive small bowel resection in a piglet model [41]. Animal studies have demonstrated an increase expression of transporter proteins including the apical sodium glucose cotransporter (SGLT 1), NA+/H+ exchanger and Na+/K+ adenosine triphosphatases [41–43]. Fatty acid transporters L-FABP, FABP-6 and I-FABP are up regulated as early as 2 weeks post resection and gradually increase over 6 weeks in parallel with the increase in total villus area [44]. Serum bile acids and serum triglycerides were observed to increase with the changes in FABP. The upregulation of L-FABP, a known determinant of bile acid metabolism in the liver is speculated to be hepatoprotective against parenteral nutrition-associated liver disease. The increase in transporter function is consequent to both villus cell hyperplasia (e.g.: SGLT1) and functional adaptation on a per cell basis (e.g. enterocytes express increased digestive enzymes and transporters). The overall net result of these changes is to increase the digestive and absorptive capacity of the residual intestine [1, 41]. The translocation of luminal bacteria to mesenteric lymph nodes, blood, liver and spleen in animal resection models have been linked to abnormalities in intestinal barrier permeability [45]. Increased paracellular permeability occurring after small bowel resection has been linked to increased activation of toll-like receptor-4 in a mouse model [46].

Data describing the features of functional adaptation in humans is sparse and inconclusive. Glucose absorption in adults post-resection has been reported to be increased but these studies could not differentiate between increased absorptive capacity as a result of enterocyte proliferation, versus enhanced functional protein expression, or a combination of both. Whereas results of dipeptide and tripeptide transporters PepT1 expression in the human colon have been conflicting [35, 47]. Suffice to say, studies of intestinal adaptation in humans are limited for practical and ethical reasons, including the fact that massive intestinal resection is uncommon, patients are often critically ill and may have a variety of primary aetiologies resulting in the need for resection. Functional adaptation has been observed in children and adults post-resection if the ileum and/or colon are retained, as evidenced by achievement of intestinal autonomy in parenteral nutrition dependent patients, sometimes several years following resection [2, 48–51].

Patients with Jejunum–Colonic Anastomosis, Ileostomy or Jejunostomy

There is limited evidence for structural (morphological) adaptation in patients with a jejunostomy; however, there is evidence for functional adaptation in patients with jejunum anastomosed to a functioning colon and in patients with an ileostomy. In patients with jejunum in continuity with a functioning colon there is a small reduction in faecal weight in the 3 months following a small bowel resection [14]. There is also increased jejunal absorption of macronutrients, water, sodium, glucose and calcium with time [36, 51–54], associated with an increased chance of the patient being able to stop parenteral nutrition [51, 54, 55]. Patients who have an ileostomy following a colectomy (usually for ulcerative colitis) have a reduction in stomal output over the first 4 months after surgery [56–58]. This is not the case, however, when there has also been an ileal resection. In a study of patients who had an 'ileostomy' after an ileal resection, Hill et al. showed, that there was no decrease in ileostomy water, sodium and potassium losses over the period from 11 days to 6 months after the resection [58]. Nightingale et al. demonstrated no change in the nutritional or fluid requirements of patients with a jejunostomy from 6 to 24 months after their last resection [59]. Thus there is no clinical or experimental evidence for functional adaptation in jejunostomy patients.

Timing of Adaptive Changes

In animal models, features of the adaptive response are observed within hours following a surgical resection. In the rat, there is an increase in mucosal DNA synthesis within 24–36 h after a bowel resection. Villus epithelial hyperplasia, probably occurring as a result of increased crypt cell production rather than villus tip cell loss, is evident at 1–2 weeks and maximal at 1 month [13].

In 1959, Pullan described three clinical phases ("Extensive Mucosal Disease: Coeliac Disease and Eosinophilic Enteritis" chapter) after massive small bowel resection in patients with the colon remaining intact. Following the large fluid losses that occurs (phase 1), in phase 2 the emphasis shifts from fluid balance to nutritional support, and over the

next 12–24 months as diarrhoea improves, the amount of nutritional support can be reduced or even stopped. It is during this phase that most adaptation occurs. In phase 3 there is no further clinical improvement and no major adaptive changes occur [60].

While major adaptive changes are clinically evident within a few weeks in those with a retained colon, the full clinical benefits may take years to be complete. For example, intestinal calcium absorption may continue to increase for more than 2 years after the resection [54]. If parenteral nutrition is still required 2 years after a bowel resection, the chances of subsequently being able to wean from parenteral nutrition without additional intervention is limited (~6% of patients) [55]. Data from adults on home parenteral support suggests that no further changes in parenteral nutrition requirements occur after 3 years following resection [1]. Of 57 patients who have bowel continuity restored after a small bowel resection due to mesenteric infarction, 20 (35%) patients were successful weaned from PN within 1 year, 29 (50%) patients weaned within 2 years and 44 (77%) patients with 5 years suggesting that adaptation can continue to occur for up to 5 years in a favourable intestinal environment [51]. There is no reliable measure to determine who will successfully adapt or when maximum adaptation has occurred, although predictions can be made based on a range of clinical factors including age, underlying disease, the length and section of bowel remaining and other co-morbidities. There is currently no accurate biomarker to monitor the adaptative response. Plasma citrulline has been proposed as a useful clinical marker to assess changes in enterocyte cell mass. However the accuracy of plasma citrulline to monitor the progress of the clinical adaptive response remains controversial [61, 62].

Mediators of Intestinal Adaptation

The mediators of intestinal adaptation are multiple and contribute individually to overall intestinal adaptation. These include delivery of intraluminal nutrients, anatomic factors and gastrointestinal resections (Table 1). More recently, research and clinical advances have focussed predominantly on identifying trophic factors that successfully induce rapid adaptation and eventual enteral autonomy (Table 1).

Intraluminal Nutrients

The presence of food within the intestinal lumen ('luminal nutrition') is the most potent stimulus for intestinal epithelial cell proliferation [63]. In the absence of luminal nutrients mucosal atrophy and a decrease in digestive enzyme and transport function is observed. The mechanism whereby food induces adaptation is not entirely known, however, increased dietary complexity and some nutrients, including

Table 1 Factors influencing intestinal adaptation in humans

Factor	Structural adaptation	Functional adaptation
Patient related factors [1, 2, 6–8, 15]		
Age [33, 50]	Potential for >increase in length in young	
Underlying disease mechanism	↓with ongoing inflammation	↓with ongoing inflammation
Co-morbidities	↓with chronic pathology	↓chronic pathology
	↓with multisystem disease and/or specific drugs	↓with multisystem disease and/or specific drugs
Factors related to remaining intestine [1, 12, 13, 15]		
Site of resection/ segment remaining	Maximum adaptation requires presence of ileum	
Extent of resection	~100 cm of SI or 60 cm SI with residual colon needed to wean from PN	
Stoma present		
Jejunostomy [36–39, 50]	Nil significant	Nil significant
ICV absent [1]	↑risk of bacterial overgrowth	Loss of inhibition on gastric emptying and SI transit
Colon present [56–58]	↑crypt depth, ↑cells per crypt, ↑surface area	
Integrity of remaining intestine	↓with ongoing inflammation and disease	↓with ongoing inflammation and disease
Dysmotility [17, 25–31, 174–177]	Dilatation, ↑risk of bacterial overgrowth	
Nutritional factors [63–78]		
Composition (e.g. diet complexity, protein, short chain fatty acids, pectin, glutamine, long chain triglycerides)	Stimulation of intestinal growth	Stimulation of intestinal function
		Modification of intestinal transit
Nutritional status	Support mucosal integrity and repair	Maintain mucosal barrier function
Gastrointestinal secretions [79–84]		
Pancreatic [79, 80]	↑volume of secretions	
Biliary [98, 99, 173]	↑volume of secretions	Alteration in bile acid profile
Hormones and peptide growth factors

Table 1 (continued)

Factor	Structural adaptation	Functional adaptation
Growth hormone [131, 132]	Conflicting data	↑absorptive capacity (PN weaning)
IGF-1 [119–126]		?downstream effector of GLP-2
GLP-2 [85–106]	↑crypt cell proliferation, ↑villus height, ↑surface area	↑absorptive capacity (↓fluid and PN requirement)
		↑absorptive capacity
		↑Tolerance of enteral nutrition
Epidermal growth factor [110–116]		No change in intestinal permeability
Peptide YY [127–130]		↓gastric emptying, SI transit
		↓stimulated intestinal secretion
Gut microbiome		Production of short chain fatty acids
Dysbiosis [166–171]	?enterocyte turnover	Impairment of T-cell proliferation
		?alternation in enteric nervous system function and gut motility
		Microbial-derived metabolites potentially impact a range of functions

PN parenteral nutrition, *SI* small intestine

glutamine, pectin, short chain fatty acid (SCFA) and long chain fatty acids, have a specific trophic effect [64].

Glutamine, a non-essential α-amino acid has been studied extensively with mixed results [65]. Glutamine is the major substrate for mitochondrial in enterocytes with the majority of absorbed glutamine metabolized by the intestine. Glutamine has many functions in the intestine including modulating tight junction expression and inhibition of apoptosis [65–67]. Nevertheless, there is sparse evidence of glutamine supplementation improving adaptation, with lower enterocyte protein and DNA levels observed in participants treated with glutamine when compared to controls [68, 69].

Fats, especially long chain triglyceride, appear to promote intestinal adaptation [70, 71]. Whether polyunsaturated or saturated long chain fat is of greater benefit remain to be convincingly established. Studies of rats fed high polyunsaturated fatty acid showed greater increase in DNA, protein and mucosal weight [72]. While, two other studies of high saturated fat diet showed increase in the transport of glucose, increase villus height and crypt depth [73, 74]. Similarly, intravenous short chain fatty acids (SCFA) have been shown to enhance intestinal adaptation in rats [75, 76]. The tolerability of high fat diet in humans to allow for intestinal adaptation is limited by steatorrhea, especially in those with the colon in continuity. While the data for pectin derived SCFA did not achieve statistical significance for increased fluid absorption in the colon.

Colostrum, which is rich in growth factors (including EGF) and antibacterial peptides, enhanced adaptation in a piglet short bowel syndrome model but in a randomized cross-over study in nine children with short bowel syndrome was not associated with improved intestinal function [77, 78].

Intestinal Secretions

In addition to providing nutrition to the intestinal mucosa, feeding into the gut stimulates pancreatic secretions, stimulates factors essential for bile acid transport and gastrointestinal hormone secretion (i.e. glucagon like pepetide-2 (GLP-2)) and plays a key role in the intestinal adaptive response. In animal models of biliopancreatic bypass, the mucosa of the bypassed limb maintained normal morphology despite exposure only to bilio-pancreatic secretions [79]. The intensity of the adaptation in the bilio-pancreatic limb is markedly less in comparison to animals subjected to massive small bowel resection alone [80]. Sequential experiments introducing bile with or without pancreatic secretions highlighted the compounding effect of pancreatic secretions to intestinal adaptation [81]. Bile delivered to the ileum increased the adaptive hyperplasia of the ileum, regardless of pancreatic secretions. The addition of pancreatic secretions further augmented the adaptation process in the distal small bowel. Bile salt dependent lipase (BSDL) in pancreatic secretions has been identified to have proadaptive activities likely mediated by the Wnt signalling pathway in the enterocytes [82]. The presence of nutrients in the colon may be important in promoting small intestinal adaptation. A colonic infusion of glucose in rats caused jejunal adaptation as measured by an increase in the crypt cell production rate, mucosal wet weight, DNA and protein content per unit length of small intestine [83]. Based on this observation the authors postulated that plasma enteroglucagon is a colonic derived growth factor that stimulates small bowel growth [83]. The reduction of colonic carbohydrate fermentation induced by administration of metronidazole in rats was associated with decreased small intestinal adaptation [84].

Glucagon-Like Peptide-2

Glucagon-like peptide-2 GLP-2) is a 33 amino acid proglucagon derived peptide released by the enteroendocrine L cells located predominantly in the ileum and proximal colon

[85]. GLP-2 is released in response to stimulation by luminal nutrients such as glucose, fatty acids and dietary fibre [86]. The half-life of GLP2 is approximately 7 min before it is cleaved to the inactive GLP-2(3-33) by DPP-IV [87, 88]. The DPP-IV resistant GLP-2 analogue, Teduglutide has greater bioactivity because of the longer circulating half-life [89]. GLP-2 is also cleared by glomerular filtration [90].

The intestinotrophic effects of GLP-2 are both morphologic and functional. Administration of GLP-2 or its analogues induces crypt cell proliferation, villus hypertrophy and inhibits enterocyte apoptosis resulting in an increase of absorptive surface in both the small and large intestine of animals [91–94]. The functional gains following the administration of GLP-2 include increase glucose transport via activation of the SGLT-1 and GLUT-2 transporters, increase expression of numerous brush border digestive enzymes and facilitates the intestinal absorption of lipids and secretion of chylomicrons [92, 95]. In addition to the intestinal structural and functional changes, GLP-2 decreases gastric emptying and proximal gut motility, decreases intestinal permeability with enhanced tight junction protein expression and has local intestinal anti-inflammatory effects that are mediated via vasoactive intestinal polypeptide [96, 97]. GLP-2 treatment is associated with alterations in the hepatic expression of genes involved in bile acid synthesis at a transcriptional level, including an up regulation of Farnesoid X receptor (FXR), cytochrome P450, family 7, subfamily A, polypeptide 1 (CYP7A1), multidrug resistance-associated proteins 2 (MRP2) and MRP3 [98]. The differences in bile acid profile observed with GLP-2 treatment may explain the improvement of parenteral nutrition-associated cholestasis reported following treatment with GLP-2 [98, 99].

The intestinotrophic effects of GLP-2 are mediated via the Glucagon-like peptide-2 receptor (GLP-2R) mainly localized to the intestine, with limited expression in the central nervous system. The highest expression of GLP2R is in the jejunal, with expression in enteroendocrine cells, enteric neurons, subepithelial myofibroblasts, vagal afferents and colonic submucosal glia [100, 101]. The expression of GLP-2R in different cell compartments of the intestinal suggests that GLP-2 may act indirectly via multiple mediators [102].

In preclinical models, elevated GLP-2 levels were associated with adaptation, while immunoneutralization diminished morphological adaptation in rats with proximal intestinal resection [103, 104]. Conversely, the adaptive potential in distal intestinal resection is diminished in comparison to proximal resection, possibly due to removal of the ileum and a significant proportion of the intestinal L cell mass in the ileum [105]. While, chronic administration of exogenous GLP-2 in rats with proximal intestinal resection demonstrated increases in growth, digestive, and absorptive capacity and barrier function of the remnant intestine [106].

In adults and children, the exogenous administration of long acting GLP-2 (teduglutide) has been found to improve measures of intestinal growth and function. Twenty-four weeks of treatment with teduglutide resulted in a reduction (≥20%) in PN requirements in 63% of adults who had required 3 days or more per week of PN compared with 30% who received placebo ($p < 0.01$) [107]. Improvement was associated with an increase in small bowel villus height and total surface area in responders. Twelve months after cessation of teduglutide, 15 of 37 (40%) of patients required an increase in PN volume, 15 of 37 patients (40%) maintained the same PN volume and 7 patients had a further reduction in PN volume, including 3 patients who ceased PN (8%). In the post-hoc analysis of the phase 3 study of teduglutide in patients with short bowel syndrome, the greatest benefit on parenteral volume and nutrition was observed in patients with higher baseline requirements, including patients with a jejunostomy or ileostomy [108].

The early experiences with teduglutide treatment in children with short bowel syndrome associated intestinal failure have been encouraging [109]. Following 12 weeks of teduglutide administration in children, 3 of 15 subjects (20%) who received 0.05 mg/kg/day and 1 subject of 14 subjects (7%) who received 0.025 mg/kg/day developed independence from parenteral nutrition although 4 weeks after discontinuation of teduglutide 2 of the 4 subjects had resumed PN. At a dose of 0.05 mg/kg/day for 12 weeks, PN volume reduced a median of −1.3 L/week (−11.0, 1.0), and PN energy content of −17 (−45, 53) kcal/kg/day, while enteral energy intake increased by a median of 7 (−1, 63) kcal/kg/day. With more prolonged therapy with teduglutide, changes in PN volume observed at 12 weeks were maintained through to a total of 24 weeks treatment [109]. It remains unclear whether teduglutide has a role in augmenting early intestinal adaptation immediately following massive intestinal resection.

Epidermal Growth Factor

The epidermal growth factor (ECF) family of peptides include EGF, transforming growth factor-alpha (TGF-α), heparin binding growth factor (HB-EGF), neuregulin and neuregulin-2. The major sites of EGF synthesis are the salivary glands and kidney [110]. The normal small intestinal epithelium does not synthesize EGF except in duodenal Brunner's gland in response to injury. The main EGF receptor (EGFR) is present on the majority of epithelial and stromal cells, with EGFR expressed on the basolateral surface of enterocytes [110]. Activation of EGFR results in numerous downstream cellular signals involved in enterocyte proliferation and apoptosis, while selective inhibition of EFGR abrogates the adaptive response after massive intestinal resection [111, 112].

EGF therapy has been shown to promote morphological and functional intestinal adaptation in rodent models of SBS [113, 114]. Enteral EGF administration in the rat intestinal resection model increases villus height, crypt depth, attenuates enterocyte apoptosis and decrease permeability to macromolecules. In unresected piglets, EGF administration stimulated weight gain and reversed the weaning induced loss of glucose cotransporter SGLT1 [115]. EGF downstream signalling is important for the trophic effects of GLP-2 in the intestine. The collective information from experimental models of mutated EGFR mice, GLP-2R knockout or EFGR receptor inhibitors indicate EGF signalling is required for the trophic effects of GLP-2, although the exact mechanism remains to be fully elucidated [101, 116]. Interestingly, the combined administration of EGF and GLP-2 to neonatal piglets with short bowel syndrome resulted not only in the known trophic effects of the hormones, but also lengthening of the bowel, particularly in the absence of the ileum [117].

There is limited experience of EGF therapy in humans. In a study of 5 paediatric patients, enteral administration of EGF for 6 weeks resulted in improved both carbohydrate absorption and enteral energy intake but not weight gain [118].

Insulin-Like Growth Factor-I

Insulin like growth factor-1 (IGF-I) is secreted by many cells in the body, including the gastrointestinal tract. The circulating IGF-1 is predominantly synthesized by the liver and its secretion is regulated by growth hormone (GH), insulin and protein/caloric intake [119]. Unlike GLP-2, circulating IGF-I concentration doesn't increase following massive intestinal resection. The adaptive growth effects of IGF-I are thought to be pleiotropic as a result of its paracrine/autocrine and endocrine effects on the different compartments of the intestinal tract [120–123]. In transgenic mice with IGF-I over-expression in the myofibroblasts, a 50% increase in intestinal length was reported post-resection suggests that IGF-1 plays a role in intestinal lengthening post-resection [122]. Following exogenous administration of IGF-I an increase in intestinal wet weight, villus height and crypt depth in the jejunum and intestinal lengthening is observed [124].

It is suggested that IGF-I is a downstream effector of GLP-2 in the intestine based on data from IGF-I knock-out mice and IGF-I receptor null animals [125, 126]. In the IGF-I knock out mice, administration of GLP-2 failed to increase intestinal weight, morphometry or enterocyte proliferation [125]. Similarly, IGF-I receptor null mice did not exhibit increase crypt-cell proliferation following chronic exposure to GLP-2 [126].

Peptide YY

Peptide YY, like GLP-2, is produced by the L cells of the ileum and colon; it slows gastric emptying and small bowel transit and may be responsible for the 'ileal' and 'colonic' brakes [127]. At physiological doses in man, peptide YY increases small bowel transit time and reduces stimulated intestinal secretion [128]. Peptide YY serum levels are high in patients with a retained colon and low in patients with a jejunostomy, thus it may be responsible for part of the functional adaptation that occurs in patients with a retained colon [3]. It is unlikely to be responsible for any structural changes as it does not induce gut growth in rats fed only with parenteral nutrition [129, 130].

Growth Hormone

Growth hormone (GH) is a polypeptide produced by the somatotroph cells of the anterior pituitary gland. GH secretion from the pituitary is under neural control from the hypothalamus via growth hormone releasing hormone (GHRH), somatostatin and ghrelin [131]. Negative feedback on GH secretion is exerted by IGF-1 and by GH levels. IGF-1 inhibits GH secretion by influencing GHRH and somatostatin production in the hypothalamus. GH acts via the GH receptor (GHR) in its target cells and stimulates IGF-1 production locally. In the intestine, GHR is localized throughout the intestinal epithelium, lamina propria, muscularis mucosa, submucosa and muscularis propria, indicating the potential for GH therapy within the intestine [132].

Results from preclinical animal experiments of GH therapy following massive intestinal resection have been conflicting. Early data from GH deficient and hypophysectomy rats demonstrated impaired intestinal adaptation while GH supplementation normalised this process [133–135]. Data from a number of animal models of GH supplementation in short bowel have demonstrated trophic effects, including an increase in jejunal-ileal length, villus height, ileal cell proliferation and ileal villus height [136–138]. Conversely, other studies did not demonstrate GH-induced morphologic adaptation in rats [139, 140]. Although the evidence to support structural adaptation following GH treatment is conflicting, GH has been shown to increase the functional capacity of the residual intestine. The administration of GH in animal models resulted in significant increases of brush border transport of glutamine and leucine, increase glucose transport across ileal mucosa, and stimulated sucrase and maltase activity in the small intestine [141, 142].

The clinical experience of GH supplementation with or without glutamine in human intestinal failure is probably of historical interest especially in the current era of alternate intestinotrophic therapeutic options. Initial data from non-randomized controlled studies were encouraging with a

modest reduction in PN requirement in a third of patients with about 50% of subjects eventually weaning from PN [143–146]. However, randomized controlled double blind cross-over studies of GH therapy with or without glutamine supplementation, albeit with small sample sizes, demonstrable no improvement in absorptive capacity of the residual intestine [147–150].

Other Potential Mediators of Intestinal Adaptation

Keratinocyte growth factor (KGF), also known as FGF7, is a potent mitogen and exerts its effects via the FGF receptor 2 which is expressed by various types of epithelial cells, including the intestinal epithelium [151]. KGF expression is strongly upregulated following acute and chronic injury. In animal models of massive intestinal resection, KGF administration augmented small intestinal growth, including mucosal thickening, villus length and modestly increased both small intestinal and colonic crypt depth [152]. KGF administration also improves the functional indices of adaptation such as basic ionic transport, alanine and glucose absorption [153, 154].

Other potential trophic mediators that have been studied include vasoactive intestinal peptide (VIP), vascular endothelial growth factor (VEGF), hepatocyte growth factor (HGF) and oral insulin [155–158]. Both VIP and VEGF have been identified to be downstream mediators of GLP-2 function, therefore upstream GLP-2 administration possibly provides adequate stimulation of both VIP and VEGF pathways for intestinal adaptation [155, 156]. Oral insulin has been studied in a small human trial involving ten paediatric subjects [159]. Although two infants were weaned of PN, the role of oral insulin remains uncertain complicated by the significant degradation of insulin in the stomach.

There is limited data of R-spondin1 in short bowel syndrome. However, it is a peptide of interest because of its potent and specific proliferative effects on intestinal crypt cells mediated via the wnt signalling pathway [160]. In vivo experiments using exogenous administered R-spondin1 lead to expansion of many intestinal parameters including small intestinal diameter, weight, crypt density and intestinal stem cell numbers [161]. In rats with induced colitis, exogenous R-spondin1 administration ameliorated the intestinal inflammation while preserving the mucosa integrity in both small and large bowel by stimulating epithelial cell mitosis [162].

Aminoguanidine

Within the epithelial cell, ornithine is converted by ornithine decarboxylase to polyamines (putrescine, spermidine and spermine) which are responsible for inducing epithelial hyperplasia [163]. The concentration of polyamines in jejunostomy fluid increases with refeeding [164]. It is postulated that this occurs in response to the presence of nutrients, increased mucosal blood flow, a neural or a humoral response [164]. Aminoguanidine, which inhibits diamine oxidase and reduces polyamine breakdown, has been used successfully in animals to induce epithelial hyperplasia and increased nutrient absorption [165].

Intestinal Microbiome

The gut microbiome contributes a wide range of metabolic and biochemical activities that support the host to digest, absorb, metabolise and excrete nutrients. Following massive intestinal resection, the intestinal microbiome changes in response to the new luminal environment [166]. Independent of the surgery, multiple factors contribute to the change in the microbiome including stress response, use of antibiotics, fasting and exposure of the intestinal lumen to oxygen. Experimental models have shown intestinal resection reduces the diversity of the microbiome in the remnant bowel, specifically a predominance of gram-positive *Firmicutes* phyla and a decrease of *Bacteroides* [167, 168]. Gnotobiotic animal models have smaller intestinal crypts, lower proliferation index but taller villi post intestinal resection [169, 170]. Following the introduction of microbes into gnotobiotic mice, there was an increase in both crypt depth and enterocyte proliferation. Microbiota induced inflammation was associated with significantly deeper crypts, taller villi and proliferation index in interleukin-10 deficient mice, while genes involved with adaptive and innate immunity were up-regulated following intestinal resection in zebrafish [169, 171]. These observations suggest a possible synergistic effect between the immune system, microbiota and intestinal adaptation.

Metabolites generated from the breakdown of luminal nutrients by intestinal bacteria play an important role in intestinal adaptation. Short chain fatty acid (SCFA), the most studied metabolite of commensal colonic bacteria fermentation has been shown to improve adaptation in the small and large bowel, enhance intestinal barrier function and modulate energy salvage [75, 76, 172]. Specifically, butyrate appears to be the main SCFA responsible for the increase structural and functional changes in the early adaptation [173].

Intestinal Maladaptation

The goal of intestinal adaptation following massive intestinal loss is the eventual return of enteral homeostasis. Clinically this is reflected in the successful transition from the state of

intestinal failure necessitating parenteral nutrition support, to enteral insufficiency and subsequently enteral autonomy. As described above, the process of adaptation involves a complex series of structural, functional and molecular responses. However, there may be unexpected consequences of the adaptive process. Segments of dilated intestine tend to have poorer motility [174]. The severity of the dysmotility is variable ranging from mild to functional obstruction; and is frequently proportional to the length, extent and site of the dilated loop of intestine [175]. Generally marked dilatation of a proximal bowel loop presents with feeding intolerance and vomiting; whereas, a distal distended bowel segment often is associated with lower gastrointestinal symptoms such as diarrhoea. While stasis of intestinal content promotes the likelihood of small intestinal bacteria overgrowth or dysbiosis with its antecedent complications of worsening diarrhoea, D-lactic acidosis and increase risk of bacteria translocation [176–178]. Intestinal microbiome dysbiosis results in significant bile acid dysmetabolism which may contribute to the observed disturbance in FXR-mediated pathways in the gut and liver. It is postulated that this may play an important role in the development of Intestinal Failure-Associated Liver Disease [179]. It remains unclear whether short bowel syndrome with its associated adaptive response and complications is an independent risk factor for the development of gastrointestinal malignancy.
