Part V

Assessment and Treatment of Intestinal Failure

Assessment of Nutritional and Fluid Status

Kirstine Farrer and Sorrel Burden

Key Points

1. Traditionally nutritional screening is done using a measurement of body mass index, percentage weight loss and the likelihood of being able to eat/drink.
2. A nutritional assessment additionally includes measurements of body composition and a review of the dietary intake.
3. In many countries "subjective global assessment" is used and it includes weight change, dietary input, gastrointestinal symptoms, underlying disease, functional capacity and physical examination.
4. The Global Leadership Initiative on Malnutrition (GLIM) is being increasingly used and incorporates five criteria for malnutrition 3 are phenotypic criteria (non-volitional weight loss; low body mass index; and reduced muscle mass) and 2 etiological ones (reduced food intake/assimilation and inflammation/disease burden). The diagnosis of malnutrition is based upon the presence of at least one phenotypic criterion and one etiologic criterion.
5. Body composition can be measured in the clinical environment with anthropometric measurements such as mid upper arm circumference (MUAC), triceps skin fold thickness (TSF), and mid arm muscle circumference (MAMC). Muscle function may be assessed using hand grip strength (hand-held dynamometer).
6. More detailed assessments of body composition are available including: dual-energy X-ray absorptiometry, bioelectrical impedance analysis, and computer tomography or air displacement plethysmography. These techniques are usually only performed in a research setting.
7. Underhydration is detected by a rapid weight loss, thirst, fall in postural systolic blood pressure, low urine output, and a rise in serum urea and creatinine.
8. Overhydration is commonly due to excessive amounts of intravenous saline being given and causes rapid weight gain, pitting oedema of the extremities, ascites, pleural effusions and a raised jugular venous pressure. It many take 10 or more days to excrete the saline load.

Introduction

Nutritional health is maintained by a state of equilibrium in which nutrient intake and an individual's requirements balance. Protein-energy malnutrition occurs when net nutrient intake (nutrient intake corrected for abnormally large faecal or urinary losses) is less than requirements. Protein-energy malnutrition leads to a succession of metabolic abnormalities, physiological changes, reduced organ and tissue function, and loss of fat mass and skeletal muscle mass. Concurrent stresses such as trauma, sepsis, inflammation and burns will accelerate loss of tissue mass and function [1–3]. Nutritional screening aims to quickly detect patients who may be or be at risk of becoming malnourished. A nutritional assessment is a more detailed evaluation of intake, body function/losses and needs. It is performed beside an assessment of hydration.

The assessment of hydration is of immediate importance and a nutrition support team may spend more time in managing hydration issues than managing the nutritional support. This is because sick patients including those who have, sepsis or inflammation or refeeding, often retain salt and water while patients with stoma or fistulae or drains may lose much fluid. A patient's hydration is assessed by observing weight changes, fluid balance, postural systolic blood pressure, skin/

mucus membrane turgor, central venous pressure and biochemical measures.

This chapter will briefly address nutritional screening then will concentrate on methods of doing a nutritional assessment before summarizing how subjective global assessment (SGA) [4] and Global Leadership Initiative on Malnutrition (GLIM) [5] are performed. It completes with hydration assessment and some of the abnormalities encountered.

Nutritional Screening

There are a number of screening tools that incorporate these criteria including the UK Malnutrition Universal Screening Tool ('MUST') [6] (Fig. 1). The Mini Nutritional Assessment (MNA) includes more information than 'MUST' and is often used in older adults. In addition to percentage weight loss and BMI the short form includes food intake, mobility, neuropsychological status and a measurement of calf circumference [7].

Nutritional Assessment

Nutritional assessment involves a more detailed careful evaluation of a patient's nutritional status and is a broader topic. It is important for two reasons. Firstly for it to be of clinical importance the ideal method should be able to predict whether the individual would have an associated morbidity and mortality risk in the absence of nutritional support. Unfortunately, disease and nutrition interact so that disease may cause secondary protein-energy malnutrition, or pre-existing protein-energy malnutrition may adversely influence the underlying disease. Secondly the measurement of nutritional status is essential for determining the provision of nutritional interventions and subsequent monitoring of interventions administered [8]. Assessment of nutritional status is required to determine requirements for nutritional support and accurately assess energy and protein requirements if predictive formulas are being employed [8, 9]. Monitoring the provision and adequacy of nutritional support treatment plans is also reliant on being able to assess changes in nutritional status and body composition.

Nutritional assessment methods encompass a variety of different types of measurements looking to determine very different aspects of the human physical form. These include anthropometric measurements, body composition measurements, biomarkers and measurements of functionality. Anthropometry is the measurements of the human body and forms in integral part of assessment of nutritional status in clinical practice. Anthropometric measurements include measurement of whole body weight, height, body mass index, trunk measurements including: waist and hip circumferences; sagittal abdominal diameter; limb measurements (mid-upper arm and calf circumferences) and skinfold thickness [10]. Body composition measurements aim to assess individual components of the human body including fat, muscle, bone and water content. Body composition measurements that are available include bioelectrical impedance, ultra sound, computed tomography, magnetic resonance imaging, air displacement plethysmography, isotope dilution, dual-energy X-ray absorptiometry and whole body counting/neutron activation.

Biomarkers in nutritional assessment aim to identify indicators of nutritional status and can be assessed by any biological specimen that is derived from dietary intake or metabolism [11], including measuring serum, plasma or urine levels. Functional measurements aim to determine muscle strength as a potential indicator of body muscle status or function [12]. There are also a number of questionnaires available to determine overall assessment derived from a combination of measurements, visual observations and points about disease type and severity [13]. Finally, there are numerous nutritional screening tools available some of which have been validated.

Anthropometric Measurements

Body Mass Index and Percentage Weight Loss

Body weight is a simple measure of total body components and although is useful for identifying changes, within individuals, is of limited use without interpreting in conjunction with height and age. Weight is usually used to calculate body mass index (BMI) or Quetelet index and is BMI is calculated as weight in kilograms divided by height in meters squared [14] (Appendix 1). A BMI indicating an individual is underweight is <18.5 kg/m^2 and a normal BMI within a healthy range is 18.5–24.99 kg/m^2 [14]. A BMI indicating undernutrition has been shown to correlate with an increase in all-cause mortality [15]. However, measurements of body weight in patients in hospital cannot be seen in isolation without considering fluid balance and hydration status. Both dehydration and over hydration are well recognised consequences of illness particularly in the critically ill, postoperative period, liver disease, cancer and renal failure, which can lead to oedema and ascites [16].

Unintentional weight loss greater than 10% is a good prognosticator of clinical outcome [17, 18] (Appendix 2) However, it may be difficult to determine true weight loss. However, weight loss is often subject to memory recall and this has been shown to vary considerable in relation to the length of time weight history is required, gender, age and also BMI [19, 20]. Furthermore, the nutritional significance of changes in body weight can again be confounded by changes in hydration status, particularly an increase in extra cellular fluid.

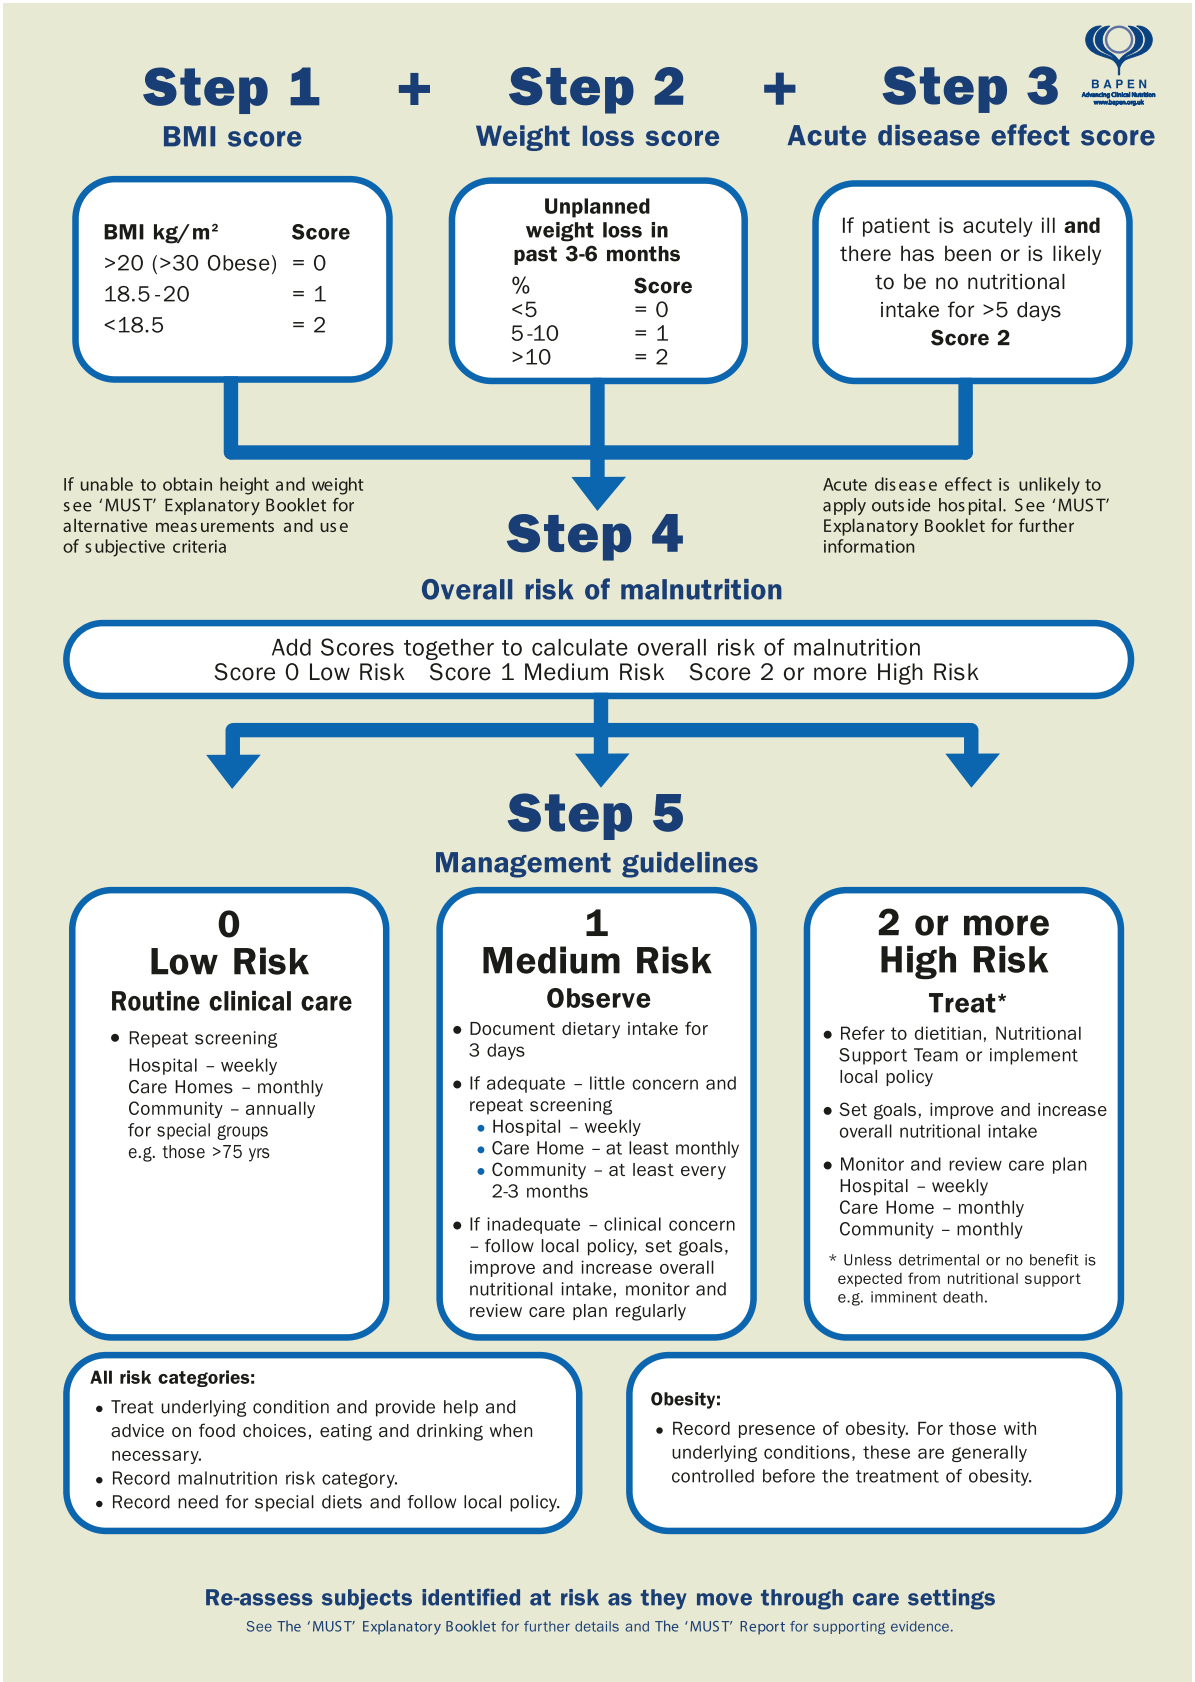

Fig. 1 Malnutrition Universal Screening Tool 'MUST'. (Reproduced with the kind permission of BAPEN (British Association for Parenteral and Enteral Nutrition). For further information on 'MUST' see www.bapen.org.uk')

Mid-arm Muscle Circumference

Triceps and subscapular skinfold thickness provide an index of body fat and have been described in detail [21, 22]. Mid-arm muscle circumference (MAMC) provides a measure of muscle mass and can be calculated from skinfold thickness and mid upper arm circumference (MUAC) (Appendix 3). MUAC has been used to identify chronic energy deficit and has been found to be of prognostic value in relation to mortality in patients who are in hospital [23, 24].

The reliability of skinfold thickness is debated and there has been some debate about the reproducibility of these measurements. The measurements have been shown to be more reliable in thinner people where there is less fat to measure and more reproducible when the same observer performs sequential measurements [25]. Experienced practitioners can achieve a high rate of reproducibility and more so then those observers who are less experienced, although there is measurement error in reproducibility between people [26].

There are references ranges that can be used for skin fold thickness, MUAC and mid arm muscle circumference based on population distributions (Appendix 4). Values less than the fifth percentile have been used to classify individuals as undernourished, although due to changes over time within populations, older reference values have been questioned [27, 28].

The most commonly used standards for triceps skinfold thickness and mid-arm muscle circumference are those reported by Jelliffe [29], which are based on measurements of European male military personnel and low-income American women, and those reported by Frisancho [30] which are based on measurements of white males and females participating in the 1971–1974 United States Health and Nutrition Survey. The use of these standards to identify protein-energy malnutrition in many patients is problematic because of the restricted database and the absence of correction factors for age, hydration status and physical activity on anthropometric parameters. Several studies have demonstrated that 20–30% of healthy control subjects would be considered undernourished based on these standards [28, 31] and that there is poor correlation between the Jellife and Frisancho standards in classifying patients [28]. Although attempts have been made to create standards for diseases such as renal dialysis patients [32] the validity of standards have been questioned and interpretation of data may be limited by inter-rater variability [33].

Body Composition

Assessment of nutritional status based on body composition involves detecting the loss (or gain) of body components relative to previous measurements and relating these values to standard reference ranges bases on healthy populations or data derived from specific populations. The former is affected by the reproducibility and error in the measurements, while the latter is dependent upon the relevance of the reference data or standards available.

Body composition measurements have been divided into a five-level model to provide a structural framework [34]. The five levels include atomic, molecular, cellular, tissues-organs and whole body. Each of these levels measure difference components to determine body composition that can include fat mass: fat free mass; total body water; body cell mass; bone mineral; skeletal muscle or total body protein [34]. The most frequently used measurements of body composition use the 2-compartmental model which measures fat mass and fat free mass [35]. It is important to note that some models measure a component of fat free mass then calculate fat free mass and then secondarily derive fat mass (e.g. bioelectrical impedance) whereas the other techniques measure fat mass then subsequently calculate fat free mass (e.g. ultra sound) [35]. This is important when evaluating the precision of measurement and the potential for the degree of error incurred during the measurement.

In healthy weight stable subjects there are relatively constant relationships between these components which are correlated with each other.

Isotope Dilution

Total body water, measured by, is usually the largest molecular level component. Water maintains a relatively stable relationship to fat-free body mass and thus measured water isotope dilution volumes allow prediction of fat-free body mass and fat (i.e. body weight minus fat-free body mass). The relationship between total body water and other body composition components may change with disease and this should be considered when interpreting data from hospitalised or chronically ill patients. The usual approach is to measure a dilution volume using one of three isotopes, tritium, deuterium, or ^{18}O-labelled water. This first step allows estimation of a dilution volume of one of the three isotopes. In the second step it is assumed that the proportion of fat-free body mass as water is constant at 0.732. This allows calculation of fat-free body mass and fat [36].

Dual-Energy X-Ray Absorptiometry

Dual-energy X-ray absorptiometry (DEXA) is a method developed originally for the measurement of bone density and mass. Systems today also quantify soft tissue composition, and it is possible to measure total and regional fat, bone mineral and bone mineral-free lean components with DEXA. The method is based on the attenuation characteristics of tissues exposed to X-rays at two peak energies. Mathematical algorithms allow calculation of the separate components using various physical and bio logical models. Software can be used to measure regions separately if desired. A typical whole body scan takes approximately

30 min and exposes the subject to ~1 mrem radiation. This method provides an accurate and practical means of measuring bone mineral mass and offers the opportunity to study appendicular muscle mass.

Bioelectrical Impedance Analysis

Bioelectrical impedance analysis (BIA) is a method of estimating body fluid volumes by measuring the resistance to a high frequency, low amplitude alternating electric current (50 kHz at 500–800 mA). The amount of resistance measured (R) is inversely proportional to the volume of electrolytic fluid in the body, and to a lesser extent on the proportions of this volume. A regression equation is then developed based between a reference measurement of fat-free body mass (i.e. isotope dilution) and the measured R, height and other variables. Recent research in this area has focused on separate measurements of extra- and intracellular water. In healthy adults it is possible to predict total body water within 2–3 L however; these prediction may not be reliable in individuals with medical conditions that effect fluid balance including renal and cardiac disease. So caution needs to be taken where fluid shifts are a likely occurrence in disease states [37].

In a cohort of patients with intestinal failure BIA had good agreement with air displacement plethysmography (ADP) as a criterion measure when measuring body composition [38], which is in accordance with previous data measuring percentage fat in 41 healthy participants using ADP and BIA where good agreement was shown [39]. Phase angle derived from BIA has been shown to be predictive of mortality and hospital length of stay in people with intestinal failure on home parenteral nutrition [40].

Computed Tomography and Magnetic Resonance Imaging

These methods measure components at the tissue-system level of body composition, including skeletal muscle, adipose tissue, visceral organs and brain. Computed tomography (CT) systems measure X-ray attenuation as the source and detector rotate in a perpendicular plane around the subject. Magnetic resonance imaging (MRI) systems measure nuclear relaxation times from nuclei of atoms with a magnetic moment that are aligned within a powerful magnetic field.

The use of CT and MRI imaging is becoming more popular in research and clinical practice internationally. The development of computer software packages that allows body composition to be determined from CT and MRI images is now readily available. These software packages have been reviewed and been found to be highly correlated for the measurement of cross sectional muscle area [41]. The level of the third lumbar vertebra (L3) is often used as a reference point and this has been found to correlate well with whole body composition [42]. Fat and muscle mass areas can be calculated from CT images described by Prado et al. [43], including the quantification of muscle within a Hounsfield unit (HU) range of −30 to +150, and fat within −190 to −30.

The value obtained for muscle mass area (cm^2) is linearly related to whole-body muscle mass [42], and can be standardised according to height by dividing muscle area by $height^2$ to provide a skeletal muscle index, which can be compared to cut off values for the identification of low muscle mass [43, 44]. Low muscle mass derived from CT images was found not to correlate with survival in a cohort of patients on home parenteral nutrition with intestinal failure [45].

Magnetic resonance imaging can be used to assess body composition and is useful as it does not expose individuals to radiation. MRI images for whole body assessment with a full set of images to evaluate full body composition can take about 30 min. However, there is validation work enabling the use of a single slice at lumbar vertebra 4 and 5 to assess skeletal muscle mass and adipose tissue [46].

Air Displacement Plethysmography

This is four compartmental method of measuring body composition. Participants are asked to wear swim wear and a cap over their hair. All jewellery is removed as well as glasses. Participant weight is taken on the Air displacement plethysmography (ADP) scales before they enter the capsule. Participant is asked to sit in the ADP chamber, remain relaxed and breathe normally. The door is closed and the participant is asked to remain as still as possible during a 30–50 s period, whilst the machine takes a reading. The measurement is taken twice unless the machine instructs a third measure to be taken. Body fat mass and fat free mass is calculated by the ADP machine software (BODPOD). The BODPOD uses the principles of whole body densitometry to determine body composition.

This method of assessment was offered to patients receiving home parenteral nutrition with short bowel syndrome, although in a research environment the uptake was very low [38]. It was suggested that this was due to the requirement to wear swimwear which was possibly due to individual's being self-conscious about body image due to the presences of a stoma [47]. In addition, in this study the BODPOD was located at a different location so travel may have been a factor in the low uptake for this measurement [38].

Ultrasound

Ultra sound is a fairly fast noninvasive method of assessing body composition in clinical practice and research, it is relatively inexpensive and also portable device are available. It does not subject people to any radiation so suitable for sequential measurements. Ultra sound uses high frequency sound waves that travel in the form of cyclical waves greater than 20 KHz [48]. A transducer produces pulses of ultrasounds that are transmitted through the skin and when the

beam comes into contact with a tissue interface of either skin, fat, muscle or bone an echo is sent back though the transducer [48]. These echoes are then processed by the transducer and turned into signals. It is these signals that are represented by waves. To perform an ultrasound scan the transducer is moved over the skin where gel has been applied and for a single site measurement this movement is approximately 5 cm. However, whole thigh or calf can be scanned depending on what is required. The image is then read on a screen using software. Some packages have been designed for the purpose of measuring fat, muscle and bone and reliability and validity data are available for the A Mode ultrasound [49, 50].

Ultra sound has been compared to air displacement plethysmography (ADP) in a small number of patients with intestinal failure and showed for fat free mass measured by ultrasound in comparison to ADP there was a moderate intraclass correlation (ICC) (ICC 0.659, 95% confidence interval −0.27 to 0.92), although this was poor for fat mass (ICC −0.005, 95% CI −0.73 to 0.65) [38].

Clinical Assessment of Nutritional Status

The clinical assessment of nutritional status involves a focused history and physical examination in conjunction with selected measurements of body composition or laboratory tests. Laboratory tests can identify specific nutrient deficiencies and body composition measurements can assess the incidence of sarcopenia, myopenia or sarcopenic obesity. A full nutritional assessment can also potentially identify those who are at risk of becoming malnourished or developing future nutritional abnormalities.

History

The nutritional history should evaluate the following questions:

1. Has there been a recent change in body weight, particularly in the last 3 months and was the change intentional or unintentional?
2. Is dietary intake adequate? An assessment of habitual eating and current dietary intake should be assessed by a dietitian in relation to overall nutritional adequacy and specific micronutrient intakes. An assessment of nutrient supplements being taken needs to be undertaken and their contribution to nutrient intake including both macro and micronutrient intakes. A diary documenting food intake may be useful when the history is inconclusive and this can be in the form of a paper diary or one of a number of digital applications that are available to use on SMART phones or tablets [51].
3. What reasons are given for the change in dietary intake? Has appetite changed? Is there a disturbance in taste, smell, or the ability to chew or swallow food? Has there been a change in mental status or increased depression? Has there been a change in the ability to prepare meals? Are there gastrointestinal symptoms, such as early satiety, post-prandial pain, nausea, or vomiting? Is the patient taking medications that affect food intake?
4. Is there evidence of malabsorption? Does the patient have gastrointestinal disease? Has there been a change in bowel habits?
5. Are there symptoms of specific nutrient deficiencies including macro-minerals (e.g. sodium, potassium, calcium or magnesium), micronutrients and water?

Physical Examination

The physical examination corroborates and adds to the findings obtained by history:

Anthropometric Assessment

Current body weight should be compared with previously recorded weights, if available (Appendix 1). Weight for height should be compared with reference values for BMI (Appendix 2). A search for evidence demonstrating depletion of body fat and muscle masses should be made. A general loss of adipose tissue can be judged by clearly defined bony, muscular and venous outlines, and loose skinfolds. The presence of hollow cheeks, buttocks and perianal area suggests body fat loss. An examination of the temporalis, deltoids, and quadriceps muscles should be made to search for muscle wasting.

Fluid Status

An evaluation for dehydration (hypotension, tachycardia, postural changes, mucosal xerosis, dry skin, and swollen tongue) and excess body fluid (oedema, ascites) should be made (see below).

Evaluation for Specific Nutrient Deficiencies

Rapidly proliferating tissues, such as oral mucosa, hair, skin, and bone marrow are often more sensitive to nutrient deficiencies than are tissues that turn over more slowly.

Laboratory Tests

The results of the history and physical examination may lead to a suspicion of specific nutrient deficiencies, which can be further corroborated by appropriate diagnostic laboratory tests.

Functional Assessment

Hand Grip Strength

Handgrip strength is a measure of muscle function or strength and is used in research and clinical practice. Handgrip measure has been seen to be valid in hospitalised patients and reliable when undertaken in the sitting or supine position [52]. Handgrip strength has been shown to correlate with outcome in hospitalised patients, surgery and cardiovascular disease [53, 54].

Biomarkers: Serum Proteins

There is no laboratory test that is both sensitive to and specific for protein energy malnutrition. Historically albumin and pre albumin have been used as markers of nutritional status and to identify energy and protein malnutrition. However it has since been recognised that hepatic proteins are not good markers of nutritional status, but measurements of disease even though there is evidence of correlation between mortality, morbidity and recovery from disease. During a critical illness, factors that alter serum albumin and prealbumin may include the following: the acute-phrase response; hydration (intravascular volume) status; disease state; clinical condition; leakage of albumin from intravascular to extravascular spaces; and severe zinc deficiency. Evidence has demonstrated that serum levels of these proteins do not change in relation to the intake of protein. They should not be used in clinical environments to assess disease related malnutrition but are useful as a tool to indicate severity of disease [8, 55]. It is imperative that the dietitian interprets hepatic protein levels in the context of overall health and lifestyle [8, 56].

Subjective Global Assessment

World-wide the Patient-Generated Subjective Global Assessment (PG-SGA) is often used. It is a clinical method for evaluating nutritional status, termed subjective global assessment (SGA), encompasses historical, symptomatic and physical parameters [4, 13, 57]. This approach defines undernourished patients as those who are at increased risk for medical complications and who will presumably benefit from nutritional therapy. The basis of this assessment is to determine whether nutrient assimilation has been restricted because of decreased food intake, or malabsorption, whether any effects of protein-energy malnutrition on organ function and body composition have occurred, and whether the individual's disease process influences nutrient requirements. The specific features of the history and physical examination used in the SGA are listed in Tables 1, 2, 3, and 4.

The history used in the SGA focuses on five areas. The percentage of body weight lost in the previous 6 months is characterized as mild (<5%), moderate (5–10%), and severe (>10%). The pattern of loss is also important and it is possible for a patient to have significant weight loss but still be considered well-nourished if body weight (without oedema or ascites) recently increased. For example, a patient who has had a 10% body weight loss but regained 3% of that

Table 1 Features of subjective global assessment

History		
1. Weight change and height		
Current:	Height	_____ cm
	Weight	_____ kg
Overall loss in past 6 months:		_____ kg
		_____ %
Change in past 2 weeks (use + or −):		_____ kg
		_____ %
2. Dietary intake change (relative to usual intake)		
No change		
Change:	Duration ____ days	
Type:	Suboptimal solid diet	
	Hypocaloric liquids	
	Starvation	
Supplement: (circle)		
	Nil	
	Vitamins	
	Minerals	
3. Gastrointestinal symptoms that persisted for >2 weeks		
None		
Nausea		
Vomiting		
Diarrhoea		
Pain:	At rest	
	On eating	
4. Functional capacity		
No dysfunction		
Dysfunction:	Duration____ days	
	Type:	Working sub-optimally
		Ambulatory but not working
		Bedridden
5. Disease and its relation to nutritional requirements		
Primary diagnosis: _____		
Metabolic demand (stress):		
	No stress	
	Moderate stress	
	High stress (burns, sepsis, severe trauma)	
Physical status (for each trait specify: 0 = normal, 1 = mild deficit, 2 = established deficit)		
Loss of subcutaneous fat		
Muscle wasting		
Oedema		
Ascites		
Mucosal lesions		
Cutaneous and hair changes		
SGA Grade _____		
A: well nourished; B: moderate or suspected protein-energy malnutrition; C: severe protein-energy malnutrition		

weight over the past month, would be considered well-nourished. Dietary intake is classified as normal or abnormal as judged by a change in intake and whether the current diet is nutritionally adequate. The presence of persistent gastrointestinal symptoms, such as anorexia, nausea, vomiting, diarrhoea and abdominal pain, which have occurred almost daily for at least 2 weeks, is recorded. The patient's functional capacity is defined as bedridden, suboptimally active, or full capacity. The last feature of the history concerns the metabolic demands of the patient's underlying disease state. Examples of high-stress illnesses are burns, major trauma and severe inflammation, such as acute colitis. Moderate-stress diseases might be a mild infection or limited malignant tumour.

The features of the physical examination are noted as normal, mild, moderate, or severe alterations. The loss of subcutaneous fat measured in the triceps region and the mid-axillary line at the level of the lower ribs. These measurements are not precise, but are merely a subjective impression of the degree of subcutaneous tissue loss. The second feature is muscle wasting in the temporal areas and in the deltoids and quadriceps, as determined by loss of bulk and tone detectable by palpation. A neurological deficit will interfere with this assessment. The presence of oedema in the ankle and sacral regions and the presence of ascites are noted. Co-existing disease such as renal or congestive failure will modify the weight placed on the finding of oedema. Mucosal and cutaneous lesions are recorded, as are colour and appearance of the patient's hair.

The findings of the history and physical examination are used to categorize patients as being well-nourished (category A), having moderate or suspected protein-energy malnutrition (category B), or having severe protein-energy malnutrition (category C) (Table 5).

The rank is assigned on the basis of subjective weighting. Equivocal information is given less weight than definitive data. Fluid shifts related to onset or treatment of oedema or ascites must be considered when interpreting changes in body weight. In general, a patient who has experienced weight loss and muscle wasting but is currently eating well and is gaining weight is classified as well nourished. A patient who has experienced moderate weight loss, continued compromised food intake, continued weight loss, progressive functional impairment, and has a 'moderate-stress' illness is classified as moderately undernourished. An individual, who has experienced severe weight loss, continues to have poor nutrient intake, progressive functional impairment and muscle wasting is classified as severely undernourished independent of disease stress. Baker et al. [57] and Detsky et al. [4] found that the use of SGA in evaluating hospitalised patients gives reproducible results and there was more than 80% agreement when two blinded observers assessed the same patient.

Table 2 Subjective global assessment—clinical observations of loss of subcutaneous fat stores

Physical examination	Normal	Mild/moderate	Severe
Under eyes	Slightly bulging area	Somewhat hollow look, slightly dark circles	Hollow look, depression, dark circles
Triceps	Large space between fingers	Some depth to fat tissue, but not ample. Loose skin	Very little space between fingers or fingers touch
Ribs, lower back, side of body trunk	Chest is full, ribs are not visible, slight to no protrusion of the iliac crest	Ribs obvious and indentations are not marked. Crest somewhat prominent	Indentation between ribs very obvious, iliac crest very prominent

Table 3 Subjective global assessment: clinical observations of loss of muscle mass

Physical examination	Normal	Mild/moderate	Severe
Temple	Well defined muscle	Slight depression	Hollowing depression
Clavicle	Not visible in males, may be visible but not prominent in females	Some protrusion; may not be all the way along	Protruding/prominent bone
Shoulder	Rounded	Not square in appearance, acromion process may protrude slightly not all areas	Square appearance, bones prominent
Scapula/ribs	Bones not prominent no significant depressions	Mild depressions or bone may show slightly not all areas	Bones prominent significant depression medially
Quadriceps	Well defined	Depression/atrophy medially	Prominent knee. Severe depression medially
Interosseous muscle between thumb and forefinger (back of the hand)	Muscle protrudes could be flat in females	Slightly depressed	Flat or depressed areas

Table 4 Subjective global assessment—clinical observations of fluid retention

Physical examination	Normal	Mild/moderate	Severe
Oedema	None	Pitting oedema of extremities/pitting to knees, possible sacral oedema if bedridden	Pitting beyond knees, sacral oedema if bedridden may also have generalised oedema
Ascites	Absent	Present (may only be present on imaging)	Present (may only be present on imaging)

Table 5 Subjective global assessment—categories

Category A	Well-nourished no decrease in food/nutrient intake; <5% weight loss; no/minimal symptoms affecting food intake; no deficit in function; no deficit in fat or muscle mass OR an individual with criteria for SGA, B or C but with recent adequate food intake; non-fluid weight gain; significant recent improvement in symptoms allowing adequate oral intake; significant recent improvement in function; and chronic deficit in fat and muscle mass but with recent clinical improvement in function.
Category B	Mildly/moderately malnourished definite decrease in food/nutrient intake; 5–10% weight loss without stabilization or gain; mild/some symptoms affecting food intake; moderate functional deficit or recent deterioration; mild/moderate loss of fat and/or muscle mass OR an individual meeting criteria for SGA C but with improvement (but not adequate) of oral intake, recent stabilisation of weight, decrease in symptoms affecting oral intake, and stabilisation of functional status.
Category C	Severely malnourished severe deficit in food/nutrient intake; >10% weight loss which is on-going; significant symptoms affecting food/nutrient intake; severe functional deficit OR recent significant deterioration obvious signs of fat and/or muscle loss. Cachexia—If there is an underlying predisposing disorder (e.g. malignancy) and there is evidence of reduced muscle and fat and no or limited improvement with optimal nutrient intake, this is consistent with cachexia sarcopenia—If there is an underlying disorder (e.g. aging) and there is evidence of reduced muscle and strength and no or limited improvement with optimal nutrient intake

Illustrative Cases

Case 1

A 55-year-old woman was admitted to the hospital for elective resection of a colon carcinoma. Her weight was 65 kg, height 1.65 m and BMI 23.9 kg/m^2. She had lost 10% of her initial weight over a 6 month period before admission. However, she recently gained weight after therapy with nutritional supplement drinks providing an additional 600 kcal + 25 g protein per day and these have subsequently been stopped as her dietary intake is classified as 'normal'. She has no adverse gastrointestinal symptoms or pain. Current weight 68 kg (BMI 25 kg/m^2). She continued to work as a teacher and is active. On physical examination, there was no loss of subcutaneous fat stores; her ribs are not visible and there is no protrusion of the iliac crest. There are no signs of muscle wastage; her shoulders are rounded and the temple shows no signs of depression. She is classified as SGA—'A', 'well nourished'.

Case 2

A 40-year-old man with an acute exacerbation of Crohn's disease had lost 10% of his body weight within the previous 2 weeks. His weight is 65 kg, height 1.83 m, BMI 19.4 kg/m^2 and he was drinking liquids to avoid gastrointestinal discomfort associated with ingesting solid food (vomiting, nausea and diarrhea). He was ambulatory, but he was not going to work. On physical examination, he had slight loss of subcutaneous tissue manifested by a reduced buccal fat pad (on the facial cheek), his ribs are obvious and iliac crest somewhat prominent and loose skinfolds over the arms. His acromion process protrudes slightly and his interosseous muscle on the back of his hand is slightly depressed. He is classified as SGA 'B'—'moderate or suspected protein energy malnutrition'.

Case 3

A 67-year-old man with oesophageal cancer had minimal food intake for almost 3 months. His weight was 55 kg, height 1.77 m and BMI 17.6 kg/m^2. He has lost 15% of his body weight during the previous 4 months and is continuing to lose weight—1 kg per week. He was able to move around the house but had marked muscle weakness and fatigue and did not walk outdoors. Hi oral intake is restricted to fluids 1.5 L/day (soup, ice-cream and milk). On physical examination, he lacked subcutaneous fat tissue, had hollow temples, dark circles under his eyes, deltoid wasting, square shoulders, prominent knees, and mild pitting oedema. He is SGA 'C'—severe protein energy malnutrition.

Global Leadership Initiative on Malnutrition (GLIM)

In 2016 the global consensus for diagnosing malnutrition in adult patients was launched; commonly known as the Global Leadership Initiative on Malnutrition (GLIM) [5]. Nutritional screening is the first line of nutritional assessment and is now informed by the Global Leadership Initiative on Malnutrition (GLIM) where appropriate criteria are specified for phenotypes and aetiological criteria (Table 6). A **global team of experts agreed on five criteria for malnutrition which include non-volitional weight loss; low body mass index;**

Table 6 Thresholds for severity grading of malnutrition (both need one phenotypic criteria) [5]

	Weight loss		BMI[a]	
	In last 6 months	Beyond 6 months	kg/m^2	Muscle mass
Stage 1				
Moderate malnutrition	5–10%	10–20%	<20–22[a,b]	Mild/ moderate deficit
Stage 2				
Severe malnutrition	>10%	>20%	<18.5 <20 if aged 70 years or over	Severe deficit
Aetiological criteria				
Reduced food intake or assimilation				
• 50% of ER >1 week, or any reduction for >2 weeks, or any chronic GI condition that adversely impacts food assimilation or absorption				
Inflammation				
• Acute disease/injury or chronic disease-related				

[a] 20 in less than 70 years old and 22 if more than 70 years old
[b] Lower BMI in Asian population <18.5–20

and reduced muscle mass as phenotypic criteria, and reduced food intake/assimilation and inflammation/disease burden as etiologic criteria. It was proposed that the diagnosis of malnutrition be based upon the presence of at least one phenotypic criterion and one etiologic criterion.

Conclusions About Nutritional Assessment

Protein-energy malnutrition results in a continuum which starts when an individual fails to eat sufficient oral diet to meet their nutritional requirements. There are numerous methods to assess nutritional status and body composition and some methods are suited to research and others to clinical practice. Measurements can now be used to start identifying malnutrition, sarcopenia, sarcopenic obesity and myopenia. However, there is also the need to assess risk of those individuals who are likely to become malnourished in the future, because prevention is better than cure.

The identification of risk of malnutrition and malnutrition should follow with the appropriate intervention being made available to correct macro and micro nutrient deficiencies. Appropriate assessment and monitoring of disease related malnutrition allows the correct intervention to be administered with the ultimate aim of effecting change in an individual's disease trajectory, whilst influencing overall mortality, morbidity and patient reported outcome measures. There is a vast literature on the reliability and validity of measurements of body composition and nutritional status covering multiple measurement techniques. It is the skill in application of these techniques in different settings that facilitates appropriate assessment and monitoring of individuals and ensuring the monitoring is the role of a dietitian/registered nutritionist.

Assessment of Fluid Status

Water and salt are critically important constituents of the body, and disturbances of salt and water have quicker and more profound effects on health than nutrients. Body water comprises 73% of the lean body mass but 54% of body weight because fat does not contain water. Consequently, obese persons have less water in relation to body weight. Of total body water, 40% is the volume in which chloride is distributed and is extracellular; 60% resides in cells and is called the intracellular water in which body potassium and magnesium is distributed. The assessment of fluid status depends upon recognizing that body fluids are composed of isotonic saline and free water. The changes in the normal saline content alters the volume of the extracellular fluid and leaves the electrolyte concentration unchanged, while changes in free water alter the osmolarity and change plasma sodium concentration.

Clinically the hydration status is assessed by:

1. History of conditions which can cause deficits or overload.
2. History of symptoms suggestive of abnormal fluid status.
3. Physical examination.
4. Biochemical tests.

Underhydrated (Hypovolaemic, Extracellular Fluid Depletion)

This is common especially when there are large losses such as diarrhoea, large stomal/intestinal fistula output and/or vomiting. When the changes are mild with less than 10%

reduction of extracellular fluid volume (ECF), the patients may have very few complaints except for rapid weight loss. When there is a greater reduction of ECF then there are symptoms of marked weight loss, dizziness and palpitations on changing from a recumbent to an erect posture, weakness, thirst and fainting. On examination there is postural tachycardia and fall in systolic blood pressure on changing posture. In normal individuals or those with <7% volume depletion the pulse will rise by 10 beats/min, the systolic pressure will fall by 5–10 mm and the diastolic will rise by 5–10 mm when the posture is changed from a recumbent to an erect state. With greater loss of the ECF the pulse rises by 20 beats/min and the postural change in systolic pressure will be 20 mm or more without a similar compensatory rise in the diastolic pressure. Weight loss always occurs, with severe depletion (>15%) the jugular venous wave is not seen even when the patient is lying flat. The changes in blood pressure may be missed unless the blood pressure is taken only after waiting for 10 min after change of position. The clinical features of ECF volume depletion are summarized in Table 7 and the electrolyte changes in Table 8.

On biochemical testing the plasma sodium concentration is normal unless the patient has been drinking water to quench thirst, in which case the plasma sodium may fall below the normal range (hyponatraemia). When patients have a short bowel, losses of fluid from a jejunostomy, which is isotonic will cause serious volume contraction but leave the plasma sodium, potassium, chloride and bicarbonate concentrations normal. Losses from other sites can change the plasma electrolyte picture as indicated in Table 8. In addition renal urine electrolytes will show a marked reduction in sodium concentration <10 mmol/L.

Table 7 History and clinical features of hypovolaemia/ECF depletion

History	Symptoms	Physical signs
Losses of fluid: vomiting and diarrhea	Weakness, thirst, dizziness, postural	Weight loss
Renal disease with diuresis	Symptoms	Dry mucous membranes
Diuretic therapy		Reduced skin turgor
		Reduced central venous pressure
		Postural changes in pulse >10 beats/min and a fall in systolic pressure >15 mm

Table 8 Changes in plasma electrolytes with conditions resulting in loss of ECF

Clinical condition	Sodium	Potassium	Chloride	Bicarbonate
Vomiting	Normal	Low	Low	High
Jejunostomy losses	Normal	Normal	Normal	Normal
Pancreatic fistula	Normal	Normal	High	Low
Ileostomy	Normal	Normal or low	Normal or high	Normal or low
Diarrhoea	Normal	Low	High	Low

Overhydrated (Hypervolaemic, Increased Extracellular Fluid)

This commonly occurs when excessive saline is given intravenously (e.g. after vigorous resuscitation with sodium-containing fluids or in the perioperative period). Two liters of 0.9% saline given to healthy volunteers reduced the albumin by about 10 g/L and it took 2 weeks to return completely to normal [58]. Thus humans have poor mechanisms for excreting a sodium load. Saline overload causes rapid weight gain, swelling of the extremities and abdomen, and breathlessness. On examination there may be one or more of the following: acute weight gain, pitting oedema (pretibial or if bed bound of thighs or sacral area), ascites, raised jugular venous pressure and pleural effusions. In this condition the plasma electrolytes will be normal unless the patient has received diuretics and continues to drink water or receive fluids without sodium (e.g. isotonic glucose). These patients need saline intake restricting, or very occasionally are given intravenous albumin with or without a loop diuretic.

				TRICEPS SKIN FOLD THICKNESS CM												

$$\text{MAMC} = \text{Mid} - \text{arm circumference} - \left(3.14 \times \text{Triceps skin fold thickness}\right)$$

The mid-arm circumference and triceps skin fold measurement are made mid-way between the tip of the acromion (shoulder tip) and the olecranon process (elbow) on the relaxed extended left (non-dominant) arm

Appendix 4 MID-ARM MUSCLE CIRCUMFERENCE (CM) PERCENTILES

				cm			
		Men				**Women**	
	5th	10th	15th		5th	10th	15th
Age (years)							
20–29	22	23	24		18	19	19
30–39	22	23	23		18	19	19
40–49	23	23	24		19	19	20
50–59	22	23	23		19	19	19
60–69	22	23	23		19	19	20
70–79	21	22	23		18	19	19
80–89	20	21	22		17	18	18
>90	20	20	21		17	17	18
All ages	22	22	23		18	19	19

This 'normal range' of mid-arm muscle circumference (MAMC) has been chosen as it includes a large age range [59]. A MAMC of less than 19 cm in women and less than 21 cm in men of all ages, would detect most patients found to be undernourished by a loss of 10% body weight or a body mass index of less than 19.0 kg/m^2 [60].

The MAMC is useful for monitoring the progress of nutritional support especially in patients who cannot be weighed, have fluid retention or are obese

Radiology in Intestinal Failure

Arun Gupta, Alex Fitzhugh, Chun Wah So, Aia Mehdi, Anmol Gangi, Michele Marshall, and Rajapandian Ilangovan

Key Points

1. The radiologist is a key member of the intestinal failure multidisciplinary team and helps with both diagnostic and therapeutic procedures.
2. The choice of radiological technique depends upon the availability of equipment, the expertise of the local radiology department, and whether the patient is acutely unwell or stable with chronic problems.
3. A plain abdominal radiograph is useful in the acute setting to diagnose obstruction, ileus, perforation and the extent/severity of colitis, and can be helpful in monitoring progress.
4. Computerised tomography (CT) is usually the best choice in an acute setting where it is easily accessible, quick to perform, can be relatively easier to interpret and allows an extra-intestinal assessment including the state of the abdominal wall.
5. Magnetic resonance enterography (MRE) produces high quality images of the small bowel, but it can be challenging to obtain high quality images in all patients. Patient movement, bowel peristalsis or inability to maintain a breath hold can result in sub-optimal non-diagnostic images, so careful patient selection is needed.
6. Ultrasound (US) is user dependent, but with appropriate expertise, US scans can provide greater resolution and information than is possible with other imaging modalities, particularly in thin patients or when the probe can be placed close to the pathology.
7. Intra-abdominal sepsis is usually detectable by CT, but a multi-modality approach may be needed. Drainage can be achieved by CT or US guidance, depending upon which provides the best accessibility or visibility of the collection.
8. Diagnosis of obstruction or ischaemia can be challenging. If there is a strong clinical suspicion of either and the initial radiology report doesn't match the clinical concern, urgent review by a specialist Gastro-intestinal radiologist maximises the chance of making a correct diagnosis.
9. A barium follow through (BFT) alone or in combination with a CT scan will usually give the information required (length and quality of bowel) for mapping bowel before reconstructive surgery.
10. Contrast fluoroscopy (with bowel distension) is good to determine the patency, length and quality of out of circuit bowel prior to distal feeding or reconstructive surgery.
11. Mapping a fistula tract is dependent on its location, accessibility and complexity, and upon the general state of the patient. A CT and /or BFT can provide an accurate overview, with fluoroscopy (fistulogram) or focussed MRI adding more detail.
12. Expert review of all current and previous imaging, including those obtained in other institutions, may provide an understanding of complex anatomy not discernible on a single examination or modality, and can guide further imaging.

Introduction

Diagnostic imaging and interventional radiology is used frequently in managing patients with IF. The radiologist should be regarded as part of the multidisciplinary team caring for the patients with IF. They are able to help define the initial diagnosis of perforations, sepsis, ischaemia and obstruction/ileus. Small bowel obstruction can easily be misdiagnosed as ileus, and similarly reversible bowel ischaemia can be missed as signs can be non-specific. Using a variety of modalities they can accurately map the remaining bowel (length and quality) and abdominal wall before reconstructive surgery.

An increasing number of therapeutic procedures, from draining sepsis to inserting enteral and parenteral feeding lines, require radiology input and a dynamic and collaborative interface with the radiology department will facilitate best clinical practice. This chapter covers the imaging modalities, the radiological assessment of relevant conditions, and techniques for bowel and fistula mapping.

Imaging Modalities

Plain Films: Conventional and Digital Radiography (CR & DR)

Radiography is the oldest imaging modality, and its persistence in spite of the many advances in medical imaging is testament to its extensive utility. Its most common role lies in the assessment of the acutely unwell patient, with particular advantages including ease of access (such as the potential for portable films for the unstable patient) and a relatively low radiation dose (usually <0.5 mSV). Plain films can often be more readily interpreted than other modalities, allowing rapid identification or exclusion of major pathology.

Abdominal radiographs (AXRs) are most commonly requested for emergency presentations such as suspected bowel obstruction, though may also demonstrate other pathologies such as colitis and perforation leading to pneumoperitoneum. They are used in the diagnosis of small bowel ileus (either post-operative or related to other systemic processes), and pseudo-obstruction. Serial AXRs are useful and accurate for monitoring colonic disease and dilatation in ulcerative colitis.

AXR following water-soluble contrast (e.g. oral Gastrografin®) can be used in prognostication of acute small bowel obstruction, helping to predict which patients can be managed conservatively. Our institution utilises 100 mL of contrast diluted with an equal volume of water with films taken at 4 and if necessary 24 h post-ingestion. Post operatively, some centres may also administer water-soluble contrast orally for its potential therapeutic effect (to stimulate bowel peristalsis), as well as for its use as a diagnostic aid.

The position of enteral support devices such as nasogastric (NGT) and nasojejunal (NJT) tubes as well as central venous catheters (peripherally inserted and internal jugular) can be readily assessed with radiography. An improperly sited NGT may be ineffective at decompressing the stomach and represent a risk of aspiration.

Chest radiographs are used to identify complications related to acute IF, such as pneumonias (aspiration or nosocomial), or an erect film when a perforated viscus is suspected.

Fluoroscopy

Until recently fluoroscopy relied on the fluoroscopic properties of crystalline media, converting x-rays to collectible light to form a visible image. Modern digital fluoroscopy units now use digital flat panel detectors that convert the transmitted x-rays directly into electrical current allowing higher resolution images and potentially lower radiation doses. Fluoroscopy has the distinct advantage over most other modalities of allowing the operator to provide functional assessment by acquiring dynamic ('cine') images.

Fluoroscopy utilising either barium based or iodinated (water-soluble) contrast remains a useful tool in the IF patient. Water soluble contrast can safely be administered via any route, including vascular or where there is risk of entering the peritoneal cavity, whereas barium is generally only safe to administer into the lumen of the GI tract.

Barium is generally preferred when opacifying the GI tract, as it provides more detail and does not become so diluted in the distal bowel, which can minimise the interpretation difficulties due to overlapping bowel segments [1]. In addition the greater density and other properties of barium may increase the sensitivity in identifying a fistula. Barium should be avoided where acute, non-mature enteric fistulae are suspected, and generally should not be given within 3 months of acute fistulation. Water soluble contrast may be useful in these circumstances and when there is a risk of acute perforation or if surgery may be performed soon after the study. This is because barium can precipitate peritonitis if it enters the peritoneal cavity either at the time of the radiology examination or through inadvertent spillage during surgery if residual barium remains in the bowel.

Barium Follow Through

After a period of fasting (between 4–12 h), to ensure the small intestine is empty, a barium follow through (BFT) involves ingestion of barium suspension (typically 300–600 mls of 50% w/v BaSO4). In addition, some centres use aerogenic powder (30 min before the examination) but this is only necessary if mucosal detail is required. Ingestion of oral barium is followed by imaging every 10–15 min until the barium has passed through the ileocaecal valve into the colon.

Whilst historically BFT studies have been the mainstay for evaluation of the small bowel, expertise is reducing in many parts of the world, particularly where CT or MR enterography (CTE or MRE) are readily available. Nonetheless, the examination still has significant utility in particular circumstances, and can provide greater assessment of mucosa and fold pattern for example (Fig. 1), not easily appreciable on other tests. Increased fold density, and subtle global or segmental fold thickening as seen in vascular insufficiency or low protein states, can be important signs or indicators of underlying pathology or disease response.

Fig. 1 Barium follow through which demonstrates the alteration in fold pattern seen in some conditions such as idiopathic sprue, coeliac and other malabsorptive states

Fig. 2 Water soluble contrast enema. The rectum and colon are filled with contrast and there is reflux into the terminal ileum. Note the contrast in the bladder (arrow) and renal collecting systems due to iv contrast given earlier for a CT

Cine images and serial evaluation over the course of several (usually 2–4) hours can demonstrate evidence of evolving or intermittent obstruction (most commonly due to adhesions) or dysmotility which can be difficult to differentiate on static modalities such as CT and MRI (although newer MRI techniques described later which are still evolving may allow similar dynamic evaluation).

Contrast is generally given orally to assess the 'in circuit' bowel, but can be instilled via the afferent orifice of a defunctioning loop or an end stoma as well as via the efferent stoma orifice to assess the downstream 'out-of-circuit' bowel ('loopogram'). A combination of these techniques can help determine residual lengths of in situ bowel when planning further surgery (either for stoma formation or restoring continuity), to identify and localise the origin of fistulae (entero-enteric and entero-colic), evaluate strictures, and determine suitability for distal limb feeding in patients with short bowel.

Fistulography

A contrast fistulogram may be obtained by cannulating the cutaneous opening of a suspected entero-cutaneous fistula and contrast injected in order to demonstrate its communication to bowel. This examination and other techniques to evaluate fistula are also described later in the chapter.

Contrast Enemas

Water soluble contrast enema studies, are performed by retrograde administration of approximately 500 ml of dilute contrast into the rectum (Fig. 2) or an ileal pouch. They are used to assess the integrity of anastomoses, length and diameter of a stricture and identify any fistula related to a number of causes such as complications of prior pelvic surgery, as well as neoplastic or inflammatory disease.

Other Procedures

Fluoroscopy may be used in siting enteral support devices (nasojejunal tubes and radiologically inserted gastrostomies), insertion of and assessment of vascular devices (peripherally inserted or central venous catheters for total parenteral nutrition), and in placement of trans-jugular intrahepatic portosystemic shunt (TIPSS) for portal hypertension.

Computed Tomography

Modern (spiral) multi-detector computed tomography (CT) utilises an x-ray source and sensor array directly opposite it mounted on a gantry. Through software it effectively creates

a three-dimensional volume of data as it rotates around the patient. It is now widely accessible and has become the most frequently utilised cross sectional examination in most radiology departments. This is in part due to its widespread availability, but also its excellent diagnostic utility and it offers advantages for both patient (often more convenient compared to an MRI) and radiologist (greater consistency of obtaining a high quality scan) compared to other imaging options. Intravenous iodinated contrast is routinely used and further augments the versatility of CT, allowing better differentiation between structures and clear visualisation of vasculature.

Though CT of the abdomen and pelvis carries a relatively high radiation dose (5–10 mSv), the short scanning time (less than 10 s in modern scanners) and out-of-hours access available in most acute hospitals, make it the superior modality for the acutely unwell patient compared to MRI, where diagnostic images are reliant on patients' ability to remain still and follow breathing instructions.

Contrast enhanced CT (CECT) utilises intravenous contrast, which can be optimised with specific contrast phases, mainly by using unenhanced, arterial (at 30 s), and portal venous (at 70 s) phases, the choice of phases being determined by which structures are being investigated. The widespread use of CECT increases the ability to identify ischaemia, arguably at earlier stages, which in turn may improve prognosis, [2] and this in addition to a range of other benefits likely justifies the increased use.

Studies may be further augmented by use of very dilute water-soluble or barium oral contrast media, which acts as a 'positive' contrast. A dilution of 1 part contrast to 10 parts water is effective for most cases (see Table 1 below). Dilution of oral contrast is required to optimise the density for CT, as undiluted contrast used for other x-ray examinations results in "streak" artefact, significantly compromising the image quality. Therefore CT should generally be avoided soon after enteric gastrografin® administration due to residual relatively undiluted contrast. Such a situation may arise when a CT is requested for example following an abdominal radiograph, taken 4 h after oral intake of gastrografin, which demonstrates features of small bowel obstruction (SBO). In these circumstances, a delay in CT scanning should be considered if feasible, to allow either absorption or dilution of the luminal contrast to avoid excess artefact.

Due to the risks of barium entering the peritoneum in enteric perforation, water soluble contrast is used in most CT examinations, particularly in acute settings, and barium is generally reserved for specific indications such as allergy or other contraindication to water soluble contrast. In recent years, routine use of any oral contrast is reducing, in part due to the increased logistical complexity and delay required before scanning, and additional cost and therefore it is usually reserved for answering a specific question or concern in more complex patients. Indications for positive oral contrast in IF include: better delineation of bowel anatomy in the complex surgical abdomen, to aid differentiation of bowel from adjacent collections, or to demonstrate points of fistulation and anastomotic compromise/leak.

Table 1 Water soluble luminal contrast in CT

Indication	Protocol[a]	Considerations
Small bowel	250–1000 ml over 45–60 min and scan after 45–60 min	More than 500 ml is usually impractical in small bowel obstruction and a more realistic volume of 250–500 ml helps reduce risk of patient vomiting
Large bowel	1000 ml over 60 min and scan after 2–4 h	If scan is for a distal colonic/rectal anastomosis, rectal contrast may be more successful
Rectum	Depends on height of anastomosis, but ~100–300 ml injected via Foley catheter in the rectum Catheter balloon: generally avoid inflating if recent anastomosis	Consider need for a pre-contrast scan to define anastomosis level

Considerations:
Enteric tubes should be clamped
Timings may need to be increased in suspected obstruction or shortened in patients with short bowel
[a]Contrast dilution: 1:10 is sufficient for most cases in CT, e.g. 50 ml contrast in 500 ml of water

Though most commonly given orally or via a nasogastric tube, luminal contrast may alternatively be administered via a stoma, rectally via a catheter, or even through a suspected entero-cutaneous fistula. It is naturally important to consider the patient's anatomy and what route of contrast will feasibly reach the area of concern, particularly relevant in patients with defunctioned bowel.

CT-fistulography may be performed in cases where an external opening is present and prolonged fluoroscopic fistulography is not practical, or when greater anatomical detail and relationships to adjacent structures is required, though it lacks the benefit of dynamic cine imaging. The fistula is cannulated and dilute contrast injected (1:10) with the volume used informed by previous imaging and surgical history, though this can be difficult to predict. A single CT can be immediately acquired, usually with intravenous contrast [3].

CT-Enterography

CT-Enterography (CTE) is a specific modification to the standard CT technique to allow detailed assessment of the small bowel. The protocol involves oral administration of 1.5–2 L of a contrast agent such as dilute mannitol solution (or a similar alternative) to act as a neutral or low-density luminal contrast (so appears the same as water) and provide small bowel distention. This is followed by intravenous con-

trast timed in the enteric phase, which is obtained by scanning at 50 s post-intravenous contrast administration, the timing of which maximises mucosal enhancement [4].

The administration of oral contrast is usually started around 45 min prior to CT, following a 4–12 h fast. Immediately prior to the scan, an intravenous injection of an anti-spasmodic agent (most commonly Hyoscine butylbromide (Buscopan®)) is given to reduce small intestine muscular tension. Relatively rapid image acquisition and the use of antispasmodics reduce motion artefacts caused by respiratory and gastrointestinal peristalsis respectively. CT has the advantage of providing volumetric data, allowing multiplanar imaging reconstruction and the ability to use image analysis software (for example vascular and bowel luminal software) which can allow 3D virtual reconstruction. CTE provides the additional benefits over radiography of a combined luminal assessment and evaluation of extramural structures and other organs.

Specific indications include assessment of strictures, inflammatory bowel disease, fistulae, small bowel and mesenteric root tumours, and obstruction related to above mentioned conditions or other causes including adhesional disease. The necessity for the patient to ingest a large volume of fluid generally limits the use of CTE to well outpatients.

Magnetic Resonance Imaging

An advantage of magnetic resonance imaging (MRI), compared to the imaging options described above, is the lack of ionising radiation. MR scanners employ very powerful magnets and receiving coils to create the images. The strength of these magnets is measured in units of Tesla (T). In theory, the more powerful the magnet, the better or quicker the images can be obtained. Most MR scanners in clinical use currently have a 1.5T magnet. The most powerful MRI magnets available for routine clinical indications are 3T. Unfortunately they can have greater problems with artefacts and more practical limitations than 1.5T scanners, including increased risks of localised heating causing tissue damage. As manufacturers find solutions to overcome these problems, increasingly 3T scanners are becoming more widely available in hospitals, leading to the potential for significant improvements in the quality of MR imaging.

When high quality MR scans are obtained, they can provide excellent anatomical detail, in addition to assessments of disease activity (Fig. 3). Newer functional MR techniques can evaluate other parameters such as motility (described in more detail later).

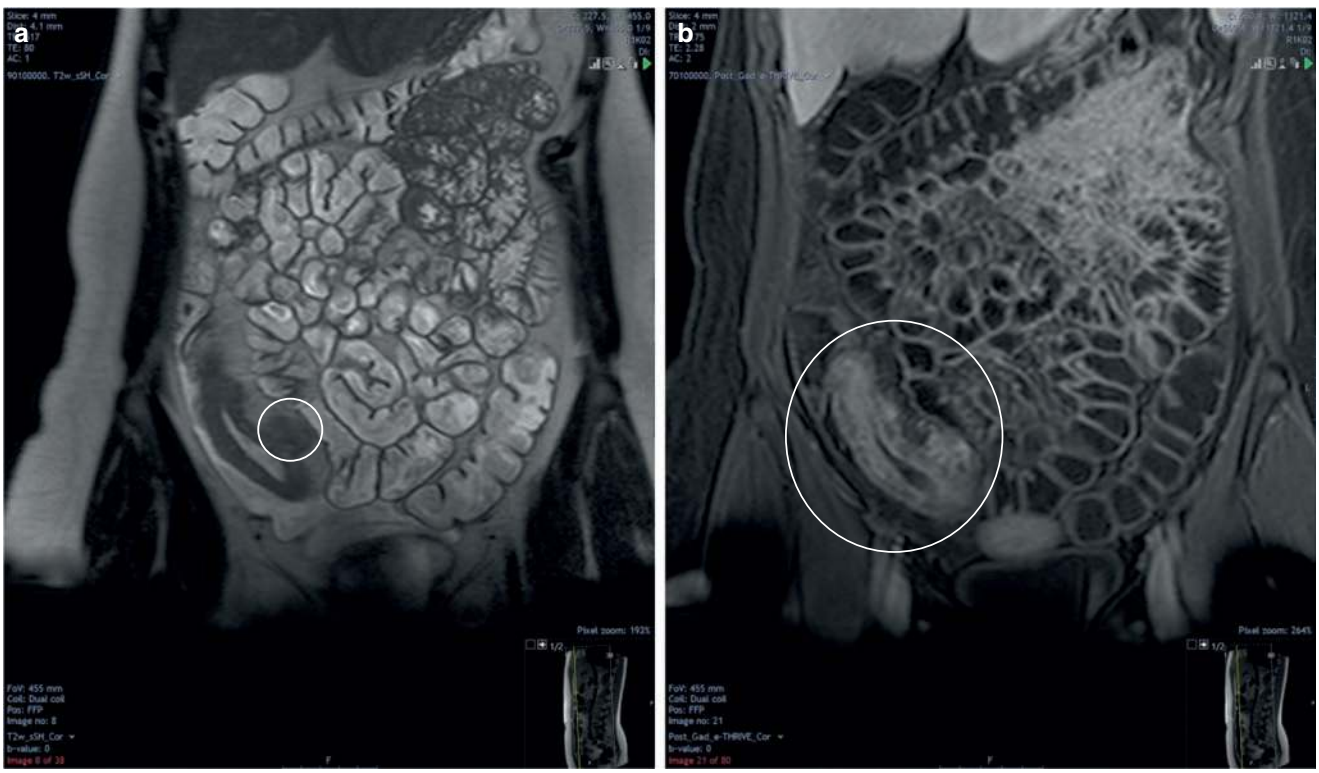

Fig. 3 MRE (**a**) Coronal T2 sequence showing Terminal Ileum mural thickening, with fat hypertrophy causing loop separation and penetrating disease demonstrated by adjacent mesenteric abscess (circled) and on the (**b**) coronal T1 post contrast image, there is mural stratification of the thickened TI (circled)

MR Enterography

MR Enterography (MRE) shares some elements of patient preparation with CTE, including the requirement for the patient to drink up to 1.5 L of oral solution, after a period of at least 4 h of fasting. There are a number of oral solutions available [5], but the most commonly used in the UK are mannitol or Lactulose based solutions. The choice of oral solution will generally be determined by local preference. Most oral contrast has an increased osmolality compared to water, which reduces absorption in the small bowel, but as a direct consequence, this often leads to the commonest side effect which is diarrhoea. MRE also requires intravenous injection of an anti-spasmodic agent (Hyoscine butylbromide (Buscopan®)) to reduce small intestine muscular contraction, and to reduce motion artefacts caused by gastrointestinal peristalsis. Any movement is a significant problem during many MR sequences, and therefore any bowel, respiratory or patient motion can markedly degrade the images.

Most MRE protocols generally utilise a gadolinium based intravenous contrast agent, which can be an advantage in those patients who have an allergy to iodine based agents required for CT.

Most radiology departments have access to MR scanners, but availability in some centres may be more limited compared to CT or other modalities. The time taken to acquire an MR scan is longer compared to CT, which can be a factor in determining how quickly or easily an MR scan can be arranged, particularly in the acute setting. MR enterography usually requires the patient to be in the scanner room for up to 45 min (compared to 10 min scanner room time for many CT scans), or longer if additional sequences are utilised. This relatively long scan time is also one of the reasons MRI is usually a more expensive scan than other imaging modalities.

To avoid respiratory motion artefact, the patient is asked to hold their breath for up to 20 s during most MRE sequences, whilst the images are acquired. Most MRE protocols will include around 8–10 breath hold sequences. If a patient is unwell, claustrophobic or finds it difficult holding their breath (particularly in older or younger patients), undergoing an MRE can be quite challenging or even unpleasant. As a result, achieving high quality MRE examinations consistently is difficult as it requires full compliance. It is therefore helpful for clinicians to be aware of these issues when discussing imaging requests with their radiologist to decide when MR is the most appropriate imaging option.

Ultrasound

Ultrasound (US) is made up of mechanical waves that can transmit through different materials like fluids, soft tissues and solids. Medical ultrasound machines generate and receive ultrasound waves with a frequency ranging between 2 and 20 MHz. Changing the frequency of ultrasound waves will alter the penetration and resolution of the images. The higher the frequency, the better the resolution is, however the depth of penetration decreases. Utilising the highest frequency probes (15–20 MHz), sub-millimetre resolution can be achieved, but the structures being evaluated must be within 3–4 cm of the probe to obtain this resolution. It is therefore easy to understand why US can be optimal when scanning thin patients, and conversely may be of limited value in patients with high BMI or where the probe can't be placed close to the site of the pathology. Views may also be limited if there is gas between the probe and the area to be visualised (e.g. in bowel or in enteric perforation causing free gas). In addition, the quality of images can be poor in patients who are tender, preventing the operator from pressing the probe deeper into the abdomen, which is often required to optimise resolution. US scanning may also be hindered by overlying dressings, stoma bags and subcutaneous oedema, though communication between referring clinicians and radiologists and good patient preparation can help optimise studies.

US of the bowel can provide real time evaluation of features such as motility, and correlation with areas of patient tenderness can allow accurate localisation of pathology. Most centres don't require patients to drink any oral solution, or cannulation for intravenous agents, which means that typically US is less intimidating for children than an MRE. As a consequence, many centres now advocate the use of US as a first line or as a complementary test to MRE [6], for younger children in particular. However, it should be borne in mind that US is very operator dependant, and so unsurprisingly its use is dependent on the availability of appropriately skilled operators (radiologists, sonographers or other clinicians).

Common indications for Imaging in Intestinal Failure

Sepsis

Radiology plays an essential role in the localisation of sepsis, particularly given that patients may present atypically due to their impaired immunity and failure to thrive may be the only manifestation [7].

Contrast-enhanced CT is a highly sensitive test and has the benefits of being quick to perform and well tolerated except in the most unstable patients. Positive oral contrast can be crucial in problem solving in the complex abdomen, and particularly in helping to differentiate bowel from intra-abdominal collections.

Radiation dose from studies should be minimised, but this must be balanced against the benefits of identifying and then

potentially draining infected collections, given the high mortality rates associated with sepsis [3, 7].

Ultrasound can provide greater anatomical detail for evaluation of the biliary system than CT and is superior in differentiating cholecystitis from physiological gallbladder oedema. Its portability also means it is useful in assessing patients who are too unstable to attend for CT.

Fluoroscopy's dynamic aspect can be helpful in identifying suspected fistulae which may be driving sepsis, particularly those that are more subtle and less apparent on static cross-sectional studies [3, 7].

MRI generally has a more limited role in the acutely unwell IF patient, when clinical questions can usually be answered with other modalities, and is therefore generally confined to problem solving following other imaging. Pelvic sepsis is one exception where MRI can be superior to CT, as the relative lack of respiratory motion that makes abdominal MR imaging difficult, can allow for detailed analysis of pelvic structures. Optimal MRI scans of the main pelvic cavity require meticulous attention to detail and close co-operation between clinician, radiologist and radiographer to utilise the full potential of modern MRI scanners. In these circumstances, pelvic MRI can be successful in identifying the source of sepsis, when other techniques have failed.

Once the underlying site of sepsis has been detected, imaging can be used for planning further management. Percutaneous radiological drainage (either under CT or US) may provide a safer alternative to surgery and allows antimicrobial rationalisation following culturing of aspirate.

Collections, often rim enhancing on CT scans, are common in the early days after surgical intervention especially in undernourished patients, due to a reactive and exudative process in the peritoneum. The presence of an enhancing rim alone is not sufficient to define an infected collection, and its shape is equally important, looking for imaging features to indicate whether it is under tension and becoming spherical and deforming, or if it conforms to the peritoneal recesses. Clinical assessment is critical, and in the post-operative period collections should only be drained if symptomatic with swinging fevers or localising pain or persistently elevated/rising inflammatory markers. If there is an enteric leak driving the collections then in most circumstances a fistula will develop along the drainage track. Consideration should therefore be given to the location of the drain with respect to an amenable site for placing a stoma bag later. Small inter-loop collections should generally be left to evolve, unless they are amenable to trans-gastric or other safe drainage option.

Small Bowel Obstruction

Small bowel obstruction (SBO) is a common condition occurring when normal transit of bowel contents is prevented by mechanical or functional causes [8]. In the UK it accounts for nearly half of all laparotomies performed, with an associated 30-day mortality rate of 7% [9]. Effective treatment depends on a rapid and accurate diagnosis, requiring a comprehensive approach with imaging often playing a pivotal role.

Definitions of SBO [10]:

1. Complete/high grade obstruction: no fluid or gas passes beyond the site of obstruction
2. Partial/low grade obstruction: some fluid or gas is able to pass beyond site of obstruction
3. Closed loop obstruction: a segment of bowel that is obstructed at two points along its length and is at risk of ischaemia
4. Strangulated obstruction: indicates that blood flow has been compromised.

The causes of SBO can be divided into three main categories:

1. Intrinsic: inflammatory disease, neoplastic, vascular, haematoma, intussusception
2. Extrinsic: adhesions, hernia, haematoma, endometriosis
3. Intraluminal: gallstones, bezoars, foreign bodies

Traditional teaching states that three main aetiologies account for most causes of mechanical SBO: adhesions, hernias and neoplasia [10]. Adhesions are the most common cause of obstruction, and account for 50–80% of SBO cases [8, 11, 12]. Whilst hernias remain common in developing countries, Crohn's disease has now replaced hernias in Western society as one of the most common causes of SBO [8, 12].

Identification of Obstruction

As well as confirming a diagnosis of SBO, imaging can be used to determine its site and cause, and identify any associated complications [10].

Plain film radiography is advocated as the initial examination due to widespread availability and low cost, although it has a reported accuracy ranging from 50 to 60% [12]. A more recent study reported sensitivities of around 80% [13]. However, in a setting of IF where surgery is not imminent, and removing diagnostic uncertainty may change management, then cross-sectional imaging is warranted. Multi-detector computed tomography (CT) has become the mainstay of imaging where available, with a sensitivity of 82–100% [8]. Ultrasound is often unhelpful due to intraluminal bowel gas obscuring the view of deeper structures, rendering the images non-diagnostic.

Plain Abdominal Radiograph Findings

The hallmark of SBO is the presence of dilated bowel loops (>3 cm) proximal to the obstruction. There are a range of other findings in radiographs for SBO, including a 'string of beads' sign, secondary to slow resorption of intraluminal air, with residual small bubbles trapped between the valvulae conniventes [14]. However, aside from inguinal hernias and gallstone ileus, the cause of SBO is rarely seen on a radiograph, and hence further cross-sectional imaging is usually obtained.

CT Technique and Findings

CT is the preferred investigation for SBO, given its speed and sensitivity. It has a greater ability to determine the site of the transition point, its cause and exclude a closed loop obstruction. The transition point is the point of abrupt calibre change (Fig. 4). If a clear transition point is identified, then the cause can almost always be determined or inferred.

Traditionally, positive oral contrast was administered in patients suspected of having SBO. An advantage to this approach includes a prognostic element, based on the observation that if the contrast passes distally into the decompressed bowel, then high grade SBO is excluded. However, many centres now scan without oral contrast, because (a) nauseated patients may vomit potentially leading to aspiration; (b) in SBO the retained intraluminal fluid serves as an excellent neutral contrast agent, without the need for additional positive oral contrast; (c) its omission eliminates the need for a delay in the examination [10]. Similarly, CTE, which requires ingestion of a large volume (usually at least 1 L) of oral contrast, is therefore not usually performed in an acute setting.

Intravenous contrast is administered, and the patient scanned in the portal venous phase (60–70 s delay) which provides optimal assessment of most abdominal and pelvic structures and also achieves good enhancement of the bowel wall.

The diagnosis of SBO on CT is determined by the presence of dilated small bowel loops (>3 cm diameter) proximal to a transition point, with normal calibre or collapsed loops distally. The colon is often decompressed, depending on the degree of SBO.

The 'small bowel faeces' sign is the presence of particulate material with gas bubbles in the small bowel, similar to the appearance of stool in the colon. This is presumed to be secondary to delayed transit, with increased fluid absorption and accumulation of undigested food as a result of obstruction or stasis [15, 16]. Whilst studies disagree about whether its presence correlates to the degree of obstruction, it serves as a useful aid in finding the transition point [17].

The many causes of SBO have differing appearances; some of the most common causes are outlined below:

Adhesions

Adhesions are bands of fibrous tissue which connects surfaces or organs within the peritoneal cavity that are normally

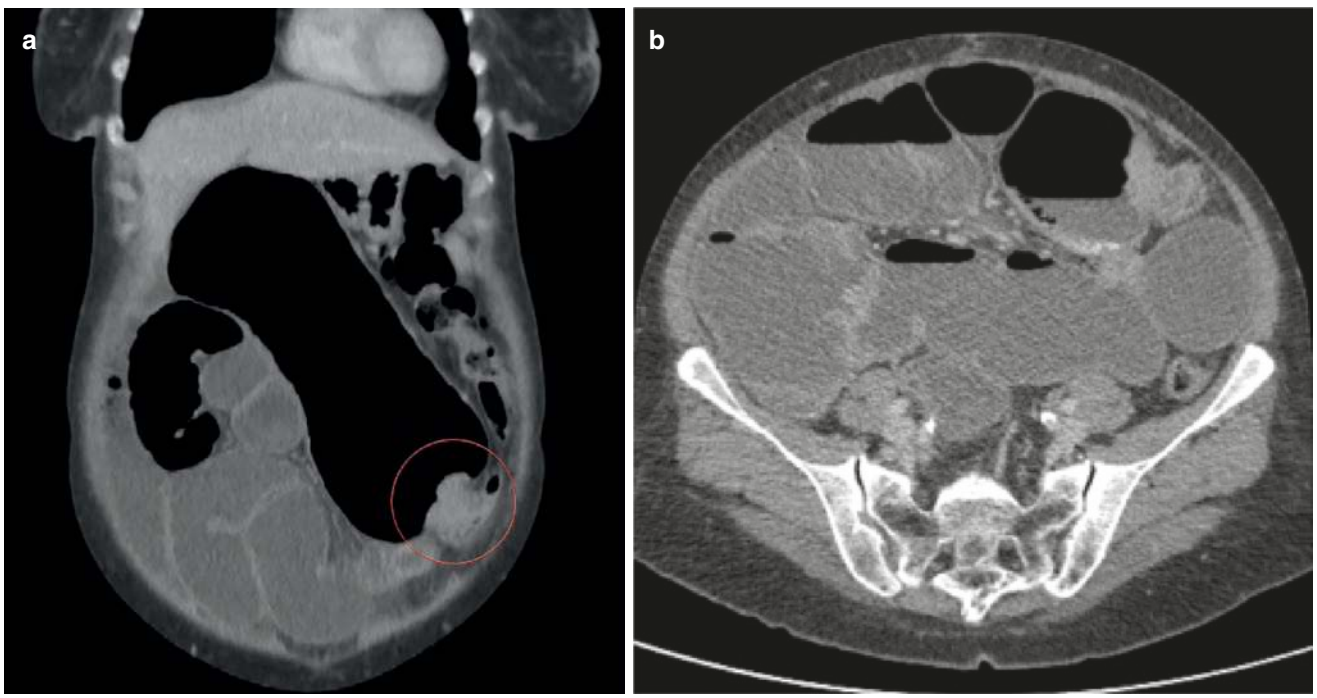

Fig. 4 Coronal (**a**) and axial (**b**) CT shows large bowel obstruction due to transverse colon cancer associated with a clear transition point (arrow) and collapsed colon distal to this

separated [18]. Almost all are secondary to surgery, with a minority caused by peritonitis. The adhesion itself is usually not visible on CT and as such, typically is a diagnosis of exclusion; its presence is inferred when there is an abrupt transition point or sharp angulation of bowel loops, in the absence of an alternative identifiable structural cause [10]. On a BFT, absence of movement of the bowel with respiration or on extrinsic compression increases the level of confidence for adhesions but this assessment is limited by large body habitus and presence of fistula or stoma. Similar observations can also be made with MRI on cine sequences or on US, but again both of these modalities may be challenging in large or unwell patients.

Whilst BFT and CT remain the key examinations for identification of adhesions in clinical practice, a review of multiple studies has shown that both transabdominal ultrasound and dynamic MRI can achieve a diagnostic accuracy between 76% and 92%. Ultrasound can identify adhesions by assessing movement of small bowel, small bowel morphology and visceral glide. Dynamic MRI on the other hand can be assessed during breathing or straining to assess visceral slide. However, one large limitation of most of these studies is a lack of blinding, as surgeons were made aware of findings prior to intraoperative correlation [19].

Crohn's Disease

When SBO occurs due to the acute presentation of Crohn's, this is characterised by stenosis of the bowel lumen, usually secondary to the transmural inflammation. Affected segments may demonstrate wall thickening and hyperenhancement (Fig. 3), associated with mesenteric hypertrophy, vascular engorgement and lymphadenopathy [20]. Classically, the adjacent fat appears clean homogeneous and black in contrast to the oedematous fat stranding seen in other inflammatory conditions. SBO may also manifest in chronic disease, seen on imaging as stenotic strictures but without evidence of active inflammation.

Hernias

Hernias are classified by the anatomic location of the defect through which the bowel protrudes [8]. They are broadly classified as either internal or external, with external being the most common. Common hernia sites include the inguinal canal, the femoral canal and the anterior abdominal wall. The hallmark of SBO secondary to a hernia is the presence of dilated bowel loops with a transition point at the entrance in to the hernia sac and decompressed bowel exiting from the sac [10].

Complicated SBO: Closed Loop Obstruction

A closed loop obstruction is a segment of bowel that becomes obstructed at two points along its length, essentially leading to its isolation from the remainder of the bowel. Commonly, it is caused by a single adhesive band, but internal hernias or iatrogenic defects in the mesentery are also recognised causes [10].

CT findings of closed loop obstruction depend on the orientation of the loop relative to the plane of imaging. Fluid-filled dilated loops with a U-shaped or C-shaped configuration (in longitudinal section) and a corresponding radial distribution (in an orthogonal plane) [21] can be best identified by using multi-planar reformatting for image review. Fusiform tapering at the site of obstruction ("beak" sign) may be present [21]. A "whirl" sign, representing rotated intestinal vessels surrounded by mesenteric soft tissue, fat and bowel loops has also been described [21, 22]. Strangulation occurs in 10% of patients with closed loop obstruction, leading to ischaemia [23] and the earliest sign of this is oedema and associated effects in the affected segmental mesentery together with venous engorgement/dilatation.

Post-operative Ileus

Post-operative ileus (POI) is the impairment or arrest of gastrointestinal motility following surgery. Despite its reported incidence rate of 10–30% for abdominal surgery [24–29] with resultant increase in morbidity and length of stay, there remains no internationally accepted standard definition of POI, nor any consistent distinction between the 'normal' physiological period of dysmotility and the prolonged pathological entity [30, 31].

Whilst clinical presentation of mechanical obstruction and POI are similar in early stages, key differences in radiological findings may sway the diagnosis. A reported feature on abdominal radiographs is gaseous distension of both the small bowel and colon. However, this finding is not reliable, as the colon is difficult to visualise when it is fluid-filled, or if the patient has had a colectomy [32]. CT is more definitive, usually demonstrating dilated bowel loops similar to SBO, but without an abrupt transition point, often gradually tapering to normal calibre distally.

In cases of prolonged ileus, there should be a low threshold for considering alternative underlying pathologies such as anastomotic leak, perforation or collection – all of which can be seen on CT.

Gut Ischaemia

Ischaemia can increase the morbidity and mortality associated with SBO. The physical examination and laboratory findings are not specific and imaging findings can support a diagnosis of ischaemia in the correct clinical context. Accuracy of CT varies amongst studies, with a reported 83–100% sensitivity and 61–93% specificity [33–35].

CT technique for ischaemia remains a contested issue, with some centres advocating for 'triple phase' approach (unenhanced, arterial and portal venous), stating that (a) the unenhanced study allows for a point of reference when determining bowel enhancement and (b) unenhanced increased

bowel wall density reflects haemorrhagic transmural necrosis [36]. However, others argue that unenhanced CT is not required for diagnosis of ischaemia, with its low sensitivity [37]. Most centres opt for a dual phase approach, with an arterial phase to assess the arterial vasculature and portal venous phases to assess bowel wall enhancement and mesenteric/portal venous system.

CT Findings: Arterial vs Venous Ischaemia

The appearances of bowel ischaemia on CT include: bowel wall thickening (>3 mm); mesenteric oedema and/or fluid in the mesentery or peritoneal space; decreased bowel wall enhancement; pneumatosis (intramural gas) with or without associated gas in the mesenteric/portal veins [10]. Pneumatosis is a late sign and is suggestive of infarction. The vasculature should be carefully scrutinised, with accompanying knowledge of the arterial supply and venous drainage of the bowel.

Arterial

Arterial thromboembolism can be seen as a filling defect within or occlusion of the supplying artery, best visualised on the arterial phase. There may be extensive background atherosclerotic disease. Bowel enhancement is absent or decreased due to cessation of arterial supply, with bowel wall thickening rarely occurring unless reperfusion occurs [38]. Perhaps most useful, is the identification of a difference in bowel enhancement within a segment of bowel, compared to adjacent proximal and distal bowel, and may be matched by reduction or absent enhancement of the supplying arterial vessels. The bowel wall may become thinner as ischaemia progresses, leading to pneumatosis as infarction develops (Fig. 5) [39]. Mesenteric inflammatory stranding and ascites are rare but can occur with infarction and perforation [39].

Venous

Venous occlusions accounts for 5–10% of bowel ischaemia [39]. Impairment of the venous drainage increases the hydrostatic pressure, leading to extravasation of fluid into the bowel wall and mesentery [39]. Thrombus in the mesenteric venous system is usually visible [40]. Bowel wall thickening, fat stranding and ascites are commonly present [38].

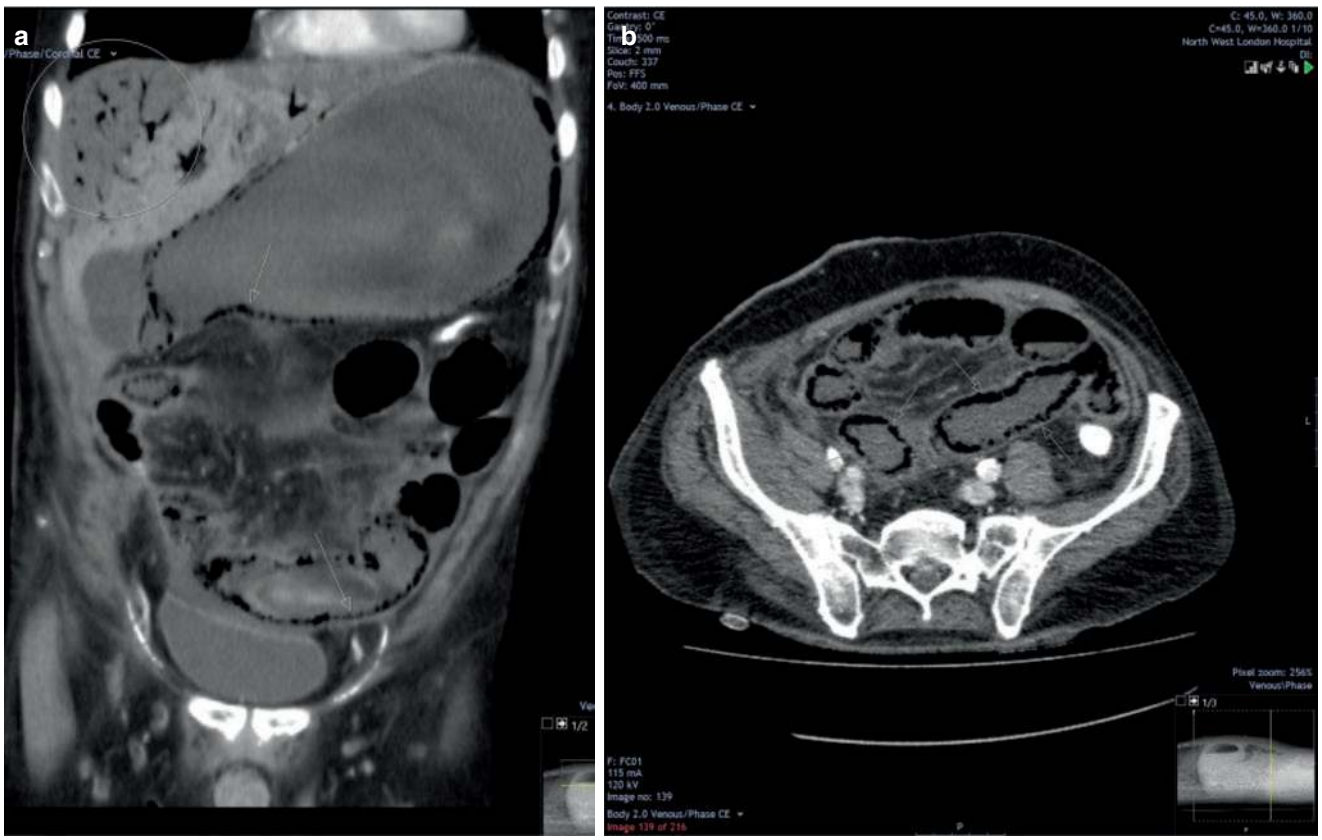

Fig. 5 CT demonstrates extensive pneumatosis indicating bowel infarction. On the coronal image (**a**), there is gas in the wall of the stomach (upper arrow), and in the small bowel (lower arrow). In addition there is portal venous gas associated with liver infarction (circle). Axial CT (**b**) there is gas in the wall of most the visible small bowel (arrows)

Management

Whilst historically management of acute mesenteric ischaemia has focussed on a surgical approach, with restoration of blood flow and resection of necrotic bowel, endovascular treatment (EVT) is now playing an important role [38]. A variety of techniques including catheter directed thrombolysis, embolectomy and stenting can be employed to treat acute thrombotic superior mesenteric artery occlusion [41]. Anticoagulation or low molecular weight heparin is recommended as first line treatment for venous thrombosis, EVT can be considered in certain scenarios if patients deteriorate despite medical treatment [42].

In summary, there are a wide range of CT findings which may or may not be present depending on the stage of ischaemia, and sometimes these changes may be reversible, exacerbating the challenge in making a timely diagnosis, and explaining why there is such a wide range of diagnostic accuracy for identification of ischaemia by CT. Clinicians as well as radiologists must be mindful of the difficulty in excluding bowel ischaemia even with good quality imaging. Clinicians and radiologists should have a low threshold to seek early specialist GI radiology review, as perhaps the most efficient route to addressing any diagnostic uncertainty, if there is a discrepancy between the initial imaging report and clinical suspicion of ischaemia.

Assessing Length of Small Bowel

An accurate understanding of the length of small intestine remaining is particularly important in patients requiring repeated small intestine resection, which may result in short bowel syndrome (SBS) [43]. The morbidity and mortality of SBS is directly related to remaining small intestine length [44], with the degree of malabsorption being influenced by the length of remnant small intestine as well as the status of the patient, their colon, underlying disease process and other absorptive organs [45–48]. Remnant small intestine length is an important indicator for management decisions including autologous small intestine lengthening procedures [49–51], and can be an important factor in assessing likelihood of patients surviving without parenteral nutrition [52]. Therefore, accurate measurement of the remnant small intestinal length is important for clinical prognostication and treatment planning.

Intra-operative

Intra-operative measurement of small intestinal length by an experienced gastrointestinal surgeon, which involves measuring along the anti-mesenteric border (without stretching the bowel) from the ligament of Treitz to the end of the small intestine using known lengths of suture material and a ruler, is regarded as the gold standard [53]. However it is usually only an appropriate option when surgery is indicated for some other reason and length assessment is carried out by a surgeon familiar with the technique. Whilst knowledge of intestinal length is crucial for future decisions, direct measurement may not be available due to: surgery being performed in an emergency situation, variation in surgical expertise, a hostile abdominal environment, or simply an inability to review detailed patient records. Therefore, measurement of small intestinal length by non-invasive radiographic examination is a common route for developing patient specific management plans.

Barium Follow Through

Two studies have demonstrated a correlation between bowel length assessment measured by BFT and clinical prognosis [50, 51]. It is a relatively cheap and widely available study but is limited by 2D imaging, wherein collapsed or superimposed/overlapping bowel segments and loops may result in underestimation of the length when remnant bowel length is over 150 cm. Moreover, patients in the post-operative context can frequently suffer from adhesions and sometimes related to this, pelvic bowel loop aggregation, both of which may further reduce accuracy if overlapping loops can't be separated. Application of an opisometer can improve the accuracy of BFT length assessment [54]. Overall the BFT-surgical measurement correlation was found to be moderate (r^2 values <0.75) [1, 55], including in studies of SBS patients [54].

In our institution, BFT compares favourably with intra-operative measurements of bowel length, particularly with residual lengths of less than 150 cm, and may allow a more accurate assessment of length, compared to CTE or MRE.

One of the limitations of BFT is that it is only able to measure in circuit bowel length. In order to accurately assess length of the out of circuit bowel, a further examination is often required, such as a distal loopogram, with barium or water soluble contrast introduced per catheter, to the afferent limb or fistula, to access the out of circuit bowel.

CT Enterography

The use of CTE had a statistically significant correlation with surgical measurement and outperformed BFT with regards surgical measurement correlation, in a small study of SBS patients [54].

MR Enterography

Measurements of small intestine length are performed on a range of rapid image-acquisition techniques, usually utilising assessments on a range of sequences obtained as each can have a different advantage or drawback for measurement of length (Fig. 6). On some studies, MRE has been shown to more accurately correlate with surgical measurement than CTE [54, 56] but may be very operator dependent.

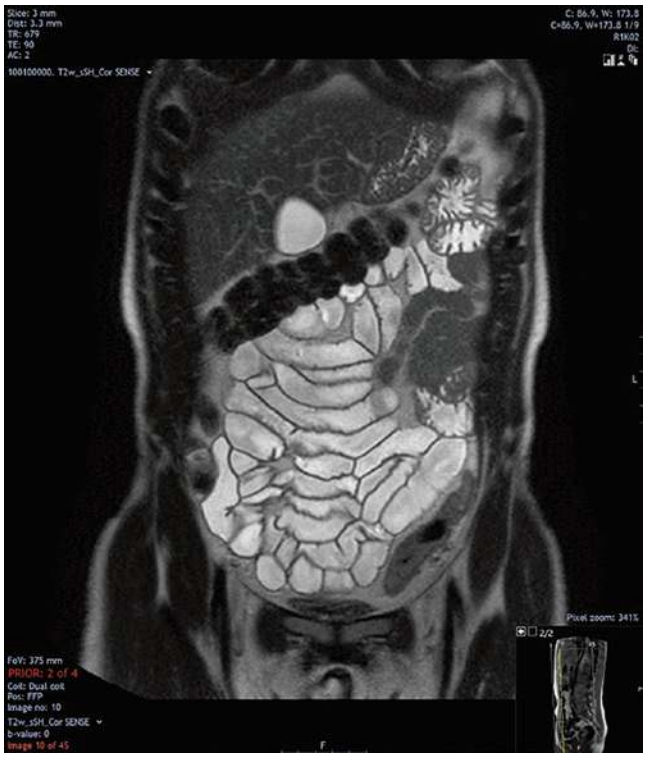

Fig. 6 This is a single coronal image from a T2 sequence of a normal MRE. The majority of the small bowel is well distended, and the quality allows a good assessment of bowel length, when following the course of the small bowel on all of the images in this sequence

Novel Techniques

Preliminary studies have evaluated the use of software aided manual [56] and algorithm based automated [57] methods of small intestine measure on MRE images. Although the latter has so far only been conducted in mice studies, the results are promising and in the future may provide a useful adjunct to improve accuracy of non-invasive methods [57].

The measuring tools available on all PACs software allow accurate measurement of bowel length with all of the modalities described above. However, despite the ability of CT and MR to view the bowel in multiple planes, the course of the bowel may weave in and out of the standard planes, necessitating a very time consuming process of measuring multiple short segments, by repeatedly changing planes to follow all the twists and turns of the entire small bowel. In practical terms, whichever technique is utilised, time is required to meticulously navigate the course of the bowel, either while acquiring the images (BFT) or when analysing them on PACs. A BFT is still readily available in many centres and can be inexpensive, but may be limited by 2D imaging, adhesions, aggregation, pelvic pooling and overlapping bowel loops, and potentially requires more radiologist time to perform the exam. However if good quality images are obtained, paradoxically, the time required to measure bowel length is often less when compared to CT or MR. CTE has been shown on some studies to be superior to BFT and to strongly correlate with surgical measurement. In our institution, CT is gradually becoming the most common technique utilised for assessment of length, in part because many of the patients will have had a CT at their base hospital prior to being referred to our unit.

In general the longer the remaining length of bowel, the longer it will take to complete this process, and the harder it may be to get an accurate measurement of the length. In addition, in patients who have multiple collapsed or adhesed segments, measurement may be difficult or of limited value on a single examination. However, many of these patients will have had at least 2 or more scans at different times, typically associated with acute admissions. In such patients, an accurate measurement may only be obtained by analysis of multiple different examinations at different times, assuming segments that are poorly visible on one exam, are better visualised and hence more easily measured on a different exam obtained at a different time.

Assessment of Quality of Small Bowel

The quality of small bowel and the disease affecting it are important determinants of its ability to carry out its functions of absorption and motility, which are linked to morbidity even when bowel length is maintained [3].

Fluoroscopic examination with luminal contrast is an effective technique for short bowel segments (<150 cm) [58] and contrast can be introduced via multiple routes including orally, via stoma or fistula or per rectum. As a dynamic study it allows a more targeted examination than other modalities, and is particularly helpful in assessment of the distal out of circuit bowel where there has been a defunctioning stoma created, or an enterocutaneous fistula (ECF). There is a significant benefit in watching and controlling luminal distension and in the assessment of fistulae tracts in real time.

Often, studies using a variety of modalities and instillation routes may be required to assess bowel segments independently to overcome issues such as under-distended or overlapping loops, maximise accuracy and provide as much detail as possible to optimise management decisions.

Cross sectional (CT/MRI) imaging has the added benefit of global intestinal and extra-intestinal assessment; mural and mesenteric pathologies can be occult at luminal imaging such as fluoroscopy or capsule endoscopy but may be apparent on CT which is now the mainstay of imaging assessment in most centres due its sensitivity and ubiquity. CT is performed individually or adjunctive to fluoroscopy, for cases

with complex post-surgical anatomy. Water soluble oral contrast is often used with CT to delineate fistulation, sinuses or to demonstrate collections where these are suspected. CTE protocol with bowel distension (as described earlier) is often the optimal technique for assessment of mucosa, wall thickness and bowel lumen calibre, particularly if strictures are suspected [59].

It is important to be aware of the normal cross sectional appearances and parameters of small bowel: fold patterns varies between jejunum, possessing feathery thin closely spaced folds (valvulae conniventes), and ileum which demonstrates a lesser density of folds. On CTE normal small bowel wall thickness should be less than 3 mm when the lumen is distended [60]. Intravenous contrast enhancement is assessed at multiple phases timed following high flow bolus administration of contrast; bowel mucosal enhancement is optimally assessed in the enteric phase (50 s following contrast injection) [61, 62] but can also be adequately assessed on portal venous phase imaging (70 s) [63], whilst arterial phase (30 s) is useful for assessment of vascular compromise.

Features of acute inflammation include: mural hyper-enhancement, bowel wall thickening and stratification (with mural hyper-enhancement being the most sensitive CT imaging sign of active inflammation in the setting of Crohn's disease [61]. Mural stratification describes the laminated appearance to the bowel wall, the appearance occurring due to the presence of mucosal hyper-enhancement with submucosal thickening and hypo-attenuation due to oedema/inflammatory infiltration. Intramural fat can be a normal finding in the ileocaecal valve but can be a sign of chronic inflammation elsewhere [60].

Inflammatory changes in Crohn's disease are frequently on the mesenteric aspect of the bowel and can be penetrating, with a spectrum ranging from ulceration to fistula, appearing as hyper-enhancing transmural/extra-mural tracts within the mesentery. Mesenteric hypertrophy produces a characteristic expansion of the mesenteric fat easily identified on CT with a clean and sharp appearance of fat creating a striking contrast to the increased size and prominence of the mesenteric vascular arcades and producing a classical comb sign in an affected hyperaemic bowel segment. Beyond the acute stages, chronic intestinal inflammation and deposition of extracellular matrix protein are contributory factors to small bowel fibrosis; on imaging this is suggested by the presence of wall thickening in the absence of mural oedema or hyper-enhancement, upstream dilatation and delayed enhancement [64].

Many of the features described above can also be seen on MRE (Fig. 3). Cine MRI is an evolving technique described further in the next section, may in the near future may be a more widely available adjunct to MRE in providing a non-invasive and non-ionising assessment of gut motility [65]. Diffusion weighted imaging, a technique already widely used in other systems notably neuro-imaging, provides an alternative to intravenous contrast for functional evaluation which is particularly valuable in patients with renal impairment, when unenhanced CT would be of limited use. MRE has a high sensitivity and specificity for assessing disease activity in Crohn's disease [58, 60] and when it includes "cine" sequences, can be particularly useful in assessing and demonstrating strictures and complex adhesions.

Mapping Distal Bowel for Distal Feeding and Pre-operative Assessment

With the improvement in clinical nutrition, critical care medicine and minimally invasive bowel sparing surgery, there has been great progress in the management of enterocutaneous fistulae. However, high output fistulae pose a clinical challenge with associated malnutrition and organ dysfunction due to high volume loss of water and electrolytes [66]. This is particularly significant in the setting of patients with a short bowel or small intestine dysfunction, where the absorptive capacity of the remnant gut is reduced.

The conditions for utilisation of enteric nutrition are intestinal continuity and a minimum length of 75 cm of bowel [67]. In these patients imaging assessment with a combination of CT and fluoroscopy, is often used to map the distal bowel and assess integrity prior to feeding; including measurement of the length of the distal bowel, the continuity or otherwise of the remaining segments, as well as the mural and luminal status.

Fluoroscopy can be in the form of a loopogram where a stoma allows access to distal bowel or fistulogram if a fistula is present which may be a suitable entry point for distal feeding. The calibre of the distal bowel is assessed and, in particular, strictures and obstruction should be excluded as these may prohibit distal feeding (Fig. 7) or surgical anastomosis for restoring continuity. The orientation, fold pattern and lumen calibre of the excluded distal bowel may appear abnormal on the imaging assessment however it is worth noting that the imaging appearances may also underestimate structural and functional changes of bypassed segment related to altered blood flow, motility, hormones, secretions and mucosal surface area.

Fistuloclysis involves insertion of a balloon Foley catheter into the fistula and advancement of the catheter under fluoroscopic guidance to a depth of 5 cm into the distal intestinal lumen followed by insufflation of the balloon catheter. The proximal intestine lumen is intubated with a double pipe to collect intestinal fluid [67].

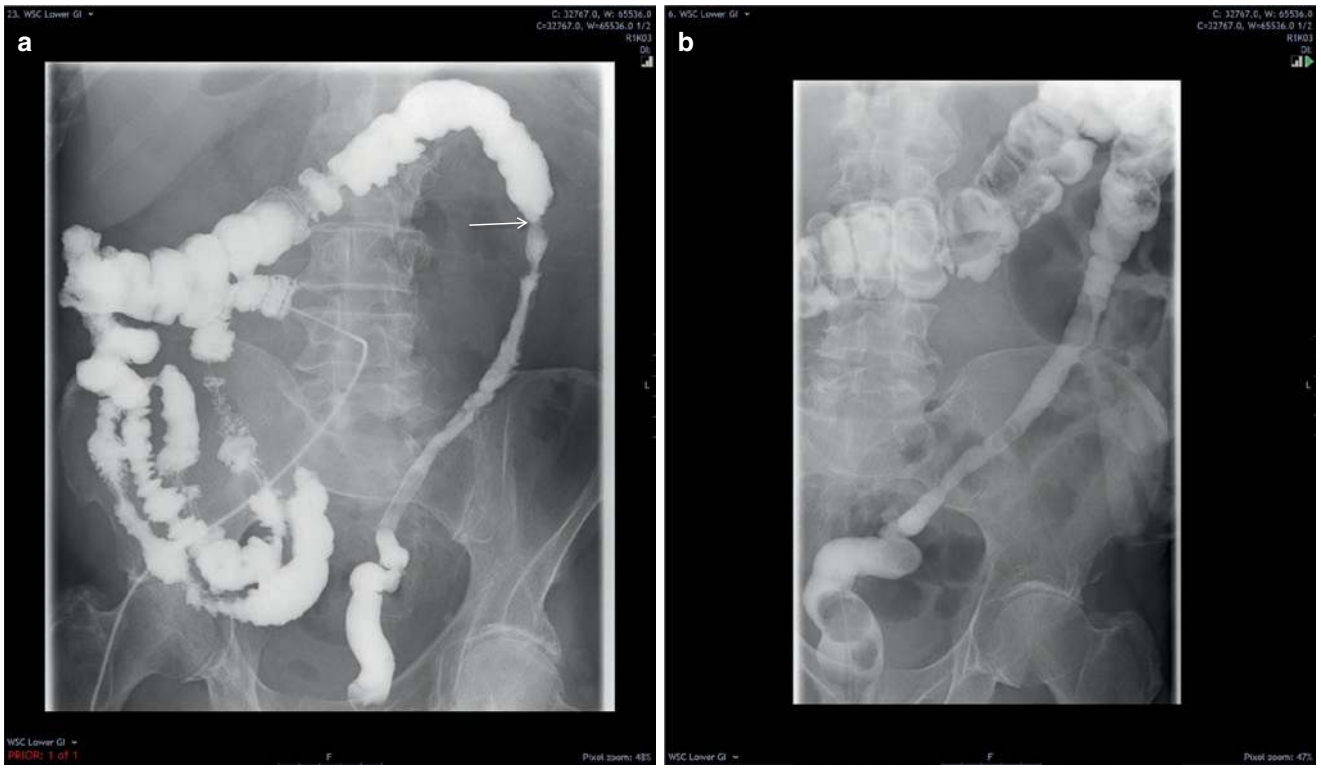

Fig. 7 (**a**) Distal loopogram to assess colon pre distal feeding, shows narrowing of the descending colon (arrow) with a clear transition from normal to reduced calibre. (**b**) A water soluble contrast enema, in the same patient after a period of distal feeding shows increased calibre of the descending colon

Motility Assessments

Dynamic small bowel imaging, which allows assessment of motility, is an evolving area of research, and includes various techniques which increasingly are being used in routine MRI small bowel protocols. Small single centre studies have shown that motility assessment protocols not only increases lesion detection rate compared with conventional MR enterography, [68] but that motility also is altered in distant macroscopically non-affected segments with active Crohn's disease (CD) [69]. Active inflammation, penetrating disease and a fixed stricture are associated with decreased small bowel motility [70]. Terminal ileum motility correlated with histology findings for active and chronic CD but did not allow differentiation between active and chronic disease, [71] and during flares, small bowel motility correlated with blood markers including calprotectin and CRP [72]. The length of inflammatory segments and wall thickening on the other hand did not correlate with the frequency of contractions [73].

Several studies have investigated the quantification of small bowel motility. One study has shown that quantification of small bowel motility is repeatable and sensitive to changes in response to drug therapy [74].

Fistula Tract Mapping

Fistulography

A fistulogram has been considered the best way of mapping a fistula tract when there is an external opening. Contrast is injected through the external opening and images are acquired using fluoroscopy [75]. One key limitation is the limitation in visualisation of adjacent or extramural pathology [76]. When an external opening cannot be identified, other contrast techniques described below and elsewhere can be carried out per stoma or per rectum to identify the luminal origin of the ECF.

Barium/Water Soluble Contrast Follow-Through

A small bowel follow through (SBFT) study can help to delineate the fistula tract when fistulography is inconclusive and to assess the bowel both proximal and distal to any fistula. Utilising barium rather than water soluble contrast may increase the sensitivity for detection of tracts. However, SBFT may fail to locate the tract if contrast passes through quickly or if the tract is small or occluded. As a consequence of this and the inability to evaluate occluded or incompletely patent fistula, SBFT may have a lower accuracy than CT and MRI [77].

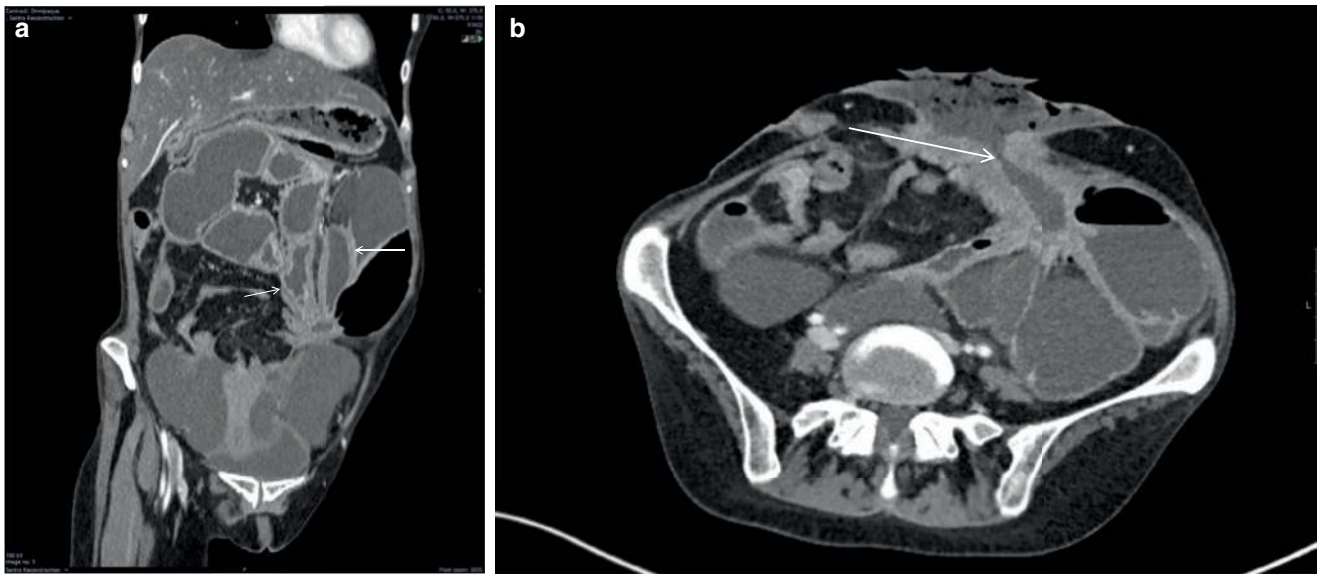

Fig. 8 (**a**) Coronal CT showing multiple loops converging towards a EC fistula. The increased mucosal enhancement and wall thickness indicates active disease (arrows). The whole of the EC fistula is fully appreciated on the axial CT (**b**) which shows the EC tract reaching the external opening (arrowed)

CT

CT allows high spatial resolution images of the fistula tract and its relationship to adjacent structures (Fig. 8). Positive oral contrast can help to better identify bowel loops especially in cases where patients lack intra-abdominal fat. Furthermore, if contrast opacifies the tract, it not only makes identification of a fistula tract easier, it also confirms patency. Another option is carrying out CT fistulography with injection of dilute contrast material through the external opening prior to CT. Care should be taken to ensure that very dilute contrast is used as the concentration required for per-oral or per fistula techniques on fluoroscopy are too high for use in CT where considerable artefacts will be generated. The typical appearance of an ECF is a tubular structure extending from a bowel loop anteriorly towards the peritoneum, crossing subcutaneous tissues towards the skin. Loops of bowel can become adherent to the anterior abdominal wall converging towards the fistula tract.

MRI

MRI has an established role in perianal and other pelvic fistulating disease, but can also be used in the assessment of cutaneous fistulae throughout the abdomen and pelvis. Use of high resolution T2 scans (Fig. 9) focussing on the region around an external opening or expected site of fistula (based on prior imaging) is often the most effective way of identifying a tract. It is critical that Hyoscine Butylbromide or other gut paralytic agent is given at the start of the examination to ensure bowel movement artefact is minimised. Heavily T2 weighted, fat saturated and post contrast sequences can also help to delineate tracts, and are therefore routinely used in perianal protocols. If patients are prone to repeated CT imaging then MRI can have an important role to minimise radiation dose, in patients that are not acutely unwell or can manage the requirements of an MRI scan (Figs. 9 and 10).

Ultrasound

Ultrasound can have a similar diagnostic accuracy as fluoroscopic contrast studies for identifying fistulas, reaching up to 87% sensitivity and 90% specificity, however ultrasound has the additional advantage of identifying other extra-luminal disease e.g. collections. In those departments with better access to US than other imaging modalities, it may provide a quick and convenient assessment or provide additional information to aid the interpretation of other tests. The use of hydrogen peroxide inserted through the skin opening can increase the sensitivity of detecting the internal opening [78].

Malignancy and ECFs

In instances when patients have spontaneous or unexpected ECF, underlying malignancy needs to be excluded. Although rare, any mass like areas with irregular or asymmetric wall thickening with an abrupt transition on CT and MRI should raise the suspicion of neoplasia. Malignant transformation associated with longstanding ECF or other fistulating inflammatory disease is well recognised and not only should patients be appropriately counselled, where surgery or curative therapy is not an option, but consideration of surveillance imaging is important. Both squamous and adenocarcinomas are described and the prognosis is poor.

Fig. 9 (**a**) High resolution axial MR T2 sequence shows entero-enteric fistula (arrowed) and this also communicated with a gas containing abscess in the muscle of the anterior pelvic wall (elipse). (**b**) Sagittal MRI T2 sequence shows entero-enteric fistula (circled), with changes extending to the dome of the bladder where there is wall thickening (arrow) and the gas filled collection in the anterior pelvic wall (ellipse)

Abdominal Wall Assessment

Detailed assessment and reporting of the abdominal wall is important in IF patients as often these patients have had previous surgeries and may have a stoma, cutaneous fistula, hernia, or abdominal wall collection. No dedicated imaging of abdominal wall or modification of the imaging techniques is necessary. Most of the necessary information regarding the abdominal wall can be obtained by focused specialist review of previous cross-sectional imaging, especially CT scan.

Assessment should specifically comment on the presence or absence of an abdominal wall hernia. If one is present, the following features should be noted; its location, size of abdominal wall defect (maximum length and width in cm), contents, assessment of loss of domain, complications of the hernia, abdominal wall thickness and quality and evidence of previous surgery (including presence of mesh). The report should also highlight if there are any adhesions and the location of any fistula or stoma in addition to the standard report of the abdomino-pelvic viscera [79].

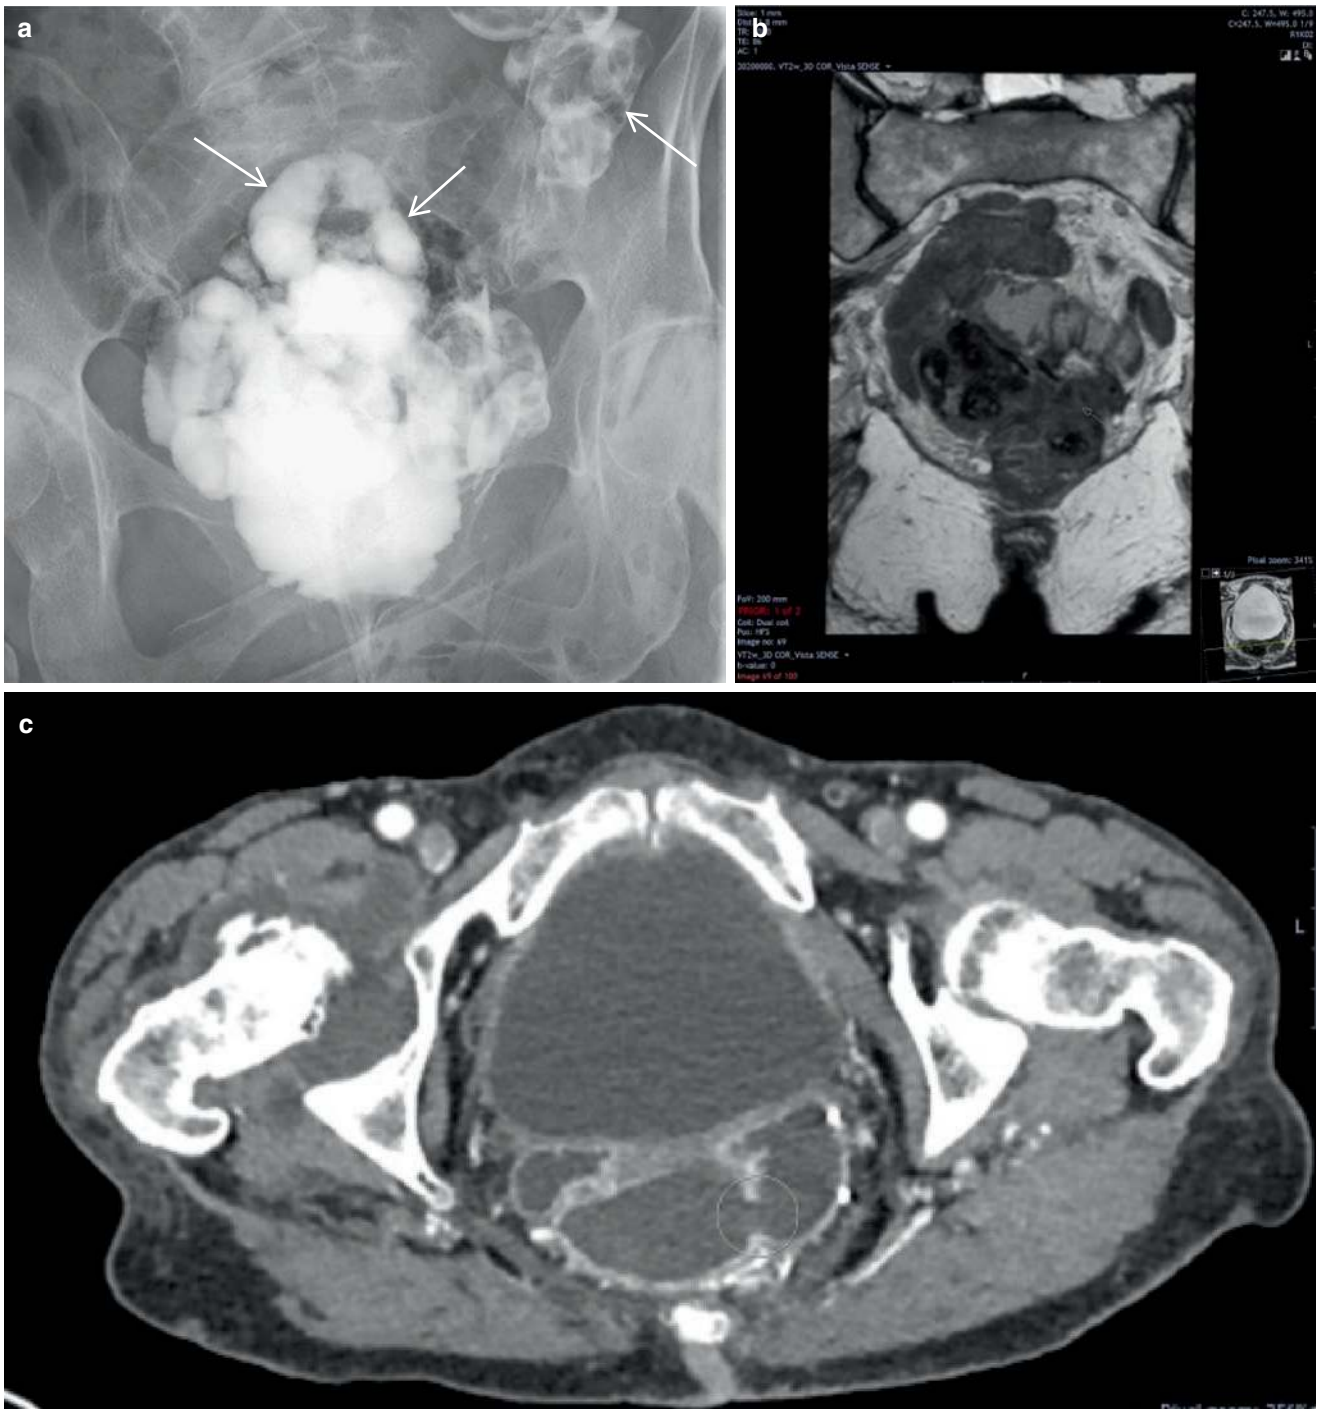

Fig. 10 (**a**). Contrast enema shows abnormal filling of the small bowel (thin arrows), with only small volume of contrast in the descending colon (broken arrow), but the site of fistula was not visible. An MR (**b**) was done, but the site of fistula (arrow) was still hard to identify, until reviewed in conjunction with the CT (**c**), which more clearly shows the entero-rectal fistula (circled)

Insertion, Types and Care of Enteral Feeding Tubes

Jeremy M.D. Nightingale

Key Points

1. Enteral nutrition (EN) is given for no or insufficient oral intake when it is safe to do so and when there is adequate functioning small bowel present.
2. Nasogastric tubes need the tip position carefully checking with an acidic aspirate (pH < 5) and if doubt a chest radiograph.
3. Gastrostomy tubes are most commonly and most safely inserted at endoscopy.
4. Jejunal tubes may be inserted at the bedside (with or without an electromagnetic devise), during an endoscopy, using radiological screening or at surgery.
5. After gastrostomy insertion feeding may start after 2–4 h, the tube should be on very gentle tension for a week, then this is relaxed and the tube rotated daily and pushed in 2–10 cm once a week.
6. Distal feeding into defunctioned bowel or a fistula is done via a small diameter feeding catheter or balloon catheter providing there is no distal obstruction. The feed may provide all the nutrition required (complete) or a small amount to stimulate motility and be trophic to the mucosa.
7. A buried gastrostomy internal flange (bumper) occurs if there is much traction on a gastrostomy tube. A buried internal flange can, if patent, sometimes be removed by stiffening and pushing the tube inwards, and/or dilating or cutting (with an endoscopic needle knife) the gastric tissue to free the internal flange.

Introduction

Most patients receiving enteral nutrition will have oral (intake) failure most commonly due to neuromuscular disorders, head/neck cancer and occasionally cardio-respiratory diseases or dysmotility/malabsorption problems. If those with IF cannot absorb adequate macronutrients and fluid with an increased intake, dietary/fluid modifications and sip feeds, then enteral feeding may be needed. EN may be given to utilize the gut for longer periods (e.g. with an overnight enteral feed) [1, 2]. Enteral feeding is usually preferred to parenteral nutrition as it is more physiological, less expensive, prevents biliary sludge formation and originally was thought to be associated with less severe complications than parenteral nutrition (PN); however with the safer administration of PN, EN may have a similar incidence of severe complications [3] or more (e.g. after pancreaticoduodenectomy [4]). It was thought to maintain the gut barrier function to prevent endotoxin and bacterial translocation [5–7] which could lead to sepsis and multi-organ failure; however the evidence for this is not convincing [8]. Previous metabolic and septic problems with PN may have related to overfeeding and hyperglycaemia, and less careful attention to the care of the feeding catheter. Now less energy is given especially in critical care so metabolic problems are less frequent; great care is given to the aseptic care of parenteral feeing catheters so septic complications are much less frequent.

EN is usually contraindicated if there is mechanical bowel obstruction, peritonitis or ischaemia, or if there has been a recent major gastrointestinal haemorrhage. Percutaneous abdominal tubes are relatively contra-indicated if a coagulopathy or if a patient has ascites (accumulation needs to be prevented for 7–10 days after the procedure to allow adherence of the gut to the abdominal wall) or the presence of a ventriculo-peritoneal shunt (as it can be infected and cause meningitis) [9, 10].

EN and PN may be used together when PN is being weaned, but generally should not be used together in the

Enteroclysis and fistuloclysis

long-term as the management of both becomes very complex and time consuming.

This chapter outlines the methods of inserting enteral feeding tubes and advises upon their subsequent care.

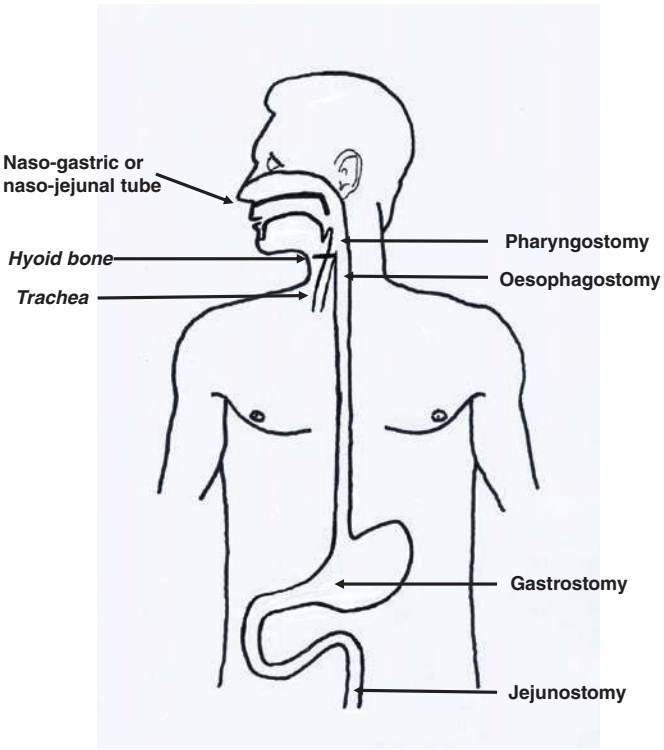

Fig. 1 Enteral routes for feeding into upper gut

Access Routes to the Gut

There are many ways to access the gut (Table 1, Fig. 1) [11]. Direct feeding into the colon/rectum has been successful in the past [12] but is not currently used. If there is a mucus fistula or fistula connecting to defunctioned ileum or colon, saline, a peptide feed or the effluent from a high stoma may be instilled into it to help with fluid/nutrient balance. This distal feeding can give all the nutritional requirements or can give a small amount of feed to help the bowel function/mucosal growth before continuity is surgically re-established. This procedure can be unpleasant and technically demanding ("Distal Feeding and Hydration" chapter).

Nasoenteric Feeding

An enteral feed may be given by a tube passed through the nose into the stomach, duodenum or jejunum (nasogastric, nasoduodenal and nasojejunal feeding). It has become traditional to insert enteral feeding tubes through the nose rather than the mouth as it is thought to be more comfortable for the patient and eliminates the possibility of the tube being bitten. Fine bore naso- or oro-enteral tubes are chosen for short-term feeding (up to 4–6 weeks) and a gastrostomy or jejunostomy tube for long-term enteral feeding.

Feed may be delivered into the stomach if there are no problems with aspiration or inadequate/delayed gastric emptying (e.g. if opioid or anticholinergic drugs including cyclizine have been given). The stomach tolerates hypertonic feeds, higher feeding rates and bolus feeding better than the small intestine. After abdominal surgery, owing to increased sympathetic activity, the stomach may take 1–2 days to regain its motor function and the colon may take 3–5 days, but the motor and absorptive functions of the small bowel usually remain normal [13, 14]. Thus post-pyloric feeding may be started safely within 12 h of surgery/trauma, especially if the patient is already undernourished. Many units wait for at least 24 h to allow for the 'ebb phase' of hypometabolism and some surgeons delay for 5 days, often to 'protect a distal anastomosis' [15, 16]. Clinically the return of hunger, the passage of stomal or rectal wind and the presence of bowel sounds suggests the return of gut function. It is helpful if access for feeding, via the gut, is achieved at the time of surgery (e.g. by a nasojejunal tube or needle jejunostomy). Post-pyloric/jejunal feeding is indicated when there is altered gastric anatomy (e.g. gastrectomy, gastric bypass or Whipple's procedure), gastroparesis, high risk of aspiration or an intolerance of gastric feeding [10].

The passage of a tube through the nose can induce the patient to cough and so the procedure is considered an aerosol (less than 5 μm diameter) generating procedure and FFP3 masks and visas should be worn if the patient has or is at risk of having a disease spread by an aerosol (e.g. COVID) [17].

Nasogastric Tubes

Nasogastric tubes are generally marketed for single use; however, the manufacturers of some tubes advocate cleaning and re-passing of the same tube on the same patient if it is accidentally dislodged. The maximum rate of flow through an enteral feeding system depends mainly upon the tube diameter and length, and less upon the viscosity and temperature of the feed [18]. They are generally only used for 4–6 weeks [11].

Material

Fine-bore nasogastric tubes are made of polyvinyl chloride (PVC), latex, polyurethane or silicone, and are available in a variety of sizes and lengths. Polyurethane is preferred to polyvinyl chloride (PVC) and latex as it is more resistant to kinking. Polyurethane allows the tube wall to be thinner than with silicone, so that while its outer diameter is the same its internal diameter is larger, so allowing high flow rates. Nasogastric tubes made from PVC tend to lose plasticizers after a few days; they become brittle and rarely can cause pressure necrosis of soft tissues. PVC tubes are damaged by radiotherapy. PVC tubes require changing after 7–10 days, whereas polyurethane or silicone tubes can remain in situ for a month. Many tubes are impregnated with a water-activated lubricant to help insertion, and most are radio-opaque.

Diameter

Large-bore Ryles tubes, used for gastric drainage, are uncomfortable and may be associated with rhinitis, oesophageal reflux, and oesophageal strictures. Fine-bore tubes (1.4–4.0 mm diameter, 4–12 Fr) are more comfortable and cause less trauma to the nasopharynx and oesophagus. Fine-bore tubes are more easily displaced by coughing or vomiting than large-bore tubes, and there is a greater chance of them being accidentally inserted into a bronchus, especially in an unconscious patient. The presence of an endotracheal tube does not preclude the tube being accidentally passed down the trachea into the lung.

Quoted tube size is based on external diameter; the internal diameter is usually about 1 mm less. The diameter of a tube is the single most important limitation to flow, and an increase in internal diameter from 1 to 2 mm results in a tenfold increase in flow. The limitation to flow is rarely clinically relevant; for example an 8 FG 100 cm long tube connected to a giving set and a feed container will discharge 100 mL of 24 °C solution (viscosity 4.25 cps which is similar to/higher than most feeds) at a pressure of 75 cm water (about the height of a drip stand) within 5 min [18]. The fine-bore tubes used in clinical practice vary from 1.4 mm (4 FG) for small infants, to 2.7–4.0 mm (8–12 FG) for older children and adults. All commercially available feeds can be administered with good flow through an 8 FG tube though even smaller tubes may suffice (e.g. infants may be fed boluses via a 4 FG tube with no problems). Only if there is a need to give drugs through the tube, or if gastric juice needs to be aspirated regularly in adults, is a larger tube required.

Length

The total length of a nasogastric tube varies between 40 and 90 cm and is selected to ensure a manageable amount of external tubing. The longer the tube, the greater is the resistance to flow [18]. A weighted tip on a nasogastric tube does not make the tube easier to pass or less likely to become displaced [19].

Insertion of Nasogastric Tubes

The method of insertion is outlined in Box 1. The tube must not be forced, and special care must be taken if a tube is considered necessary in a patient with mucositis or oesophageal varices. The tube may be passed through the mouth if there is a severe rhinitis. Soft, pliable nasogastric tubes made of polyurethane or silicone generally have a

Box 1 Passing a Nasogastric Tube at the Bedside

This is considered a clean procedure. Equipment: non sterile gloves and plastic apron, tray, sterile/boiled water, glass of water ± straw, tissues, sterile paper towel, sterile receiver (galipot), receptacle for aspirate, hypoallergenic tape or other fixative, glass of water, lubricating jelly, nasogastric tube (CE marked), enteral syringes of 10 and 50 mL, pH indicator strip (CE marked), measuring tape.

Method

1. Explain the procedure and arrange a signal for patient to give if he/she wants the procedure to stop.
2. Check that the nostrils are patent by asking the patient to sniff with each nostril occluded in turn.
3. Wash hands and dry hands, apply hand rub and assemble the equipment.
4. Put out the equipment. Sterile paper towel onto trolley/tray then put onto it the NG tube, galipot and enteral syringes. Ensure the glass of water, lubricating jelly, hypoallergenic tape and pH paper are near.
5. Put on gloves
6. Position the patient upright and do not tilt the head backwards (if insertion is difficult it can be helpful to put the head forwards and/or turn it to one side).

7. Measure the distance from the nose to an earlobe to the xiphisternum (NEX distance which is 50–60 cm in adults) then add 5–10 cm to this.
8. Mark the tube (if not marked) with the measured distance. If there is a guidewire in the tube, remove it and flush the tube with 10 mL water, then reinsert the guidewire; this allows the wire to be withdrawn freely. Check that the guidewire does not protrude through the end of the tube and that it is freely mobile within the tube.
9. The clearest nostril may be sprayed with lignocaine. Lubricate the tube with a small amount of lubricating jelly (or water).
10. Gently slide the tube backwards along the floor of the clearest nostril. At a distance of 10–15 cm the tube can usually be seen at the back of the pharynx. If possible, at this point ask the patient to take a mouthful of water and hold it. Ask the patient to swallow and at that moment advance the tube 5–10 cm, stop when the swallowing stops and repeat 3–6 times. If the patient becomes distressed, continually coughs or becomes blue, remove the tube. If there is difficulty passing the tube, the patient can turn his/her head either way by 90° and flex the head.
11. When the mark (at 50–60 cm in adults) is reached, stop advancing the tube and gently remove the guidewire. If does not remove withdraw tube gently and twist as it may be coiled Do not attempt to replace the guidewire when the tube is in situ as it may exit from the side of the tube and cause a perforation.
12. Check the tube position by aspirating 2–5 mL gastric juice and check that the pH is less than 5.5 or below using pH indicator strips (CE marked for human aspirate). If so, the tube is in the correct position and can be secured at the nose and feeding begun. If not, the tube may not be in the stomach or the stomach may not be producing acid (e.g. if the patient is taking a proton inhibitor drug); a chest radiograph is needed to confirm that the tube has not entered the lungs. Auscultating for bubbles is unreliable as bubbles can be heard even if the tube is in the lung.
13. Document the procedure: time, indication, consent verbal/written, tube type, size and two health care workers should sign to confirm the pH reading and the position of the tube. If a chest radiograph is needed the name of the clinician confirming the correct position should be recorded.

Additional comments

- If the patient is heavily sedated or has had a general anaesthetic, the head can be flexed to 30° and the larynx lifted anteriorly [22].

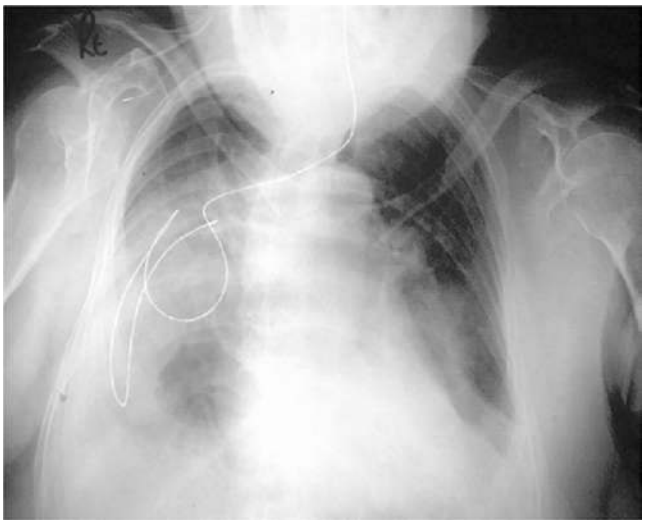

Fig. 2 A NG tube accidentally placed in the right lung

guidewire to aid insertion, while those made of PVC do not. There is still a small risk of misplacement (1.3%) [20], oesophageal or pulmonary perforation. In the UK intrapulmonary or pleural placement of a nasogastric tube with administration of feed or medication or fluid is considered a "never" event that must fully investigated (Fig. 2) [21]. Due to the trauma involved for staff when these never events are investigated it is advised that two staff are present at the insertion to confirm the tube position (with a pH indicator strip). There is a high rate of nasogastric tubes 'falling out'. This 'non-elective removal' has been reported to be as high as 25% within the first 24 h [20].

Checking Position of Nasogastric Tubes

The intra-gastric position of a nasogastric tube should be confirmed before using the tube for feeding or administering medication. This should be carried out every time the tube is used; failure to do so could result in feed or medication being delivered to the lungs. Only checking the gastric pH and chest X-ray are acceptable methods.

Aspiration

Two to 5 mL of gastric juice is aspirated through the nasogastric tube using a 50 mL syringe. A 50 mL syringe exerts less negative pressure and so is less likely than a smaller syringe to create a vacuum and cause damage. The aspirate is checked, using a pH indicator strip (CE marked), and should show an acidic fluid with a pH of between 1 and 5.5 [23–25]. Care in interpreting the pH is advised if little fluid is aspirated and much lubricating jelly has been used, as lubricating jelly has an acidic pH. Fluids aspirated from the respiratory and intestinal tract or from a patient receiv-

ing a proton pump inhibitor should all have an alkaline pH. However some of the occasions in which the tube has been accidentally inserted into the lung in UK have had an acidic pH documented. In future, a means of both measuring pH and detecting a gastric (e.g. pepsin) or intestinal enzyme (e.g. trypsin) may become available.

Chest/Abdominal Radiography

Abdominal radiography is the definitive way to confirm the correct position of a radio-opaque nasogastric tube. Most tubes have radio-opaque markings, or contain a radio-opaque compound (e.g. bismuth trioxide). Although it is a reliable method, it is only indicative of the position of the tube at the time of X-ray, and is therefore not necessarily correct at the time the patient starts feeding, when aspiration should again be done. It may be used as a check on initial placement of the tube if an acidic gastric juice cannot be aspirated. Due to the occurrence of "never events" some units advocate chest radiographs on all patients with a neurological disease or impaired consciousness. Many community hospitals, and patients at home, do not have access to X-ray facilities and so do not have this checking system. When tubes are dislodged frequently (e.g. in patients with neurological problems), repeated X-rays are not practical and the radiation exposure becomes unacceptable. An additional problem is that feeding is delayed while a patient is waiting for a radiograph and its interpretation.

The features on a CXR that show correct position of a naso/oro-gastric tube are: The naso-gastric tube should remain in the midline through thorax down to the level of the diaphragm, it bisects the carina, and is clearly visible below the left hemi-diaphragm (unless situs inversus). Its tip should be approximately 10 cm beyond the gastro-oesophageal junction (i.e. within the stomach). Figure 2 shows a malplaced NG tube.

Laryngoscopy

If the patient is unconscious, the tube can be visualized passing into the upper oesophagus using a laryngoscope or endoscope.

Tests of NG tube position <u>not to be</u> relied upon

1. *Auscultation*

   Air is injected into the stomach via the nasogastric tube and at the same time the observer listens with a stethoscope over the upper abdomen ('whoosh' test); bubbling should be heard and the site where they are loudest is noted. This method can be falsely reassuring and bubbles may be heard (in the epigastrium) when the tube is incorrectly in the lung base. This technique should not be relied upon.

   A feeding tube can be attached to a specially adapted stethoscope; if the tube is in the trachea or bronchi, loud breath sounds are heard [26].

2. *Monitoring bubbling at the end of the tube*

   The end of the tube can be left in a glass of water as the tube is inserted. If the tube then enters the lung, there may be bubbles in the water. Again this is not a method that can be relied upon.

3. *Monitoring for respiratory distress*

   Tubes can be inserted into the lung with no patient distress (until feed is given) especially in neurological disorders.

4. *Observing the appearance of NG tube aspirate*

   The aspirate from the lung can look similar to that from the stomach/duodenum.

5. *Testing the acidity/alkalinity of aspirate using blue litmus paper*

   Only pH indicator strips (CE marked for human aspirate) are considered accurate. A pH of less than 5 is taken to indicate a gastric aspirate. However rarely bronchial secretions, especially if infected, can cause a similar low pH.

Problems

No aspirate in syringe.

If this occurs, check that the correct/usual length of tubing is visible externally and that the tube is firmly secured to the face. If a longer length of tube than expected is visible, the tube may have slipped back and thus needs to be removed or resited. If the tube appears to be of correct length, it may be that the tip is not in contact with gastric contents; in this case, the position of the patient can be changed (i.e. to lie on the left or right side, sit up, etc.) and aspiration again attempted. Alternatively, if some oral intake is possible, the patient can be given a drink to increase the volume of the gastric contents before another attempt is made to aspirate the stomach. If these methods fail, the tube may be advanced a short distance (2–5 cm) and aspiration again tried. This may not be possible with some polyurethane tubes.

Aspirate is not acidic.

This may occur if the patient is taking antacids, H_2 antagonists or proton pump inhibitors. A confirmatory chest radiograph may be needed.

Nasoduodenal and Nasojejunal Tubes

Post-pyloric feeding may be indicated when there is delayed gastric emptying (gastroparesis) or an increased risk of aspiration (large hiatus hernia). Nasoduodenal/jejunal tubes may be single lumen (as for a nasogastric tube but of a longer length) or double lumen, allowing feeding into the small intestine while aspirating gastric secretions.

Insertion of Nasoduodenal/Jejunal Tubes

Post-pyloric tube placement may be difficult, and various techniques have been adopted. They may be inserted at the bedside (Box 2), radiologically, in endoscopy or at an operation. Post pyloric feeding compared to gastric feeding in critically ill patients resulted in a 30% lower rate of pneumonia and an increase in the amount of nutrition delivered to these participants [11, 27, 28].

Bedside Placement

Box 2 Methods for Passing a Nasojejunal Tube at the Bedside

When the tube is in the stomach (60 cm), the guidewire inside the tube can be removed and a 30° bend made 3 cm from the tip. The wire is then carefully replaced. This allows the tube to be rotated to assist its passage through the pylorus [29]. In addition, when the tube is at 60 cm, the patient is turned onto his/her right side and the tube advanced to about 70 cm. This usually results in passage of the tube; if not, the stomach can be rapidly inflated with 500–1000 mL of air before the tube is advanced further [30]. Rotating the tube clockwise and giving 10 mg intravenous metoclopramide may also help the tube pass the pylorus [30]. Sometimes referred to as the 10-10-10 method as 10 mg metoclopramide is given, then there is a wait of 10 min before advancing the tube 10 cm. The tube position should be checked radiologically with a plain abdominal radiograph or ideally screened so that the tube tip is positioned at or beyond the duodeno-jejunal flexure.

It may be advantageous to give metoclopramide (10-10-10 as above) or erythromycin (cisapride in the past) just prior to any insertion procedure to increase gastric emptying and help the tube pass the pylorus. Neostigmine may also be used, but careful cardiac monitoring is needed as it may cause a severe bradycardia.

Auscultation and aspiration techniques may be used to attempt confirmation that the tube is situated beyond the pylorus, but they are not conclusive [31]. If air is injected down the tube during insertion, the loudest place that bubbling is heard (with a stethoscope) is initially on the left side of the abdomen (in the stomach) then, when the tube is past the pylorus, on the right side of the abdomen. In addition, the volume of air that can be aspirated from a post-pyloric tube, after 60 mL air has been instilled, is usually about 10 mL as compared to 40 mL if the tube is in the stomach. A more reliable method is to aspirate fluid which should show a pH change from less than or equal to 4 in the stomach, to greater than or equal to 6 in the duodenum/small bowel.

In an intensive care setting the blind insertion of an NJ tube had a 43% successful placement rate and was most likely to be successful if the greater curve of the stomach was cephalad (higher) than L1-L2 disc [32]. The success rate and time to insert a tube using endoscopy or fluoroscopy was the same (95% taking about 15 min) [33].

A randomized prospective trial in 1993 showed that tubes with weighted tips were less likely than unweighted tubes to pass through the pylorus [34]. This may be because a weighted tip naturally falls into the antrum to a level below that of the pylorus.

Self-Propelling Tubes

A nasojejunal tube which develops a spiral coil when the guidewire is removed (e.g. Bengmark) can be inserted into the stomach and in most patients will pass spontaneously into the small bowel, probably being carried there by the fasting migrating myoelectrical complex. This type of tube may stay in position more reliably than a straight tube [35, 36].

Electromagnetic Guided Tubes

Electromagnetic bedside feeding devices (e.g. Cortrak®) are increasingly being placed with over 60% successful placement [37]. They have an electromagnetic stylet that can be tracked and provide a display of the path of the feeding tube during placement. The system consists of an LCD monitor unit, specific nasoenteral feeding tubes each containing a stylet with a transmitter, and a signal receiver unit. Thus they provide real-time location information on the tube tip placement. There is as with all naso-enteric tubes a risk of accidental placement into the lung [38].

Other Techniques

Other methods for placing a transpyloric tube include the use of ultrasound or a magnet on the tip of the tube and on the abdominal wall (88% achieved transpyloric feeding) [39]. The Kangaroo™ feeding tube with IRIS technology uses direct vision via an integral 3 mm camera as the tube is placed and may have a role in the future.

Image Guidance Insertion

Image guidance (fluoroscopic) techniques are generally successful [40, 41], more so than blind placement and almost as often successful as endoscopic placement [33, 41]. Radiologists may be familiar with the technique as it was used to perform a small bowel enema examination.

Endoscopic Insertion

Endoscopic placement may be difficult [42]. If the nasoenteral tube is grasped with forceps and taken to the distal duodenum/proximal jejunum using a paediatric colonoscope, it easily becomes displaced during withdrawal of the endoscope, even when the guidewire has been left within the tube. It is technically easier to position a long guidewire through an endoscope into the jejunum, and then withdraw the endoscope completely to leave the guidewire in situ. The wire can be re-routed through the nose (using a short tube passed through the nose and out of the mouth). The lubricated nasoenteric tube is passed over the guidewire into the jejunum while being careful to maintain the same length of guidewire outside the patient (Figs. 1 and 3).

Many NJ tubes are passed through an endoscope, ideally using an ultrathin transnasal gastroscope [43], but if a normal gastroscope is used rerouting from the mouth to the nose is required, however it is easy for the tube (especially if not kept stiff with a guidewire) on withdrawal to form a loop in the stomach and this may cause the enteral tube to fall back into the stomach.

An endoscopic nasoenteral feeding tube may have a clip placed at the end of the tube to anchor it to the jejunum and this results in fewer repeat endoscopies than standard endoscopic naso-enteral tube placement [44].

Post Insertion of Jejunal Feeding Tube

A plain abdominal radiograph should be taken 8–12 h after insertion to confirm position, except in pregnant women or patients in whom a tube is replaced at home. A polyurethane tube of 105–145 cm can be expected to last about 10 days; the longer-length tubes can be positioned further into the intestine and allow more free tube outside the nose; they do not block more frequently than shorter ones [45].

Securing a Nasoenteric Tubes with a Nasal Loop (Bridle)

A nasoenteric tube can be secured with a non-allergenic fixative on the maxilla, and the tube can be hooked over the ear.

A technique of making a nasal loop (bridle) for confused patients was described in 1980 [46]. A catheter is passed through one nostril and brought out of the mouth (as done initially for re-routing a tube from the mouth to the nose). Surgical ribbon is taped to the catheter coming out of the mouth. The catheter is pulled gently back out of the nose and a 15 cm length of ribbon is left emerging from one nostril. The procedure is repeated through the other nostril, and the ribbon is cut 15 cm from the nose. Thus ribbon passes into one nostril, goes round the nasal septum, and exits through the other nostril. The ends of the tape are tied through tape fastened round the nasoenteric tube [47]. Subsequently a simpler way of inserting the nasal loop was by inserting magnets attached to the distal ends of the catheter and a probe (magnetic retrieval system). After inserting the catheter into one nostril and the probe into the other, the magnets come in contact posterior to the vomer bone, the probe is withdrawn pulling the catheter and tape out of the nostril leaving tape passing round the back of the nasal septum. The end of a feeding tube is securely connected with the tape [47]. A nasal loop inserted in this way on an intensive care unit resulted in less tube displacement 10% (4 of 40) compared with 36% (18 of 50) whose tube was secured by tape only [48].

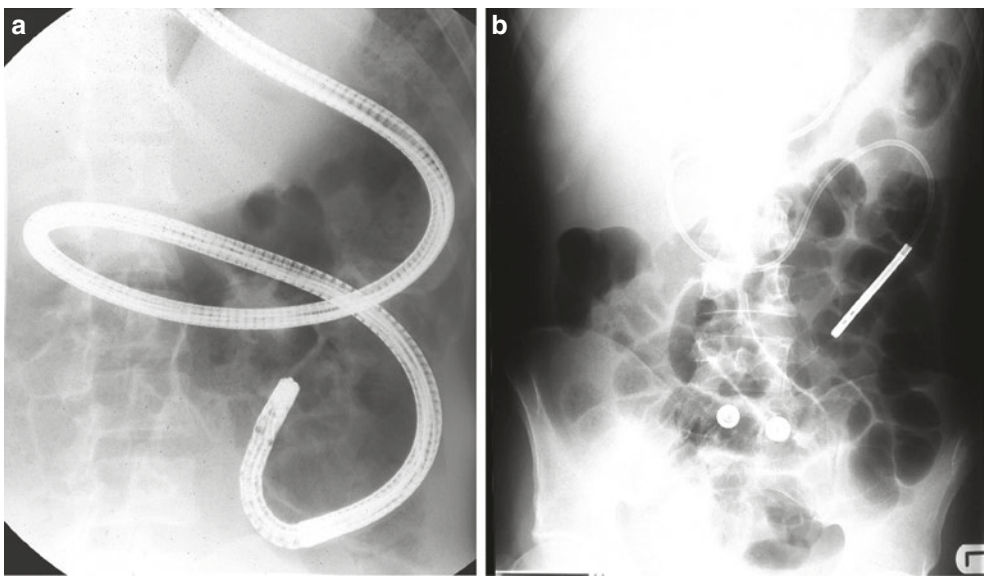

Fig. 3 (**a**) Passage of endoscope (lateral view) into small bowel and guidewire emerging. (**b**) Endoscopically placed nasojejunal tube in situ beyond the DJ flexure

Cervical Pharyngostomy and Oesophagostomy

A tube with its insertion in the neck above the cricoid cartilage is termed a pharyngostomy; one below the cricoid is an oesophagostomy. Either may be performed after maxillofacial surgery, often performed for head/neck cancer. These are basically blind procedures that carry not only the risks of any operation but also the risk of pharyngeal or oesophageal leaks or salivary fistulas. The tubes are just as visible as nasoenteric tubes and are extremely uncomfortable for the patient, as whenever the neck is moved it pulls on the tube. Now that percutaneous endoscopic or radiologically guided enterostomies can be made, usually prior to surgery, pharyngostomy and oesophagostomy are rarely performed except in the very rare circumstance that, for anatomic reasons, a nasoenteric tube, gastrostomy or jejunostomy cannot be placed.

Cervical pharyngostomy was first described by Shumrick in 1967 [49]. It can be performed using open dissection, a percutaneous approach [50], or a combination of both. The pyriform sinus is located with an index finger passed down the lateral pharyngeal wall until below the hyoid bone; a right-angle forceps is inserted through the mouth and pushed out in this position. A small stab incision is made through the skin, then mainly blunt dissection is used to reach the forceps, which are pushed out of the side of the neck. Tape is grasped and pulled back into the pharynx, Kelly forceps hold onto the tape, so are pulled from outside the neck into the pharynx, the proximal end of an already in situ orogastric tube is grasped by the Kelly's forceps and pulled out through the skin incision [51]. If a long-term pharyngostomy is required, a more definitive incision is made along the anterior border of the sternocleidomastoid muscle, and it and the carotid sheath are retracted laterally. The exit site is made as before but the pharyngeal mucosa is sutured to the cervical skin.

Cervical oesophagostomy was described by Klopp in 1951 [52]. The approach is usually on the left side of the neck as the oesophagus lies to the left of the midline in this area. A formal dissection requires a 4–6 cm oblique supraclavicular incision. The sternocleidomastoid muscle is retracted laterally after careful open dissection that does not damage the thyroid or its vessels, trachea, recurrent laryngeal nerve, carotid sheath and contents or thoracic duct. A tube is then inserted through a 5 mm incision in the lateral wall of the oesophagus. The tube feeds into the stomach and either exits through the lower end of the incision or from a separate stab incision [53].

For both procedures the position of the feeding tube tip can be checked as for other nasoenteric tubes.

Gastrostomy Feeding

A gastrostomy may be inserted surgically, endoscopically or under radiological/ultrasound guidance. It means that the patient can be fed without having to swallow and is likely to receive a greater amount of the prescribed feed than from a nasoenteric tube [54, 55]. Gastrostomy feeding devices are currently made from polyurethane or silicone, and may vary in diameter from 9 Fr to 26 Fr. As with nasogastric tubes, the smallest diameter that is adequate for feeding is chosen. Thin tubes are cosmetically most acceptable to patients. Gastrostomy tubes differ in appearance, but share most of the same features. An inner radio-opaque fixation device (a soft flange or a balloon) sits against the anterior stomach wall. It prevents the tube from being accidentally pulled out and, as long as it is held securely against the gastric mucosa, it prevents leakage of gastric contents. An external fixation device is positioned comfortably against the skin and is adjusted to accommodate weight changes. It prevents migration of the tube through the pylorus, and also prevents leakage and soreness due to excessive inward/outward movement of the tube.

Before a gastrostomy is inserted an INR is checked, the procedure may proceed if it is less than 1.5. Clopidogrel is usually stopped 7 days before the procedure and warfarin 5 days [9].

Endoscopically Placed Gastrostomy

An endoscopic gastrostomy can be inserted, under light sedation (e.g. midazolam 2.5 mg) and using local anesthetic, in over 95% of adult patients. A gastrostomy placed at endoscopy is a less expensive procedure than one placed at open operation. It may not be possible to insert an endoscopic gastrostomy safely if a patient has had a gastrectomy, has ascites, hepatomegaly, a neoplastic/infiltrative disease of the gastric wall, an obstructing oesophageal lesion, a coagulation problem or is in the later stages of pregnancy. It may be difficult if the patient is obese and if it is not possible to bring the anterior gastric wall into contact with the anterior abdominal wall.

All techniques involve gastric insufflation to bring the stomach wall into apposition with the abdominal wall, percutaneous placement of a tapered cannula into the stomach, passage of guidewire/thread into the stomach, placement of the gastrostomy and verification of its position. There are two ways in which an endoscope can be used to help position a gastrostomy tube: by a pull (traction) or a push method in which the endoscopist mainly observes the procedure. The tubes inserted by the pull method is commonly referred to as a PEG (percutaneous endoscopic gastrostomy). The pull technique was introduced in 1980 [56] and takes only

15–20 min to perform (Box 3) [57–59]. The original push technique was similar to the pull technique except that a 300 cm flexible-tipped guidewire was inserted into the stomach instead of a thread, the wire was snared and brought out through the mouth, and the gastrostomy tube was then pushed over it down through the mouth and into the stomach [59]. The push technique has subsequently been used to refer to a technique (used by radiology and endoscopy) in which the stomach is first fastened to the abdominal (gastropexy) and then a trochar is inserted and through its sheath a balloon gastrostomy is inserted (see below). No significant differences have been found between the push and pull techniques in terms of procedure time or complications [59, 60].

Antibiotics are usually given (e.g. a single dose of 2.2 g co-amoxiclav 30 min before the procedure) to reduce the risk of a peristomal wound infection [43, 61]. An antiseptic mouthwash before the procedure may also be beneficial.

The external fixation device (disc/plate) is made of non-irritant material and provides a secure external grip on the catheter, keeping it in contact with the skin; it also prevents the tube from kinking/looping. It may alter the tube angle by 90°.

Box 3 Pull Method for Placing a Percutaneous Endoscopic Gastrostomy (Fig. 4)

1. The procedure is explained to the patient/relative/carer and written informed consent obtained. The platelets and INR may need to be corrected if there is a risk of bleeding. The patient is fasted for 6 h before the procedure. Prophylactic antibiotics may be given half an hour before the procedure. Some units may stop H_2 antagonists/PPI for 1–3 days before the procedure, and some carefully clean the mouth with an antiseptic mouthwash immediately before the procedure.
2. The PEG inserter (A1) sets up a trolley near to the endoscopy table and examines the patient's abdomen for scars and enlarged organs. The size and position of the aorta is noted. The patient is sedated with an intravenous injection of a short-acting benzodiazepine. The gastric smooth muscle is relaxed by an intravenous injection of 20 mg hyoscine butylbromide.
3. The endoscopist (A2) performs a full upper gastrointestinal endoscopy, noting in particular any evidence of a hiatus hernia or oesophagitis (duodenal biopsies and test for *Helicobacter pylori* may be done). The patient is turned onto the back. The stomach is distended with air. A1 pushes a finger gently into the epigastric region about halfway between xiphisternum and umbilicus, A2 sees if this is visible in the gastric antrum. The site of maximum indentation is chosen. If no indentation is seen, the endoscope light power is turned to full brightness and A1 observes if the light can be seen through the abdominal wall. Sometimes, on transillumination a shadow from the transverse colon can be seen and this area must be avoided. These two techniques locate the route that the PEG's sheathed trocar (with air valve) will take to enter the stomach. Originally, the site chosen for a gastrostomy was one-third of the distance from umbilicus to left costal margin in the mid-clavicular line. Although the PEG can be inserted anywhere in the abdomen, the rectus abdominis muscles and abdominal creases are best avoided.
4. A1 washes and dries hands, opens the dressing pack, and puts on sterile gloves. Antiseptic solution is poured into a small container. Five milliliters of 1% lignocaine solution is drawn up.
5. A1 cleans a 15 cm area of abdominal skin and puts a small dressing towel below the intended insertion site. Using a small, then a long injection needle, the skin and route to the stomach (including peritoneum) are anaesthetized with about 2–3 mL of 1% lignocaine solution. The longer needle can often be seen by A2 to enter the stomach. If this can be done there is rarely any problem in subsequently inserting the sheathed trocar. The PEG set is opened and tipped onto the open dressing pack.
6. A1 makes a 1–3 mm vertical skin incision about 5 mm deep with a pointed scalpel. The sheathed trocar is carefully inserted along the line by which the long needle entered the stomach; it is advanced with short jabs. Sometimes the needle can only be made to fully enter the stomach with the help of biopsy forceps used by A2. When 1–2 cm of needle are inside the stomach, the trocar is removed to leave the sheath in place; the latter may need a cap over it to prevent air escaping.
7. A narrow long thread is inserted down the sheath. A2 catches this in the stomach with biopsy forceps or a snare and withdraws the thread up into the endoscope. A1 must take care that not all the thread is pulled up into the endoscope. The endoscope is withdrawn and the thread is left coming out of the mouth.
8. The PEG is held by A1 and tied to the thread. A1 then pulls the PEG down through the mouth into the stomach and, using gentle traction, pulls the dilating end of the PEG out onto the abdominal wall.
9. The dilating end of the PEG is cut off and attachments made according to the manufacturer's instructions. The patient returns to the ward with clear written instructions about subsequent care for the next 2 weeks.

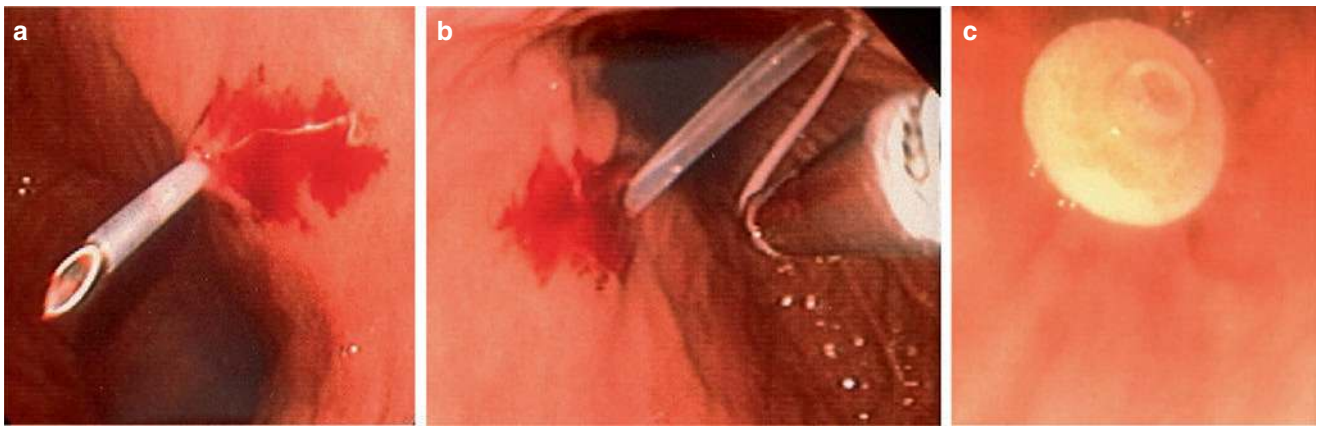

Fig. 4 (**a**) Sheathed needle entering the stomach at the start of a pull PEG insertion. (**b**) Biopsy forceps capture the thread. (**c**) Internal flange at end of the procedure

Problems After PEG Insertion

Complications requiring surgery occur in fewer than 5% of patients; the procedure-related mortality rate is 0.3–2% [62–64]. Most deaths are caused by the underlying illness. The main problems are infection of the insertion site and peristomal leakage [65, 66]. Other rare early problems include peritonitis, septicaemia, tube dislodgement, pulmonary aspiration, bowel perforation, gastro-colic fistula and necrotizing fasciitis [67]. Bleeding problems should be avoided if coagulation abnormalities are corrected before the procedure.

Poor wound healing may occur if the patient is undernourished (e.g. cancer/HIV infection) [66, 67], immunosuppressed or taking steroids or have EDS. Mortality is higher during the first month in patients with previous aspiration or urinary tract infections or those who are more than 75 years old [68].

A benign pneumoperitoneum is common and can be seen on abdominal or chest X-rays in as many as 38% of patients [69, 70]. It is important to recognize this as a normal finding—it does not mean that the patient has a significant bowel perforation.

In the long term, aspiration pneumonia may occur in 23% of patients [71].

Direct Puncture Gastrostomy Insertion

Endoscopically (Push Technique)

A different technique for inserting a PEG without the tube passing down the oesophagus can be done endoscopically. This may reduce the chance of entry site infections as the tube has not passed through the mouth and may also prevent the seeding of an oropharyngeal or oesophageal tumor to the PEG site (risk 0.3–0.5% with a standard pull PEG) [72, 73].

The endoscopic technique involves distending the stomach with air via the endoscope, an assistant injects local anaesthetic into the abdominal wall, and introduces 2–4 stitches (or T fasteners) into the stomach to anchor it to the anterior abdominal wall (gastropexy). Then after making a small stab incision (2 mm) a trocar with a peel away sheath over it is introduced into the stomach (e.g. Pexact®). Under endoscopic observation the trocar is removed, a balloon gastrostomy inserted through it, filled with water, the peel-away sheath is split and removed before gentle traction is applied to the balloon which is fixed to the abdominal wall. Originally a needle was inserted with Seldinger wire then serial dilators were pushed over this to make a tract for a balloon gastrostomy to be inserted [74].

Radiologically

Percutaneous Radiological Gastrostomy (PRG)

A percutaneous radiological gastrostomy (PRG) is also referred to as a radiologically inserted gastrostomy (RIG) or percutaneous fluoroscopic gastrostomy (PFG). PRG can be used as alternative techniques for the placement of a feeding tube into the stomach, if an endoscopically guided tube placement cannot be performed. Of 180 tube attempts a failed gastrostomy tube placement occurred in 15.7% of PEGs and 1.9% of RIGs. Post-procedure aspiration was recognized after 10.5% PEG and 0% PRG attempts [74]. Originally the risk of peritonitis, balloon failure and hence tube displacement, and mortality was lower for a PEG than a PRG [75–77]. However with time the outcome of a PRG has improved and is associated with an equal number or even less complications than a PEG [78, 79]. A study of 133 patients who underwent PRG placement found a 1.5% incidence of major complications requiring operative intervention and a 3% incidence of minor complications [76]. Both PEG and PRG are effective for long-term EN support in selected individuals, PRG may be a better option in patients with motor neurone disease especially if they have significant respiratory impairment [80]. PRG can be performed as an outpatient procedure [81, 82].

The technique for insertion of a PFG is very similar to that performed endoscopically (Box 4) except that it starts

with distending the stomach with air via a nasogastric tube and using ultrasound to position the fasteners (gastropexy) before inserting the trocar; the rest of the procedure is the same [82]. Often a PFG or PFGJ (percutaneous fluoroscopically placed gastrojejunostomy) succeeds when a PEG has not been possible [9, 83, 84], though it does not allow the upper gastrointestinal tract to be carefully inspected.

Box 4 Radiological Method of Placing a Percutaneous Gastrostomy

A gastrostomy tube can be placed using ultrasound or X-ray guidance (fluoroscopically) or both.

1. Ultrasound may be used to determine the position of the liver and transverse colon relative to the stomach. Occasional injections of air into the colon via a rectal tube can be used to delineate the transverse colon, but too much gas makes ultrasound difficult.
2. A nasogastric tube is passed into the stomach, and the stomach is distended with air.
3. Upon selection of a site in the mid-body of the stomach, an aseptic technique is used, gloves are worn, the skin is cleaned and the area draped with towels. The skin, subcutaneous tissues and peritoneum are injected with local anaesthetic.
4. The abdominal wall is punctured with a needle through which a T fastener is passed to anchor the anterior gastric wall to the abdominal wall. One to four of these may be inserted.
5. The abdominal wall between the anchoring clasps is punctured with a needle inside a sheath. Using fluoroscopic guidance, the needle is inserted into the stomach and then withdrawn, leaving the sheath in place.
6. A water-soluble contrast agent may be injected to confirm the position of the sheath within the stomach.
7. A wire is passed into the stomach and the sheath removed. The opening may be dilated using progressively larger dilators. A catheter (pigtail or balloon type) is passed into the stomach over the wire. The wire is removed and the threads to a pigtail catheter released or a balloon inflated.
8. Contrast may again be injected through the catheter to try to ensure that there is no leakage into the peritoneal cavity. If a jejunal tube is needed a catheter can be inserted through the pylorus into the duodenum or jejunum.
9. An external flange (fixing device) is attached and sutured to the skin.

Surgical Gastrostomy

A surgical gastrostomy may be fashioned at the time of other abdominal surgery using the Stamm technique [85]; a laparoscopic technique has also been described [86]. The Stamm technique uses concentric submucosal purse-string sutures (two rows) that invaginate the serosa about a mushroom-tipped tube passed into the anterior stomach wall at the junction of the body and antrum. An exit separate from the laparotomy incision is made for the tube. The gastric serosa is sutured to the peritoneum and transversalis fascia [87].

A surgical gastrostomy is rarely performed as percutaneously inserted gastrostomies are quicker to accomplish, avoid a general anaesthetic, and usually have a lower incidence of stomal leakage and wound infection [88–90]. Two studies have shown no difference in the complications following a PEG, laparoscopic or open gastrostomy [90, 91]. A PEG or, rarely, a balloon catheter can be inserted at the time of surgery, though the latter may be difficult to connect to a giving set and may not last as long.

Button Gastrostomy

When a gastrostomy tract has become established, the catheter may be replaced with a button-type gastrostomy, especially in children [92]. The button-type gastrostomy (14–28 FG) consists of a small catheter with an internal water or saline balloon containing 5–20 mL. It is anchored externally with a flange, and the button opening is flush with the skin. The button has a duckbill anti-reflux valve, which prevents leakage of gastric contents. A feeding extension clicks into it when in use, and a cap fits into it when not in use. It has the advantage of being level with the skin and so more convenient and cosmetically acceptable.

When inserting a button for the first time, the length of the abdominal wall tract is measured by inserting a balloon catheter with measurements along its side. The balloon is inflated with 5 mL air and pulled back, the length of the tract is measured and a suitable size button is selected. If the shaft length is too long, the balloon does not sit close to the gastric mucosa. This may cause leakage of the stomach contents around the button shaft. If the shaft is too short, skincare may be difficult and soreness can result. If the tube is tight or painful, a lateral abdominal X-ray is performed to check that the balloon is in the stomach, not the peritoneal cavity. The balloon volume should be checked every 7 days, as there is always a small loss of volume.

Post-pyloric Feeding

Percutaneous Gastrojejunostomy

If a percutaneous endoscopic gastro-jejunostomy (PEGJ) is to be done, a large (e.g. 15 FG) gastrostomy tube is inserted and through this the jejunostomy tube is passed with a stiffening wire in its centre. The patient is re-intubated with a long endoscope (e.g. a paediatric colonoscope), the end of the jejunostomy tube is grasped by biopsy forceps, and the tube is taken slowly (using the push-pull techniques of colonoscopy) about 30–50 cm distal to the pylorus (at or beyond the duodeno-jejunal flexure). The endoscope is withdrawn to the gastric body while the forceps are advanced to keep the jejunal tube in position. The biopsy forceps let go of the tube and are gently shaken as they are withdrawn to try to prevent the jejunostomy tube from returning into the stomach. When the forceps have been fully withdrawn, the stiffening wire is removed from the jejunostomy tube. The view from the endoscope will show the tube passing through the pylorus. An abdominal radiograph is done to confirm the post-pyloric position of the jejunostomy tube tip. Only when the tip is considered to be in a satisfactory position is the tube cut and connected to the inner gastrostomy tube. Some tubes allow the stomach to be drained at the same time as the jejunal feed is given. If the tube cannot be placed endoscopically, it may be done radiologically (PFGJ or RIGJ), which may be easier if the PEG has been inserted through the greater curve of the stomach.

The procedure can be done through a gastrostomy tube using an ultra-thin endoscope [43, 93].

There have, in the past, been many difficulties with PEGJ tubes [71–73, 94–96]. In particular, PEGJ tubes often become displaced back into the stomach [96] (Fig. 5) or become disconnected and the whole tube passes through the PEG and down the gut. A PEGJ does not necessarily prevent aspiration [94], though a patient with a PFGJ is less likely to develop pneumonia than one with a PEG [97]. Tube blockage, leakage, migration or fracture occurred in 53% of PEGJs compared to 24% of PEGs with a mean follow-up of 275 days [95]. Designs of jejunostomy tube with a distal flexible, non-weighted tip that can easily be grasped with biopsy forceps may be better; though the connection of the jejunostomy tube to the gastrostomy tube can still become detached and result in the tube falling into the gut.

Direct Percutaneous Endoscopic Jejunostomy (D-PEJ)

A technique similar to PEG insertion can be used to insert a direct percutaneous endoscopic jejunostomy (D-PEJ) in patients who have had a gastrectomy. Sometimes a paediatric colonoscope can be positioned in the distal duodenum, the duodeno-jejunal flexure or beyond, and under radiological guidance a needle inserted into the bowel just distal to the scope. If thread can be introduced through a medium-sized needle (the large introducers supplied with a PEG set are usually too big and do not penetrate the bowel) then a PEG-type tube can be inserted in the usual way (to prevent the thread being cut, the needle must be completely withdrawn as the thread is pulled into the endoscope). Radiological screening also helps to prevent other structures (especially the transverse colon) being entered with the needle. The procedure may also be done using double balloon enteroscopy [98].

Surgical Needle Jejunostomy

It is difficult at surgery to manipulate a nasoenteric tube round the duodenum and into the jejunum. It can be difficult to both aspirate the stomach and feed into the small bowel at the same time, though tubes are available to do this. For these reasons a needle jejunostomy is often inserted at the time of

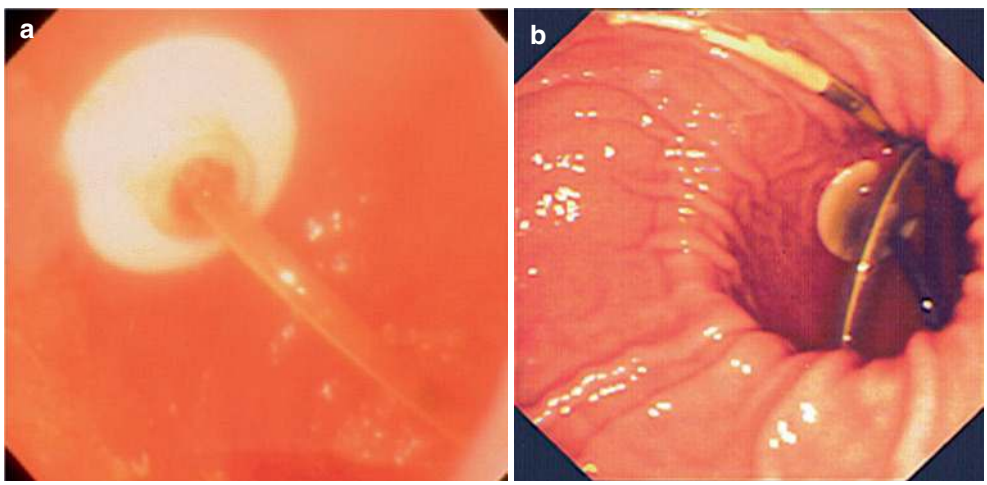

Fig. 5 (**a**) PEGJ in situ. (**b**) PEGJ tube that has become displaced back into the stomach

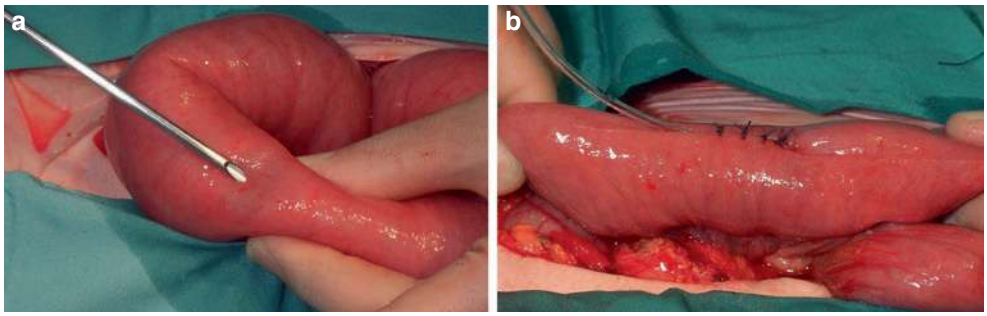

Fig. 6 (**a**, **b**) Insertion of a needle surgical jejunostomy and the Witzel tunnel

operation (Box 5) (Fig. 6) [99–103]. A laparoscopic method of inserting a needle jejunostomy has been described [104]. Complications are common, especially tube dislodgement or obstruction [103, 105], and the outcome is no better than for a well-placed and cared-for surgical tube jejunostomy [106]. The bowel can kink at the catheter entry point, so causing obstruction, or leakage can occur. The incidence of aspiration pneumonia is still high at about 16% [104]. The tube is always left in for 3–5 weeks, even if feeding has stopped, so that a tract can become established and the purse-string suture holding the tube will have dissolved. This may take longer if the patient is taking steroids. There are many types of surgical gastrostomy tubes some have a Dacron cuff that can embed 1–2 cm from the exit site in a similar way to that on a Hickman-type catheter.

Box 5 Surgical Placement of a Needle Jejunostomy

At the end of the laparotomy a needle jejunostomy may be inserted. This takes about 20 min.

1. A loop of jejunum about 10–30 cm distal to the duodeno-jejunal flexure or gastrointestinal anastomosis is selected and orientated. The distance should be sufficiently great to allow tension-free apposition to the abdominal wall.
2. A 1 cm diameter purse-string absorbable suture is placed on the anti-mesenteric border of the jejunum at the site selected for jejunal catheter insertion. The ends are left untied.
3. A submucosal tunnel is created on the anti-mesenteric border using a 12–14 gauge hollow needle with a retractable obturator. With the obturator withdrawn, the needle is pushed into the sero-muscular layer within the purse-string suture. The obturator is advanced and the blunt end used to create an intramural tract for 2.5–5.0 cm before the obturator is withdrawn and the sharp needle is advanced into the lumen. If the needle tip position is uncertain, 10 mL of air can be injected into the bowel and distension observed; if there is resistance the needle is withdrawn and another attempt is made to enter the bowel lumen.
4. If present, the flexible J end of the guidewire is identified and put into the catheter (but not so that it protrudes from the catheter). The catheter (with guidewire) is then advanced through the needle into the bowel lumen.
5. The needle is removed while grasping the catheter within the bowel; the catheter is advanced for 20–45 cm. If necessary, the J end of the guidewire may be advanced to just beyond the distal end of the catheter to help passage. Care is taken to prevent the catheter from kinking or curling within the bowel. The guidewire is removed and the purse-string is tied.
6. In addition to the submucosal tunnel, a short (2–3 cm) Witzel tunnel is often made by suturing two parts of the sero-muscular layer (from the same circumference) together around the catheter, so covering the catheter. The sutures must not be tight enough to cause occlusion of the catheter or to cause tissue necrosis.
7. A second sheathed hollow needle that can be split (or that has a sheath that can be split) is inserted through the left abdominal wall at a position where there will be no tension on the bowel. The catheter is fed through this (or if necessary the needle is removed) and the needle (or introducer) is split and removed.
8. The jejunum is stitched to the anterior abdominal wall using 2–3 sutures around the catheter.
9. The catheter is placed in an external fixative device (retainer) which is sutured with non-reactive monofilament sutures to the skin.
10. The site may be covered with a clear dressing and any attachments are connected to the catheter. Catheter patency is confirmed using 20 mL air, saline or contrast.

Distal Enteral Feeding

Distal enteral feeding includes feeding through the distal limb of an enterocutaneous fistula (fistuloclysis) or through a defunctioned distal small bowel stoma/mucus fistula (enteroclysis). The distal feeding (DF) may be complete/total (CDF) where the aim is to administer all nutrition and hydration (±chyme) via the enteral tube or just trophic (TDF) where it aims only to provide enough nutrition/hydration to maintain bowel structure and function usually before a surgical re-anastomosis [107] ("Distal Feeding and Hydration" chapter). Proximal and distal contrast studies of the bowel are done before starting DF to ensure there is no disease, obstruction or leak present in the distal bowel. The feeding is done by inserting an enteral feeding tube (fine bore nasogastric tube or balloon gastrostomy) more than 5 cm into the distal intestine. A polymeric or semi-elemental feed or chyme may be given, ± added salt through the distal feeding tube. The action of DF in addition to providing nutrition/fluid, is by neural and humeral mechanisms, to reduce upper gastrointestinal secretions and motility, and thus proximal stomal/fistula output and so reducing the amount of nutritional/fluid support needed.

TDF consists of a small volume (100–500 mL/24 h) bolus being given once or twice daily into the distal bowel. It helps maintain the bowels anatomical structure and motility (preventing gut atrophy), so making a surgical re-anastomosis more likely to be successful (easier anastomosis, faster postoperative return of function and a lower chance of an anastomotic leak); but parenteral support may still be needed while this continues.

Care of a Patient Receiving Enteral Feeding

Skin Care

It takes 2–4 weeks after insertion for the anterior gastric or jejunal wall to become adherent to the abdominal wall and then an intraperitoneal leak is improbable. After insertion very low traction without tension should be applied to the tube and the distance from the internal flange to the skin recorded (usually 2–4 cm) for 1 week. It is a common error for the traction to be completely removed after insertion and this can allow a leak/bleed to occur as the stomach has not adhered to the anterior abdominal wall. This is suggested by pain and an increase in the distance between the internal flange and abdominal wall. Each day, after the insertion of a percutaneous gastrostomy or jejunostomy, the site should be cleaned gently with unperfumed soap and water and the tube gently rotated by 90°, but not pushed inwards (till 7–10 days). The gastrostomy tube of a gastrojejunostomy should not at any stage be rotated as it can dislodge the jejunostomy tube. A loose absorbent dressing may be applied. Glycerin hydrogel or glycogel dressing may be used as alternative to classical aseptic wound care in the first weeks. After healing occurs 10–14 days after placement (longer if malnourished or taking steroids) the dressings (if one is needed) are changed once or twice a week [11]. The traction is loosened after 3–5 days and after 7–10 days the external flange (also called a fixing plate or fixing device) is undone and the gastrostomy tube rotated (not if a gastroenterostomy tube) then pushed in (2–10 cm) [11] and, and the skin cleaned and dried [11, 43]. The tube is pulled with very light traction and the external flange is reattached and the distance from the internal flange to the abdominal wall skin noted. There may be 0.5–1 cm between the skin and the external flange. If the external flange is positioned while the patient lies supine, it may be tight when sitting/standing and have to be loosened. The external flange may also need loosening as the patient puts on weight. If the tube is kept too tight and not rotated, epithelial overgrowth (buried bumper) may occur [108, 109].

The skin around a gastrostomy or jejunostomy tube is kept clean and dry to prevent soreness/infection; the use of gauze and talcum powder is discouraged. Creams are kept off the tube as these can cause the external flange to slip. If the external flange slips when dry, it should be replaced.

If a nine FG PEG is used, the skin incision is so small that early PEG problems are very rare [110]; however visceral perforation with peritonitis, fasciitis, and pericatheter leaks are reported [111] in addition to bleeding [43] Leakage of gastric contents onto the skin should not occur if the stoma is healthy and the external flange correctly positioned. When it does happen, however, it can result in extreme soreness partly because of the low pH of the gastric juice. It requires a review of the tube and skin care to prevent recurrence. The skin can be protected by zinc oxide based barrier skin protectants, foam dressing and giving a proton pump inhibitor drug. The formation of granulation tissue may be prevented by regular rotation of the tube. Silver nitrate can be gently applied to areas of excessive granulation tissue but can burn the surrounding skin, so an antibacterial/steroid creams are often preferred.

For showering, bathing and swimming the tube is capped and the site should be covered with a water proof dressing.

Mouth Care

Patients, especially those who have no oral intake, are advised to clean their mouth with a mouthwash and to brush teeth and gums twice daily. They may need artificial saliva if their mouth is very dry. Some patients like to have something to taste (sweet) in their mouths when they receive their EN. For patients on an intensive care unit, the normal or induced production of saliva can be useful because of saliva's natural bactericidal activity. Lemon and glycerine swabs are avoided as they lower the pH in the mouth to 2.3–3.9, which can cause decalcification of teeth.

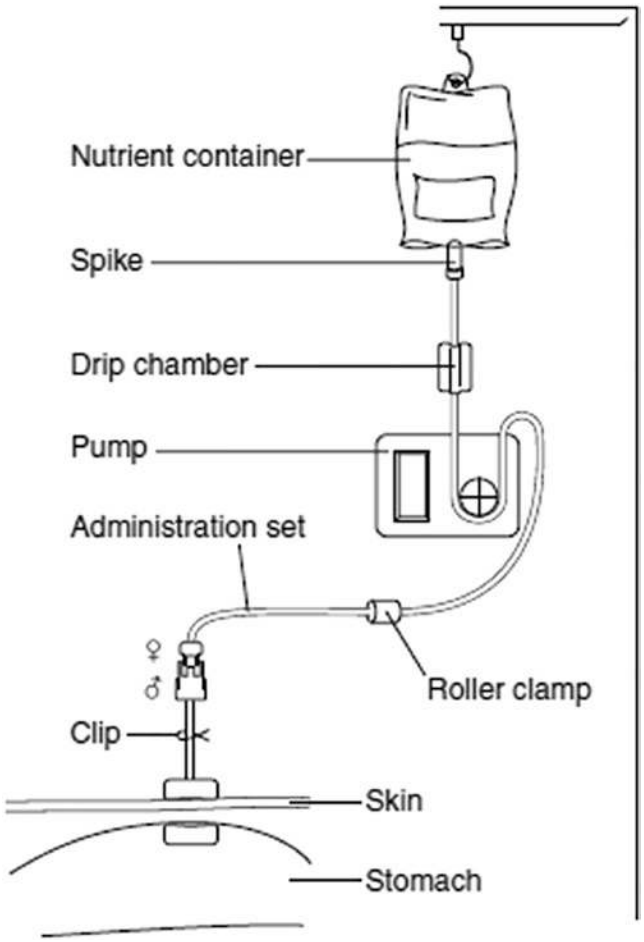

Fig. 7 Diagram of an enteral feed being given through a gastrostomy. Most systems no longer have a drip chamber

Care of the Feeding Tube

Enteral feeding can start 2–4 h after a percutaneous feeding tube has been inserted, there is no evidence to support giving water alone at first [11].

Enteral feeding tubes are used for the administration of feeds, water and, if necessary, medications (Box 6) (Fig. 7); they may become blocked by feed or medication solidifying within the tube. Feed may block the tube if there is a failure to flush the tube, interrupted feeding (e.g. due to a pump malfunction) or if the feed is of a high viscosity and contains whole protein. Acidic fluids with a pH of less than 5 (e.g. gastric acid or fruit juices) and the warmth of the body may cause casein-derived feeds to coagulate and thus block the tube. However, feeds containing free amino acids, small peptides (elemental or peptide feeds), egg albumin or whey proteins do not coagulate at a pH of less than 5 [18, 112] and thus can be used if recurrent blockage occurs. Crushed tablets and potassium and iron preparations are especially likely to block tubes. Many drugs are in a hyperosmolar solution which, in addition to making line blockage more likely, may cause nausea and diarrhoea [113].

To prevent blockage, the tube should be kept clean by flushing with water (usually 30–50 mL of fresh tap water, cooled boiled water or sterile water in accordance with local policy) before and after administering feed or medication. A 50 mL syringe is used for flushing, fitting either directly onto the feeding tube or onto the side port of a giving set. The quantity of water used to flush the tube should be sufficient to clear the tube and meet the patient's fluid requirements. Some units recommend that the tube be flushed weekly with a carbonated drink (e.g. Coca Cola®, 7 Up®, or a sodium bicarbonate solution) or pineapple juice, followed by cooled boiled or sterile water, to prevent blockage. Drugs should not be given through an enteral feeding tube, if possible; if such administration is necessary, they should be obtained in liquid form after establishing compatibility. When more than one medication is required, the tube should be flushed after each medication to prevent the two from mixing within the tube.

Box 6 How to Set Up an Enteral Feed

1. Check the expiratory date on the feed, which should be at room temperature. Record the time/date the feed was set up. Invert the feed container 2–3 times.
2. Wash and dry your hands. (Some units recommend putting on gloves.)
3. Remove the cover from the feeding container and clean the inferior surface with spirit.
4. Close the giving set clamp/roller, then spike the feeding container and attach the giving set.
5. Invert the container and hang it on the drip stand. For gravity feeding, the feeding container should be 1 m above the proximal end of the feeding tube.
6. Remove the distal cap from the tubing and slowly open the roller/clamp to prime the giving set.
7. Flush the feeding tube with the prescribed quantity (usually 50 mL) of cooled boiled or sterile water.
8. Connect the giving set to the feeding tube.
9. Insert the drip chamber or length of tubing into the pump.
10. Set the pump rate, unclamp the giving set and run.

Approximate drip rates[a]	
mL/h	drips/min
125	35
100	28
75	21
50	14
25	7

$$\text{drips / min} = \frac{\text{mL / h} \times 17}{60}$$

[a] The drip rate is affected by viscosity of feed, temperature of feed and giving set material. It is not necessary to know this for most modern pumps

It may be possible to clear a blocked tube by flushing with warm water, a carbonated drink, pineapple juice or sodium bicarbonate solution. Cranberry juice is less effective than Coca Cola® or water in preventing blockage [114]. An alkalinized solution of pancreatic enzymes (Viokase® at pH 7.9 with sodium bicarbonate) is effective in unblocking most lines [115], and the same mixture has been advocated for giving after a feed and a water flush to prevent tube blockage [116]. This solution can be made by adding 5 mL of water to one crushed tablet of Viokase® and one of sodium bicarbonate.

Before the enteral feeding tube is connected to a giving set, air is expelled. Some 'backflow' of gastric contents into tube is normal and is a reassuring sign of the correct position of the tube within the stomach, though it may be perceived by a carer to be a problem.

Some types of gastrostomy or jejunostomy tube have a clip/clamp on the tube to prevent leakage when the feeding ports are open. If left closed when the tube is not in use, these clamps can cause damage to the tube, which may eventually break at the point where the clamp was located.

It may be possible to replace certain parts of an enteral feeding tube (e.g. the Luer lock end) if damaged.

Gastric Aspirates

It is uncommon for a nasogastric tube to be inserted routinely after abdominal surgery to 'decompress the stomach' as patients with a tube in place have more infective complications and it is longer before they can take food orally [117]. Sedative drugs and high circulating catecholamine levels delay gastric emptying. If a gastrostomy or nasogastric tube has been inserted post-operatively or in an intensive therapy unit, the residual volume should not prevent feeding from starting, but care must be taken when aspirating more than 200 mL from a nasogastric tube or 100 mL from a gastrostomy tube [118]. If, more than 2 h after starting to feed, there is an aspirate of more than 200 mL or more than 2 times the hourly feeding rate, gastric emptying is likely to be delayed and extra care is needed, however the feed does not necessarily need to be stopped. Some intensive therapy units aspirate all the gastric contents every 4 h and replace 200 mL. Metoclopramide 10–20 mg three times a day (0.1–0.2 mg/kg in children) orally or intravenously, domperidone 10 mg four times a day, erythromycin 125–250 mg four times a day (3 mg/kg in children over 1 h) or, rarely, neostigmine 1 mg may all be used to increase the gastric emptying rate. Cisapride 10 mg four times a day used to be helpful but has unfortunately been withdrawn. If a high gastric aspirate is preventing feeding, jejunal feeding should be considered.

A fine-bore feeding tube used to aspirate gastric fluid is much more likely to become blocked as the acid coagulates casein-derived protein [119].

Feeding Regimen

Starter Regimens/Feeding Rates

A gastrostomy or jejunostomy is not used for 2–4 h after insertion (though longer after surgery/trauma), then fed is given at 20–45 mL/h for the next 12 h, before being increased (sometimes over 2–4 days) to the amount needed to meet the patient's requirements [120]. Some units starts the feed at 25 mL/h and increases it every 4 h in 25 mL/h increments until the calculated rate is reached. With an overnight feed the rate rarely exceeds 150 mL/h. Often a jejunal feed is started at a slower rate 10 mL/h and gradually increasing and reaching the target by day 6.

With continuous infusions in patients who have had some oral intake in the last week, starter regimens that either dilute [121] or reduce the feed volume [122] are not necessary and may prolong the period of negative nitrogen balance. However, if vomiting/bloating or diarrhoea (not related to antibiotic therapy) occurs, the feed rate may be reduced for a trial period.

Energy/Composition

If high-energy feed is given, hepatic steatosis, osmotic diarrhoea, refeeding syndrome, uraemia or hyper-capnia may occur. Care must be taken not to overfeed a patient who is being ventilated as the energy requirements are likely to be up to 1000 kcal/24 h less than calculated; a feed with less carbohydrate is usually given. Ten to 30% of tube-fed patients will have hyper-glycaemia [123] and may need to be given an oral hypo-glycaemic agent or subcutaneous insulin before starting the feed. It is important not to underfeed patients. Keeping a patient 'nil by mouth' while waiting for investigations, stopping feeding because of a high nasogastric aspirate, cardiac problems or the tube 'falling out' can all worsen the problems of undernutrition.

If a patient has a non-functioning gut and full nutrient requirements are being met by parenteral nutrition, minimal enteral feeding (10 mL/h) with or without added glutamine is often given on the basis that it may preserve the gut's barrier function and prevent villous atrophy, however there is no good evidence in man that it reduces bacterial translocation [124].

Most commercial feeds contain 1.0–1.5 kcal/mL and are nutritionally complete. In the long term, a feed containing fibre (fructo-oligosaccharide) is often given as it may result in a normal formed stool. If a patient is being fed into the jejunum and a polymeric diet has caused symptoms of dumping syndrome, then an isoosmolar peptide feed may be given.

Feeding Method

Gravity, a pump or a syringe can be used to deliver a feed, which may be given continuously, intermittently or by boluses.

Continuous feeding keeps the intragastric pH high/neutral [125]; this used to be thought to protect against haemorrhage from 'stress ulceration' in critically ill patients. If the gastric contents are not acidic, however, they will not be bactericidal and the stomach can become colonized by enteral bacteria [126, 127]. The gastric contents can reflux up the oesophagus and spill over into the lungs where micro-organisms can cause pneumonia and an increased mortality [128]. Administration of an H_2 antagonist (cimetidine) increased the risk of patients on a ventilator developing pneumonia [129]. Bile reflux into the stomach raises gastric pH and ultimately predisposes to colonization of the lower respiratory tract by gastric bacteria [130]. Four Gram-negative bacteria (*Escherichia coli, Enterobacter cloacae, Klebsiella pneumoniae* and *Serratia marcescens*) are mainly responsible for stomach-to-airway colonization. At a pH of less than 2.7, all 4 bacterial species are killed within 90 min [131], thus a period free from a feed that allows a normal low gastric fasting pH to be reached should be beneficial. An additional problem in ventilated critically ill patients is that their gastric motility is disrupted, making them more likely to have viable bacteria in their stomach [132].

The time a patient should be rested from a feed has not been determined; Bonten et al. showed that colonization of the stomach, oropharynx and trachea was the same with 4 h fasting every 24 h as with continuous feeding [133]. With 8 h fasting every 24 h, the incidence of pneumonia on an intensive therapy unit fell from 54% to 12% [134]. A break in feeding (probably of 4–8 h) allows both the stomach pH to return to normal and catch-up time to ensure that all of a feed is given.

Continuous and intermittent feeding is usually done via a pump (and no drip chamber), which provides a resistance to flow, so preventing excessive amounts of feed abruptly being delivered into the stomach/small bowel. Whole protein feeds may be of high viscosity but the pump does not need to generate a high pressure [18]. It would be cheaper and simpler for most patients to use gravity feeding with a variable or fixed resistance to control the feeding rate.

In bolus feeding, boluses of 200–400 mL feed are generally given (though 800 mL has been used) into the stomach over 20 min (range 15–60) [135]. Bolus feeding would seem more physiological and akin to what happens in real life. Bolus feeding may cause bloating and diarrhoea and, if given into the jejunum, may cause a dumping type syndrome. Bolus feeding can be done by pouring the feed into an inverted 50 mL syringe which has had the plunger removed. The syringe is then either connected directly to the feeding tube or via an extension tube and the feed is run in slowly. If the rate is too slow the plunger can be replaced and the feed gently injected. The syringes can be washed between uses, depending upon local policies but they do need to be replaced weekly as they become hard to use.

Drugs

Drugs should be given in liquid form and the tube flushed before and after use with 30 mL water [11]. Care should be exercised if digoxin and fibre, or warfarin and vitamin K/E are given together as they may make digoxin and warfarin, respectively, less effective. Sucralfate that is allowed to mix with enteral feed in the stomach or in an enteral tube can form a solid mass and so block the tube. Phenytoin can interact with protein, so it is given 2 h before or 2 h after enteral feeding.

Contamination of Feeds

An enteral feed is an ideal culture medium and can easily become contaminated. The feeding tube itself is also an important reservoir for bacteria, including those that are multi-resistant [136]. The factors that determine whether contamination will cause a problem are the dose of infecting organism, the route of administration (stomach or jejunum) and host resistance, which is reduced in elderly, undernourished or immunosuppressed patients.

Unacceptable contamination of a feed is said to occur when there are more than 10^4 colony-forming units per mL of feed, and levels greater than this have been associated with diarrhoea [137]. In ventilated patients the organisms that contaminate a feed have often come from the gut [130]. Contamination is common if a feed is hung for more than 24 h [138]. It is important that asepsis is maintained in the preparation and delivery of a feed, especially for those patients on the intensive therapy unit, immunocompromised patients, patients taking proton pump inhibitors or H_2 antagonists, and neonates. Hand washing is the single most important measure to prevent contamination. A mask should be worn if the carer has a cold, sore throat or respiratory tract infection. No part of the system that comes into contact with the feed should touch the hands, clothes, skin or any non-disinfected surface [139, 140]. The number of manipulations to a feed should be kept to a minimum. A recessed spike on the giving set helps to reduce the chance of contact and thus contamination of the feed. Bottles with a ring pull that needs decanting should be avoided as the feed is usually poured over the area the thumb has touched to remove the ring. If a feed has to be decanted it should be hung for a short time.

Acidifying an enteral feed preserves gastric acidity and reduces gastric colonization in critically ill patients and thus may reduce the incidence of pneumonia [141].

Patient Position

Patients should always be fed in the semi-supine position (propped up) for nasogastric or gastrostomy feeding and for 30 min after finishing, as there is a high and often unrecognized risk of aspirating the feed. While this position does not prevent aspiration, it reduces its frequency and severity [19].

Equipment

Pumps

Most pumps in Europe give a flow rate that varies from 1 to 300 mL/h and they comply with European Device Standards. It is suggested that no more than 500 mL be given over 4–6 h without a pump. An enteral feeding pump should not be able to generate a pressure of more than 15 psi, and syringes smaller than 50 mL should not be used as they can exceed this pressure. A parenteral nutrition pump should never be used as this generates high pressures. Pumps may have alarms for occlusion, air in the line or low battery.

Several small portable pumps with carrying packs are available and allow feeding to occur while the patient is mobile.

Drip Stands

A large hospital drip stand is often provided, but small bedside stands are available. The LITRE (Looking Into The Requirements for Equipment) group in United Kingdom has designed a small portable drip stand that can be used for carrying a feeding bag for enteral or parenteral nutrition.

Dry Goods

The feeding catheter connects to a flexible giving set, which in turn connects to the nutrient-feeding bag (Fig. 7).

Feeding tube The position of the feeding tube should be regularly checked by looking at the markers on its side to ensure that it has not slipped out. Some jejunal feeding systems allow the stomach to be drained while feeding continues into the jejunum. Tubes with a balloon may not last as long as those with a flange and may need to be changed every 3–6 months or according to the manufacturer's instructions [43]. A PEG tube may last for 2 years, a jejunostomy tube for a shorter time of about 6 months. There is no difference in blockage between an 8, 10 or 12 FG feeding tube, though it is harder to aspirate fluid from the smaller tube [142], and leakage and peristomal infections were not significantly more common with a 20 FG compared to a 12 FG tube [143]. A radiologically placed gastrostomy will last about 6–12 months.

Connectors ENFit is the global enteral feeding device connector design that complies with International Standard (ISO 80369-3). ENFit devices will not be compatible with a Luer connection or any other type of small bore medical connector, so preventing the accidental intra-venous administration of an enteral feed. Unlike current parenteral and oral syringes with male syringe tips that fit into female connectors, the ENFit devices are the opposite. They have *a female* tip on the syringe that will fit around a *male* connector on feeding tubes. All the same, care should be taken to label the delivery system to prevent its contents from being accidentally administered intravenously, especially as adapters that change male Luer lock or push-in connections to female ones are available. 'All parts, joints and connectors of an enteral giving set and catheter shall withstand a linear tensile strength of 15 N without disconnection, rupture or cracking' and there should be no leakage when the system is pressurized to a minimum of 150 kPa with water for 2 min [144].

Giving set/nutrient containers/syringes There may be local policies concerning the feed administration sets and handling procedures. The feed administration set and nutrient containers are discarded after a single use while syringes may be washed and reused.

Disconnecting an Enteral Feed

An enteral feed is disconnected after hands have been washed; the tube is flushed with cooled boiled or sterile water, then capped off. All feeding equipment except syringes is discarded. An open nutrient container can be refrigerated and reused for 24 h only.

Discharge Planning

Before discharge from hospital, the patient/carer must be trained in the setting up/taking down of a feed, flushing the tube, giving medication through the tube, care of the exit site, prevention and treatment of tube blockage, and repair of the hub. They must understand some basic anatomy and physiology as well as how to set up and operate the pump (if used). They must have made arrangements for delivery so that there is an uninterrupted supply of the feed/dry goods. They should have contact numbers in case of illness or if they have problems with the equipment. They should have follow-up appointments arranged. All patients, those receiving enteral nutrition, are reviewed at least annually by a specialist nutrition team.

Monitoring

When an enteral feed is first started, especially if the patient is very undernourished, haemoglobin, clotting, sodium, potassium, urea, creatinine, liver and bone chemistry and magnesium are measured, as is a random urinary sodium concentration. Within the first 24 h of starting the feed the serum phosphate and potassium are measured. These tests, along with serum magnesium, are done at least weekly for 2 weeks, then every 2–12 months depending upon the clinical

condition of the patient. Refeeding problems are common with enteral feeding largely due to the incretin effect ("Refeeding Problems" chapter).

The patient is ideally weighed daily in hospital, but often this is not possible; mid-arm muscle circumference and hand grip dynometry may be determined and measured every week until discharge, then every 2–4 months. After discharge weight, muscle mass/strength, hydration, food intake, complications and quality of life are assessed with routine blood testing that may include serum transthyretin (pre-albumin) [11].

Psychosocial Implications

It is difficult for a patient to feel that he/she is part of the family if he/she cannot eat; fortunately, patients with intestinal failure are usually able to eat normally and use the feeding as a way of getting extra energy, usually at night. They can lead a moderately normal life and can bathe/shower/swim 2–4 weeks after a gastrostomy or jejunostomy has been inserted.

Problems of Enteral Tubes

The long-term problems include over granulation of tissue at the exit site, tube blockage, aspiration, leakage around entry site or at the connection and discharge at exit site and buried bumper. All are covered in "Enteral Nutrition" chapter but buried bumper which occurs due to too much traction being applied to a percutaneous enteral feeding tube is discussed here.

Accidental and Elective Tube Removal/ Replacement

Accidental Removal

A percutaneously inserted tube should not be removed, nor reinserted along the new tract until at least 4 weeks after insertion, as a fibrous tract needs to have become established to prevent intraperitoneal leakage [11, 43]. If a tube becomes displaced in the first 4 weeks then a full new insertion needs to be done. If the tube is inadvertently displaced more than 4 weeks after initial placement, direct replacement can be safely attempted (within 12 h) before the tract closes [11]. A flexible guidewire is often the easiest way of finding the tract. Its soft end can be inserted into the tract. An endoscopist can see the wire emerge in the stomach and can catch it with a polypectomy snare or grasping forceps. The wire is pulled up into the endoscope, which is withdrawn to leave the wire coming out of the mouth. A new PEG is tied to this and pulled into position in the usual way by the assistant at the abdominal wall. Another option is to dilate the tract with dilators of gradually increasing diameter and to insert a button or balloon-type gastrostomy.

Elective/Planned Removal

Planned removal may be by cutting the tube and allowing it to pass, or careful endoscopic A gastrostomy tube with an internal fixation device that deflates can be removed by withdrawing air/water from it and gently pulling. If it does not come out easily, however, it may need to be removed in the same way as a tube with a non-deflating internal fixation device. If a gastrostomy tube is pushed inwards to check that it is free, then pulled upon and transected as near to the skin as possible, it will usually pass through the gut with no problems [145]; however, in a few cases (2%) the tube does not pass [146]. This method may be appropriate if the patient has a normal gut (no Crohn's disease or distal strictures). If a gastrostomy tube with a rigid internal fixation device is removed endoscopically, the tube is pushed 1–2 cm inwards and a polypectomy snare is put over the internal fixation device and tightened round the tube. The tube is cut about 5 cm from its skin entry point and the endoscopist withdraws the scope and tube. The patient is usually kept nil by mouth for 12 h following tube removal. Abdominal fistulae rarely develop, even in patients with Crohn's disease [147].

When a PEG/PEJ tube needs replacement because of breakage/leakage that cannot be corrected with repair kits/replacement parts, it can usually be done endoscopically. The PEG can be transected about 10 cm from the exit site and the new double-looped introducing thread of the new PEG pushed in through the lumen of the old PEG and into the stomach. The closed polypectomy snare from the endoscope is pushed through this loop, and then opened; this traps the thread round the snare. The snare is then put round the internal fixation device and closed; the thread is caught in this and, when the PEG is removed, the thread will again come out of the mouth ready to be attached to a new PEG. An alternative way is to cut a 1 mm hole 5–10 mm from the end of the cut PEG; the introducing thread from the new PEG set is put through the newly cut side hole and tied. The old PEG can then be removed, using a polypectomy snare, as already described. The thread will emerge from the mouth and the new PEG is attached to this and pulled into position in the usual way.

When a PEG is removed it is sometimes replaced with a button, especially in children.

Burried Internal Flange (Buried Bumper)

Traction on an enteral tube (and without pushing it in each week) particularly one with a flat disc can result in the gastric mucosa growing over the disc and eventually occluding it. While the tube may rotate it will not push into the stomach

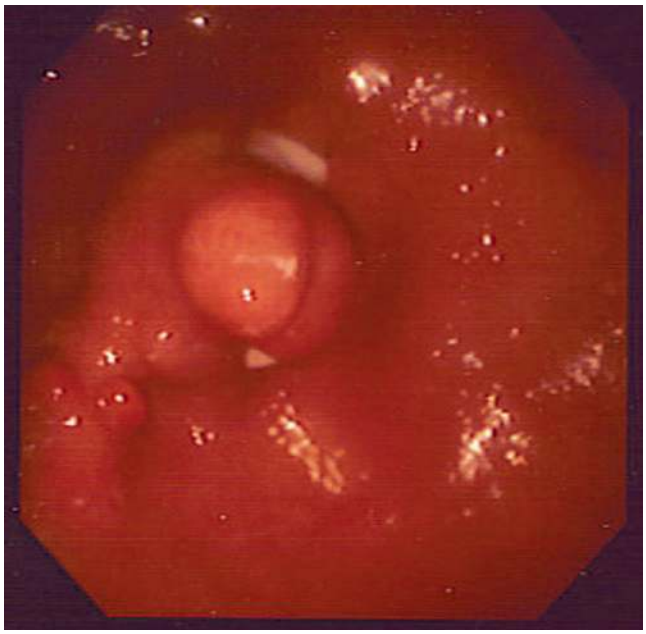

Fig. 8 Burried bumber. As the white of the internal flange (bumber) can be seen, it should be possible to remove

Fig. 9 A PEG tube has almost eroded out of the abdominal wall in a very thin patient. It was removed after injecting local anaesthetic

(this can be hard to tell as the tube may kink within its tract). The flow through the tube with a flush or a feed becomes slow, there may be peristomal leakage, and eventually flow stops completely and it is not possible to flush the tube. At endoscopy some (Fig. 8) or no internal flange (bumper) (Fig. 9) may be seen and the flushing fluid may or not be seen to enter the stomach.

The tube can be cut flush to the skin and left [148], which may be the best option if no internal flange is seen. However if a little flange is visible, it may be possible to remove the enteral tube. There are many techniques described. One is to stiffened the PEG tube, so the tube can be pushed inwards. This can be done with a guidewire (if it will pass into the stomach) or more effectively a oesophageal balloon dilator which is inflated (10–12 mm) when the first 2 cm of dilator is seen in the stomach. This balloon dilator both acts as a stiffener so the tube can be pushed inwards and it may disrupt some of the overgrown tissue so allowing the tube to enter the stomach. If this is not successful radial incisions with an endoscopic needle knife onto the internal flange can aid the balloon's passage into the stomach [43, 149]. If it does not pass it is worth leaving the tube alone on no traction and repeating the procedure a week later, and often the tube relocates easily into the stomach. Another technique with good results reported is to cut the PEG tube short close to the abdominal wall and pass biopsy forceps through the PEG; then through an endoscope pass a snare which is grasped by the biopsy forceps and pulled out; a 2 cm piece of the old PEG tubing is placed through the snare and closed to create a t-piece which is pulled by the endoscope; thus the PEG should emerge into the stomach [150]. A new PEG can usually be reinserted through the old tract.

If the PEG tube cannot be seen at all an abdominal CT scan may help identify its position.

Formulation and Administration of Enteral Feeds

Gil Hardy and Hazreen Abdul Majid

Key Points

1. Enteral nutrition (EN) is generally accepted to be the first choice for nutrition support of most patients. However, EN and/or parenteral nutrition (PN) are both equally efficacious, if prescribed and used appropriately
2. There is no good evidence for trophic EN. It is suggested to give either EN or PN. A combination of both may be used when converting from PN to EN or when EN is insufficient to meet energy requirements, at the discretion of the multidisciplinary nutrition support team (NST).
3. After the stomach, all parts of the gut can absorb water, macro-nutrients, minerals and vitamins, so some nutrition from EN will be absorbed in all parts of the small and large intestine.
4. Distal enteral tube feeding (DETF)/fistuloclysis whereby EN or gastrointestinal secretions (chyme) is administered through an enterocutaneous fistula in the distal bowel can be effective.
5. Enteral feeds (EF) divide into three main formula types, standard (whole protein), peptide (semi-elemental) and specialized formulas. EF then further sub-divides into, oral/sip feeds and tube feeds.
6. Most liquid EF are ultra high temperature (UHT) sterilised, but heat processing can destroy some vitamins (e.g. all B vitamins especially thiamine and vitamin B_6, folic acid and pantothenic acid) and heat-sensitive amino acids (e.g. glutamine and cysteine). Extra vitamins and some individual amino acids may need to be supplemented.
7. Enteral feeding tubes (EFT) are increasingly used as vehicles for administering medications, but pharmaceutical advice should be taken to avoid drug-nutrient interactions (DNI) and managed by the multidisciplinary NST.
8. To avoid tube blockage, the tube should be flushed with water before and after feeding. Tubes should also be flushed before and after any medication is administered.
9. Quality assurance procedures should be followed to avoid contamination of EF during administration, but most contamination may not be clinically relevant unless a patient is immuno-suppressed, is taking drugs to inhibit gastric acid production, or is being fed directly into the small bowel.
10. Protein deficiency decreases absorption of vitamin A, dietary fat decreases calcium absorption, copper and zinc supplements inhibit iron absorption, whereas vitamin C enhances absorption of non-haem iron.
11. Do not aim to achieve the full energy target with early EN. Early feeding that exceeds actual energy expenditure is harmful. Hypocaloric early EN appears to be safe and can frequently meet protein targets.
12. There are published practical guidelines for prescribing and administering EN for paediatric and adult, surgical and critically ill patients.

Introduction

In considering the nutritional support of hospital patients the general, almost obligatory, rule that has been promulgated in recent years is 'if the gut works, use it'. However with the recent advancement in research, it is crucial to ensure at least the patients are fed [1]. Delivering early nutrition therapy, generally within 48 h in the ICU [2], primarily by the enteral route, is now seen as a proactive therapeutic strategy that may reduce disease severity, diminish complications, decrease length of stay (LOS) in the ICU, and favourably impact patient outcomes [3]. Nutrition support via enteral nutrition (EN) and/or parenteral nutrition (PN) for patients is

Table 1 General principles and precautions for using early EN (EEN) in critically ill patients at risk of intolerance

Starting and continuing EEN	Start EN at a slow rate (10–20 mL/h) while carefully monitoring abdominal/gastrointestinal symptoms
	Increase EN slowly once previous symptoms are resolving and no new symptoms occur
	Do not increase EN in cases of intolerance or new symptoms, such as pain, abdominal distension or increasing intra-abdominal pressure. In these circumstances EN should be either continued at a slow rate or ceased depending on the severity of symptoms and suspected underlying sinister pathology (e.g. mesenteric ischaemia)
Energy target during EEN	Do not aim to cover full energy target with EEN. The optimal energy and protein target in the early phase of acute critical illness is not known. EEN that exceeds actual energy expenditure appears harmful and should be avoided [12, 13], whereas hypocaloric EEN may be safe [14–16]
Monitoring and protocolised management of GI dysfunction during EEN	In case of gastric retention without other new abdominal symptoms use prokinetics and/or postpyloric feeding in a protocolised way [17]. Monitoring gastric residual volume (GRV) is typically conducted to observe signs of feeding intolerance, but a meta analysis of 4 RCT provided no evidence that returning residual gastric aspirates provides more benefits than discarding them [18] (chapter "Insertion, Types and Care of Enteral Feeding Tubes").
	During introduction and increasing the rate of EN, measurement of intra-abdominal pressure (IAP) provides an additional numeric value to detect negative dynamics of IAP during EN in patients with severe abdominal pathology, hypoperfusion or fluid overload
Individualized approach	For patients with diminished consciousness and inadequate swallowing, precautions to prevent aspiration of gastric contents may be useful, including considering post pyloric feeding
	Premorbid health and course of the acute illness may differ between patients with similar diagnose; therefore an individual approach should always be applied

crucial with no superiority for either, if prescribed and used appropriately. EN is claimed to: be physiological, improve gastrointestinal function, prevent bacterial translocation and improve patient outcome while being less expensive than PN.

There is no documented evidence for reduced bacterial translocation or improved intestinal function in humans, although there are animal data [4] which show that intestinal mass, mucosal weight, villus height and disaccharidase activity all decrease in animals fed with PN compared with EN. Although there is no direct evidence that patient outcome or safety is better, there are studies which show fewer complications with EN compared with PN. These include patients with pancreatitis [5], following a total gastrectomy [6] and after hepatic resection [7]. There are fewer septic complications [5] and natural killer cell activity is higher in patients fed with EN compared with PN [7]. The frequently quoted paper in favour of EN, by Moore et al. [8], is a meta-analysis of eight studies (six unpublished). Their analysis shows no difference between EN and PN in non-infectious complications, mortality rates or length of hospital stay. However, more septic complications were noted with PN in patients who had had abdominal trauma. A comprehensive review of published prospective randomized controlled trials by Lipman [9] concluded that with the exception of reduced septic morbidity in abdominal trauma (which was offset by an increased incidence of EN-related complications) the only significant difference between EN and PN was the lower cost of EN. A more recent study of critically mechanically ventilated patients concluded that ventilator-associated pneumonia rates, ICU and hospital lengths of stay, ICU and hospital mortality rates of patients receiving PN were not significantly different than those receiving EN [10].

A balanced approach to the route of nutrition support therapy is appropriate. It is important to consider the nutritional support requirements of each individual patient, then choose the most appropriate route of delivery for that patient. Guidelines, as proposed by Blaser et al. [11] for successfully feeding critically ill patients suggest giving early EN in order to meet nutritional goals (Table 1). It is important that individualised approach to be used to ensure nutritional optimization.

History, Ingredients and Manufacturing

Various mixtures of milk, egg, beef or chicken broth, wine, brandy and pancreatic tissue have been administered to patients rectally since Ancient Egyptian times [19]. John Hunter in 1790 successfully used a 'tube' passed through the mouth into the stomach to feed a patient who was unable to swallow due to 'paralysis of the muscles of deglutition'. The 'tube', which was designed by a watchmaker, consisted of eel skin wrapped round a flexible whalebone and was attached to a pig's bladder which acted as a reservoir. Hunter recommended that jellies, eggs beaten with a little water, sugar and wine or milk should be given as food [20].

Today whole protein enteral feeds (EF) are made from milk components (e.g. calcium caseinates) or soya protein isolates as the predominant protein sources, various oils (e.g. soya, corn or safflower) as lipid sources, and ingredients derived from corn starch (e.g. maltodextrin), sucrose, and glucose as sources of carbohydrate. Some have insoluble and/or soluble fibre added. The protein sources in semi-elemental EF (peptide or elemental diets) are based upon the

products of hydrolysis of milk components (caseinates, whey protein and lactalbumin) or soy protein, with some specific amino acids and medium-chain triglycerides added. Most EF intended for use as sole source of nutrition, are fortified with essential vitamins, minerals and trace elements. Some also contain other nutrients such as choline, taurine, arginine and glutamine.

Manufacturers of EF invariably endeavour to achieve maximum nutrient content in minimum volume. Technological challenges for new product R&D involve packaging development to ensure the final product maintains nutritional, microbiological and organoleptic integrity. Sensory assessment is important during the product development stage. The elderly have different perceptions of taste and smell to younger people, and it is now known that further alterations occur during hospitalisation. Sensory testing is initially conducted 'in-house' but then usually involves consumer and patient panels that must be conducted according to the Medical Nutrition Industry Code of Conduct [21]. Finally, extensive stability testing in the laboratory is required to establish shelf life, pilot production runs and larger scale-up for industrial processing.

Stability

The stability of macro- and micro-nutrients depend upon the exposure of the EF to heat, pH, light and air (Table 2). Heat processing to produce a sterile liquid feed can destroy some vitamins (e.g. all B vitamins especially thiamine and vitamin B_6, folic acid and pantothenic acid) and heat-sensitive amino acids (e.g. glutamine and cysteine). Hence glutamine and cysteine are absent from most commercial EF. The amount of vitamin and amino acid lost will depend on the time for which heat is used to destroy harmful organisms. Thiamine is more stable to heat at low pH, but when the pH is high, losses are considerable. Riboflavin is unstable at high pH and is light-sensitive. Vitamin A losses can occur if light and air are not rigorously excluded. Vitamin C is the least stable of all the vitamins; it is readily oxidized in air, a process which is catalysed by heat, light, high pH and the presence of copper and/or iron. Whilst vitamin C is partially protected by the addition of bisulphite, thiamine destruction is accelerated. Vitamin E is relatively stable to heat but oxidized in the presence of air. Average nutritional claims for the content of EF are those which are declared on the label.

Table 2 Vitamin and amino acid stability in EF

Heat
Vitamins
B vitamins (especially thiamine and B_6), folic acid and pantothenic acid
Amino acids
Cysteine and glutamine
Light
Vitamin A and riboflavin
pH
Riboflavin and thiamine at high (alkaline) pH
Air
Vitamins A, C and E all oxidize

Most liquid, ready-to-use feeds are filled aseptically into cartons, plastic containers or glass bottles. These are then subjected to ultra-high temperatures (UHT) to kill any bacteria present. A temperature of about 143–152 °C is maintained for 5–10 s. The resultant sterile feed will keep for several months but variable losses of vitamin C and folic acid may occur during storage. It is difficult to give precise values for expected losses, and they will be accentuated when the containers are opened and exposed to air. However, if they are kept in the closed carton in which they are transported, the contents will be protected from light and oxygen. The process of freeze drying has been used for over 50 years, and was refined during World War II in order to supply huge quantities of dried plasma and penicillin to the armed forces. It is now used extensively in the pharmaceutical industry as one of the best methods for preserving biological materials and for protecting heat-sensitive drugs. It has also been successfully adopted for producing some EF.

Manufacturers generally fortify EF to levels designed to compensate for losses, which occur during processing. In addition, most manufacturers have rigorous quality assurance programmes designed to test levels of all nutrients during the 'quarantine' period after products are manufactured, but before they are released for sale, to ensure that nutrient levels, which are listed on the labels, are accurate. Most companies also conduct routine stability trials to determine the average levels of nutrients over the shelf-life of the product. Feeds can usually be stored at room temperature unopened for up to 1 year.

Formulations

The type of EN formulation used, as for PN, is directly dependent on the nutrient needs and goals of therapy for the patient [22]. EF divide into three formula types, standard (whole protein), peptide (semi-elemental) and specialized formulas. EF then fall into two different categories, oral/sip feeds and tube feeds:

Oral (or Sip) Feeds

Most prescribable sip feeds are nutritionally complete and can be used as sole source of nutrition. However, in general they should only be used to supplement a patient's diet to

Table 3 Nutritional considerations for enteral feed constituents

1.	Protein source (whole protein, peptides or amino acids)
2.	Carbohydrate content and source (e.g. lactose free)
3.	Fat content and source (long-chain triglycerides (LCT) vs. medium-chain triglycerides (MCT))
4.	Energy density
5.	Energy distribution (i.e. % of energy supplied by protein, carbohydrate and fat)
6.	Fibre content, type and source
7.	Renal solute load
8.	Electrolyte composition
9.	Lactose/gluten content
10.	Vitamin and mineral content (i.e. volume required to supply RNI)
11.	Osmolality
12.	Viscosity
13.	Palatability and patient acceptance

Table 4 Classification of prescribable enteral products in UK[a]

1.	Oral supplements (sip feeds)—to provide greater nutritional value and/or energy density to the diet
2.	Polymeric tube feeds—nutritionally complete feeds with high/whole protein, maltodextrin, LCT, PUFA/ MUFA, immune modulating formula and often fibre
3.	Elemental/peptide feeds for sip and/or tube feeding—mono/oligo-peptides and mono/oligo-saccharides which may be more easily digested and absorbed (but have a high osmolality, especially the elemental diet)
4.	Disease-specific formulae—for short bowel, liver or renal failure
5.	Modular diets (e.g. powdered carbohydrate or protein supplements—to individualize a patients diet)
6.	Feeds for inborn errors of metabolism (e.g. phenylketonuria)
7.	Infant formulas (e.g. lactose free feeds or those which do not contain cow's milk)

[a] This list is not exhaustive and does not include gluten-free foods or low protein foods

achieve optimum nutrition. There is a wide range of 'ready-to-use' commercial sip feeds.

Tube Feeds

Tube feeds are administered as nutrition support via a naso-enteric tube (for short term) or via a percutaneous endoscopic gastrostomy (PEG) or jejunostomy (for long term). They are nutritionally complete and can be safely given as the sole source of nutrition. These include whole protein feeds for patients with 'normal' gut function, peptide feeds often used for jejunal feeding, and specialised feeds (free amino acids hence hyperosmolar) to treat some patients with malabsorption such as Crohn's disease. Some of the nutritional considerations relating to EF are shown in Table 3.

A comprehensive list of prescribable EF (classified as 'Borderline Substances') can be found in the British National Formulary (BNF) [23]. Unlike in the USA, very little EN 'compounding' is carried out in UK pharmacy departments. EN products can be classified into seven groups (Table 4).

Protein

In the UK it is common to refer to protein requirements for EN and nitrogen requirements for PN. The eight essential amino acids (EAA) (in adults: isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan and valine) cannot be manufactured by the body but can be used to make the non-essential amino acids (NEAAs), which provide most of an individual's metabolic need for nitrogen. The quality of protein is as important as the quantity. Whilst chemical scores based on reference standards for egg or milk proteins provide useful data, they do not take into account imbalances in protein amino acid patterns, different digestion rates and absorption of specific amino acids and losses during processing. Published data based on actual protein and EAA requirements for humans that accommodate age and lifestyle factors, allow reasonably accurate amounts to be determined. Nevertheless, most enteral and parenteral products have a lower protein quality value when compared to egg or milk.

Glutamine

Glutamine is key for immune function as the primary fuel for proliferation of lymphocytes, production of cytokine, and macrophage phagocytic and secretory activities [24]. Glutamine is also the precursor for amino acids, proteins and nucleotides synthesis, and also ammonia genesis in the kidneys [25]. Since glutamine is available abundantly from animal and plant-based protein sources, individuals consuming a balanced diet can easily meet their nutritional requirements for glutamine. However during periods of metabolic stress or catabolic conditions, such as critical illness, sepsis, burns, post-surgery, and malnutrition; glutamine becomes conditionally essential, as the demand for glutamine increases drastically. Recent research has shown that glutamine can positively affect gut health by supporting the gut microbiome, gut mucosal wall integrity, and by modulating the inflammatory response [26]. Because glutamine is heat labile, standard EF do not contain adequate amounts of glutamine, due to losses during the manufacturing process. Therefore, glutamine may be provided to those individuals as modular supplements in the form of the more heat-stable glutamine dipeptides.

Arginine

Just like glutamine, arginine is also a conditionally essential amino acid during metabolic stress and trauma, due to the increased protein turnover and energy requirements of the immune system. Arginine is involved in various metabolic pathways. It is converted into biologically active compounds such as ornithine, nitric oxide, polyamines and citrulline. Hence, arginine is involved in the modulation of immune function, regulation of blood flow, angiogenesis and also wound healing [27]. Arginine is stable to heat processing and can therefore be formulated into EN regimens. All protein-based enteral feeds contain theoretically between 3 and 5 g arginine per 1000 kcal (4200 kJ) whilst some have been further enriched with additional free amino acid. Lower infection rates and reduced hospital stays have been reported with these arginine-enriched diets, but it remains difficult to interpret the potentially beneficial effects of arginine supplementation because of its co-administration with other immune-stimulating nutrients during many trials [28].

Nucleotides

Nucleotides plays an important role in the structural integrity of DNA and RNA, especially in the development of immune system, and differentiation of rapidly growing cells, such as: skin, intestinal mucosal, lymphocytes, etc [29]. During periods of rapid growth, tissue injury, infection and certain disease states, the physiological demand for nucleotides beyond de novo synthesis [30]. Hence, they are also incorporated into immune-enhancing formulas.

Carbohydrate

Carbohydrate is an essential component of enteral feeds, however Recommended Nutrient Intakes (RNIs) have not been published [24]. Most enteral feeds are designed to supply a non-protein calorie to nitrogen ratio of between 94:1 and 154:1. These proportions of energy and protein help to ensure that the carbohydrate in the feed is used for energy.

Lipids

Lipids are included in most enteral feeds as they act as a source of energy to help meet energy requirements and to minimize endogenous protein catabolism. Unlike carbohydrate and protein, lipids do not contribute to osmolality. Enteral formulas contain essential fatty acids like alpha-linolenic acid (omega-3 fatty acid), linolenic acid (omega-6 fatty acid) and other polyunsaturated fatty acids (PUFAs) as they cannot be synthesized *de novo*, and have to be consumed from the diet.

In peptide-based enteral formulas, fractionated coconut oil is often added as a source of medium-chain triglycerides (MCTs) for better absorption. MCTs are absorbed directly into the lymphatic system, hence, may minimize steatorrhea in patients with malabsorption.

Vitamins and Minerals

Enteral formulas whether to be used as sip or tube feeds, that are intended for use as sole source of nutrition; are fortified with essential vitamins, minerals and trace elements adequate to supply the RNI in volumes about 1–2 L [31]. The RNIs are a guide to the requirements for healthy individuals, therefore may not be representative of the micronutrient requirements of metabolically-stressed patients, who will have increased requirements for nutrients due to changes in metabolism. Therefore, some enteral formulas contain higher amounts of micronutrients, which will be beneficial for patients, in account for the increased nutrient requirements [32]. Recommendations for adult and paediatric daily micronutrient requirements in EN and PN have been published by ASPEN [33] and ESPEN [34] and for paediatric requirements by ESPEN/ESPGHAN [35].

Osmolality

Osmolality is the measure of the size and quantity of ionic and molecular particles within a defined volume, usually in the measure of mOsm/kg of water. A standard enteral formula of approximately 300 mOsm/kg of water is considered "isotonic" as it falls within the normal physiologic range of the human body. However, with energy and nutrient-dense formulas, the osmolality of the formula increases as more molecular particles are present within the same amount of volume. Generally, commercially available enteral feeds are tolerated by most individuals. Tolerance to higher osmolality formula may vary according to different medical conditions and gut integrity. Patients with gastrointestinal diseases or on jejunal tube feeding may experience intolerance such as osmotic-induced diarrhoea, when given high osmolality enteral feeds at a high rate. Therefore, it is advisable to start the enteral feeds at a lower infusion rate and advance gradually, and to monitor the patient for gastrointestinal intolerances. Patients with a high output jejunostomy may need a solution with an osmolality near to 300 mOsm/kg and a sodium content of 90–120 mmol/L (chapter "Management of a High Output Stoma, Jejunotomy or Uncomplicated Enterocutaneous Fistula"). In some units additional sodium

is added (using aseptic procedures) to the feeding bag prior to administration, but this will increase the osmolality.

Feeding Routes/Administration

The choice of feeding route is determined by alimentary tract function, previous gastrointestinal surgery (e.g. gastrectomy), accessibility of the gastrointestinal tract (GIT), practicality of using the GIT and patient preference. In patients who are able to eat, but unable to meet their nutritional requirements with everyday food and drink, fortified foods or sip feeds can help to increase intake of energy, protein and other nutrients.

In those who are unable to eat, but have a functioning GIT, tube feeds may be administered via a nasogastric tube in the short-term, or a gastrostomy or jejunostomy in the long-term. Nasogastric feeding is the most common form of tube feeding, and can be used to meet total nutritional requirements, or to complement oral or parenteral nutrition. A gastrostomy (most commonly a PEG) or jejunostomy is used for patients who are expected to require tube feeding for longer than about 3 weeks. Jejunostomy feeding is used when the stomach cannot be used (e.g. if patient has had a gastrectomy) and the patient has otherwise a functioning GIT. Jejunostomy feeding has been successfully used to feed patients after liver transplantation [36]. In patients who do not have adequate functioning gut, or whose nutritional goals cannot be met by EN, parenteral feeding is indicated.

Delivery Techniques

For most tube-fed patients, a feeding pump is used to deliver the feed. Pump controlled feeding can be continuous or intermittent. In the hospital setting, continuous feeding is the most common. For patients who require feeding at home, intermittent feeding allows more flexibility and freedom. In addition, when feeding is stopped for 4 or more hours each day, the gastric pH drops to below 2.5 and this has the additional advantage of having an antibacterial effect. Gravity or bolus feeding, which supplies 100–400 mL of feed over 10–30 min several times a day, can be used with stable patients who may find it better psychologically. However, if not introduced carefully, it can increase the incidence of diarrhoea, cramps, nausea, bloating and/or abdominal discomfort [37] (chapter "Enteral Nutrition").

Tube Blockage

Tube blockage can occur in enterally fed patients and may lead to the EFT needing to be replaced. Protein coagulation, which occurs at low pH, is usually the cause of blockage and may be aggravated by the administration of medications through the tube. To avoid tube blockage, the tube should be flushed with water before and after feeding, and some advocate every 4 h during feeding. Tubes should also be flushed before and after any medication is administered and certain medications should never be mixed as this may cause EF to become unstable, thus increasing the potential for the tube to become blocked (see below). Along with other measures (chapter "Insertion, Types and Care of Enteral Feeding Tubes"), a suspension of pancreatic enzymes and bicarbonate can prevent tube blockage and decrease the rate of tube occlusion tenfold [38] (e.g. a Creon® capsule dissolved in 10 mL 8.4% sodium bicarbonate).

Diarrhoea

Much research has been undertaken to understand and define the pathogenesis of enteral feeding-related diarrhoea. Factors such as antibiotics, high osmolality feed, lactose intolerance, contaminated feeds, laxatives and overflow incontinence have all been implicated (chapter "Intestinal Adaptation"). A systematic review of 26 studies has shown that diarrhoea can be moderated by fibre in patients receiving EN [39] and fibre is well tolerated within 72 h of feeding in ICU [40]. However, the addition of prebiotics (fermentable fibre), which lead to specific changes in the composition and/or activity of gut microbiota that benefit the well-being and health of the host) in minimising diarrhoea in ICU settings remain inconclusive [41]. In addition, a meta-analysis of 30 trials with 2972 patients had shown the potential use of probiotics in reducing VAP infections but high quality clinical trials are needed in a broader selection of patients to substantiate this interesting and low cost approach for diarrhoea prevention [42].

Administration and Compatibility of Drugs with Enteral Nutrition

Providing optimal nutrition therapy is as vital to patient outcome as prescribing the correct drug, but as our knowledge of clinical nutrition and pharmaconutrition has expanded, so too have the complexities of the nutrition and drug therapies that patients are prescribed. The two extremes of nutritional status i.e. malnutrition and obesity, can both influence drug disposition and drug absorption when administered with EF in infancy and childhood; pregnancy and lactation; and especially in the elderly. Around 10% of the population in most western countries is over the age of 65 but this relatively small percentage of patients uses more than a third of all medicines prescribed. Moreover, polypharmacy or multiple drug therapy and malnutrition are more prevalent in older

people. It is estimated that over 40% of home enteral tube feeding (HETF) patients are over 70 years old and the majority will have a permanent feeding device with only 20% using nasogastric tubes.

As a result of the heightened awareness of the benefits of home artificial nutrition (HAN) support, EF are now increasingly seen as a useful vehicle for administration of medications. However, interactions between drugs and nutrients in an EF can cause an alteration of the pharmacokinetics of the drug or nutrient (bioavailability, distribution, metabolism, excretion) leading to compromised nutritional status. Drug-nutrient interactions (DNI) can be categorised as: physical, pharmaceutical, pharmacological, physiological, pharmacokinetic or pathophysiological and may occur when certain medications are administered together with EF, causing reduced absorption of the medication or nutrients, or tube blockage. Factors contributing to DNI have been comprehensively listed by Rollins in Table 5 [43]. The clinical consequences of an interaction are related to alterations in the disposition and effect of the drug or nutrient and can include nutritional deficiencies, drug toxicity or loss of therapeutic efficacy.

Typical DNI usually occur during absorption in the gastrointestinal tract. For example, there is a reduction in absorption of phenytoin when an EF is being administered at the same time. Hence, adjustments to the timing of feeds and phenytoin administration are needed, whereby the EF is stopped for 2 h before administration of intravenous phenytoin; and plasma levels of phenytoin need to be monitored routinely [43]. Additionally, protein deficiency decreases absorption of vitamin A, dietary fat decreases calcium absorption, copper and zinc supplements inhibit iron absorption, whereas vitamin C enhances absorption of non-haem iron by binding and solubilising ferric iron. Another example of DNI involves warfarin, whereby the effect of medication is dependent on the vitamin K content of the EF. In such cases, once feeding has been established and the patient will be on long term EN, INR should be monitored routinely and dosage of warfarin should be adjusted accordingly [43]. Most drugs contain excipients that could also interact with an EF. Sorbitol, used as a solubilizing agent and as a sugar-free sweetener in liquid formulations can cause severe cramping and diarrhoea. It has now been eliminated from some drugs, such as paediatric antibiotics, but it is wise to check with the drug manufacturer. Nevertheless, it must be remembered that these actions will breach the product licence of the drug. Consequently, adding an oral medication directly into the EF is generally discouraged in favour of direct enteral bolus or via the EFT after consultation with the pharmacist.

Table 5 Factors contributing to drug-nutrient interactions (adapted from [43])

Administration related	Tube characteristics size, length, material
Regimen	Continuous, cyclic, intermittent or bolus
	Flushing fluid (e.g. water) frequency and volume
Site of feeding	Gastric, duodenal or jejunal
Medication	Tablet, capsule, solution, elixir (contains alcohol), syrup (contains sugar), suspension
	Osmolality and viscosity of liquids
	Excipients: sorbitol, alcohol, stabilizers
Absorptive environment	Acid, base, hydrophilic or lipophilic
Therapeutic index	Important if narrow
Formula	Protein content - intact, hydrolysed, caseinate, isolated milk protein, soy, whey
	Components affecting GI motility: lipid content, osmolality, viscosity
	Vit K content
Disease related factors	Visceral protein and GI motility/digestive enzymes and mucosal absorption

DNI in patients on EN can be avoided or minimised by the following: avoid mixing drug and the EF formula, change the route of administration, change the drug dosage form to a therapeutic equivalent, change the EN formula, use minimum drug dose, dilute the drug and flush EFT before and after dosing. Liquid solutions or liquid suspensions of drugs are preferred and can be administered directly via the EFT. Tablets or capsules, need to be either crushed and dissolved, or opened and dissolved in water before administering through the EFT. When administering medication via the EFT, it is advisable to flush with 20–30 mL of water before and after the medication is administered. If adding more than one drug, flush the EFT with 10 mL of water between the different medications. Mixing drugs together and adding medications directly into the EF is generally discouraged in favour of direct enteral bolus. Modified or extended release tablets, enteric coated tablets or capsules, cytotoxics, and hormones should not be administered as the pharmacokinetic properties (bioavailability, distribution, metabolism, excretion) of the medication may be significantly altered.

The US Pharmacopoeia [44] contains release characteristics of drug dosage forms and data on DNI with EF or EFT. The BPNG Handbook of Drug Administration via Enteral Feeding Tubes provides legal, practical and technical aspects that clinicians should consider for safe and effective prescribing and administration of drugs via EFT [45]. Whenever possible a licensed formulation should be used but the individual drug monographs in the book provide guidance on alternative medications when appropriate. Nevertheless, it must be remembered that administering a crushed or opened oral drug or an intravenous drug via an EFT usually falls outside the drugs product licence. There could be a risk of inaccuracies in dosing, tube blockage or an adverse patient reaction—in which case the drug manufacturer is no longer accountable, but the responsible health pro-

fessional could be liable for any adverse reaction experienced by their patient. The ASPEN Enteral Nutrition Handbook [1] contains the latest recommendations on safe practices and new information on preparation, labelling, and dispensing of EN. It provides a step-by-step, practical guide to caring for patients receiving EN therapy. The ASPEN website [46] also has useful references including updates on the ASPEN ENFit® project to standardise enteral connections in accordance with the ISO standards [47]. The US FDA is in the process of developing guidance for the pharmaceutical industry on oral drug products for ETF. The draft guidance, which is out for public consultation, will cover in vitro testing and labelling recommendations for manufacturers to ensure oral drug quality and bioequivalence when evaluating a drug's suitability for administration via an EFT [48].

Administration of drugs via an EFT has implications for all members of the multidisciplinary NST. In particular, the pharmacist has several responsibilities to ensure the correct drug formulation is prescribed and that clinical colleagues are aware of the legal implications of using an unlicensed drug. Rational drug or nutrition therapy requires clinical management based on accurate interpretation of symptoms, correct diagnosis and sufficient knowledge about drugs to select the right medicine and administer it in the right dose for the optimum length of time by the most appropriate route. More comprehensive education on DNI in EN will enable health care providers to better manage their patient's clinical outcome.

Feed Contamination

Safety must be a primary focus for the preparation and administration of an EF. According to the ASPEN Safe Practices for Enteral Nutrition Therapy Task Force [49] before any drug is considered for administration via an EFT, the pharmacist should be consulted, who can ensure that national equivalents of OSHA and NIOSH [50, 51] are complied with for the use of hazardous drugs in hospital settings. Additionally, the patient should be assessed to determine whether they can tolerate and manage oral administration of the prescribed licensed medication. Detailed practice recommendations have been compiled by ASPEN [49].

Microbial contamination of EF can occur during preparation, decanting and assembly of mixed or ready-to-use products, or more commonly during the subsequent manipulation of the feeding system and might be a source of nosocomial infection [52, 53]. It has been assumed that micro-organisms present in a feed administered into the gut (especially the stomach), will be destroyed by gastric acid and digestive enzymes, in the same way as food. Hence, infection control procedures have remained less stringent for EN than those for PN. However, the risk and magnitude of contamination is directly related to the type and number of manipulations of the system and the use (or non-use) of aseptic techniques [54]. Nurses often do not wash their hands before handling EN systems but micro-organisms detected in patient's feeds can be transferred from nurses' hands or from patients themselves [55, 56]. Typical organisms isolated from EF include the skin contaminants *Staph. epidermidis* and Gram-negative bacilli. Retrograde spread of organisms from the patient, via the giving set, to the EN container have been reported [57]. Microbiological contamination of EFT may be due to the practice of flushing the tube with tap water [58]. The practice of flushing and rinsing giving sets when changing EN containers is common in the USA, but rinsing may be unnecessary if the sets are changed at least every 24 h [59]. Historically, hang-time for paediatric formulas has been only 4 h, but by using sterile closed EN systems hang times may be extended up to 24 h [49].

Several policies and procedures intended to minimize EN contamination have been published in USA and Europe [48]. Anderton et al. [60] published guidance notes for the British Dietetic Association and recommended that at no time should any internal part of the nutrient container or giving set be allowed to come into contact with hands, clothes or surrounding surfaces. Contamination is more likely in patients on an ICU if EF are reconstituted or diluted with non-pasteurized water rather than with sterile water. Contamination of a EF may not be clinically relevant unless a patient is immuno-suppressed, is taking drugs to inhibit gastric acid production, is being fed directly into the small bowel or if there is an enteropathic organism in the feed. As such patients may not be immediately identified, it is therefore recommended that EFs are always prepared and administered using aseptic technique.

Other Feeding Options That Need Microbiological Monitoring

Blenderised food is becoming increasingly popular with HEN patients. It involves administering liquidised or pureed table food vi an EFT. There may be physiological benefits such as improvement in symptoms of vomiting, reflux and abnormal bowel habits for some tube-fed individuals. Additionally, the parents and carers of some tube-fed children report social and emotional benefits. Nevertheless, this mode of EN has been met with caution, by some professionals who consider there could be increased risks of nutrient deficiencies, blockage of EFT or infection, in comparison to commercial EF. The UK BDA has produced a position statement designed to inform dietitians and ensure effective, evidence-based patient care [61].

Chyme reinfusion (CR) into the distal gut is known to improve nutritional status of patients with high output enter-

ostomies but use has been limited by complicated equipment, safety concerns and low patient acceptance. However, recent clinical experiences in Europe and Australasia [62] have demonstrated that the procedure can be microbiologically safe, reduce dependency on PN and improve gut rehabilitation before surgery (chapter "Distal Feeding and Hydration").

It is important for a multidisciplinary NST, ideally comprising a physician, dietitian, pharmacist, nurse and a microbiologist, to have an ongoing quality assurance programme for EN and PN. The team approach to quality assurance with the key participation of the pharmacist and/or microbiologist has been previously advocated by Anderton, [63] who proposed an adaptation of the food industry's Hazard Analysis Critical Control Point (HACCP) system for the preparation and administration of EF that has been successfully employed over the years [64].

Access for Parenteral Support

Arun Abraham, Geert Wanten, and Jeremy M.D. Nightingale

Key Points

1. Assessment prior to the insertion of a central feeding catheter consists of examining for evidence of previous venous thrombosis or its predisposing factors (dehydration and sepsis).
2. Reviewing current medication including anti-coagulants.
3. The choice of catheter is influenced by the underlying diagnosis for Intestinal Failure (IF), predicted duration of parenteral support (PS), the frequency and composition of the PS mixture, intravenous medication needed, the person who will be setting up the infusion, the patient and IF team preference.
4. A catheter needed for long-term home PS is usually tunnelled to reduce the risk of dislodgement.
5. If possible ultrasound is used to help placement of all central feeding catheters commonly into the jugular or subclavian veins.
6. The routes for parenteral nutrition can be described according to the position of the catheter tip as large, medium or small vein feeding.
7. A central vein catheter tip needs to be at the atrial/caval junction. If more proximal the risk of thrombosis increases.
8. An arteriovenous fistula is an effective way to give parenteral support and should be considered if many catheter-related blood stream infections (CRBSI) have occurred.

Introduction

Venous access is essential for providing parenteral support (PS) (nutrition and/or fluids and electrolytes) to patients with Intestinal Failure (IF). PS is required when the gut is not functioning, is functioning insufficiently, is being left to 'rest' or if enteral nutrition is unsuccessful [1]. Successful outcomes for the management of PS venous catheters relate not only to obtaining venous access but more importantly to the skilled after care of the catheters provided initially by nursing staff (chapter "Nursing Care of Patients Receiving Home Parenteral Support"). This chapter provides a practical guide about central and peripheral feeding catheter insertion. It is helpful for all members of a nutrition support team (NST)/ IF team to have an understanding of the considerations made in obtaining and maintaining venous access.

Indication of PN

The most common indication for intravenous nutrition support is short term reversible (type I) IF during the peri-operative phase, however the duration of nutritional support is widely variable from a few days in the initial post-operative days when an ileus may occur, to a several weeks for those who are severely malnourished due to underlying disease or requiring gut rest. Some of these patients may progress to having medium term reversible (type II) intestinal failure depending upon the severity of the underlying disease. In some cases, patients with an abdominal catastrophe need long-term (type III) IF as a consequence of an extensive bowel resection usually due to a disease process or ischaemia.

Preserving Venous Access

Preservation of venous access is important both for fluid/nutrition delivery and medication administration. An intravenous catheter may need to be changed due to a catheter-

J. M.D. Nightingale (ed.), *Intestinal Failure*, https://doi.org/10.1007/978-3-031-22265-8_34

related blood stream infection (CRBSI), venous thrombosis or due failure of the device. An underlying pro-thrombotic condition (e.g. inflammation, dehydration or a coagulopathy) that will contribute to a hypercoagulable state and thus venous thrombosis should be detected and managed. Dehydration which is often due to fluid losses and/ or poor compliance with the oral must be avoided as in addition to predisposing to venous thrombosis makes venous detection more difficult [2]. Medication (e.g. cyclizine) inserted into a PS catheter can cause damage and an increased the risk of occlusion. Venous thrombosis is often irreversible and therefore contributes to a loss of venous access. Thrombosis of more than two major veins is an indication for discussion about an isolated small bowel transplant (chapter "Intestinal Transplantation"). Preserving access is very relevant to a small number of long-term (type III) IF patients who may require renal replacement therapy.

PN Composition

The lower osmolality of some formulations of parenteral nutrition may be compatible with a short term peripheral infusion (small vein), however there are limitations with many of these formulations as they do not meet the higher energy/volume requirements needed by some patients (lower volume and glucose content). Some of the components of parenteral nutrition (especially glucose and electrolytes) can cause a high osmolality which in theory could lead to irritation of the vein's endothelium and so predispose to thrombosis but surprisingly this has not been shown in one study [3]. The amino acids used in parenteral nutrition may have a low pH and can affect the final pH of the admixture and this may increase the risk of thromboembolism. Therefore on theoretical grounds parenteral nutrition, especially if long-term and of high osmolality (greater than 600 mOsmol/kg), and/or with low pH may be best delivered into the circulation at a point of maximal dilution (e.g. the vena cava/atrial junction).

Central and Peripheral Vein Nutrition

The routes for parenteral nutrition can be described according to the position of the catheter tip as large, medium or small vein feeding (Table 1, Fig. 1). Previous descriptions have addressed the site of catheter insertion as either central

Table 1 Parenteral nutrition routes

Catheter tip	Venous insertion site	Type of nutrition
Large vein	Subclavian/jugular/cephalic vein	Central
	Brachial vein in cubital fossa (PICC)	Central
Medium vein	Brachial vein in cubital fossa	Peripheral
Small vein	Vein on back of hand	Peripheral

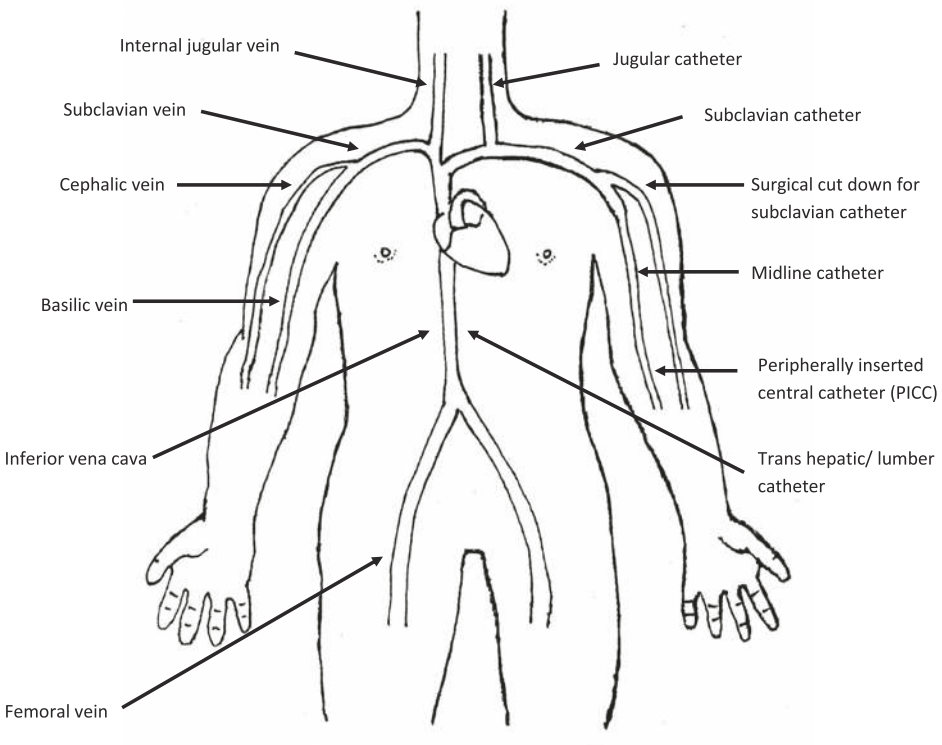

Fig. 1 Schematic venous anatomy and sites for large and medium vein cannulation for the administration of parenteral nutrition

or peripheral. This may lead to confusion as peripheral nutrition may be given through a short cannula with its insertion site and tip in a small vein (e.g. on the back of the hand or on the forearm), or via a catheter inserted into the basilic vein with its tip in the axillary vein.

Nomenclature is most clear when both insertion site and catheter tip position are named (e.g. with peripherally inserted central catheters (PICCs)). PICCs are long small diameter catheters inserted into the basilic vein in the cubital fossa with their tip at the superior vena caval (SVC)/right atrial (RA) junction.

Catheter Materials (Types and Size)

The ideal catheter material is flexible, strong, chemically inert, non-thrombogenic, radio-opaque and does not kink. It should have a measurement scale on its side. The wall of the vein may be damaged by pressure, if the catheter material is relatively inflexible, and this can lead to thrombosis [4]. Small diameter flexible catheters that effectively float in the bloodstream are less likely to cause injury.

The chemical composition of a catheter has not changed and remains an important factor in causing thrombophlebitis of peripheral veins. Most plastics contain additives that may produce a chemical phlebitis. Rubber, polyethylene, polyvinylchloride, Teflon® and uncoated polyurethane are all thrombogenic [4–8]. For parenteral nutrition either a polyurethane-hydromer or silicone elastomer (also called silicone rubber or silastic) catheter is used because they are biologically relatively inert. When compared, thrombophlebitis occurred less frequently with a polyurethane-hydromer coated catheter [9–11].

The coating of a polyurethane-hydromer catheter contains a hydrophobic polymer made from polyvinylpyrrolidone and anisocyanate prepolymer. When a hydromer-coated catheter is wetted, water is absorbed onto the coating and the resulting gel acts as a barrier between the blood and the catheter material so that platelets do not adhere to it. This gives the practical advantage that when wetted by body fluids (e.g. blood) the catheter becomes slippery, which makes the passage of the catheter through a peripheral vein relatively easy and so less likely to cause trauma to the vein. It also has the advantage of being physically stronger than a silicone elastomer catheter, allowing its external diameter to be reduced; in addition, it does not easily kink. Thus polyurethane-hydromer catheters are used when the insertion site is a medium or small vein. Silicone elastomer catheters, which are soft and flexible, are commonly used for long-term central vein feeding where they can last for 10 years without problems.

Some catheters have an antimicrobial (e.g. minocycline) incorporated into the material [12]. Other catheters have an extra cuff (VitaCuff®) containing collagen impregnated with silver ions; the collagen cuff swells to 2–3 times its original size and the silver acts as an antimicrobial [13]. Antimicrobial catheters are not routinely used in current practice due to limited difference in outcome [14, 15].

A central catheter internal diameter is variable but usually 6.6–9.6 FG and a PICC is 2–6 FG. To avoid thrombosis the catheter vein ratio should be 45% or less [16, 17].

Choice of Catheter

The choice of catheter is influenced by the underlying diagnosis for IF, predicted duration of PS, the frequency and composition of the PS mixture, intravenous medication needed, the person who will be setting up the infusion, the patient and IF team preference. In acute IF the choice of catheter for patient care may be different to that of patients requiring a catheter for PS at home. At the onset of IF after an abdominal catastrophe, due to their physiological and metabolic instability, a patient often requires access for multiple therapies. The onset may be more insidious when IF is limited to an episode of illness that fails to resolve or when there is a decline in gut function on a background of chronic illness. The dependence on intravenous support may changes after surgery that either resects bowel or brings more into continuity.

The Bard Groshong valve is a three-way valve incorporated into the tip of a large-vein catheter which, in the absence of a negative or positive pressure, remains in the closed position. It opens inward when negative pressure is applied for aspiration and outward with positive pressure used for infusion. It should prevent blood from the venous circulation entering the lumen, so making catheter occlusion less common, and should reduce the risk of air entering the catheter. While generally performing well, [18] they were no better than Hickman-type lines in terms of CRBSI or thrombosis formation, and they malfunctioned more frequently [19].

For long-term home PN a tunnelled catheter is preferred as the risk of dislodgement after 2 weeks is minimal (Fig. 2) [20].

Peripherally Inserted Central Catheter

In patients with acute IF, a multiple lumen peripherally inserted central catheter (PICC) may be considered initially and then later changed to a tunnelled catheter if long-term home PN is appropriate. As they are relatively easy to insert and remove, there is a growing tendency to use a PICC to deliver HPN for a short time (e.g. less than 3–6 months). However, they remain less ideal for long-term parenteral feeding due to the risk of dislodgement of the catheter as there is no cuff to anchor the catheter to soft tissues. The exit site position on the arm restricts normal arm movement making daily living activities difficult and almost impossible if

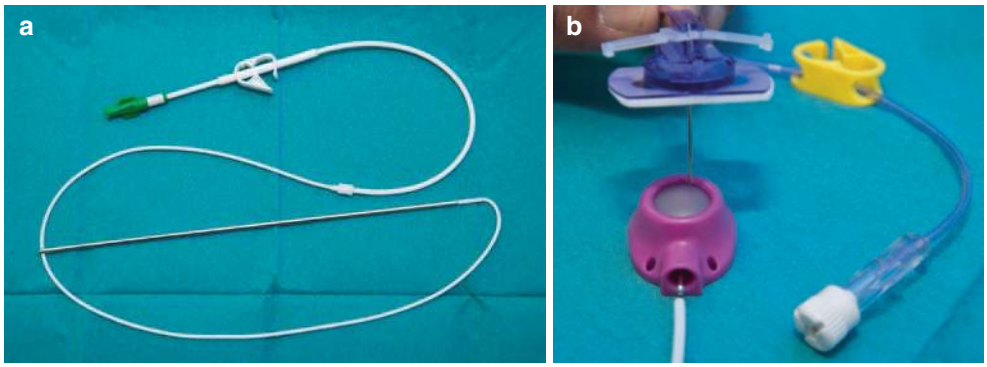

Fig. 2 Types of catheter for long-term PS. (**a**) Cuffed single lumen feeding catheter for long-term use with insertion needle attached. (**b**) Implantable port for long-term feeding (or medication) with external insertion needle attached

the patient is doing the procedures themselves. There is an increased incidence of thrombosis when a larger diameter PICC is used and if there is an underlying malignancy [21]. In other countries such as Canada there is an established practice in using PICC for HPN [22]. They are not suitable for patients who use crutches or a wheelchair.

Implanted Subcutaneous Port

An implanted subcutaneous port is used by some centres for HPN [23]. The first fully implantable venous access device or reservoir device (port) appeared in 1982 [24]. Since that time they have gained in popularity and are now used widely and have few complications [25]. They consist of a vascular catheter attached to a subcutaneous port. The port segment is a cone-shaped chamber made of stainless steel, titanium or plastic covered with a self-sealing compressed silicone septum that can be punctured up to 2000 times by a non-coring needle. Ports are available in single or dual lumen configurations with a pre-attached or attachable silicone rubber or polyurethane catheter. The advantage of an implantable port over other catheters is the cosmetic appearance as it is concealed under the skin and therefore would be an ideal solution for those who prefer the appearance, do not require frequent infusions or wish to swim. However, if patients require daily infusions the advantage of concealed lumen is lost when the Huber needle is left in situ for 5–7 days a week. Daily puncture of the skin overlying the port can lead to ulceration and imflammation of the skin over time. Port site infections can easily lead to CRBSI; salvaging a port when infected is difficult partly due to the reservoir and they usually have to be completely replaced [23].

Preparation

Marking of Catheter Exit Site

The nutrition nurse specialist will discuss with the patient the possible sites for the catheter to exit the skin (especially if a long-term catheter). He/she will then mark at least two appropriate sites with permanent ink that will not come off when the skin is cleaned.

Table 2 Key features included in the WHO surgical checklist [26]

Confirmation of patient, surgical site
Comorbidities and medications identified (anticoagulation)
Allergies specified
Sedation and local anaesthetic identified
Infection precautions
Equipment (instruments/ultra sound/X ray compatible table) confirmed
Post procedure care identified

Place for Procedure

Ideally a large vein feeding catheter is inserted in the radiology department using ultrasound and fluoroscopy. Long-term tunnelled catheters (e.g. a Hickman type catheter or implanted port) are most commonly inserted. Fluoroscopy is useful to ensure the tip of the catheter is at the cavo-atrial junction at the time of placement. Placement of a catheter with the help of fluoroscopy or in interventional radiology should especially be considered to assess and navigate venous anatomy if changed by thrombosis or if there have been several catheter placements.

WHO Surgical Safety Checklist

For any invasive procedure it is recommended to have a checklist to decrease errors or misadventure and a version of the WHO surgical safety checklist is most commonly used [26]. All members of team are present for the WHO check list to appraise patient factors and discuss any issues anticipated for the procedure. The key features within the sign in, time out and sign out headings are listed below (Table 2) [26].

Venous Anatomy Assessment

Multiple visible veins on the chest are suggestive of collaterals (Fig. 3) and should raise concerns about chronic occlusion. A large dilated internal jugular vein seen on ultrasound should raise concern about occlusion of central large veins. Patients who have had multiple central venous catheters, prolonged intensive care stay, multiple episodes of sepsis, or an indwelling catheter for a few years, or have a thrombophilia disorder, or are transitioning from paediatric to adult services are at risk of compromised vascular access. Their venous anatomy may be assessed with the help of a CT (or MRI) venogram. There should always be a high index of suspicion for a venous thrombosis; however assessment of venous anatomy for a long term HPS patient is undertaken only when there is a clinical concern. A comprehensive review of venous anatomy is important prior to undertaking a placement of a new catheter for an existing HPN patient. It is also useful to have upper limb venograms in high risk patients prior to placement of PICC.

New Methods

For non-invasive venous imaging there are developing techniques that use the property of haemoglobin (concentration and oxygenation) as a strong absorber of visible and near-infrared (NIR) light (650 and 950 nm) to show the size and site of veins. For visualising superficial veins (e.g. for venous cannulation/PICC insertion) NIR imaging [27], with or without transillumination, can be used. For deeper veins NIR can be combined with ultrasound imaging (photoacoustic imaging). There are smartphone apps being developed that provide an NIR function.

Equipment

Ultrasound

Ultrasound has changed the practice of insertion of central venous catheters with a significant decrease in incidence of complications [28]. A linear probe with high frequency is used. The probe is placed in a horizontal as well as longitudinal plane to assess the anatomy (Fig. 4a, b). When the probe is placed in horizontal plane the vascular structures appear circular, whereas when the probe is placed in a longitudinal plane it appears as tubular. Veins are collapsible and therefore can be compressed when pressure is applied. Arteries may be compressed; however there is a distinct pulsatile appearance to them. Further confirmation is possible with help of Doppler. The blue colour on Doppler (blood flowing away from the probe) identifies the veins. Red colour on Doppler identifies the artery with blood flow in the opposite direction. If the veins are not collapsible with absence of flow (there is no colour on Doppler) a thrombus must be considered (Fig. 5).

The ultrasound setting should be confirmed to avoid automatic time out.

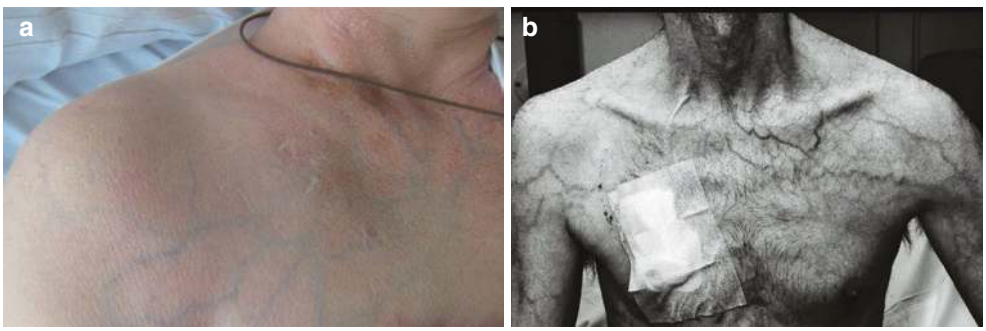

Fig. 3 Collaterals on the upper chest wall due to previous superior vena caval thrombosis. (**a**) Difficult to see and (**b**) very obvious

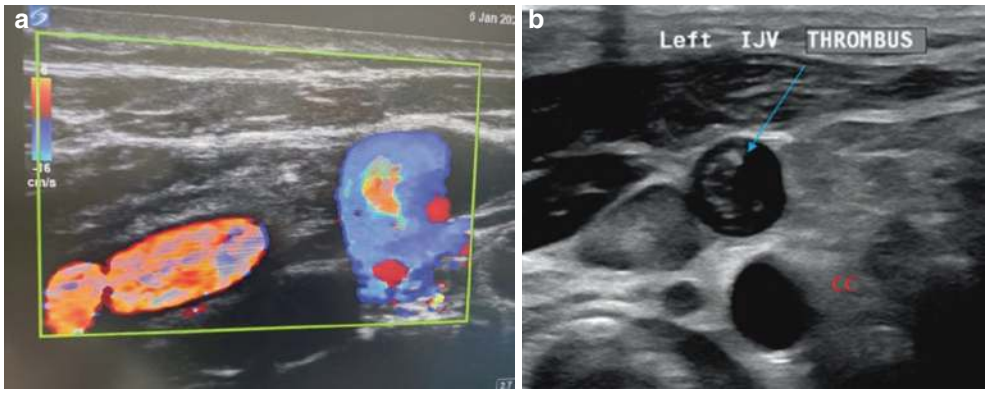

Fig. 5 (**a**) The direction of flow red towards the probe and blue away. (**b**) Thrombus in IJV (internal jugular vein) and common carotid artery (CC) posteriorly

Local Anaesthetics/Sedation

Most of the tunnelled CVCs can be inserted under local anaesthetic. A volume of 15–20 ml of 1% lidocaine is required particularly for the tunnel. Local anaesthetic volume can be increased if 0.25% levobupivacaine hydrochloride (Chirocaine®) is used however it is preferred not to use local anaesthetic with adrenaline. The syringes used for local anaesthetic should be clearly labelled to avoid the error of accidental flushing of catheter with local anaesthetic. Some patients would prefer to have the procedure done under sedation or general anaesthetic due to discomfort or anxiety. General anaesthetic would be essential if a patient cannot lie still. Prophylactic antibiotics are not routinely administered.

Consent and Exit Site

Patient is consented and the exit site marked. Discussion with patient about exit site is important as the catheter can be insitu for a significant period, therefore patient preference should be considered with regards to clothing and ability to care for the catheter. The exit site should be away from the crease of axilla as the skin flora from axilla are different from those on the chest wall [29]. Males patients should have their chest hair trimmed. If the femoral vein is used the exit site may be marked on the lower abdomen or thigh. If a patient is very confused and at risk of pulling the catheter, it can be tunnelled onto the back between the scapulae.

Position

The patient is placed in supine position with table tilted with slight head down. The table should be compatible with X-ray fluoroscopy. Patient may be monitored with an ECG tracing, as well as pulse oximetry. ECG monitoring is useful to detect early arrhythmias caused by the guide wire (if placed into the heart).

Insertion of Large Vein Central Venous Catheter

The operator assess venous anatomy to confirm the site of insertion and then washes hands with surgical scrub, puts on sterile gown, gloves and completes the instrument check. The skin is cleaned with Chlorhexidine in alcohol solution [30–33] and allowed to dry. The site is kept sterile by applying sterile drapes exposing the lateral side of neck as well as the exit site. Head drapes are useful to cover hair and head to maintain a sterile field. The surgical drapes must be adjusted on side of the face to avoid covering patients face completely as this would cause anxiety for patients. The introducer needle is primed with 10 ml syringe with approx. 5 ml of saline in the syringe. It is important to ensure there are no air bubbles in the syringe to help assess if there has been a puncture of lung during the procedure.

Internal Jugular Veins

When internal jugular veins (IJV) are used, the point of entry of catheter should be as low as possible into the root of the neck. If the point of entry is higher in the neck this would lead to an acute angulation of catheter when the catheter is tunnelled under the skin which can lead to occlusions of catheter in the future. A catheter placed as low as possible in IJV will curve anterior to the clavicle forming an arch when tunnelled under the skin which is apparent in a lateral view chest X-ray.

IJV's are commonly used to support acute care and a quad lumen central venous catheter (CVC) may be in situ as the patient recovers and requires support for long term parenteral nutrition. A tunnelled CVC may be placed in the opposite side or the same side if the quad lumen CVC is placed in a more cranial position. The placement of two catheters in the same vein for a prolonged period of time can compromise flow in the vein which can lead to thrombosis, [17, 34] and if one catheter becomes infected, there is a risk of it infecting the other. It is often less difficult to pass the guidewire from the right side than the left. There is some suggestion that the right side has lower risk of thrombosis than the left, possibly due to the catheter being angulated at the junction of the SVC and brachiochephalic vein [35].

Subclavian Vein

Subclavian veins (SC) have always been considered as the vein of choice for PN [36]. as the catheter exit site is not obviously visible, is relatively easy to tunnel from the insertion site and was thought to have a lower incidence of CRBSI. However the introduction of ultrasound reduced the risk of insertion related complications (pneumothorax/haemopneumothorax and arterial puncture) [28]. As it was technically more difficult, with ultrasound, to find and cannulate the subclavian vein there has been a move towards the preferred first insertion site being the internal jugular vein. There is very little difference in the risk of CRBSI from whichever vein a tunnelled CVC is inserted [37]. However, many patients would prefer to have a catheter in the SC for cosmetic reasons as the catheter is not visible over the clavicle (Fig. 6). Rarely a SC catheter may be compressed between the first rib and clavicle (pinch off syndrome).

Femoral Vein

Non tunnelled CVC's placed in a femoral vein are considered to have very high risk of CRBSI. However, for tunnelled CVC's, there is very little difference in rate of CRBSI between the femoral and other sites [37–39]. The catheter can be tunnelled on to the antero-lateral part of thigh or onto the lower abdominal wall taking care to avoid any large collaterals that may have appeared due to a supra-cardiac thrombosis. The risk of a more distal thrombosis with a tunnelled femoral CVC is unknown, partly because most patients needing a femoral catheter have had a thrombosis and are already anticoagulated.

Cardiac and Transhepatic Insertion of a Central Catheter

Rarely all major veins are thrombosed and it is necessary for the cardiothoracic surgeons to insert a feeding line through a

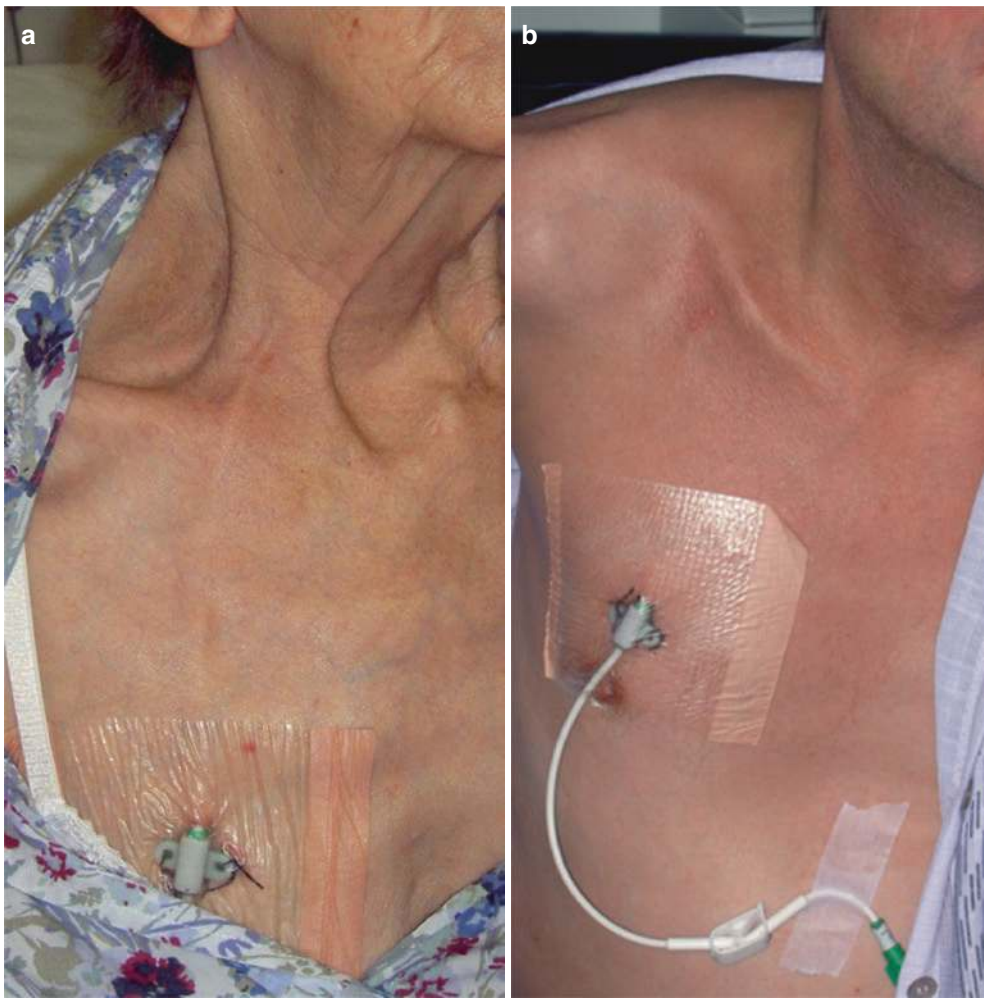

Fig. 6 A recently places (**a**) internal jugular and (**b**) subclavian long-term Hickman type feeding catheter. Note the visible catheter in its tunnel above the clavicle in the jugular insertion

right anterior thoracotomy and through the right atrial appendage into the right atrium [40, 41]. A catheter may be inserted radiologically through the liver and into the inferior vena cava. This technique has mainly been reported in children [42].

Large Vein Catheter Insertion

Boxes 1–4 show the detail about inserting a catheter into a large vein: using ultrasound/radiology (Box 1), directly into the subclavian vein without ultrasound/radiology (Box 2) or surgically using the cephalic vein (Box 3) and the insertion of an implantable port (Box 4). ECG guidance (especially if from an electrode at the tip of the catheter) has helped in knowing when the tip of a catheter is within the right atrium. A catheter tip in the right atrium near the sino-atrial node may cause an atrial tachycardia (often when feed is given) [43]. In most care settings a catheter is placed with radiological screening and the use of ultrasound guidance. In the rare circumstances when this is not possible bedside placement may be performed (Box 2).

Box 1. Ultrasound Aided Cannulation of a Large Vein

1. A sterile probe cover is used to cover the ultrasound transducer. Venous anatomy is confirmed by compressing the vein. The trajectory of insertion needle noted, and skin marked for local anaesthetic. Local anaesthetic is checked and administered about a 1 cm under the skin raising the level of the skin with some blanching. When infiltrating local anaesthetic care must be taken to avoid any small air bubbles which can cause the images to be compromised. The ultrasound probe is used to familiarise the operator with the anatomy.
2. The introducer needle is used to pierce the skin under direct vision. The linear probe is placed horizontally across the vein and needle is positioned at the midpoint of the linear probe (usually marked on the probe). This allows a clear view of the posterior wall and surrounding structures. There are many methods used for cannulation with ultrasound. Most commonly used is the "crepe" method where needle is placed at a small angle to the probe and advanced under direct vision. The probe is tilted as the needle is advanced to ensure the tip of the needle is always in view (Fig. 7). It is important to assess the tip of the needle constantly in relation to the vein. In patients who are underfilled or in older patients with tougher venous wall the introducer needle may not cannulate the vein despite complete indentation of the anterior wall of the vein. Continuous firm pressure with the needle will enable to pierce through the anterior wall of the vein. Cannulation is confirmed by free flow of venous blood into syringe on aspiration and the needle is then tilted towards the skin. The syringe is disconnected keeping the needle steady and guide wire is passed. Absence of pulsatile bleeding from the needle before insertion of guide wire is reassuring. The needle is removed, and ECG tracing is checked to ensure the rhythm is unchanged and the position of the guide wire is confirmed with fluoroscopy.
3. The guide wire is secured, and the skin is incised at the site of cannulation by 0.5 cm. It is good practice to have the full length of the needle under direct view. This is possible when the needle is introduced along the longitudinal plane. However, in some anatomical locations a horizontal plane is more suitable, in such circumstances when the needle is introduced along the horizontal plane it is important to ensure the tip of the needle is always under direct view. It is not possible to have the full length of the needle under direct view when introduced along the horizontal plane and therefore there is a greater risk of piercing the posterior wall of the vein due to difficulty in assessing the tip of the needle. The images seen in horizontal plane can easily led to error in confirming the tip of the needle and therefore the probe must be adjusted regularly to confirm the tip of the needle by identifying the absence of the needle (Fig. 8).
4. The dilator with a peel away sheath is now inserted over the guidewire using a Seldinger technique. When inserting the dilator resistance is felt at the site of cannulation. The dilator is advanced firmly with constant pressure, after a few seconds the resistance gives way and the dilator can be pushed in without any significant resistance. If excess resistance is felt ensure the skin incision is adequate prior to advancing again.
5. Once the dilator is inserted and guide wire secured, a subcutaneous tunnel needs to be formed. Local anaesthetic is infiltrated subcutaneously from the exit site to the entry site (cannulation of vein) with a series of injections. An incision is made at the

marked exit site and the line tunnelled with help of a tunneller (usually a metal rod). The tunneller attached to the catheter is removed via the wound in the neck and the catheter pulled through under the skin. Occasionally some resistance is felt at the clavipectoral fascia. The cuff is pulled through approximately halfway between the clavicle and the marked exit site. The catheter is cut from the tuneller and placed on the chest wall and assessed for positioning and length with the help of fluoroscopy before cutting the catheter to length. If the procedure is not done under fluoroscopy, measurements can be made from the manubrium to predict desired length. If the catheter is placed too far into the right atrium it is easier to withdraw later as long at the cuff is not close (within 3 cm) of the exit site, however if the catheter is too high it cannot be pushed further inwards. Patients with COPD and kyphosis may require further adjustments to the length of the catheter due to their distorted thoracic anatomy. The guide wire and the detachable part of the dilator is removed, and the catheter is then inserted into the vein via the "peel away" sheath. The "peel away" sheath is peeled apart, and catheter tip is positioned with help of fluoroscopy.

In femoral catheter placements the tunnel may be better placed in the outer lateral aspect of thigh as opposed to on the lower abdominal wall.

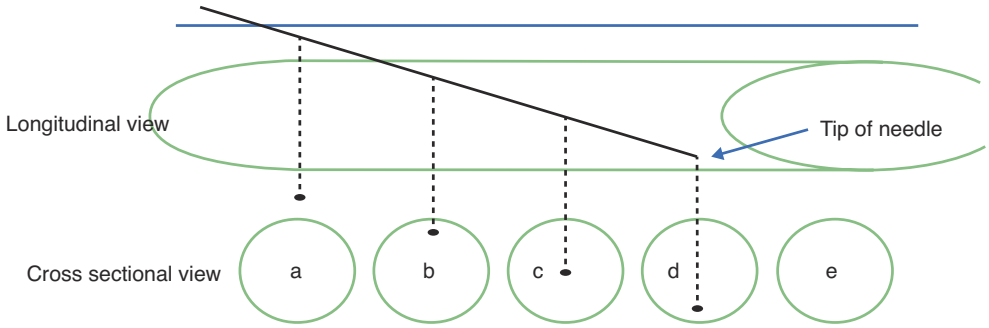

Fig. 7 Diagram to show the different U/S views as the needle is advanced into a large vein. This diagram demonstrates the tip of the needle at points (a) to (e) as the probe is advanced along the vein. The tip of the needle should be confirmed by absence of needle as in point (e)

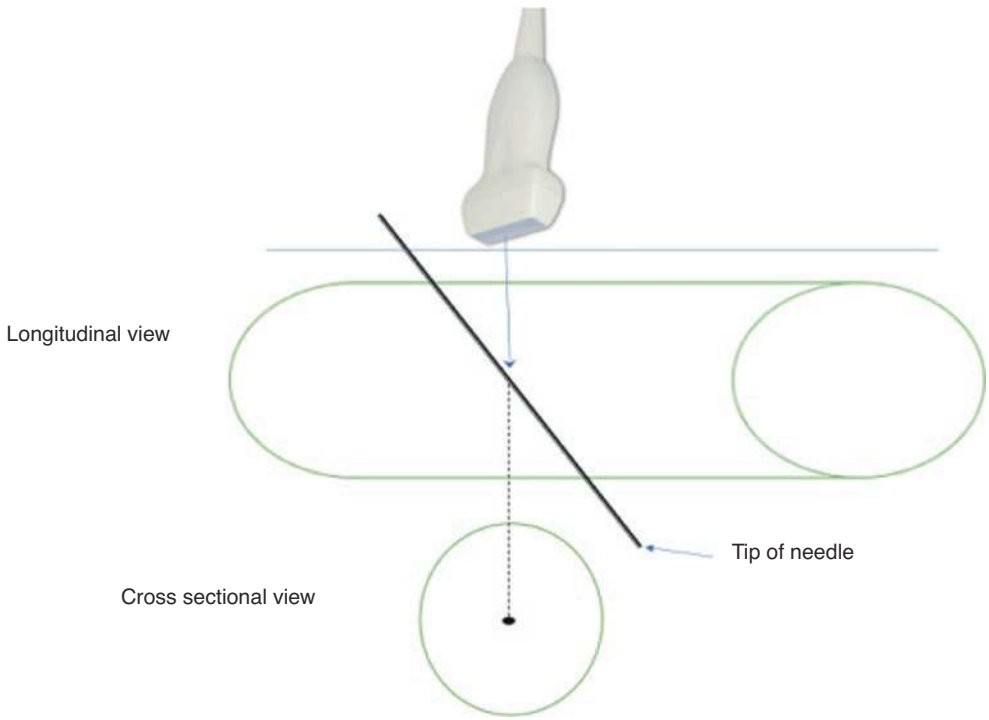

Fig. 8 Diagram to show the tip of the needle which has passed through the vein and is not in position for a guidewire insertion. It demonstrates the limitations of a cross sectional U/S view in which you can see only a small portion of the needle and falsely gives the impression that the tip of the needle is in the centre of the vein

Box 2. Long-term cuffed Subclavian Catheter Placement (*Subclavicular Approach to Large Vein Catheterization without Radiology Often Done at Bedside or in a Dedicated Room)*

The equipment needed is variable but includes a gown, gloves, sterile drapes, needles, syringes, dissecting scissors, scalpel, suturing equipment, cleaning solution, local anaesthetic, a feeding line (Hickman or the smaller Broviac type of line), tunneller, split introducer, Seldinger wire and needle.

1. Patient lies supine, ideally with the head and shoulders positioned lower than the body (some put a small sandbag or rolled pillow between the shoulders). The operator selects the right or left subclavian vein. There is a tendency to choose the right as there is less risk of damaging the thoracic duct and thus of causing a chylothorax. The side furthest away from any abdominal stomas or fistulae is chosen. If the right subclavian vein is selected, the following anatomical landmarks are noted: the tip of the left shoulder, supra sternal notch, the junction of the lateral one-third and middle two-thirds of the right clavicle, the site of the right internal jugular vein and carotid artery.
2. The operator 'scrubs up', puts on a sterile gown and gloves, then checks the equipment on the operating trolley.
3. The operator cleans the chosen site with a chlorhexidine in spirit solution. Sterile drapes are put over the patient's hair and round approximate 30 cm^2 of skin, which leaves all anatomical landmarks visible except the left shoulder tip, which can be felt.
4. Once the skin is dry, a local anaesthetic (lignocaine 1%) is injected intradermally about 1–2 cm below the junction of the lateral one-third and medial two-thirds of the clavicle. An assistant then holds the patient's right hand and pulls gently down towards the patient's feet. The patient turns their head away from the operator and the head of the operating table is lowered. The needle is changed to a longer one, reintroduced and passed under the clavicle, then it is redirected aiming to pass both under the sternal notch and at the left shoulder tip for a distance of about 5 cm. The syringe aspirates every few millimetres before injecting local anaesthetic, usually the subclavian vein will be encountered.
5. The operator may change their gloves, then make a small 1 cm transverse skin incision over the site of the intradermal local anaesthetic injection. Blunt dissection may be done (closed scissors are inserted and opened) to make it easier for the introduction of a splittable introducer. Then the 18 gauge needle from the catheterization pack is connected to a 10–20 ml syringe (some fill this with saline) and advanced in the same way as for the local anaesthetic, with gentle suction being applied from the syringe until there is a good flashback of venous blood into the syringe indicating that the vein has been entered. Holding the needle still, the syringe is removed and the soft end of the guidewire is pushed gently down the needle for a distance of about 30 cm. Hardly any pressure is put on the guidewire. Keeping the guidewire in position, the needle is withdrawn.
6. While the guidewire is left in position and covered lightly with a piece of sterile gauze, the subcutaneous tunnel is made. The tunnel is usually about 15 cm long, the exit site is chosen to be approximately midway between the mid point of the sternum and the nipple position of a man. The exit site should be on a flat area of chest, well away from the moist warm potentially bacteria prone axilla. Skin creases should be avoided. This aids security and comfort by making the catheter easier to anchor, and it reduces the chance of bacterial infection. Local anaesthetic is inserted at the exit site and along the line of the tunnel with 3–4 injections. A small 1 cm vertical incision is made at the exit site. Blunt dissection is performed by opening and closing surgical scissors in the line of the tunnel for a distance of about 7 cm from the exit site. The tunnel is created by pushing, with a rotating action, either a hollow plastic tube into the exit site and up towards the entry site or attaching the feeding catheter to a sharp-ended metal tunnelling rod and pushing this up. Some blunt dissection is usually needed to get the tunnelling instrument out of the entry site. Care should also be taken to maintain a superficial approach so that the Dacron® cuff will easily be felt below the skin. A single pass

may reduce the chances of the patient developing a haematoma, infection or pain.

7. The catheter may be primed with either saline or heparinized saline, reducing the risk of air entering the venous circulation. The catheter is positioned in the tunnel either by putting it into the hollow plastic tunneller or it is pulled behind a metal rod. The dacron cuff is positioned halfway up the tunnel. It must not be at the exit site as cuffs situated adjacent to the exit site readily become infected, which can lead to the loss of the catheter.
8. The tunnelling rod is removed from the catheter, and the length of catheter needed estimated by lying the catheter on the chest wall in the shape of the subclavian vein and SVC (usually about 15–20 cm of catheter will be needed). The catheter is then cut. Care needs to be taken not to contaminate the catheter.
9. The rigid dilator surrounded by the splittable introducer are advanced over the guidewire, checking that the guidewire remains free all the time until the wings of the splittable introducer are close to the patient's skin. The guidewire and rigid introducer are removed leaving the splittable introducer in position. The catheter is then quickly fed through the splittable introducer (forceps may be needed). If the catheter cannot immediately be fed into the splittable introducer the operator may temporarily place their thumb over the splittable introducer to reduce bleeding and prevent air from entering the venous circulation.
10. The working field may be covered and the catheter tip position checked radiologically. However, with experience the operator can achieve a good position. The ideal position for the tip is the SVC/RA junction.
11. If the position is good, the splittable introducer is slowly peeled apart as the catheter is advanced into the vein (non-toothed forceps may be needed to prevent the catheter coming out), until the entire catheter is in place and the sheath has been completely split and removed.
12. Five millilitres of 50 units/ml heparin is instilled into the lumen of the catheter and the line is either capped or connected to a saline infusion.
13. One stitch is put over the insertion and exit site. The long threads from the exit site are tied round the catheter to help prevent it from being pulled out. The entry and exit sites may be sprayed with povidoneiodine. Adhesive sterile gauze dressings are placed over the cannulation and exit sites (Fig. 2). The catheter is curled round or over the dressing and taped to prevent traction.
14. The patient is advised to stay in bed for 2–3 h for the effect of sedation to wear off. A postero-anterior chest radiograph is taken about 3 h after the procedure to check the catheter tip position (Fig. 9) and to warn of a pneumothorax. If the catheter tip position is satisfactory then parenteral nutrition may be started.

Providing the catheter is mechanically stable and not infected, connective tissue will grow into the interstices of the cuff over the following 6 weeks. Sutures are removed after 2–3 weeks, but if the patient is receiving corticosteroids they are left in for at least 5 weeks.

Insertion of non-cuffed short-term feeding line.

If a non-cuffed line is used, the tunnel may be much shorter (5–10 cm). After the subclavian vein has been cannulated, the central needle is withdrawn leaving a plastic sheath in situ, the catheter is fed quickly through this for a measured distance (marks on the catheter usually make this easy). The plastic sheath is removed then the tunnel is made. Local anaesthetic is applied, but no incision made at the exit site. In order to reduce the risk of piercing the catheter with the tunnelling needle, the tunnelling needle without its plastic sheath is pushed from the entry site down the tunnel and out of the exit site. The exit site may need to be enlarged to about 2 mm. About 5 mm of plastic sheath is then pushed gently onto the needle at the exit site. The tunneller needle is gently pulled while the plastic sheath is pushed until the plastic sheath exits from the entry site. The tunneller needle is removed, the catheter is fed down this and the plastic cannula withdrawn. The attachments are put on the end of the feeding line, which is then flushed. A plastic clip, sutured to the skin may be used to hold the line in position.

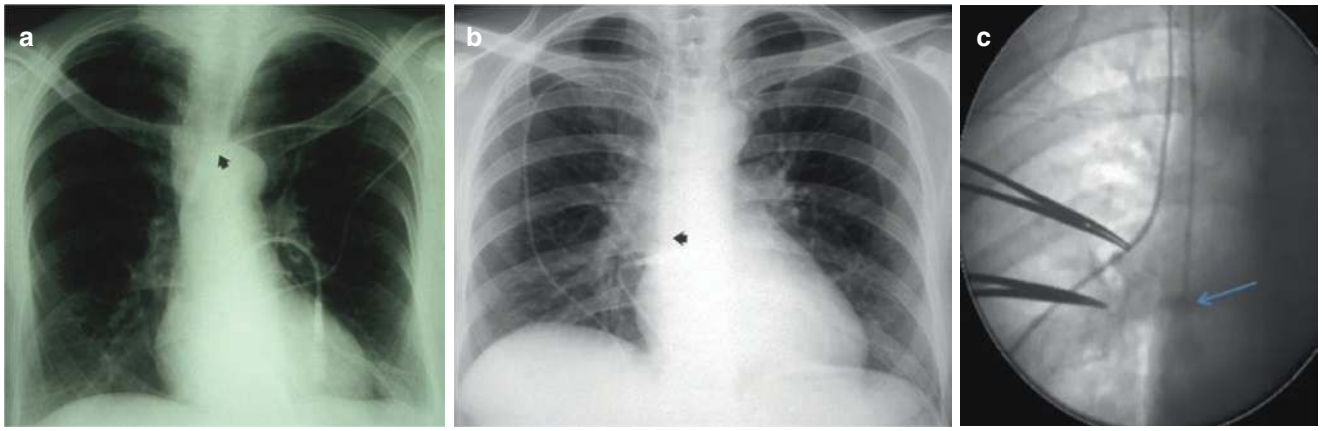

Fig. 9 Chest radiographs after insertion of a central venous catheter. (**a**) Catheter tip (arrowed) too proximal and at high risk of causing a central vein thrombosis. It should be replaced and not used for PN. (**b**) Ideal placement of a central catheter and (**c**) good flow of contrast (arrowed) shown in a well-placed central venous catheter

Box 3. Cephalic Vein Approach to the Subclavian Vein

The cephalic vein lies in the deltopectoral groove and is well placed for surgical insertion of a long-term venous feeding catheter. After injecting local anaesthetic, a 1–3 cm incision is made approximately 1–2 cm below the lateral end of the clavicle. The cephalic vein in the clavipectoral fascia is identified and is controlled by proximal and distal ligatures. A subcutaneous tunnel is created in the same way as described in the percutaneous approach, with the tunnelling rod and catheter exiting at the subclavicular incision. The required length of the catheter is decided and advanced into the cephalic vein via a venotomy made between the proximal and distal ligatures. The tip of the catheter is located at the SVC/RA junction. The ligatures supporting the catheter are tied. The lumen is checked by venous aspiration and flushed with heparinized saline. The clavicular incision is sutured with a subcutaneous catgut suture first, then finally with 2–3 silk skin sutures, which are left in for approximately a week. The exit site of the catheter is secured using the same method as the percutaneous approach.

Box 4. Implantable Port Insertion

After the procedure in Box 1 has been done the procedure to place a subcutaneous port begins. A subcutaneous pocket in made by dissecting a subcutaneous space over the chest wall at the marked site. After the catheter is inserted, tunelled and the position confirmed the port is connected the end of catheter and inserted into a subcutaneous pocket. The port may be anchored in the subcutaneous space with an absorbable suture. Immediately after a port has been placed, an access needle is placed in the port and heparin is locked into it. This is done because swelling and inflammation will make access to the port very difficult for the next week. It is especially important to do this if the port is not going to be used within the next 4 days. When the noncoring needle is in place it must be secured safely and comfortably in place with a sterile gauze dressing.

Unable to Advance Guide Wire

Occasionally there is difficulty in advancing the guidewire after the wire has been inserted into a vein. The tip of the wire may remain at the confluence of brachiochephalics. Manipulation of the wire under fluoroscopy helps to place it in the RA however if the wire does not fall in place with ease there should be a high index of suspicion of an occlusion or stenosis. Ideally an on-table venogram will help reassess the anatomy and so make insertion easier. However if this is not possible further attempts may be made after a detailed assessment of venous anatomy with CT or MR imaging. It is not safe to advance a dilator if the guide wire has not passed into the distal RA.

Venous anatomy on the right side often lies in straight line to RA and therefore placement is less complicated. Left sided catheter placements may require some manipulation of the catheter particularly at the confluence of right and left brachiochephalic veins when the catheter tends to flip upwards into the right brachiocephalic vein. The thoracic duct is on the left side and can be damaged during jugular/subclavian puncture. The left common iliac veins are often anatomically placed at a steep angle to IVC and hence it is easier to use the right side.

Securing the Catheter (Excluding Implantable Port)

The catheter is secured with a 2′0 prolene stitch at the exit site. The sutures at the exit site are kept in place for about 6 weeks to allow the dacron cuff to completely embed in soft tissues. Some of the catheters come with a fixation device, however when they are used it becomes difficult to clean around the exit site. This ensures that the catheter does not get displaced when used regularly. The entry site the neck is closed with absorbable sutures.

After Catheter Insertion

The position of the tip of the central vein catheter is crucial in preventing thrombophlebitis leading to endothelial injury and a SVC thrombosis. This thrombosis may also be promoted by a low pH and/or high osmolality PS infusion. Therefore the tip should be ideally placed at vena cava-atrial junction [44, 45]. This can be confirmed either by fluoroscopy at the time of placement of catheter or by CXR after the catheter is placed. It is worth noting that in women if the catheter cuff is placed close to breast tissue, the tip of catheter is different when they are supine compared to that seen on an erect CXR. This is due to the movement of the cuff which is anchored to the soft tissue of the breast.

Complications of Large Vein Cannulation

Arterial puncture and pneumothorax were common prior to use of ultrasound in venous access practice. Insertion-related complications are reported in 3–12% patients [46] (Table 3) and are less if they are inserted by a nutrition team [47].

Counter Puncture

The venous wall may have resistance and not give way when advancing the needle under US guidance resulting in indenting the anterior wall of the vein and approximating on to the posterior wall, predisposing to risk of counter puncture. The risk can be avoided by applying constant gentle pressure with the needle for some time to allow the needle to pass through the anterior wall of the vein. The root of the neck has a neuro vascular bundle as well as the apex of the lung present. Occasionally the subclavian artery lies posterior to IJV at the root of neck and can be injured by counter puncture without any immediate signs of bleeding. If the US guiding probe is pressed too hard on the neck, the veins may be collapsed making cannulation difficult.

Venous Wall Tear

The risk of tearing the venous wall is substantial if excessive force is used with dialator, furthermore “twisting movement along with excessive force” may lead to a spiral tear of the vein which is difficult to repair [48]. To prevent this complication when introducing the dilator, a firm pressure should be applied.

Malposition

When using a subclavian approach, the catheter can pass up into the jugular vein, a clue to this is that the patient may complain of a pain in their ear when the guidewire is

Table 3 Insertion-related complications of central vein catheterization

• Counter puncture
• Venous wall tear
• Malposition (cardiac arrhythmia’s or perforation)
• Arterial puncture (haemothorax or haemomediastinum)
• Pneumothorax
• Air or catheter embolism
• Nerve injuries (brachial plexus, phrenic or recurrent laryngeal nerve)
• Thoracic duct damage

inserted. If the procedure is done under fluoroscopy the guide wire can be positioned correctly. The catheter can advance into the ventricle or pass into the opposite subclavian vein. The catheter can be redirected using radiological guidance or it may (especially if cuffed) need to be replaced. Rarely the guidewire can induce cardiac arrhythmias, if so it is withdrawn, or cardiac perforation and tamponade have been described. Rarely a catheter can be malpositioned in the pleural cavity or mediastinum and this will cause a pleural or pericardial effusion respectively when the feeding is started.

Artery Puncture

There should be a high index of suspicion of arterial puncture if blood appears bright red when passing the guidewire in to vein. This may be misleading if patient is having a general anaesthetic. Arterial punctures may occur if the needle has gone through the posterior wall of the vein. If so, the needle is removed, and firm pressure applied for 5 min. If the carotid or subclavian artery is injured and the patient's coagulation status is normal, another attempt can be made on the same side. After passing the guidewire repeat assessment with ultrasound to confirm placement of wire in the vein will help decrease the risk of arterial injury with the dilator. Blood can collect in the pleural space (haemothorax) or mediastinum (haemomediastinum) following subclavian arterial puncture. If haemothorax is moderate a wide bore surgical chest drain should be inserted to drain blood from the pleural cavity.

Injury to the common femoral artery is managed by applying direct pressure over it. Rarely the injury leads to retroperitoneal haematoma.

The catheter entry site is observed for signs of bleeding after catheter insertion and blood pressure is monitored. If bleeding occurs, a pressure dressing is applied over the exit site and coagulation studies may be performed.

Haematoma

The needle may be dislodged if the guidewire cannot be inserted in to vein after an initial flash back. To avoid a haematoma and allow a second attempt on the same side it is better to pull the needle out and apply pressure for 5 min.

Pneumothorax

If air is aspirated during cannulation of the subclavian vein (or less commonly the jugular vein), a pneumothorax is likely to develop. This is often not apparent until several hours after the procedure when the patient complains of pleuritic chest pain and breathlessness; a physical examination reveals tachypnoea, tachycardia, a hyperresonant lung with reduced breath sounds. An immediate post-insertion chest radiograph may have been normal; hence one is usually done about 3 h after insertion if there is concern of pneumothorax. A small pneumothorax may be asymptomatic and can be left alone, larger ones can be aspirated and only rarely is a formal chest drain insertion needed [49].

Air/Catheter Embolism

The risk of air embolism is higher in cannulation of supracardiac veins due to change thoracic pressure during breathing. Care is taken to ensure a closed system is always maintained during the procedure, furthermore patient is positioned tilted head down to decrease the risk of air embolism. If an air embolism is ever suspected (e.g. if the catheter suddenly becomes detached) the catheter is clamped as near to the skin as possible and the patient is positioned on their left side with their head tilted downwards. Rarely part of the catheter can break away and pass as an embolus which may get dislodged in lungs depending on the size of the fragment. An attempt should be made to retrieve large fragments wedged in Right atrium with help of interventional radiology. Small fragments that embolise to the lungs can be left alone but if an abscess develops may have to be surgically removed.

Nerve Injuries

If the introduction needle hits the brachial plexus, numbness and tingling can develop in the arm and/or specific muscles can become weak. The exact pattern of weakness depends upon which part of the brachial plexus has been damaged. A neuropraxia can follow and may take several months to resolve. Rarely the phrenic nerve is damaged resulting in diaphragmatic paralysis; the recurrent laryngeal or vagus nerves can also be damaged causing hoarseness.

Thoracic Duct Damage

This can occur from left subclavian vein cannulation and rarely causes a chylothorax.

Peripherally Inserted Central Catheter (PICC) Insertion

As nutrient infusions into small or medium-sized veins are associated with a high risk of thrombophlebitis, it is preferable to site the tip of feeding lines in a large vein. This was first reported in 1975 [50] and can be done using a long catheter inserted into a medium-sized vein. A PICC is made of radio-opaque silicone rubber or polyurethane-hydromer and comes with a single (4Fr) or dual lumen (5Fr). PICCs are inserted into

the basilic, median cubital or cephalic veins in the ante-cubital fossa and the tip of the PICC terminates at the SVC/RA junction. Their insertion can be done at the patient's bedside by a trained nurse [51]. or at interventional radiology if there are concerns of previous thrombosis or abnormal anatomy related to deformities such as severe kyphoscoliosis. The common sites for PICC are the upper limb basilic veins. In common with large vein catheters they may be open ended or have Groshung valve incorporated into the tip. Often PICC's are used at the initial setting of abdominal catastrophe or medium term (type II IF) whilst the patient recovers and stabilised for parenteral nutrition support. Basilic vein often has a good calibre and runs medially away from the neurovascular bundle, however there are variations in anatomy such as small basilic vein with most of the venous drainage via accompanying veins of brachial artery. In some cases, if patients do have upper limb thrombosis, saphenous vein may be considered along with anticoagulation and expert nursing care as access in these circumstances is high risk. Some PICC's are compatible with administration of IV contrast for CT imaging which may be a consideration if access is difficult. As PICCs are placed by cannulating a peripheral vein, they are easier to insert, associated with fewer insertion complications than centrally placed lines [52].

PICCs remain less ideal for long-term parenteral feeding due to the risk of dislodgement of the catheter as there is usually no cuff to anchor the catheter to the soft tissues. The exit site position on the arm restricts normal arm movement making daily living activities difficult and sometimes challenging for the patient if they are doing the procedures themselves.

Box 5. Insertion Procedure for a PICC

The equipment needed includes a gown, gloves, sterile drapes, cleaning solution, local anaesthetic, PICC line, securing mechanism (Securecath®, Steri-strips® and Stat-lock®) and a plastic dressing (e.g. Opsite IV 3000®), Ultrasound and micro puncture kit. The choice of number of lumens is determined by the frequency and type of therapy the patient requires, however it is considered best practice to a use single lumen if the access is required only for administration of PS [53–55]. A tourniquet is applied to distend the veins.

1. The area of insertion is assessed with ultrasound (if available) for a suitable vein before the operator scrubs. The site should be sufficiently above the bend of elbow or 2–3 cm below to prevent kinking of catheter when bending the elbow.
2. The operator 'scrubs up' and puts on sterile gown and gloves.
3. Using strict aseptic technique the skin is prepared with chlorhexidine in spirit.
4. The required length of PICC line is measured pre-insertion in anticipation of the final tip location.
5. An ultrasound may be used to aid cannulation of the basilic vein in the mid arm (similarly to the technique for cannulation of large veins) with a micro-puncture needle (21Gauge).
6. If cannulation was unsuccessful it is important to remove the needle and apply pressure for 5 min to prevent a haematoma and also allowing a second attempt. If there is a haematoma around the vein it is better to abandon the procedure and attempt again a few days later.
7. Once cannulation is confirmed with free flow of venous blood a micro wire is inserted whilst the needle is held steady. The needle is removed over the wire. When PICC is inserted at bed side it is important to ensure the wire is advanced freely to have the assurance that the catheter can be advanced. Inability to advance wire freely should raise concerns about abnormal venous anatomy or thrombosis therefore further attempts should be done only after assessment of venous anatomy and possibly in interventional radiology.
8. A 4 or 4.5 Fr dilator is passed over the guide wire and the catheter is placed through a peel away sheath.
9. If there are good dilated veins, venous cannulation may be achieved with help of 14g needle and catheter inserted, however this is suitable only for those catheters where the hub may be attached after placement of the catheter such as the Groshung valved catheters.
10. In advancing the catheter at the junction of subclavian and jugulars, there is tendency for the catheter tip to follow cranially into IJV. To prevent this, the arm is often abducted and the patient is asked to turn their head towards the operator and to flex head with chin touching clavicle. Alternatively, you may ask another person to press on jugular vein whilst advancing catheter.
11. Lubricating the line with sterile normal saline may help insertion. The PICC line (Fig. 10a) is then gradually advanced until the measured point. It is preferable to insert the catheter slightly longer than the estimated length as the catheter cannot be advanced further at later time if the site of the tip is unsatisfactory when the sterile felid is lost, but it can be easily pulled back in to the correct position.
12. The catheter is secured (e.g. Secure-cath®, with Steri-strips® and a Stat-lock® dressing). A small gauze square or release dressing is placed over the entry site, then a plastic dressing (e.g. Opsite IV

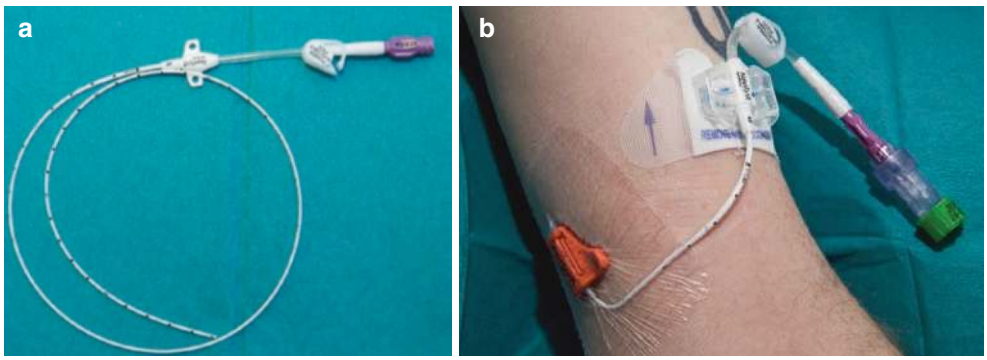

Fig. 10 (**a**) PICC catheter and (**b**) its dressing in the cubital fossa after insertion

3000®) is applied over the exit site for security, a light bandage (or Tubigrip®) is applied again for security and comfort (Fig. 10b)

13. A chest X-ray is taken to ascertain the position of the catheter tip.
14. If the catheter tip is displaced in IJV, a jet flush of 10 ml saline often helps the catheter to fall in place. The catheter may also align itself in SVC over 24 h. If conservative measures fail the catheter may be rewired at bedside again or with help of interventional radiology. It is important to note that the catheter must not be used when it is not placed correctly.

Small-Vein Nutrition

After the introduction of Intralipid® allowed feeding solutions to become less hyperosmolar, it again became possible to consider parenteral nutrition through a small vein [56]. Small-vein parenteral nutrition is administered through a short plastic cannula inserted into the small veins on the forearm, on the back of the hand, or on the scalp of babies. The limiting feature of this type of parenteral feeding is the high incidence of thrombophlebitis which means that a cannula does not often remain patent for more than 3 days [57–60]. It is recommended that a cannula used for feeding in a small vein is re-sited every 1–2 days. This type of feeding is rarely used now that PICCs can be relatively easily inserted.

Managing Access with Complications

Catheter Related Blood Stream Infections (CRBSI)

If catheter is infected and decision is made to remove the catheter, the insertion of a new catheter should take place only after adequate treatment of infection to avoid seeding of infection to the new catheter [61]. It is preferable for patient to be apyrexial for a 2–10 days and any possible metastatic infection treated prior to insertion of a new tunnelled catheter [62]. The interval between removal of catheter and insertion new has been variable in asymptomatic patients, usually the duration is 48 h between the removal of old catheter and insertion of new catheter, however there is very little evidence to support this practice. Negative blood culture is often considered to ensure the infection has been treated particularly with fungus or staphylococcus aureus CRBSI. Rewiring of an infected catheter is often not successful [43], however in extreme cases where the access is very poor, antibiotics is delivered through the infected catheter and later changed over a guide wire with further delivery of antibiotics via the new catheter.

Exit Site Infection

Failed salvage of exit site infection [43] will require a new catheter with a new tunnel away from the old tunnel. Sometimes the opposite site has to be considered due to extent of inflammation or type of organism (pseudomonas) affecting the exit site.

Occluded and Fractured Catheter (Rewiring)

Prior to any intervention with catheter it is important to assess for possible CRBSI. If there is any suggestion of CRBSI it is safer to remove the catheter and insert a new catheter in keeping with CRBSI management. Occlusion of a catheter is not uncommon and often managed with lock solutions; but if unsuccessful a new catheter is inserted. A fracture of the catheter may occur at the exposed part of catheter and is often managed with a repair. Both scenarios can be managed by rewiring a new catheter over a guidewire.

For a short term uncuffed catheter the catheter is dissected at the point of insertion and looped out. The proximal end is secured to prevent dislodgement in to the vein and cut. The old catheter is removed over guide wire and a dilator inserted.

Occasionally there may be scaring at the site of insertion which will prevent advancing the dilator, this should be suspected if there is resistance when the old catheter is pulled out. A new catheter is placed subcutaneously with a new tunnel as described earlier and the catheter inserted. For a cuffed catheter an incision is made over the cuff or at the point of insertion to release the catheter from the soft tissue. The catheter is cut after securing it with a Halstead mosquito clip. A guide wire is inserted, and the old catheter removed over the guide wire. Cannulating with an 18G venflon® into the catheter and flushing may help if the guide wire cannot be passed through the catheter.

In both these scenarios the tip of the old catheter should be sent for culture and sensitivity to determine if there is an infection and thus will help in guidance of antibiotics if patient becomes unwell in the near future.

Thrombosis

In patients with long-term (type III) IF the objective is to maintain access and prevent further loss of venous access from thrombosis (chapter "Central Vein Thrombosis"). The strategy adopted varies depending on the clinical presentation and extend of thrombus.

Acute Thrombosis

In acute thrombosis the patient should be anticoagulated with LMWH injections and will require urgent CT or MR venogram to assess the extent of thrombosis. If the thrombus extents beyond the tip of the catheter; the catheter cannot be used for parenteral nutrition or infusion of crystalloids. However, the catheter may be used as an access for thrombolytic therapy after discussion with a vascular radiologist. If there is a significant stenosis in SVC or large veins contributing to thrombosis, angioplasty may be required prior to insertion of a new catheter ensuring the tip of the catheter is distal to stenosis [63] (chapter "Central Vein Thrombosis").

If the thrombus is proximal to the tip of the catheter and not causing any significant life or limb threatening symptoms the catheter may be used after a 2–5 days of anticoagulation. It is best practice to take blood for a thrombophilia screen prior to anticoagulation. In continuing to use the catheter the access is maintained, and the other veins are preserved for use in the future.

Chronic Thrombosis

Patients with established thrombosis around the catheter may require the catheter to be changed for non-infective mechanical problems (fracture or occlusion). It is preferable to change the catheter over a guidewire to maintain access if possible; however, it is useful to review venous anatomy with a recent venogram prior to placement of new catheter.

Other Considerations

Pacing Wires

Pacing wires are usually placed in left subclavian. It is safer to place tunnelled catheters or PICC under fluoroscopy to avoid any potential dislodgement. Furthermore, the right side is preferable to decrease the number of devices in left brachiocephalic. The tip of the catheter is placed in proximal SVC as a compromise. Infection can cross from an infected PS catheter to a pacing wire. It may be less likely to occur when a fibrin sheath fully covers both the pacing and PS catheters.

Haemodialysis

Patients requiring renal replacement therapy require preservation of venous access for dialysis or venous anastomosis of graft kidney to iliac veins. Insertion of tunnelled catheter is preferred to the contralateral side of AV fistula, usually AV fistula is on the left side and therefore tunnelled catheter on Right IJV would be the safest option. PICC is best avoided to prevent any thrombosis which may compromise life span of AV fistula.

Chemotherapy and PN

Oncology patients receiving PN as well as chemotherapy will require two separate lumens for infusion one for PN and one for chemotherapy due to concerns about compatibility of the oncology medication with PN. This may be delivered with two separate devices or a dual lumen device. The risk has to be balanced between thrombosis due two simultaneous devices versus the risk of CRBSI due to dual lumens even though one may not be used in the long-term. The choice is determined by the probable duration of PN as well as the number of chemotherapy sessions anticipated.

Removal of a Feeding Catheter

Prior to removal of any vascular access device it is important to have information about catheter insertions, complications especially CRBSI and venous thrombosis. The clinician must also be aware if a patient is anticoagulated or on anti-platelet medication. Management of anticoagulation around the procedure will vary depending on the indication for anticoagulation as well as indication for removal of a vascular access device. These procedures are performed under local anaesthetic. Implantable ports should be removed in a setting where surgical dissection can be done with adequate support usually

in a surgical theatre setting. Tunnelled catheters may be removed in a procedure room by an experienced operator with adequate emergency support. A PICC can be removed at the bedside, the length of the line removed should be recorded and the catheter tip should be sent for culture and sensitivity.

Box 6. Tunnelled Catheter Removal

Tunnelled catheters have a cuff that would have embedded to soft tissue under the skin. Removal of the cuff is essential in removing the catheter completely. The cuff may not be placed near the exit site however should be palpable along the line. In some patients the cuff may be difficult to palpate due to subcutaneous fat if they are nutritionally replete particularly if the catheter were placed at time of severe malnourished state. A 1–2 cm transverse incision is made at the superior aspect of the cuff. The soft tissue is separated with blunt dissection down to the line and cuff. The catheter is grasped with a pair of forceps and the fibrous sheath "usually off white" around the catheter formed during the time the catheter has remained in situ is defined. A careful longitudinal linear incision is made along the catheter to avoid transection of catheter and this will remove the fibrous sheath and reveal the white of the catheter. The catheter should be grasped with help of Halstead mosquito forceps between the sleeves of the fibrous sheath and pulled with gentle traction (Fig. 11). This should enable the catheter to be pulled out of the vein completely. The tip of the catheter should have a clean-cut edge suggesting the catheter has not fractured. The length of the catheter as well as comparison with a previous CXR also helps in assessing if the catheter was removed without fragmenting. Occasionally the catheter feels adherent on traction with no movement if they have been in situ for a few years. This is often due to scarring of the venous wall at the site of insertion and requires continued gentle traction for few minutes without fracturing the catheter. Rarely if the catheter is firmly adherent, despite a few minutes traction, another incision is required at the site of entry to dissect down to the vein. This may require input from the vascular services. Once the line is removed from the vein the cuff can be dissected away from the soft tissue with a combination of blunt and sharp dissection. Haemostasis is often achieved by applying firm pressure for a few minutes. Closure of the skin is done with an absorbable suture (e.g. 3′0 vicryl); once satisfactory haemostasis is achieved however in cases of an infected tunnel the wound should be packed to allow for adequate drainage of infection. It is prudent to send the tip of the catheter for culture and sensitivity so as to provide microbiological guidance should patient become febrile/unwell.

On rare occasions when removal of catheter is unsuccessful, and patient requires transfer, it is best to ligate and fix the catheter to soft tissue at the site of dissection.

When tunnelled femoral catheters are removed it is prudent to ensure post procedure, patient remains on bed rest for 4 h to check for delayed bleeding from the sheath or at the site of dissection.

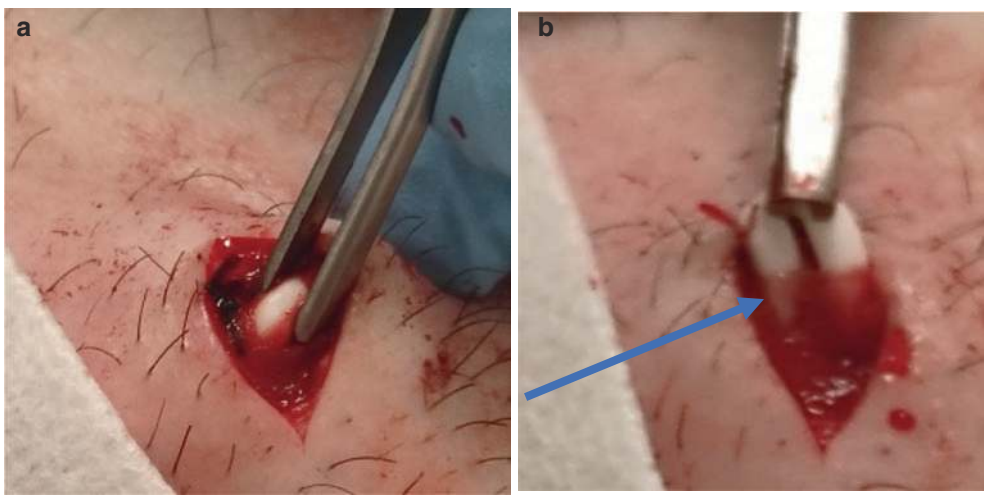

Fig. 11 (**a**) Catheter identified after incising the sheath around the catheter just above the cuff, (**b**) arrow shows the sheath as the catheter is being removed

Box 7. Removal of an Implanted Port

Port-A-Cath can be removed under local anaesthetic however dissection required in releasing the port is more extensive. Some patients who are restless or combative have required sedation with help of anaesthetic support. Incision is made over the previous incision often at the junction of catheter and port. The fibrous sheath is incised, and the catheter removed like that of the tunnelled catheters. The port may be anchored to soft tissues at four corners from the base of the port to soft tissue with non-absorbable suture. The fibrous capsule around the port is incised followed by traction on the port. The sutures if present are cut whilst the port is on traction to remove the port completely. There is a capsule firmly adherent to soft tissue pocket which may be left in situ if there is no evidence of infection. Removal of the capsule may be considered if the pocket appears infected and it may be necessary to consider packing the wound to allow drainage of infection.

Fig. 12 An arteriovenous fistula in the right cubital fossa

Arteriovenous Fistulae for Venous Access in HPN Patients

While CVCs or implantable ports are standard for long-term parenteral nutrition administration, a surgically created arteriovenous fistula (AVF) was the only available type of venous access at the inception of this treatment in the late 1960s. Upon the introduction of intravenous catheters in the 1970s AVFs became rare, also because of their high complication rate that was associated with the use of xenologous (bovine) or prosthetic (polytetrafluoroethylene-like) graft materials leading to shunt occlusion and thrombosis [64].

From the start of the HPN program in Nijmegen (Netherlands) in 1969, besides CVCs there has been a continued use of AVFs in patients with a high CVC infection rate. In 1983, a series of 7 patients using AVFs was reported [64]. Later, the group described their oldest patient who has currently remained well on HPN with an AVF for more than 45 years [65].

The notion that AVFs may still be a valuable alternative to CVCs was corroborated in a retrospective analysis of 127 HPN patients, comprising 194 AVF access years [66]. Bloodstream infections (BSI) were extremely rare (0.03/year) for AVFs compared to tunneled CVCs (1.37/year), although occlusion was more frequent (0.6 versus 0.35/year). Of note later taurolidine locks (not feasible in AVFs) were started which brought the CRBSI rate down to 0.6/year [67].

Currently the first choice for an AVF is the autogenous radiocephalic shunt on the fore-arm (Fig. 12), or less ideally, in the lower extremity. When the quality of these peripheral vessels is insufficient, more proximal fistulae such as the brachiocephalic or brachio-basilic AVF are considered at the elbow and upper-arm region. In case these options fail, graft implants may be used as a vascular conduit to construct an AVF, whenever possible with the use of an autologous transposed vein, most commonly the great saphenous vein (GSV). Such graft AVFs may also be created on the thoracic wall.

For reasons outlined above, the use of prosthetic materials such as PTFE to create AVFs for the purpose of HPN [68] is avoided. Importantly, following their creation it usually takes a maturation period of around 6 weeks before AVFs are available for (self)-puncturing by the patient or caregiver. For follow up and surveillance patients are provided with a stethoscope to detect changes in the pitch of the murmur and loss of thrill over the AVF at an early stage that might indicate stenosis, mostly at the level of the anastomosis. In this case, balloon dilation of the stenosis by the interventional radiologist usually can solve the problem. Also for this reason, regular check-ups (usually at 6-month intervals) with evaluation through ultrasound of the shunt flow to detect such abnormalities are required, and also to rule out severely increased shunt blood flow (which may become more than 3 l/min) that might lead to cardiac failure.

Thus AVFs may be a valuable alternative to other modalities to provide HPN as long as the expertise to adequately address any of the associated complications is available.

Formulation of Parenteral Nutrition Regimens

Gil Hardy and Michael Charles Allwood

Key Points

1. All parenteral nutrition (PN) compounding must be performed under strict aseptic conditions and under pharmacy control.
2. Multiple chamber bags (MCBs) have the lipid, carbohydrate and protein components physically separated, have long shelf lives (e.g. 1 year) and do not need refrigeration, before mixing, by rolling the bag just before the infusion begins.
3. MCBs can be triple chamber "All-in-One" (AIO), or double chamber "2 in 1" without intravenous lipid emulsion (ILE),
4. MCBs do not contain trace elements or vitamins which must be added aseptically or administered separately.
5. 'Bespoke' or 'tailored' PN bags can be compounded up to 2–3 weeks before administration but generally have all the necessary vitamins and trace elements included.
6. The shelf life of bespoke bags and MCB after mixing under aseptic conditions can be up to 21 days.
7. Interactions between PN components arise from physico-chemical incompatibility and/or chemical degradation that can lead to precipitation, loss of nutritional or pharmacological efficacy, and possible toxicity due to hazardous degradation products. The greatest risk of precipitation is from the formation of insoluble calcium phosphate salts.
8. The most significant limitations on stability of complete AIO PN regimens are high cation concentrations and poor control of air content and air ingress into PN mixtures during compounding and storage. The use of air impermeable bags is essential.
9. There is a loss of vitamins and other nutrients from PN mixtures after compounding due to chemical degradation (e.g. ascorbic acid and thiamine), adsorption onto the surface of the infusion bag or administration sets (e.g. vitamin A and E), and by light catalysed photodegradation. Consequently, exposure to direct sunlight must be avoided.
10. All PN systems, i.e. bags, and ideally the giving set, should have a light protective covering and an in-line 1.2 μm filter. Administration should be well away from a sunny window or at night.

Introduction

Since the first edition of this textbook, the major international professional societies, ASPEN (American Society for Parenteral and Enteral Nutrition) and ESPEN (European Society of Enteral and Parenteral Nutrition (European Society of Clinical Nutrition and Metabolism)) have published important clinical practice guidelines for parenteral nutrition (PN) prescribing, preparation and administration [1–3]. AuSPEN (Australasian Society for Parenteral and Enteral Nutrition), European Society for Paediatric Gastroenterology Hepatology and Nutrition (ESPGHAN), ESPEN and ASPEN have produced clinical guidelines for trace elements and vitamins [4–8], and international expert consensus recommendations for micronutrients in adult and paediatric PN have been recently published [9, 10]. Additionally, the United Kingdom NHS Pharmaceutical Quality Control Committee has published protocols for assessing PN stability [11]. Where appropriate, the recommendations of these expert bodies will be incorporated into this chapter.

PN-is a complex prescription therapy that is indicated in a wide spectrum of clinical situations, from surgical and intensive care unit (ICU) patients, who may require short term nutritional support (for a few days/weeks), to patients relying on long-term PN for survival because of severe impairment in gastrointestinal (GI) function. A PN regimen typically includes 40–50 components, including; amino acids, glucose and lipids, multivitamins and trace elements.

J. M.D. Nightingale (ed.), *Intestinal Failure*, https://doi.org/10.1007/978-3-031-22265-8_35

In the past PN has been associated with significant adverse effects when the therapy is used inappropriately. Safe prescribing and use is an essential component of PN therapy that requires a thorough knowledge of indications, requirements for protein and energy, macro and micro-nutrients, fluid homeostasis and acid-base balance, together with basics of sterility and infection control and associated complications. PN is administered with increasing frequency at home (HPN) or in long-term care facilities. Regardless of the setting or the number of patients receiving the therapy, classification of PN as a high-alert medication requires healthcare institutions to develop evidence-based policies and procedures to promote safe administration, and to validate the competency of those responsible for preparation and administration of this complex intravenous therapy [1]. In depth education on PN should be included as a standard component of acute care and home care training. This applies equally to all health professionals caring for PN patients and clear communications are essential.

This chapter outlines the components of a PN regimen, reviews reasons for their choice and clinical requirements, summarises the recommendations from recent guidelines and expert groups, for safely preparing and administering PN, and reviews key features relating to the stability and compatibility of PN admixtures.

Components of a PN Solution

When PN first became a treatment option in the 1960s (then often called 'hyperalimentation') [12], all components were separately administered from bottles of high strength glucose, protein hydrolysates or amino acids, with or without intravenous lipid emulsion (ILE). To some of these macronutrient containers, electrolytes and micronutrients were added by ward staff. Infusion systems comprised multiple lines with two-or three-way taps, connected to the central venous access device (CVAD). The risk of the line becoming infected was high due to contamination from changing infusion containers and handling the administration lines. Extrinsic contamination was later found to be significantly reduced if PN admixtures were compounded under strict aseptic pharmaceutical conditions. Subsequently, the single 'Big Bag' and all-in-one (AIO) systems for PN were developed and introduced in the late 1970s [13, 14].

As the clinical benefits of the AIO system were increasingly recognized by clinicians, the demand for more nutritionally complete mixtures and bags with shelf-lives greater than 24 h produced new challenges for pharmacists, who needed to ensure the stability and compatibility of these complex admixtures. This means that careful formulation and strict mixing protocols must be followed during compounding. Pharmacy-operated compounding services, either by commercial companies or hospital-based, are now common and have made a major impact on reducing infection risks in patients receiving PN. Most adult patients can be supported nutritionally with a range of standardized regimens.

Protein

Currently available solutions supply all the traditionally termed 'essential' and 'non-essential' L-amino acids. Some paediatric amino acid preparations contain the aminosulfonic acid, taurine, to alleviate taurine deficiency. However, the 'conditionally essential' amino acids; glutamine and cysteine are not usually included because of solubility and/or potential stability problems. Dipeptide additive solutions are available as a vehicle for less soluble heat-labile amino acids, e.g. glycyl-L-glutamine dipeptide, N(2)-L-alanyl-L-glutamine dipeptide and glycyl-L-tyrosine. These are chemically and heat stable but are hydrolysed to free glutamine, glycine, alanine or tyrosine in plasma and tissues [15].

Amino acid solutions are available in concentrations ranging from 5% to 15% with or without some electrolytes. High strength solutions with Nitrogen contents up to 30 g/L allow more concentrated formulations to be compounded when administration volume is important. Around the world protein may be prescribed as either g. protein equivalent/g. amino acids or g. Nitrogen [16].This may be confusing for some health professionals and it is now time for some international agreement on a standard terminology. In the meantime, the most common method of determining PN efficacy is to measure nitrogen balance. A factor of 6.23 can then be used to convert Nitrogen to protein/amino acids.

Energy

There is no longer debate as to which is the best energy source. It is generally recognised that glucose, lipids and amino acids are essential energy substrates but may play different roles in certain clinical situation for optimizing the efficiency of energy utilization and minimizing metabolic complications. Providing the administered substrate is adequately utilized, there is no difference in the efficacy of glucose or lipids with regards to protein sparing. Most centres use an admixture of glucose, amino acids and an ILE for AIO PN, but some still advocate the separate infusion of ILE administered weekly to provide essential fatty acids (EFA).

It is conventional, though illogical, to describe the energy given in PN as "non-protein energy" and the protein/amino acid energy is not usually stated, in contrast to enteral nutrition (EN) where the total energy content of a feed is indi-

cated. However, it must be remembered that amino acids are metabolically important energy substrates for cells of the immune system and should be included in total energy calculations. Moreover, Nitrogen itself is NOT a source of energy, thus the terms 'non-nitrogen calories or energy' are incorrect and should not be used.

Carbohydrate

Glucose is the carbohydrate of choice for PN and is available in concentrations ranging from 5–70% w/v, sometimes in combination with electrolytes. Alternative carbohydrate sources do not offer any advantages over glucose. The energy value of anhydrous glucose is approximately 4 kcal/g. When glucose monohydrate is used (as in USA) then a figure of 3.4 kcal/g is used.

Advantages

- Inexpensive and readily available
- Effectively metabolized in the presence of insulin
- Stimulates insulin release so encouraging nitrogen retention in muscles.

Disadvantages

- Concentrated solutions are hypertonic so preventing peripheral infusion
- Hyperglycaemia and glycosuria may occur
- Essential fatty acid deficiency can occur if used as the only energy source.

Lipid

ILE have low osmolality and allow large amounts of energy to be administered in a relatively small volume. Historically, ILE consisted of soya bean oil (SO) long-chain triglycerides (LCT) with chain lengths of 16–20 carbon atoms. These products have been used safely and with good clinical acceptance for over 50 years. More recently concerns have been expressed about the immunosuppressive pro-inflammatory effects of high doses of LCT and the adverse effects of phytosterols, present as impurities in SO. Newer ILE, were developed towards the end of the twentieth century, formulated from coconut oil (CO) or olive oil (OO) and/or fish oil (FO). Medium chain triglycerides (MCT) with chain lengths of 6–10 carbon atoms from CO are metabolised via a carnitine-independent fatty acid transport system [17]. Mono-unsaturated fatty acids (MUFA) with 9 carbon atoms, derived from OO are less immunosuppressive than LCT. and FO ILE contain anti-inflammatory long chain omega-3 poly unsaturated fatty acids (PUFA). Clinical experiences with the newer generation ILE provide evidence that the role of lipids extends beyond that of energy substrates. Lipids may influence prostaglandin and leukotriene synthetic pathways to beneficially modify the patient's response to illness [18–20].

All ILE are emulsified with egg lecithin derived phospholipids to mimic the structure of chylomicrons and contain 5% glycerol, to ensure the products are isotonic. A variety of ILE with different combinations of MCT/LCT/MUFA/PUFA and ω-3FA, are available as 10%, 20% or 30% w/v concentrations. The energy value of lipid is approximately 9 kcal/g, but glycerol contributes 1 kcal/g. Hence the energy contribution of a 10% ILE is 1.1 kcal/mL, a 20% ILE is 2.0 kcal/mL and 30% ILE is 3.0 kcaL/mL.

Advantages

- High energy content
- Isotonic allowing peripheral infusion
- Source of essential fatty acids (EFA) and vitamin E.

Disadvantages

- Expensive compared to glucose
- Lipids may interfere with routine blood tests
- Some patients may have reduced ability to clear lipid
- Risk of catheter occlusion with complex AIO regimens
- Pharmaceutical limitations on stability and shelf life.
- Increased susceptibility to microbial growth

Electrolytes

Various electrolyte salts are available as small volume parenteral injections (SVP) for inclusion into PN regimens. Examples are sodium (as chloride or acetate), potassium (as chloride or phosphate), phosphate (as mono- and dibasic potassium salts or organic compounds), magnesium (as sulphate or chloride) and calcium (as chloride, sulphate or gluconate). Organic phosphate injections, such as glucose-1 phosphate, glycero-phosphate and fructose-1,6-diphosphate reduce the possibility of calcium phosphate precipitation in PN mixtures. The phosphate group on these compounds is covalently bonded and thus is not ionized for precipitation as insoluble calcium phosphate. Some SVP and particularly calcium gluconate, can be contaminated with aluminium, which may be a problem for patients with renal impairment and preterm infants [21].

Micronutrients

While EN products and oral supplements usually include sufficient micronutrients to ensure basic nutritional completeness, Chemical and temperature stability considerations preclude vitamins from being incorporated into PN admixtures until closer to the time of administration. Fixed dose combinations and some individual micronutrients are available commercially as additives for compounding to meet specific clinical requirements. When micronutrients are administered intravenously they are 100% bioavailable and undergo the same metabolic and elimination pathways as corresponding minerals provided by oral feeding.

Trace Elements

Over a dozen trace elements are thought to be essential to biological functions, but only 9 are routinely supplemented in PN regimens. Metabolic rates after elective surgery may increase by 10–20% and with severe sepsis by up to 50%. When the metabolic rate increases there is a greater requirement for trace elements, partly because all essential trace elements are involved in enzyme-catalysed reactions, many of which are central to intermediary metabolism. There are also multiple sites from which large amounts of zinc, copper, manganese can be lost from fistula or diarrhoea during surgery or trauma [22].

The provision of precise amounts of micronutrients is therefore difficult due to uncertainty about how much to give and in what chemical form. In addition, the amino acid and other PN products may be contaminated with trace elements. Contamination has been reported for zinc, copper, manganese, chromium, selenium and most recently iron [23, 24]. Contamination levels vary between manufacturers and between lots from the same manufacturer. Consequently a daily amount to prevent clinical deficiency states must be provided in accordance with the guideline recommendations referenced earlier [4–10].

Standard PN solutions do not contain trace elements because of the aforementioned chemical stability considerations and need to be added to the PN solution shortly before administration to the patient. Trace elements may interact with vitamins, amino acids and other trace elements. Because these interactions become more significant when concentrations differ markedly from recommended daily intakes, administration of supplemental trace elements in a fixed combination single solution, has been advocated in order to maintain balance [25].

The compatibility of trace elements, especially iron, with lipid-containing PN remains controversial. Tu et al. [26] showed that the addition of small quantities of trace elements (including some iron) does not affect the physicochemical stability of ILE during storage for several days and that therapeutic doses of iron can be suitably admixed with lipid-containing (AIO) PN solutions. Nevertheless, these data have not been confirmed by other researchers and caution is still advised when considering adding iron to PN [27].

Vitamins

A number of commercial multivitamin preparations for parenteral use are available which provide the recommended daily requirements of vitamins Products with higher thiamine content may be advantageous when thiamine deficiency is anticipated or when a relatively carbohydrate-rich feeding regimen is used, in order to avoid refeeding syndrome (RFS). A continuing problem is the loss of vitamins from PN mixtures after compounding, whether due to chemical degradation, light catalysed peroxidation, by exposure to ultraviolet light, adsorption onto the surface of the infusion bag or administration sets. Because of these potential chemical losses the patient may not receive an adequate vitamin intake according to the prescription to maintain vitamin status. Light protection of the PN container and exclusion of air during compounding can help to minimise these losses [28, 29].

Water

Water makes up most of a PN regimen with the quantity varying according to a patient's needs. If large amounts are needed this is usually given in conjunction with isotonic sodium chloride, which is usually lost from the body with water.

Peripheral Parenteral Nutrition Formulations

When central vein access is limited, peripheral parenteral nutrition (PPN) should be considered for ≤5–7 days but can be given for up to 14 days if required. PPN can provide a safe, efficient and cost-effective short term route for nutrition delivery in a variety of clinical situations [30]. The most important complication limiting the use of PPN is thrombophlebitis, largely due to administering high osmolarity solutions into a small calibre vein. The major contributors to the osmolarity are glucose, amino acids and electrolytes with a greater incidence of thrombophlebitis noted from increasing electrolyte content, especially potassium. Consequently, standard PN regimens are not suitable for peripheral administration as their hyperosmolarity increases the risk of thrombophlebitis when infused into smaller veins. The likelihood of thrombophlebitis is reduced when the PPN regimen con-

tains ILE [31] and has an osmolarity of less than 900 mOsm/L [32, 33]. Given the low electrolyte composition of PPN, due to limitations with osmolarity, the patient's electrolyte levels should be checked prior to administration in order to minimise the risk of refeeding syndrome (RFS). Good administration and monitoring procedures, based on evidence-based practices, with careful surveillance for the signs of thrombophlebitis that include warmth, tenderness and pain in the affected area, often accompanied by redness and swelling, can ensure the success of PPN. The addition of heparin and hydrocortisone to infusions has been used to reduce the incidence of peripheral vein thrombophlebitis. Timmer and Schipper [34] have shown that the 'osmolality rate' (osmolarity × infusion rate) correlates more with peripheral vein thrombosis than osmolarity alone.

Compounding Standards and Regulations

All PN compounding must be performed under strict aseptic conditions and under pharmacy control. In the UK PN is a Prescription Only Medicine and all hospital pharmacy compounding units are strictly controlled by the Medicines and Healthcare products Regulatory Agency (MHRA). Pharmacies must have a Manufacturer's licence for compounding licensed PN products with a marketing authorisation (MA), or a Specials licence for compounding small batches of unlicensed products or a Section 10 exemption from licensing [35, 36]. Within Europe, individual countries have their own regulations controlling compounding pharmacies [37] and in the USA, ASPEN recommends that all healthcare organisations with 'in-house' compounding facilities shall comply with USP Chapter <797> standards [38].

Those hospitals without licensed Aseptic Units may contract their PN compounding to an outside manufacturer or compounder. A decision to outsource PN compounding requires that the commissioning pharmacy should exercise due diligence to monitor that the outsourcer operates within the jurisdiction of the MHRA, or in the USA follows USP <797> guidelines.

Procedures involved in providing a PN compounding service are described in detail by Austin and Stroud [35] and a useful Summary table of twelve recommendations for ordering, order review, compounding and labelling/dispensing of PN is included in the ASPEN Clinical Guidelines [33]. Risk management advice for health professionals performing PN compounding, by the NHS Pharmaceutical QA Committee [11], include considerations of the compounding processes, the final container choice, stability, exclusion of air and light protection, storage temperature and infusion period. Controlling impurities such as Aluminium, that has been regulated in the USA for over 20 years [39], is now a BP requirement for UK manufacturers [40].

Standard commercially available 'ready-to-use' PN products may be viable options to aseptically compounded PN products, when compliance with USP Chapter <797> and other national guidelines is not feasible [1]. Multi chamber bags (MCB) are designed to reduce the risk for instability or precipitation. Macronutrient components of the PN formulation are separated in individual chambers by a seal, until just prior to activation and administration. The contents of the chambers should be mixed and any additives made aseptically under pharmaceutical conditions, prior to dispensing the PN prescription. If MCB are used in home care then patients and/or caregivers shall be provided with thorough training regarding the procedure for properly mixing the contents before use [1, 37, 41].

Stability and Compatibility of PN Solutions

Since PN solutions are complex mixtures, there are two categories of interactions between components that can potentially take place in compounded PN admixtures: physico-chemical incompatibility leading to precipitation, and chemical degradation leading to loss of nutritional or pharmacological efficacy, and possibly enhanced toxicity from hazardous degradation products. Avoiding precipitation and minimizing degradation requires an understanding of the major reasons why they occur in certain PN regimens. The chemical composition and physical properties of PN admixtures vary greatly between regimens depending on the amino acid source, ILE type, the particular electrolyte salts used, the relative concentrations of ingredients and the final volume. In describing the potential chemical and physical interactions that can take place, it is important to realize that each regimen is chemically unique. Extrapolation of stability data from one to another regimen requires a full understanding of all the factors that can influence stability.

Physical Incompatibility

Electrolytes

The most common cause of precipitation in PN mixtures is due to calcium phosphate insolubility [35–37]. Factors influencing the solubility of calcium phosphate in PN admixtures are multi-factorial, but the most important variable is pH [42]. The final pH of a mixture is influenced by the following factors:

The amino acid product. Differences in pH, that can vary from around pH 5 to greater than 7 are important due to the strong buffering capacity of individual amino acids that are the major controllers of pH in the final PN admixture [43].

The phosphate source. Inorganic phosphates are strong buffers but potassium dihydrogen phosphate injection (acid

phosphate) has a very low pH c.5 while disodium hydrogen phosphate has a pH around 8. Thus, the choice of phosphate injection can have a marked effect on final pH of the PN mixture [42].

The Buffering Capacity of Amino Acids and Inorganic Phosphate

The chemical equilibrium for inorganic phosphate salts in water is shown in Fig. 1. Note that pH is the controlling factor for which phosphate species actually predominate in any particular solution. In PN admixtures, the optimum pH lies between 5 and 7 but will depend on the amino acid source, final concentration and phosphate source. At pH 5, the dihydrogen-phosphate salt predominates, while at pH 7, the predominate salt is the mono-phosphate species [42].

Calcium mono-hydrogen phosphate is 60 times less soluble than the dihydrogen salt. As the pH increases, there is an increasing likelihood of precipitation. Since the most important cause of precipitation in PN admixtures is the formation of insoluble calcium phosphate, the calcium source needs to be considered [42].

Parenteral Calcium comes in two forms, as inorganic or organic salts: calcium chloride and calcium sulphate for injection, which are fully ionized in aqueous solution, or calcium gluconate injection which is only partially ionized in aqueous solution. These salts behave differently in PN admixtures, and precipitation is most likely with the chloride salt. Calcium gluconate is therefore preferred to reduce the risk of precipitation in PN mixtures [44] But there is a further complication. The degree of ionization of calcium gluconate is only slightly influenced by pH, but is substantially affected by temperature [42]. Raising the temperature increases the dissociation of calcium gluconate, so paradoxically, PN admixtures containing calcium gluconate stored in the refrigerator are less likely to precipitate, compared with PN admixtures at room temperature. More importantly, is the possible risk of precipitation in the administration set, as the PN infusion warms to body temperature, especially within the canopy of a neonatal cot. Consequently, a limit of 76 mg Ca per kg and a molar Ca:P ratio of 1.3:1 is recommended for neonatal PN regimens [33]. Note also the concerns about high aluminium levels in calcium gluconate injection as previously indicated [39].

Other factors that can also affect calcium phosphate solubility in PN admixtures are summarized in Table 1.

Other Possible Causes of Precipitation

There are some other possible causes of precipitation, but all are far less likely than calcium phosphate. Most are associated with trace elements and usually take many days to become evident [46, 47]. In contrast, calcium phosphate precipitates appear within 24 h of compounding. Significant trace element interactions can cause precipitation in PN admixtures. These include:

- Copper and sulphide (a degradation product of cysteine found in Vamin®, Vaminolact® and Primene products [47].
- Iron and phosphate (only reported with Synthamin® with electrolyte-containing PN mixtures) [47].
- Selenium and vitamin C at acidic pH [48].

In summary, the greatest risk of precipitation is from formation of insoluble calcium phosphate salts. In clinical practice, it is normally possible to achieve adult nutritional

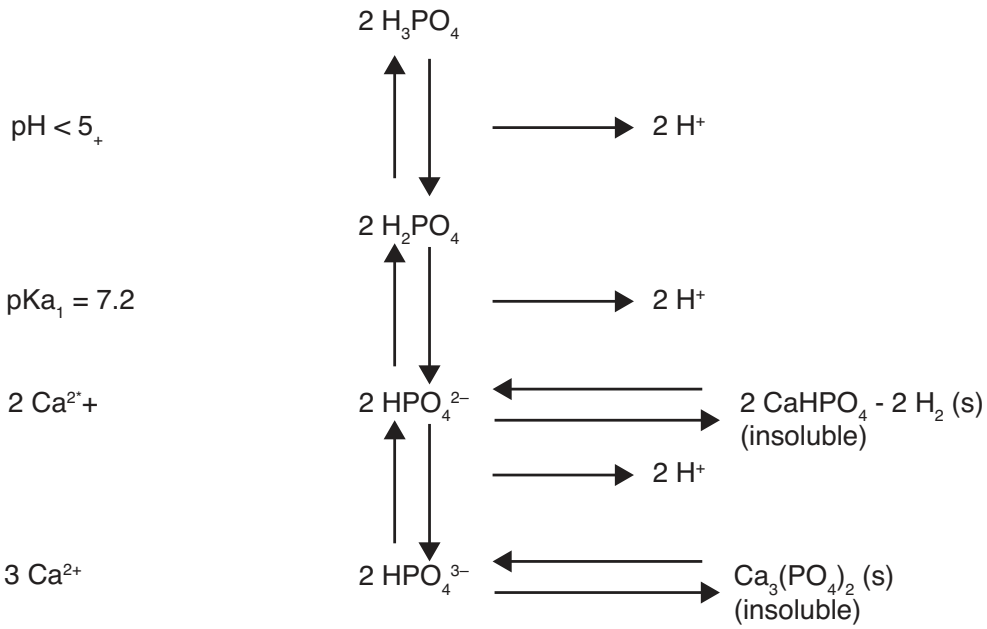

Fig. 1 Speciation of phosphate salts in parenteral nutrition mixtures

requirements without running the risk of calcium phosphate precipitation. Nevertheless, in neonates and small children, because of their greater needs for these essential compounds, it is very difficult to formulate PN regimens without creating a potentially incompatible admixture. Insolubilities can be minimised by using an organic source of phosphate, such a sodium glycerophosphate [45] with covalently bonds so there are no free phosphate ions present. Thus, the risk of forming an insoluble salt with calcium is minimised, so phosphate requirements for neonates and small children are more easily achieved.

Intravenous Lipid Emulsions

It is now routine practice to include intravenous lipid emulsions (ILE) in most PN formulations. An intravenous oil-in-water emulsion is manufactured using a homogenization process to form a very fine emulsion, egg lecithin being the emulsifying agent. Each lipid particle is kept separate by the fact that the surface is covered in the negative charges of phospholipid 'tails' around its surface. Consequently, charge repulsion maintains the emulsion in a stable state [49].

Since the average globule size is around 3–400 nm (0.3–0.4 μm), small enough to pass through the smallest capillaries, the essential requirement of any ILE after being added to a PN admixture, is that this size does not increase to the extent that it might block these capillaries. This forms the basis for deciding if the AIO regimen remains within acceptable limits. Most ILE contain added sodium oleate (c. 0.3%) as an additional surfactant to enhance the physical stability of the emulsion. Such ILE are also more stable and can tolerate both lower and higher concentrations of amino acids and glucose after dilution in a PN regimen [50].

In compounding a PN admixture, ILE is mixed with a whole range of other compounds, which, crucially, include electrolytes and specifically, cations. These positively charged ions can neutralize the negative surface charges of the oil globules. The particles start to come together as aggregates and form small clumps. Since oil is lighter than water, these aggregates tend to float to the surface and form a 'cream' layer (just like the "top-of-the-milk") (Fig. 2). Gentle shaking can disperse these clumps. Therefore, the formation of a cream layer is not normally considered hazardous because the particles remain discreet. However, if the particles start to coalesce to form larger oil globules, this is more hazardous, but can usually only be detected by careful particle-size analysis [51].

Table 1 Factors that effect calcium phosphate solubility in PN mixtures

Factor	Likely effect	Reason for effect
Magnesium concentration	Reduces likelihood of precipitation	Magnesium phosphate more soluble than calcium phosphate salts [33]
Amino acid source	May decrease or increase solubility and/or precipitation	Some amino acids specifically bind calcium and reduce salt formation, thus enhancing solubility [43]
Organic phosphate	Removes risk of calcium precipitation	Phosphate is in an organic covalent form (e.g. glycerophosphate or glucose phosphate) and so calcium phosphate does not precipitate [45]

Causes of destabilisation in AIO PN mixtures

- HIGH concentrations of calcium and magnesium
- LOW pH
- LOW relative volumes of ILE
- LOW concentration of amino acids
- HIGH ratio of acidic to basic amino acids

Fig. 2 Stages of All-in-One PN admixture instability over time

Factors that enhance stability of AIO admixtures

- HIGHER glucose concentrations, but within an upper limit
- Second emulsifying agent—sodium oleate

In fact, it requires relatively large concentrations of cations to significantly reduce these surface charges, but divalent cations are much more efficient charge neutralizers. So, in practice it is the concentration of divalent cations, which is the most important cause of destabilisation. There have been attempts to quantify the destabilising effect of cations. Although the relatively simple equations used in colloid science are more applicable to simple ILE and cannot always be applied to the more complex AIO admixtures, calculating the critical aggregation number (CAN) from the Schultz-Hardy equation [49]. can be a useful indicator and has been used for stability predictions of paediatric PN regimens [52].

The USP <729> provides pharmaceutical specifications describing stability methods and acceptance criteria defined as the "percentage of fat residing in globules larger than 5 µm (PFAT5) for a given ILE is not to exceed 0.05%". It is claimed that PFAT5 can also applied to final PN admixtures [53] and that PFAT5 has been validated for both the ILE from the manufacturer and as a total nutrient admixture (TNA) from the compounder in both animal models and human subjects [54]. Nevertheless, although the principle of PFAT5 is sound, as with the CAN approach, there are concerns that the USP monograph cannot be applied accurately to all AIO admixtures and that the recommended light obscuration techniques will not pick up the smaller lipid droplets which may have an important role in indicating instability. A recent study by Zhao B et al. [55]. that assessed the stability of MCT/LCT-based PN admixtures by measuring mean droplet diameter (MDD), PFAT5, pH, and osmolality, reported that all TNA met USP <729> but there were some significant differences between MDDs and PFAT5s.

To date, the USP standards have not been officially accepted in the UK or Europe but PFAT5 is used by some manufacturers, as part of routine stability testing for PN admixtures [56]. Other testing laboratories prefer a combination of assessments methods based on visual, microscopic and particle size analysis (e.g. laser diffraction, light obscuration) together with their extensive historical laboratory comparative data to determine and predict AIO PN stability.

The ASPEN consensus recommendations for a stable AIO PN regimen [1, 33], provide a useful 'rule of thumb' and can be summarised as follows:

Glucose >10% (excluding PPN)
Amino Acids >4%
Lipid >2%
Ca/Mg <20 mEq (10 mmol)/L
Na/K <200 mEq (mmol)/LNB: Stability information should never be extrapolated between PN admixtures with different commercial sources of amino acids and/or ILE.

Chemical Degradation

Most PN components are remarkably stable after compounding, at least during the normal shelf lives of PN admixtures, and in particular the 30-day shelf life most commonly used in practice. It is important to consider stability at two stages: (a) during storage after compounding and (b) during administration. There are three possible chemical mechanisms for the degradation of specific PN ingredients (Table 2) primarily involving vitamins. Thus, it is often the addition of vitamins that subsequently limits the shelf life of PN admixtures [57–62].

Vitamin C (Ascorbic Acid) Oxidative Degradation

Ascorbic acid is the least stable ingredient in any PN admixture and some loss during compounding, storage and administration is inevitable. There are two important factors to note from the degradation pathway for ascorbic acid in Fig. 3.

First, the initial reaction is reversible; this is important because dehydro-ascorbic is equally biologically functional. Second, the degradation involves oxygen which can originate from:

1. Air in infusion solutions and additives—glucose, electrolytes, water for reconstituting vitamins, (but not amino acid infusions or ILE, both of which are usually protected by a nitrogen gas overlay).
2. Air in the bag after compounding, if not removed prior to sealing
3. Air which dissolves in the infusions during the filling process especially as solutions pass through the filling lines
4. Oxygen permeating through the bag wall during storage.

Oxygen reacts with ascorbic acid rapidly, catalysed by copper ions [63, 64]. Within an hour or two, the oxygen will have reacted to reduce ascorbic acid to dehydroascorbic acid

Table 2 Chemical mechanisms for PN degradation

Reaction	Most important candidate(s)
1 Oxidation	Vitamin C (ascorbic acid)
2 Reduction	Vitamin B_1 (thiamine)
3 Photodegradation	Vitamin A (retinol) Vitamin E (tocopherol)

[64]. This in turn is further oxidized and/or hydrolysed to keto-gulonic acid, so the amount of ascorbic acid degraded depends almost entirely on the amount of oxygen present in the PN admixture after compounding.

It can be expected that the quantity of ascorbic acid degraded after compounding a typical 2–3 L adult formulation will amount to 40–60 mg [63]. The amount the patient receives depends on the quantity of oxygen in the PN bag, and on the type of bag used. Degradation will continue as oxygen permeates through the semi-permeable wall of PVC or EVA PN bags, accounting for a further loss of 10–15 mg per day [64]. In an EVA bag, the maximum shelf life must therefore be only 3–5 days, because of the high oxygen permeability of the plastic. This phenomenon can be minimised by using multi-layered bags, which are virtually impermeable to oxygen. A comparison of ascorbate (AA + DHAA) degradation in single layer EVA versus multi-layered bags is illustrated in Fig. 4. Note how degradation is initially rapid, but then the rate of losses level off to almost zero, after a few hours. This is accounted for by the initial reaction with dissolved oxygen already in the PN admixture. Once all the oxygen has reacted, no further degradation of ascorbic acid takes place. Thus, in multi-layered bags, which are now commonly used in UK and some other countries, the shelf life of PN admixtures can be extended, commonly up to 30 days, provided the initial compounding is undertaken efficiently, to minimise aeration during filling, and any residual air is removed before sealing the bag [63–65].

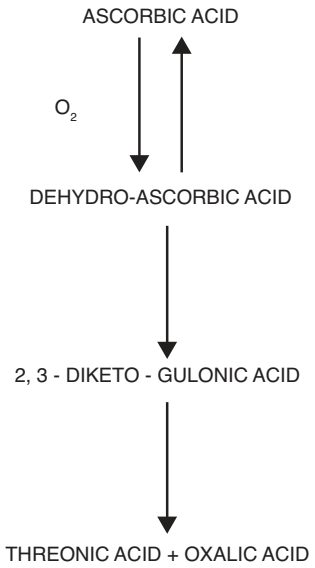

Fig. 3 Ascorbic acid degradation pathway

Unfortunately, the plastic films used to fabricate MCB's are also semi-permeable to oxygen. Consequently, following removal of the outer wrap, mixing of the main ingredients and the addition of multi-vitamins, degradation of ascorbic acid will occur as described above, such that shelf lives should be restricted to 48–72 h, including infusion time. The shelf lives of these products can be further extended to at least 60 days, usually in a high GMP industrial facility, by re-packaging the MCB (after mixing and adding vitamins), in a gas-impermeable overwrap. Any remaining air between the MCB and its overwrap is replaced by nitrogen gas before sealing the overwrap under vacuum. An oxygen scavenger is also commonly included.

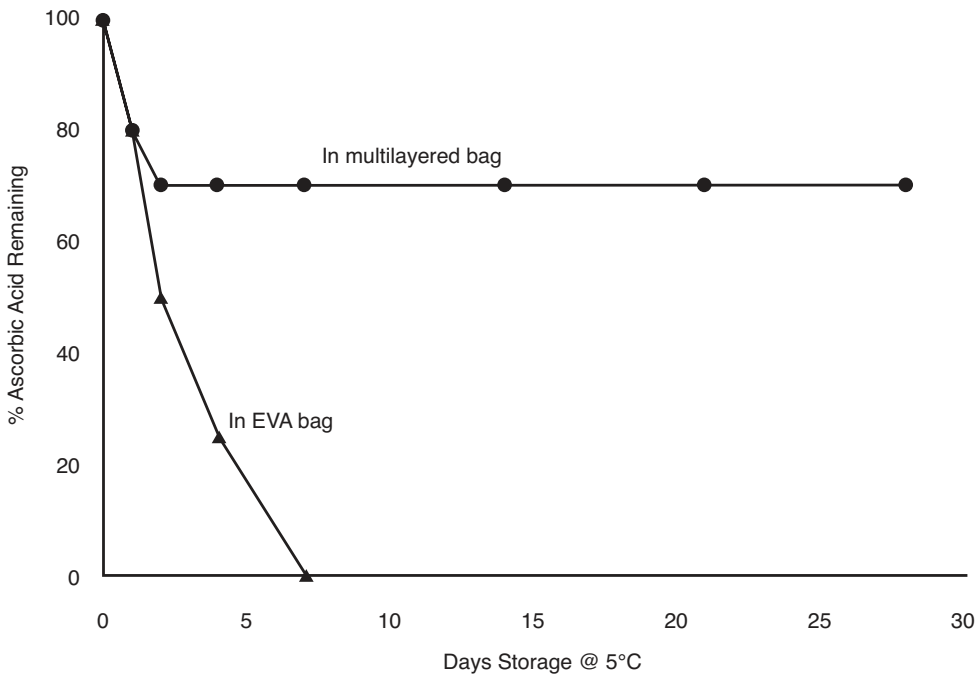

Fig. 4 Degradation of ascorbate in PN mixture during storage

Vitamin B_1 (Thiamine) Reduction

Thiamine is degraded by a reduction reaction with sodium metabisulphite [33]. Historically, some amino acid infusions contained sodium metabisulphite as a reducing agent to prevent oxidation of amino acids during manufacture and storage. In the absence of metabisulphite, thiamine is stable for at least 28 days in PN mixtures [66].

Vitamin A (Retinol) Photodegradation

The most light-sensitive ingredient of any PN admixture is retinol (vitamin A) [28, 67]. Many factors can influence the rate of light induced retinol degradation during PN administration, including the time of day, the position with respect to light from the window, volume in bag, infusion rate, ILE in the admixture and the presence/absence of a light protecting cover over the PN bag [28, 67].

But note the following important points:

- Since degradation is caused by exposure to ultraviolet light (below 350 nm wavelength), only daylight degrades retinol [67]
- Artificial light contains very little UV emission
- Photodegradation will occur both in the bag and in the administration set as the solution is infused, if the system is not protected [65].

Drug Additions to PN Mixtures

It is generally recommended that drugs should NOT be added to PN admixtures unless absolutely necessary. According to ASPEN [33] a decision to make drug additions should be supported by data on the physicochemical compatibility and stability of the medication and of the final admixture, under conditions of typical use. In addition, clinical data on the expected therapeutic advantages of incorporating the drug into the PN admixture should be available. Evidence is available which identifies the compatibility and stability of specific drugs in particular PN admixtures [68, 69]. The most commonly added drugs are, the histamine type 2 receptor antagonists, heparin, insulin:

H_2 Antagonists

Cimetidine is stable in PN regimens, and shelf lives of up to 28 days have been indicated in certain mixtures [52]. In contrast, ranitidine is far less stable. Half-lives of only a few days are indicated in many regimens, although it is possible to extend this in multi-layered bags, and/or by adding vitamin C, as ranitidine degradation is by light-induced oxidation [70–73].

Heparin

Heparin is commonly added to PN regimens for neonates, but great care is necessary to avoid destabilizing the ILE in AIO admixtures, or when lipid-free PN admixtures mix with ILE via a Y-set. Standard heparin interacts with the emulsifying agent in ILE, in the presence of calcium ions, to form calcium-heparin bridges [74]. The emulsion rapidly destabilizes and cracks within a few minutes. This risk can be avoided by using low molecular weight heparin [52].

Insulin

Insulin infusions may be required for poorly controlled diabetic patients or for those patients developing insulin resistance. Addition of insulin to PN regimens has also been advocated to promote anabolism but this can lead to further metabolic disturbances. Moreover, if added to the PN admixture, insulin can partially adher to the plastic container and giving set, limiting its bioavailability. Addition is therefore discouraged [33, 35].

Various other medications such as hydrocortisone or albumin have been demonstrated to have only limited stability and short shelf lives [33] Overall, limited or inconclusive stability, bioavailability and the potential for introducing contamination make the addition of all non-nutrient medications undesirable and generally not recommended

FDA Recommendations for Compounding During the Covid 19 Pandemic and Other Particles [75]

Personnel who compound sterile drugs such as PN are required to use PPE to reduce the risk of microbes and other particles present on human skin, hair and clothing contaminating the product they are preparing. Where PPE are in short supply, the FDA recommends that compounding practices can be modified as follows

- Use other PPE, if obtainable, that confer equal protection
- Preserve the existing supply of PPE by
  - Limiting the number of personnel conducting aseptic activities
  - Reducing compounding activities

Mitigation strategies to reduce the risk of contamination relating to compounding without standard PPE, include

- Increase the frequency of cleaning compounding areas and gloves
- Increase the frequency of environmental monitoring
- Use standard PPE beyond the designated shelf life, if stored appropriately
- If no other PPE are available:
  - Reuse masks during the same shift but do not share between personnel
  - Reuse masks on subsequent days, only if stored correctly and free from defects
  - Use an appropriate agent to disinfect masks
  - If sterile gloves are unavailable, non sterile gloves may be disinfected and used, after checking material and manufacturers recommendations
  - Foot covers should not be reused

PN Administration After Compounding

PN administration errors that occur at the point of patient contact are less likely to be intercepted and more likely to cause harm. Two relatively simple precautions to be taken are:

1. To protect the PN system from oxygen and light
2. To filter the PN before reaching the patient.

1. It has been well known since the pioneering work with AIO in Montpelier, France [13] that some components of PN admixtures are susceptible to oxidation and light catalysed degradation. Photooxidation is defined as a "a chemical reaction occurring as a result of absorption of light in the presence of oxygen". The presence (or absence) of oxygen is therefore key to the stability of nutrients in aqueous solution. This phenomenon has been well demonstrated in our laboratories over the past 30–35 years [67] and the point is made in the introduction to the UK NHS advisory paper on PN Stability published in 2016 [11] As indicated earlier, vitamins, and ILEs appear to be the most susceptible to photooxidation when exposed to intense sunlight, including the ultraviolet range in the presence of air, but ambient light can also have significant effects [76, 77].

   Cressex and colleagues [78, 79] most recently demonstrated that premature neonates, and the critically ill are most susceptible to light induced oxidative stress. In consequence the most recent guidance from ESPEN [79] and ASPEN [80] make recommendations to light protect PN systems for premature babies and neonates and the regulatory agencies, MHRA and EMA have now made this a requirement for PN manufacturers [81, 82].

   In practice it has long been a standard recommendation in UK for *all* PN systems to be protected from light [29, 35, 76].
2. In-line filters during PN administration reduce the potential for patient harm due to particulates, microprecipitates, microorganisms, and air emboli. The most recent advice from ASPEN [83] and ESPEN [84] for inclusion of a filter in a PN administration system follows the much earlier UK recommendations from BPNG [85, 86].

   It is now generally recommended to use a 1.2 micron in-line filter for administration of all PN regimens, whether AIO or '2 in 1' PN (without lipid) or ILE when separately infused [83].

   Single use filters should be placed as close to the catheter hub for AIO admixtures or below the Y-site where the amino acid/dextrose admixture and ILE co-infuse [83] and should be changed according to the manufacturer's guidelines, typically every 24 h. Due to the potential for contamination and subsequent release of endotoxin, filters should not be connected to the PN system in advance but should be primed with fluid immediately before initiating the infusion.

   When an occluded filter triggers pump alarms, the PN infusion should be stopped and the PN pharmacist should review the PN formulation to determine if incompatibility issues are the cause of the problem and to recommend appropriate action.

Practical Tips for Maintaining Stability During PN Administration

- Use an in-line 1.2 μm filter for all PN [83]
- Avoid exposure to direct sunlight [76, 81, 82]
- Protect the bag content with a light excluding cover [76]
- If possible, light protect the giving set; not protecting the set will lead to some nutrient losses [76]
- Administration at night or well away from a window will reduce losses substantially [76].
- The ILE in AIO admixtures may offer some protection to vitamin degradation but will itself be subjected to peroxidation [76].

Procedures to Follow Before PN Administration

Various Check Lists have been published for final inspection of a PN admixture [11, 33, 35].

Key points include:

- Compare label to prescription
- Compare calculated weight to actual weight
- Visually check for:
  - Colour changes
  - Precipitates
  - Leaks
  - Phase separation
- Establish an expiry date
- **IF IN DOUBT 'THROW IT OUT'**

Parenteral Nutrition Education and Training

PN errors caused by insufficient competency and poor proficiency with automatic compounding devices (ACD) are areas of concern. A lack of competency-based educational curriculum in schools of pharmacy or pharmacy technician training programmes in preparation of sterile products and admixtures, may contribute to PN errors [33].

PN compounding and administration errors often stem from failure to adhere to the verification steps of PN which parallel the "five rights" of medication safety: Right patient, Right drug, Right dose, Right route and Right time. For PN these rights must include; confirmation of Patient identity, visual inspections, verification of PN label, documentation to trace container and administration set to point of origin, and independent double checks by nurses. Since non compliance with labelling and set tubing changes can lead to pump errors, some have advocated a 'sixth right' to ensure the Right Pump and Accessories are used to administer the PN [87].

Educating pharmacy and clinical staff about the proper use and effectiveness of double checks and procedures for reporting errors, near misses and barriers to safe practice in a non punitive environment are essential [33].

Designing Parenteral and Enteral Regimens

Nicola Vernon, Beth Rye, and Jeremy M.D. Nightingale

Key Points

1. Enteral nutrition (EN) feeding alone is used when there is a functional and accessible gastrointestinal tract.
2. Parenteral nutrition (PN) is used when there is a non-functioning or short gut, inaccessible, inadequate, or unsafe EN route.
3. A patient's nutrient (including fluid) requirements start with understanding their current anatomy and physiology.
4. Assessing the macronutrient requirements starts with calculating the total energy needed, then determining the protein component and then dividing the remaining energy between carbohydrate and lipid.
5. The total volume of water and amount of electrolytes (sodium, potassium, calcium, magnesium, phosphate and chloride) needed is determined by firstly calculating their baseline requirements, with additions made for any gastrointestinal losses, for example from vomiting, stool, stoma or fistulas.
6. After macronutrient, fluid and electrolyte needs have been assessed the vitamin and mineral requirements are calculated.
7. Both EN and PN requirements involve also considering a patient's; oral intake, degree of gastro-intestinal absorption and losses (e.g., from stoma/fistula).
8. The initial requirements provide guidance for the primary EN and PN regimen, with it being essential to undertake careful monitoring until a stable regimen has been established.
9. Over-time, the requirements and subsequent EN/PN regimen may change as the clinical needs of a patient changes or adaptation of the gastrointestinal tract occurs.
10. In addition to a patient's nutrient requirements, it is also important, when designing a EN and PN regimen, to consider a patient's personal wishes and quality of life.

Introduction

Wide ranges of enteral nutrition (EN) and parenteral nutrition (PN) regimens are required for different types of patients with intestinal failure. The patients range from the premature newborn infants with necrotizing enterocolitis to adults with a short bowel, and from those requiring short-term nutritional support in hospital to long-term support at home. The regimens must be of proven efficacy and based on an understanding of nutrient requirements in the different groups of patients.

In general, the gut is used for EN if it is accessible and functional. These requirements are usually less complex than those for PN, as the components given are essentially the requirements based upon current/desired growth or weight. The nutritional and fluid requirements for patients needing PN are very variable, largely because these patients continue to eat and absorb some nutrition from their gastrointestinal (GI) tract. In addition, they may have large fluid losses from one or more stomas or fistulas. It is relatively unusual for a patient to depend totally upon parenteral nutrition for their nutritional requirements, unless they have a bowel obstruction, a gastric/duodenal stoma/fistula or severe dysmotility.

This chapter considers how requirements vary with clinical state in both adults and children, including neonates. The nutrient requirements of growing children vary with age, but recommendations at any specified age are based on extrapolations from other age groups. Enteral feeds come from the manufacturers already compounded

J. M.D. Nightingale (ed.), *Intestinal Failure*, https://doi.org/10.1007/978-3-031-22265-8_36

with all the components, including vitamins, minerals and trace elements added, while parenteral feeding bags are generally compounded specifically for an individual patient (bespoke), where most of the components need to be specified. Although increasingly patients are being given ready-made ("off the shelf") multi-chamber PN bags, that are especially useful if there is a problem with compounding and during a pandemic. Greatest emphasis will be given to the design of a PN regimen, which is covered before an enteral regimen. It will show how patients are established, then stabilised on a regimen and how this is adjusted with time.

Parenteral Nutrition Regimens

After an assessment has been performed (Table 1), there need to be clear objectives for when PN is begun (e.g. treat dehydration/undernutrition, reduce diarrhoea, reduce obstructive symptoms, improve nutritional status for surgery etc) and criteria for stopping (e.g. oral intake resumed, surgical resolution, adaptation has occurred, unethical etc). It is important that when patients commence PN, that they are managed by a multidisciplinary nutrition support team consisting at least of a clinician, dietitian, specialist nurse and pharmacist [1].

Table 1 Assessment prior to starting nutritional support

1. Underlying illness and co-morbidities
2. Gastrointestinal anatomy (e.g. length of small bowel, fistula(s) etc)
3. Fluid status (e.g. gut losses, oral/intravenous intake, urine output etc)
4. Nutritional status (Body mass index (BMI), percentage weight loss, mid arm muscle circumference) and current oral/enteral intake
5. Outcome targets
6. Growth in children

Table 2 How to work out an adult parenteral regimen

1 Calculate total energy using appropriate kcal per kg body weight; will need to factor in age, BMI and clinical condition. Add additional physical activity level as appropriate
2 Calculate amino acid requirement by firstly calculating the protein requirement; 0.8–2 g/kg/day, then divide by 6.25 g to calculate nitrogen. Add repletion if appropriate (0.1 gN per kg weight lost)
3 Calculate amino acid energy: gN × 27
4 Calculate maximum amount of fat allowed (1.5 g fat/kg)[a]
5 Calculate carbohydrate energy as: Total energy − (fat energy + amino acid energy)
6 Calculate fat: carbohydrate calorie ratio and ensure it is about 40:60
7 Check safety of derived glucose, amino acid and lipid infusion rates
8 Calculate/estimate volumes of water, sodium, potassium, magnesium, calcium and phosphate

[a] Many nutrition units divide the non-amino acid energy by 2 to give a fat: CHO energy ratio of 50:50. The exact ratio then is varied so that all the contents of a commercial lipid container are used in the feeding bag

The Overall PN Regimen

PN requirements are based upon a careful assessment, which if the patient is eating will involve an estimate of how much total fluid/nutrition is being absorbed and lost in secretions. Whilst the initial regimen will be relatively standardised for the hospital, the regimen and subsequent prescription at home will be designed around not only the patient's nutritional needs but also their wishes and preferences (e.g. nights off feed, duration/timing of feed, frequency of lipid, desired weight, frequency of deliveries etc.), to allow an adequate quality of life.

Anatomical Considerations

If the gut is short (includes an entero-cutaneous fistula that drains all gut contents) but has normal function, then the long-term type of nutritional/fluid support can be predicted from a knowledge of the small intestinal length in circuit and the presence or absence of a colon in continuity. With time (up to 3 years), patients with a colon in continuity are likely to have a degree of anatomical (villus hypertrophy) and functional adaptation (slowing transit and improvement in some biochemical pathways) so that less PN support is needed. This is not the case for patients with a jejunostomy whose nutritional/fluid requirements change little with time [2].

Initial Stabilisation of PN Regimen in Hospital

The formulation of a PN regimen is a stepwise approach aiming to optimise a patients nutritional and hydration status. The stepwise reasoning behind the design attempts to provide enough macronutrients to maintain or improve nutritional status, enough nitrogen to optimise tissue nitrogen deposition, alongside the fluid, electrolyte, and micronutrient (vitamin/mineral) needs of the patient (Table 2). This is whilst dealing with the constraints such as volume restrictions for PN stability and/or maximum safe doses of macronutrients (for example by compromising on the less critical carbohydrate: fat ratio), and/or maximum and safe doses of the infusion of electrolytes.

Energy: Adults

Energy is administered in parenteral admixtures containing macronutrients with different energy densities: carbohydrates (CHO) (~3.75 kcal/g glucose), fats (9.4 kcal/g), and

amino acids (~27 kcal/g nitrogen). To know the quantity of each of these to provide in a PN (or EN regimen), it is firstly important to ascertain what a patients total energy expenditure (TEE) and thus overall energy requirements are.

Whilst total energy intake (EI), can be readily calculated from the intake of individual macronutrients with known energy densities, TEE over a prolonged period of time, can only be accurately and directly calculated by continuous 24-h calorimetry or tracer techniques such as the gold standard method of doubly labelled water [3]. As this is often not realistic in clinical practice, more often, TEE is calculated by adding together the perceived components of TEE (Table 3). In sick patients a period of negative energy balance, particularly over a prolonged period of time, depletes the body of glycogen, fat and protein. This negative energy balance can be corrected by administering more energy than TEE. In general, about 0.2 g of tissue are accreted for every kcal deposited under anabolic conditions.

Previously predictive equations were used to estimate basal metabolic rate (BMR) such as Harris and Benedict 1919 [4], Schofield 1985 [5] and Henry 2005 [6], with additional factors for metabolic stress, DIT and physical activity added as appropriate [7] to subsequently estimate the TEE. However, the latest recommendations for energy calculations are based on firstly using energy values per kilogram of bodyweight or per kilogram of fat free mass, which vary dependent on a patients age, disease state and body mass index, to estimate REE [8] (Table 4). Onto this calculation for estimating REE, is then added a combined factor for DIT and physical activity, also known as a PAL (Table 5), as appropriate. Whilst these calculations for estimating TEE for patients vary dependent on age, disease state and BMI, the TEE commonly falls within the range 20–35 kcal/kg/day [9, 10, 12], and rarely more than 40 kcal/kg/day [13].

Care should be taken not to provide excess energy as occurred in the 1970/80 s and which resulted in hyperglycaemia, liver function test abnormalities and high rates of infection. With often requirements being adjusted to promote weight gain in those under nourished (BMI <18 kg/m^2) and to avoid over feeding in obesity (BMI >30 kg/m^2) (Table 4). Particularly in the obese population, regular anthropometry is important to monitor changes in body composition and prevent rapid muscle loss.

Once the overall energy requirements (TEE) have been calculated, this total is split between the two main energy sources in parenteral nutrition: carbohydrate and lipid. Whilst the ratio of glucose to lipid starts at 50:50 (or 60:40) at first, this ratio is not critical and varies between centres. Within the first month the glucose to lipid ratio is reduced to approximately 70–85% from glucose and 15–30% from lipid, and particularly if the patient is for long term HPN [12]. However, if a central line catheter tip becomes high (in SVC or brachiocephalic vein) and replacement is not an immediate option the feed may be adjusted to have a much lower osmolality (to reduce the risk of venous thrombosis) by relying on a high lipid, low glucose content.

Other clinical factors to consider when calculating a patient's estimated energy requirements are:

- **Basal Metabolic Rate (BMR):** BMR is classically measured in relaxed, motionless subjects after an overnight fast in thermoneutral ambient conditions. Its most important determinant is the size of the lean body mass. Equations that estimate BMR from body weight and height are popular and have been established from measurements of BMR in large numbers of healthy volunteers. These equations include the Roberston-Reid [14], Fleish [15] and Harris-Benedict [4] equations, which have been found to overestimate BMR of healthy volunteers by a mean of 0%, +2.5% and + 4.1% respectively [16]. However, these equations do not necessarily apply to patients with disease (e.g. sepsis which frequently accompanies intestinal failure (IF)), undernutrition, or disturbances in hydration (e.g. oedema).
- **Stress factor**: sepsis increases BMR by 5–40% [17, 18], fever raises BMR by approximately 13% per °C rise in body temperature [7]. Intestinal irradiation, chemotherapy, bowel infarction and major surgery also raise BMR (0–30%).

- **Physical activity**: intestinal failure (IF) patients, who are bed-bound or mechanically ventilated and minimally active, have an estimated physical activity component of about 10% of BMR. In contrast, ambulant adult IF patients receiving cyclic nocturnal PN at home have been reported to have a physical activity component of about 30% of BMR [19]. Similar, if not higher, values occur in children.
- **Growth/repletion**: additional energy is required for tissue repletion or for normal growth in children (about 5 kcal/g of tissue deposited [20]). A positive energy balance (EI > TEE) of about 500 kcal/day in adults can achieve slow weight gain, but faster repletion can be achieved with higher intakes.
- **Diet-induced thermogenesis**: enteral or parenteral feeding induces a rise in energy expenditure that is proportional to the EI (DIT approximates to 10% of the metabolizable EI) [19–21].
- **Malabsorption:** in patients with intestinal failure enteral tube feeding may be poorly tolerated and the absorption is poor (50% or more of the energy may not be absorbed), so that nutrients may have to be given in increased amounts and often continuously. Oral and enteral intake is taken into account with an estimate of a malabsorption factor. In patients with a short bowel and jejunostomy at 100 cm from the duodeno-jejunal flexure approximately 40% of the oral diet is absorbed and at 50 cm only 20% [22].

Carbohydrate: Adults

Fructose, xylitol, sorbitol and glycerol all have their potential merits as carbohydrates in PN but glucose (e.g. dextrose monohydrate at 3.4 kcal/g) is both popular and most widely available. Calorimetric studies by King et al. [23]. have shown that infusing dextrose (as the sole non-protein energy source) at approximately 7 g/kg/day will produce a non-protein respiratory quotient (npRQ) of approximately 1.0 in patients with mild metabolic stress. At this point, fat oxidation gives way completely to oxidation of glucose. With more rapid glucose infusions, up to about 30% of the extra glucose infused will be diverted into synthesis of new fat, a process that dissipates a large amount of the extra energy infused. In severely stressed patients with intestinal failure (e.g. peritonitis, post-radiotherapy enteritis) net fat oxidation (npRQ <1) is likely to persist despite glucose infusions [24]. As a result, such high rates of glucose infusion should normally be avoided.

Glucose requirements can be set at 3–6 g/kg/day [12]; being aware that excess glucose provision can cause problems particularly with causing hyperglycaemia or abnormal liver function tests. Glucose oxidation rate can be calculated (4–7 mg × kg × 60 × 24/1000 × 4) to give an indication of the maximum amount of glucose that can be utilized per 24 h. However, it is possible to exceed these requirements in malnourished patients requiring weight gain.

Glucose-only regimens are often discouraged initially because they are often associated with higher volumes and osmolalities, result in higher rates of carbon dioxide production (a possible clinical disadvantage in pulmonary disease), and they are more likely to produce hyperosmolar complications and essential fatty acid deficiency, than those that contain fat.

Lipid: Adults

Adult fat infusions are increased cautiously to a dose that does not usually exceed 1.5 g fat/kg/day or 0.15 g fat/kg/h and aims to provide no more than 50% of the non-nitrogen energy needed. During cyclic PN, gross lipaemia at 6 h after ending the infusion indicates the need to reduce the dose of lipid administered since continuation may lead to impaired reticuloendothelial and immune function and impaired gas diffusion across the lung. During continuous lipid infusions, plasma triglycerides are typically kept below 400 mg/dL. 20% lipid emulsions may be preferable to 10% lipid emulsions because of their lower phospholipid:triglyceride ratio, which is associated with less inhibition by phospholipid lysosomes of the clearance of infused triglycerides from plasma.

The infusion of a minimum of 0.5 g fat/kg/day will prevent essential fatty acid (EFA) deficiency, which can develop rapidly on continuous glucose-amino acid infusions in the absence of lipid. Conversion of infused fatty acids to longer polyunsaturated fatty acids (PUFA), which are necessary for brain development, is slow in infants. Since PUFA are not available for intravenous use, they are given enterally if tolerated.

During the preparation of fat emulsions for intravenous use, soya-bean oil or coconut oil are fractionated yielding long-chain triglycerides (LCT) (14–24 carbon atoms) or medium-chain triglycerides (MCT) (6–12 carbon atoms) [24], emulsified by addition of phosphatidyl-choline and rendered isosmolar to plasma by the addition of glycerol. While there are many advantages of giving lipid, it is not considered appropriate to give it with no glucose, partly because some tissues have a particular preference or need for glucose (leucocytes, repairing tissues, brain), and partly because lean tissue is more rapidly accreted in the presence of glucose. In addition, large doses of parenteral lipids can have detrimental effects.

Most patients are provided with lipid, in particular in those patients with little enteral intake. Long-term intravenous lipid provision is kept below 1 g/kg/day (i.e. 500 mL 20% intralipid provides 1000 kcal, approximately 100 g lipid) as above this chronic cholestasis is common [25]. A 20% soya-based lipid emulsion given once weekly is adequate to prevent essential fatty acid deficiency. If a patient is having no lipid and has a dry skin they can apply 10 mL sunflower or safflower oil to their skin daily [26, 27].

Medium-Chain Triglycerides

Compared to LCTs, MCTs are more soluble in phospholipid, and are present in higher concentrations on the surface of fat droplets, which makes them more accessible to tissue lipases. Their greater tissue availability is complemented by their ability to cross the hepatocyte mito-chondrial membrane independently of carnitine [27]. Therefore, MCT are cleared more rapidly from plasma, and are oxidized more rapidly than LCT. They are also alleged to cause less depression of immune function [28] and to be more effective in sparing protein in the catabolic patient. Their energy density (8.3 kcal/g) is only slightly lower than that of LCT (9.4 kcal/g). Since MCT do not contain essential n3- and n6-fatty acids (EFAs), commercial preparations are only available as a 50:50 MCT/LCT admixtures. Their use might be considered in the following situations:

- *Patients with PN-associated liver dysfunction*; Balderman et al. [29] found that PN-associated rises in transaminases, liver size and liver density occurred less frequently with MCT/LCT infusions than with LCT infusions alone.
- *Patients at risk of infusional hyperlipidaemia;* the half-life of infused MCT is only about half that of LCT. The faster clearance of MCT droplets may be due to their smaller size and less inhibition of lipoprotein lipase (LPL) by fatty acids released during their hydrolysis, and their metabolism by different biochemical pathways (see above).

Nitrogen: Adults

RIV for total amino acids (AA) have been largely based on nitrogen (N) balances, and RIV for specific amino acids on additional measurements of circulating and tissue concentrations. The doses of amino acids, which yield approximately 27 kcal/g nitrogen, required to meet patient requirements [30] can be calculated (Table 6). Many patients with intestinal failure will be nutritionally depleted through malabsorption or protein-losing enteropathy, and they may require extra nitrogen (up to 0.1 g nitrogen/kg/day) to replete the protein losses. The nitrogen is more likely to be retained in depleted patients than non-depleted patients in energy balance. Furthermore, approximately 1–2 mg nitrogen is retained per kcal of energy administered in excess of energy expenditure in non-stressed patients, and possibly more in depleted patients. In metabolically stressed patients, nitrogen losses may exceed 20 g/day, and positive balances are difficult to achieve, even with increased energy and nitrogen intake [31]. Large nitrogen losses are documented in sepsis, major trauma and burns. An unstressed patient with normal organ function will require 0.14 g–0.2 g nitrogen/kg/day [32]. If a patient has a low muscle mass and requires more nitrogen 0.3 g–0.6 nitrogen/kg/day may be used [33].

It has been customary in some countries, including the UK, not to include nitrogen energy (usually 200–300 kcal) in the quoted total energy in a PN regimen (unlike with enteral nutrition where the total energy quoted includes the nitrogen energy).

Table 6 Approximate recommended intakes of intravenous amino acids [8, 9, 30]

Metabolic stress	Example	Nitrogen (g/kg/day)[a]
Nil	Healed extensive intestinal resection	0.128–0.16
Mild	Mild Crohn's disease in small intestinal remnant	0.192
Moderate	Crohn's fistula with abscess	0.24
Severe	Intestinal failure associated with acute pancreatitis or severe infection	0.32
In obese patients: BMI >30 kg/m^2: use 75% of the value estimated from actual weight BMI >50 kg/m^2: use 65% of the value estimated from actual weight		

[a]One gram of nitrogen is equivalent to approximately 7.33 g of intravenous amino acids or 6.25 g of oral protein. Give extra 0.1 g N per kg of body weight lost. One mole of amino acid (typically ~110 g) contains one mole of water (18 g) derived from the hydrolysis of protein

Specific Amino Acids

Most commercial parenteral nutrition solutions lack glutamine because of concerns about its instability (spontaneous degradation to ammonia and pyroglutamic acid). However, free glutamine can be added to PN solutions shortly before use. The alternative is to use a stable dipeptide (e.g. alanyl-L-glutamine). Glutamine is a non-essential amino acid that acts as a carbon and nitrogen carrier, e.g. between skeletal muscle, which produces glutamine, and the small intestine, which utilizes it. Glutamine is an important oxidative fuel for the enterocyte, an essential precursor for nucleotide synthesis [34], which is necessary during rapid cell division (especially epithelial and immune cells) and a regulator of acid base balance. In rats, glutamine-enriched PN has been reported to reduce intestinal villus damage after 5-fluorouracil (5-FU) administration [35], minimize intestinal disuse-atrophy [36] and restore mucosal integrity associated with experimental endotoxaemia [37]. In man, although intravenous glutamine supplementation may improve postoperative nitrogen balance, [38] beneficial effects on mucosal growth and absorption are not proven [39, 40] or are limited to case studies [41]. However, PN regimens enriched with glutamine have been reported to improve nitrogen balance and reduce hospital stay in patients undergoing bone marrow transplantation and major colonic surgery [42, 43]. Other amino acids, which have putative benefits, but which have not always been present in PN solutions include arginine, which may be an important immuno-nutrient, and taurine, which may act as an oxidant scavenger during persistent inflammation.

Energy and Nitrogen: Children

Pre-term infants when starting PN, are often started on 6–10 mg dextrose/kg/min, whilst monitoring glucose tolerance, which usually improves with post-natal age. Newborn infants are at risk of developing tissue carnitine deficiency, and infants of low gestational age are at an even greater risk [44]. MCT may be used in such patients because they enter the mitochondrion in a carnitine-independent fashion, where they are oxidized to ketone bodies. Hyperketonaemia, which may have detrimental effects, is prevented by concomitant administration of LCT and/or glucose. MCT have a lower affinity for plasma albumin. This property, together with their faster clearance from plasma, makes them less prone to displace bilirubin from its binding sites on albumin. This minimizes the danger of brain damage by free bilirubin, which crosses the blood–brain barrier. In newborn infants an initial, continuous, separate, infusion of less than 1 g fat/kg/day is slowly increased to a maximum of 3 g fat/kg/day. Higher infusion rates are more likely to have adverse consequences including impaired pulmonary gas exchange, and possibly reduced host defense against bacteraemia (a common accompaniment of necrotizing enterocolitis) [45].

An infant tolerating 7 mg/kg/min of intravenous dextrose can be started cautiously on a paediatric amino acid solution (PAA) increasing to a maximum of 0.34 g N (approximately 2.5 g AA/kg/day) while monitoring serum ammonia and urea levels. Modern PAA contain an amino acid mixture that aims to establish a circulating amino acid profile that is similar to that of healthy breast-fed term infants (or to that of umbilical cord-blood in pre-term infants) [46]. However, this cannot always be achieved because some amino acids are unstable, too acidic, or potentially toxic. Furthermore, several solutions contain a variety of 'non-essential' amino acids that may become conditionally essential during the metabolic demands of refeeding. The following are examples: arginine, because its synthesis may not meet the demands of the urea cycle, and because of possible immune-enhancing properties; cysteine, because of absence of cystathionase in fetal liver; and taurine [47], because low circulating concentrations are observed in infants receiving long-term PN. The low taurine concentrations may result from the loss of taurine-conjugated bile salts in patients without a functioning terminal ileum or due to an inadequate supply of its precursor (cysteine) in PN admixtures. Therefore, it is recommended that these amino acids are included in neonatal PN solutions.

Fluid and Electrolytes: Adults

Typical daily intakes of water, sodium, and potassium in adult patients without abnormal gastrointestinal fluid losses are about 2.5–3.0 L, 90 mmol and 80 mmol respectively. However, changes in the underlying condition of the patient, particularly large variations in the loss of gastrointestinal effluents, will affect these requirements. Patients with intestinal failure may have variable losses of fluids and electrolytes from stool, stoma, or fistulae. A clinical guide to the additional quantities of electrolytes that need to be replaced can be established from the composition of different intestinal effluents (chapter "Normal Intestinal Anatomy and Physiology"), with patients with an end-jejunostomy having the highest losses of water, sodium, and divalent cations. Overall, in patients with intestinal failure, it is important to replace these losses, especially where there are large fluid outputs.

For the initial regimen, baseline fluid and electrolyte requirements are calculated (Tables 7 and 8), with the standard ranges initially assuming normal organ function and no intestinal losses. Depending on the clinical situation, intestinal anatomy and subsequent gastrointestinal losses of the patient, additional fluid, sodium, potassium, and magnesium may be required. Table 9 provides some indication of the amount of electrolytes lost in different gastrointestinal secretions, to guide the increased amount required. However, when using these requirements as a baseline, it is also important to consider the clinical situation of the patient. Examples of this include; whilst each litre of most effluents contains about 100 mmol of sodium, acute disease may reduce the capacity of the kidneys to excrete a sodium and water load, predisposing to dilutional hyponatraemia and refeeding oedema. Potassium and magnesium depletion will aggravate renal water handling, while protein-losing enteropathy will produce further sodium retention through hyperaldosteronism. PN regimens should also consider potassium losses from gastrointestinal effluents, renal losses due to diuretics or amphotericin [49], glucose-induced entry of the ion into cells, and deposition into lean tissue such as muscle (approximately 3 mEq of K+ per gram nitrogen deposited) [50].

Furthermore, it is also important to consider, when calculating electrolyte requirements that renal calcium reabsorption is lower during PN induced diuresis [51] and may also be influenced by poor vitamin D status resulting from malabsorp-

Table 7 Estimation of fluid requirements before GI losses considered [48]

18–60 years old	35 mL/kg body weight
>60 years old	30 mL/kg body weight
Pyrexia	Add 2–2.5 mL/kg for each °C body temperature is above 37 °C

Table 8 Estimation of electrolyte requirements before GI losses considered [8]

Sodium	1–1.5 mmol/kg
Potassium	1–1.5 mmol/kg
Magnesium	0.1–0.2 mmol/kg
Calcium	0.1–0.15 mmol/kg
Phosphate	0.5–0.7 mmol/kg or 10 mmol/1000 Kcal
Chloride	1–1.5 mmol/kg

tion, which is associated with low intestinal levels of calcium-binding proteins [52]. It has long been known that the plasma phosphate concentration can drop precipitously during refeeding, especially with glucose (no fat) regimens, due to intracellular shifts, which partly result in the formation of intracellular high energy phosphate bonds. Lastly it is important to consider that chronic intestinal losses of divalent cations are worsened by the presence of fat in the diet [53], and are not reversed by octreotide [54] or omeprazole [55].

As medical and dietary therapy is maximised, (e.g. for high output jejunostomy—restricting oral hypotonic fluid restriction, sipping an oral glucose-saline solution and taking anti-diarrhea and anti-secretory drugs) and/or adaptation of the GI tract occurs over time, losses will reduce. Consequentially, the fluid and electrolyte requirements may need to be recalculated and subsequent adjustments to the content of the PN regimen undertaken.

Micronutrients: Vitamins and Trace Elements

The reference intake value (RIV) for vitamins have been largely based on studies of oral intake, with additional increments for disease and repletion of stores. The recommendations are also based on measurements of vitamin status and on losses during preparation, storage and administration of PN admixtures (e.g. photo-degradation of vitamin A, oxidation of vitamin C), thus the RIV of vitamins for PN is often higher than that for EN (Tables 10 (adult) and 11 (children)).

Table 9 Approximate daily volume and composition of intestinal Secretions produced in response to food (from chapter "Normal Intestinal Anatomy and Physiology")

	Volume (L)	pH	Na^+ (mmol/L)	K^+ (mmol/L)	Cl^- (mmol/L)	HCO_3^- (mmol/L)	Mg^{2+} (mmol/L)	Ca^{2+} (mmol/L)
Saliva	0.5	7	45	20	44	60	0.7	1.3
Gastric juice	2.0	2	10	10	130	0	0.5	2.0
Pancreatic juice	0.6	8	140	10	30	0	0.2	0.3
Hepatic bile	0.9	7	145	5	100	28	0.6	2.5
Small bowel secretion	1.8[a]	7	138	6	141	<5	<0.1	2.5
Serum		7.4	140	4	100	24	1.0	2.4
Jejunostomy fluid		6	100	15	–	–	4.2	16.1

[a] This fluid is released and absorbed on the mucosa and rarely needs to be taken into account in calculating fluid losses, estimates of its electrolyte composition are unreliable

Table 10 Adult recommended vitamin intakes in enteral and parenteral regimens[a]

	Enteral adult (b) dose/day	Parenteral adult (c) dose/day	Comments
Vitamin A µg (retinol equivalents)	700	3300 IU	Increased losses in steatorrhoea, high losses in nephrotic syndrome, low storage in liver disease; enteral requirement in IF patients typically 3000–15,000 µg/day [56]
Vitamin D (cholecalciferol) µg	0–10	5	Increased losses in steatorrhoea, routine PN supplementation may induce hypercalcaemia and osteomalacia [56]; adult recommendations assume adequate sunlight exposure; IF patients need typically 4000 µg/day by enteral route
Vitamin E (alpha-tocopherol) µg[a]	>4000	10,000–50,000	Requirements depend on iv or enteral intake of PUFA, selenium supplementation decreases requirements; enteral requirements of IF patients typically 34,000 µg/day [56]
Vitamin K µg[d]	1 µg/kg/day	10 mg menadione/week	Increased losses in steatorrhoea, increased requirements in neonatal period and during broad spectrum antibiotic treatment
Vitamin B_1 (thiamine) µg	900 (males) 800 (females)	1200–5000	Increased requirements during high carbohydrate intake
Vitamin B_2 (riboflavine) µg	1300 (males) 1100 (females)	3600	Contribution by colonic bacteria unquantified, accelerated flavoprotein breakdown in catabolic patients interferes with assessment of requirements
Niacin µg	6600 µg (NE) per 1000 kcal	40,000	Low intakes of tryptophan, pyridoxine or riboflavine may increase requirements
Vitamin B_6 (pyridoxine) µg	1400 (males) 1200 (females) or 15 µg/g protein	4000	Malabsorbed in diseased/bypassed small intestine, requirements related to total amino acid metabolism (co-factor in transaminases, decarboxylases, etc)
Vitamin B_{12} (cobalamin) µg	1.5	3	Malabsorbed in ileal resection or bypass, utilised by small intestinal bacteria which reduce its bioavailability
Folic acid µg	200	400	Sulfasalazine reduces absorption, alcoholism increases requirements
Vitamin C (ascorbic acid) µg	40,000	100,000	Enteral administration further increases risk of oxalate stones in SBS—colon patients. Critically-ill patients probably need 500,000 µg/day iv
Panthotenic acid µg[d]	3000–7000	15,000	
Biotin µg[d]	10–200	60	Bioavailability of biotin synthesised by colonic bacteria unknown

a Amounts not adjusted for absorption or excess loss of nutrient
[b] Amounts based on oral Reference Nutrient intakes ([d] or safe intake) [57]
[c] Refers to patients without excess gastrointestinal loss [56, 58, 59]

Table 11 Child recommended vitamin intakes in enteral and parenteral regimens[a]

	Enteral	Enteral	Parenteral	Parenteral	
	dose/day Preterm (b, c) dose/kg/day	Term (d) dose/day	Dose/day Preterm (e) dose/kg/day	Term (e) dose/kg/day	Comments
Vitamin A μg (retinol equivalents)	99–248	350	500	700	Preterm infant invariably depleted at birth. PN-related toxicity reported in infants at doses above 1300 μg/day
Vitamin D (cholecalciferol) μg	Up to 5.0	8.5	4	10	Concentration in preterm formulas should not exceed 3 μg/100 kcal
Vitamin E (alpha-tocopherol)[a] μg	At least 660	400 μg/g PUFA	2800	7000	Preterm formulas should contain at least 0.9 mg/g PUFA. Large iv doses induced liver failure in preterm infants
Vitamin K μg[f]	Nil	10	80	200	Phytoquinolone recommended. Synthetic water-soluble preparation causes dose dependent toxicity. Preterm infants need 0.5–1.0 mg im at birth, then 2–3 μg/kg weekly till breast-fed
Vitamin B_1 (thiamine) μg	22–413	200	350	1200	Supplementation of preterm breast milk (20 μg/100 kcal) only if milk is heat-treated
Vitamin B_2 (riboflavine) μg	66–990	400	150	1400	Renal clearance of excess iv dose reduced in preterm infant
Niacin μg	90–800	3000	6800	17,000	Preterm formulas should contain at least 800 μg/100 kcal
Vitamin B_6 (pyridoxine) μg	39–413	200	180	1.0	Preterm formulas should contain at least 15 μg/g protein and/or 300 μg/100 kcal
Vitamin B_{12} (cobalamin) μg	At least 0.17	0.3	0.3	1000	Marked elevation of serum B_{12} reported in preterm infants receiving 600 μg/kg/day iv
Folic acid μg	At least 66	50	56	140	Red cell folate levels adequate in preterm infants receiving 75 μg/kg/day iv
Vitamin C (ascorbic acid) μg	8300–66,000	25,000	25,000	80,000	Preterm infants need lower doses than term infants to maintain normal plasma ascorbic acid levels (>34 μmol/L)
Panthotenic acid μg[f]	At least 330	1700	2000	5000	Preterm formulas should contain at least 300 μg/100 kcal

[a] Amounts not adjusted for absorption or excess loss of nutrient
[b] Data from ESPGAN 1987 [60]
[C] Data from Lucas 1991 [61]
[d] Amounts based on oral Reference Nutrient intakes ([f] or safe intake) [62]
[e] Data from Greene et al. 1988 [63]

The RIV and subsequent parenteral doses of trace elements have been largely based on those for oral intake, multiplied by a factor for absorption, which varies from <0.1 to 1.0, depending on the trace element. Further adjustments are made to consider losses in GI effluents and measurements of trace element status. For many trace elements, RIV is often much lower in PN than EN (Tables 12 (adult) and 13 (children)). This is because only proportions of trace elements are absorbed via the GI tract. Prolonged excess administration of trace elements can lead to toxicity because the regulatory role of the gut is bypassed (e.g. the gut is the only major site regulating iron status within the body). Toxicity may also occur because of reduced excretion of trace elements in urine (e.g. when there is renal impairment) or in bile (e.g. of manganese when there is liver impairment).

Vitamins and trace elements are included in PN regimens, especially if there is no enteral nutrition or poor GI absorption. However, where ready-made multi-chamber PN bags are used, the infusion of the vitamins and trace elements must be undertaken separately, or an assessment made on if there is adequate access and absorption via the enteral route. The vitamins and trace elements for PN come as commercially ready-made preparations (Tables 14 and 15) which generally provide amounts in excess of basal requirements as they are intended for patients who are nutritionally depleted. Depending on the vitamin and trace element status of the patient and enteral absorption, these preparations can be given daily or on alternate days. Additional supplementation of vitamins and trace elements, particularly iron, vitamin D, and selenium, may be needed in addition to PN if serum levels remain low upon monitoring.

Adjustment of PN Regimen During Hospital Stay and the Final Script for HPN

Often during the hospital stabilisation period, sepsis is treated, and a stoma/fistula output becomes more established, as does the patients oral intake. Fluid balance usually dominates the clinical picture and a stable regimen, particularly regarding establishing the regimens water and electrolytes. Fluid balance, weight, clinical symptoms/sign of

Table 12 Adult recommended mineral and trace element intakes in enteral and parenteral regimens[a]

	Enteral adult (b) dose/day	Parenteral adult (c) dose/day	Comments
Sodium (Na) mmol	70	50–100	Healthy gut absorbs >95%, IF patients may require more than 200 mmol/day. Intestinal losses increase during high enteral intake and decrease during ORS administration
Chloride (Cl) mmol	70	50–100	Healthy gut absorbs >90%, IF patients may need more than 200 mmol/day
Potassium (K) mmol	90	50–100	Suspend K administration if oliguria develops
Calcium (Ca) mmol	17.5	6–10	Healthy gut absorbs up to 40%, IF patients may need up to 120 mmol/day [56] patients with a functioning colon have lower Ca requirements [64]
Phosphorus (P) mmol	17.5	20–40	Healthy gut absorbs 50–60%, IF patients need up to 40 mmol/day
Magnesium (Mg) mmol	12.3	6–12	Healthy gut absorbs up to 75%, for clinical hypomagnesaemia give 17 mmol Mg iv over 30 min before starting TPN: steatorrhoea, nephrotoxic drugs, alcohol increase requirements [65]
Zinc (Zn) µmol	142	38–62	Oral phytate, Ca, Zn reduce absorption, IF patients require 1200 µg (18 µmol) per litre of intestinal effluent, renal losses of Zn increased during amino acid infusions
Copper (Cu) µmol	19	4.7–7.8	Oral phytates, Vitamin C, Cd, Zn reduce absorption, diarrhoeal losses not proportional to effluent volume, increase Cu intake in diarrhoea, reduce intake in liver dysfunction
Chromium (Cr) µmol[d]	0.48	0.19–0.29	Glucose loading increases urinary clearance
Selenium (Se) µmol	0.95	0.51–1.01	High losses in pus + fistula fluids
Manganese (Mn) µmol[d]	25	1.1–1.8	Absorption: adults <4%, neonates up to 50%, >90% excreted in bile
Molybdenum (Mo) µmol[d]	0.52–4.17		Excreted mostly in urine, significant increased losses in short bowel syndrome; 300 µg (3 µmol)/day iv recommended in SBS patients [66]
Iodine (I) µmol	1		PN addition of 1 µg (0.008 µmol)/kg/day recommended only in depleted patients

[a] Amounts not adjusted for absorption or excess loss of nutrient
[b] Amounts based on oral Reference Nutrient intakes ([d] or safe intake) [57]
[c] Refers to patients without excess gastrointestinal losses [56, 58, 59]

dehydration (thirst/dry mouth)/over hydration (oedema, raised JVP) are assessed daily and blood tests (renal and liver function) undertaken as needed (usually 2 or more times a week). A urine output of greater than 1000 mL/24 h with a random urine sodium of 20 mmol/L or more is desirable. The energy given depends upon the oral intake, estimated absorption (which can be better predicted if a bowel length has been measured either at surgery or more commonly radiologically) [71], blood glucose and weight/muscle mass targets (which should increase in hospital). The regimen is adjusted until these are all within desirable ranges and weight/muscle mass is on the appropriate trajectory.

The HPN prescription is formulated towards the end of the patient's hospital admission when they are clinically stable and when they are consuming a similar amount of food and drink each day. Depending upon their nutritional and fluid status they are reviewed in outpatients 1–8 weeks after discharge and subsequently every 3–6 months.

Monitoring and Adjusting the HPN Regimen in Outpatients

During the multi-disciplinary clinic (MDT) visit, a brief clinical examination assessing hydration (postural blood pressure), nutritional status and underlying condition is performed. Weight, mid arm muscle circumference, triceps skinfold thickness is measured so BMI and mid arm muscle mass can be calculated, along with handgrip dynamometry and an oral intake diet history. Blood tests including renal, liver function, along with mineral (especially magnesium), trace elements and vitamins (mainly fat-soluble ones) [10] are taken and a random urine for sodium concentration is collected. Over time intestinal adaptation in patients with a retained colon may reduce the parenteral requirement for fluid, energy, nitrogen, and electrolytes. In addition, it is common for a patient's oral intake to improve at home, and this may result in less PN being needed.

Table 13 Child recommended mineral and trace element intakes in enteral and parenteral regimens[a]

	Enteral preterm (b, c) dose/kg/day	Enteral term (d) dose/day	Parenteral preterm (e, f) dose/kg/day	Parenteral term (f, g) dose/kg/day	Comments
Sodium (Na) mmol	1.3–3	9	3–5	2–4	Beware of hyponatraemia due to high insensible water loss, hypotonic diarrhoea, immature renal tubular Na reabsorption
Chloride (Cl) mmol	1.4–3.2	9	3–5	2–3	Doses of Cl above 6 mmol/kg/day may cause hyperchloraemic acidosis
Potassium (K) mmol	2–5	20	1–2	2–3	Beware of non-oliguric hyperkalaemia due to immature distal tubular secretion of K
Calcium (Ca) mmol	1.9–5.7	13.1	1.5–2.2	0.2–1.2	During low fluid intakes Ca and PO4 in PN should be in a 1:1 molar ratio and should not exceed 15 mmol/l [63]
Phosphorus (P) mmol	1.8–4.8	12.9	1.5–2.2	1–2	
Magnesium (Mg) mmol	0.3–0.8	2.3	0.3–0.4	0.12–0.5	Danger of hypermagnesaemia in renal insufficiency
Zinc (Zn) µmol	9.3–27.9	61	6.1	3.8	PN intakes refer to stable infant [67]; 2–3 times more Zn may be required during diarrhoea
Copper (Cu) µmol	1.6–3.1	3.1	0.32	0.32	PN intakes refer to stable infant [67]; do not administer iv Cu in cholestasis
Chromium (Cr) µmol[h]			0.004	0.004	Do not supplement preterm enteral formulas routinely
Selenium (Se) µmol		0.13	0.025	0.025	Do not supplement preterm enteral formulas routinely
Manganese (Mn) µmol[h]	0.04–0.24	0.3	0.018	0.018	1 µg (0.018 µmol)/kg/day induces positive Mn balance in infants without diarrhoea [67]; withhold iv Mn in cholestasis; monitor Mn status by serum levels [56] and MRI [68]
Molybdenum (Mo) µmol[h]		0.015–0.05	0.003	0.003	Do not add Mo routinely to enteral formulas or short term PN regimens [67]
Iodine (I) µmol	0.09–0.58	0.39	0.008	0.008	Infants absorb extra iodine from topical disinfectants

Table 14 Sources of parenteral micronutrients

Trace element	Addaven (µmol/10 mL)	Nutryelt (µmol/10 mL)	Tracutil (µmol/10 mL)
Zinc	77	153	50
Copper	6	4.7	12
Selenium	1.0	0.9	0.3
Iron	20	18	35
Manganese	1	1	10
Chromium	0.2	0.19	0.2
Molybdenum	0.2	0.21	0.1
Iodine	1.0	1.0	1.0
Fluoride	50	50	30

Table 15 Sources of parenteral vitamins

Fat soluble vitamin	Vitlipid adult	Cernevit
Vitamin A (µg)	990	1000
Vitamin E (µg)	9.1	10.2
Vitamin K (µg)	150	–
Vitamin D (µg)	5	5
Water soluble vitamin		
Vitamin B_1 (µg)	3.1	3.5
Vitamin B_2 (µg)	4.9	4.1
Vitamin B_6 (µg)	4.9	5.5
Niacin (µg)	40	46
Folic acid (µg)	400	414
Vitamin B_{12} (µg)	5.0	6.0
Biotin (µg)	60	69
Vitamin C (µg)	11	125

Factors with HPN That May Result in Adjusting the Feeding Regimen

Poor Sleep

Patients are often kept awake at night by the pump noise and/or its bright lights and they may get up 2–3 times during the night to pass urine. These problems can be reduced by having nights free from feed, keeping the feed volume as low as is possible to maintain hydration and running the feed through as fast as is safe. Whilst one of the main aims is to give the feed on as few nights as possible, this can usually be easily done in patients with a colon in continuity but not in patients with a jejunostomy who rapidly become salt and water depleted and need fluid daily. Some patients prefer to feed during the day and may have a backpack containing a pump and the feeding bag.

Cramps

Many complain of cramps during the feed [72]. This may be due to a low sodium concentration feed that is given quickly or due to sodium depletion. In the long-term these can be corrected by increasing the sodium content in the feed, but in the short-term immediate relief can be obtained by taking oral table salt. Magnesium depletion may also contribute.

Thirst

While thirst is most commonly due to water and sodium depletion, it can also be due to high concentrations of sodium in the feed. A low random urinary sodium gives an indication of the cause.

Faint/Nausea When Feed Stops

This can be due to reactive hypoglycaemia and may be avoided if the feed is slowed gradually over the last hour of feeding; also known as ramping the feed.

Unwell After Feeds Containing Lipid

Many patients complain of malaise, joint pains and/or nausea after a lipid feed. It can be given less frequently (e.g. once a week) or occasionally it is omitted altogether. Alternatively, sometimes changing to a different lipid preparation helps.

Frequent Feeding Bag Deliveries (Feed Bag Stability)

If a bag has good stability, it may be delivered every 2 or more weeks. If not, then it may be weekly. Stability is more likely to be a problem if there is lipid in the feed or if the feed is of a very large volume (e.g. 4 l or more).

Enteral Nutrition Regimens

The calculations for energy requirements are the same as for parenteral nutrition, however the nitrogen supplied is quoted in grams of protein. Examples of typical commercial enteral feeds are shown in Table 16. Whilst the composition of the commercial enteral feeds is set and unable to be manipulated, occasionally more sodium chloride (to bring the total sodium concentration to 100 mmol/L) is added to the feed, in patients with high output stomas or fistulae while trying to keep the osmolality near to 280–300 mOsm/kg.

Although early minimal enteral feeding (MEF) (e.g. 200 mL/day in adults) does not contribute significantly to nutrient requirements, it may help to reduce PN-associated intestinal atrophy and minimise trans-intestinal bacterial translocation. The addition of low-dose enteral feeding to intravenously fed rats has been reported to increase nitrogen retention, reduce bacterial translocation [73] and reduce PN-associated increases in macromolecular lactose permeability [74]. MEF increases neonatal gut motility and promotes the release of gut trophic hormones, such as gastrin and enteroglucagon. Enteral feeding has been reported to reverse PN-induced enterocyte atrophy in human volunteers [75] and to preserve intestinal mucosal integrity in PN-fed

Table 16 Composition of typical enteral feeds per 100 g

	Polymeric (ca 1 kcal/mL)[a]	Monomeric (ca 1 kcal/mL)[b]	Elemental (ca 0.75 kcal/mL)
Energy (Kcal)	440	440	364
Fat:CHO:Protein energies (kcal)	38:49:13	38:49:13	17:71:12
CHO (g)	60 (maltodextrin)	59 (maltodextrin)	70
Lactose	0.17	0	0
Protein	13.8 (whey protein)	13.8 (peptides, 86% of MW <1000)	10.0 (as amino acids)
Gluten	Nil	Nil	Nil
Glutamine (g)	Nil	Nil	0.09
Fat (g)	18 (arachis oil)	18 (sunflower + MCT oils)	6.64 (arachis oil)
LCT:MCT	100:1	17:83	100:1
Fibre	Nil	Nil	Nil
Osmolality (mOsm/kg)	269	389	684

[a] IF patients with normal transit time and good pancreatic function may absorb LCT

[b] Moderate osmolality, peptide content, and MCT supplementation are desirable properties in IF patients, fibre supplementation should be considered

critically ill patients [76]. These effects have been ascribed to a variety of nutrients/physicochemical properties of the feed, including its tonicity [77] and the presence of peptides [78], which have higher intestinal transport rates and higher capacity for transport than that for free amino acids [79]. Enteral glutamine has been reported to improve splanchnic blood flow in rats [80] and to reduce small intestinal damage in dogs receiving therapeutic doses of radiation [81]. However, no benefits have been observed in adult human patients suffering from 5-FU-induced mucositis [82].

Carbohydrate that is not absorbed in the small intestine (including fibre present in some enteral feeds) is fermented to short-chain fatty acids, which are subsequently absorbed for further metabolism in human tissues. Such a process can provide a substantial amount of energy (up to 4 MJ/day in a group of patients with IF) [83] and result in improved intestinal adaptation, as in rats with a short bowel [84]. Long chain triglycerides (LCT) have also been reported to improve mucosal height and leucine balance in rats with a short bowel [85]. The theoretical advantages of arginine [86] or nucleotide [87] supplementation merit further clinical evaluation. Exposing the ileal remnant to fat [88] or starch [89] retards gastric emptying (the 'ileal brake') [90] through release of peptide YY [57]. Enteral feeding is also sometimes given to distal defunctioned bowel either to give complete distal feeding or in a small amount as trophic distal feeding (see chapter "Distal Feeding and Hydration").

Neonates requiring PN (e.g. sick pre-term infants, infants recovering from necrotizing enterocolitis) may be gradually started on mother's milk or a pre-term formula, fortified with phosphate and other additives as necessary, aiming to deliver daily 110–165 kcal/kg of energy and 0.46–0.64 g N/kg in protein for pre-term infants, and 115 kcal/kg and ~ 0.29 g N/kg for term infants [61]. When enteral feeds are not tolerated MEF (e.g. 1 mL of infant formula per hour) should be encouraged.

Nursing Care of Patients Receiving Home Parenteral Support

Cathy Cawley and Mia Small

Key Points

1. The aim of nursing care of patients receiving home parenteral support (HPS) is for the patient to understand their condition, treatment and potential complications and so feel in control and able to enjoy an acceptable quality of life (QOL).
2. An intravenous catheter with the minimum number of lumens to meet the vascular access needs of the patient should be used so as to reduce the risk of catheter-related complications.
3. A peripherally inserted central catheter (PICC), tunnelled cuffed Hickman™ type catheter or totally implanted port can be used for home parenteral support (HPS).
4. The choice of device should be made between the clinical team and the patient/carer and take into account an assessment of the patient's veins (ultrasound/venography). The catheter/vein ratio should be 45% or less.
5. Catheter manipulations should be kept to a minimum, and an aseptic non-touch technique (ANTT) should be used for all procedures. Key elements of the technique include hand decontamination, not touching key parts, ensuring that sterile items do not come into contact with non sterile ones, and effective disinfection of the needle free connector/catheter hub.
6. Patient discharge on HPS requires a collaborative multidisciplinary approach which covers;
   - Funding
   - Delivery of the prescribed parenteral support
   - The ancillary items required to administer it
   - Who is going to care for the CVC
   - Ongoing support and information about how to obtain advice quickly.

Introduction

The loss of a major organ's function challenges the integrity of the whole person. Although the primary changes may be physical they have an impact on how the person thinks and feels and this can impact upon future enjoyment of life.

Some patients with intestinal failure (IF) experience only a short illness before complete recovery whereas others such as those with an entero-cutaneous fistula may have longer periods of illness, possibly being left with a stoma an open wound, or in some cases both. A few are left permanently affected requiring long-term enteral and/or parenteral support. All patients require the same level of attention to their needs. Even those who appear to have responded well to treatment and achieved excellent clinical outcomes may be left with disabling fears resulting from their experiences.

Hospital admissions can be prolonged and the external world shrinks to that around the bedside, with the healthcare team, particularly nurses who usually spend most time with the patient, becoming the focus of social contact. Interactions take place while the nurse is giving personal care and treatment. As progress is commonly very slow and the care required exacting, for example changing a fistula appliance, nursing such patients can be physically and emotionally demanding.

Support systems to maintain the well-being of nurses, enabling them cope with the stress resulting from the care of patients with IF need to be built into departmental organization. This can be achieved through strong leadership from an expert clinical nurse, staff development programs, an open environment where feelings can be shared and the clinical governance systems provide a framework for safe, up to date evidence based, low risk practice during hospital care, rehabilitation and ongoing treatment at home. Obtaining and maintaining physiological stability often takes priority over other aspects of care because the physiological consequences of intestinal failure can threaten survival and impair other functions, such as the ability to think clearly, understand and learn.

J. M.D. Nightingale (ed.), *Intestinal Failure*, https://doi.org/10.1007/978-3-031-22265-8_37

This chapter aims to outline the nursing care of patients receiving HPS. It is recognised that the set up and continuation of HPS at home will vary from country to country. Examples from the process in England where there is a national framework agreement for the supply of HPS services are given for reference. Where specific products are mentioned, this is for information only and should not be seen as an endorsement. The chapter will cover the patients' understanding of intestinal failure, equipment used, the procedures to connect and disconnect the HPS, and common problems or complications.

The Patients' Understanding of Intestinal Failure

Some of the features of intestinal failure which may include pain, nausea, diarrhoea, the effects of fistulas, difficult stomas, electrolyte imbalance and undernutrition can undermine the patients' dignity and sense of self-worth. There may be frequent, prolonged hospital admissions and numerous operations, each one being more difficult to face as the patients' experience of perioperative problems increase.

During acute illness feelings of helplessness are common and realistic. There is little the patient can control and events appear as an assault on the body and mind challenging the patients' belief in themselves as autonomous adults. For example, an inability to control the bowel and possibly seeing, and smelling, faeces draining from an abdominal wound may evoke primitive feelings about bowel function and being controlled by others in early life. Open wounds are often in a position where the patient can look into the body and see physical evidence of degeneration.

For the patient who develops chronic IF there is the daunting task of learning how to manage the condition at home, of becoming re-integrated into the family and society, and adapting expectations of daily life to one which may be different from that of other people and from their premorbid life. Until discharge the patient may not have got dressed and the transition from being in a hospital gown to putting on clothes should not be underestimated. The patient has entered an unfamiliar arena where jargon and medical abbreviations are widely, used and the nurse is well placed to provide information in a simple to understand format. It is important that the patient understand their new anatomy, how it has altered, and the length of residual bowel they have.

The patient being discharged on HPS will need to use, and find space for, numerous pieces of medical equipment. The role of the nurse is to help the patient identify where equipment will be stored in the home, alongside facilitating their understanding of the medical devices they now require, for example their central venous catheter, stoma/fistula appliances or enteral tubes.

Central Venous Catheter

Reliable venous access is required for home parenteral support. To reduce irritation to the vein it is given via a central venous catheter (CVC)—CVC or "line"—that has been inserted into a large vein with good blood flow. In most people this will be the superior vena cava. Occasionally, if this vein is not suitable/accessible the inferior vena cava is used. To reduce the risk of thrombosis the catheter tip should be at the vena cava/right atrial junction [1]. Although popular in some countries, the use of an arterio-venous fistula for parenteral support is not widely used.

Ensuring the catheter is accessible to the patient and in a position where it will not be visible when clothing is worn is of equal importance to selecting a device suitable for long-term use. The choice between a PICC, Hickman™ type catheter with an external segment and a totally implanted port should be made following discussions with the patient, although choice of device may be limited to what is available at the hospital and who holds the budget for vascular access devices. Factors affecting the choice of catheter used include how long it is needed, the condition of the veins, and lifestyle considerations. As patients with IF may require lifelong vascular access it is imperative that measures are taken to preserve the viability of the patient's veins—peripheral and central, and it is suggested that a validated assessment guide such as the UK Vessel Health and Preservation (VHP) Framework is used [2]. In addition, vein lumen size should be measured using an ultrasound as the size of catheter within the vein can result in a reduction in flow and increased rate of catheter related thrombosis [3, 4]. To reduce the risk of thrombosis a catheter vein ratio of 45% or less [3–5] is recommended. While these studies have been on PICCs the same principle can be applied to Hickman™ type catheters and totally implanted ports.

Catheters can have one, two or three lumens. To reduce the incidence of catheter associated complications—most notably infection—the minimum number of lumen to meet the patient's vascular access requirements should be selected [6–8]. Figure 1 shows a single and double lumen catheter.

The design of a triple lumen catheter is the same as a double lumen but with an extra lumen.

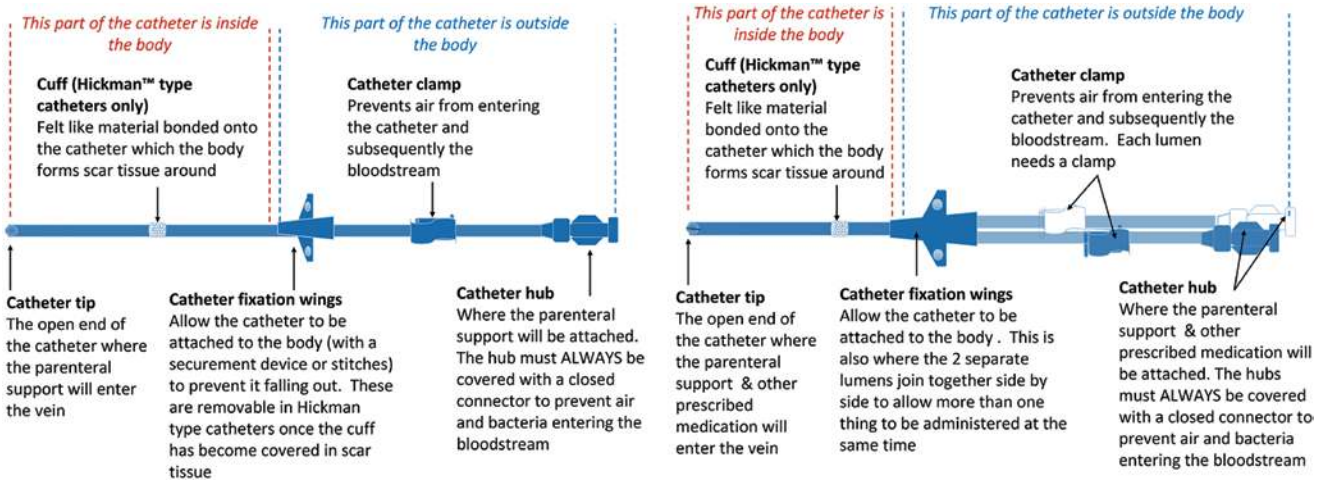

Fig. 1 Single and double lumen catheter

Peripherally Inserted Central Catheter

Peripherally inserted central catheters (PICC) are inserted via one of the veins in the upper arm with the tip lying in the superior vena cava. See Fig. 2. Single, double and triple lumen PICC are available.

Due to their ease of insertion and removal PICC are often chosen for individuals who only require home parenteral support for a few months. They can however remain in place for years. The device with the minimum number of lumen to meet the patient's vascular access requirements should be selected, and it must be appreciated that the double and triple lumen PICC will be a larger Fr gauge than single lumen devices so as to accommodate the multiple lumen (1 Fr = 1/3). This can increase the risk of catheter related thrombosis [9]. In the UK PICC are inserted directly into the vein however, some overseas centres tunnel the PICC with the intention of reducing the risk of infection and thrombosis [10]. While their study established that the tunnelling technique was successful, they conclude that the extent to which tunnelling a PICC reduces complications warrants further study.

PICCs need to be secured and covered with a sterile dressing. Careful consideration needs to be given to the method used as inadequate securement could lead to a number of complications for example; outward PICC migration, infection, vessel trauma from the catheter being able to move in and out of the vein ("pistoning"), and medical adhesive-related skin injury (MARSI) [11–13]. Broadly speaking methods can be classed as adhesive or mechanical. See Table 1.

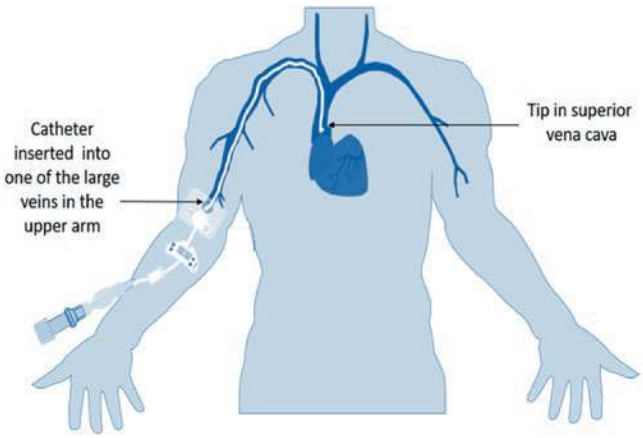

Fig. 2 Peripherally inserted central catheter (PICC)

Table 1 Types of adhesive and mechanical securement

Securement type	Examples
Adhesive	Gauze and surgical tape
	Steri-strips and semi-permeable transparent dressing
	Combination dressing and securement, for example SorbaView® SHIELD
	Manufactured sutureless device, for example Statlock®, or Griplok®
	Tissue adhesive
Mechanical	Subcutaneous metal skin anchor - SecurAcath®

Adhesive securement devices need (Fig. 3) to be changed weekly, or at any time they become loose or soiled. To reduce skin damage the manufacturers advice about removal should be followed (e.g. some must be removed with alcohol containing products).

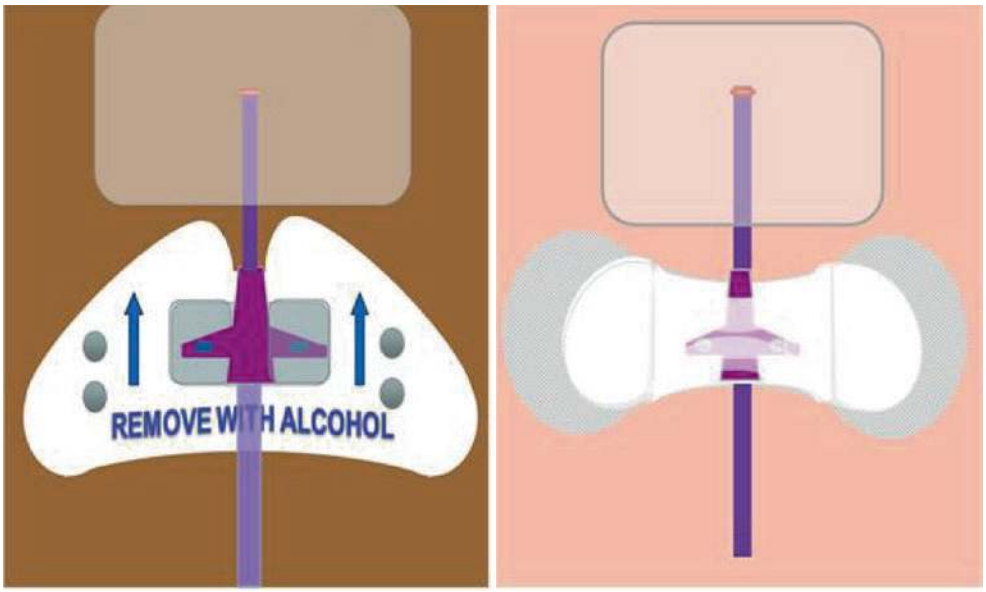

Fig. 3 Commonly used adhesive securement devices

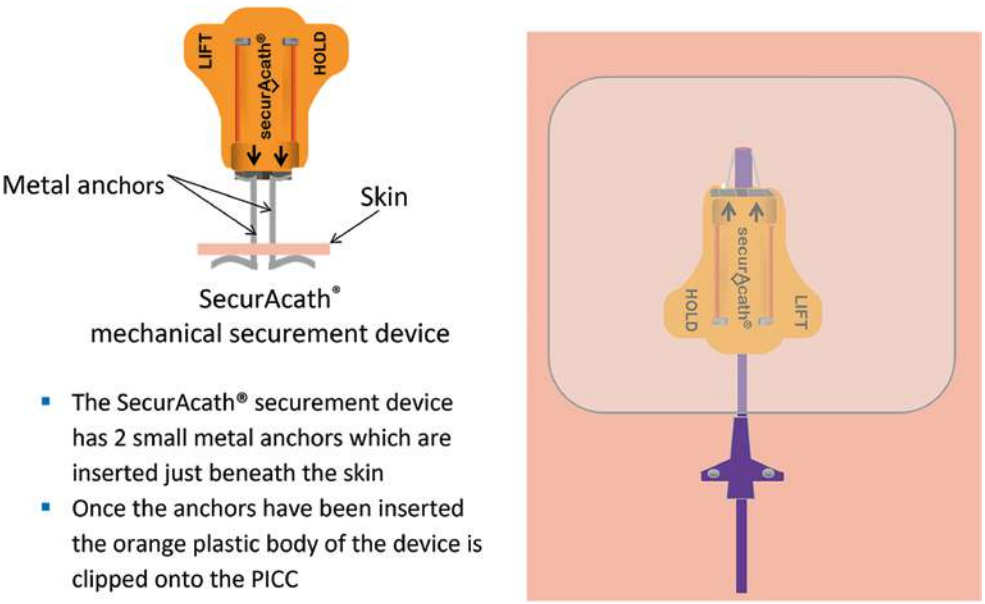

Fig. 4 Mechanical securement device—SecurAcath®

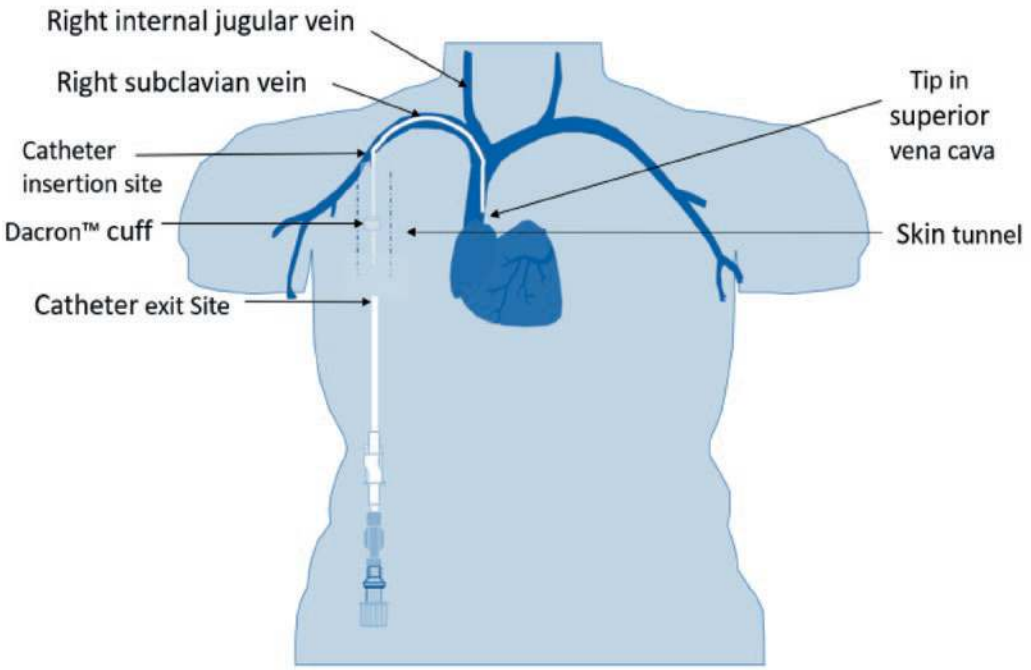
SecurAcath® has been the subject of a National Institute of Clinical Excellence (NICE) Medical Technology Assessment [12, 13]. They concluded that there was evidence to support the use of the device in reducing unintentional catheter migration especially when the PICC would be in-situ for more than 15 days (Fig. 4).

Cyanoacrylate glue has been used successfully by a number of centres to stabilise a PICC, however a review of the evidence supports its use primarily as a means to reduce post insertion site bleeding and extra-luminal catheter contamination [11].

Tunnelled Cuffed Hickman™ Type Catheter

This type of device is the one most commonly used for HPS as they can remain in place for many years (Fig. 5). It is named after Dr Robert Hickman who led the group of surgeons that developed it [14]. The catheter is tunneled under the skin to exit the body on the chest wall. It is held in place underneath the skin by a small cuff made from a felt-like material called Dacron™ that the body forms scar tissue around. The term Hickman is a trademark and refers to a tunneled catheter of a particular size made by one company;

a The catheter in situ



b The skin tunnel and cuff

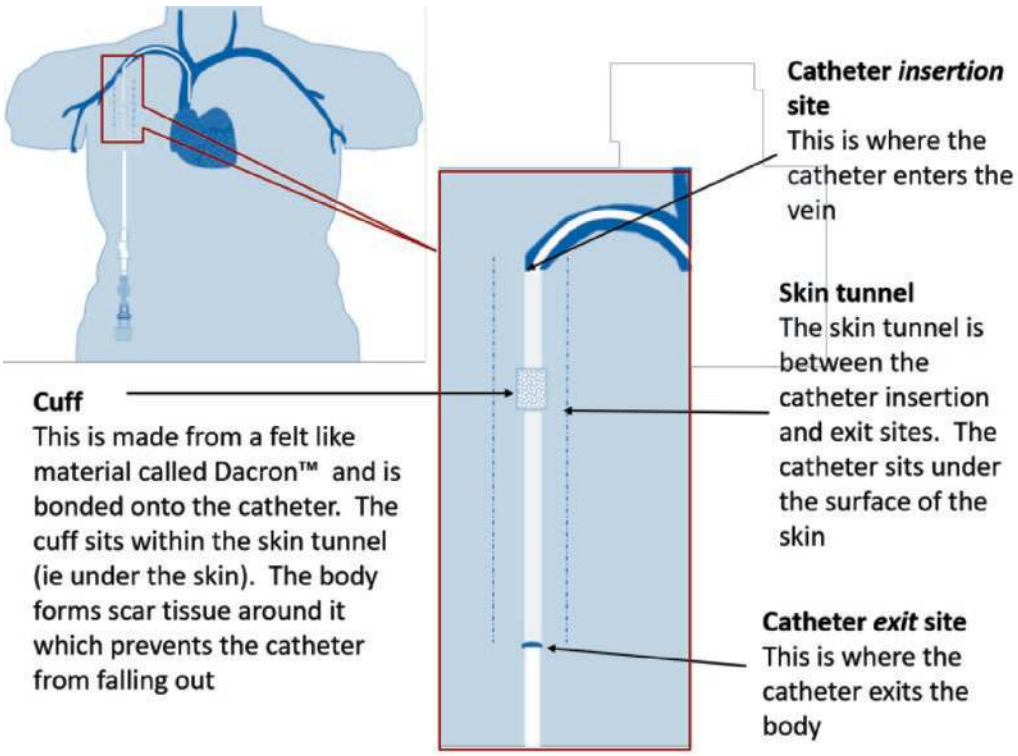


Fig. 5 Hickman™ type catheter. (**a**) The catheter in situ. (**b**) The skin tunnel and cuff

however it tends to be used to refer to any make or size of tunneled cuffed catheter. Nutrition teams often use a Broviac™ catheter, which is narrower (6.6Fr) than a Hickman™ (9.6 Fr). The smaller size is believed to reduce the risk and incidence of thrombosis as there is a better catheter : vessel ratio with the smaller sized device taking up less vessel space than the larger [3–5]. Single, double and triple lumen devices are available.

Hickman™ type catheters need to be secured until the cuff becomes embedded (Fig. 6). This is achieved by either suturing around the line or using a removable stitch fixation device which can either be sutured in place or attached with an adhesive securement device. One make of Hickman™ catheter has two suture rings bonded onto the catheter which allows sutures to be placed.

The sutures/devices only need to be in place until the cuff has become embedded—typically 3–6 weeks.

Totally Implanted Port ("Port-a-cath™")

A totally implanted port is a small metal reservoir filled with a self-sealing silicone disc. The port is inserted under the skin on the chest wall. The port has an attached catheter which is inserted into the superior vena cava via the subclavian or internal jugular vein. Totally implanted ports are often called "ports" or "Port-a-Cath™ which was the name of the first manufactured device (Fig. 7a).

The implanted port is accessed by inserting a removable infusion set with a non-coring (Huber) needle through the skin and silicone disc (Fig. 7b). Using a hypodermic needle will remove small sections of the silicone disc on removal thereby reducing the lifespan of the device. The needle needs to be long enough to go through the silicone septum and reach the back of the port. Failure to reach the back of the port can result in sluggish flow or occlusion.

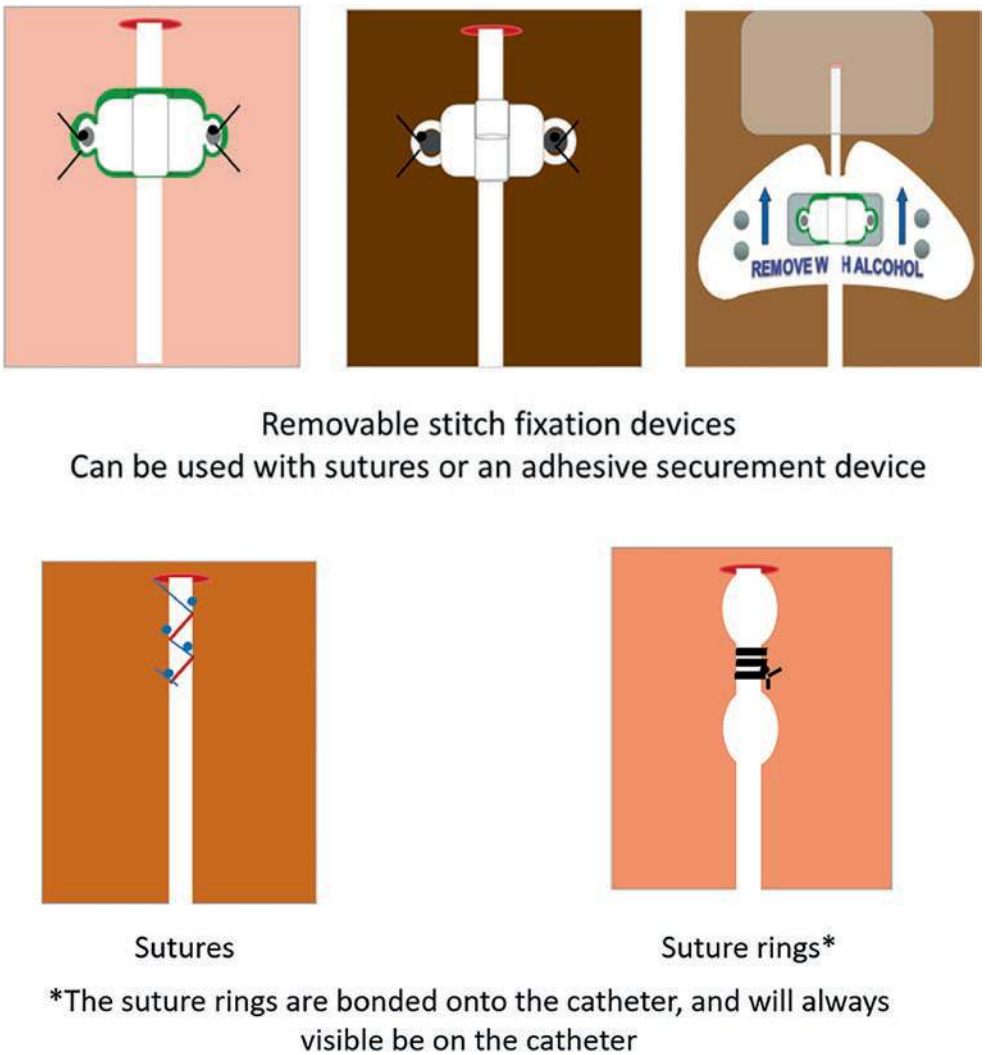

Fig. 6 Hickman™ catheter securement methods

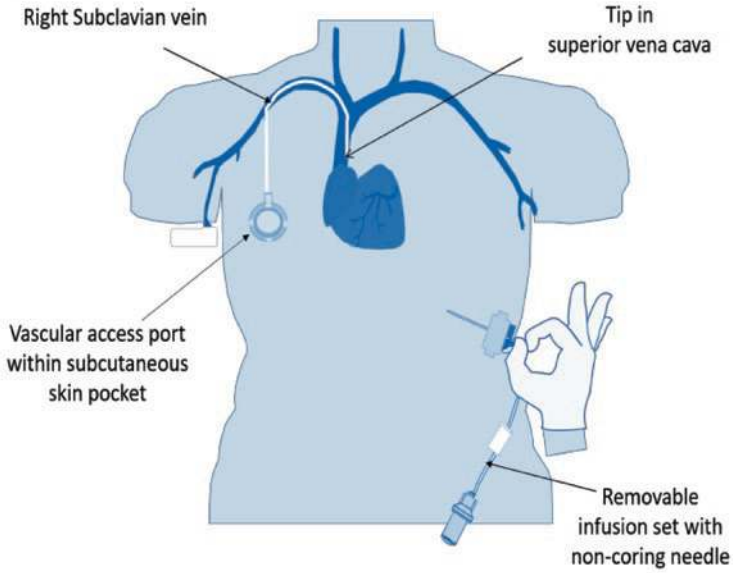
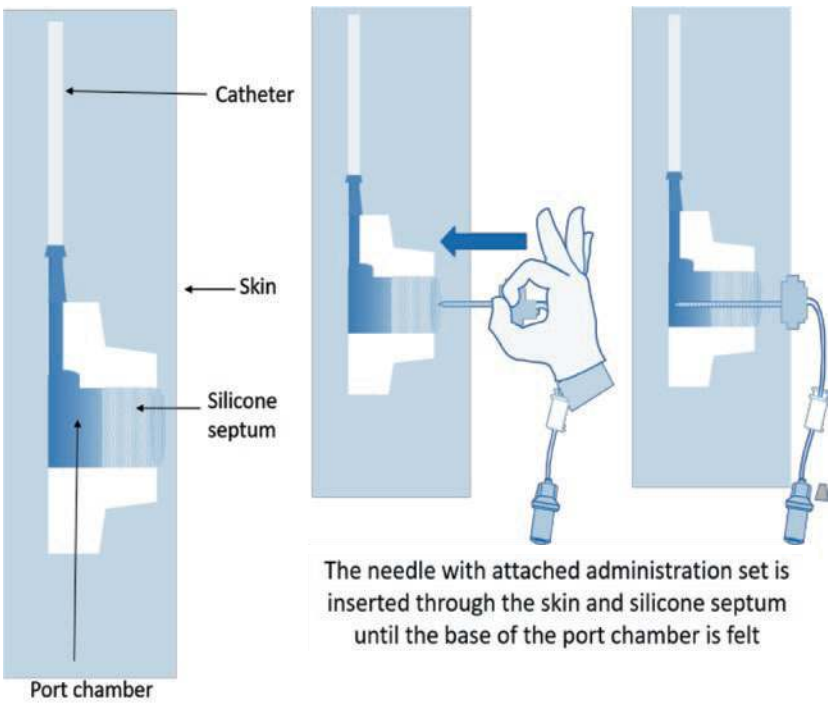
Fig. 7 Totally implanted port. (**a**) Front view. (**b**) Lateral view with the needle in the port

a Front view



b Lateral view with the needle in the port



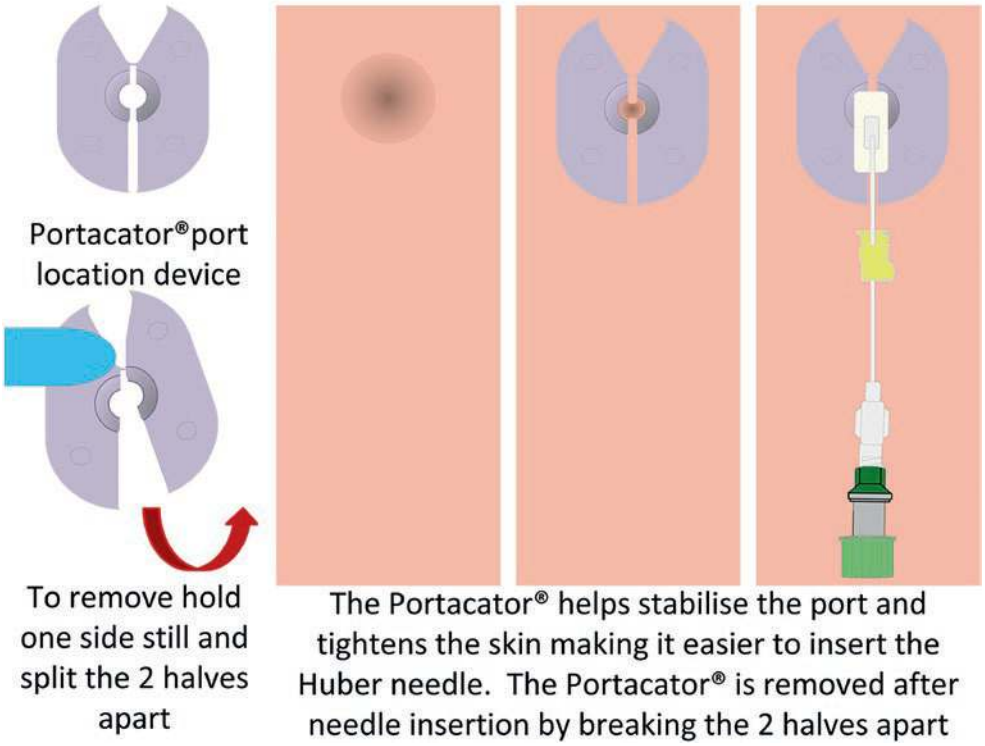


Fig. 8 Portacator® port location device

At the end of the infusion the infusion set can be removed leaving the patient with no visible device during infusion free periods. The infusion set can be left in situ for up to 7 days, however, there is no definitive data to support this [7, 15]. Further study is needed to determine how long it is safe to leave an infusion set in-situ and if this guidance would vary depending on the nature of the infusate, for example parenteral nutrition or chemotherapy.

Using an implanted port for home parenteral support relies on successful insertion of an infusion set with Huber needle. As such their use is not suitable for patients with a needle phobia.

Fluctuation in weight and how mobile the port is within the skin pocket can make insertion difficult, which can lead to missed infusions and/or the possibility of insertion in the subcutaneous tissue. Multiple attempts at insertion can not only be painful, but increase the risk of infection particularly if the same needle is used for successive attempts Using a port location device (Portacator®, PFM Medical), can help overcome this by stabilizing the port and isolating the silicone septum [15]. See Fig. 8.

Valved Catheters

Valved catheters have a pressure sensitive bi-directional valve at either the distal or proximal end of the catheter. The valve is believed to reduce the risk of blood backflow and subsequent catheter occlusion. As the valve prevents air from entering the catheter they do not have a clamp. The pressure sensitive valve is closed unless a syringe or giving set is attached and fluid injected. The valve will also open if the plunger on an attached syringe is pulled back thereby allowing blood sampling. Some patients prefer valved catheters as the absence of the clamp makes the catheter more discreet and comfortable (Fig. 9).

There is mixed evidence surrounding the benefit of a valved device vs. a non-valved one, a summary of which can be found in Table 2.

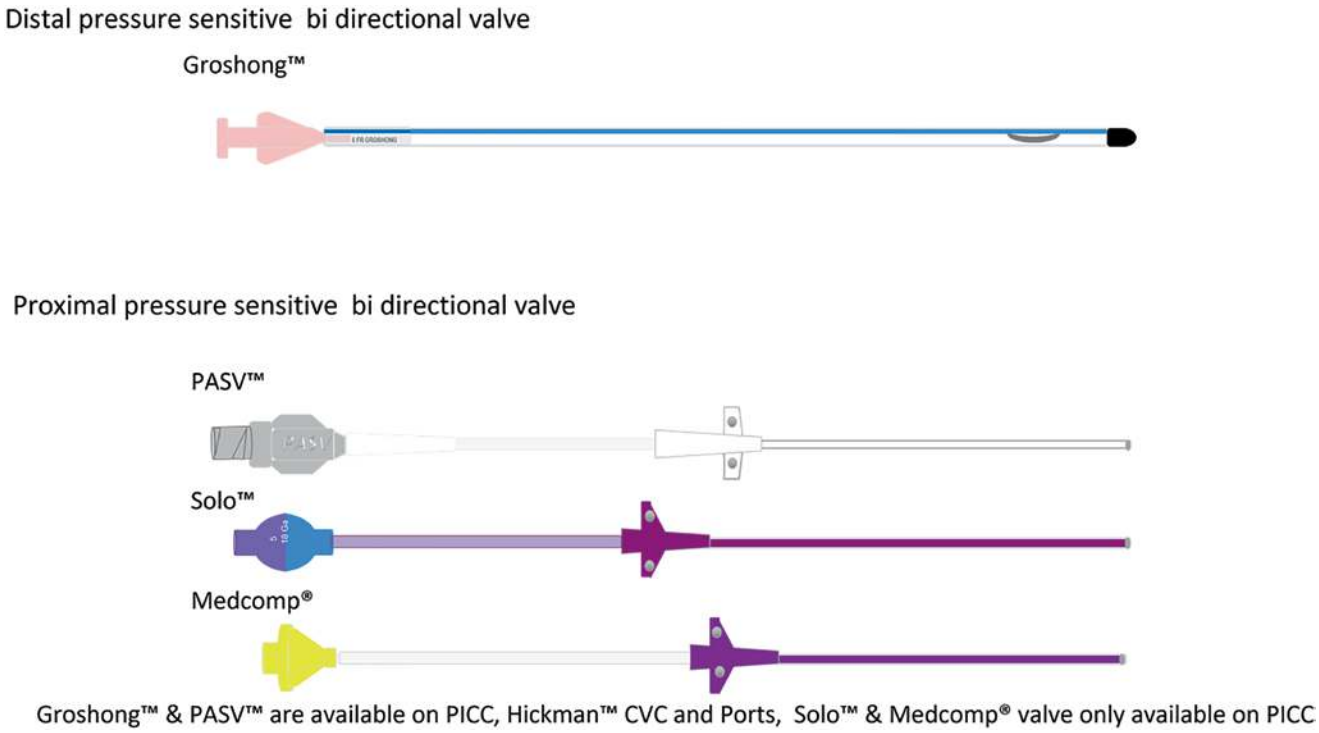

Fig. 9 Common valved catheters

Table 2 Comparison of valved vs. non valved catheters

PICC	Tunneled	Port
PASV less occlusions than Groshong, n = 100 p = 0.06 [16]	PASV easier to aspirate than non valved, n = 54, p = 0.004 [17]	More catheter malfunction valved vs non valved p < 0.05 [18]
Solo vs PASV vs unvalved, n = 180, no difference [19]	PASV easier to aspirate vs non valved, n = 73, p = 0.02 [20]	Increased ball valve effect → risk of thrombosis n = 356 p < 0.01 [21]
		n = 35 no difference in infective or mechanical comps [22]

Power Injectable Catheters

Power injectable catheters are designed to withstand power injection of CT contrast. They are available in PICC, Hickman™ type catheters and totally implanted ports. To distinguish them from non-power injectable devices they are usually purple and/or have purple hubs. This could potentially lead to wrong route administration as the purple has been adopted by most enteral tube and syringe manufacturers. Due to them being made from stronger polyurethane there is concern that their use is associated with a higher risk of catheter related thrombosis than in non-power injectable devices [9].

There are many considerations in selecting a central catheter for an individual patient (Table 3).

Table 3 Central venous catheter selection

Catheter type	Advantages	Disadvantages
PICC	• Easy to insert at bedside	• Require addition of extension set to be able to self access
	• Non invasive easy removal at the bedside	• Requires constant use of dressing and securement device
	• Waterproof covers available to allow bathing and swimming	• Visible if short sleeved clothing worn
		• Increased risk of thrombosis
		• Not all PICC can be repaired
Hickman™ type	• Longevity. Can remain in place for many years	• Requires surgical cut down to remove
	• Infected devices can often be salvaged	
	• Not visible under clothes	
	• Can be repaired	
	• Minimal scarring left on removal	
	• Waterproof covers and dressings available to allow bathing and swimming[a]	

(continued)

Table 3 (continued)

Catheter type	Advantages	Disadvantages
Totally implanted port	• Not visible when not being accessed	• Shorter lifespan than Hickman™ type device due to the eventual failure of the silicone septum to seal after needle removal
	• No need for a covering dressing when not in use	• Need to insert needle to access, so not suitable for anyone with needle phobia
	• No restriction with bathing and swimming	• Removal either under local or general anaesthetic
		• Noticeable scarring on removal
		• Salvage of infected devices difficult due to surface area of the port chamber and silicone disc, and the inability to target antibiotic therapy to all of the puncture sites a needle has been inserted
Valved	• More discreet as do not need a clamp	• Risk of air entry if valve fails
	• Valve *might* help reduce risk of occlusion	
Power injectable	• Allow power injection of CT contrast	• Increased risk of thrombosis
		• Potential for wrong route administration as purple is commonly used to denote enteral devices and syringes

[a]Several waterproof options for patients with Hickman™ are now available; Independence Activity Pouch (Independence Direct), Cath Dry™ pouch and Secuderm® dressing (Vygon UK). Within England, the Independence Activity Pouch and Cath Dry™ pouch are available via NHS Prescription, while Secuderm® can be supplied via the national framework

Needle Free Connector

A Needle Free Connector (NFC) is a removable device which permits the connection of administration sets and syringes to the hub of an intravenous catheter without the use of needles. When in situ they create a closed system which prevents air entry and minimises bacterial ingress (Fig. 10). Their use in patients on HPS is recommended to help reduce bacterial contamination of the catheter [7].

There are many different connectors available, but they all work in a similar way. The connector has an internal 2-way valve which is depressed when a syringe or intravenous giving set is applied allowing fluid to flow into the catheter. Depressing the valve also permits blood to be drawn from the catheter. The individual specification of devices varies in several ways;

- Connection surface (flat or slightly recessed)
- Dead space
- Fluid pathway
- Frequency of change
- Intricacy of valve mechanism
- Amount of fluid displacement on insertion or removal of a syringe
  - Positive connector—a small amount of infusion fluid is forced into the catheter end
  - Negative connector—a small amount of blood moves back into the catheter end
  - Neutral connector—no movement of fluid in either direction
- Clamping sequence
  - Positive connector—apply clamp after removing syringe
  - Negative connector—apply clamp before removing syringe
  - Neutral connector—apply clamp before removing syringe
- Ease of application/access

The extent to which these features *may*, or may *not*, influence catheter related complications such as infection and occlusion has yet to be determined [7, 23]. For the patient being discharged on HPS the two most important considerations are the connection surface and how easy it is for it to be effectively disinfected, and the ease of application and access. Some connectors have a smaller profile and as such can be difficult for some individuals to apply, connectors with an irregular surface may not always be adequately disinfected, while some connectors require more force to depress the valve with a syringe. Logistically, which connector is used in the home will depend on what is available locally. Under the national HPN framework for England any make of connector can be requested which means that the individual needs of the patient can be met. Manufacturer's guidance should be followed regarding the frequency of change as this can vary.

It is important that the patient knows the name of the connector they have, and that there are different brands available, so that if they are admitted to a hospital that uses a different brand they understand that this is an acceptable difference. This is particularly relevant on discharge so that the patient knows to remove the connector used in hospital and apply the one they are supplied with at home.

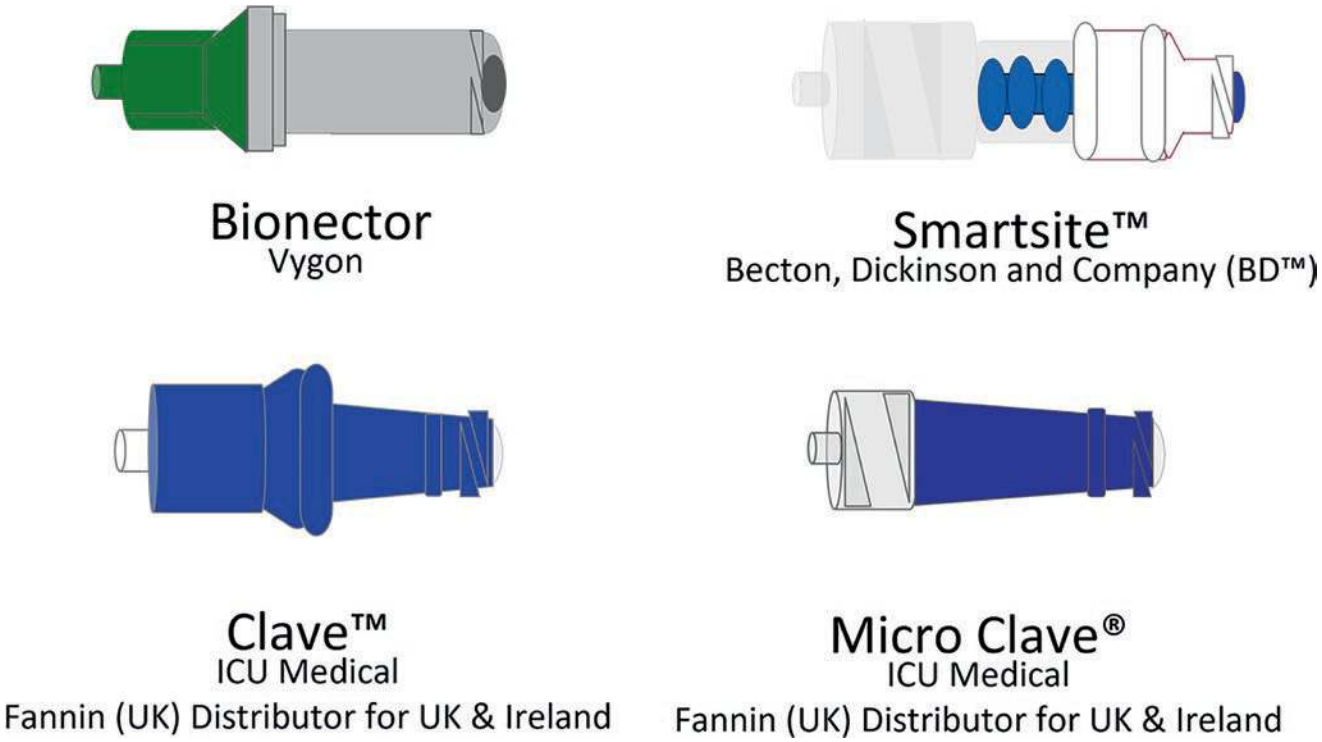

Fig. 10 Commonly used Needle Free Connectors

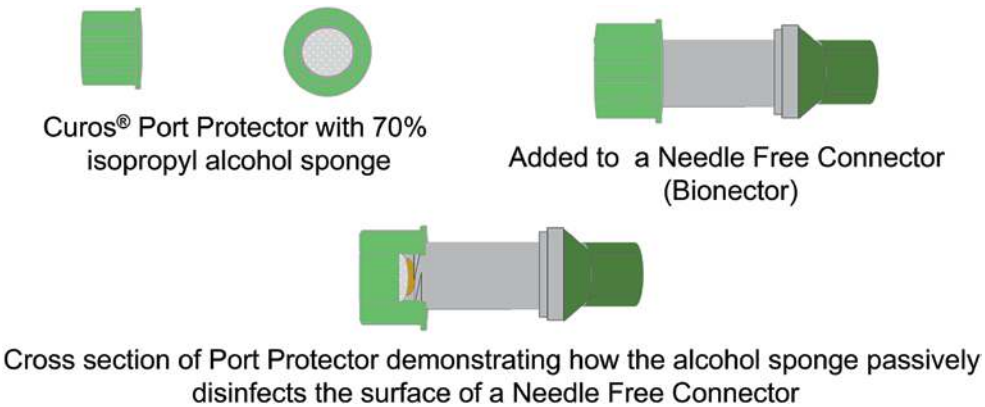
Fig. 11 Port protector cap



Port Protector Cap

A port protector cap is a single use protective cover, similar to a bottle cap in design, containing a 70% isopropyl alcohol foam disc (Fig. 11). When applied to a needle free connector during infusion free periods it provides continuous passive disinfection *plus* a physical barrier to cross contamination. There are a number of different caps available but they all work in the same way by providing direct contact with the surface of a needle free connector with 70% isopropyl alcohol.

Initial studies have shown promising results in reducing catheter related bloodstream infection [24, 25], and these have been followed by other prospective studies [26, 27], in-vitro evaluation [28] and abstract presentations also showing a reduction in infection rates As the success of passive disinfection relies on full contact of the alcohol impregnated sponge with the surface of the needle free connector knowing which brand of port protector and needle free connector was evaluated is essential. It is also important to note that to date there have not been any comparative studies evaluating each available protector on each available needle free connector. Muslim patients need to be reassured that there are no restrictions on them using any medical devices containing alcohol [29].

In-Line Filters

Although intravenous solutions may appear clear to the naked eye, they contain particles of 1–25 μm, which can induce sterile inflammation and cause granulomas elsewhere such as lungs and brain [30]. The particles consist of glass, cotton fibres, precipitated proteins, microcrystalline drug particles, degenerative products of interactions between fluids and glass, plastic and even rubber stoppers. Some arise from glass ampoules [31] and some from syringes themselves [32]. Consequently, the use of in line filtration is common practice for patients on home parenteral support, and the importance of using a 1.2 μm filter is reiterated in an American Society for Parenteral and Enteral (ASPEN) Position Paper [33]. As well as filtering out particulate matter, in line filters can also filter some harmful bacteria. It is for this attribute that The European Society of Enteral and Parenteral Nutrition (European Society of Clinical Nutrition and Metabolism) (ESPEN) recommend their use [7].

In line filters are integrated into all ambulatory pump giving sets primarily to filter out air as the giving set does not have a drip chamber. A separate in line filter should be used if patients are using a static pump. If patients are receiving any long term IV medication the use of a filter straw or needle to draw these up and reconstitute will provide additional protection against particulate matter.

Infusion Pumps

Infusion pumps and accessories used for home parenteral support have evolved over the years, with advances in the size and weight of the pump, battery life, running noise and backpack design. In England ambulatory pumps are now standard practice for all patients which is in stark contrast to 20+ years ago when only 7% of patients had them [34]. The freedom of movement with an ambulatory pump has been associated with an increased quality of life [35]. Pump selection will depend on what is available locally, but if there is a choice then consideration should be made including the parameters listed in Table 4. One pump may be more suitable for a patient than another, especially with respect to ease of inserting the giving set into the bag of parenteral support, inserting the giving set into the pump, and programming the pump.

Table 4 Pump parameters

Parameter	Comments
Pump weight and size	• Noise level increases with increase in flow rate
	• Pump weight needs to factor in weight of parenteral support bags
Battery	• Can the patient receive their full infusion on a single battery charge?
Giving set	• How easy is it to grip and insert?
	• Is the giving set kink resistant so as to reduce occlusion alarms?
	• How easy is it to place in the pump?
Backpack	• How easy is it to secure the pump and infusion fluid?
	• What carrying options, handle(s), wheels, carrying straps are available
Programming the pump and alarms	• How easy is it to programme?
	• Are keys intuitive to use and easy to depress?
	• Are pump alarms easy to understand and correct?

Adapted with permission from LITRE (Looking into the Requirements for Equipment) [36]

Central Venous Catheter Care

Reducing the risk and incidence of central venous catheter related infection is paramount in the care of patients receiving parenteral support. To reduce the risk of infection it is important to understand *how* infection occurs, and *where* infection comes from. There are a number of ways in which infection can occur. The skin surrounding the exit site is the major source of local infections, whereas the catheter hub is the major source of blood stream infections [37].

Local infections can occur if the skin becomes over colonized by micro-organisms. This could be from the environment (for example if the area is not kept covered with a sterile dressing), from the hands during dressing changes if they have not been adequately washed, from using contaminated (unclean) equipment, or contact with body fluids, for example stoma or fistula content.

Catheter hub contamination can occur from the hands, from any contact with non-sterile equipment, from using contaminated equipment, or contact with body fluids, for example stoma or fistula content.

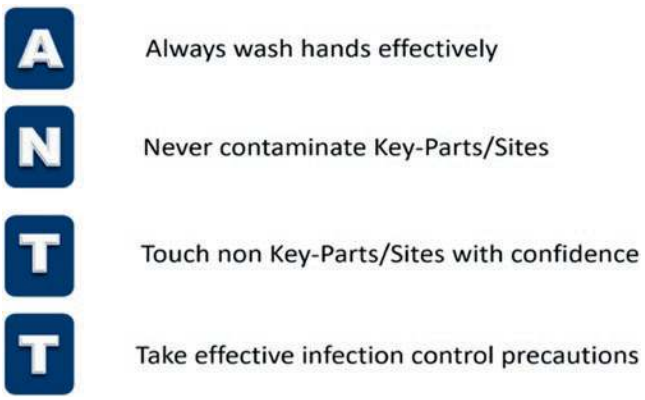


Fig. 12 General principles of ANTT®

Aseptic Technique

The risk and incidence of local and systemic infection can be significantly reduced if there are strictly adhered to procedures for the care of the catheter and administration of parenteral support. The aim of these procedures is to reduce both skin colonization *and* catheter hub contamination.

This can be achieved by using an aseptic technique. Asepsis is the **absence of** bacteria, viruses, and other micro-organisms [8]. An aseptic *technique* therefore aims to prevent bacteria, viruses, and other micro-organisms being introduced onto the skin, or into the catheter and subsequently the bloodstream. An aseptic technique is used widely in healthcare—essentially for all clinical procedures from basic wound care to surgery. There are numerous ways of effectively performing an aseptic technique, consequently there are differences between hospitals in the way it has been taught and performed, which will inevitably result in differences in how patients and carers are trained.

The acknowledged differences with how aseptic technique has been taught and undertaken led to the development of a technique known as Aseptic Non Touch Technique® (ANTT®). This was introduced with the aim of improving the efficacy of and standardizing the technique [38–40]. ANTT® has been adopted by many hospitals within the UK *and* internationally. It is a theory and practice framework using standardized principles and terminology [41]. The general principles of ANTT® can be found in Fig. 12.

Standard vs. Surgical-ANTT®

The ANTT framework describes two types of technique, Standard-ANTT® or Surgical-ANTT®, based on the complexity of the procedure and the number of Key-Sites and Key-Parts. What isn't clear from these definitions is how many Key-Parts/Sites count as numerous, which can lead to confusion and debate between health care professionals as to which technique is the correct one to use. It is important to remember that the principles are the same for each approach, so both are acceptable for central venous catheter care for home parenteral support. The most important thing is that the key principles—**"A" "N" "T" "T"** are followed as described below.

A: Always Wash Hands Effectively

Hands are the most common vehicle by which micro-organisms are transmitted; therefore effective hand hygiene is essential to remove them and reduce the risk of infection. Hand hygiene is a general term that covers both handwashing *and* hand decontamination. This can be achieved by using an antibacterial hand wash solution, or a combination of non-antibacterial hand wash solution followed by antimicrobial hand rub.

There are two types of micro-organisms present on the skin which effective hand hygiene will address;

- transient skin flora
  - These micro-organisms are acquired on the skin through contact with other people, objects, or the environment. These can be easily removed by handwashing.
- resident skin flora
  - These are micro-organisms, which have adapted to the natural condition of the skin. They live in deep skin crevices, hair follicles, sweat glands, and moist areas, such as beneath rings. These are harder to remove.

The hand washing procedure involves three stages—preparation, washing and rinsing, and drying [8].

Preparation

Forearms should ideally be free of any clothing which could impede effective hand washing or potential contamination of equipment, and rings and bracelets should be removed. If jewellery cannot be removed, the washing (and drying) of items into the handwashing technique should be incorporated. In particular, rings should be rotated to allow washing of the skin underneath them. The largest concentration of micro-organisms is found under the fingernails; therefore, nails should not be so long as to interfere with the handwashing process. There have been numerous reports linking the use of artificial nails with an increased risk of line infections [42–45]. Consequently, their use is not recommended. This may prove restrictive for some patients, and also difficult to enforce. Patients/carers should be made aware of the risk so they can make an informed decision. Although not men-

tioned in the literature, bitten nails could also be an infection risk due to the ridges and open areas present on the fingers. Nailbrushes are also not recommended as they will harbour micro-organisms, and could also damage the skin, making it more susceptible to infection

The hands should be moistened with running water before applying the liquid soap. This ensures complete coverage of the hands with soap, and also reduces the drying effect of the soap on the skin. It is important to use running water rather than standing water, for example water in a bowl or basin, as hands could become re-contaminated. The temperature of the water does not matter as it does not affect how many micro-organisms are physically removed and having the temperature too hot can lead to skin irritation.

Washing and Rinsing

Hands must be washed thoroughly to ensure micro-organisms are removed, but should not damage the skin, as this will increase the risk of infection. The procedure should take a minimum of 20 s. Liquid soap is advised rather than bar soap as this can easily become contaminated. Micro-organisms will remain on areas of the hand not exposed to soap and water therefore, the handwashing technique needs to consider *all* aspects of the hands and wrists. Hands and wrists should be rinsed thoroughly before drying so as to remove all soap debris, as this will contain micro-organisms and residual soap could lead to skin irritation.

Drying

Hands should be dried with good disposable quality paper towels. Paper towels are advised to be used as they are disposable. Cloth towels can rapidly become damp and can quickly become contaminated [8]. Some patients may want a more environmentally friendly option than using disposable paper towels. In this instance, the use of muslin cloths or cotton face flannels could be substituted. They would need to be used once only and bulk washed on their own in the washing machine at 60 °C.

The use of a clean paper towel/muslin cloth/cotton face flannel to switch off the tap, carry the rucksack or manouevre the drip stand should also be employed to protect the newly cleaned hand from re-contamination.

Hand Decontamination

In addition to handwashing, hands can be effectively decontaminated by applying alcohol hand rub. The hand rub will rapidly destroy any micro-organisms on the skin surface. Alcohol hand rub should be applied to clean, dry hands, and the hands rubbed together, following the steps in the handwashing technique, until they are completely dry.

Skin Care

Damaged or sore skin can make washing hands uncomfortable, and increases the risk of infection; therefore it is important to keep your skin healthy. In order to protect the skin warm, not hot water, should be used to wash the hands. Water that is too hot or too cold can crack the skin and allow micro-organisms to enter.

The regular use of hand lotion can help prevent chapped hands—in particular the cuticles—which can increase the risk micro-organisms entering the skin. Even skin that does not look dry to the naked eye may have small cracks in it. Hand lotion should be applied at the end of each procedure to help keep hands well moisturized. Assessing efficacy of hand washing using UV disclosing lotion is common in hospital settings and it seems reasonable to include in patient/carer teaching.

N: Never Contaminate Key-Parts/Sites

Key-Part

A Key-Part refers to the part, or parts, of a piece of equipment which if contaminated with micro-organisms could introduce infection. For example, touching, exposure to the environment, or using non-sterile equipment all have the potential for the transmission of micro-organisms. When trying to identify the Key-Parts/Sites for any procedure ask the following question *"Could touching this with unwashed hands lead to infection?"* If the answer is yes, then it is definitely a Key-Part. The number of Key-Parts will vary depending on the procedure being undertaken and also the equipment used. Figure 13 demonstrates the difference in the number of Key-Parts when accessing a Needle Free Connector with a prefilled syringe vs. a manually drawn up syringe.

Key-Site

Key-Sites are open wounds or breaks in skin integrity (such as where the catheter exits the body) which that need to be protected from contamination with micro-organisms. See Fig. 14.

Key-Parts and Key-Sites are protected during an aseptic procedure by using a non-touch technique, which as the name suggests, means not directly touching them with anything that is not sterile, or allowing them to come into contact with any non-sterile items.

In addition, the Key-Parts and Key-Sites are protected by creating an aseptic field. An aseptic field is an area created to maintain asepsis during a clinical procedure. This is achieved by using a sterile towel or sterile packaging, either to place equipment or Key-Parts on. The aseptic field needs to be large enough to protect the Key-Parts. See Fig. 15.

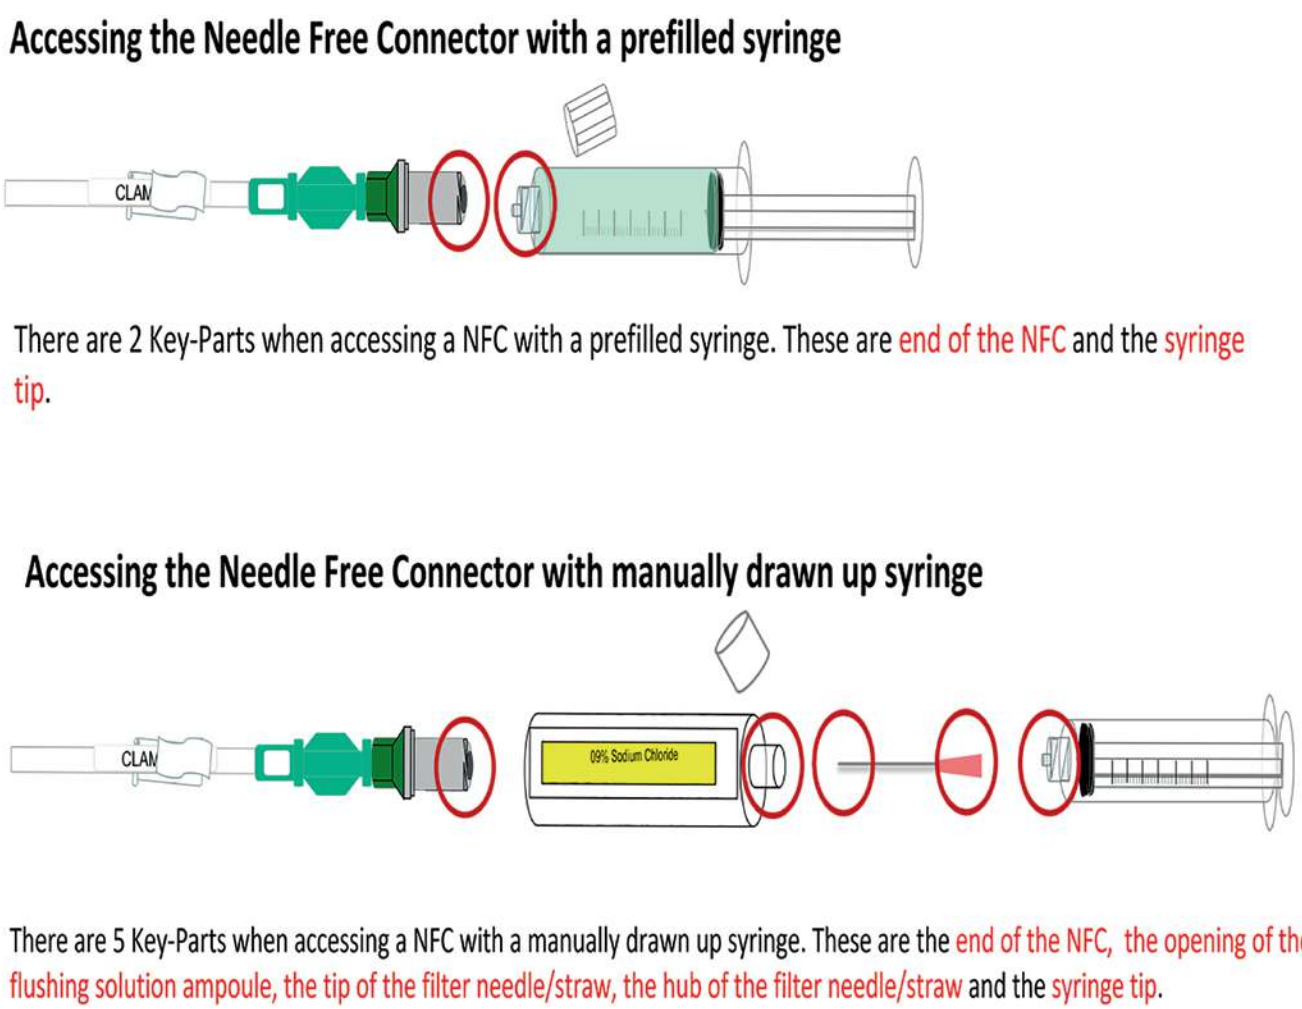

Fig. 13 Key-Parts when accessing a Needle Free Connector (NFC) with a prefilled syringe vs. a manually drawn up syringe

T: Touch Non Key-Parts/Sites with Confidence

Non Key-Parts/Sites can be touched with confidence as there is no risk of transmitting micro-organisms by doing so. Essentially, non-Key-Parts are *any* part of the equipment which is *not* a Key-Part. When trying to identify the non Key-Parts/Sites for any procedure ask the following question *"Could touching this with unwashed hands lead to infection?"* If the answer is no, then it is a non-Key-Part. Using the example outlined in Fig. 14 of Key-Parts when accessing a Needle Free Connector(NFC) with a prefilled syringe vs. a manually drawn up syringe, Fig. 16 illustrates the non Key-Parts.

T: Take Effective Infection Control Precautions

Infection control precautions include the use of personal protective equipment (PPE), and the appropriate preparation and use of any equipment (sterile or unsterile), used during the care of the catheter and administration of home parenteral support.

As more knowledge is gained around the control of infection it is possible that new products may be introduced and/or changes made to how the procedures are undertaken. There may also be temporary changes, for example, during a national pandemic.

Gloves

Gloves are worn to reduce the risk of infection during the aseptic procedures. The wearing of gloves is not a substitute for handwashing, but in addition to it [8]. Microscopic punctures can develop in the gloves, which are not visible to the naked eye, and if the hands have not been thoroughly washed this could result in contamination with micro-organisms and subsequent infection.

It has been standard practice for many years to use sterile gloves for any procedures involving central venous catheters, however, as a non-touch technique is used clean non-sterile gloves may be safely used [8, 46]. If recommending the use

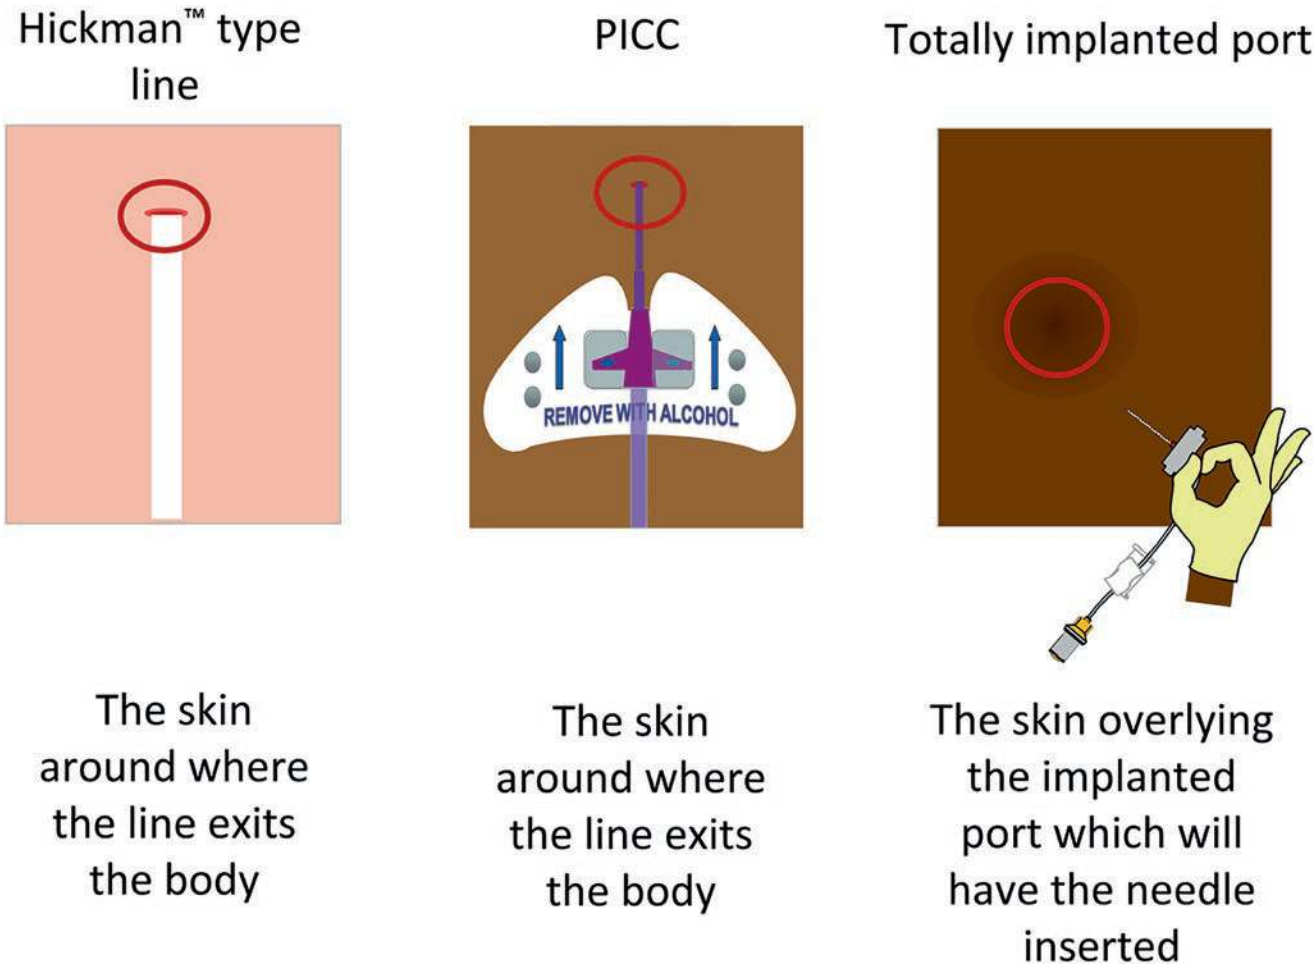

Fig. 14 Key-Sites in central venous catheter care

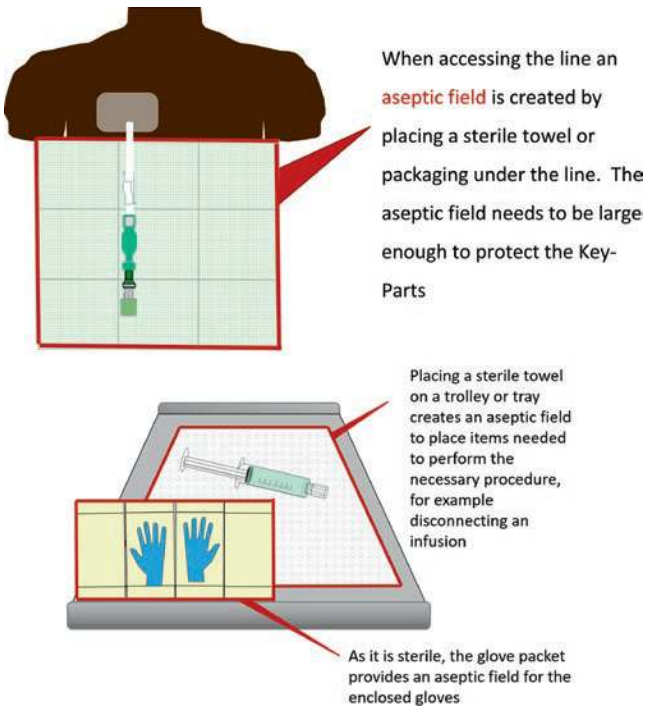

Fig. 15 Creating an aseptic field

of clean non-sterile gloves it is important to consider how they are stored prior to use and assess the potential for cross contamination. Assessment criteria should include ease of removing gloves from the box, and if it is possible to do this without contaminating the glove fingers. Patients should be advised not to replace any surplus gloves that are removed along with the ones they will be using as this could result in contamination.

Trolley/Procedure Tray

Selecting equipment for patients on parenteral support to use at home will depend on what is available locally, but it isn't always necessary to replicate what the patient has been used to seeing in hospital. An example of this is what is used to place the sterile items on in order to undertake the procedures. In hospital this will either be a trolley or a procedure tray(s), however, any flat surface that can be effectively cleaned and disinfected is suitable. Patients should be encouraged to think of what will work for them in their home environment, especially if space is limited. Whatever surface is used it needs to be cleaned and then disinfected. Cleaning

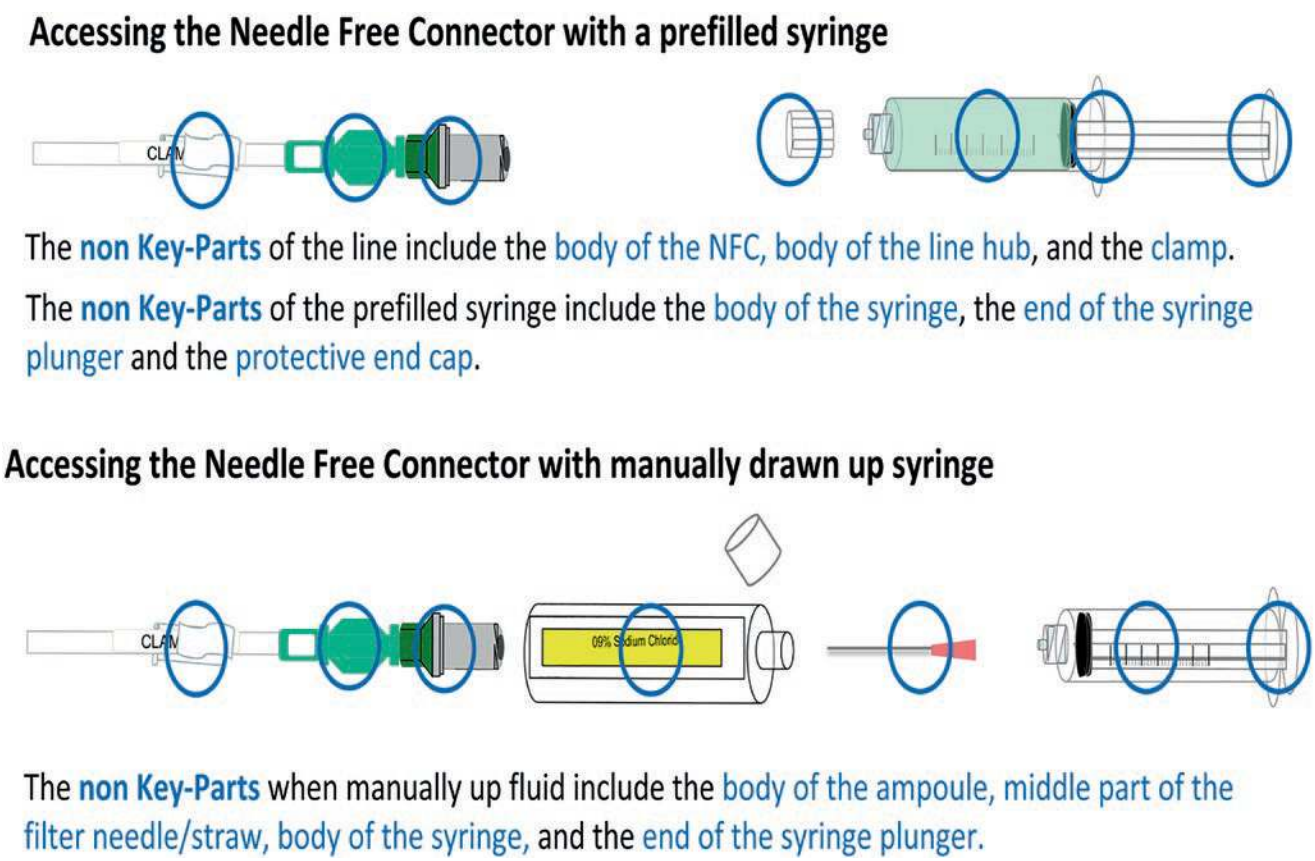

Fig. 16 Non-Key-Parts when accessing a Needle Free Connector (NFC) with a prefilled syringe vs. a manually drawn up syringe

with soap and water or a detergent wipe will remove any dust which contains micro-organisms, and visible dirt. Once this has dried the surface needs to be disinfected with either a disinfection wipe or spray. A lot of emphasis is often placed on this activity, especially whether or not it is acceptable to use a back and forth motion or to only wipe in one direction. The topic can cause a difference of opinion between nurses and often reflects the way they were first taught how to do an aseptic technique. The crucial thing is that the entire surface comes into contact with the products being used.

Needle Free Connector

The membrane of the needle free connector needs to be effectively disinfected prior to connecting a syringe or giving set to it, to avoid the transfer of micro-organisms into the line. This is probably the most important step in any procedure during which the line is accessed. See Fig. 17.

A single use sterile wipe impregnated with Chlorhexidine 2% and 70% Isopropyl Alcohol should be used for a minimum of 15 s using pressure and friction in a twisting action as if juicing an orange [8, 47]. This is often referred to as "scrub the hub". The connector should then be allowed to dry for 30 s before accessing [8]. When teaching patients/carers emphasis needs to be placed on that the membrane of the sterile end connector is the Key-Part and where the disinfection should concentrate. As the length of the catheter and clamp are non Key-Parts it is not necessary to disinfect them. Repeatedly exposing the catheter material to 70% Isopropyl Alcohol (one of the ingredients of the disinfection wipes) *could* lead to it becoming brittle over time. If it gives patients/carers peace of mind to disinfect the clamp this is fine, but it should to be disinfected *after* the membrane of the needle free connector. See Fig. 18.

Due to the importance associated with this part of any procedure where the line is accessed it seems reasonable to assess the patient/carer's efficacy in disinfecting the needle free connector membrane. This can be achieved by using dummy lines and connectors and UV disclosing lotion. The membrane is covered in UV disclosing lotion which is invisible to the naked eye. Following disinfection the patient/carer can be shown how much of the disclosing lotion they have removed by using a UV black light detector. This assessment would also be applicable for reassessing established home parenteral support patients who have developed catheter related bloodstream infection.

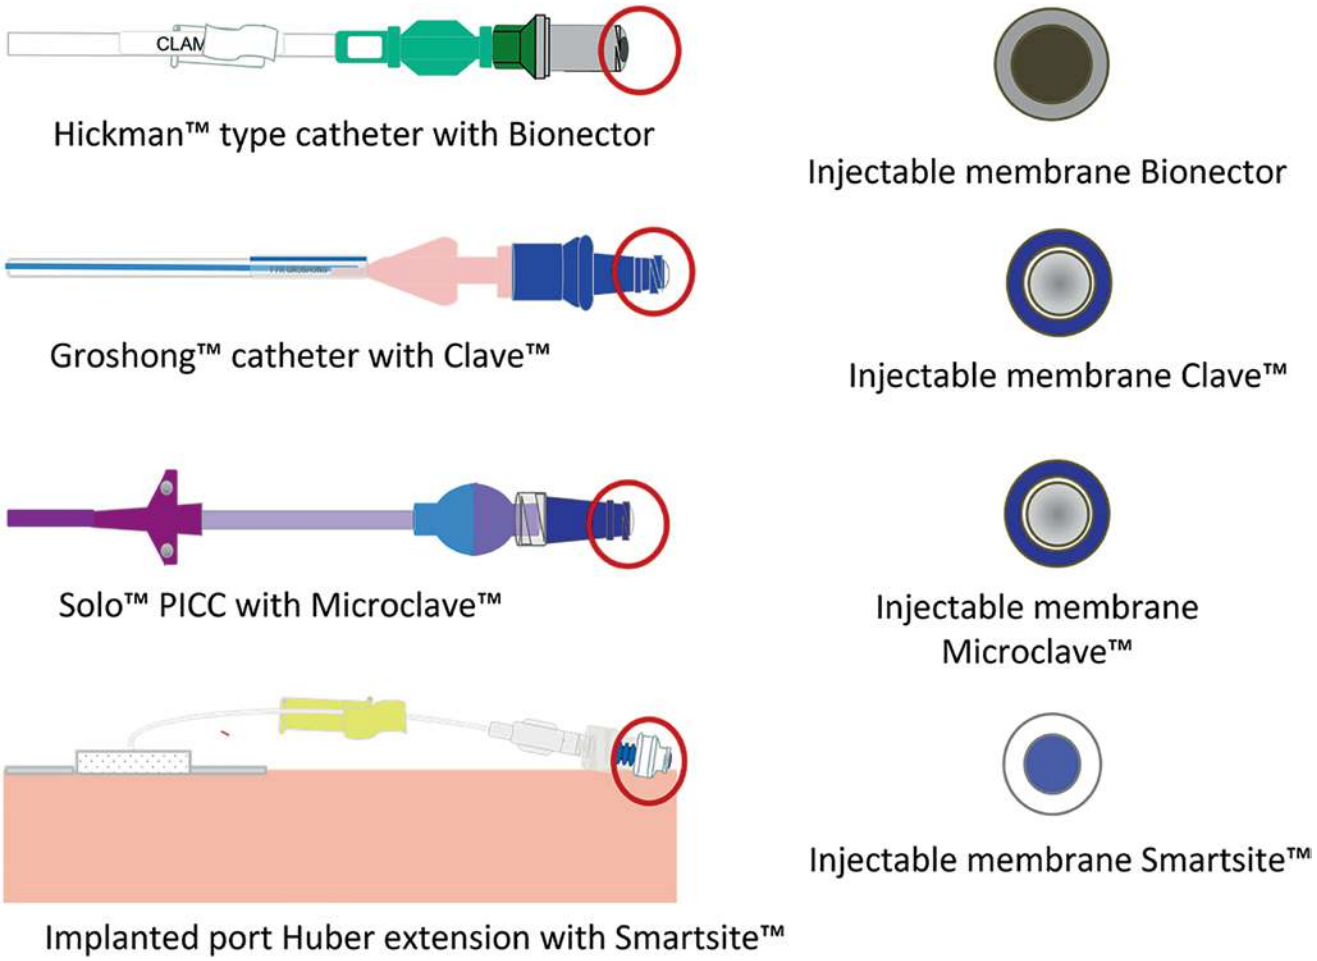

Fig. 17 Commonly used NFC showing the wipeable membrane

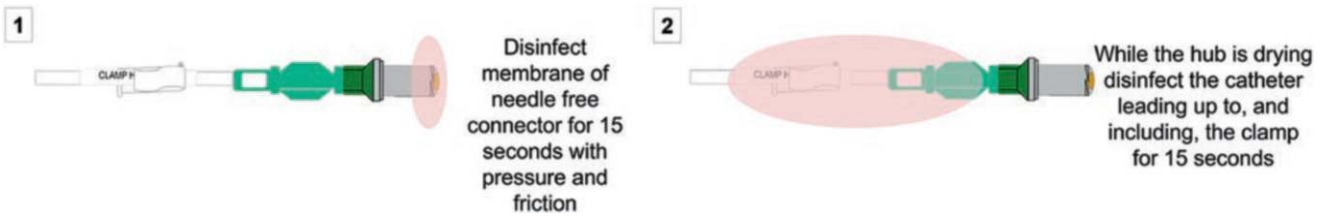

Fig. 18 Order of disinfection—membrane *then* clamp

Sterile Dressing

To protect the skin surrounding where the line exits the body from contamination that could lead to a local infection, the site needs to be covered with a sterile dressing (Fig. 19). Dressings should be vapour permeable, which means they prevent the build-up of moisture under the dressing, as this could increase the risk of infection [8]. Transparent dressings allow the exit site to be continually inspected, not just at dressing changes, however, a dressing with an absorbent pad is recommended if there is any discharge from the exit site. It is still unclear however, if there is a difference in infection rates between different dressing and securement devices [48]. When appraising the literature it is important to note the following;

- Catheter type
  - Direct venous access, PICC or tunneled Hickman™
- Dressing details including the Moisture Vapour Transmission Rate (MVTR)
  - The higher the MVTR greater the ability of the dressing to allow skin moisture to evaporate
- What type of infection
  - Local and/or systemic?

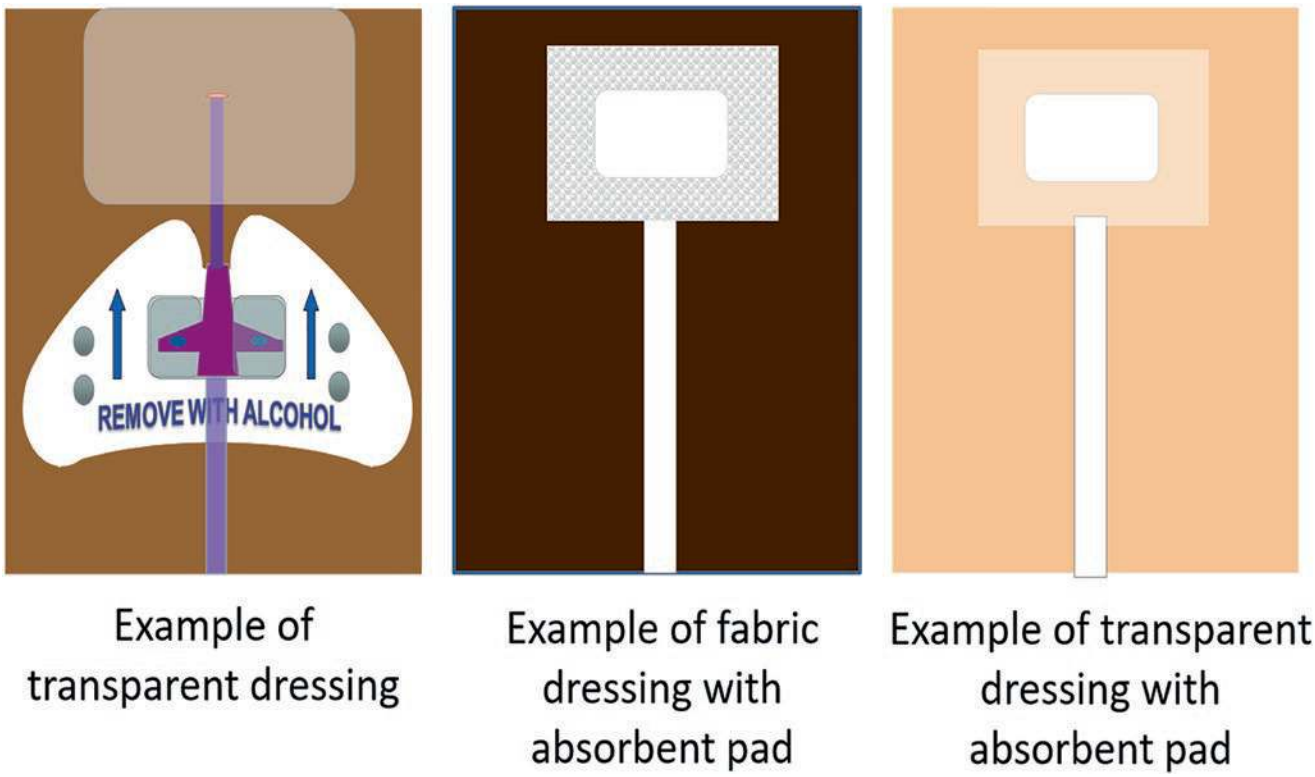

Fig. 19 Examples of sterile exit site dressings

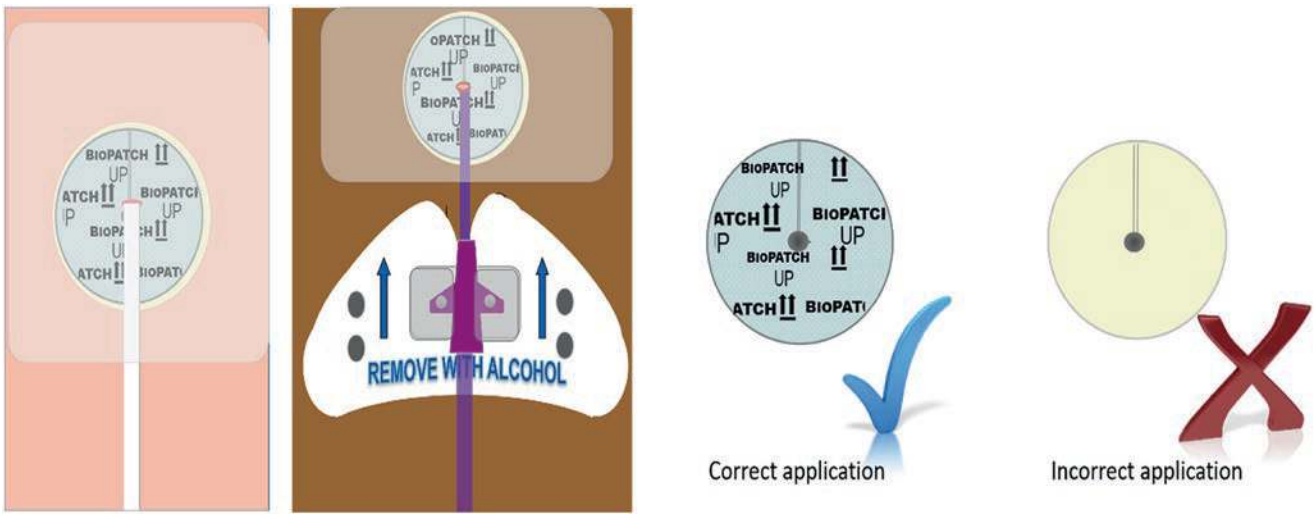

Fig. 20 Biopatch® dressing

An important consideration for the patient/carer is the ease of dressing application. There are some "1 hand" dressings available which as the name suggests can be applied with 1 as opposed to both hands.

Dressings should be changed every 7 days, or at any time they become loose or soiled [7, 8]. The dressing only needs to be large enough to cover the exit site and a few cm of surrounding skin, however, not all suitable dressings are available this small, so a larger dressings may need to be used. Sometimes it may be clinically indicated to use an chlorhexidine impregnated dressing, for example Ethicon Biopatch® or 3M™ Tegaderm™ CHG [8, 48, 49]. While these dressings do not treat infection, they may be helpful in reducing the risk of infection in individuals who have had a history of line site infections. The active ingredient is slowly released into the skin over a period of days. They should be changed every 7 days, or at any time it becomes saturated with fluid. See Fig. 20.

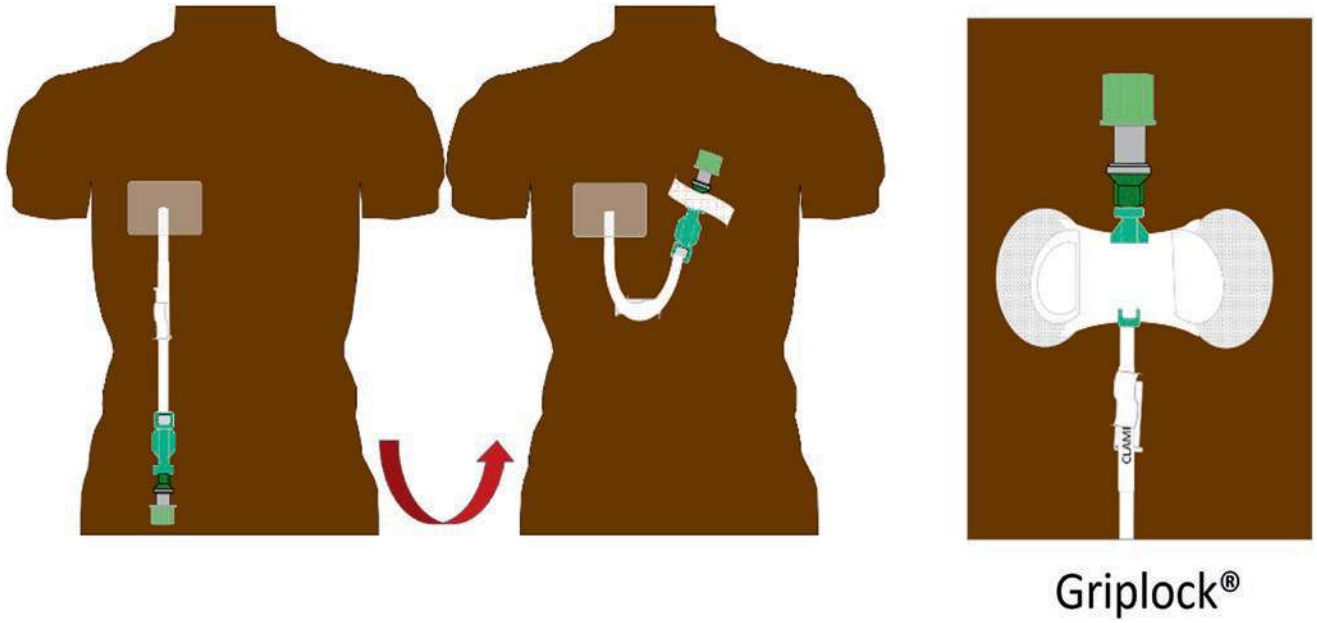

Fig. 21 Securing the catheter hub

Securing the Catheter Hub

Even if the catheter hub is protected with a port protector, for example Curos™, during infusion free periods, keeping it secured away from a stoma or fistula site is an important, but sometimes, overlooked, infection control precaution. This is particularly relevant with Hickman™ type catheters. The hub can be secured with surgical tape or a special dressing, for example Griplok® that can stay on the skin for a number of days. See Fig. 21.

It has been common practice to recommend the catheter hub is wrapped in gauze when not in use. There are a number of proposed benefits to this namely; acting as a deterrent to non-qualified staff accessing the catheter, patient comfort, and reducing the risk of infection. There is no evidence to suggest that wrapping the catheter end in gauze is an effective infection control strategy, as gauze has an open weave design which will not repel micro-organisms, and if wet *could* actually increase the risk of infection. If wrapping is done to reduce discomfort from the catheter hub and clamp from digging into the skin then this is acceptable. For catheter safety any wrapping needs to be easy to remove without the use of scissors.

BIFA Unified Protocol: Standardised Parenteral Support Catheter Guidelines

Despite the popularity of ANNT® a Royal College of Nursing investigation on the understanding of aseptic technique concluded there was still disparity in definition and standardisation [50]. As any procedure should be based on the evidence-based elements of central venous catheter care the reason behind such variation is hard to comprehend. Aware of differences in catheter care NHS England requested a standardised set of procedures so as to reduce any confusion for patients, service users and health care professionals. The unified protocol was developed by the IF units at St Marks and Salford Royal Hospitals and was supported by the National Nurses Nutrition Group (NNNG), British Association for Parenteral and Enteral Nutrition (BAPEN), and the patient support group Patients on Intravenous and Naso-gastric Nutrition Treatment (PINNT). The unified protocol outlines key principles during connection, disconnection and changing the dressing [51]. See Appendix 1 at the end of this chapter.

Catheter Related Complications

Catheter related complications can impact on morbidity and mortality therefore prompt identification and initiation of appropriate treatment is vital.

Catheter Related Infection

Catheter related infection is an umbrella term covering both systemic infection and local infection [8]. Local infections can be categorized according to the amount of skin affected

Table 5 Localised catheter related infections

Type of infection	Signs and symptoms	Suggested treatment
Exit site infection	Erythema and/or induration within 2 cm of the catheter exit site in the absence of systemic infection [37]. A purulent discharge may also be present	Targeted oral antibiotic therapy. IV antibiotics may be required if absorption is severely limited. Once resolved the use of a Chlorhexidine Gluconate dressing is recommended [8, 48, 49]
Tunnel infection	Tenderness, erythema and/or induration >2 cm from the exit site along the subcutaneous tunnel in the absence of systemic infection [37]. A purulent discharge may also be present	As the infection is more widespread targeted IV antibiotic therapy is required, although removal may be required if the infection does not respond to treatment Once resolved the use of a Chlorhexidine Gluconate dressing is recommended [8, 48, 49]
Descending tunnel infection (suggested definition in the absence of any formal definition)	Tenderness, erythema and/or induration >2 cm from the catheter vein insertion site along the subcutaneous tunnel in the absence of systemic infection. A purulent discharge may also be present	As the infection is more widespread targeted IV antibiotic therapy is required, although removal may be required if the infection does not respond to treatment Once resolved the use of a Chlorhexidine Gluconate dressing is recommended [8, 48, 49]
Complete tunnel infection (suggested definition in the absence of any formal definition)	Tenderness, erythema and/or induration along the entire length of the subcutaneous tunnel in the absence of systemic infection. A purulent discharge may also be present	As the infection is more widespread targeted IV antibiotic therapy is required, although removal may be required if the infection does not respond to treatment Once resolved the use of a Chlorhexidine Gluconate dressing is recommended [8, 48, 49]
Cuff infection (suggested definition in the absence of any formal definition)	Tenderness, erythema and/or induration localised over the cuff of a tunneled catheter in the absence of an exit site, tunnel or systemic infection. A purulent discharge may also be present	Targeted IV antibiotic therapy as the infection is likely to be deeper than in an exit site infection. The catheter may need to be removed or it may spontaneously fall out if the infection disrupts the tissue anchoring the cuff in place
Port pocket infection	Purulent fluid in the subcutaneous pocket of a totally implanted port in the absence of a systemic infection [37]	Targeted IV antibiotics

and type of device they can occur with [37]. The definitions have not been revised since 2002, and do not distinguish an isolated cuff infection, or that a tunnel infection can be ascending (from exit site up the skin tunnel), descending (from insertion site down the skin tunnel), or complete (affecting the entire tunnel). Localised infections along with signs and symptoms and suggested treatment are shown in Table 5.

Medical Adhesive Related Skin Injury ("MARSI")

While not an infection, Medical Adhesive Related Skin Injury (MARSI) can be mistaken for one, and could lead to infection if not appropriately treated. MARSI refers to skin damage from prolonged and/or frequent contact with medical adhesive. If left untreated it can lead to infection and loss of skin integrity [52]. Patients on home parenteral support may use a number of products with different types of medical adhesive; for example dressings, securement devices, surgical tape and stoma appliances. The adhesive products will need to be repeatedly applied and removed to the same areas of skin making maintaining skin integrity an important nursing consideration.

The risk of MARSI increases with inappropriate adhesive selection, application, or removal. The skin damage may not be immediately noticeable. MARSI can take the form of redness, skin tears, or blisters and be painful and very itchy. It is often mistaken for an allergy to the dressing or an infection. Secondary infection can occur if MARSI results in breaks in the skin as bacteria are able to enter.

It is thought that MARSI is largely avoidable. Things which can help minimize the risk of developing MARSI include using medical adhesive remover when removing the dressing and protecting the skin with a silicone barrier wipe prior to dressing application [53].

Other strategies include alternating the size of dressing used and/or using dressings with an absorbent pad. This helps by not having the same area of skin constantly in contact with the medical adhesive. Alternatively, a dressing with a low tack adhesive can be used.

Care should be taken not to stretch a dressing when applying it as this can cause microscopic skin tears as the skin contracts once the dressing is in place (Fig. 22). In addition, dressings should be removed as per manufacturer's

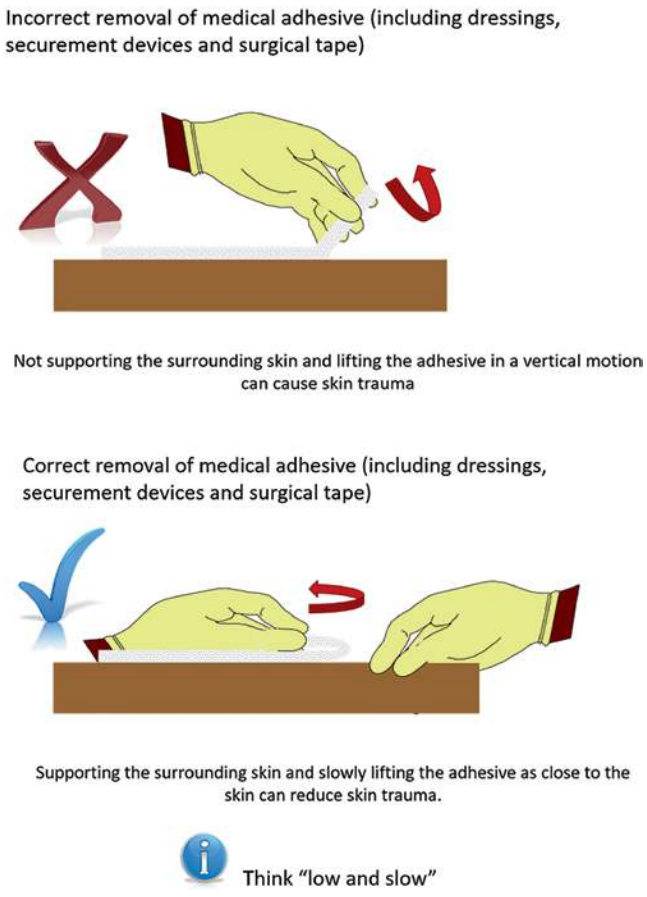

Fig. 22 Removing medical adhesive from the skin

guidelines. For example, some dressings need to be removed using alcohol-based products, or by being stretched outward to remove the contact with the adhesive, as opposed to lifting them off. When lifting off a dressing the surrounding skin should be supported, and the dressing peeled back slowly and as close to the skin as possible. This has been termed the "low and slow" method [54].

Systemic Infection: Catheter Related Blood Stream Infection

Of all of the potential complications of home parenteral support, catheter related bloodstream infection (CRBSI) is arguably the one which patients fear the most. Patients/carers need to be aware of how systemic infection can occur, alongside how it can present and the implications of not seeking urgent medical attention. Information needs to be given in simple language the patient understands without causing undue anxiety, however does need to include some medical terms, such as bloodstream infection or sepsis, so that patients are able to accurately convey their concerns to healthcare professionals. Patients with signs and symptoms of CRBSI often say they think they have a "line infection" which to health care professionals not used to caring for patients with long term CVC suggests a local skin infection rather than a systemic infection. This misunderstanding could lead to ineffective treatment, or even no treatment, being initiated. Providing patients with pre printed proforma letters for common complications can aid in them accessing appropriate treatment if they attend the emergency department.

Not everyone with CRBSI present with the same symptoms, and it is important to help the patient recognize symptoms which may be subtle, for example, general malaise or thinking they have a cold, or overt such as a temperature of 38 °C or more and rigors. It is also important to note that a temperature of less than 36 °C or less can indicate systemic infection, which may not seem obvious to patients. Patients should be advised that while symptoms are often experienced during an infusion or post flushing the catheter, they *can* also occur during infusion free periods.

To be able to benchmark outcome measures it is suggested that IF centres aim for an inpatient catheter related bloodstream rate of less than 3/1000 catheter days and an outpatient one of less than 1/1000 catheter days [55]. To date, there has been no recommendation to report infection rates per type of device. As the risk of catheter related infection varies between PICC, Hickman™ type and implanted ports it seems reasonable to suggest reporting individual device infection rates in addition to the overall rate. The identification and treatment of CRBSI is covered in chapter "Prevention, Diagnosis and Management of Catheter-Related Blood Stream Infections".

Catheter Occlusion

Reduction in central venous catheter patency can result in missed infusions and if not resolved will require insertion of a new device. Central venous catheter occlusion may be thrombotic or non-thrombotic in nature. Thrombotic occlusions arise from the formation of a thrombus either within, surrounding, or at the line tip. They can also arise from backflow into the catheter during infusion free periods, or failing to adequately flush the catheter post blood sampling [56].

Non-thrombotic occlusions can occur from particulate debris or lipid particles [57]. There are also numerous mechanical causes of occlusion and it is important to exclude any of these before considering pharmaceutical intervention. See Table 6.

Occlusion can be complete where it is not possible to instill or aspirate anything, partial where there is resistance on instillation, or a persistent withdrawal occlusion (PWO) where fluids may be infused but it is not possible to withdraw

Table 6 Mechanical causes and interventions of occluded central venous catheters

Possible cause	Intervention
Kinked/clamped line	1. Straighten line
	2. Ensure line clamp is open
	3. Examine reinforcement sleeve for indentations & massage line between thumb and index finger to remove any kinks
Faulty Needle Free Connector	Remove connector and reassess patency by flushing with 0.9% sodium chloride for injection directly via line hub
Faulty pre filled syringe	Try flushing with a new prefilled 0.9% sodium chloride for injection syringe in case the seal on the one used previously wasn't completely released
Obstruction within line hub	1. Direct observation inside the catheter hub to check no obvious obstruction, for example a sponge from Curos™ Port Protector
	2. If connection between hub & line is obscured consider manual extraction of debris. Manual extraction of debris should not be attempted in catheters with proximal valves, for example PASV™ or Solo™ valves as this could damage the valve
Constriction of sutures/dressing	Remove any potentially constricting sutures/dressings. (re-suture if catheter in-situ <3 weeks)
Catheter tip against vessel wall	1. Change patients position (supine/upright or vice-versa)
	2. Try the Valsalva manoeuvre and reassess patency
Catheter tip migration or malposition	1. Check notes and/or CXR for initial tip placement
	2. Perform repeat CXR to assess current tip position
	3. Measure external length of catheter (PICC) and compare against length on insertion
"Pinch-off" syndrome (subclavian vein catheters only)	1. Check patient's notes for verification of venous access route
	2. Assess if the occlusion is intermittent or positional (relieved by rolling shoulder forward or raising arm on ipsilateral side). If the occlusion is relieved by rolling the shoulder or raising the arm the CVC will need to be removed and replaced as there is no treatment for pinch-off syndrome
Implanted ports: needle displacement	1. Insert new Huber™ needle and reassess patency
	2. Consider inserting longer needle if the back of the port is not felt
Displacement/ misalignment of catheter repair segment	1. If the metal spike from the catheter repair segment has dislodged then the segment may no longer be in alignment with the native catheter. This will restrict flow
	2. If a patient has a repaired catheter consider removing the repair segment and performing a new repair

blood [58]. Simple strategies to resolve a PWO include changing the patient's position (e.g. raising their arms above their heads or asking them to cough). While thrombus, lipid and precipitate (protein or drug deposits) can all cause PWO, the commonest cause is a fibrin sheath formed around the catheter [59, 60].

A fibrin sheath is a collection of fibrin and platelets that can be demonstrated in 40% of all catheters with radiological screening after radio-opaque dye has been injected down the catheter [61]. It starts from where the catheter enters the vein and spreads towards the tip. It does not generally cause a problem until it surrounds the catheter tip when it may classically act as a one-way valve such that a solution can be infused down the catheter but not withdrawn.

Treatment of Catheter Occlusion

Simple strategies should be tried first, such as asking the patient to raise their arms and cough, and massaging out any kinks within the clamping reinforcement area. Having atraumatic clamps to hand is essential to be able to clamp the catheter should any attempt to restore patency results in catheter rupture. Gaining a history of the occlusion will help guide treatment options, for example;

- Was it sudden onset?
- Has the catheter been getting sluggish over a period of time?
- Has the catheter been used for blood sampling and not flushed afterward?
- Have they noticed any blood leaking from the needle free connector?
- Is the catheter used for any medication?
- Does their parenteral support regimen include lipid containing bags?

It is also important to rule out catheter related thrombosis as a cause.

Possible signs of thrombosis include;

- Ipsilateral swelling of the arm, neck, head or face
- distended collatoral circulation over chest wall
- Jaw and shoulder pain
- Headaches and/or a feeling of head fullness
- Localised pain and or numbness [62]

Catheter Related Thrombosis Is Covered in Chapter "Central Vein Thrombosis"

Any attempts to unblock CVC should only be attempted by healthcare professionals who are experienced with the management of such devices and have demonstrated competency in the procedures and management of any potential complications for example catheter rupture.

As part of the initial assessment of a blocked catheter to determine the nature of the occlusion it is recommended that the catheter hub is directly observed to identify if the opening between the catheter hub and catheter has become obstructed with any debris or foreign body, for example a sponge from a port protector. There should be a clear pin prick opening visible when the inside of the catheter hub is viewed. Any visible debris can be removed by using a green (21G) safety needle. The technique should not be attempted on catheters with a proximal valve, for example PASV™ or Solo™. While this may seem an unorthodox method, it must be appreciated that only the external catheter hub is being manipulated. In some cases this method is the only intervention required to restore patency. In a case series of 39 (30 total, 9 partial) occlusions hub clearout with a green (21G) needle was used successfully in 5 (17%) episodes of total occlusion. In 2(7%) episodes this was the only method used. Of the 9 partial occlusions, hub clear out alone was used on 7 (78%) occasions [63].

Before instilling a pharmaceutical agent it is also suggested that manipulation with 0.9% Sodium Chloride for Injection is attempted. During this method a 10 mL Luer lock syringe with 5 mL 9% Sodium Chloride for Injection is attached directly to the catheter hub. A gentle back and forth motion on the syringe plunger is then employed to see if this will dissolve the obstruction. The plunger should only be depressed up to the level of resistance, as forcing the plunger all of the way in could result in catheter rupture. If this process is successful debris from the catheter will become visible in the syringe. Patience is required as it can take up to 30 min plus to dissolve all of the intraluminal debris. Although this method is not cited in the literature, it has been standard practice at St Mark's Hospital UK for more than 20 years.

If these methods do not restore patency then instillation of an appropriate pharmaceutical agent can be considered. During instillation the catheter needs to be monitored catheter closely for signs of "ballooning" or traumatic fracture, and it is essential to have atraumatic clamps close to hand in case of catheter rupture. If the instillation of the selected pharmaceutical agent actually resolves the occlusion, the patient should be observed for at least 30 min. Although uncommon, patients may develop systemic sepsis following restoration of patency and so should be advised of this potential risk, and the need to seek urgent medical treatment if they become unwell. If the pharmaceutical agent is being left in situ for a set time period it is advisable that the patient return for removal of the drug and reassessment of patency by an experienced healthcare professional as opposed to the patient doing this themselves at home.

The evidence supporting the use of different pharmaceutical agents is mixed with studies using different doses, mode of instillation (bolus or infusion) and different dwell times. The type of occlusion (full, partial or complete) is not always mentioned, or the catheter type (PICC, tunneled or implanted port), number of lumens (single, double or triple), catheter material (silicone or polyurethane) valved or non-valved devices and size of syringe used. All of these variables could impact on the results. A review of thrombolytic treatment of catheter occlusion concluded that further randomized comparative studies were needed to determine the most effective management for catheter occlusion [64]. Table 7 outlines commonly used pharmaceutical agents for unblocking central venous catheters. From this it can be appreciated that there is the most evidence supporting thrombotic occlusions, and very scant evidence for occlusions resulting from lipid or drug deposits. There may be restrictions on use in some countries, for example Urokinase is not licensed for use in the United States [64] and Hydrochloric Acid [71] which was used to dissolve drug precipitate is no longer available in the UK.

Table 7 Commonly used pharmaceutical agents for unblocking central venous catheters

Urokinase	Alteplase (t-PA)	Ethanol	Sodium hydroxide
n = 19. 5000 units Urokinase, 5–10 minutes dwell time followed by attempted aspiration, repeated every 5–10 min for a maximum of 30–60 min or successful clearance. Successful restoration in 6 of 19 (32%) cases [65]	n = 25. t-PA 6 occlusions failed to clear with 10,000 units Urokinase 4 h dwell time, 5 of these successfully cleared with 2 mg/2 mL t-PA 4 h dwell time [66]	n = 5. 3 mL Ethanol 70%, 1 h dwell time, patency restored in 4/5 (80%) cases [67]	n = 13 totally implanted port. Partially occluded. 10 mL 0.1 Sodium Hydroxide solution at a rate of 1 mL per hour followed by a 2 h lock. Increase in patency determined by formal assessment of gravity flow rate pre and post intervention. All 13 cases demonstrated an improvement in flow rate [68]
n = 19. 6 h Urokinase 40,000 units per hour. Patency restored in 15/19 (79%) cases [69]	COOL 1 trial. n = 995. Single lumen 26%, double lumen 39%, triple lumen 6% and totally implanted ports 29%. 2 mg t-PA, dwell time 30–120 min. Single dose-restoration of patency in 52% devices at 30 min and 78% devices at 120 min. Second dose—restoration of patency in 84% devices at 30 min and 87% at 120 min. Restoration of patency 86% single lumen devices, 93% double lumen devices, 90% triple lumen devices and 79% totally implanted ports [70]	n = 9. 70% Ethanol up to 3 mL, patency restored in 7/12 (58%) cases. 0.1 Hydrochloric acid up to 3 mL bolus with second dose if unsuccessful left for up to 1 h. Patency restored in 2/3 (67%) cases [71]	
PASSPORT 1 trial. n = 200. Bolus with 12,500–50,000 units Urokinase, or catheter infusion with 100,000–250,000 units of Urokinase. The cumulative success rate for thrombolysis was 90.5% after first intervention, 97% after second intervention, and 99% after three [72]			
PASSPORT 2 trial. n = 117. 53% withdrawal occlusion, 47% total occlusion, Withdrawal occlusion patency restored in 80% cases, total occlusion patency restored in 88% cases. Success dose dependent, 83% success with 5000 units Urokinase, 92% with 25,000 units Urokinase [73]			

Syringe Techniques

Applying a specific syringe technique, on its own or in combination, with 0.9% Sodium Chloride for Injection or pharmaceutical agent, can aid in the restoration of patency. A Luer lock, rather than a Luer slip, syringe must always be used so as to prevent the syringe being expelled during the unblocking procedure. A 10 mL syringe should be used to avoid catheter damage, however only part filling this can be beneficial as it makes it easier to assess the level of blockage. The amount of "give" within the catheter can be determined by pressing the syringe plunger with the thumb. If there is total resistance this suggests that the occlusion affects most of the catheter, whereas if it is possible to depress the plunger with some back and forth motion this suggests that the occlusion does not affect the entire catheter and instillation of any pharmaceutical agent will be possible.

Negative Pressure Technique

This is achieved by using 3 way tap, although it can be undertaken without. The aim is to create a vacuum within the catheter which will then automatically draw whatever fluid is being used to restore patency, i.e. 0.9% Sodium Chloride for Injection, Urokinase, Alteplase or Ethanol [74]. Figure 23 illustrates the negative pressure technique using a 3 way tap or with a single syringe.

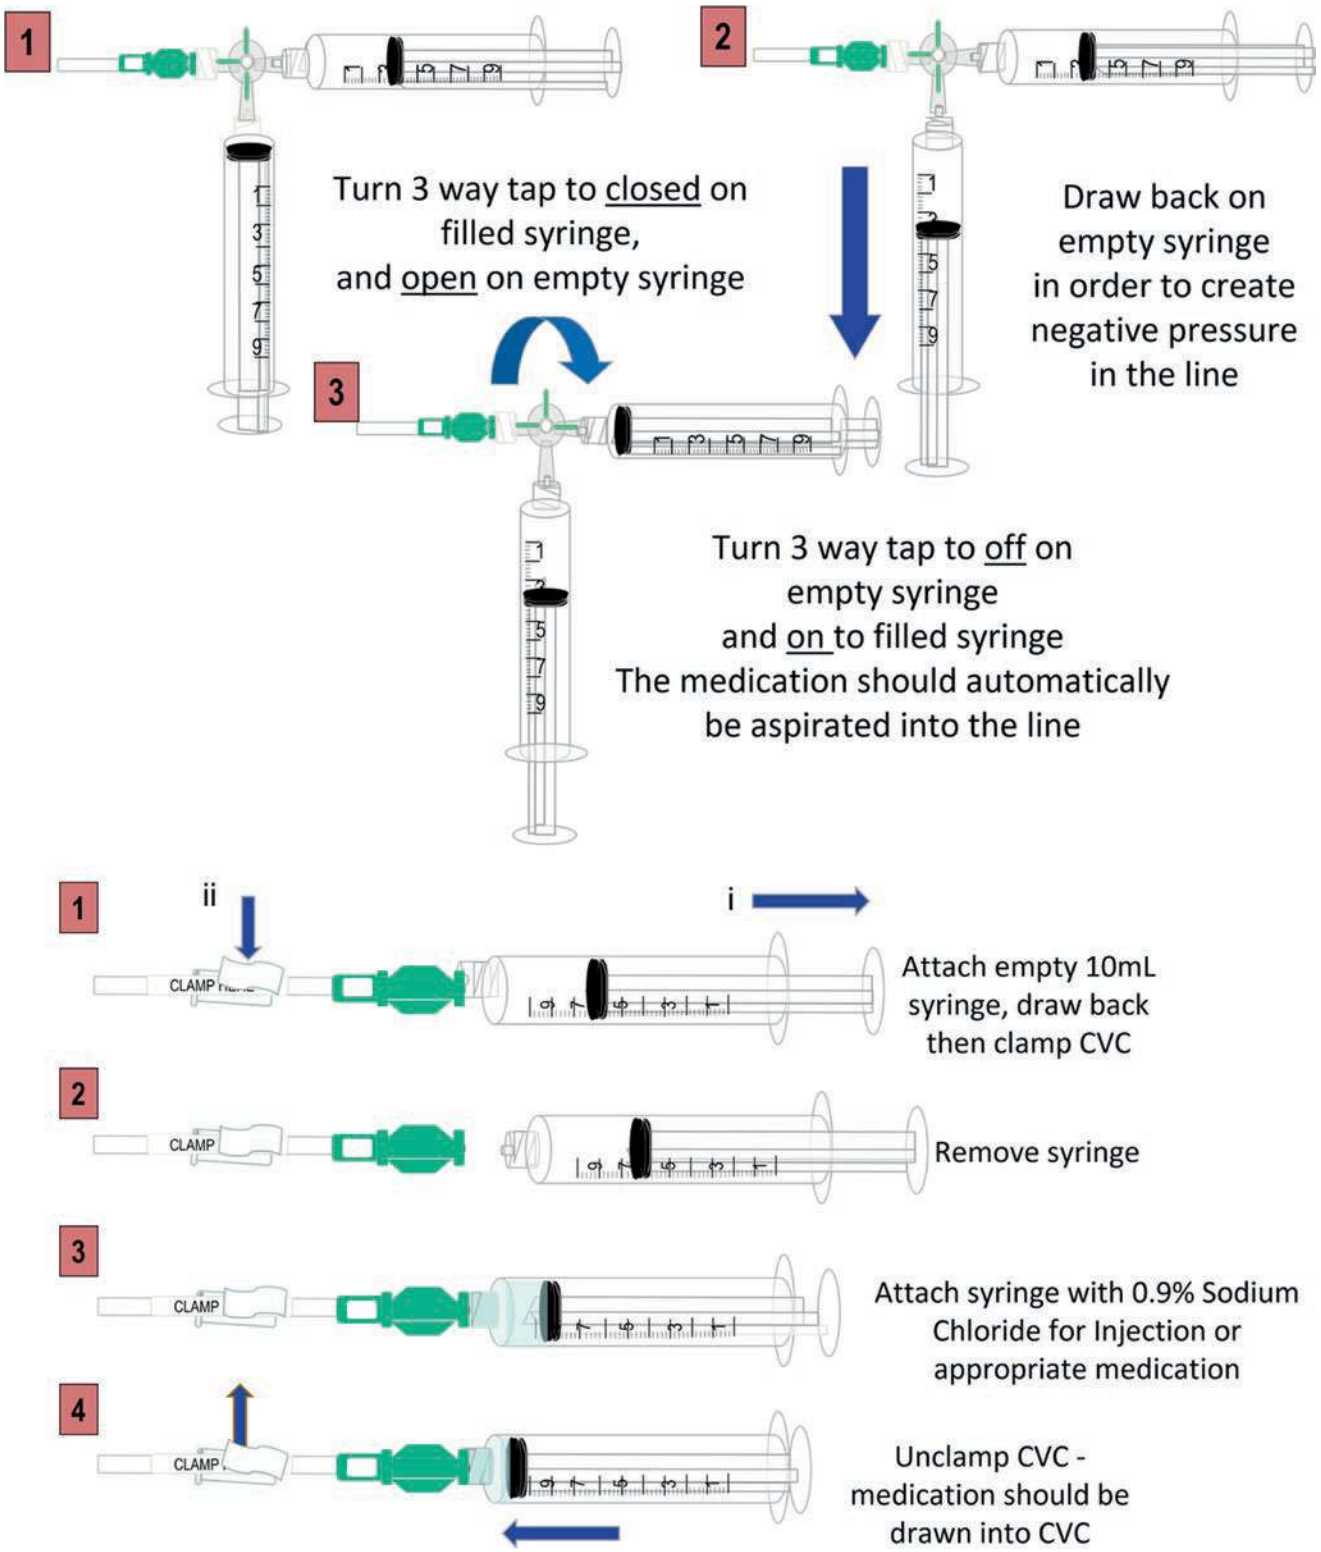

Fig. 23 Negative pressure technique for restoring patency

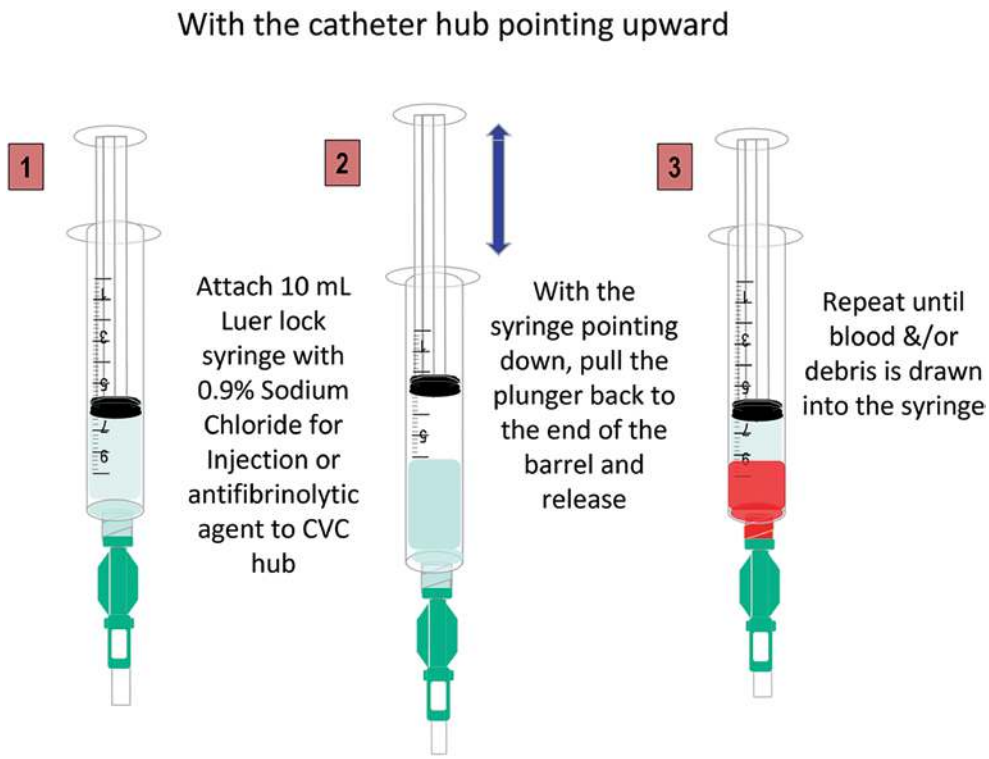

Fig. 24 Percussive POP technique

Percussive POP Technique

The percussive POP technique generates shock waves through the CVC thereby loosening the obstruction and allowing it to be extracted, rather than introduced, into the patient. There is limited evidence to support this technique, however two in-vivo evaluations demonstrated no catheter damage and/or adverse patient outcomes [63, 75]. The first study reported a 94% success rate in 50 catheters with no complications, and the second had a 93% success rate in 39 catheters also with no complications. A further in-vitro evaluation [76] in 30 PICC had a 86% success rate and no catheter damage. As an in-vitro assessment permits the entire catheter length to be occluded with blood this gives valuable information regarding the safety associated with this method. In addition, the POP technique is simple and inexpensive. See Fig. 24.

Maintaining Patency

To maintain patency it important that any infusion fluid is not allowed to sit within the catheter. The catheter should be flushed promptly with 0.9% Sodium Chloride for Injection at the end of an infusion to clear any residue adhering to the inner surface of the catheter [8]. The catheter also needs to be flushed prior to commencing an infusion, and in between any medication. Using effective techniques to flush and minimise the risk of blood backflow into the device should be incorporated into catheter care guidelines. Two established measures are the use of push pause flushing and positive pressure clamping.

Push Pause Flushing

Flushing with a stop start—"push-pause"—motion causes turbulence of flow, thus preventing the build-up of blood and/or infusion deposits within the catheter, which could lead to occlusion [77]. A review of the literature found that pulsatile (push pause) flushing is most efficient when undertaken briskly with only a 0.4 s pause between each push [78]. See Fig. 25.

Syringe size is important when flushing a CVC due to the pressure that is generated. Syringes of 10 mL or greater should be used as smaller syringes generate more pressure which could rupture the CVC [46].

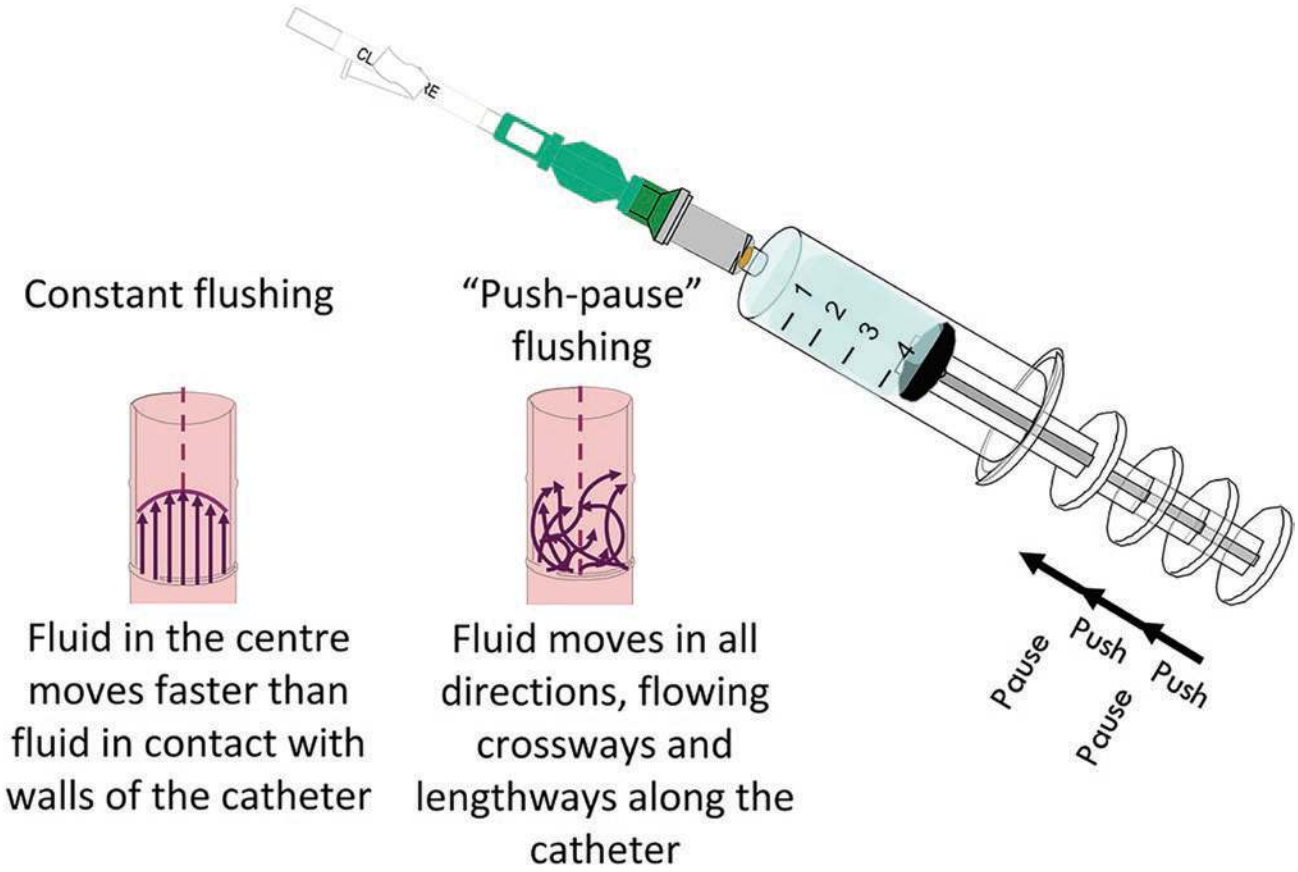

Fig. 25 Push pause flushing

Positive Pressure Clamping

Maintaining a positive pressure within the catheter lumen may reduce the risk of occlusion resulting from blood backflow into the catheter tip. Clamping the catheter while injecting the last few millilitres of fluid seals a column of fluid in the catheter and this may limit the amount of blood that refluxes back up the catheter [46]. For valved catheters with no integral clamp, positive pressure can be achieved by keeping the thumb on the syringe plunger while removing the syringe. See Fig. 26.

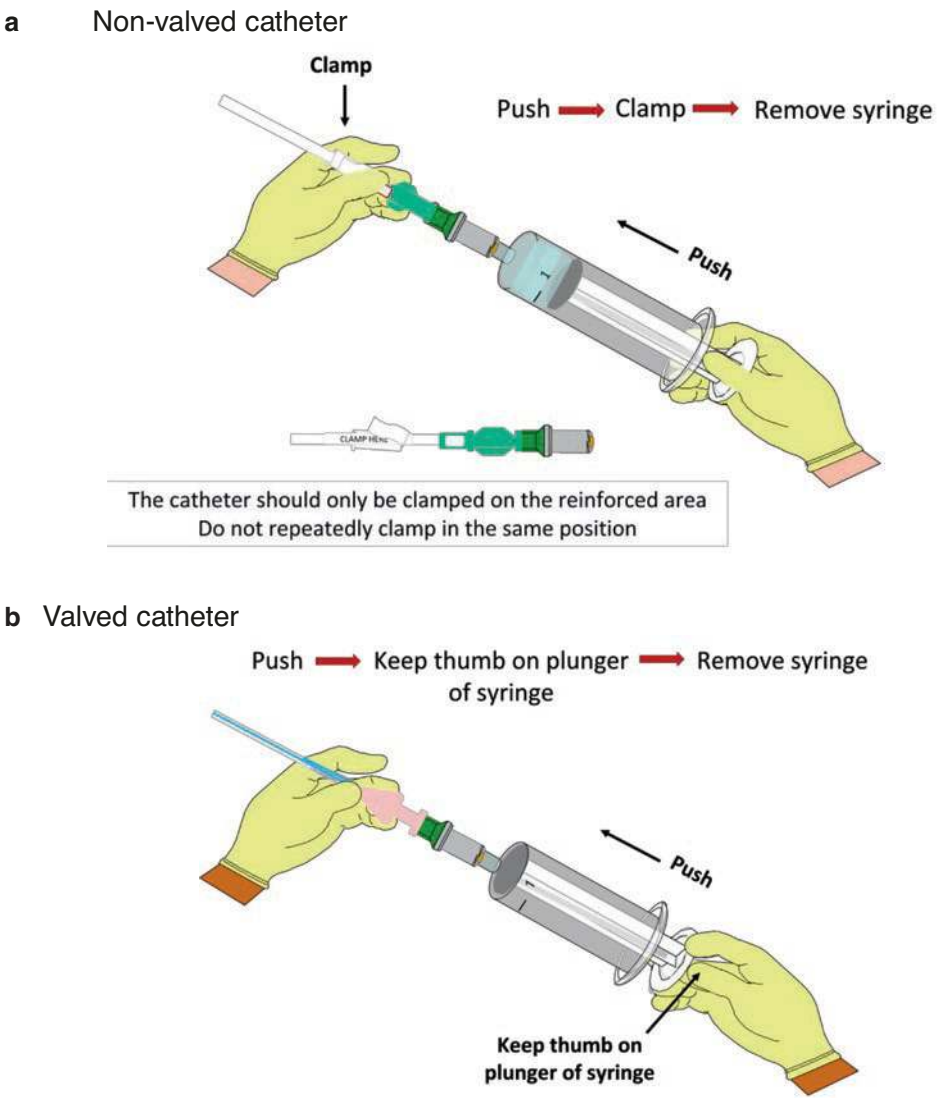

Fig. 26 Positive pressure clamping in non-valved and valved catheters. (**a**) Non-valved catheter. (**b**) Valved catheter

Positive Pressure and Anti-reflux Needle Free Connectors

Positive pressure can also be obtained with the use of either a positive pressure Needle Free Connector, or an anti-reflux Needle Free Connector. Positive pressure connectors, for example CLC2000® (ICU Medical), will expel a small amount of flushing solution from the catheter tip thereby preventing or minimising the amount of blood backflow. To achieve this they require a different clamping sequence than standard needle free connectors (NFC). The syringe should be removed *before* the line is clamped—as opposed to after.

There is conflicting data on their ability to reduce occlusion when compared to other types of connector [79]. This may be due to the variation in design making it hard to draw definitive conclusions. If considering the introduction of positive pressure valves it is recommended that individual manufacturers safety and efficacy data, alongside any restrictions of use, for example valved catheters, is reviewed.

An anti-reflux connector, for example TKO® valve bonded onto a needle free connector, may also help reduce blood backflow. The TKO® 3 way pressure sensitive valve is closed unless a syringe or giving set is attached and fluid injected. The valve will also open if the plunger on an attached syringe is pulled back thereby allowing blood sampling. Jasinsky and Wurster demonstrated a statistically significant reduction in occlusion rates, from 30% to 12.5% of catheters ($p < 0.01$) over a 3 month period when using a TKO® valve bonded to a Nexus needle free connector [80]. In the UK the TKO® valve is bonded to a Vygon Bionector. The TKO® valve should not be used with catheters which already have a valve, for example Groshong™, PASV™ and Solo™. See Fig. 27.

Fig. 27 Example of a positive pressure valve and anti-reflux connector

Catheter Damage and Repair

The ability to be able to repair damaged devices is of clinical benefit as it can mitigate the need to change the catheter. There are a number of ways a catheter can become damaged, for example;

- Flushing against resistance
- Use of small syringes (<10 mL)
- Power injection of contrast material in non-power injectable devices
- Use of scissors/sharp objects near CVC
- Repeatedly clamping in the same place
- Getting catheter caught in a door
- Contact with pets

Prevention strategies include;

- Routine movement of clamp along reinforcement area
- Securing end of the CVC to prevent contact with sharp objects

It is possible to repair Hickman™ CVC with manufacturer specific repair kits. There are different ones available for single and double lumen catheters, and whether a single lumen pigtail or both lumens are affected. There needs to be sufficient undamaged native line available—approximately 5 cm from the exit site—as the damaged section will be removed to allow a new catheter segment with clamp and hub to be applied. While a formal repair kit with new catheter segment and hub is available for Groshong™ catheters, replacement hubs are also available, meaning that a repair can also be more simply achieved by removing the damaged section and inserting a new Groshong™ hub.

Catheter repair kits should be available and staff familiar with their application. A skillful repair to a damaged/split line prevents the trauma and risk of a fresh insertion and can maintain the integrity of a line for several years. Catheter repair has not been associated with an increase of infection [81–83].

Discharge Planning

Discharging a patient on home parenteral support is complex and will inevitably vary from country to country depending on funding arrangements, availability of equipment, and provision of any specialist nursing support. Within England there is a national framework agreement which covers compounding and delivery of the parenteral support, ancillaries, equipment and specialist nursing support if clinically indicated. Key documents from this framework are included as examples, as it is recognised service specifications will vary according to what is available locally.

Discharge planning needs to consider the following criteria;

- Is the patient suitable for homecare?
- Who will fund, prescribe and provide the parenteral support?
- What are the specific nutrient and/or fluid requirements?
- Who will fund and provide the necessary ancillaries and equipment?
- Who will care for the catheter and administer the parenteral support?
- Ongoing support arrangements for patients once discharged

Is the Patient Suitable for Homecare?

This assessment needs to consider where the patient intends to reside on discharge, practical issues such as mobility and dexterity alongside identifying any potential safeguarding concerns, psychological well-being, and the patients' social support network. The English National Framework Patient Needs Assessment form can be found in Appendix 2 at the end of this chapter. A pre-discharge home assessment is recommended to ensure the basic requirements—electricity and running water—are in place. While some patients may want a separate room to undertake their procedures, this isn't clinically necessary, and the nurse is well placed to guide the patient in identifying where equipment and ancillaries will be stored, and also where the procedures will take place.

The challenge arises if it is felt that a patient is *not* suitable for homecare, for example safety concerns regarding the line, as there is no easily identifiable and sustainable alternate way for the infusions to be administered.

Who Will Fund, Prescribe and Provide the Parenteral Support?

Funding streams will vary from country to country. It is recommended that one staff member is allocated the task of securing funding so as to act as a central point of contact

with the relevant commissioning body. It is important to identify who will be prescribing and providing the parenteral support, when the first delivery will be made, how frequent subsequent deliveries will be, and what time of day these will occur. Upon discharge there should be a supply of sufficient Parenteral Support to ensure uninterrupted therapy The Parenteral Support may be provided by a commercial homecare company, hospital pharmacy or community pharmacy depending on what is available locally.

Within England funding is automatically secured by an online high cost management system known as Blueteq. Only hospitals who have been approved to provide a home parenteral support service have access to this, and approval is automatic as long as all of the clinical criteria set out are met.

What Are the Specific Nutrient and/or Fluid Requirements?

When formulating a home parenteral support prescription consideration the needs to be made regarding the practicalities of the regimen being administered at home. For example, while it may be possible to gain stability on a 4 L bag, will the patient be able to lift and carry this around? Although the infusion becomes more manageable as more fluid is infused, sometimes it may be necessary to have two infusions of a manageable size, for example a 3 L bag followed by a litre bag.

How long a patient infuses for can impact on their daily routine so this needs to be considered when sending a patient home on parenteral support. Infusion rates in hospital are usually dictated by the shift pattern of nursing staff, but at home the self-caring patient can have more flexibility. Things to consider when determining flow rates include the hourly content of glucose and certain electrolytes, for example potassium and magnesium. Patients/carers should be informed of the maximal hourly infusion rate they can use, but some may choose to infuse over a longer period so as to not have to wake early to disconnect.

The infusion *mode*—same volume throughout, or variable—also needs to be considered. A variable rate is achieved by programming the infusion pump to taper run the infusion at a slower rate at the beginning and end of the infusion. This can be useful in preventing rebound hypoglycaemia [84].

Who Will Fund and Provide the Necessary Ancillaries and Equipment?

It is easier if the ancillaries and equipment can be provided by the same provider as the Parenteral Support, but it is appreciated that this may not be possible in all countries. Ancillaries and equipment *may* need to be provided by a number of providers depending on the classification of the product, for example dressings may need to be provided from a different source than disinfection wipes or needle free connectors.

When selecting ancillaries there should be consideration of whether or not the patient and/or carer is able to use them, and not just replicate what has been used in hospital. For example, some dressings require both hands to apply which may prove challenging, so "1 hand" dressings which have a rigid frame to keep the dressing material wrinkle free during application may be easier to use. This may seem trivial, however it could mean the difference between a patient being able to undertake their own dressing change or needing to rely on someone else to do this. Other considerations include the use of gloves with textured finger tips to aid with inserting the pump giving set into the bag of parenteral support, or selecting a larger profile needle free connector which is easier to manipulate.

All ancillaries and equipment must meet local medical device related regulations, for example CE/UKCA marking, and it must be determined that the patient and/or carer are not allergic to any of the materials contained within them.

The patient will need to identify suitable storage for ancillaries and equipment and this needs to be discussed with them prior to discharge, so as to prepare them for the volume of items which need to be stored. Ancillaries need to be stored off the floor in a clean and dry environment. Some patients may opt to buy plastic storage units with drawers, but a chest of drawers or cupboard is equally suitable. Fridges may be stored in an outside garage or shed but they may need to be moved inside during the winter months as fridges can only work normally if the temperature of the room in which they are situated is warmer than the temperature inside the fridge. If the patients' regimen includes the use of sharps then they need to be supplied with an approved sharps container which needs to be stored out of reach of children or pets. The patient needs to be aware of how to dispose of filled containers and receive replacements.

Who Will Care for the Catheter and Administer the Parenteral Support?

Where possible the patient should be trained to care for their catheter and administer the parenteral support. Not only does this promote autonomy it also reduces the number of people accessing the catheter. Assessment to determine if a patient will be able to self-care includes visual acuity, manual dexterity and strength. Deficiency in any of these might impact upon the patient's ability to undertake the procedures themselves, but thinking creatively may help resolve the issue(s). For example, patients often struggle to insert the giving set spike into the parenteral support. As well as using gloves with textured fingers, having the bag of parenteral support laid on a flat surface as opposed to hanging on a drip stand might enable the patient to successfully insert the giving set.

Patients with manual dexterity issues may benefit from having prefilled 0.9% Sodium Chloride for Injection syringes as opposed to manually drawing up flush solution. Even if patients cannot undertake all of the required procedures they may be able to undertake *some*, for example they may be able to disconnect and change their dressing, but not be able to connect an infusion.

If a patient is unable to undertake their own procedures then alternative arrangements need to be made. It may be possible to identify a family member/carer who is able *and* willing to be trained. Due to the severity of potential complications, most notably sepsis, both parties need to be happy with this arrangement. Logistics, such as availability for all connection and disconnection visits, also needs to be determined.

Nursing support will need to be secured for patients unable to undertake their own procedures and have no identifiable family member/carer who can learn. This can prove challenging as not all community based nursing services will have experience of central venous catheter management and administration of parenteral support. While community based IV therapy services may exist their remit is usually for short term IV medication administration, and doesn't extend to long term infusion therapies. Within England, the National HPN Framework also includes specialist nursing support. These nurses have to be able to demonstrate competency in the understanding of gastrointestinal function, parenteral support, care of central venous catheters, and recognition of common catheter related complications. These competencies can be found in Appendix 3. While they may seem excessive it serves to illustrate the complexity of care a patient on home parenteral support requires.

Patient/Carer Training

Just as with the nurse competencies there is an English national framework patient competency document outlining what the patient/carer needs to learn. Broadly speaking these cover;

- Understanding how their gastrointestinal function has changed,
- How to safely access the catheter and administer the prescribed parenteral support
- Care for the skin around the catheter
- Troubleshooting common catheter and infusion related complications

The full patient/carer competency document can be found in Appendix 4.

The specific steps needed to undertake these procedures will vary depending upon a number of things;

- The type of catheter, PICC, tunneled Hickman™ type, or implanted port
- Whether the catheter is valved or non-valved
- If the patient is receiving additional medications via the catheter
- Number of lumen the catheter has
- If the patient is receiving one infusion at a time or 2[1]

There are common elements to all procedures, for example hand decontamination and putting on sterile gloves. In addition, all procedures start and end with a social handwash, and can be broadly broken down into the following stages;

- Create an aseptic field with equipment needed to undertake procedure
- Create an aseptic field around the catheter
- Undertake procedure

Creating a Suitable Environment

Patients do not need to make any alterations to their home, but there are some basic "housekeeping" principles to bear in mind when deciding on where the procedures will be undertaken;

1. Where will the procedures take place?

The patient needs to think about how easy it will be for themselves, their carer and/or the nurses to get from where they will wash their hands to where the procedures will take place. Doors should be left open if possible and clean hands protected with a clean paper towel/muslin cloth to minimize the hands becoming contaminated from manoevering the drip stand/back pack. If training is happening in hospital, this should be identified at the outset, so that the patient feels confident to undertake their procedures in a new setting when discharged.

2. Is there anything within the chosen area that could be an infection risk?

There should be no vacuuming during the procedures, or fans in operation, as these will generate dust, and dust contains micro-organisms. It is advisable that any windows are closed and pets kept in a separate room while the procedures are in progress.

In addition to the practical procedures training also needs to consider troubleshooting and lifestyle considerations such as bathing and showering. The full version of the patient training competencies can be found in Appendix 4.

[1]The UK has seen a move from all patients being able to have a compounded regimen to using Multi Chamber Bags with additional IV fluids where clinically possible. This has been due to capacity constraints and product shortages, and has resulted in different ways of administering parenteral support, including separate vitamin/mineral infusions, use of double/triple spike giving sets which allow multiple concurrent infusions (stability permitting), and double lumen extension sets.

Table 8 Catheter and infusion related problems

Problem	Detail
Local infection	Can identify signs and symptoms of
	• Exit site infection
	• Tunnel infection
	• Cuff infection (Hickman™ type catheter only)
	• Port pocket infection (implanted port only)
	• Can identify the correct action to take
Bloodstream infection	• Can identify signs and symptoms of a bloodstream infection and the correct action to take
Blocked catheter	• Can identify signs of a blocked catheter
	• Knows simple first aid measures, for example massaging under the clamp, changing the needle free connector
	• Can identify the correct action to take
Catheter fracture	• Can identify catheter fracture
	• Knows to apply atraumatic clamp above the damaged area
	• Can identify the correct action to take
Catheter related thrombosis	• Can describe signs and symptoms of thrombosis (all catheters)
	• Can describe signs and symptoms of thrombophlebitis (PICC)
	• Can identify the correct action to take
Fluid overload	• Can describe signs and symptoms of fluid overload
	• Can identify the correct action to take
Dehydration	• Can describe signs and symptoms of dehydration and when additional IV fluids are required
Catheter malposition	• Knows function of cuff (Hickman™ type catheter) and approximate location within skin tunnel
	• Knows external length of PICC (If applicable)
	• Understands the implication of catheter malposition and correct action to take

Troubleshooting

Correct and early recognition of catheter and infusion related problems is essential in patients receiving home parenteral support. Patients/carers need to be able to identify the complications listed below *and* the correct action to take (Table 8).

Body Image

It is easy to appreciate how a patient with a stoma or fistula may experience issues with body image, however the impact from a central venous catheter is probably underestimated. While patients may be grateful that there is an effective treatment for their medical condition this doesn't necessarily mean that the presence of a central venous catheter isn't associated with psychological issues [85]. Negative feelings associated with a central venous catheter include the catheter being viewed as the intrusion of a foreign body which can become the focus for neglect, self-harm and abuse. There are reports of patients deliberately damaging their catheter and of injecting faecal matter through it. Patients have described being tethered to the pump during infusions with associated restriction in their daily activities. Rather than being seen positively as a lifeline, patients may describe the catheter tethering them like an umbilical cord to the hospital and healthcare professionals. The catheter has also been associated with disruption in gender identity. This is presumably due to having something hanging from the body, however it may also be experienced by patients with totally implanted ports if the size and shape of the port are clearly visible on the chest wall [85]. For some, having nutrition and/or hydration in liquid form parenteral support may be seen as a return to early childhood where they were reliant on liquid nutrition.

Being aware of the possible psychological issues patients may experience will hopefully facilitate conversation between the nurse and patient, and identify possible measures to alleviate some of these. Examples include suggesting an implanted port, positioning the exit site of a Hickman™ type catheter in a less visible position such as on the side of the body below the armpit and discussing infusion times and how they can be best fitted in around their day.

Ongoing Support Arrangements for Patients Once Discharged

Patients need to know of ad hoc and scheduled support arrangements once they are discharged. It is important to manage patients expectations regarding this, particularly regarding the frequency of scheduled follow up. Before being discharged on Home Parenteral Support patients will have had a lengthy inpatient stay during which they would have been reviewed regularly by the multidisciplinary team, individually, and as a team. They may also have developed friendships with other patients. This stops on discharge which some patients might find daunting.

Once discharged patients need to know *who* and *how* to contact should they have any questions, or think they have developed a line or Parenteral Support related problem. This must include out of normal working hours, weekends and public holiday arrangements. Encourage patients to enter any relevant phone numbers into their mobile phone *before* they are discharged, as paper copies may be lost among the volume of paper information they will receive on discharge.

It must be appreciated that patients may initially feel overwhelmed on discharge when the reality of how Intestinal Failure has changed their pre admission life becomes truly

Table 9 BIFA recommendations for haematological and biochemical monitoring of HPN (Home Parenteral Nutrition) [86]

British Intestinal Failure Alliance (BIFA) Guidance. Haematological and biochemical monitoring of adult patients receiving Home Parenteral Nutrition
1. All haematological and biochemical monitoring of HPN (home parenteral nutrition) patients should be individualised and may change with their clinical condition. The point at which patients become stable post discharge will vary
2. Routine blood tests, including standard electrolytes, chloride, bicarbonate (as a measure of acid-base balance), calcium, magnesium, phosphate, renal and liver function tests, glucose, full blood count, ferritin and CRP should be performed monthly for the first 3 months after discharge. If stable this may then be 3–4 monthly
3. When discharged patients should have their prothrombin time, cholesterol and triglyceride, HbA1c, vitamin D & B12 and folate concentrations checked. These should then be monitored at least 6-monthly
4. Patients who are to receive long-term HPN should have baseline vitamins A&E, zinc, copper, manganese and selenium concentrations checked and then monitored 6-monthly
5. If the CRP is significantly raised (>20 mg/l) iron can be measured with transferrin and transferrin saturation to assist interpretation of iron status. In this situation care must be taken in the interpretation of zinc, copper, selenium and vitamins A, D and E in view of their inflammatory response
6. When measuring zinc, copper, manganese or selenium use a trace element-free collection tube
7. If the triglyceride concentration is elevated a fasting concentration should be repeated
8. Urine sodium concentration is useful for assessing sodium balance in patients with a short bowel and a 24-h urinary oxalate collection for assessing risk of renal stone formation in patients with a short bowel and colon in continuity

apparent. The initial joy of being home may be replaced by anxiety over how to incorporate parenteral support and or stoma/fistula management into their daily life. Patients should be made aware of patient support groups, for example PINNT (Patients on Intravenous and Nasogastric Tube Therapy, www.pinnt.com) who can provide support, education and practical advice about living with parenteral support. Encouraging an activity, within physical capacity, which gives pleasure and expresses individuality, may help to provide continuity with their past life and serve as hope that not all aspects of their pre intestinal failure life are over. It needs to be recognized that patients will have different goals for example one patient may view going on an overseas holiday to be a major achievement, whereas others may view getting dressed and going out for coffee to be of equal achievement.

Patients should be regularly reviewed in a specialized multidisciplinary outpatient clinic with staff experienced in intestinal failure and parenteral support [7]. Frequency and nature of this follow up will depend on how stable the patient is with regard to their prescribed regimen. BIFA (British Intestinal Failure Alliance) statement regarding haematological and biochemical monitoring are listed in Table 9 [86].

In addition to the haematological and biochemical monitoring, outpatient review should also cover appropriateness of current parenteral support regimen, weight, anthropometry, review of the central venous catheter, any issues with deliveries of parenteral support and necessary ancillaries, and quality of life.

Summary

Patients receiving home parenteral support have a lot to incorporate into their daily lives including the administration of parenteral support, maintenance of their central venous catheter and stoma/fistula management. In addition they may also have debilitating symptoms such as nausea/vomiting and chronic pain. Nurses are well placed to help patients integrate back into the community and live as full a life as possible.

Appendix 1. British Intestinal Failure Alliance (BIFA) Guidance

Standardised Parenteral Support Catheter Guidelines

Connecting a Parenteral Support (PS) Infusion

Key Principles of Care and Management of Central Venous Catheters.

- Identify the key parts.
- Ensure no touching of any key parts during the procedure.
- Apply alcohol hand rub directly to hands during the procedure if touching any non-sterile contents and/or if there is any risk of contamination.

Social Handwash

Step 1—Gather & Check Equipment

- Bag of parenteral support (PS) (Check PS prescription, integrity of bag & expiry date)
- Trolley/tray
- Detergent wipes (or paper towel, soap and water)
- 2% CHG & 70% IPA disinfectant wipes • Sterile dressing-pack or dressing towels
- Gloves of choice (as recommended by HPN Centre)
- 10mL pre-filled syringe(s) 0.9% sodium chloride for injection

- Alcohol hand rub
- Sterile intravenous giving set
- Surgical tape
- Infusion pump, stand/rucksack

Step 2—Aseptic Handwash
Step 3—Prepare Equipment

- Clean & disinfect trolley/tray surface
- Attach strips of tape to the edge of the trolley/tray
- Open sterile dressing pack/towel onto trolley/tray surface to create an aseptic field
- Open equipment needed onto aseptic field
- Using gloves (as recommended by HPN Centre) spike bag of PS and prime giving set

Step 4—Prepare Patient & Catheter

- Open sterile towel & place under catheter. Tape in place.
- Remove any outer dressing covering the catheter (if used) & port protector (if used)

Step 5—Access Catheter

- Put on gloves
- Disinfect needle-free device (The order of these first 2 steps can be interchanged depending on HPN Centre recommendation)
- Prime pre-filled syringe(s)
- Attach syringe to needle-free device and flush catheter using push pause flushing and positive pressure clamping technique (as recommended by HPN Centre)
- Attach giving set

Step 6—Start infusion & Secure Catheter

- Ensure giving set & catheter clamps are released
- Start infusion at prescribed rate
- Remove gloves
- Secure catheter (as recommended by HPN Centre)

Step 7—Clear away

- Complete any documentation

Social Handwash

Disconnecting a Parenteral Support (PS) Infusion

Key Principles of Care and Management of Central Venous Catheters.

- Identify the key parts.
- Ensure no touching of any key parts during the procedure.
- Apply alcohol hand rub directly to hands during the procedure if touching any non-sterile contents and/or if there is any risk of contamination.

Social Handwash
Step 1—Gather & Check Equipment

- Trolley/tray
- Detergent wipes (or paper towel, soap and water)
- 2% CHG & 70% IPA disinfectant wipes
- Sterile dressing-pack or dressing towels
- Gloves of choice (as recommended by HPN Centre)
- 10mL pre-filled syringe(s) 0.9% sodium chloride for injection
- Alcohol hand rub
- Port protector (as recommended by HPN Centre)
- Surgical tape

Step 2—Aseptic Handwash
Step 3—Prepare Equipment

- Clean & disinfect trolley/tray surface
- Attach strips of tape to the edge of the trolley/tray
- Open sterile dressing pack/towel onto trolley/tray surface to create an aseptic field
- Open equipment needed onto aseptic field

Step 4—Prepare Patient & Catheter

- Switch off pump and close clamp on giving set
- Open sterile towel & place under catheter. Tape in place.
- Remove outer dressing (if present) to release catheter and clamp catheter (if present and recommended by HPN centre)

Step 5—Access Catheter

- Put on gloves
- Disconnect giving set from needle-free device (The order of these first 2 steps can be interchanged depending on HPN Centre recommendation)
- Disinfect needle free device
- Prime pre-filled syringe(s)
- Attach syringe(s) to needle-free device and flush catheter using push pause flushing and positive pressure clamping technique (as recommended by HPN Centre)
- Attach port protector (as recommended by HPN centre)

Step 6—Secure catheter

- Remove gloves
- Secure catheter (as recommended by HPN Centre)

Step 7—Clear away

- Complete any documentation

Social Handwash

Changing the Parenteral Support (PS) Catheter Dressing

Key Principles of Care and Management of Central Venous Catheters

- Identify the key parts.
- Ensure no touching of any key parts during the procedure.
- Apply alcohol hand rub directly to hands during the procedure if touching any non-sterile contents and/or if there is any risk of contamination.
- This procedure should not be incorporated into any other procedure in which the catheter hub is manipulated so keeping the risk of cross contamination to a minimum.
- Dressings need to be changed every 7 days, if they are soiled or have become loose. A fabric island type dressing is recommended if there is discharge from the exit site.

Social Handwash

Step 1—Gather & Check Expiry Dates of Equipment

- Trolley/tray • Detergent wipes (or paper towel, soap and water)
- 2% CHG & 70% IPA disinfectant wipes
- Sterile dressing-pack or dressing towel
- Gloves of choice (as recommended by HPN Centre)
- Single use 2% CHG & 70% IPA sponge applicator(s)
- Sterile dressing(s) of choice
- Alcohol hand rub
- Suture-less securement device (if required)

Step 2—Aseptic Handwash

Step 3—Prepare Equipment

- Clean & disinfect trolley/tray surface
- Open sterile pack/towel and create an aseptic field
- Open equipment needed onto aseptic field

Step 4—Prepare Patient & Catheter

- Remove existing dressing(s) &/or suture-less securement device
- Attach anchoring strip (if present) from suture-less securement device

Step 5—Access Catheter

- Put on gloves of choice (as recommended by HPN Centre)
- Disinfect skin with single-use 2% CHG & 70% IPA sponge applicator(s)
- Apply dressing(s) &/or suture-less securement device as per manufacturer's recommendation

Step 6—Secure Catheter

- Remove gloves
- Secure catheter (as recommended by HPN Centre)

Step 7—Clear away

- Complete any documentation

Social Handwash

Glossary of Terms

Alcohol hand rub
An alcohol containing product (gel or foam) designed to reduce the number of micro-organisms on the hands. It should be applied to clean, dry hands, and the hands rubbed together, following the steps in the aseptic hand washing technique, until they are completely dry.

Aseptic hand wash
A thorough hand wash procedure concentrating particularly on the areas of the hands where resident bacteria can be found. To be effective the hand wash solution must come into contact with all of the surfaces of the hands and wrists. While there are many different hand washing techniques cited in the literature (with 6–13 steps) the principles are the same, to make sure all surfaces of the hands (including the wrists), are adequately washed, rinsed and dried, especially those areas which may be missed such as finger tips, thumbs and between the fingers.

CVC
A vascular access device whose tip lies in the lower third of the superior vena cava or the upper third of the inferior vena cava (ideally at the vena cava / right atrial junction). They can either be centrally inserted via the subclavian, internal jugular or femoral veins or peripherally inserted via the brachiocephalic veins. The femoral route, which may have a higher risk of infection, is chosen when the upper veins cannot be accessed.

Disinfectant wipes
Single use wipes containing 2% chlorhexidine and 70% isopropyl alcohol (2% CHG & 70% IPA). The combination of both disinfectants is thought to be more effective than when either is used alone.

Key-Part(s)
Things which if touched directly or indirectly could result in the introduction of micro-organisms. They include the catheter hub, the end of the giving set, syringe tip and the skin surrounding the exit site.

Needle Free Connector (NFC)
A device which permits the connection of administration sets, and syringes to the hub of a vascular access device without the use of needles. They were introduced to reduce the incidence of needle stick injuries. They should be disinfected using pressure and friction for a minimum of 15 s prior to, and after, each time they are accessed.

Parenteral Support (PS)
A term which covers both parenteral nutrition and parenteral fluids.

Port Protector Cap
A disposable single use disinfection cap that contains 70% Isopropyl Alcohol (IPA). The port protector twists onto the end of a needle free connector to passively disinfect *and* protect from cross contamination during infusion free periods.

Positive pressure clamping technique
The catheter is clamped while flushing with the last mL of solution so as to seal a column of fluid within the catheter. This may reduce the backflow of blood and thereby the risk of occlusion.

Push-Pause flushing technique
Flushing with a stop/start motion causes turbulence of fluid within the catheter that may help reduce the build-up of any deposits and reduce the risk of occlusion.

2% chlorhexidine gluconate (CHG) & 70% isopropyl alcohol (IPA) sponge applicator
These are single use sponges contain 2% CHG and 70% IPA are designed to disinfect the skin around the exit site. By using gentle, repeated back and forth strokes for 30 s this provides an effective reduction on bacterial load on the skin.

Social hand wash
Also known as a routine hand wash. A general hand wash to remove transient microbes picked up on the hands during daily activities.

Sterile gloves
These have traditionally been advised as best practice for the administration of parenteral support however non sterile gloves can be used. Sterile gloves had been thought to reduce the risk of infection by reducing the transfer of micro-organisms to and from the wearer's hand. The wearing of gloves is not a substitute for hand washing.

Sterile towel
This can be either supplied separately or within a dressing pack. The towel is used to create the aseptic field onto which the sterile items are placed. A second sterile towel is used to lie under the patient's catheter thereby creating an aseptic field when accessing the catheter.

Appendix 2. Patient Needs Assessment Form for HPN, NHS England 2019® (Used with Permission)

The purpose of this document is to assess if the patient is suitable for homecare and HPN. It should be used in conjunction with discharge planning documents used in the Purchasing Authority. It can also be used once the patient is at home if there are any changes in the patient's circumstances and/or to periodically assess a patient's suitability to undertake training for care of their central venous catheter.

Date of Assessment:	**Assessment conducted by:**	
Patient Name	**DOB**	**NHS Number**
Preferred name	**Employment/Education Status**	
Permanent address:	**Secondary address:** (students, initial discharge address (if different from permanent), children living at 2 addresses including temporary foster care placement	
General	**Concerns and Comments**	
Underlying illness leading to intestinal failure		
Does the patient have any co-morbidities that may result them being unsafe at home?		
What is the patient or carers' understanding of the risks and benefits of having a central venous catheter (CVC)? Are there any concerns that the patient may be unsafe with a CVC?		
What medications is the patient on?		
Psychological wellbeing with regards to HPN. Are there any concerns here such as self-harm, neglect or abuse?		
Is there family support for the patient going home on HPN? Are there any concerns? Include details of any hospice/respite facility referrals or details.		

Are there any safeguarding issues? Include Social Worker details and any safeguarding plans.		
Home environment—use RPS standard document for assessment		
Physical	**Comments**	
Mobility:		
Are there any concerns regarding mobility		
Yes/No		
If yes		
Physio assessment/OT		
Yes/No		
Date:		
Dexterity:		
Is dexterity limited		
Yes/No		
Can patient perform activities of daily living?		
(Washing, dressing etc.?)		
Yes/No		
If issues		
OT assessment		
Yes/No		
Vision:		
Does the patient have any visual impairments Yes/No		
If yes—what modifications are needed before discharge?		
Hearing:		
Does the patient have hearing impairments? Yes/No		
If yes—what modifications are needed before discharge?		
Other health concerns:		
Yes/No		
Stoma care, wound care, palliative support, medication, diabetes, respiratory conditions, drug / alcohol intake etc.)		
If yes—please list what extra services are required		
The following 3 questions need to be completed for both the patient and carer(s) who would be undertaking administration of parenteral support and care of central venous catheter	**Patient**	**Carer(s)**
Communication: (Reading and spoken)		
Reading barriers		
Yes/No		
Language barriers		
Yes/No		
If yes—how will this be addressed before discharge		
Cognition:		
Does the patient have a clear understanding of procedures and protocol? Yes/No		

Specific training assessment questions		
These questions are aimed at determining an individual's physical ability to undertake HPN procedures		
Can they use a smartphone/ electronic tablet? Yes/No		
Unscrew/screw on a lid such as on a toothpaste tube?		
Yes/No		
Open a packet, such as a plaster/ packet of crisps		
Yes/No		
Can they lift a weight equivalent to a bag of PN such as 4 litres of milk?		
Yes/No		
Can they raise it as high as a drip stand?		
Yes/No		
Recommendations for administration of HPN and care of CVC		
Train to become independent		
Yes/No		
Re-assess once at home		
Yes/No		
Family member* to train		
Yes/No		
Joint care (patient / family member*/nurse) Yes/No		
Full nursing support		
Yes/No		
Transition training (paed-adult services)		
Yes/No		
*It is recommended that any family member taking on the responsibility is 18 years of age or older		
For patients assessed as being able to train to independence		
Does patient understand the remit of the nursing service and that NHS England expects patients to self-care unless assessed as being unable to learn?		
Yes/No		
General Comments:		
Action plan		**Date achieved**
Signature of healthcare professional undertaking assessment:		**Date**

This record should be made available to the Contractor and the record kept in the patients notes at the Purchasing Authority

Appendix 3. Home Parenteral Nutrition Nurse Competencies NHS England 2019® (used with permission)

Home Parenteral Nutrition Nurse Competencies

Aim: The nurse administering home parenteral nutrition (whether from a homecare company or an NHS nurse undertaking this work) will need to acquire the knowledge and skills listed below.

All nursing staff need to be aware of the following British Intestinal Failure Alliance (BIFA) documents;

- Guidance Standardised Parenteral Support Catheter Guidelines, https://www.bapen.org.uk/pdfs/bifa/standardised-parenteral-support-catheter-guidelines.pdf
- Intestinal Failure Alliance (BIFA) Recommendations for Catheter Related Blood Stream Infections (CRBSI) Diagnosis https://www.bapen.org.uk/pdfs/bifa/recommendations-for-crbsi-diagnosis.pdf
- British Intestinal Failure Alliance (BIFA) Recommendation Management of Catheter Related Blood Stream Infections (CRBSIs) https://www.bapen.org.uk/pdfs/bifa/recommendations-on-management-of-crbsi.pdf

Learning outcome	Achieved (date)	Signature
1. Intestinal failure		
a. Understands principles of normal intestinal function		
b. Can describe how gut function has changed in someone with intestinal failure		
c. Understands common drug therapy used in patients with intestinal failure.		
d. Knows how to minimize effect of GI changes on fluid balance in someone with intestinal failure		
e. Has an understanding of the paediatric specific nursing considerations (where applicable)		
2. Vascular access devices used for home parenteral nutrition		
a. Can identify the following devices; tunneled catheter, PICC, implanted port		
b. Can identify commonly used tunneled catheters, for example Vygon, Bard and Cook		
c. Can identify commonly used valved devices, for example Groshong, PASV and Solo and knows the position of the valve		
2. To understand principles of asepsis		
a. Washes and dries hands effectively		
b. Applies hand rub correctly		
c. Applies gloves correctly		
d. Cleans and disinfects general aseptic field (for example, plastic tray/trolley) correctly		
e. Correctly opens sterile items onto aseptic field		
f. Can identify key parts and non-key parts		
g. Understands the concept of key part and key site management		
h. Disinfects needle free connector for minimum of 15 seconds with pressure and friction, and allows to dry for 30 seconds		
3. To safely disconnect and flush catheter		
a. Deals appropriately with pump and catheter at end of infusion		
b. Prepares syringe with flushing solution correctly		
c. Understands the rationale behind pulsatile flushing and can demonstrate flushing a catheter with push-pause technique		
d. Understands the rationale behind positive pressure clamping and can demonstrate effectively when disconnecting a syringe (open ended catheter)		
e. Understands the rationale behind maintaining positive pressure and can demonstrate effectively when disconnecting a syringe from a valved catheter		
f. Care of unused lumens (if applicable)		
g. Prepares and instills antimicrobial lock correctly (where applicable). Knows the active ingredient(s) within the prescribed lock, indications for use and possible side effects		
h. Removal and safe disposal of Huber needle (port only)		
i. Knows purpose of a port protector and mode of action. Applies 70% isopropyl alcohol port protector correctly and knows frequency of change		
j. Secures catheter as per hospital protocol and can explain to the patient the rationale behind such securement		
4. Administration of any additional prescribed medications (if applicable)		
a. Prepares and administers any additional prescribed medications correctly. Knows the indications for use for these, any contraindications and possible side effects		
b. Knows how to safely dispose of used ampoules/vials/sharps		
c. Knows what to do in case of needlestick injury		
5. Addition(s) to IV fluid (if applicable)		
a. Completes all patient identity checks with the prescription		
b. Can identify additive port on IV fluid container		
c. Prepares any prescribed additions correctly as per manufacturer's instructions using appropriate aseptic technique		

d. Adds any prescribed additions to the IV fluid container correctly using a safety needle, and is aware of the correct order of any additions, using appropriate aseptic technique		
e. Ensures any additions have been dispersed adequately within the IV fluid container		
f. Primes giving set correctly (primary infusion)		
g. Primes any additional administration set for simultaneous secondary infusion, for example Y-site or Octopus double lumen extension set.		
h. Knows how to use Micrel double spike giving set and administration tubing (if used)		
i. Knows how to safely dispose of used ampoules/vials/sharps		
6. To safely set up PN or IV fluids		
a. Checks solution correctly		
b. Can identify if a bag is not safe to administer, ie cracking, creaming, particles		
c. Primes giving set (single, or double spike if used) correctly either manually or via pump. (Note: for manually primed giving sets NHS Improvement have recommended that once primed the giving set is placed into the pump before being connected to the catheter so as to reduce the risk of accidental free flow)		
d. Checks patency of line before connecting infusion (as per hospital protocol)		
e. Has received training on all pumps on the HPN framework		
f. Deals with pump alarms appropriately		
g. Protects bag from light (where applicable)		
h. Insertion of Huber needle (port only). Can identify if needle has been inserted correctly and is the correct length		
i. Knows how to use Portacator (port location device) and when it would be recommended		
j. Can deal appropriately with blood backflow in giving set		
k. Protects giving set/line connection during infusion (if applicable and as per hospital protocols)		
l. Knows what to do or advise if the PN bag is damaged/leaking/contaminated or the delivery is delayed/missing. (note: paeds do not always have a buffer bag)		
m. Knows how to use a gravity giving set and when this would be indicated		
n. For insulin dependent patients. Can measure blood glucose and administer insulin prior to connecting parenteral nutrition. (Only in cases where patient/carer is unable to do)		
7. Calculates infusion rates correctly		
a. Knows maximum hourly infusion rate for prescribed parenteral support		
b. Knows maximum hourly infusion rate for additional IV fluids		
c. Knows how to ramp up and ramp down infusion on each of the pumps on the framework and when this would be indicated		
8. Care of exit site		
a. Can describe appearance of a healthy exit/implanted port site		
b. Assesses exit/implanted port site at each catheter manipulation		
c. Knows when to clean exit site		
d. Knows what to clean exit site with and method of cleaning. Can suggest alternative cleaning solutions in cases of proven allergy		
e. Suitable dressings to use and correct method of application and removal. Can suggest alternative suitable dressings in cases of proven allergy		
f. Knows frequency of sutureless securement device change		
g. Can change commonly used sutureless securement devices and the necessary measures to reduce catheter dislodgement		
h. Knows when and how to remove exit site sutures from all types of devices including how to remove an external stitch fixator		
i. Can identify possible medical adhesive related skin injury (MARSI) and how to treat this		
j. Can identify any skin impairment from a SecurAcath device (if used)		
9. How and when to change needle free connector		
a. Knows how often the following needle free connectors should be routinely changed Vygon Bionector Fanin Clave/Microclave Fanin Neutron Carefusion Smartsite ICU Medical CLC2000 Vygon Bionector TKO		
b. Knows any additional times connector should be changed		
c. Can change connector during disconnection procedure		
d. Can change connector during connection procedure		
e. Knows the difference between specific clamping sequence needed for use with a positive pressure needle free connector, and how this differs from the clamping sequence required for neutral and negative connectors		
f. Knows any incompatible connector/device combinations, for example if anti reflux connector (TKO) can be used with a valved CVC		
10. To detect possible infection		
a. Can identity signs of possible bloodstream infection		
c. Can identify signs of possible exit site/tunnel infection		
d. Can identify signs of possible cuff infection		
e. Can identify overgranulation tissue at exit site		

f. Can identify signs of possible port pocket infection (port only)		
g. Can identify action to take and point of contact for above		
11. To detect possible hypoglycaemia		
a. Can identify the signs of possible hypoglycaemia.		
b. Can identify measures taken to prevent hypoglycaemia.		
c. Knows the at risk periods of hypoglycaemia.		
d. Can identify action to take and point of contact for further advice.		
12. To prevent air embolism		
a. Knows how air can enter bloodstream and infusion		
b. Can describe signs and symptoms of suspected air embolism		
c. Can describe position patient should be placed in if air embolism is suspected		
d. Knows when and how to clamp catheter		
e. Can identity what an approved replacement catheter clamp looks like and can apply to a non valved catheter		
f. Knows how to deal with "air in line" during infusion		
g. Knows what to do in case of catheter falling out		
13. To act appropriately with a blocked catheter		
a. Can identify common reasons catheters can become blocked		
b. Knows signs of catheter blockage		
c. Can identify and perform simple "first aid" measures to try and restore patency		
d. Can identify action to take and point of contact		
14. To act appropriately with catheter fracture		
a. Knows how catheters can become fractured		
b. Can identify signs of catheter fracture		
c. Knows what to do in case of catheter fracture		
d. Can identify when a catheter has been repaired and can assess the integrity of the repair		
e. Can identify point of contact for the above		
15. Can identify possible catheter malposition		
a. Knows the approximate external length of catheter (Cuffed and PICCs)		
b. Knows function of cuff and how to locate approximate location within skin tunnel		
c. Can identify an exposed cuff		
d. Understands function of SecurAcath engineered securement device(if used) and how to identify it is correctly placed		
e. Knows where a catheter tip should be and understands the implication of catheter malposition		
f. Can identify action to take and point of contact for the above		
16. Can recognize signs of possible thrombophlebitis and thrombosis		
a. Can describe and recognize signs of thrombophlebitis in patients with a PICC		
b. Can describe possible signs and symptoms of a central venous catheter related thrombosis		
c. Can identify action to take and point of contact for the above		
17. Correct storage of PN, IV fluids and any other prescribed IV medication		
a. Can describe how to correctly store PN		
b. Can read expiry date correctly		
c. Understands about stock rotation		
d. Understands importance of cleaning fridge		
e. Can describe how to correctly store any IV fluids		
f. Can describe how to safely dispose of any unused prescribed PN/IV fluids or other prescribed medication		
18. Can identify signs of fluid overload		
a. Can recognize signs and causes of possible fluid overload		
b. Can identify action to take and point of contact.		
19. Can identify signs of dehydration		
a. Can recognize signs and causes of possible dehydration		
b. Is aware of the sodium content of the following commonly prescribed prn fluids 1 L 0.9% sodium chloride 1 L 4% dextrose & 0.18% sodium chloride and when it would be clinically appropriate to administer them		
c. Can identify action to take and point of contact		
20. Can take blood from central venous catheter		
a. Knows when a discard volume is necessary and why		
b. Knows how much discard volume to take with different vascular access devices		
c. Can identity measures to facilitate blood return in cases where blood cannot be easily aspirated		
d. Flushes catheter following blood sampling		
21. Safe disposal of healthcare waste		
a. Can describe how to safely dispose on healthcare waste associated with the administration of PN/IV fluids and any other prescribed IV medication		
22. Lifestyle issues		
a. Knows how to advise patient on how to safely care for external surface of the line and clamp		
b. Knows how to advise patient on how protect line during showering/bathing (as per hospital protocols)		

c. Can advise patient re process to follow if they want to go on holiday		
23. Care of venting gastrostomy tube (if applicable)		
a. Understands function of venting gastrostomy tube		
b. Can access tube with appropriate enteral syringe		
c. Can aspirate and flush tube as per hospital protocol		
d. Understands rationale behind, and can demonstrate, rotating and advancing tubes		
e. Can undertake routine balloon care (balloon tubes only)		
f. Knows advice to give and point of contact if tube falls out.		
24. Knows about and informs patients about the patient support group PINNT		
a. Knows about and informs patient about the PINNT Verify tag		
b. Knows about and informs patient about the PINNT restaurant card		
c. Knows about and informs patient about the Patient Safety poster

Appendix 4. Home Parenteral Nutrition Patient Competencies, NHS 2019® (used with permission)

Home Parenteral Nutrition Patient Competencies

Name _____

_____

Aim: The patient/carer* will acquire the knowledge and skills necessary to safely and effectively administer parenteral support (nutrition and or intravenous fluids) and care for the central venous catheter. *It is recommended that any family members undertaking administration of parenteral support and care of central venous catheters are 18 years of age or above.

Learning outcome	Achieved (date)	Signature
1. To understand why parenteral support is required		
a. Principles of normal intestinal function		
b. How gut function has changed		
c. How to minimize effect of GI changes		
d. How and when to administer additional IV fluids		
2. To understand principles of asepsis		
a. Washes and dries hands effectively		
b. Applies hand rub correctly		
c. Applies gloves (if recommended)correctly		
d. Cleans and disinfects trolley/tray correctly		
e. Correctly opens sterile items onto aseptic field		
f. Can identify key parts and non-key parts		
g. Understands the concept of key part and key site management		
h. Disinfects needle free connector for minimum of 15 seconds with pressure and friction, and allows to dry for 30 seconds		
3. To safely disconnect and flush catheter		
a. Deals appropriately with pump and catheter at end of infusion		
b. Prepares syringe with flushing solution correctly		
c. Flushes catheter with push-pause technique		
d. Uses positive pressure clamping technique when disconnecting syringe (open ended catheters)		
e. Uses positive pressure when disconnecting syringe (valved catheters)		
f. Care of unused lumens (if applicable)		
g. Prepares and instills antimicrobial lock correctly (if applicable)		
h. Removal and safe disposal of Huber needle (port only)		
i. Applies 70% isopropyl alcohol port protector correctly (if recommended)		
j. Secures catheter as per hospital protocol		
4. Administration of any additional prescribed *bolus* medications via central venous catheter (if applicable)		
a. Prepares and administers any additional prescribed bolus medications correctly		
b. Knows how to safely dispose of used ampoules/vials/sharps		
c. Knows what to do in case of needlestick injury (if applicable)		
5. Addition(s) to IV fluids (if applicable)		
a. Can identify additive port on IV fluid container		
b. Prepares any prescribed additions correctly as per manufacturer's instructions using an appropriate aseptic technique		
c. Adds any prescribed additions, using an appropriate aseptic technique to the IV fluid container correctly using a safety needle and is aware of the correct order of any additions		
d. Ensures any additions have been dispersed adequately within the IV fluid container		
e. Primes giving set correctly		
f. Primes any additional administration set for simultaneous secondary infusion, for example Y-site or Octopus double lumen extension set		
g. Knows how to use Micrel double spike giving set and administration tubing (if used)		
h. Knows how to safely dispose of used ampoules/vials/sharps		
6. To safely set up parenteral support (PN or IV fluids)		

a. Checks solution(s) correctly		
b. Can identify if a bag(s) not safe to administer, ie cracking, creaming		
c. Primes giving set (single, or double spike if used) correctly either manually or via pump. (Note: for manually primed giving sets NHS Improvement have recommended that once primed the giving set is placed into the pump before being connected to the catheter so as to reduce the risk of accidental free flow)		
d. Checks patency of catheter before connecting infusion (as per hospital protocol)		
e. Uses pump correctly		
f. Deals with pump alarms appropriately		
g. Protects bag from light (where applicable)		
h. Insertion of Huber needle (implanted port only). Can identify if needle has been inserted correctly and is the correct length		
i. Knows how to use Portactor (port locating device) if recommended (port only)		
j. Can deal appropriately with blood backflow in giving set		
k. Protects giving set/catheter connection during infusion (if applicable as per hospital protocol)		
l. Knows how to use a gravity giving set and when this would be indicated		
7. Calculates infusion rates correctly		
a. Knows maximum hourly infusion rate for prescribed parenteral support		
b. Knows maximum hourly infusion rate for additional IV fluids		
c. Knows how to ramp up and ramp down infusion (where applicable)		
8. How and when to dress exit site		
a. Knows frequency of dressing change and cleaning of exit site		
b. Knows how to remove dressing to minimize skin impairment (+/- medical adhesive remover)		
c. Knows what to clean exit site with and method of cleaning		
d. Knows how to apply silicone skin protection (if recommended)		
e. Suitable dressings to use		
f. Knows frequency of sutureless securement device change (PICC only)		
9. How and when to change needle free connector		
a. Knows name of connector used an how often this should be routinely changed		
b. Knows any additional times connector should be changed		
c. Can change connector during disconnection procedure		
d. Can change connector during connection procedure		
10. To detect possible infection		
a. Can identity signs of possible bloodstream infection		
c. Can identify signs of possible exit site/ tunnel infection		
d. Can identify signs of possible cuff infection		
e. Can identify signs of possible port pocket infection (port only)		
f. Can identify action to take and point of contact for above		
11. To prevent air embolism		
a. Knows how air can enter bloodstream and infusion		
b. Knows when and how to clamp catheter		
c. Knows how to deal with “air in line” during infusion		
d. Knows what to do in case of catheter falling out		
e. Can identify point of contact		
11. To act appropriately with blocked central venous catheter		
a. Knows signs of central venous catheter blockage		
b. Can identify simple “first aid” measures		
c. Can identify action to take and point of contact		
12. To act appropriately with central venous catheter fracture		
a. Knows how catheters can become fractured		
b. Can identify signs of catheter fracture		
c. Knows what to do in case of catheter fracture		
d. Can identify point of contact		
13. Can identify possible catheter malposition		
a. Knows function of cuff (tunneled catheter) and approximate location within skin tunnel		
b. Knows external length of PICC (if applicable)		
c. Understands function of SecurAcath device (if used)		
d. Understands implication of catheter malposition		
e. Can identify action to take and point of contact		
14. Can recognize signs of possible thrombosis		
a. Can describe possible signs and symptoms of a central venous catheter related thrombosis		
b. Can identify action to take and point of contact		
c. Can describe possible signs and symptoms of thrombophlebitis (PICC only)		
d. Can identify action to take and point of contact		
15. Correct storage of PN, IV fluids and any other prescribed IV medication		
a. Can describe how to correctly store parenteral support		
b. Can read expiry date correctly		
c. Understands about stock rotation		

d. Understands importance of cleaning fridge		
e. Can describe how to correctly store any IV fluids		
f. Can describe how to safely dispose of any unused prescribed PN/IV fluids or other prescribed medication		
16. Can identify signs of fluid overload		
a. Can recognize signs of possible fluid overload. b. Can identify action to take and point of contact.		
17. Can identify signs of dehydration		
a. Can recognize signs of possible dehydration		
b. Can identify action to take and point of contact		
18. Safe disposal of healthcare waste		
a. Can describe how to safely dispose on healthcare waste associated with the administration of parenteral support and any other prescribed IV medication		
19. Lifestyle issues		
a. Knows how to safely care for external surface of the catheter and clamp		
b. Knows how to protect catheter during showering/bathing (as per hospital protocol)		
20. To know points of contact at		
a. Discharging hospital		
b. Homecare company		
21. Care of venting gastrostomy tube (if applicable) Training to be carried out by nurses from Purchasing Authority		
a. Understands function of venting gastrostomy tube		
b. Can access tube with appropriate enteral syringe		
c. Can aspirate and flush tube		
d. Understands rationale behind, and can demonstrate, rotating and advancing tubes		
e. Can undertake routine balloon care (balloon tubes only)		
f. Knows what to do and point of contact if tube falls out.		
22. Knows about patient support group PINNT and Half PINNT		
a. Knows how to join		
b. Knows about PINNT Verify tag		
c. Knows about PINNT restaurant card		
d. Knows about PINNT Safety poster

Care of Intestinal Stoma and Enterocutaneous Fistula(s)

Louise Williams and Gordon L. Carlson

Key Points

1. Good nursing care of intestinal fistulas and stomas is essential to the effective management of patients with intestinal failure.
2. A stoma should be presited (marked) on flat skin away from bony prominences, skin creases or where clothing may grip, at a site agreed by the patient.
3. An understanding of the relevant intestinal anatomy may be helpful in predicting the short and long-term behaviour of an enterocutaneous fistula (ECF) or stoma.
4. Effective skin care involves avoiding contact between stoma and fistula effluent and the skin, especially in the case of more proximal stomas and fistulas, from which the effluent is highly corrosive.
5. A well-fitting adhesive appliance will protect the skin, remove unpleasant odours, reduce risk of cross-infection, allow assessment of fluid losses, preserve dignity and allow the patient mobility and rest.
6. Fistula and stoma appliances which incorporate negative pressure and drainage devices should be considered in higher output fistulas and stomas, in order to facilitate skin care.
7. In cases where there is uncontrollable and unmanageable leakage from a fistula, early surgery to produce a temporary proximal loop jejunostomy may greatly facilitate nursing care and improve patient wellbeing.
8. Accurate recording of fluid balance (and notably fistula or stoma output) is essential for the effective management of patients with high output fistulas.
9. Measurement and a photographic record of an ECF should be kept.

Introduction

Patients with acute intestinal failure complicated by the presence of an intestinal stoma or enterocutaneous fistula should be managed by a multidisciplinary team. Suboptimal care of stomas and/or fistulas may result in adverse physical and psychological consequences [1] and may prejudice nutritional support, surgical treatment or spontaneous fistula closure.

This chapter outlines the fundamental principles of management of patients with intestinal stomas and enterocutaneous fistulas in patients with intestinal failure. Distal enteral feeding which may be complete or trophic is increasingly being performed into a distal unobstructed segment of bowel (stoma or fistula) and is discussed in chapter "Distal Feeding and Hydration".

Definitions

Intestinal Stoma

An intestinal stoma is a surgically created opening in the abdominal wall related to a portion of the gastrointestinal tract. Its purpose is to provide a pathway for digested material to leave the body when the normal pathway is obstructed or its function otherwise impaired [2]. An intestinal stoma may involve the stomach (a gastrostomy), part of the small intestine (duodenostomy, jejunostomy, ileostomy) or a part of the large intestine (colostomy). Some stomas may even involve two separate segments of the gastrointestinal tract (for example an ileocolostomy). A stoma is termed an end stoma (in which the bowel at the site selected is divided and brought up to the skin) or a loop/defunctioning stoma when the bowel is not divided but simply opened (Fig. 1). A defunctioning stoma is usually intended for a few months often to defunction an anastomosis distal to it (e.g. in low anterior resection or the rectum or ileoanal pouch). In each case, the bowel is ideally brought out through the rectus

J. M.D. Nightingale (ed.), *Intestinal Failure*, https://doi.org/10.1007/978-3-031-22265-8_38

abdominis muscle to minimize the chance of a parastomal hernia developing [3] and then sutured to the skin after an approximately 2.5 cm circular area of skin has been removed. Large bowel stomas (colostomies) are generally sutured flush with the skin, whereas small bowel stomas (ileostomy, jejunostomy, duodenostomy) usually have an everted 2.5–3.0 cm spout. This modification, devised by Brooke, enables the corrosive effluent to be kept away from the skin and appliances to be kept on with relative ease [4].

Enterocutaneous Fistula

An enterocutaneous fistula is an abnormal communication between the gastrointestinal tract and the skin. Enterocutaneous fistulas may develop as result of complications of surgery or as a result of intrinsic disease of the gastrointestinal tract (e.g. in Crohn's disease, malignancy or diverticular disease of the colon). Enterocutaneous fistulas (Fig. 2) are classified according to the site of origin and attachments, the number of openings, the orientation with respect to the long axis of the intestinal tract and the presence of an associated abscess cavity. When more than one organ system is involved, fistulas are described as complex. For example, a fistula arising from the side of the terminal ileum and passing directly to the skin of the abdomen would be described as a simple lateral ileal fistula (Fig. 2a). A similar track passing from the side of ileum into an abscess cavity, and the bladder then to the skin is described as a complex lateral ileovesicocutaneous fistula (Fig. 2b). Fistulas that arise perpendicular to the long axis of the gut are referred to as end fistulas and may arise following complete anastomotic dehiscence or rectal stump blow out after Hartmann's procedure. They classically develop from the duodenal stump after a Polya gastrectomy. An enteric fistula occurring in the setting of an open abdomen creating a communication between the GI tract and the external atmosphere may be referred to as an enteroatmospheric fistula (EAF). Intestinal fistulas are most commonly caused by an anastomotic or suture line leakage, trauma, inflammatory bowel disease,

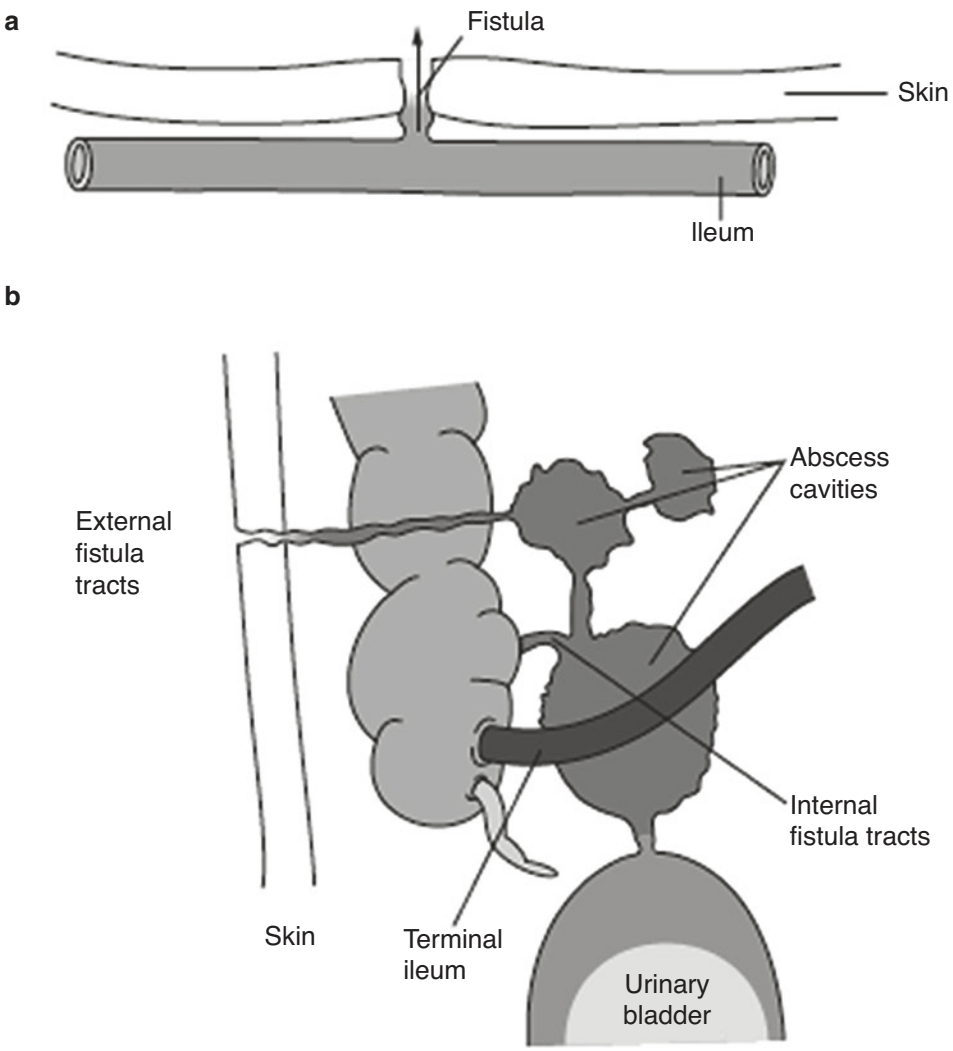

Fig. 2 Classification of intestinal fistulas, showing (**a**) a simple lateral ileocutaneous fistula track and (**b**) a complex track involving skin and bladder with intervening abscess cavities

malignant disease, diverticular disease of the colon, or as a consequence of radiotherapy [5].

The "Normal" Stoma

It is usual for a stoma to be oedematous after surgery and to shrink over the first 1–2 postoperative weeks. This usually results in a requirement for a smaller template.

Choosing the Stoma Site

The Stoma Care Nurse should discuss the planned surgery with the patient, using diagrams to explain what a stoma is, how it will affect their life, how it is managed and how to manage problems. The ideal site for the stoma is selected after careful evaluation of the patient. A flat area of normal skin contour, below the belt or waistline (except for a transverse colostomy) is chosen away from bony prominences (iliac crest or costal margin), surgical scars/skin folds/creases and unobscured by pendulous breasts. The optimal site avoids places where clothing grips the abdomen or where the bag would be conspicuous or easily damaged. The site chosen is marked with indelible ink and should be just medial to the linea semilunaris. The patient is asked to sit, bend, stand and walk to check the suitability of position (it may be useful to apply a bag if difficulties are evident or if the patient requests). A reserve site may also be chosen as type of stoma brought out during surgery may change, some surgeons may ask for patient to be sited on both sides.

Colostomy

A colostomy generally begins to act 2–5 days after surgery. Flatus, followed by watery faeces, will first become apparent but with the introduction of oral fluids and diet the effluent will become solid. The volume of output will be influenced by the diet, the presence of coexisting intestinal disease and the precise location of the stoma with respect to the colon. In general, a colostomy output varies between 200 and 600 mL/24 h.

Ileostomy

An ileostomy generally starts to work within 24 h. During the first week, an output of about 1.2 L of watery stool is expected and this falls for the second week to about 600 mL daily of porridge-like stool. The output initially rises as food is taken. A normal ileostomy may reduce its output over the following few months.

Jejunostomy

The output from a jejunostomy increases dramatically after food/fluid is taken orally and may reach more than 6 L if less than a metre of jejunum remains. Patients with a jejunostomy are likely to require continued intravenous fluid and electrolyte therapy in order to prevent metabolic complications. It should be stressed that excessive thirst due to dehydration should be treated with oral fluid restriction (typically to <1500 mL/day) and the loss replaced intravenously. Allowing such patients unrestricted access to oral fluids results in a vicious cycle in which excessive fluid intake results in increasing fluid output from the stoma and greater thirst. It is important to remember that each litre of jejunostomy effluent contains approximately 100 mmol of sodium and 20–40 mmol of potassium and these electrolytes must be replaced. Maintenance electrolyte fluids are available for intravenous replacement in these circumstances.

In patients with a newly-created jejunostomy, careful attention to monitoring of fluid and electrolyte balance should be undertaken. Although daily plasma measurements are of value, homeostatic mechanisms result in failure of plasma measurements to detect dehydration or electrolyte depletion until late in their evolution. A more useful and more acceptable means of monitoring the patient's fluid and electrolyte status is to weigh the patient and perform measurement of urinary sodium concentration at least twice-weekly. The finding of a urinary sodium of less than 20 mmol/L in such patients implies sodium depletion and a need for further assessment (chapter "Management of a High Output Stoma, Jejunotomy or Uncomplicated Enterocutaneous Fistula").

Diet with a Stoma

Patients with stomas can be reassured that they will not have to make major modifications to their diet. Some foods, however, may cause discomfort or even intestinal obstruction, malodorous flatulence or diarrhoea and may be best avoided, although patients will ultimately determine their dietary preferences on an individual basis.

Nuts and fibrous foods such as dried fruits (e.g. raisins and sultanas) and 'pithy' fruit (e.g. orange) may cause discomfort or even obstruction in patients with an ileostomy. Other foods that may be partly digested include celery, coconut, coleslaw (raw cabbage), sweet-corn, orange, mushroom, nuts, peas, popcorn, pineapple, relishes (e.g. chutney), seeds and skins (e.g. apples/pears). Foods that may cause flatulence/malodour are generally avoided (asparagus, baked beans, cabbage, broccoli, brussel sprouts, fish, cauliflower, eggs, beer, carbonated beverages, onions and parsnips).

Reduction of Odour

Deodorizing drops can be put into a stoma bag if there is perceived to be a major problem of malodour. Neutralizing sprays can also be used. If there is a malodorous wound it may be redressed with a charcoal- or metronidazole-based dressing. Some foods may cause flatulence (e.g. brassicas such as sprouts) and the diet can be restricted if desired.

Training of Patient/Carer

The patient and/or their carer must learn how to empty the stoma bag and change and dispose of a one- or two-piece appliance. They need to know how to look after the peristomal skin and cope with leakage, flatus or malodour. They also need to identify a reliable source of supply of stoma care products.

Irrigation

Some patients try to regulate their colostomy output by irrigation, enabling 'continence'. It is undertaken every 24–48 h, cleansing the colon. One litre of warm water is inserted slowly via a cone on the end of soft tubing sited 5–10 cm into the stoma. Some patients prefer to use a pump to administer the water at a slow pace, their stoma nurse can provide this for them from one of the stoma care company's and trained them how to use it. After a period of time a long drainable pouch is connected over the stoma allowing faeces and water to drain into the toilet. The procedure is time-consuming and some patients prefer to do the procedure at night when the bathroom is not in constant use [6]. Irrigation is **not** suitable for an ileostomy.

Activities

A patient may cover their stoma with a minibag for swimming or sexual intercourse. A bag is usually changed after swimming. Participation in most sports is possible though heavy contact sports (e.g. rugby) should be undertaken with caution and a shield can be provided to wear over the stoma to protect it, weight-lifting may make a stoma more likely to prolapse. When flying, it is helpful and reassuring for the patient to carry spare stoma bags in both the aeroplane hold and in the hand luggage. A journey of any length requires an appropriate supply of spare products in case there is a need to change the appliance whilst travelling [7]. They are advised to do short trips first to gain confidence. The insurance company will need to be informed that the patient has a stoma in case of any complications. During the flight a good fluid and salt intake needs to be ensured as patients with a stoma may be at increased risk of dehydration.

Psychological Care

Psychological care is an integral part of the management of patients with stomas and fistulas. This is especially important in the patient who presents with a fistula after repeated failed surgical procedures. In such cases there may be complete loss of confidence in the carers and a state of profound depression and withdrawal. Interestingly, few, if any, clinical psychologists have specific experience in the problems faced by such patients and are unable to relate to the unique problems associated with complex and repeated surgery, multiple fistulas and stomas and prolonged hospitalization. In general, trained members of nursing staff have proven to be the most effective source of psychological support. The patient should be given sufficient information at all times to be aware and actively engaged in their treatment plan. This may include explanations of investigative procedures, surgical options, intended outcomes and any possible complications. It is necessary to repeat these discussions several times so that uncertainty can be avoided. Family members should also be included whenever this is thought to be appropriate. The availability of the spouse or partner is of vital importance and their support is invaluable in offsetting the initial feelings of shame and mutilation felt by many patients [8]. Education should be given to the relatives so that the sharing relationship is allowed to continue, and the family needs to behave normally and demonstrate continued acceptance of the patient, promoting positive attitudes and dispelling possible feelings of rejection or revulsion [9]. The new body image can be difficult to accept but if there is time for the consideration of change then mental adjustment will be easier. However, sudden developments, as in the occurrence of a fistulae or emergency surgery requiring a stoma can give rise to rejection, denial and the problems of withdrawal. Other factors influencing body image are the visibility of the change and its encroachment on lifestyle [8]. Encouragement and allowing ample opportunities to talk will be much needed for both parties and they should be encouraged to voice concerns and fears. Reassurance regarding the progress or possible outcomes will be constantly required and the nurse must answer honestly but never offer false or premature reassurance [9].

Problem Stomas: Leakage

There are many reasons for leakage (Table 1). While the stoma site and complications relating to it may be respon-

Table 1 Reasons for stomal leakage

1. Badly sited stoma on bony prominence, skin creases, dips or scars
2. Stoma shrinkage, retraction, prolapse, or peristomal herniation
3. Poor technique (can be due to poor vision or manual dexterity)
4. Weight change (gain or loss)
5. Pancaking
6. Peristomal skin allergy or granulation tissue

sible, a poor technique is often the cause. This may be due to poor vision or manual dexterity, an overfull appliance, one that has been left on for too long or alternatively changed too frequently. An uneven skin surface due to sitting in one position for a long time or changing weight (increase, decrease or pregnancy) may affect the way an appliance fits, thus making it liable to leak. Pancaking of solid stool at the top of a stoma can cause leakage. It can be helped by putting baby oil onto the inside top of the appliance, covering the filter or an adhesive bar can be placed on the outside of stoma to form a bridge. This prevents both pancaking and also the stoma bag sticking to the stoma. Peristomal skin irritation can be due to allergy to plaster or the appliance adhesive and a change of these may help. The hairs around an appliance may need to be shaved. Fungal infections frequently occur on moist, warm peristomal skin. Granulation at the stoma edge is harmless but can cause bleeding or prevent bag application. This responds to cautery with a silver nitrate pencil.

The Complicated Stoma

Specific medical and nursing care may be required to manage the stoma when complications occur. The principal general complication associated with creation of a stoma relates to fluid and electrolyte balance in patients with a high output proximal stoma (chapter "Management of a High Output Stoma, Jejunotomy or Uncomplicated Enterocutaneous Fistula"). Local complications associated with stoma formation may be apparent early or late in the postoperative period. Complications of stomas are common and 20–30% of patients will require further surgery within 5 years for a problem with the stoma.

Early

In the first days after surgery, local complications relating to the blood supply of the stoma and its attachment to the skin are common. These include obstruction from torsion or oedema of the stoma (especially in the presence of a loop ileostomy), bleeding, retraction, necrosis and peristomal infection. Infection is surprisingly uncommon in the absence of an element of necrosis at the mucocutaneous junction. These complications may require further surgery. Necrosis of the stoma (Fig. 3) may be managed conservatively, provided that the patient is systemically well, has no signs of spreading peritonitis and viable mucosa is identifiable outside the patients' abdominal wall. This can usually be easily ascertained by gently inserting an endoscope into the stoma or even using a lubricated test-tube and shining a torch along it for illumination. When conservative management is successful, the stoma generally heals with stenosis (Fig. 4) and may require subsequent refashioning.

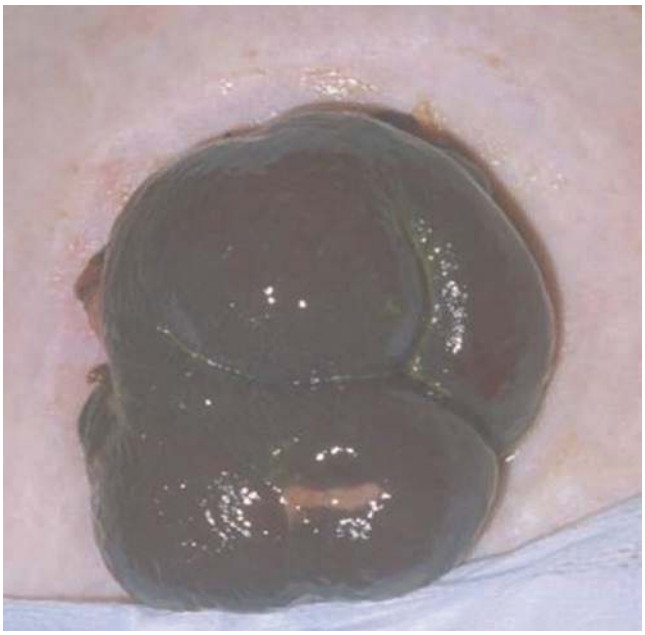

Fig. 3 Superficial necrosis and healthy tissue is seen underneath the covering

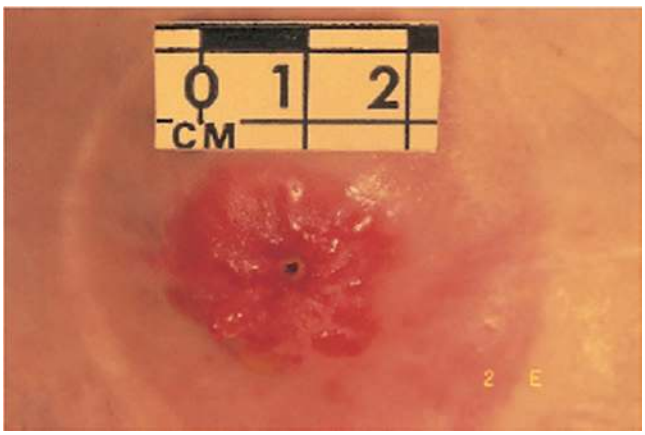

Fig. 4 Stenosis of the stoma following superficial necrosis

Late

Local complications that develop in the weeks or months after fashioning a stoma, generally relate to stoma care itself, the development of a parastomal hernia or intestinal disease.

Skin Damage

Intestinal effluent is a digestive juice and can rapidly digestive the peristomal skin. Skin excoriation will begin to occur within half an hour of exposure to jejunostomy/ileostomy fluid and protective powder or barrier spray should be applied to the area to help healing and to protect the skin. Ulceration around a stoma may be due to a poorly fitting stoma appliance but in patients with inflammatory bowel disease, pyoderma gangrenosum (Fig. 5) should be suspected, with typical 'punched out' ulcers.

Bowel Damage

Ulceration, excessive granulation tissue and bleeding from the mucosa, usually of an ileostomy, are common complaints and may be attributable to a poorly fitting stoma appliance (Fig. 6). In patients with Crohn's disease, recrudescence of disease within the stoma may occur and present with pain, bleeding and visible ulceration. In severe cases, the associated stricturing may lead to intestinal obstruction. A biopsy may be required to establish a definitive diagnosis.

Herniation

Parastomal herniation is very common complication of an end colostomy particularly if a stoma brought out is lateral to the rectal sheath and if the abdominal musculature is very weak as often occurs in the elderly. There is some evidence to suggest that coordinated abdominal wall exercises in the postoperative period may reduce the frequency and/or severity of herniation. The Stoma nurse should offer advice and expertise on the prevention of a parastomal hernia in the form of exercise and wearing a support belt when participating in strenuous activates [10]. A parastomal hernia may predispose to intestinal obstruction and strangulation, is disfiguring for the patient and may make it difficult to fit an appliance.

Parastomal hernias are difficult to correct surgically. A variety of surgical approaches may be adopted, ranging from local suture repair and mesh repair to laparotomy and transposition of the stoma, depending upon the size of the hernia and the age and condition of the patient. The long-term results of repair are poor, however, with up to 50% of patients reporting a recurrence of their hernia. In general, surgical repair of a parastomal hernia is avoided unless the hernia prevents the fitting of a stoma appliance or is narrow-necked and symptomatic.

Fig. 5 Pyoderma gangrenosum around an ileostomy

Fig. 6 Granulations and superficial ulceration of an ileostomy, due to a poorly fitting stoma appliance

Prolapse

Prolapse of a stoma is generally associated with the development of a parastomal hernia and is characterized by an 'elephant's trunk-like' everted protrusion of the stoma. This may prevent satisfactory fitting of an appliance and is especially common in patients with a transverse loop colostomy, which should therefore be avoided if at all possible. Surgery may be required to refashion the stoma, especially if prolapse interferes with stoma care.

Emergency surgery may be avoided in some cases by techniques to reduce oedema of prolapsed stomas, for example by application of granulated sugar, which may facilitate reduction of prolapse [11] (Fig. 7). Elective refashioning will usually be required however.

Stenosis and Retraction

These complications both result from defective surgical technique. Stenosis results from circumferential fibrosis at the mucocutaneous junction, most commonly as a secondary consequence of ischaemia and necrosis. If it is too painful to perform a digital examination of the stoma to assess the depth of mucosa stricture then patient may need referring onto a surgeon for dilatation under general anesthetic or refashioning of the stoma [12]. It must be remembered that refashioning an ilesotomy may involve a considerable amount of bowel being resected (>5 cm) and this can be very important if the patient has intestinal failure.

Fig. 7 Prolapsed stoma

Stoma retraction occurs when insufficient bowel has been mobilized to allow the mucosa to be sutured to the skin edge without tension. In the absence of impaired vascularity (as opposed to stenosis) the bowel does not become necrotic but the opening of the stoma lies in a depression. This leads to leakage under the flange, which may then lift off. Persistent leakage, which cannot be compensated for by the use of an appropriate appliance, is an indication for surgical refashioning of the stoma.

Enterocutaneous Fistula Management

The key principles in the management of a patient with an enterocutaneous fistula is the adequate treatment of abdominal sepsis, which is the most common cause of death [13] (chapter "Acute Surgical Intestinal Failure. Sepsis and Enterocutaneous Fistula(s)"). When possible, abdominal sepsis is managed by percutaneous drainage, but in some cases, notably those in which sepsis has arisen due to anastomotic dehiscence, a laparotomy will usually be required for drainage of abscesses and creation of a proximal defunctioning stoma to divert the faecal stream.

Once abdominal sepsis has been treated, attention is given to skin care, nutritional and metabolic support. Many fistulas will heal spontaneously but they will not if there is continuity between the gut mucosa and the skin, disease at the site of the fistula (for example Crohn's disease), distal obstruction and/or an intervening undrained abscess cavity [5]. In such cases enteral nutritional support with a low residue diet is appropriate for low output (<200 mL/day) fistulas in the distal ileum or colon, whereas patients with high output (>500 mL/day) fistulas, which are typically found in the proximal small bowel will usually require parenteral nutrition. It is the authors' preference to restrict such patients to sips of fluid only (some units say "nil by mouth") if contrast radiology suggests that a fistula is likely to close spontaneously. It should be noted that spontaneous closure will not occur when there is exposed bowel mucosa at the fistula opening. Such fistulas eventually mature and behave much like stomas. Where closure is unlikely (as above) and bowel content is not leaking into the abdominal cavity, prevention of oral intake is unnecessary and such patients can be allowed relatively unrestricted access to fluids and diet, provided fluid intake is not excessive and does not make local management of the fistula impossible. The same principles apply to the management of the high output fistula as the high output stoma (e.g. restriction of oral fluid intake and the use of oral glucose–electrolyte solutions, drugs that

reduce motility and intestinal or secretions) (chapter "Management of a High Output Stoma, Jejunotomy or Uncomplicated Enterocutaneous Fistula").

Management of the Patient with an Enterocutaneous Fistula (or Complicated Stoma)

Skin Care

Care of the skin around a stoma or fistula is perhaps the most important component of nursing care. The principal objective is to keep the effluent away from the skin. The more proximal in the gut a fistula, the more likely its output is to discharge corrosive fluid with activated pancreatic enzymes that can cause painful skin destruction (Fig. 8).

Management of the peristomal skin should be pro-active, with the goal being prevention by identifying and managing the causes effectively, thus preventing skin breakdown occurring [14]. An initial assessment of the stoma/fistula and surrounding skin should first be made noting approximate measurements, skin condition/degree of excoriation, description of output and any associated nursing implications (e.g. pain). Skin contours are noted for creases where leakage could occur. It is often helpful to photograph the wounds at this time. This information, together with accurate measurements of stoma output, allows the stomatherapist to select the most appropriate appliance thus enabling collection of the effluent and controlling the problems of leakage and odour. The patient, in turn, gains comfort, confidence and independence. Key aspects of management of the patient with an intestinal stoma or fistula are the selection of appropriate equipment and the adoption of suitable management techniques.

Fig. 8 Extensive skin damage resulting from a high output enteroatmospheric fistula with inadequate skin protection

The Stoma nurse should determine the type and size of appliance and initially the frequency of bag emptying and changing. The aim is to keep the equipment and procedures simple and allow for the patient to choose their preferences. Complex ritualistic procedures must be avoided.

Stoma/Fistula Appliances

A well-fitting adhesive appliance will protect the skin, remove unpleasant odours, reduce risk of cross-infection, allow assessment of fluid losses, preserve dignity and allow the patient mobility and rest [1]. There are many types of stoma and fistula appliances available and the manufacturers also produce accessories to treat damaged skin, produce an even body contour (thus allowing better fitting of a stoma appliance) and deodorize offensive exudates. Immediately postoperatively a clear, unvented, drainable standard bag on which the aperture is cut to fit the stoma is used so that the viability of the stoma can be monitored and stool/air output can be observed. As the stomal output becomes regular and predictable a one- or two-piece bag can be used. The former attaches directly to the skin and may be closed or drainable. A closed bag is often appropriate for a colostomy, which is typically changed 2–3 times a day. A drainable appliance is appropriate for ileostomies/jejunostomies or for colostomies with a fluid output. Flatus valves (vent/charcoal filter), to allow escape of gases, are now present in most appliances. Two-piece appliances have a flange that can stay on the skin for 3–4 days and are fitted with either a drainable or closed bag. Drainable bags should be changed every 24–72 h. Stoma products have changed dramatically over the years and a large selection are now available. Bags for use over an established stoma can have a pre-cut aperture if patient prefers this and come in all different sizes as colors. Most bags hold about 200–300 mL of fluid. Extensive wound areas require a large 'wound manager' (Fig. 9). These can be adapted to the size and shape of any wound and are drained continuously. Planned stomas that are of routine size are more easily catered for, but stomas that have become flush or have retracted, can be successfully managed with the use of convex flanges incorporated within the bags.

Adhesive Flanges

An appliance usually sticks to the skin by a cohesive seal. Clean, warm, dry skin is needed. If the skin is itchy, a barrier spray or wipe can be used and helps both with itching and adhesion.

Filling Pastes/Wafers/Dressings

There are many hydrocolloid pastes that can be used to fill defects in a wound. Wafers may be used to help adherence of

Fig. 9 Fistula appliance attached to a high output collection bag hold 2 L

the appliance and may act as barriers between the bag/skin. The flanges of a stoma bag can safely cover wounds if needed.

Absorbent dressings with associated barrier creams are inadequate for outputs of more than 20 mL/day. Appropriate well-fitting/constructed stoma appliances cut to fit the area and so cover exposed skin enable successful management [15].

Techniques

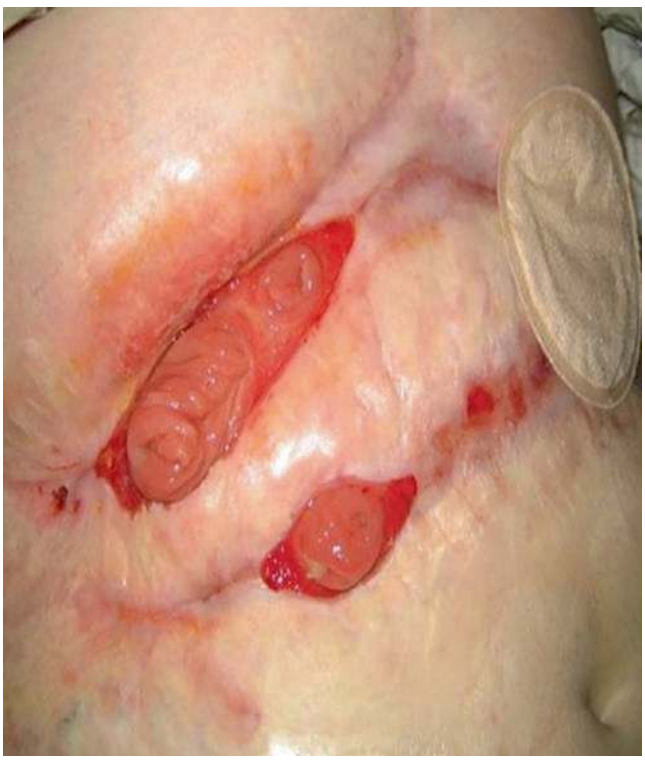
Fitting an Appliance Over a Stoma

The appliance is peeled from the skin gently by easing the skin away and barrier remover spray or wipes can be used to assist this. The surrounding skin is then cleaned using soft wipes and warm water and the area dried well with a dry wipe. Tap water alone is adequate for this purpose. However, if desired, an unperfumed, gentle soap could be used. Direct contact with the intestinal mucosa should be avoided. An appliance of the correct size is selected and cut to size. The backing is peeled off and applied gently to the abdomen over the stoma area.

An ileostomy bag is usually emptied 5–6 times/24 h (total volume is about 500–800 mL/24 h) and most patients do this once during the night. If the patient has a high stoma output the flange/bag/dressing change is undertaken when the output is likely to be lowest or when help is available. Following drainage of the bag, the end of the appliance is cleaned with a wipe and rolled up and closed securely. Odour powders/deodorant sprays may be used at this time. The bag is subsequently changed as required. In hot conditions this may need to be undertaken more frequently as the backing can 'melt' or due to the patient's skin sweating and the appliance may therefore leak.

Fitting an Appliance Over a Complex Fistula

The area should be cleaned with warm water and dried thoroughly with soft wipes and a hairdryer can be used on a cool setting. Shaving of body hair may be necessary to optimise adhesion and prevent discomfort. Excoriated skin should have Stomahesive Protective ostomy powder applied sparingly. It is often helpful in caring for large fistula wounds to make a template of the area with a piece of clear plastic material that usually comes in the packaging with the appliance. This assists with cutting the base of the bag and is useful in observing the healing process, as smaller templates will be required probably weekly. Crevices or creases of intact skin can be filled with Stoma paste or pieces of Moldable seals to even the site (Fig. 10). It may be necessary to cover this area with a protective sheet cut to fit, but the base of the wound manager alone is usually quite adequate. The immediate edge around the stoma/fistula should be filled with soft paste to help adhere and prevent leakage of the effluent between the surfaces. The readily prepared appliance should now be applied, firmly moulding it to the surface



Figs. 10–12 Applying a bag to an intestinal fistula

Figs. 10–12 (continued)

and ensuring that no creases occur during the procedure (Figs. 11 and 12). The patient should be encouraged to rest for approximately 30 min to promote adhesion of the appliance.

The technique used should be fully documented with a photographic care plan so that other team members can maintain the prescribed care. The area should be regularly inspected and any evidence of pain, burning of the skin, leakage, odour or detachment of the appliance should be investigated and treated appropriately, appliances should not be patched if leaking appliance will need replacing to prevent sore skin occurring. The plan of nursing care should be evaluated regularly and changes made as required. The patient with extensive fistula formation may not be able to participate in any practical aspects of the skin care until their general condition is improved or surgery to treat the underlying problem is undertaken. However, wherever possible the patient should be encouraged to begin to participate in caring for their stoma and so in turn gain independence, autonomy and sense of well-being. The plan to teach and involve the patient with their care should begin following discussion between the stomatherapist, nurses and, most importantly, the patient.

Some fistulas lie in large irregular cavities, which make them exceptionally difficult to manage. Such fistulas may require a short-term treatment of low suction until the area shrinks to manageable dimensions. This is applied via a catheter incorporated within the bag, through which low-grade continuous suction can be applied. This treatment should not be prolonged because negative pressure at the cutaneous surface of a fistula where there is no exposed mucosa may prevent spontaneous fistula closure and the treatment may also restricts mobilization [16]. However, the application of negative pressure where a fistula cannot, in any event, heal spontaneously (for example where there is already enteroatmospheric fistulation) may greatly facilitate nursing care.

In some cases, the configuration of the fistula may make adequate skin and fistula care almost impossible to achieve—for example where a fistula sits at the base of a deep and/or irregular cavity on a skin crease. Persistent leakage and excoriation may result in ulceration, pain, inability to eat and drink (in order to avoid leakage) and psychological distress and be associated with poor mobility and demoralization. These circumstances may represent an indication for early surgery, if only to explore the (usually relatively untouched) left upper quadrant of the abdomen, in order to establish a proximal stoma to defunction the fistula. A well-spouted proximal loop jejunostomy may have significant implications for fluid and electrolyte balance and

nutritional support, but patients invariably find them easier to tolerate (as a temporary measure) than an uncontrollable fistula.

The ultimate goal of stoma and fistula management is for the patient to be able to care for themselves. This may not always be possible, however. Depending upon the patient's individual circumstances, close relatives may need to undertake patient care or the patient may request they be at least made aware of the needs that may be required. Practical skills should be demonstrated to the patient with careful explanations that can be easily understood. Patients should be reassured that they will not be discharged from hospital until they or their carers can cope with the required stoma care. Following a period of observation, patient participation should be encouraged and this can be gradually increased.

Continuous assessment is required and the nurse must continue to support the patient even when full independence in stoma care is achieved. The patient should be informed of all aspects of stoma care from the obtaining of supplies to the disposal of appliances and should be made aware of the availability of self-help associations who can assist in the rehabilitation or with welfare issues.

Emptying Drainage Bags

Stoma bags and wound managers should be regularly emptied to prevent excessive accumulation of effluent because the weight of the fluid can dislodge the bag. Faecal matter is emptied and the bag is wrapped in a plastic bag for disposal. High output fistulas/stomas (over 500 mL/24 h) may require frequent drainage and this can disturb sleep, thus adding to stress. To prevent this, a secondary drainage container allowing continuous gravity drainage of stoma bags into a high output drainage bag with thick piping that can hold up to 2 L (Fig. 9) can be used.

Discharge

Patients need to be independent with their stoma care to ensure safe discharge from hospital, in the absence then there will need to be adequate support in place at home [17]. When the patient is discharged the stomatherapist and the district nurses will maintain continuity of care, and supportive counselling will still be required. Certain problems only become evident on discharge from hospital, especially relating to difficulties in personal or sexual relationships. These may require expert help from marriage guidance or psychosexual counsellors though the nurse can help assess the situation and make arrangements for referral if appropriate.

Management of a High Output Stoma, Jejunotomy or Uncomplicated Enterocutaneous Fistula

Jeremy M.D. Nightingale

Key Points

1. A high output stoma (HOS) or fistula is when the output causes the patient to become water, sodium and magnesium depleted.
2. A HOS tends to occur when the output is more than 1.5–2.0 L/24 h though this varies according to the amount of food/drink taken orally.
3. Management starts with excluding causes other than a short bowel (especially intermittent or partial obstruction). It is helpful to have a measurement of residual small bowel length (at surgery, or by a contrast radiological examination). The stoma and output should be inspected
4. The patient is rehydrated both to relieve excessive thirst and correct electrolyte abnormalities.
5. Oral hypotonic fluids (tea, coffee, fruit juice, alcohol or water etc.) are restricted to a litre or less per 24 h. 1–2 L of a glucose/saline solution (sodium concentration 90–120 mmol/L) (cold, taken through a straw) is sipped throughout the day +/− magnesium supplements.
6. Oral medication to slow transit (loperamide often in high dose or codeine phosphate) is taken before food/drink. For those with a net secretory output (greater than total oral intake) a proton pump inhibitor (omeprazole) may be taken to reduce the volume of gastric acid produced.
7. If hydration cannot be maintained with oral measures subcutaneous saline (usually 1 L with magnesium) given 1–4 times/week may be given before parenteral fluids.
8. In addition to renal function, the urinary sodium concentration and serum magnesium level must be monitored.
9. Consideration should be given to surgically bringing any small or large bowel that is in situ but out of circuit, back into continuity.

Introduction

Most of the classical work published about patients with a short residual length of intestine related to those with jejunum in continuity with colon [1–3]. A number of patients with a jejunostomy are being managed, mainly because the colon is often removed during the surgical treatment of Crohn's disease or it is temporarily out of circuit in the management of ischaemia or a fistula/obstruction. These patients have immediate and serious problems because of large intestinal losses of water, sodium and magnesium. The residual bowel length may not have been measured and such patients are often categorized as having ileostomy diarrhoea. The management of patients with a jejunostomy, ileostomy diarrhoea or a high-output enterocutaneous fistula is the same.

This chapter outlines the medical problems caused by the large volumes of fluid lost from the stoma or fistula and, using data from balance studies, discusses treatments. Information about stoma care is found in chapter "Care of Intestinal Stoma and Enterocutaneous Fistula(s)".

How Common Is a HOS?

A normal ileostomy may function within the first day of surgery depending upon whether an ileus occurs (often due to opiates and excessive intravenous saline). The stomal output from an ileostomy may reduce over several months as adaptation occurs and the normal output when established is 600–1200 mL/24 h. Patients with a jejunostomy (less than 200 cm small bowel remaining) do not generally show any improvement in absorption with time [4].

A high output stoma (HOS) (often called ileostomy diarrhoea) is when the output is enough to cause "dehydration" (water and sodium depletion). In general this occurs with an output of greater than 1.5–2.0 L/24 h. However this depends on the oral intake. A 2 L output for someone taking in 4.0 L will cause no problems but if only an intake of 0.5 L it will result in dehydration [5].

J. M.D. Nightingale (✉)
St Mark's Hospital, Harrow, Middlesex, UK
e-mail: Jeremy.nightingale@nhs.net

J. M.D. Nightingale (ed.), *Intestinal Failure*, https://doi.org/10.1007/978-3-031-22265-8_39

In one study a HOS occurred early in 16% patients (within 3 weeks of a stoma being formed) and late (more than 3 weeks) in 4% in whom this was a persistent problem [6]. Other studies show similar rates 16–31% following surgery [7–9]. Problems are more common in patients with a loop ileostomy or after an ileal resection. There are rarely any problems of HOS when more than half the colon remains in continuity and there is more than 50 cm functioning small bowel present [6].

Evidence that many patients with an ileostomy are salt and water depleted comes from the observation that plasma renin and aldosterone levels are high in ileostomy patients [10, 11] and 13% have a urine sodium concentration of less than 10 mmol/L [12]. Unrecognised, chronic dehydration in these patients can lead to end stage renal failure. Diuretics given to patients with an ileostomy (especially if they have had problems of HOS) may precipitate renal failure and generally should be avoided. Care must be taken with renal dialysis if needed to not remove additional fluid (indeed more may need to be given).

Presentation of Patients with a Jejunostomy

The problem of fluid loss from a jejunostomy is apparent immediately after the surgery that removes the bowel. The fasting stomal output may be less than a L/24 h but it will rise when food and drink are consumed to as much as 8 or more litres a day. This results in dehydration, sodium depletion and hypomagnesaemia. These patients are dependent on their treatment; if they miss a day of treatment, they rapidly become unwell from dehydration.

Patients with a jejunostomy do have problems of protein–energy undernutrition but these develop slowly over several weeks and are usually attended to at the same time as the fluid balance problems. As jejunal length gets shorter fluid balance problems (less than 200 cm jejunum) occur before nutritional ones (less than 100 cm jejunum). The fluid/nutritional problems should be predicted and treated before the patient becomes dehydrated or undernourished.

Causes of a High Output Other Than a Short Bowel

Causes of a HOS other than a short bowel (jejunostomy <200 cm) should be sought. This is a common group who may have a normal length of small intestine (Table 1). An early HOS is most commonly due to sepsis (a raised WBC on day 1 is a clue [9] and may be why an early HOS is more common in diabetics [7]. The other common causes of an early HOS are medication related; this can be because of a prokinetic drug (e.g. metoclopramide) or the sudden, usually accidental, withdrawal of a medication (e.g. opiates or cortisol). *Clostridium difficile* can affect the small bowel and cause a HOS [9]. A chronically HOS is most commonly due to a short bowel (jejunostomy). However intermittent/partial obstruction due to small bowel strictures is common (with associated bacterial overgrowth); a stenosis is most commonly at the stoma [8] (Fig. 1). Dilation of a stricture and a low fibre/residue diet (Table 2) may prevent the obstructive episodes and the occurrence of a HOS. Recurrent disease (including ischaemia), internal fistula, small bowel diverticula, coeliac disease and thyrotoxicosis can all contribute and if treated the HOS may resolve. If the HOS is due to strictures and there is a low serum albumin it may be

Table 1 Reasons for a high output stoma

Early (<3 weeks of formation)
• Abdominal sepsis/ileus/ischaemia (low albumin)
• Drug-related
– Prokinetic drugs (e.g. metoclopramide)
– Low cortisol
– Opiate withdrawal (e.g. codeine phosphate)
• Enteritis (*Cl difficile*)
Late (chronic more than 3 weeks)
• Short bowel—jejunostomy <200 cm
• Intermittent/partial obstruction (strictures)
• Other less common causes:
– Recurrent disease
– Internal fistula
– Small bowel diverticula
– Coeliac disease
– Thyrotoxicosis

that a section of chronically/critically ischaemic bowel remains in situ and the problem will only resolve with a surgical resection.

Balance Studies for Patients with a Short Bowel: Jejunostomy

Balance studies have provided the most useful information about the problems and the management of patients with a jejunostomy. They are easier to perform in patients with a jejunostomy than in patients with a short bowel and a preserved colon as a 1–3-day run-in period is not required, and the stomal bag allows for easier collection.

Patients with a short bowel may not feel hungry, and those with a jejunostomy are often just in positive water and sodium balance, so cannot abruptly stop treatments that are maintaining their equilibrium. Patients who suddenly stop taking codeine phosphate when they have been taking it for several months or years are likely to develop the symptoms and signs of opiate withdrawal, which include diarrhoea, manifested as a rise in stomal output. Balance studies are rarely done in the ideal experimental setting with the patient taking no medications.

There are three possible ways to study intestinal balance in patients with a short bowel. With each, a duplicate oral intake is made and assayed.

Test Meal

A standardized meal containing a non-absorbable marker (e.g. polyethylene glycol) is given and the stool or stomal output is collected for a fixed period while nothing else is taken orally. Rodrigues et al. showed that over 90% of a non-absorbable marker in a liquid test meal was recovered from jejunostomy fluid in the 6 h after the meal [13, 14]. This technique is not appropriate for patients with a retained colon as the time taken for the food residue to be passed in the stool may be 2–3 days.

Investigator-Selected Diet

For each 24-h period, the investigator specifies the exact composition and amount and the time at which food and drink are to be consumed by the patient. This is an experimental ideal but patients with a short bowel are fastidious eaters who often feel full very quickly, and such a study is difficult to perform in practice. Studies have been done, however, in which the proportion and total amount of macronutrients and fluid are fixed [15]. A 2-day collection is adequate for patients with a jejunostomy, but if the colon has been retained a run-in period of at least 2 days is needed, so that remnants of other meals will have been passed in the stool.

Patient-Selected Diet

Patients select a diet freely on the first study day and eat and drink whatever is normal for them. They keep an accurate record of the food and drink, the amount and the time at which it is consumed. On all subsequent study days they consume exactly the same food and drink in the same amounts and at exactly the same times as on the first day. All studies by Nightingale et al. use this method for 2 paired control days and 2 further paired test days when a therapy is given [16].

The way in which stool, ileostomy or jejunostomy output is analysed is important. When jejunostomy output is centrifuged, three layers are seen: fat at the top, fluid in the middle and solid at the bottom (Fig. 2). In general, the higher the output the larger the middle fluid layer; if the output is low (less than 1 L daily) then it may not be possible to see a fluid layer, and the fatty layer and the solid component merge together. While it is simpler to aspirate the fluid layer, filter it, and assay for electrolytes; this can only be done when there is a large liquid output and when the patient is taking little or no solid food. Not all studies state whether the whole stomal output is analysed or whether it is just the fluid layer. All studies by Newton, McIntyre, Rodrigues and Nightingale assayed the whole stomal sample. This involved diluting stomal samples with concentrated hydrochloric acid before flame emission photometry for sodium and potassium measurements or ashing a sample in a 550 °C furnace for 15 h before dissolving in nitric acid and using atomic absorption spectrophotometry to measure magnesium and calcium concentrations. Energy content can be determined by freeze-drying a sample then performing bomb calorimetry.

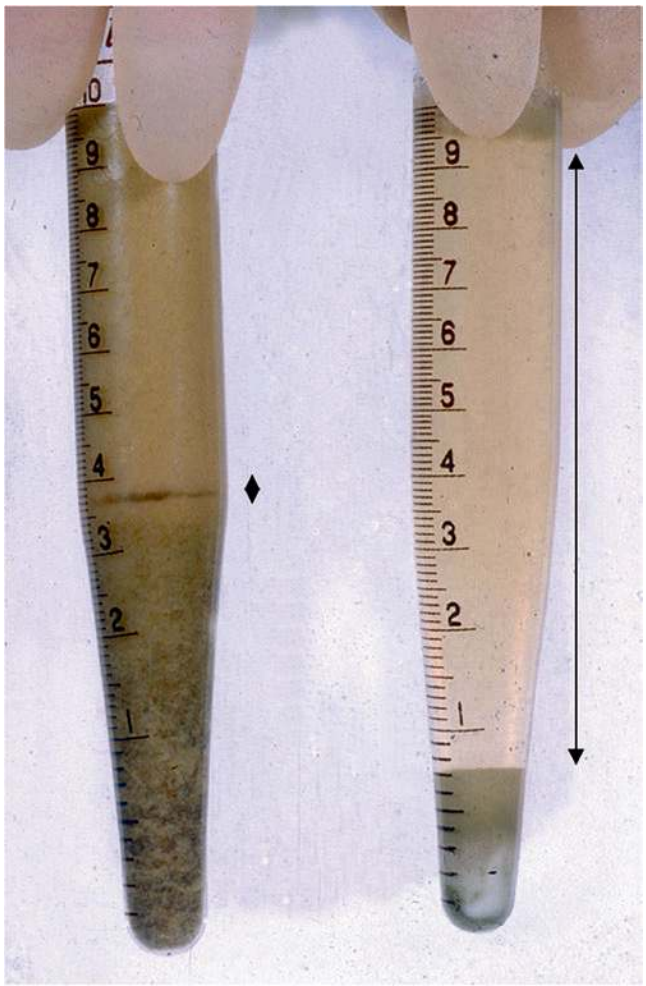

Fig. 2 Centrifuged ileostomy output. Net absorber (150 cm jejunum) on left and net secretor (60 cm jejunum) on right. Note the different size of the middle fluid layer (arrowed). The top layer is fatty and bottom is precipitate/solids

Reasons for a High Output from a Jejunostomy/High Fistula

There are four potential physiological reasons for a HOS in patients with a short bowel and jejunostomy: loss of the normal daily secretions produced in response to food, hypo- or hyper-tonic fluid/food ingestion, gastric acid hypersecretion, and rapid gastrointestinal transit. An excessive thirst may exacerbate the situation.

Loss of Normal Daily Intestinal Secretions

The most important reason for a large volume of stomal output is that the normal daily intestinal secretions produced in response to food and drink (about 4 L/day made up of 0.5 mL saliva. 2 L gastric juice and 1.5 L pancreaticobiliary secretions) cannot be reabsorbed in the short length of bowel

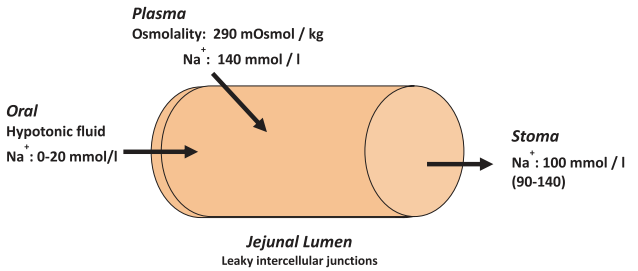

Fig. 3 Diagram to show sodium movement into the jejunal lumen when hypotonic fluid is drunk (upper gastrointestinal secretions not shown)

remaining, so are lost through the stoma. So in most normal subjects, about 6 L of chyme pass the duodeno-jejunal flexure each day and the meal is still just diluted by intestinal secretions 100 cm distal from the duodeno-jejunal flexure [17, 18]. When the small bowel length is less than this, more emerges from the stoma than is taken in by mouth. Even in the fasting state there is an obligatory loss of intestinal secretions produced with the migrating myoelectric complex (MMC) [19].

Hypo- and Hyper-Tonic Fluid Ingestion and Thirst

Jejunal mucosa is 'leaky' and rapid sodium fluxes occur across it. If water or any solution with a sodium concentration of less than 90 mmol/L is drunk there is a net efflux of sodium from the plasma into the bowel lumen [20] until a luminal sodium concentration of 90–100 mmol/L is reached. In a patient with a jejunostomy this fluid is then lost in the stomal output (100 mmol/L sodium) (Fig. 3). Hypertonic fluid (e.g. an elemental diet) will cause a net secretion of water (and sodium) into the lumen till the osmolality nears 300 mOsm/kg. Patients, who are water and sodium depleted, are often very thirsty and so may drink an increasing amount of hypotonic fluid (often containing no sodium) and the effect is to increase the stomal output and increase the sodium losses and so further increasing the thirst [12, 20–23].

Gastric Acid Hypersecretion

There is some evidence to suggest, at least in the short term, that loss of intestinal phase negative feedback inhibition results in hypergastrinaemia [24, 25] and gastric acid hypersecretion, which may all contribute to the high output from a jejunostomy. In man, gastric acid hypersecretion has only been demonstrated in the immediate postoperative period in patients

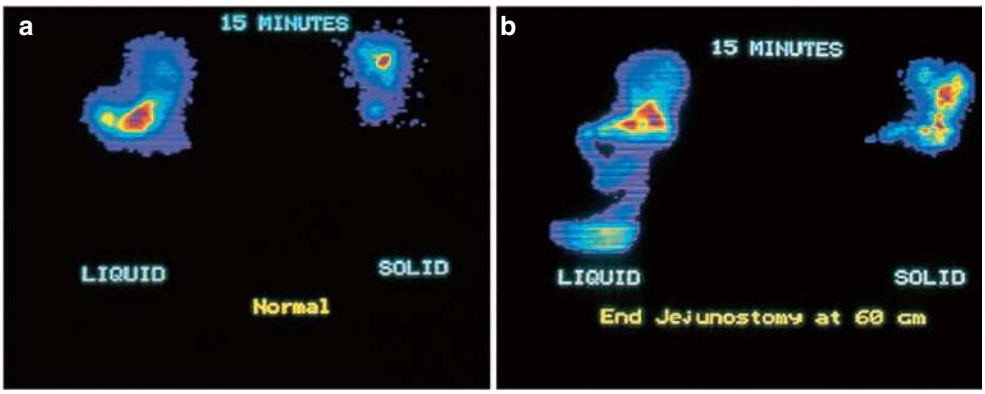

Fig. 4 Gastric emptying of liquid and solid in a normal subject (**a**) and in a patient (**b**) with a jejunostomy 30 cm from the duodeno-jejunal flexure 15 min after starting to eat a meal of a pancake and orange juice

with a retained colon [26]. It is unclear whether this phenomenon persists beyond the first weeks, but a low pH (<6) in the fresh stomal effluent when it exceeds 1 L daily is suggestive.

Rapid Gastrointestinal Transit

Rapid gastric emptying of liquid occurs and may increase the stomal output [27] (Fig. 4). The gastric emptying rate is fastest in those with the shortest lengths of residual jejunum. Small bowel transit time for liquid and solid is also very rapid [28]. Both of these effects may be mainly due to low serum levels of peptide YY [25] and, to a lesser extent, low levels of GLP-2 [28].

The Problem of High-Volume Jejunostomy Output

Water and Sodium Losses

Balance studies in patients with a jejunostomy, using a patient-selected diet, showed that the daily weight of stomal output was about 6–8 kg/d in those on parenteral nutrition with added saline and about 2 kg/d among those receiving oral supplements. The intestinal output is mostly water (mean 92%, range 85–96%) and there is a good correlation between stomal output weight and its sodium content (Fig. 5) [29]. The mean jejunostomy sodium concentration is 88 mmol/L, being lower in patients with a shorter remaining length of jejunum and higher in those with a greater length. The sodium concentration in the terminal ileum may be nearer to that of plasma (140 mmol/L).

Type of Patient with a Jejunostomy (Based Upon Water and Sodium Balance)

Classification of patients with a jejunostomy is based upon balance studies using a patient-selected diet. The weight and sodium content of the diet is compared to the weight and sodium content of the stomal output. The patients can be divided into

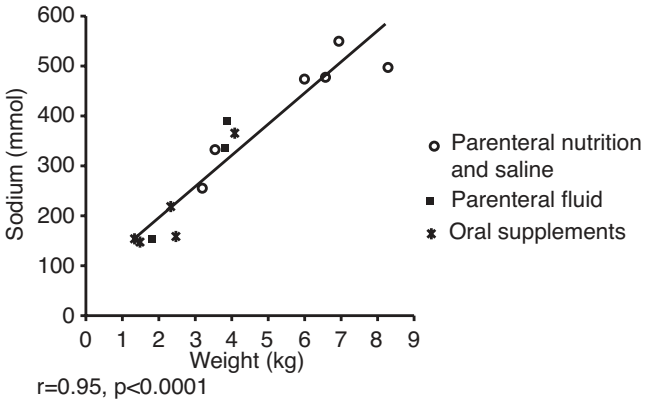

Fig. 5 Wet weight and sodium content of jejunostomy output for 15 patients with less than 200 cm remaining jejunum. ($r = 0.96, p < 0.0001$). The mean sodium concentration was 88 mmol/L (range 60–118 mmol) [29]

one of two groups, either net 'secretors' or net 'absorbers', according to intestinal water and sodium balance. This balance depends upon the degree of dilution of food and drink by digestive juices and the net absorption that has occurred [5] (Fig. 6).

'Absorbers' tend to have more than 100 cm of residual jejunum and can absorb more water and sodium from their diet (which may have been modified to have an increased amount of sodium) than they take orally. Their daily jejunostomy output is usually about 2 kg or less in 24 h, thus they can be managed with oral sodium and water supplements and parenteral fluids are not needed.

'Secretors' tend to have less than 100 cm of residual jejunum and lose more water and sodium from their stoma than they take by mouth. Usual daily stomal output may be 4–8 kg. These patients cannot convert from negative to positive water and sodium balance by taking a modified diet or sodium supplements and they need long-term parenteral supplements [5]. These requirements change very little with time [30]. The jejunostomy output from a net 'secretor' increases during the daytime in response to food and decreases at night, thus any drug therapy that aims to reduce the output must be given prior to food (Fig. 7).

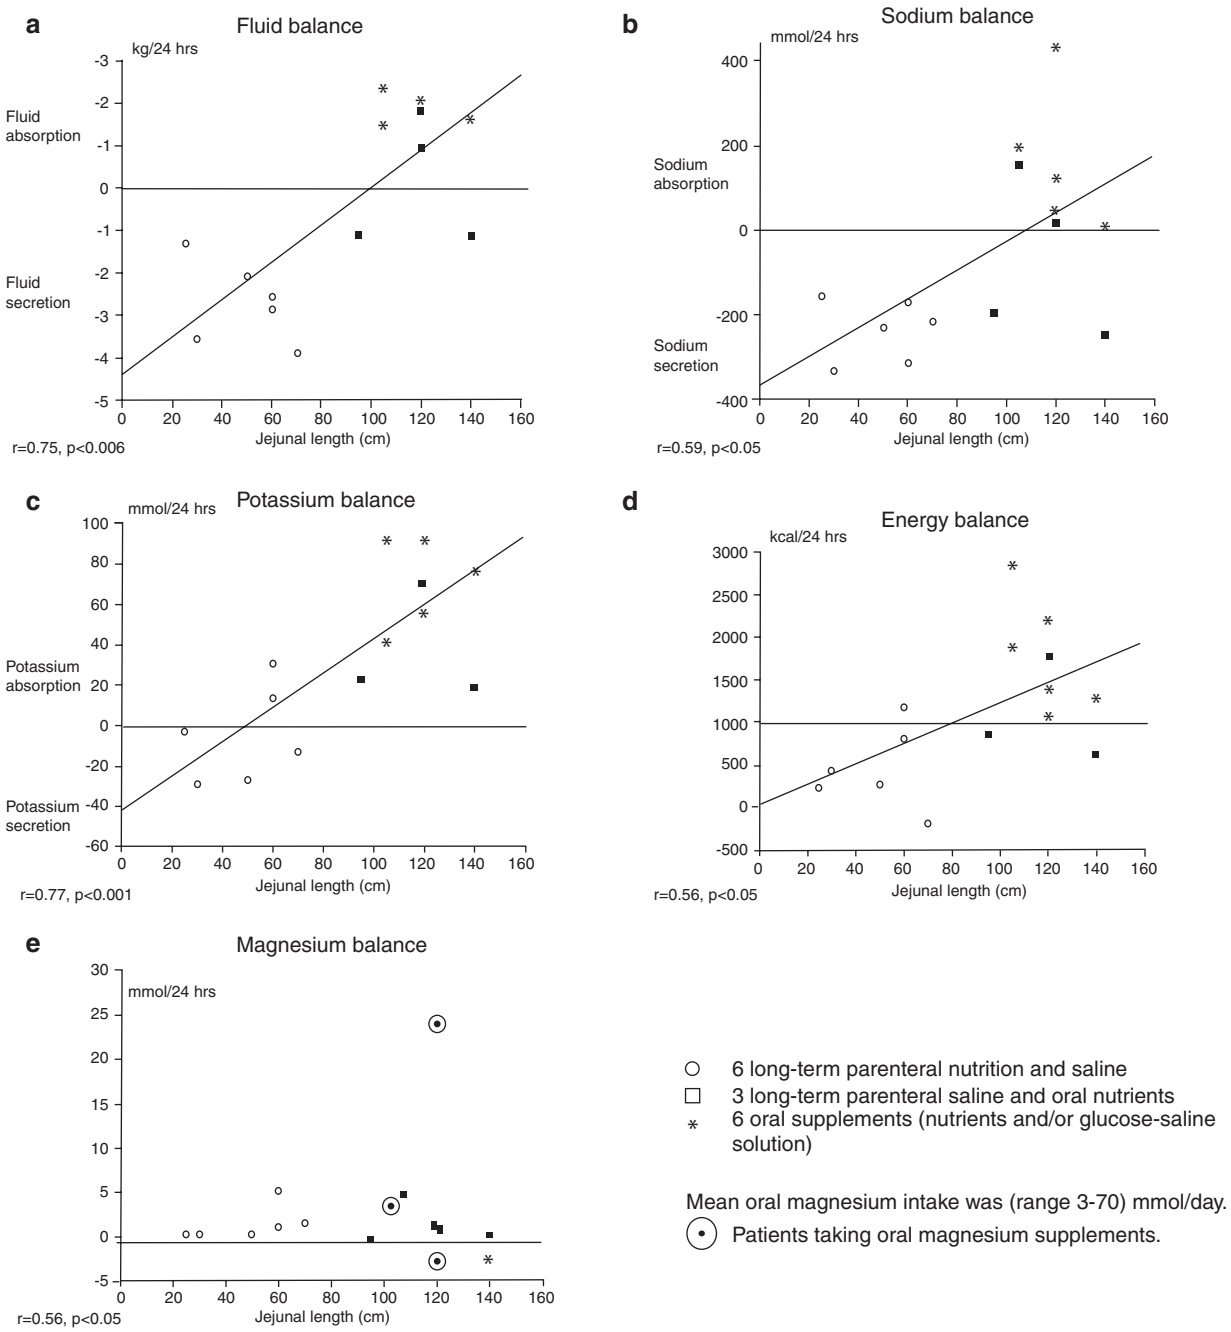

Fig. 6 Balance studies using the patient-selected diet performed for 2 days on 15 patients with a jejunostomy who were all maintaining fluid, electrolyte and nutritional status. Six needed long-term intravenous nutrition, 3 required long-term intravenous fluids but maintained their nutrition with an oral diet, and 6 took oral fluid and nutrient supplements [5]. (**a**) Total weight, (**b**) sodium, (**c**) potassium (**d**) energy and (**e**) magnesium. Note that positive intestinal fluid and sodium balance is achieved at 100 cm jejunum, potassium at 50 cm, and there was no relationship with magnesium balance

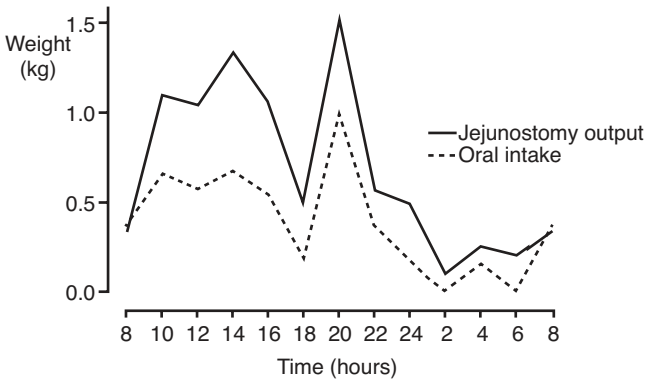

Fig. 7 Oral intake (kg) and stomal output measured every 2 h in a patient who has 30 cm of residual jejunum and shows net secretion [5]

A clinician, unlike a research worker, is unlikely to be able to perform accurate balance studies, in which case the classification can be predicted from knowledge of the residual jejunal length. The change from a net secretory state to a net absorptive state in terms of intestinal water and sodium balance occurs at a jejunal length of about 100 cm.

Potassium Deficiency

The effluent from a jejunostomy or ileostomy contains relatively little potassium (about 15 mmol/L) [5, 11, 31]. Values are higher in patients with a colostomy as the colon secretes potassium. Potassium problems are unusual and the potassium intake rarely needs to be greater than normal. Net loss through the stoma occurs only when less than 50 cm of jejunum remains [5] (Fig. 6c).

Low serum potassium levels do not usually reflect gut losses, but may occur when a patient is sodium depleted and thus has secondary hyperaldosteronism. The high aldosterone levels cause renal conservation of sodium at the expense of potassium, which is excreted in the urine in greater amounts than normal [10, 11, 31].

Hypomagnesaemia causes dysfunction of many of the potassium transport systems (e.g. the Na^+/K^+-ATPase pump) and increases renal excretion of potassium; thus hypomagnesaemia can cause a hypokalaemia, which is resistant to potassium treatment [32].

Before hypokalaemia can be corrected in patients with a high-output stoma, sodium and water depletion must be corrected and the serum magnesium brought into the normal range.

Magnesium Deficiency

Patients with a jejunostomy are often in precarious magnesium balance, and the balance does not correlate with residual jejunal length (Fig. 6e). Hypomagnesaemis is estimated to occur in 78% of patient with a jejunostomy [29]. While it may cause fatigue, depression, irritability, muscle weakness, tremor, tetany if there is associated hypocalcaemia, and, if very severe, convulsions; it is often asymptomatic even at very low serum levels (e.g. 0.2 mmol/L). The reasons for hypomagnesaemia include secondary hyperaldosteronism [33, 34], removal of ileum/colon which are key areas in the gut for absorption, free fatty acid malabsorption (so complexing with Ca and Mg) (especially if taking a high fat diet) [35, 36] and taking proton pump inhibitor drugs [37]. In the long-term hypomagnesaemia will lead to a loss of bone density with a risk of fractures, and chondrocalcinosis [38].

Nutrient Malabsorption

In the long term, parenteral nutrition with additional fluids is always needed if a patient absorbs less than one-third of the oral energy intake [5, 12] and is usually needed when less than 75 cm of jejunum remain. In some young people with high-energy requirements, parenteral nutrition may be needed even when absorption is 35–60%.

Social Problems of a HOS

Patients with a HOS may have problems with the stoma bags becoming detached and so leaking (especially at night), the skin care may be difficult and thus very sore, the frequent emptying of the stomal bag means there will be a need to find a toilet quickly, this can limit going out. The treatment for a HOS cannot be abruptly stopped otherwise dehydration results. The patient may always feel thirsty yet have to avoid quenching their thirst with hypotonic fluid. They may suffer from muscle cramps (helped by taking table salt).

Management of HOS

As stated the management starts with excluding causes of a HOS other than a short bowel and appropriately treating them. A history of colicky abdominal pain, loud bowel sounds (borborygmi); a stoma ceasing to work for a time is suggestive of an obstructive cause. The HOS occurs during recovery from the obstruction and at this time the patient may have no symptoms other than those of dehydration. Such patients often present for medical care episodically (every few months or even years). Radiological contrast examinations do not always show the stricture(s) and a trial of a low fibre/residue diet can be used both as a treatment and as a diagnostic test. If there are strictures bacterial overgrowth may be occurring and a trial of oral antibiotics (e.g.

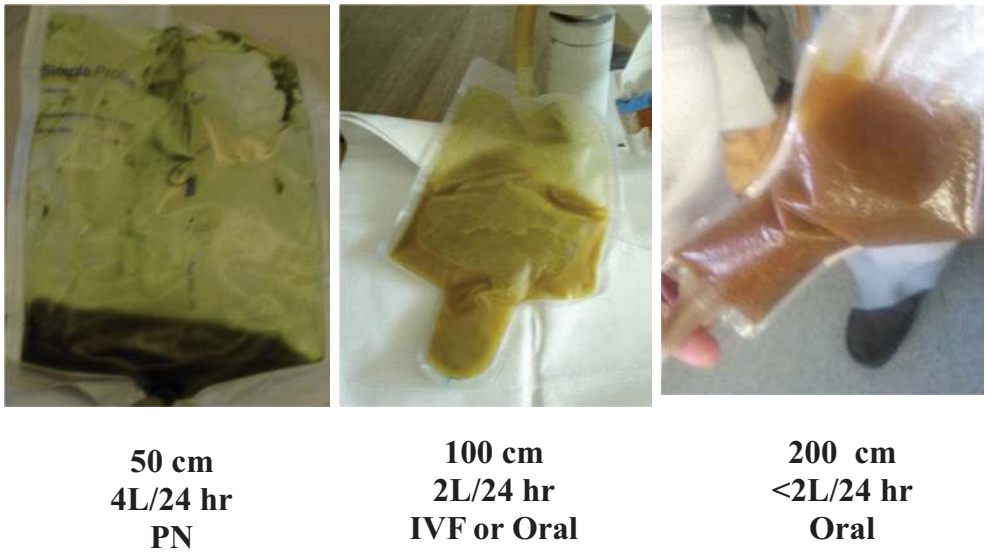

Fig. 8 Stomal output (colour/volume) on normal diet, jejunal length and type of nutritional/fluid support

co-amoxyclav or rifaximin) may be tried and if successful given in rotation (e.g. changing every 6 weeks). If pancreatic malabsorption is thought to contribute to a HOS then a trial of pancreatic enzyme replacement may be tried. A stomal elastase measurement is unlikely to be reliable due to dilution by secretions and oral fluid intake. Other medical conditions may need treatment if found (e.g. low fibre diet, steroids for Addison's, antibiotics for Clostridium, gluten free diet if Coeliac etc).

Table 3 Jejunostomy length and the type of nutritional/fluid support needed

Jejunum (cm)	Nutrition	Fluid
0–50	Parenteral	Saline
51–100	Parenteral[a]	Saline
101–150	Oral/Enteral	OGS
151–200	None	OGS

OGS oral (or enteral) glucose/saline solution
[a]At 85–100 cm may need parenteral saline only

Clinical Assessment

The initial assessment of water and sodium deficiency involves asking the patient about feeling dry, thirsty, lethargic, faint or having muscle weakness and cramps. The physical examination includes looking for dry mucous membranes, reduced skin turgor, rapid weight loss (negative fluid balance), a postural blood pressure fall (>10 mmHg), oliguria (less than 800 mL/24 h) and an assessment of the patient's nutritional status (this is usually good unless the bowel is less than 100 cm). In general, patients who have a stomal output of more than 1.5 L daily when eating are likely to require water and sodium supplements. The stomal should be inspected and the stoma effluent colour, consistency and 24 h volume should be noted (a yellow/green colour in an established stoma suggests a short length of remaining bowel) (Fig. 8). A finger should be inserted gently into the stoma to determine if there is a stenosis. However an obstruction at the stoma may not be felt if it is a functional obstruction, due to oedema or the thickness of the abdominal wall, and a trial of a wide bore catheter placed into the stoma may be tried to determine if the output reduces.

If dehydration is severe, serum creatinine and urea will rise. The creatinine may be low if there is reduced muscle mass Urinary electrolytes are usually more useful than serum measurements because the normal physiological homeostatic mechanisms preserve serum electrolyte concentrations until the late stages of depletion. A low random urinary sodium concentration (<10 mmol/L) is the best indicator of maximal sodium conservation and therefore sodium deficiency, even if serum estimations are normal. When interpreting a urinary sodium result it is important to check that the patient is not receiving diuretics or intravenous/subcutaneous saline or has renal impairment/tubular damage (e.g. from resolving acute kidney injury) when the result may be falsely normal. In addition a urinary sodium concentration can be low if the patient has hypovolaemia due to a low circulating volume secondary to a low plasma oncotic pressure (e.g. due to a low serum albumin).

Bowel Length Measurement

Predictions about the outcome can be made if the residual length of small intestine from the duodenojejunal flexure has been measured at surgery or radiologically from a small bowel meal film using an opisometer (Table 3) [39, 40]. However estimates can be made from CT/MRI enterography providing the total small bowel length is less than 200 cm. A radiological examination will also show the quality of the bowel detecting recurrent disease/obstruction [39]. Despite

this the remaining small bowel length is often unknown. Estimates made from the length of bowel resected are unreliable as the normal small intestinal length is so variable (chapter "Normal Intestinal Anatomy and Physiology").

Citrulline is an amino acid produced by functioning small bowel mucosa, fasting levels do correlate with residual small bowel length. Although clinically used to assess the progress of small bowel function after a small bowel transplant or when the colon is brought into continuity, it has not been widely adopted as a marker of functioning small bowel [41].

Treatment

Total jejunal loss of sodium increases in a linear relationship with volume (at a concentration of about 90 mmol/L) so the clinician can predict with reasonable accuracy that an effluent volume of 3 L contains 270 mmol of sodium (Fig. 5). The concentration of sodium in the output remains constant whatever treatment is given. While there is a small obligatory stomal loss when fasting, the greatest increase in stomal output is after food or drink (Fig. 7). Consideration should be given to attempting to reduce stomal output, even in patients with a jejunostomy requiring parenteral nutrition, as this may well reduce the amount or frequency of intravenous fluid replacement and the social difficulties in managing the stoma.

A patient presenting with a HOS and renal failure will need urgent rehydration and in most cases the progression to irreversible or chronic renal failure can be prevented. The replacement fluid needs to contain 100–150 mmol sodium/L e.g. intravenous normal saline, 2–4 L/day. During this time the patient may be kept "nil by mouth" to reduce the stomal output. In general dialysis is avoided as the removal of any more fluid can worsen the renal failure which may become permanent. Great care must be taken not to give too much fluid as this will readily cause oedema, partly due to the high circulating aldosterone levels [10, 11, 12, 31]. Cramps can be rapidly helped by oral or intravenous sodium chloride, and/or by magnesium supplementation.

Once renal failure has been corrected and thirst relieved, usually over 2–3 days, an attempt is made to reduce stomal output, even in patients with a jejunostomy requiring parenteral nutrition, as this may well reduce the amount or frequency of intravenous fluid replacement and the social difficulties in managing the stoma.

Sometimes, admitting patients with a chronic HOS, giving intravenous saline and keeping them 'nil by mouth' will demonstrate to them that their output is mostly driven by their oral intake. Intravenous fluids are gradually withdrawn over 2–3 days while food and oral fluids are reintroduced. These patients are dependent upon their treatment regimen and if missed/stopped for a day may result in dehydration and a hospital admission for rehydration.

The oral treatment to reduce a HOS and its consequences of dehydration starts with restricting oral hypotonic fluids and giving a glucose saline solution (or in mild cases extra oral salt) to sip. If this alone is not successful then oral medications to reduce gut motility and/or secretions may be tried.

Restrict Oral Fluids

Jejunal mucosa is 'leaky' and rapid sodium fluxes occur across it. If water or any solution with a sodium concentration of less than 90 mmol/L is drunk there is a net efflux of sodium from the plasma into the bowel lumen [19] until a luminal sodium concentration of 90–100 mmol/L is reached (Fig. 3). In a patient with a jejunostomy this fluid is then lost in the stomal output. It is a common mistake for patients to be encouraged to drink oral hypotonic solutions to quench their thirst, but this literally washes sodium out of the body [11, 19–21]. Thus patients must never be advised to "drink as much as possible" either to quench their thirst or keep up with their stomal output as this will increase stomal sodium losses, worsen dehydration and increase thirst.

Treatment for the high output from a jejunostomy, ileostomy or high fistula starts with the patient restricting the total amount of oral hypotonic fluid (water, tea, coffee, fruit juices, alcohol or dilute salt solutions) to 0.5–1.0 L/24 h (Fig. 4). To make up the rest of the fluid requirement the patient is encouraged to drink a glucose–saline rehydration solution. Many patients at home with a marginally high stomal output (1–1.5 L) will be helped by a combination of mild oral fluid restriction (less than 1.5 L per day) and the addition of salt to their diet.

Patients are often advised to take liquids and solids at different times (no liquid for half an hour before and after food), however there is no published evidence that this reduces stomal output or increases absorption of macro- or micronutrients [42].

Drink Oral Glucose–Saline Solution

Patients with stomal losses of less than 1200 mL daily can usually maintain sodium balance by adding extra salt to the limit of palatability at the table and when cooking. When stoma losses are in the range 1200–2000 mL, or sometimes more, it is possible for a patient to maintain sodium balance by taking a glucose–saline solution or salt capsules [22]. In hot weather, patients with a stoma are more likely to have problems of dehydration because of water and sodium loss in sweat.

As the sodium content of jejunostomy (or ileostomy) effluent is relatively constant at about 90 mmol/L and as there is coupled absorption of sodium and glucose in the jejunum [43–45], patients are advised to sip a glucose–saline solution with a sodium concentration of at least 90 mmol/L

Table 4 Oral rehydration solutions

	Modified WHO Cholera solution Dioralyte® strength			
	"St Mark's Solution"[b]	Single	Double[a]	Sodium citrate solution
Volume (L)	1	1	1	1
Na^+ (mmol)	90	60	120	120
K^+ (mmol)	0	20	40	0
Cl^- (mmol)	90	60	120	0
Citrate (mmol)	0	10	20	120
Glucose (mmol)	80	90	180	80

A stronger solution that can be used is is sodium chloride 7 g (120 mmol), glucose (8 g) (44 mmol) and tap water 1 L

[a]10 sachets

[b]Sodium chloride 3.5 g (60 mmol), sodium bicarbonate 2.5 g (30 mmol) or sodium citrate 2.9 g (30 mmol), glucose 20 g (110 mmol) and 1 L tap water

throughout the day. The first World Health Organization (WHO) cholera solution had a sodium concentration of 90 mmol/L [46] and is still commonly used (without the potassium chloride) (sometimes referred to as the St Mark's solution) (Table 4). Patients can prepare this solution at home using simple measuring scoops. There is no evidence that the sodium bicarbonate adds to the effectiveness of this solution [45] and it may be more palatable if sodium bicarbonate is replaced by sodium citrate. Indeed a pure sodium citrate solution (sodium concentration 120 mmol/L) was successful [47]. If the sodium concentration is increased further (e.g. to 136 mmol/L), absorption of sodium and water is improved [48]. Although taste perception changes in patients who are depleted in salt and water, they may find this solution, which tastes like 'sweet seawater', too salty to drink. Double strength Dioralyte ® is often given (Table 4). It does contain potassium and so serum potassium measurements may need to be made more frequently than 3 monthly, especially if renal impairment occurs.

A glucose-polymer (55 g Maxijul®) may be substituted for glucose to increase the energy intake by a mean of 115 kcal/d [22]. The glucose-polymer (or even a rice-based solution) can be especially useful in diabetic patients as it causes less extreme changes in blood glucose than a glucose-based solution.

The patient should be encouraged to sip a total of 1 L or more of one of these solutions in small quantities at intervals throughout the day. They should make up the majority of the oral fluid intake. As compliance is often a major problem, patients need to understand the need for the solution and can make it more palatable by chilling, and/or flavouring with fruit juice and drinking it through a straw. Compliance with the regimen is vital as if one day of fluid restriction/glucose saline solution consumption is omitted the patient may be admitted to hospital dehydrated. It is important to note that solutions with a sodium content of less than 90 mmol/L such as single strength Dioralyte® or commercial preparations used to treat infective or traveler's diarrhoea or in sport's drinks sports are not adequate.

Sodium chloride capsules (500 mg each) are effective when taken in large amounts (14/24 h), but can cause some patients to feel sick and even vomit [22]. If an enteral feed is given, sodium chloride needs to be added to make the total sodium concentration of the feed 100 mmol/L while keeping the osmolality near to 300 mOsm/kg. A hyperosmolar solution/feed (e.g. of amino acids) will cause increase stomal water losses.

Even patients with a jejunostomy receiving long term parenteral support should restrict their intake of oral hypotonic fluid and sip a glucose saline solution to prevent stomal fluid losses.

Subcutaneous or Parenteral Fluids

Some patients cannot be maintained (hydration, sodium and/or magnesium) with an oral regimen (usually if jejunal length is less than 100 cm) and regular subcutaneous or parenteral saline supplements are needed. Subcutaneous saline can be slow to run (e.g. a litre usually containing 4–8 mmol magnesium sulphate that takes 10–12 h to infuse), it may cause swelling of a limb; however it is relatively simple and quick to start with few risks of infection. It is most appropriate if the additional fluid is only needed 1–4 days a week. If more frequent or a higher volume is needed (due to thirst/dehydration) then intravenous normal saline, 2–4 L/day, often with added magnesium sulphate (4–14 mmol/L) may be given.

Patients with less than 100 cm jejunum remaining may need oral or parenteral nutritional supplements, but a few need, no nutritional supplements, only 1 or 2 L of parenteral saline daily, usually with added magnesium sulphate.

Drug Therapy to reduce the High-Volume Output from a Jejunostomy

If restricting oral fluids and giving a glucose– saline solution to drink are not adequate treatment, drugs may be needed. The intestinal output, especially in net 'secretors' rises after meals (Fig. 7), and it is therefore important to give the drugs before food. Drugs used to reduce jejunostomy output act to reduce either intestinal motility or secretions.

Antimotility (Antidiarrhoeal) Drugs

Opiate drugs such as tincture of opium (laudanum) or codeine phosphate have been used for many years to treat diarrhoea but are sedative and, in the long term, addictive. Synthetic drugs were manufactured with the aim that they should be free of opiate-like activity upon the central nervous system. Diphenoxylate (Lomotil®) was the first to be

used in clinical practice but has largely been replaced by loperamide (Imodium®) which has no central nervous system effects. Loperamide is a synthetic piperidine opioid made in 1969 (for diarrhoea), it acts on μ receptor in myenteric plexus to inhibit gut motility and reduce gastrointestinal secretions. It also increases the tone of the anal sphincter. It has peak levels within 4–5 h, a half life of 7–15 h and circulates in the enterohepatic circulation with 30–40% excreted in faeces (1% in urine). It is 97% protein bound.

Loperamide is preferred to codeine phosphate as it does not sedate and is not addictive. Codeine phosphate increases the output of stomal fat [49, 50]; loperamide does not [50, 51] although it reduces the post-prandial pancreatico-biliary secretion of trypsin and bilirubin in patients with a short bowel and preserved colon [52].

Loperamide and codeine phosphate reduce intestinal motility and thus decrease water and sodium output from an ileostomy by about 20–30% [49–51, 53, 54]. Oral loperamide, 4 mg taken four times a day, was more effective in reducing the weight and sodium content of ileostomy fluid than codeine phosphate 60 mg taken four times a day [50], but the effect of both together may be greater [55]. These drugs are effective in most patients with a jejunostomy [13], particularly net 'absorbers'. A combination of both of these drugs, taken before food, a glucose–saline solution and other fluid restriction can liberate some patients from dependence on parenteral saline supplements [55].

Loperamide circulates through the entero-hepatic circulation, but this is severely disrupted in these patients, and small bowel transit may be rapid. Thus high doses of loperamide (e.g. 12–24 mg) at a time) may be needed, as in patients who have had a vagotomy and pyloroplasty [56]. One case series suggested even higher doses (40 mg five times a day, 30 mg three times a day and 100 mg four times a day) were effective [57].

In 2017 the UK Medicines and Healthcare products Regulatory Agency (MHRA) issued an alert about serious cardiovascular events (QT prolongation, torsades de pointes, and cardiac arrest/deaths) associated with high or very high doses of loperamide when used as a drug of abuse or for self-treatment of opioid withdrawal. The British Intestinal Failure Alliance (BIFA) advice about this included performing an ECG in all patients with a high output stoma/fistula before starting high dose loperamide (more than 4 mg four times a day) and the QT interval being measured. It was suggested that the ECG should be repeated after starting the high dose and then every 3 years if the patient remained on high dose loperamide therapy. If the QT interval was prolonged cardiac co-morbidities should be considered, drugs known to prolong the QT interval are rationalised and metabolic causes (e.g. hypomagnesaemia) treated. The total daily dose of loperamide should be below 80 mg, however if this is exceeded serum loperamide levels should be measured (normal therapeutic range 0.24–1.2 mg/mL). Loperamide toxicity should be considered in any patient with fainting episodes not accounted for by dehydration or other drugs and if there is QT prolongation or a serious ventricular arrhythmia including torsades de pointes or cardiac arrest has occurred [58].

Antisecretory Drugs

Food and drink are diluted by digestive juices, thus the volume of stomal effluent can be reduced in 'secretors' by drugs that reduce the secretions from the stomach, liver and pancreas. Drugs that reduce gastric acid secretion, such as the H_2 antagonists or proton pump inhibitors or the somatostatin analogue octreotide, are most commonly used.

H_2 Antagonists/Proton Pump Inhibitors

Cimetidine (400 mg orally or intravenously four times a day) reduced the output from a jejunostomy/ileostomy when the daily output exceeded 2 L daily [59, 60]. This beneficial effect is likely to be due to the reduction in normal daily gastric acid secretion or to a reduction in gastric acid hypersecretion.

Omeprazole, 40 mg orally once a day, reduced the stomal output by a mean of 0.7 kg/24 h in 7 patients with a net secretory output [61] (Fig. 9a). Omeprazole, 40 mg given intravenously twice a day, reduced the jejunostomy output in patients whose output exceeded 2.6 kg/24 h.48 Omeprazole is readily absorbed in the duodenum and upper small bowel, but if less than 50 cm of jejunum remains it may need to be given intravenously. Giving omeprazole orally dissolved in bicarbonate may improve absorption enough for it to be successful. Omeprazole has little beneficial effect in patients who are net absorbers.

Oral omeprazole, 40 mg once daily, gave an equivalent reduction in stomal output to oral ranitidine, 300 mg twice daily, in one patient [5, 61]. Intravenous omeprazole, 40 mg twice daily, was more effective than intravenous ranitidine 150 mg twice daily, probably because the dose of ranitidine was too low [62]. Oral omeprazole, 40 mg once daily, was shown in two patients to be equivalent to intravenous octreotide 50 μg twice daily [5, 61].

Omeprazole, ranitidine and cimetidine reduce jejunostomy output in those with the highest outputs (net 'secretors') while often having no effect on net 'absorbers'. They may need to be given intravenously if less than 50 cm of jejunum remains. They do not change the absorption of energy, carbohydrate, lipid, nitrogen and divalent cations [61, 62] and do not reduce jejunostomy output sufficiently to prevent the need for parenteral fluid and electrolyte replacement.

Other PPI drugs have not been reported to reduce jejunostomy output but are likely to be as effective. The PPIs have been associated with Cl difficile infection, abnormal liver function tests, hypomagnesaemia, osteopenia/osteoporosis and increased risk of fractures (hip, wrist and spine), myo-

cardial infarction (possibly by suppressing NO production) and renal impairment [63]. When used (e.g. omeprazole 40–80 mg daily) the dose can be titrated such that fresh stomal fluid has a pH greater than 5.

Somatostatin and Octreotide

Somatostatin and octreotide reduce salivary, gastric and pancreatico-biliary secretions, slow small bowel transit, and may delay gastric emptying; for these reasons they may be expected to reduce the intestinal output from a jejunostomy in both net 'secretors' and 'absorbers'. Somatostatin has a serum half-life of 3 min so is given by continuous infusion, whereas that of octreotide is 90 min so it is usually given as regular (two or three times daily) subcutaneous injections before food.

Somatostatin

Four patients with more than 100 cm of small intestine remaining (one also had some residual colon) were given a continuous infusion of somatostatin, 4 μg/min for 24 h. Mean daily intestinal output reduced from 1.9 kg to 1.2 kg, however magnesium, nitrogen and fat absorption were unchanged [64].

Octreotide

Effect of octreotide upon water, sodium and magnesium balance. A case report in 1984 first demonstrated that 50 μg of octreotide given subcutaneously twice a day allowed a patient with ileostomy diarrhoea to stop intravenous fluids [65]. Several studies in adults have shown octreotide to reduce ileostomy diarrhoea and large-volume jejunostomy outputs (Table 5) [13, 28, 66–72]. The greatest reductions in intestinal output have occurred in net 'secretors', (Fig. 9) and many patients have been able to reduce the volume of parenteral supplements needed [71, 72]. Although some patients have achieved positive intestinal fluid balance, they have rarely been able to stop parenteral fluids completely [71, 72]. All studies have shown a reduction in sodium output which parallels that of the intestinal output [13, 28, 66–72]. Stomal output has been reported as reduced [70] in 2 and increased [28] in 2 jejunostomy patients classified as net 'absorbers'. However, in one study in which all patients had mild ileostomy diarrhoea (0.8–1.3 kg/24 h) and were thus net absorbers, the output reduced by only 0.3 kg/24 h [67]. Octreotide, 20–100 μg/24 h, has been used successfully to reduce ileostomy diarrhoea in 2 children aged 3 months and 5 years [73]. In 3 patients, an intravenous dose of 50 μg octreotide twice a day was as effective in reducing the intestinal output as 100 μg three times a day [69]. Magnesium balance has not been changed by octreotide [68, 70].

The effect of octreotide is maintained in the long term [66, 68–70, 72]. After a year's continuous therapy with 50 μg intravenous octreotide twice daily, the reduction in stomal output was the same as at the start of treatment [69, 72].

Somatostatin and octreotide both reduce the output from a high fistula and appear to accelerate the rate of spontaneous closure [74, 75].

Effect of Octreotide Upon Nutrient Absorption Although octreotide reduces stimulated gastric acid and pancreatic enzyme secretion and reduces the splanchnic uptake of amino acids [76], it does not significantly change total energy [69, 71, 72] or nitrogen absorption [66, 68, 70–72]. As

The dotted line shows the effect of intravenous omeprazole given to one patient with 30 cm jejunum after there was no response to an oral dose

pancreatico-biliary secretion is reduced, it would be expected that fat absorption would be reduced [66]. However, it is usually unchanged [69–72].

Problems of Octreotide Therapy A subcutaneous injection of octreotide may be painful, especially in the very thin, while an intravenous injection may cause flushing, nausea and headache [69]. Blood glucose generally remains within the normal range [70]. Patients with a jejunostomy have a very high prevalence of gallstones (45%) [29], and long-term octreotide therapy may further increase this [77]. Although hypoglycaemia may occur [73], there is no evidence that octreotide causes diabetes or hypothyroidism after prolonged usage. Increasing the consistency of the small bowel contents could increase the risk of developing small bowel obstruction if there are adhesions [72].

Mechanism of Action of Octreotide Octreotide increases total intestinal transit time [13, 66, 71, 72]. This probably reflects an increase in small bowel transit time as the rate of gastric emptying remains normal [66, 71]. This slowing of transit may be the mechanism whereby some net 'absorbers' respond to octreotide therapy. In net 'secretors', the reduction in jejunostomy output was similar to that achieved with omeprazole, hence the suggestion that, in these patients, octreotide acts mainly by reducing the volume of gastric acid secreted in response to food [78]. A reduction in pancreaticobiliary secretion may explain why fat malabsorption increases in some patients [66], and it may be this that increases the intestinal output in some net 'absorbers' [78].

Octreotide at a dose of 50 µg twice daily given subcutaneously or intravenously reduces intestinal water and sodium losses in most patients with a jejunostomy, and in some with ileostomy diarrhoea or a high small intestinal fistula. This effect is greatest in patients with the highest net 'secretory' output and is maintained long-term without tolerance developing. The reduction in output may reduce, but rarely avoids, the need for parenteral fluids. Some patients use these preparations, particularly octreotide, before meals to diminish the social inconvenience of a profuse jejunostomy output after food. In these patients octreotide does not affect the absorption of magnesium or nutrients.

Long Acting Somatostatin Analogues Long acting octreotide 20 mg [79] and lanreotide 120 mg [80] have both been used to treat HOS with deep subcutaneous/intramuscular injections every 4 weeks.

Mineralocorticoids

The distal ileum, with its tight intracellular junctions, can concentrate the intraluminal contents. This ability develops from 2 to 16 weeks after the formation of an ileostomy [81, 82]. This capacity for sodium absorption may partly relate to high aldosterone levels [10, 30] and can be induced by mineralocorticoids (e.g. 2 mg oral fludrocortisone or 2 mg intravenous D-aldosterone) [83–85] or high-dose hydrocortisone [86]. Although intraluminal hydrocortisone does increase jejunal water, sodium and glucose absorption in normal subjects [87], mineralocorticoids do not usually reduce ileostomy output. However, studies have only been performed in patients with a relatively normal ileostomy output. Studies of patients with a high-output ileostomy or jejunostomy are

awaited, but it would not be surprising if these were disappointing, as high circulating aldosterone levels may have already maximized sodium absorption.

Desmopressin

Desmopressin, an analogue of antidiuretic hormone, has no effect upon ileal fluid or electrolyte loss in man [88].

Cholylsarcosine

A synthetic bile acid resistant to bacterial deconjugation and dehydroxylation, cholylsarcosine (4 g taken three times a day), was given to 3 patients with a jejunostomy and resulted in an improvement in fat (18%, 37% and 51%) and calcium absorption but did not affect the volume of stomal output [89, 90].

Clonidine

Clonidine is an α_2-adrenergic agonist that prolongs gastrointestinal transit and has been used to treat chronic diarrhoea. A 0.3 mg clonidine patch (as has been used in hypertension [91]) to 8 jejunostomy patients receiving parenteral nutrition resulted in a reduction in stomal output of 0.44 kg/day (39 mmol sodium) without affecting energy, fat or xylose absorption [92]. It is rarely used but may be a treatment for those who are not responding to other conventional treatments.

Peptide Hormones (Including Growth Factors) (Chapter "Pro-Adaptive Hormones in the Rehabilitation of Adult Patients with a Short Bowel")

Patients with a jejunostomy have low circulating levels of PYY (slows transit) and GLP-2 [24, 27]. GLP-2 agonists (e.g. teduglutide, apraglutide and glepaglutide), which stimulates small bowel mucosal growth and increases absorption of salt, water and nutrients, may be used as a treatment (though are expensive and in the UK can only prescribed by specialist IF/HPN centres) [93]. While in studies teduglutide may reduce parenteral requirements by 20% and may occasionally allow a patient to stop parenteral nutrition [94–96]. A GLP-1 agonist (liraglutide) which primarily slows upper gastrointestinal transit has been used with some success [97]. There may be a future role for using combinations of peptide hormone analogues. While peptide YY analogues have been manufactured they have not been used clinically [98].

Magnesium Supplements

There are many therapeutic ways of improving hypomagnesaemia (Table 6). Dehydration and sodium depletion cause secondary hyperaldosteronism, which leads to renal magnesium loss; correction of these conditions may help to treat magnesium depletion. In addition, a diet relatively low in fat reduces stool or stomal magnesium losses [35] (chapter "Dietary Treatment of Patients with a Short Bowel").

Serum magnesium levels can usually be improved by oral supplements, however the data about the magnesium absorption from different preparations are often derived from normal volunteer studies and studies of patients with a short bowel and retained colon. Tablet dissolution and magnesium availability may be very different in patients with a jejunostomy than in normal subjects and patients with a short bowel and retained colon.

Many oral magnesium salts, which are generally poorly absorbed, have been given as a treatment and include magnesium sulphate, chloride, hydroxide, acetate, carbonate, gluconate, lactate, citrate, aspartate, pyroglutamate, oxide and diglycinate [99, 100]. In clinical practice in the UK magnesium oxide, glycerophosphate or aspartate are most commonly given. Magnesium oxide may be given to a total of 12–24 mmol daily. Oral magnesium treatment, such as three gelatine capsules each of 4 mmol (160 mg of MgO), is usually given at night when intestinal transit is assumed to be slowest and hence there is more time for absorption. This regimen increases magnesium absorption and does not appear to increase stomal output.

A topical magnesium chloride spray may help those with magnesium depletion who do not adequately absorb magnesium preparations from their gut [101] and may offer a mode of correcting serum levels and helping symptoms that may be related to hypomagnesaemia. Proton pump inhibitor drugs can reduce serum magnesium levels and a trial of stopping these may be beneficial [37].

If oral magnesium supplements do not bring the magnesium level into the normal range, oral 1α-hydroxycholecalciferol in a gradually increasing dose (every 2–4 weeks) of 1–9 μg daily has been shown to improve magnesium balance in patients with a retained colon [102, 103]. This action occurs by increasing both intestinal and renal magnesium absorption [103]. As hypomagnesaemia will have caused both a failure of parathormone release and a resistance to its action, 1α-hydroxycholecalciferol cannot be made in the kidney in adequate amounts. Thus it is important that the 1α preparation is given.

Magnesium can occasionally be given as: a subcutaneous injection of 4 mmol magnesium sulphate every 2 or more

Table 6 Summary for hypomagnesaemia treatment

Stop PPI

days, but this can cause skin ulceration; an intramuscular injection of 10 mmol/L, but this is painful; or a regular intravenous infusion of 4–8 mmol, usually in a litre of saline over 1–2 h, though this can cause a flushing sensation. Occasionally a subcutaneous infusion [104] 4–8 mmol of magnesium sulphate is infused subcutaneously in a litre of saline over 10–12 h 1–3 times a week. Initially there was a worry that this caused hardening of the subcutaneous tissues but was not supported by longer term experience.

Nutrient Absorption

Need for Enteral or Parenteral Nutrition

Most patients with less than 75 cm of jejunum remaining need long-term parenteral nutrition; most in the range 75–100 cm need parenteral saline (sometimes with added magnesium) but manage to maintain nutritional status with an enteral regimen even though they may only absorb about 50–60% of their oral energy intake.

All patients wish to eat food so as to feel normal and to maintain social relationships. In patients maintained on parenteral nutrition, an oral intake is detrimental as it increases jejunostomy losses (Fig. 7). Patients taking an oral regimen need to consume more energy than a normal person to compensate for malabsorption. Most patients can achieve this by eating more high-energy food. Oral sip-feeds may be given in addition to food, preferably taken between meals and at bedtime. By these means, a patient may increase energy intake by at least 1000 kcal/d. If oral sip-feeds during the day fail to achieve weight gain or maintain nutrition, a nasogastric or gastrostomy tube may be inserted and a feed given at night so that the short residual length of intestine is used at a time when it is usually inactive. There are rarely any problems inserting a percutaneous endoscopic gastrostomy (PEG) in patients with Crohn's disease provided that there is no distal obstruction [105].

Once weight is regained, the daily energy requirement may decrease so that a nocturnal feed can be reduced or stopped and sip-feeds during the day may become adequate. Only if these measures fail and the patient continues to lose weight, or fails to regain lost weight, is parenteral nutrition given.

Oral/Enteral Nutrition/Food

Patients with a jejunostomy absorb a constant proportion of the nitrogen, energy and fat from their diet [14, 36, 104]. Increasing fat in the diet raises fat excretion but does not usually increase stomal output, nor make the output offensive [14, 36, 106]. One study showed that increasing fat in the diet increased the loss of the divalent cations Mg and Ca [35], but this was not the case in another [106]. There is no advantage in giving a diet of small molecules (e.g. an elemental diet); this causes a feed to be hyperosmolar [106] and usually contains little sodium, so potentially increasing the losses of water and sodium from the stoma. A peptide diet still has the problem of a relatively high osmolality and thus can increase stomal output [106]. Little advantage comes from taking a diet of water-soluble medium-chain triglycerides in place of normal fat [107]. The addition of glutamine, 15 g, to a litre of rehydration solution in patients with a jejunostomy resulted in no additional benefit in terms of water or sodium absorption [108]. The fibre content of the diet plays only a minor role in determining jejunal output [49].

Thus jejunostomy patients need a large total oral energy intake of a polymeric, iso-osmolar (300 mOsm/kg) diet that is relatively high in fat with added salt (sodium concentration 100 mmol/L). The volume of the stomal output may become so high with a normal diet or with extra feeding that it is a major social disability. If this is the case, parenteral feeding may be needed to enable oral intake to be reduced.

The ideal nutrient solution with an osmolality of 300 mOsm/kg and a sodium concentration of at least 100 mmol/litre has yet to be marketed. A low fibre diet is advised if intermittent/partial obstructions is thought to be occurring and often is first used as these patients have a high probability of having adhesions and an area of bowel narrowing. Liquid diets must be near ro iso-osmolar. A hyperosmolar feed (e.g. amino acids) will cause water secretion into the gut and also if little/no sodium in the feed then sodium excretion will occur.

Monitoring

Accurate daily measurements of body weight, fluid balance (especially stomal effluent) and postural blood pressure are important. Serum electrolyte (creatinine, potassium and magnesium) and urinary sodium estimation may be done every 1–3 days initially but once or twice weekly when the patient is stable in hospital. The aims are to maintain hydration and body weight and a daily urine volume of at least 800 mL with a sodium concentration greater than 20 mmol/L. At home, if stable, measurements of weight, urine sodium concentration and serum magnesium are done every 3 months [109].

Predicting Drug Absorption

Many drugs are incompletely absorbed by patients with a short bowel and may be needed in much higher amounts than usual (e.g. thyroxine, warfarin and digoxin [110] or may

need to be given intravenously. An attempt to predict the absorption of a medication in patients with a short bowel can be made by using the time to peak levels and the biopharmaceutical classification of drugs (see chapter drugs and short bowel). A drug with a short time to peak plasma levels is likely to be absorbed in the upper gut and so be absorbed in patients with a short bowel; this will not be the case if there is a long time to peak plasma levels. The biopharmaceutical classification of drugs is based upon drug aqueous solubility and intestinal permeability [111, 112]. A drug with high solubility and high permeability (class 1) is likely to be well absorbed in a short length of gut but this will not be the case for one with poor solubility and permeability.

Changes in Jejunostomy Output with Time

Patients with a normal terminal ileostomy experience a decrease in stomal output from about day 5 to 16 weeks after its formation [113]. Hill et al. showed, in patients with an 'ileostomy' following an ileal resection, that there was no decrease in ileostomy water, sodium and potassium losses from 11 days after the resection to 6 months [114]. There is no structural change in distal duodenal mucosa in patients with an established jejunostomy [76]. Thus there is no evidence for any structural or functional adaptive changes occurring in patients with a jejunostomy. The fluid and nutrients needed change very little with time and are likely to be the same for as long as the jejunostomy remains [29].

Surgical Options

If there is small or large bowel out of circuit then if this is brought back into continuity absorption may improve and problems of a HOS resolved. This is well shown when patients after a mesenteric infarction have continuity restored and 77% were able to stop parenteral nutrition within 5 years [115]. The reversal of a 10 cm segment of small bowel has been reported to be successful in increasing absorption in some patient s with a short bowel with few complications reported [116]. The Serial Transverse Enteroplasty Procedure (STEP) is being performed if the small bowel is sufficiently dilated and has mainly been performed in children with a colon in continuity [117]. Rarely small bowel transplantation can be required mainly for complications related to intestinal failure/parenteral nutrition (e.g. liver disease or failing venous access)

Patient Support

Patients with a stoma and a high output may need psychosocial support and the help of local stoma nurses and patient support groups (e.g. ileostomy association or PINNT in the UK; Oley foundation in USA) and advice leaflets.

Future Treatments

The ideal nutrient solution with an osmolality of 300 mOsm/kg and a sodium concentration of 100–140 mmol/L has yet to be marketed. A feed of high viscosity (possibly containing non-absorbable carbohydrate) that delays gastric emptying so allowing more time for absorption may be developed.

As the awareness of the physiological changes in patients with a jejunostomy becomes better defined, treatments, especially with peptide hormones, may be more physiologically administered. For example a combination of peptide hormone analogues (e.g. GLP2 and PYY) may be given at or just after a meal.

Dietary Treatment of Patients with a Short Bowel

Morag Pearson and Jeremy M.D. Nightingale

Key Points

1. A patient with a short bowel taking an oral diet requires a malabsorption factor to be taken into account. Adaptive hyperphagia will help compensate for this.
2. Adhesions are common and so the diet may need to be low in fibre to reduce the chance of obstruction.
3. Jejunostomy patients, whose intestine does not adapt with time, need a high energy iso-osmolar (high lipid) oral/enteral intake with added sodium (and cation supplements). They should restrict oral hypotonic fluids and take an oral rehydration solution.
4. Jejunum-colon patients, whose absorption (adaptation) may improve for up to 2 years after the anastomosis, need a high carbohydrate diet (for colonic fermentation), with no excess lipid (worsens diarrhoea), that is low in oxalate with calcium supplementation (to prevent calcium oxalate renal stones).
5. D-lactic acidosis may occur in jejunum-colon patients. It causes confusion, a high anion gap acidosis and may be helped by antibiotics ideally targeted at specific faecal microbes.

Introduction

Intestinal rehabilitation aims to optimise residual intestinal function through medical, pharmacological, dietary and surgical strategies and to provide the nutrition, fluid and electrolytes required to maintain health (with a normal body weight) and growth in children. It also aims to promote nutritional autonomy and enable a reduction or weaning of parenteral nutrition (PN), so reducing associated complications and improving the quality of life.

Short bowel is categorised according to residual anatomy [1, 2]:

Jejunostomy: following jejuno-ileal resection, colectomy and formation of a jejunostomy, patients will immediately become dehydrated due to large stomal water and sodium losses, which are greatest after food and drink consumption, and rapidly develop malnutrition.

Jejunum-colon: following a jejuno-ileal resection with jejuno-colic anastomosis, patients appear well apart from diarrhoea/steatorrhoea, but in the following months may lose weight and become severely undernourished.

Jejunum-ileum: following a predominantly jejunal resection leaving more than 10 cm of terminal ileum in continuity with colon, patients rarely develop nutritional problems, but if undernutrition or severe diarrhoea arise, then they are treated as per jejunum-colon guidance so will not be discussed separately in this chapter.

Patients with short bowel and taking an oral diet only may have difficulty maintaining nutritional status, fluid and electrolyte balance. This is due to malabsorption and fluid losses which may result in malnutrition and/or dehydration if there is not adequate nutritional support and fluid replacement.

In the immediate postoperative period, many patients may require PN, but its long-term use has been associated with life-threatening metabolic, hepatic and catheter related complications [3, 4] and a reduced quality of life [5, 6]. Over time, intestinal absorption in those with a colon in continuity may improve with adaptation of the residual bowel, a process that is stimulated by intraluminal nutrients and gastrointestinal (especially pancreatico-biliary) secretions. When the gut is functional, patients are encouraged to eat, with advice on modifying oral intake to reduce stoma or stool losses. When the gut has the potential to absorb water, electrolytes and nutrients then nutritional intake should be optimised through dietary counselling, use of oral rehydration solution,

anti-secretory and anti-motility medications, overnight enteral nutrition (EN), distal feeding or other rehabilitative strategies such as surgical restoration of continuity or intestinotrophic hormones. In this way some patients may be able to reduce or withdraw their need for parenteral support [2].

Dietary aspects of intestinal rehabilitation include understanding the anatomical and physiological changes that affect nutrient, fluid and electrolyte absorption; assessing and monitoring patients, promoting adaptation (including hyperphagia) and dietary strategies to optimise absorption, reduce stoma/stool losses and short bowel related complications. The practical aspects of dietary care should be integrated within the multidisciplinary team management. This chapter focuses on the dietary aspects of intestinal rehabilitation, especially the dietary treatment to maximise absorption of nutrients, fluid and electrolytes and reduce short bowel related complications. It outlines most of the key studies on which dietetic advice is based and it gives a full practical dietetic account about D-lactic acidosis and calcium oxalate renal stones.

Remaining Bowel Length and Energy/Fluid Absorption

Balance studies, performed in short bowel patients eating their usual diet, provide an objective measure of nutrient absorption and thus residual intestinal absorptive capacity [7] (Table 1). They involve the 24-h collection of duplicate oral food and fluid intake plus all stoma/stool and urinary losses, each of which are homogenized and frozen or freeze-dried for analysis. Fluid (wet weight) absorption is calculated from the difference between the weight of oral intake and faecal losses, whilst energy content is analysed by bomb calorimetry and absorption calculated from the difference between dietary intake and stool losses.

Rodrigues et al. [8] measured energy absorption from a polymeric test drink, following an overnight fast, in 12 short bowel patients including seven with jejunostomies stable on an oral diet/enteral feed (median 110 cm small bowel) and five (three jejunostomies, one jejunocolic anastomosis to colostomy, one ileo-rectal anastomosis) on home parenteral nutrition (HPN) (median 50 cm small bowel) who remained nil by mouth during the 6-h collection of intestinal output. Median energy absorption was 67% (range 59–78%) in patients stable on diet compared with 27% (range 2–63%), ($p < 0.01$) in those dependent on PN. Energy absorption correlated with residual jejunal length ($r = 0.73$, $p < 0.01$), wet weight ($r = -0.83$, $p < 0.001$) and dry weight ($r = -0.99$, $p < 0.001$) of the stoma/stool output.

Balance studies in 15 patients (six PN, three intravenous fluid (IVF) and six diet/oral nutrient supplements (ONS)) with <150 cm jejunum to stoma, who ate their usual diet also found that jejunal length was inversely correlated with energy absorption ($r = 0.64$, $p < 0.02$) [9]. Patients who required PN had <80 cm jejunum and absorbed <35% of their oral energy intake (mean 8646 kJ (2066 kcal)/day), whereas those stable on diet had >100 cm jejunum and absorbed 58% of their oral energy intake (mean 12,782 kJ (3055 kcal)/day, suggesting an increased oral intake to compensate for malabsorption. Jejunal length was also inversely correlated with net intestinal fluid ($r = 0.75$, $p < 0.01$) and sodium losses ($r = 0.59$, $p < 0.05$), such that patients could be classified as either net 'secretors' or 'absorbers' depending on the relative weight of their oral intake and stomal output and corresponding sodium content. 'Secretors' had less than 100 cm residual jejunum and lost more water and sodium from their stoma than they took by mouth (daily jejunostomy output 2–8 kg, containing 154–551 mmol sodium). They could not convert from negative to positive water and sodium balance by taking more orally and so required long-term parenteral supplements. Their stoma output increased during the day in response to food and decreased at night, highlighting the need to take anti-motility medication prior to food. The 'absorbers' had more than 100 cm of residual jejunum and absorbed more water and sodium from their diet than they took orally (daily jejunostomy output 1–3 kg containing 149–368 mmol sodium). They were able to avoid parenteral support by taking a high salt diet with an oral rehydration solution to maintain fluid and sodium balance.

Jeppesen et al. [10] investigated energy and wet weight absorption by 48-h balance studies in 44 non-HPN patients with intestinal insufficiency (<200 cm small bowel or malabsorption exceeding 2 MJ/day) and 45 HPN patients with intestinal failure. Non-HPN patients had a higher median energy intake (11.69 MJ (2794 kcal)/day) compared with HPN patients (7.56 MJ (1807 kcal)/day), ($p < 0.001$), corresponding respectively to 178% and 134% of basal metabolic rate (BMR) as calculated by Harris-Benedict and a twofold higher energy absorption (7.92 MJ (1893 kcal)/day) compared with HPN patients (3.96 MJ (946 kcal)/day), ($p < 0.001$), corresponding respectively to 130% and 71% of BMR ($p < 0.001$). Intestinal wet weight absorption was threefold higher in non-HPN patients (2.48 kg/day) compared with HPN patients (0.84 kg/day), $p < 0.001$). Non-HPN patients, who absorbed less than half of their intake, avoided HPN through hyperphagia with energy intakes of 10–24 MJ (2390–5736 kcal)/day, equivalent to 200–400% of BMR. Non-HPN patients who maintained intestinal autonomy, tended to have an energy absorption that exceeded 84% of BMR and wet weight absorption of more than 1.4 kg/day, whereas those dependent on HPN absorbed less of either or both.

Whilst balance techniques remain the optimal way to quantify intestinal insufficiency or failure in individual patients [10], very few centres have the facilities to under-

take these meticulous metabolic studies, so clinicians use knowledge of type and length of residual bowel to predict long-term nutritional support requirements [11]. Large cohort studies in short bowel patients with <200 cm healthy jejunum report that the minimum small bowel length required to avoid long-term PN is 60–115 cm in jejunostomy and 30–65 cm in jejunum-colon patients [12–15] (Table 2). In the latter group, conservation of colon is beneficial because it absorbs water, sodium, calcium, some nutrients, maintains a normal rate of gastric emptying of liquids and may stimulate

Table 2 Guide to predicting long-term nutritional support/fluid requirements from residual bowel length in short bowel patients [12–15]

Jejunal length (cm)	Jejunum-colon	Jejunostomy

51–100	ON[a]	PN ± PS[b]; ORS
101–150	ON[a]	ON (added salt); if stoma losses >1.5 L, ORS
151–200	ON	ON (added salt) ± ORS

cm centimetre, *PN* parenteral nutrition, *PS* parenteral saline (±magnesium), *ON* oral nutrition (± oral or enteral nutritional support), *ORS* oral (or enteral) rehydration solution in combination with hypotonic fluid restriction

[a]If colon length reduced, may require added salt ± ORS

[b]At 85–100 cm may need parenteral fluid/electrolytes only

intestinal hyperplasia [13]. Preservation of more than 50% of colon in patients with less than 100 cm small bowel reduced parenteral sodium and energy requirements by half, compared with those without colon [16] and is equivalent to about 50 cm of small intestine in terms of the need for parenteral supplements [13], which explains the importance of restoration of colonic continuity where ever possible.

However, long-term nutritional support needs may be affected by both the integrity and degree of adaptation within the remaining bowel as well as patient specific factors, so each patient should be assessed and monitored on an individual basis.

Integrity of Remaining Bowel

If the remaining small bowel is affected by active Crohn's disease [16], radiation enteritis [16] or radiological proven lesions [14, 15], then its absorptive capacity may be reduced and longer than predicted lengths of small bowel may be required to achieve independence from PN [2].

Adaptation of Residual Bowel

Post-resection intestinal adaptation is a spontaneous process that attempts to increase nutrient and fluid absorption from the remaining bowel through intestinal mucosa hyperplasia to increase the absorptive area (structural adaptation) and/or by slowing of gastrointestinal transit to increase nutrient and fluid absorption (functional adaptation) [11, 17]. It is promoted by intraluminal nutrients and pancreatico-biliary secretions, the development of hyperphagia, modified gastrointestinal hormonal secretion (glucagon-like peptide-1 (GLP-1), glucagon-like peptide-2 (GLP-2) and plasma peptide YY (PYY)), alteration of the gut microbiota and accumulation of faecal D/L-lactate in some patients and is highly variable and unique to each patient [2] (chapter "Intestinal Adaptation").

Residual Anatomy

In jejunum-colon patients, no definite structural intestinal adaptation has been demonstrated, [18, 19], but functional adaptation with slowing of gastric emptying and small bowel transit may occur [20], probably due to high PYY [21] and GLP-2 [22] concentrations. There is increased jejunal absorption of macronutrients, water, sodium and calcium with time [23–26] that allows a gradual reduction in parenteral requirements with an increased chance of the patient being able to reduce or stop PN [1, 12–15]. Although most adaptation is thought to occur within the first 2–3 years post-resection [15, 27], improved intestinal absorption with reduced dependence on PN has been observed many years later [13, 28, 29] and late adaptation has been enhanced by intestinotrophic therapies [30], highlighting the importance of ongoing monitoring and optimisation of dietary and pharmaceutical management.

In contrast, there is no evidence of structural [31] or functional [13, 32] adaptation at any time in jejunostomy patients, likely due to low plasma concentrations of PYY [21] and GLP-2 [33] and leading to rapid gastric emptying and small bowel transit with reduced absorption. Thus, their parenteral nutrition and fluid needs are unlikely to change with time [1].

Enteral Nutrients

Luminal stimulation with enteral nutrients is required to maintain the structure of the intestinal mucosa [17]. Lack of enteral nutrition induces mucosal atrophy and decreases digestive enzyme and nutrient transporter activity in animals and humans, even when adequate calories are provided via PN [17]. PN-induced mucosal atrophy is reversed by reintroduction of enteral nutrition [34, 35], so it is important that food or EN are reintroduced as soon as possible after resection, even in those likely to require long-term PN. Animal studies suggest that post-resection adaptation is enhanced by nutrient complexity, fats particularly long-chain triglycerides (LCTs) and short-chain fatty acids (SCFAs), but the optimum diet to stimulate human intestinal adaptation is not yet known [17]. SCFAs are trophic [36] and make a significant contribution to energy balance in jejunum-colon patients [37]. However, in six jejunum-colon patients, 2-week dietary supplementation with 4 g daily of pectin, a starch that acts a substrate for bacterial SCFA production, increased colonic levels of SCFAs but failed to demonstrate improvements in macronutrient or fluid absorption [38].

Hyperphagia

Many patients compensate for significantly reduced energy absorption by spontaneously increasing their oral intake in a behavioural adaptation known as hyperphagia. In a study of 90 patients with <200 cm small bowel, with or without colonic resection (39 oral diet; 51 HPN), 14 of whom were studied in early (<6 months) and late (>6 months) periods after digestive continuity, 81% had hyperphagia (a spontaneous oral intake >1.5 times resting energy expenditure), which was independently and negatively related to fat absorption ($p < 0.01$) and body mass index ($p < 0.001$) but not braked by the presence of PN. There was an increase in hyperphagia over time highlighting the importance of promoting oral intake in patients receiving long-term PN to maximize residual absorptive capacity [39].

Intestinal Growth Factors

Growth hormone (GH) receptors are located throughout the intestine and GH induces growth and proliferation in many different tissues plus the production of the intestinotrophic hormone, insulin-like growth factor-1 [40]. In addition to regulating gastrointestinal motility, the hormones GLP-1, GLP-2 and PYY exert a trophic effect on the mucosa by enhancing intestinal villus and crypt cell growth [2]. These intestinal growth factors have the potential to hasten or exceed the normal intestinal adaptation response, leading to investigation of the efficacy of GH, its recombinant somatotropin and the GLP-2 analogue, teduglutide, in maximizing absorption from the remnant bowel, decreasing intestinal losses and reducing the requirement for parenteral nutrition or fluids [41] (chapter "Pro-Adaptive Hormones in the Rehabilitation of ADULT patients with a Short Bowel").

Patient Specific Factors

Patient specific factors that may delay adaptation and/or influence long-term PN requirements include the ability to restore oral feeding or develop a post-resection adaptive hyperphagia and to adapt dietary intake to decrease intestinal losses; reduced oral or enteral intake due to symptoms such as nausea, vomiting, bloating or pain, food aversion, aging, chronic narcotic use, psychological factors, underlying comorbidities and social factors [11, 28]. Occasionally PN may be required if increasing the oral or enteral nutrient intake causes a socially unacceptably high stomal output, severe diarrhoea or fails to meet nutritional needs when energy requirements are high and absorption is 30–60% [42].

Nutritional Assessment and Monitoring

Short bowel syndrome (SBS) is a complex condition that requires a multidisciplinary evaluation to determine the most appropriate therapy. Patients may rapidly become dehydrated, electrolyte depleted and malnourished, so require a comprehensive nutrition assessment at baseline (chapter "Assessment of Nutritional and Fluid Status"), which should be repeated regularly to assess the effectiveness of nutrition intervention [43], particularly during HPN weaning when close monitoring is required (chapter "Monitoring of Parenteral Nutrition at Home").

Nutritional Status

The assessment of nutritional status should include weight, body mass index (BMI) and percentage weight loss over 3–6 months. If the patient is dehydrated or overhydrated then their weight may be several kilograms below or above their actual weight and this should be taken in to account when assessing nutritional status and calculating requirements [43]. Rapid changes in body weight are likely to reflect the significant fluid shifts that may be experienced by these patients, so it is best practice to measure mid arm circumference and triceps skinfold thickness (TST) to calculate mid arm muscle circumference (MAMC) in order to monitor changes in body composition in response to nutrition support [43] (chapter "Assessment of Nutritional and Fluid Status"). Handgrip is also valuable in determining functional capacity. MAMC and handgrip should be repeated monthly in hospital [43] and at least annually in stable outpatients to detect any changes in nutritional status to inform amendments in nutritional support.

Micronutrient Status

Short bowel patients are at high risk of developing micronutrient deficiencies due to fat malabsorption and high stoma/fistula losses or diarrhoea/steatorrhoea. A serum micronutrient screen, which depending on laboratory availability, may include folate, iron, ferritin, selenium, zinc, copper, vitamins B12, A, D and E, should be performed in conjunction with the assessment of clinical signs and symptoms of deficiency at the onset of HPN and then at least once per year [4, 44] (chapter "Monitoring of Parenteral Nutrition at Home"), although frequency may vary with changes in clinical status or micronutrient prescription during PN weaning [45]. Whilst laboratory tests play an important role in determining individual requirements, it is unclear to what extent serum concentrations reflect tissue status and true requirements, especially during acute illness [46]. Serum concentrations

lack diagnostic sensitivity as they are maintained within the reference range until severe deficiency or excess develops [46]. Most plasma micronutrients fall as part of the systemic inflammatory response (with the exception of copper, which rises in association with caeruloplasmin synthesis [47]), due to redistribution between tissues and blood, making them unreliable measures of nutritional status when C-reactive protein (CRP) >10 mg/L [45]. In the absence of functional or intracellular measurements, it may be helpful to review serial measurements in relation to CRP changes [48], in the context of clinical features and potential risk factors for deficiency [46]. Micronutrient concentrations may also be affected by other factors for example recent intake (folate) [49], lipid levels (vitamin E) [50], hypoalbuminaemia (zinc) [45], oestrogens (copper) [47] as well as specimen contamination or analytical problems.

Fluid and Electrolyte Status

Fluid and sodium deficiency result in loss of extracellular fluid volume leading to thirst, hypotension and pre-renal failure. Hydration status may be assessed from clinical appearance, fluid balance charts, routine haematology and biochemistry including random urinary sodium. Dehydration is indicated by a low urine output (<1 L/24 h), rapid weight loss (1 kg in 24 h indicates fluid depletion by 1 L) and in the absence of renal disease by a raised urea and creatinine [1]. However, creatinine may be low in patients with reduced muscle mass and urea may be low if protein/nitrogen intake is reduced so making dehydration difficult to identify [51]. Because of the influence of the renin-angiotensin mechanism, the plasma sodium concentration remains normal until body stores are severely depleted [52], so a random urinary sodium provides a better indicator of sodium status (<20 mmol/L indicates maximal renal conservation in response to sodium depletion). Physical signs of depletion become apparent before major changes in blood chemistry, providing important warning signs and include thirst, dry mouth, loss of appetite, nausea, lethargy, muscle cramps, sunken dark-ringed eyes, reduced skin tone, rapid low volume pulse and dizziness on standing due to postural hypotension (confirmed by a lying to standing decrease in blood pressure >20 mmHg systolic and >10 mmHg diastolic) [53]. Inpatient hydration status should be reviewed daily (weight, clinical symptoms, fluid charts and biochemistry) until stable [4] when biochemistry may be reduced to twice per week and post-discharge at each outpatient review.

Magnesium depletion is common, especially in patients with a high stomal output and a serum value of <0.6 mmol/L may give rise to symptoms (fatigue, depression, irritability, muscle cramps and if severe, cardiac arrhythmias and convulsions; tetany may indicate a concomitant hypocalceamia) [42]. Magnesium should be monitored daily during the refeeding risk period until stable when it may be reduced to twice per week and post-discharge at each outpatient review.

Clinical Assessment

Information about underlying illness, co-morbidities and anatomy, residual bowel length and quality (from surgical records and bowel mapping studies using radiology, endoscopic or colonoscopic imaging), enable predictions to be made about absorption, long term fluid/nutrition support needs, including the potential for PN weaning and are crucial to the provision of appropriate advice on diet and fluid intake.

In addition to hydration, clinical assessment should review mobility, signs and symptoms of weight loss, muscle wasting, micronutrient and essential fatty acid deficiencies, intestinal function (nausea, vomiting, bloating, stoma/fistula losses, bowel frequency/stool type and losses from naso-enteric or venting gastrostomy/enterostomy catheters or abdominal drains), temperature, inflammatory markers and signs of sepsis, inflammation or acute disease which may increase nutritional requirements, urinalysis to monitor for ketones and glucose and review of medication including over the counter or herbal preparations which may cause side effects such as nausea, taste changes, increased intestinal losses or abnormal electrolytes [43].

Nutritional Intake

The relative contributions from parenteral, enteral or dietary intake are assessed in conjunction with factors affecting oral intake, an estimate of likely dietary absorption and review of optimisation in relation to short bowel management to inform decisions about the most appropriate form of long-term nutrition support, scope for dietary optimisation and PN weaning.

Oral nutritional intake may be assessed from a detailed food diary or diet history to establish the type and amounts of food consumed, eating patterns, food and fluid preferences, cooking methods, any previous trials of dietary modification or nutrition support, including route, rate, formula and outcome [43] as well as appetite, degree of adaptive hyperphagia and clinical (e.g. dentition, nausea, vomiting, bloating, stoma/fistula output or leakages, stool frequency, incontinence, pain, medication side effects), cultural, behavioral, social or psychological factors [54] that may affect food intake.

Dietary energy and protein intake may be compared with requirements estimated from predictive equations, adjusted for age, sex, weight, disease activity, physical activity and requirement for weight gain/loss or lean tissue gain [55]. In

short bowel patients who are malnourished, ideal body weight has been shown to be a better predictor of resting energy expenditure than actual body weight [56]. Estimated requirements should also be adjusted to compensate for nutrient malabsorption using evidence from balance studies.

Nutritional Management of Short Bowel

The nutritional management of short bowel is a dynamic process that involves overlap or transition between diet, EN and PN in response to changes in the patient's condition and intestinal adaptation [57]. Post-operatively, patients generally receive PN to maintain fluid, electrolyte and nutritional status, until their gastrointestinal function allows re-introduction of oral or EN. If the patient's residual bowel length, anatomy, quality and adaptive potential predict the need for long term PN, then dietary treatment aims to balance eating for pleasure with avoiding high intestinal losses, whereas if there is potential to reduce PN dependence, then oral intake is optimised to maximise absorption. Nutritional goals include the maintenance of a healthy weight (BMI), normal body composition (triceps skin fold thickness and mid-arm circumference measurements used to calculate mid arm muscle circumference), acceptable functional status (activities of daily living, mobility, handgrip), adequate fluid and electrolyte balance (stable weight, a daily urinary volume of at least 1000 mL with random urine sodium concentration of greater than 20 mmol/L, normal serum creatinine and urea with magnesium >0.6 mmol/L) [42], micronutrients within the normal range with no clinical signs of deficiency or toxicity and an acceptable quality of life. Whilst the ultimate goal is enteral independence, this takes time and may not be achievable, highlighting the importance of regular monitoring and individualised management by the multidisciplinary team.

Macronutrient Absorption

Balance studies show that the absorption of dietary macronutrients varies with type, length and quality of remaining bowel (Table 3).

Woolf et al. 1987 [58] investigated macronutrient absorption during a 10-day balance study in eight stable short bowel patients (five jejunostomy, three jejunum-colon, remaining small bowel length 107 cm to all, one receiving HPN), who received isocaloric diets (mean 1869 kcal (31.4 kcal/kg) per day), that matched their usual intake with constant protein, carbohydrate, fat (22%, 32% and 46% of energy respectively) and fluid (2196 mL/day) content. They absorbed 62% of dietary energy and 81%, 61% and 54% respectively from protein, carbohydrate and fat. It was concluded that short bowel patients should increase their oral intake to 35–40 kcal/kg/day of ideal body weight and 80–100 g protein/day to counteract increased losses.

Messing et al. 1991 [59] measured macronutrient absorption during a 3-day balance study in ten short bowel patients (one jejunostomy, nine jejunum-colon, mean small bowel length 75 cm, five receiving HPN) who ate a constant diet that replicated their usual intake and provided mean 3103 kcal (57.9 kcal/kg) per day) and 23%, 46% and 31% of energy from protein, carbohydrate and fat respectively. HPN provided a mean 1120 kcal/day and there was no significant difference in oral intake between parenteral and non-parenteral groups. They absorbed 67% of dietary energy and 61%, 79% and 52% respectively from protein, carbohydrate and fat, with the higher proportion from carbohydrate thought to reflect colonic fermentation. The five patients stable on diet maintained their weight by spontaneously increasing their energy intake to 2.5 times their estimated basal energy expenditure (Harris-Benedict) to compensate for malabsorption.

Crenn et al. 2004 [39] investigated oral intake by dietary questionnaire and macronutrient absorption in a 3-day balance study in 90 patients with <200 cm small bowel, with or without colonic resection (39 oral and 51 HPN), 14 of whom were studied in the early (<6 months) and late (>6 months) periods after digestive continuity. Both groups spontaneously ate a high energy diet (oral group: mean 2667 kcal (45.6 kcal/kg) per day and HPN group: 2507 kcal (48.1 kcal/kg) per day) that provided twice their estimated resting energy expenditure (Harris Benedict) and contained similar proportions of energy from protein (20%), carbohydrate (45–47%) and fat (33–35%). During the balance study they received a constant diet that replicated their usual intake and net dietary absorption was higher in the oral diet group (68% energy, 70% protein, 73% carbohydrate and 61% fat) compared with the PN group (57% energy, 52% protein, 65% carbohydrate, 47% fat). In the subgroup, re-establishment of digestive continuity improved fat and protein absorption in the first 6 months by 30% and 37% respectively with a further 15% increase in protein absorption after this period. It was concluded that macronutrient absorption may be improved by restoration of colonic continuity and promotion of spontaneous adaptive hyperphagia as an oral nutritional strategy.

Estívariz et al. 2008 [60] investigated the habitual home oral diet (7-day food diary plus dietetic review) and macronutrient absorption during a 4-day balance study in 19 short bowel patients (five jejuno- or jejuno-ileostomies, 14 jejunum-colon, mean small bowel length 118 cm), who had received HPN but no dietary instruction for 31 months prior to starting a bowel rehabilitation programme. Mean spontaneous energy and protein intakes were respectively 2656 kcal (39 kcal/kg) and 17 g N_2 (0.22 g N_2/kg) per day, with 15%, 53% and 31% of energy from protein, carbohydrate and fat.

[a]Range not available

[b]mean not available

There was no difference in fat and carbohydrate consumption, whether the colon was present or absent. Simple sugars comprised 43% of oral carbohydrate intake, whilst oral fluid intake averaged 2712 mL/day, primarily from water, coffee, sodas, fruit juices and sports drinks. During the balance study they received a constant diet that replicated their usual intake and mean dietary absorption was 59% energy, 42% nitrogen, 76% carbohydrate and 41% fat. It was concluded that patients were consuming types of foods and fluids that were incorrect for their residual intestinal anatomy and function, which may worsen malabsorption and thus increase HPN requirements. This highlights the importance of individualised nutritional assessment and counselling to facilitate intestinal rehabilitation.

Studies of macronutrient absorption include patients with varying lengths of small bowel, with or without colon in continuity, which makes comparisons difficult, but on average, patients who achieved enteral autonomy, absorbed two-thirds of their oral energy and protein intake [8–10, 39, 58–60]. They compensated for significantly reduced energy absorption by spontaneously increasing oral energy intake to >1.5 times resting energy expenditure through hyperphagia [39]. One study found that patients, who absorbed less than half of their intake, avoided HPN by increasing energy intake to 200–400% of basal metabolic rate equivalent to 10–24 MJ (2380–5714 kcal)/day [10]. Thus, short bowel patients are recommended to compensate for malabsorption by taking a hyperphagic diet containing 30–60 kcal/kg and 0.2–0.25 gN_2 (1.25–1.5 g protein)/kg/day [57] from regular meals, snacks, food fortification, ONS or overnight EN. However, balance studies demonstrated differences in response to dietary manipulation depending on the presence or absence of colon, leading to the recognition that dietary advice should be tailored to the residual bowel anatomy to optimise absorption and minimise complications [4] (Table 4).

Table 4 Dietary recommendations in short bowel patients according to intestinal anatomy [57]

Dietary content	Jejunostomy or ileostomy	Jejuno-ileal or jejunocolic anastomosis
Energy	30–60 kcal/kg/day	30–60 kcal/kg/day
Nitrogen	0.2–0.25 g/kg/day	0.2–0.25 g/kg/day
Protein	1.25–1.5 g/kg/day	1.25–1.5 g/kg/day
Fat	30–40% of total energy	20–30% of total energy
Medium-chain triglycerides (MCT)	No proven benefit	up to 50% of total fat
Carbohydrate	40–50% of total energy[a]	50–60% of total energy[b]
Lactose	No need to restrict	No need to restrict
Oxalate	Normal	Low
Sodium chloride	Extra required from salty foods, addition of salt in cooking or to food on serving	Normal
Oral nutritional supplements or enteral nutrition	Polymeric	Polymeric or semi-elemental with high MCT content
Oral fluid	Restriction of hypotonic fluids with substitution of oral rehydration solution	No restriction usually required

Dietary Treatment for Patients with Jejunum in Continuity with a Functioning Colon

Carbohydrate (Table 5)

The recognition of the colon, not only as an organ for fluid and electrolyte absorption, but as a potential energy-salvaging organ has altered dietary recommendations for jejunum-colon patients [61].

Energy salvage from bacterial fermentation of unabsorbed carbohydrate was demonstrated by Royall et al. 1992 [62], who measured hourly breath hydrogen and blood acetate concentrations in twelve short bowel patients (seven with and five without colon) and six normal volunteers after consumption of a 50 g carbohydrate bread meal following an overnight fast. Breath hydrogen levels were significantly higher in jejunum-colon than jejunostomy or normal volunteers ($p < 0.01$), indicating capacity for fermentation and blood acetate levels were also significantly higher ($p < 0.05$), reaching a peak at 4 h suggesting their production from colonic fermentation. It was proposed that colonic carbohydrate fermentation could provide unrealised clinical benefits in terms of energy balance.

The effect of colon on energy absorption was also demonstrated indirectly in two large cohort reviews, which noted that preservation of at least half the colon was equivalent to about 50 cm of small intestine in terms of the need for parenteral supplements [13], and in patients with <100 cm small bowel, it reduced parenteral energy requirements by 50% compared with stoma patients with the same small bowel length [16].

Nordgaard et al. 1994 [61] investigated the effect of manipulating carbohydrate and fat intake on nutrient and fluid absorption in eight patients with 50–245 cm small bowel to colon, who were maintained on isocaloric diets (10.7 MJ (2557 kcal)/day, 20% protein) and randomised to receive either a low carbohydrate, high fat (20:60% of energy) or a high carbohydrate, low fat (60:20%) diet, each over 4 days. The high carbohydrate low fat diet reduced faecal energy loss by 2.0 MJ (478 kcal)/day ($p < 0.00001$) and significantly increased energy absorption from 49 to 69% ($p < 0.001$) compared with the low carbohydrate, high fat diet. Faecal excretions of carbohydrates were low and not affected by change in carbohydrate intake whereas faecal fat increased from 44 to 75% as dietary fat intake increased. There was no change in the faecal volume between the two diets, but the amount of water consumed with the high carbohydrate diet was one litre more than with the high fat diet, suggesting that the colon is capable of reabsorbing additional fluid or that the high carbohydrate diet may improve fluid absorption.

A second study in 82 patients with varying lengths of small bowel in continuity with colon, who consumed their habitual diet (mean 9.9 MJ (2366 kcal)/day), which was high in carbohydrate (55% total energy) found that colonic digestion can supply up to 4.2 MJ (1000 kcal) per day as small bowel failure proceeds, highlighting the importance of encouraging patients with <200 cm to take a high carbohydrate diet [37]. However, high carbohydrate diets increase the volume of food to be eaten (Fig. 1), which may reduce energy intake and colonic fermentation produces gases, which may increase bloating and flatulence [4], so patients should be supported to find a balance between maximising carbohydrate intake for energy and avoiding unwanted side effects.

Pectin is water soluble, non-cellulose fibre, which may prolong gastrointestinal transit time and is fermented by the colonic bacterial flora to produce SCFAs, which may enhance energy absorption. Atia et al. 2011 [38] investigated the effect of giving a pectin supplement (4 g three times per day for 2 weeks) on intestinal absorption and transit in six short bowel patients with 50 cm small bowel anastomosed to colon

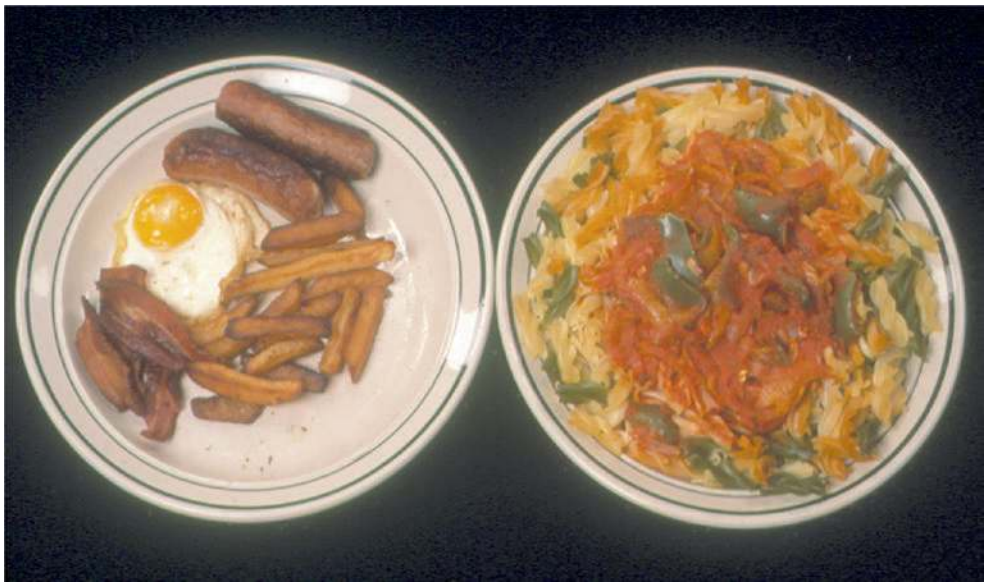

Fig. 1 Two 700 kcal meals. A high fat fried meal and a pasta meal. While the pasta meal is ideal for jejunum-colon patient it is a much larger volume so can be hard to consume

(four HPN). Whilst there was an increase in short chain fatty acid production ($p = 0.02$), there was no change in percentage energy ($p = 0.438$), carbohydrate ($p = 0.56$) or fat ($p = 0.22$) absorption, faecal wet weight ($p = 1.00$) or urine production ($p = 1.00$). There was a non-significant increase in gastric emptying and oro-colonic transit time. As the addition of soluble fibre did not enhance overall intestinal absorption, supplementation is not recommended in short bowel [4].

Lactose

Small bowel resection may cause secondary lactose intolerance due to reduced absorptive surface and shortened transit. Arrigoni et al. 1994 [63] randomised 17 patients with <150 cm small bowel (six jejunostomy, 11 jejunum-colon) to receive a 20 g lactose load from milk or yogurt after a 12 h fast, then measured faecal weight and carbohydrate excretion from lactose and hexose flow rates (stoma) or breath hydrogen excretion (colon) over the next 8 h. There were no clinical signs of intolerance or increase in faecal weight, but lactose was better absorbed from yogurt than milk (76% versus 50%, $p < 0.05$) in the stoma patients with no significant difference in colon patients.

In a follow-up study, Marteau et al. 1997 [64] studied a single 20 g lactose load in 14 fasted patients with <150 cm small bowel (six jejunostomy, eight jejunum-colon) and then randomised them to receive their usual diet plus either 20 g/d lactose or no lactose, each over 3 days, with an interval of 7 days in between. Lactose absorption from the single load was 61% and 53% in the stoma and colon patients respectively. There were no symptoms of intolerance and no differences in faecal weight between the lactose rich or lactose free diets in the stoma ($p = 0.36$) or colon ($p = 0.19$) patients. Since foods containing lactose provide a valuable source of energy, protein and calcium, they should not be restricted unless there is a clear association between lactose ingestion and increased diarrhoea [4].

Fat (Table 5)

Unlike carbohydrate and protein, long chain fatty acids (LCFAs) are only absorbed from the small bowel and their malabsorption in to colon results in steatorrhoea and a concomitant diarrhoea [65], that led to the use of a low-fat diet for symptomatic treatment after ileal resection [66].

Balance studies compared the effect of a high fat (100 g/day over two to four 4-day periods) versus low fat intake (40 g/day over 16–24 days) on stool output in 13 patients with diarrhoea post-ileal resection (ten ileal-colonic anastomosis, two active Crohn's disease and one ileostomy), who ate a constant energy and protein diet [67]. The low-fat diet reduced mean faecal fat excretion from 23 to 9 g/day with a marked reduction in faecal water and sodium excretion by 36% and 11% respectively, such that ten patients passed formed stool. There was a mean weight gain of 1.5 kg despite a lower energy intake during the study (mean 2420 kcal) compared with usual intake (mean 3290 kcal). However, it is not known whether these patients had a true short bowel and the reduction in fat was accompanied by an increase in protein and carbohydrate intake, which may have influenced colonic absorption.

A follow-up study in nine of these patients found that the low-fat diet increased absorption of magnesium (not significant), calcium ($p < 0.01$) and zinc ($p < 0.01$), although interpretation is limited by the higher mineral content of the

low-fat diet, which occurred as a consequence of its increased protein content [68].

In their comparison of a low fat (20%), high-carbohydrate (60%) versus high-fat (60%) low-carbohydrate (20%) diet in eight patients with 50–245 cm small bowel to colon Nordgaard et al. 1994 [61] found that fecal fat excretion increased from 44 to 75% as dietary fat intake increased and this accounted for differences in faecal loss of energy.

Whilst a low-fat diet decreases steatorrhoea/diarrhoea, calcium, magnesium and zinc losses and oxalate absorption [69], it may have the adverse effect of reducing food palatability and oral energy intake as it is less energy dense than comparable weights of carbohydrate. In practice, patients should be supported to find a balance between including fat for energy and avoiding steatorrhoea. Symptomatic patients who report pale, oily stools that float and are difficult to flush, may benefit from reducing intake of high fat foods and changing to lower fat products and cooking methods. The combination of severe fat malabsorption (>25–50% of dietary fat intake) [70] and a low-fat diet [71] may increase the risk of essential fatty acid deficiency, so these patients should consume fats that are rich in essential fatty acids [71]. They should be monitored for clinical signs of deficiency (dry flaky skin), which may be prevented or treated by cutaneous application of sunflower oil [72] or safflower oil [73]. These patients are also at risk of developing fat soluble vitamin deficiency [71, 74] so require oral supplementation, often at above recommended doses to compensate for malabsorption, with regular monitoring for clinical signs of deficiency and trends in serum concentrations [4, 27].

Medium-Chain Triglycerides (MCTs) (Table 5)

MCTs are rapidly absorbed by passive diffusion from the small bowel into the portal system, without the need for cholecystokinin, pancreatic enzymes or bile [75], so may be beneficial in patients with a short bowel. Early case reports noted that the substitution of long chain fatty acids (LCT) with MCT reduced steatorrhoea and supported weight gain [76–78], whilst colonic absorption of MCT was reported in animal studies [79].

Jeppesen et al. 1998 [79] investigated colonic absorption of MCT in 19 small bowel resected patients (six jejunostomy and three ileostomies, mean small bowel length 203 cm; ten jejunum-colon, mean small bowel length 143 cm), who were randomised and crossed over between two isocaloric (10 MJ (2390 kcal)) high fat diets containing 50% of energy from LCT or a 50% substitution of LCT with MCT, each over 3 days. Jejunum-colon patients absorbed MCTs considerably better than those with a stoma. In jejunum-colon patients, faecal excretion of MCT was negligible suggesting almost complete (>90%) absorption of MCT even when LCT was malabsorbed. The replacement of half LCT with MCT increased fat (MCT + LCT) absorption from 23 to 58% ($p < 0.001$) and increased bomb calorimetric energy absorption from 46 to 58% of dietary intake ($p = 0.02$) corresponding to 1.308 MJ (313 kcal)/day, with no significant increase in faecal volume. In stoma patients, MCT increased fat absorption from 37 to 46% ($p = 0.05$), but did not improve overall energy absorption because there was a concomitant decrease in protein and carbohydrate absorption, possibly related to increased stoma volume (2177 to 2729 g/day; $p = 0.07$). It was postulated that MCTs are water-soluble so may be absorbed from the colon in a similar way to short chain fatty acids (SCFAs) and may therefore provide an alternative energy source for jejunum-colon patients, particularly in those struggling with satiety or wind on a high carbohydrate diet or who are at the borderline of requiring PN [4].

MCTs are unsuitable as the sole source of fat as they do not contain essential fatty acids or fat-soluble vitamins, but may be used to partially replace LCTs through the inclusion of natural food sources like coconut or palm kernel oil, commercial MCT oil preparations or ONS with a high MCT content. MCT containing products should be introduced slowly in divided doses to prevent gastrointestinal symptoms like abdominal discomfort, bloating or diarrhoea [75].

Management or Prevention of Complications in Jejunum- Colon Patients

D-Lactic Acidosis

Although conservation of colon is beneficial, its presence is associated with the extremely rare occurrence of D-lactic acidosis (DLA). A systematic review identified 98 original case reports published between 1977 and 2017 in patients aged 7 months to 86 years [80]. It is associated with the rapid degradation of large quantities of unabsorbed carbohydrate in individuals with an altered colonic microbiota that increases D-lactate production, leading to faecal accumulation, increased concentrations in blood and urine, metabolic acidosis and neurological symptoms.

Lactic acid has two optical isomers, L- and D-lactate, which are metabolized to or produced from pyruvate by isomer specific enzymes, L-lactate dehydrogenase (L-LDH) and D-lactate dehydrogenase (D-LDH). Human cells lack D-LDH but do contain L-LDH so the primary isomer formed during anaerobic glycolysis is L-lactate, although small quantities of D-lactate are produced via the methylglyoxal pathway [81], which are metabolized to pyruvate by the enzyme D-2-hydroxyacid-dehydrogenase (D-2-HDH) [82, 83] located mainly in liver and kidney or excreted in urine [84] so blood concentrations normally remain low. However, colonic bacteria can produce both L- and/or D-lactate depending on the L-LDH and D-LDH content of bacterial species [85] and the

presence of DL-lactate racemase, which converts one lactate isomer to the other [85]. Both isomers may be degraded to SCFAs [85, 86], absorbed in to the circulation [87] or excreted in the stool so do not usually accumulate as their production does not exceed metabolism [88].

In jejunum-colon patients, the bacterial degradation of large amounts of unabsorbed carbohydrate increases organic acid production, which leads to a progressive decrease in intraluminal pH, favouring the growth of acid-resistant, lactate generating bacteria [85, 89] with increased numbers of the Lactobacillus/Leuconostoc group and reduced numbers and diversity of Clostridium and Bacteroides [90, 91]. If D-lactate producing bacteria become predominant, then degradation of large amounts of carbohydrate, particularly readily fermentable simple sugars, increase D-lactate production, leading to accumulation and raised concentrations in blood and urine [92]. Other contributory factors include the use of antibiotics [90, 93, 94] or probiotics [95, 96] that alter the intestinal flora to promote D-lactate-producing bacteria [80], a reduction in intestinal bacteria able to convert D-lactate to SCFAs [92], decreased metabolism due to inhibition of D-2-HDH by reduced pH [83] or hyperoxaluria [83] and reduced renal excretion due to impaired renal function or hypoperfusion secondary dehydration [97, 98].

The occurrence of DLA is unpredictable and may reflect an imbalance between microbial formation and the individual's ability to metabolise D-lactic acid [85, 97, 98]. Mayeur et al. 2013 [99] investigated the microbiota imbalance in 16 short bowel patients (<150 cm jejunum in continuity with colon) who had been stable for 2 years and found two subtypes: those who had no detectable lactate (44%) and those who accumulated D- and L-lactate in faeces (56%). Patients who did not accumulate lactate or who preferentially accumulated L-lactate had never developed DLA, whereas those with a high faecal D/L-lactate ratio and low plasma bicarbonate values had an increased risk of developing DLA. It was concluded that the D/L faecal lactate ratio may provide a better index of imbalanced microbiota and higher DLA risk than D- and L-lactate faecal concentrations per se.

DLA presents with neurological symptoms including impaired alertness, ataxia, gait disturbances, weakness, slurred speech, deep rapid breathing (Kussmal breathing), confusion, nausea or vomiting, blurred vision, nystagmus, aggressive or inappropriate behavior and stupor that may progress to coma [80, 98, 100] and a metabolic acidosis with an increased serum anion gap that is confirmed by increased concentrations of D-lactate in blood and urine, while L-lactate is often normal [97, 98].

Whilst neurological symptoms are attributed to elevated D-lactate concentrations, there is poor correlation between the onset or severity of symptoms and plasma concentrations [101, 102]. In normal subjects, the infusion of D-lactate to produce comparable plasma concentrations to those found in DLA did not cause neurological symptoms [87, 97, 103] and other types of acidosis of comparable or greater severity do not cause such symptoms [98]. It has been hypothesized that noxious substances produced during colonic fermentation like aldehydes, alcohols, mercaptans and amines may act as false neurotransmitters to cause neurological symptoms [88] or that inhibition of pyruvate dehydrogenase (PDH) by thiamine deficiency [104] or low intraneuronal pH from D-lactate accumulation may affect pyruvate metabolism by altering neurotransmitter production and neurological functioning [105].

Acute episodes of DLA are treated with parenteral bicarbonate to correct acidosis [89, 106], rehydration with lactate free crystalloids [100] to optimize renal excretion of D-lactate [92], carbohydrate restriction to decrease the substrate available for further D-lactate production [106, 107], non-absorbable broad-spectrum oral antibiotics to reduce D-lactate producing bacteria [1], thiamine repletion to increase PDH availability for pyruvate metabolism [92] or haemodialysis to clear both isomers in severe D-lactate toxicity [108]. Temporary fasting is associated with a rise in serum bicarbonate and fall in serum and urine D-lactate levels within 72 h [109] that allows rapid improvement in encephalopathy. Malnourished patients may be given short-term PN during fasting, as calories derived primarily from carbohydrate or lipid had no significant effect on either acid or D-lactate concentrations [110].

However, the prevention of repeated episodes is more challenging. Simple sugars should be restricted with substitution of modest amounts of slowly digestible, less easily fermentable polysaccharides to limit the substrate available for bacterial fermentation [85, 106, 109]. Serum D-lactate concentrations rise through the day to peak after the last evening meal and then fall during the night to their lowest concentration just before the first morning meal, so consuming modest amounts of carbohydrate over 4–6 small meals will lower peak serum concentrations [111]. Overnight EN should be used with caution as it will prevent the usual decline in serum D-lactate concentrations and thereby increase acidosis risk [111].

Maintaining adequate hydration supports renal clearance of D-lactate, so the usual dietary and pharmacological measures to reduce stool output should be emphasized [92]. The inhibition of D-2-HDH activity by hyperoxaluria may be reduced by consumption of a low oxalate, moderate fat diet in conjunction with calcium supplements to bind dietary oxalate [92].

Recurrent DLA symptoms may be prevented by a rotating course of oral antibiotics, although efficacy varies widely. Alternatively, some patients may take antibiotics when they recognize early neurological disturbances to prevent the development of encephalopathy [92]. However, antibiotic therapy can induce DLA by promoting overgrowth of D-

lactate producing organisms, which may be prevented though selection of appropriately targeted therapy using stool culture antimicrobial sensitivities [93, 94]. Long-term use may promote antibiotic resistance, so probiotics have been tried as an alternative therapeutic option [112]. Depending on the supplemented strains, there are reports of DLA being induced [95, 96] or prevented by probiotics [112–115] or synbiotics [116, 117]. More recently the microbiological analysis of stool facilitated the selection of a strain-specific non-D-lactate producing daily probiotic that prevented further episodes of DLA in a 4-year-old boy with short bowel [112]. There is a need for randomized controlled trials to test strain-specific effects and to determine the duration and frequency of probiotic use [118]. If dietary and medical therapies fail, then surgical strategies such as intestinal lengthening [85] or colonic resection may be considered whilst promising results from fecal transplantation have been reported [119, 120].

Calcium Oxalate Renal Stones

In contrast to short bowel patients with a jejunostomy, those with less than 200 cm jejunum in continuity with colon have a 25% increased risk of developing symptomatic calcium oxalate renal stones, which develop at a median of 30 months (range 2–67) post-surgery due to increased colonic oxalate absorption leading to hyperoxaluria [13] (chapter "Nephrolithiasis and Nephrocalcinosis").

Urinary oxalate is derived from the diet, endogenous production (metabolism of glycine, glycolate, hydroxyproline and synthesis from glyoxylate) and breakdown of ascorbic acid [121]. Normally less than 10% is derived from diet [122] but this may increase up to 50% depending on oxalate intake, its bioavailability, the presence of oxalate-binding cations and oxalate-degrading bacteria and gastrointestinal absorption [123, 124]. Oxalic acid is present in plant foods including nuts, fruits, vegetables, grains and legumes as soluble (sodium or potassium oxalate) or insoluble (calcium or magnesium oxalate) salts that may be absorbed throughout the gastrointestinal tract by active or passive mechanisms [125]. Since oxalate cannot be further metabolised, it is excreted in urine with a peak 2–4 h after ingestion, suggesting that small intestine is a key absorptive site and that oxalate rich foods can induce transient hyperoxaluria that may not be noticed in 24-h urine samples [126, 127].

In health, urinary supersaturation is affected by solute concentration, ionic strength, pH value and the presence of promotors (calcium, sodium, oxalate, low urine volume and low urine pH) or inhibitors (citrate, magnesium, phosphonates and other organic substances) of stone formation, which may vary during the day depending on fluid intake, dietary intake and body metabolism [128, 129]. Urine is often supersaturated with respect to calcium oxalate in a metastable solution that is prone to precipitate upon small increases in oxalate concentration [128] and higher oxalate concentrations substantially increase the risk of nucleation, growth and aggregation of kidney stones [130]. Nephrolithiasis results in renal colic, obstructive uropathy (which may cause irreversible renal damage), urinary tract infection, (which in the presence of obstruction may cause pyonephrosis) and rarely nephrocalcinosis with progressive renal impairment [131].

The association between hyperoxaluria, ileal resection and increased oxalate absorption was first demonstrated by Chadwick et al. 1973 [132] who measured urinary excretion of the isotope ^{14}C oxalate taken with food. Ileal-resected patients absorbed up to five times more oxalate than control subjects but oxalate excretion returned to normal with a low oxalate semi-synthetic diet (<4 mg oxalate per 24 h). Extensive ileal resection (≥100 cm compared with <50 cm) was associated with increased urinary oxalate excretion and there was a direct correlation between fat malabsorption and urinary oxalate excretion such that increasing dietary fat further increased urinary oxalate excretion [133].

Steatorrhoea was associated with increased colonic absorption of dietary oxalate [134–136], especially in the distal colon [137]. Calcium and oxalate normally form an insoluble complex that is passed in the stool, but ileal resection results in malabsorption of free fatty acids in to the colon, where they bind with calcium to release soluble oxalate for absorption [138]. Both free fatty acids and unabsorbed bile acids increase colonic permeability to oxalate, thereby facilitating its absorption [139]. An infusion of chenodeoxycholate in to the colon increased oxalate absorption fivefold [140], whilst cholestyramine (a bile-salt binding drug) taken orally reduced oxalate absorption [132, 141]. Colonic oxalate absorption is increased by low dietary calcium, hyperparathyroidism and vitamin D administration, all of which reduce calcium concentration in the colon and thus the extent to which oxalate is bound to calcium in the gut lumen [131, 135, 142–145].

Oxalate absorption may be reduced by the presence of intestinal bacteria able to metabolise oxalate including 'generalist oxalotrophs' like bifidobacterium and lactobacillus that degrade other carbon sources as well as oxalate and 'specialist oxalotrophs' like Oxalobacter formigenes which is a commensal anaerobe that metabolises only oxalate [146]. Treatment with antibiotics markedly reduces colonisation with Oxalobacter formigenes [147–149]; it is cultured less frequently from the stools of patients with Crohn's disease or steatorrhoea [150] and its growth is inhibited by low bile acid concentrations [151], all of which may contribute to increased oxalate absorption and nephrolithiasis in jejunum-colon patients. A study of 37 idiopathic calcium oxalate stone formers (excluding enteric hyperoxaluria) found that colonisation with oxalobacter formigenes was associated

with a reduced risk of calcium oxalate stone formation and a significantly lower urinary oxalate excretion compared with non-colonised patients whilst on a controlled diet [152].

The concentration of lithogenic substances in urine is determined by the excretion rate of calcium and oxalate and independently by the excretion of water [131]. Jejunum-colon patients who experience bowel frequency may become dehydrated with a reduced urinary volume, which increases calcium and oxalate concentrations and makes nucleation more likely to occur.

Prevention of Calcium-Oxalate Stones from Enteric Hyperoxaluria

The incidence of calcium-oxalate stones may be reduced by restriction of dietary oxalate and fat in conjunction with adequate oral calcium to reduce oxalate absorption and maintenance of hydration to achieve adequate urine volume.

Reduction of Dietary Oxalate and Fat

The restriction of dietary oxalate and fat intake in metabolic studies of enteric hyperoxaluria [69, 132, 134, 153] reduced urinary oxalate excretion but this has never been confirmed by randomised controlled trial [131, 154]. Holmes et al. 2016 [155] cited that loading studies in normal subjects consuming controlled oxalate and calcium diets found that increasing oral oxalate from 100 to 750 mg/day increased urinary oxalate by 2 mg per 100 mg of oxalate consumed [123, 156]. Calcium-oxalate stone formers with hyperoxaluria had a 36% reduction in urinary oxalate excretion when they consumed a low oxalate (80–100 mg/day) and normal calcium (1000 mg/day) diet [157].

Both clinical investigation and dietary advice have been hampered by inadequate or inaccurate data on the oxalate content of foods and variations in its bioavailability and gastrointestinal absorption [123]. Differences in oxalate values for a single food may reflect the analytical technique, with methods utilising colorimetric [158, 159] or enzymatic [160] assays reported to be less specific or reproducible than high performance capillary electrophoresis and ion chromatography [161, 162].

Accuracy is further limited by variation in amount of oxalate synthesized by the plant due to cultivar, growing conditions and time of harvest [163]. The amount of oxalate absorbed from a food is affected by its salt form (oxalate absorption is proportional to the amount of soluble oxalate [164]), food processing and cooking methods (boiling vegetables reduced oxalate content by 30% due to loss of soluble oxalate [165]) and meal composition (simultaneous consumption of calcium and magnesium reduced oxalate absorption by formation of insoluble salts [124, 166]), gastrointestinal transit time, the presence of oxalate degrading bacteria in the large bowel [161, 162] and inherited capacity to absorb oxalate [167].

As there is no definitive information on the oxalate content of foods or their effect on urinary excretion and oxalate rich meals may cause a transient rise in renal oxalate load that is amplified by increased intestinal absorption [123, 168], it is reasonable to advise jejunum-colon patients to reduce hyperoxaluria by avoiding foods that are high in oxalate [124, 154] including spinach, rhubarb, beetroot, wholemeal bread, bran-containing cereals, black tea, chocolate, cocoa, nuts, beans, soybeans and soy products. If individual patients require more specific dietary advice, then dietitians should select food analyses based on reliable methods and use averages for the food concerned [124, 169]. Regular dietary counselling at clinic visits significantly reduced urinary oxalate by 55.5% in 137 patients with urolithiasis risk, managed initially with only dietary intervention [170].

Whilst fat restriction is theoretically helpful, it may not be desirable for nutritional reasons, so patients should be supported to moderate their fat intake to reduce steatorrhoea and thus limit hyperoxaluria. Substitution with MCTs may be helpful in reducing oxalate absorption [138].

Adequate Dietary Calcium

Studies in patients with ileal disease or resection and jejuno-ileal bypass found that the degree of hyperoxaluria correlated directly with severity of steatorrhoea and inversely with dietary calcium content [135, 138]. High calcium diets [135] and oral calcium supplements [143–145] reduced oxalate absorption and urinary oxalate excretion, although this has never been confirmed by randomised controlled trial [131, 154].

A loading study in twelve healthy volunteers consuming a controlled oxalate diet (250 mg oxalate/day) found that reducing calcium from 1002 to 391 mg increased urinary oxalate excretion by a mean of 28.2% [123]. Another study in eight healthy volunteers consuming a controlled diet (2500 kcal, 83 g protein, 63 mg oxalate) found oxalate absorption depended linearly on calcium intake with mean oxalate absorption decreasing from 17 to 2.6% as calcium intake increased from 200 to 1200 mg/day. Within this range, an increase in calcium supply by 70 mg decreased oxalate absorption by 1% and vice versa. Calcium addition beyond 1200 mg/day reduced oxalate absorption only one-tenth as effectively [171].

The American Urological Association guidelines [154] note that large prospective epidemiological studies found an increased risk of stone formation with lower calcium diets [172–174] whilst higher calcium diets were associated with reduced oxalate excretion [175]. When the recommended daily quantity of dietary calcium was consumed, calcium oxalate stone risk was not significantly affected despite a relatively high dietary oxalate intake [176]. However, supplemental calcium was associated with an increased risk of stone formation in older women [172], but not younger

women and men [174]. The discrepancy between risks associated with dietary calcium and supplemental calcium may be due to the timing of calcium supplement intake and/or overzealous supplementation resulting in excessive total calcium [177].

A randomized controlled trial in recurrent hypercalciuric calcium oxalate stone formers, not known to have enteric hyperoxaluria or bowel resection, reported a 51% reduction in stone recurrence in men consuming a normal calcium (1200 mg/day), lower sodium (1200 mg/day) and animal protein (52 g/day) diet compared with a low calcium diet (400 mg/day) at 5 years [178]. Oxalate consumption was thought to be similar in both groups as they were advised to restrict intake of oxalate-rich foods. Although urinary calcium declined in both groups, urinary oxalate increased in the lower calcium group and decreased in the normal calcium group. However, it is not possible to determine the independent effect of calcium due to the use of a multicomponent diet [154, 179].

Consequently jejunum-colon patients should be advised to consume calcium in line with dietary recommendations [154, 179] from either dairy or non-dairy sources [180]. If dietary intake is inadequate, then calcium supplements in doses not exceeding 1000–1200 mg daily [154] may be taken with meals to enhance gastrointestinal binding of oxalate [135, 144, 145, 181].

Prevention of Dehydration

In health, fluid intake is the main determinant of urine volume and as such a high fluid intake is a critical component of stone prevention. Observational studies found that higher fluid intake reduces the risk of stone formation [172, 174, 182], whilst a randomized controlled trial found reduced stone recurrence rates among recurrent calcium oxalate stone formers randomized to a high fluid intake compared with a comparable group given no specific recommendations (12% versus 27%, respectively at 5 years) [183]. Although there is no definitive threshold for urine volume and increased risk, stone formers are generally recommended to take a fluid intake that will achieve a urine volume of at least 2.5 L daily [154, 179]. However, a high fluid intake may increase stool frequency in jejunum-colon patients, so their hydration and urine output should be optimised through dietary and pharmacological measures to reduce stool output although some may require parenteral fluid support.

Probiotics

Small studies have assessed the use of oral probiotics containing oxalobacter in primary hyperoxaluria [184–186] or different combinations of lactobacillus, bifidobacterium, enterococcus and other oxalate degraders [157, 187–192]. They found promising but mixed results, in part due to transient reductions in urinary oxalate excretion that were reversed when probiotic treatment was stopped; the use of different probiotic preparations containing multiple bacterial strains that varied in their administration with meals and variations in the control of dietary factors that might confound probiotic-induced effects [193]. Research in this field is still in its early stages and more work is required to determine the exact strain and dose and validate oxalate-targeting probiotics.

Vitamin C

Ingested vitamin C is partly converted to oxalate and excreted in urine, which may increase the risk of calcium oxalate stone formation and a metabolic study in 47 stone formers found that supplementation with 1- or 2-g vitamin C increased mean urinary oxalate by 61% and 41% respectively [194]. In a large epidemiological study, total and supplemental intake of ≥1000 mg/day vitamin C was significantly associated with a higher risk of incident kidney stones in men, but not among women [195], but there was no association with dietary vitamin C in any cohort. Whilst it may not be generalizable to women, it is prudent to advise avoidance of vitamin C supplements [154].

Dietary Treatment for Patients with a Jejunostomy

Macronutrient Absorption

Carbohydrate Versus Fat (Table 5)

Since protein and carbohydrate are mostly absorbed from the first 200 cm of jejunum [196] and fat malabsorption is increased by ileal resection and bile salt deficiency [197], jejunostomy patients were historically advised to take a low fat, high carbohydrate diet to improve absorption [66]. However, reducing fat intake may compromise energy intake and increasing carbohydrate, particularly from simple sugars, may increase intestinal luminal osmolality and thus stomal fluid losses [198, 199].

The potential for a higher fat intake to improve energy absorption without increasing jejunal losses was first suggested by Simko et al. 1980 [200] who measured fat absorption from three isocaloric, isonitrogenous liquid formula diets (3850 kcal/24 h) with varying proportions of fat and carbohydrate in a patient with a jejunostomy at 137 cm. Although fat losses increased proportionately with increasing intake, the percentage fat absorption remained remarkably constant irrespective of dietary intake. Increasing dietary fat from 64 to 200 g/day, with a reciprocal decrease in carbohydrate from 759 to 453 g/day, led to a linear increase in fat absorption from 44 to 133 g/day ($r = 0.99$) without shortening intestinal transit time, increasing stool weight or causing undesirable side effects. Continuation of the high fat

diet led to 16 kg weight gain over 12 months and discontinuation of parenteral fluids and electrolytes.

Woolf et al. 1983 [201] investigated absorption in eight patients (five jejunostomy, three jejuno-transverse colon), who were maintained on isocaloric, isonitrogenous diets with constant fluid and fibre content, but randomised and crossed over between a high fat, low carbohydrate diet (60:20% energy) or a low fat, high carbohydrate diet (20:60% energy), each over 5 days. There were no significant differences in total energy, percentage fat or protein plus carbohydrate absorption, stool weight or absorption of calcium, magnesium and zinc between the two diets. Faecal fat excretion was three times higher on high fat than low fat diet, but there was no difference in the proportion of ingested fat that was absorbed. As the low-fat diet conferred no benefits in calorie, fluid or divalent cation absorption, it was concluded that dietary fat should not be restricted. However, these results were reported as a mean of the two anatomical types of short bowel, which may limit their application.

Ovesen et al. 1983 [199] evaluated the effect of fat versus carbohydrate as an energy source and the effect of substituting saturated with polyunsaturated fat on the absorption of fat, fluid, sodium, potassium, calcium, magnesium, zinc and copper in five jejunostomy patients (35–125 cm jejunum), stable on HPN. They were randomised to receive three isocaloric, isonitrogenous diets: one low fat (30% kcal), high complex carbohydrate (55% kcal), and two high fat (60% kcal), low carbohydrate (25% kcal) diets with differing polyunsaturated: saturated fatty acid ratios of 1:4 or 1:1, each over 9 days, with collection of excreta on the last two. Although the high fat diet increased steatorrhoea, neither the type nor amount of dietary fat had any consistent effect on jejunostomy volume or fat absorption (40–45%), raising the possibility of greater net energy absorption from high fat, but this could not be confirmed as carbohydrate absorption was not measured. The sodium and potassium concentration of the jejunostomy fluid stayed constant, suggesting that losses reflected jejunostomy volume rather than the fat or carbohydrate content of the diet. However, the high fat diet did increase stomal losses of calcium, magnesium, zinc and copper, which in most cases were converted to net absorption by the low fat, high carbohydrate diet. Altering the polyunsaturated/saturated fatty acid ratio had no effect on divalent cation losses. It was concluded that patients should be advised to either reduce their fat intake or receive supplementation to achieve adequate cation status.

McIntyre et al. 1986 [202] measured absorption in four patients with a jejunostomy (60–150 cm jejunum), who were randomised and crossed-over between three diets, which contained equivalent quantities of nitrogen, calories, electrolytes and minerals but varying amounts of fat and fibre to provide high fat/high fibre, reduced fat/high fibre or reduced fat/normal fibre intakes, each over 2–3 days. There were no significant differences in energy, nitrogen or fat absorption or weight of stoma effluent between the three diets. The high fat diet led to a non-significant increase in faecal fat excretion, but did not increase jejunostomy effluent or sodium, potassium, calcium or magnesium losses. There was no detriment with a high fibre diet compared with a normal fibre diet. It was concluded that a liberal attitude towards fat and fibre intake was acceptable in patients with a high jejunostomy.

In their comparison of a high carbohydrate, low fat (60:20% of energy) versus low carbohydrate, high fat (20:60%) diet in six patients with 100–250 cm small bowel to a jejunostomy maintained on isocaloric diets (10.6 MJ (2533 kcal)/day, 20% protein), Nordgaard et al. 1994 [61] found no significant difference in energy excretion between high carbohydrate (4.8 MJ/day) and high fat diets (5.9 MJ/day; $p = 0.08$) with carbohydrate and fat excretions proportional to the amounts ingested. Energy absorption was similar between the high carbohydrate (55%) and high fat (48%) diets ($p = 0.21$). However, the high carbohydrate diet increased stomal effluents by mean 732 mL/day ($p = 0.10$) compared with the high fat diet. Beverage intakes were similar (3154 versus 2880 mL for high carbohydrate and high fat respectively) but the higher water content of the high carbohydrate (1420 mL/day) compared with the high fat diet (717 mL/day; $p = 0.0003$) resulted in a higher fluid intake of about 1000 mL/day, which may have implications for fluid management.

In a 3-day balance study of macronutrient absorption in 90 patients with <200 cm small bowel who received a constant diet that replicated their usual intake (Table 3), Crenn et al. 2004 [39] reported that fat absorption was significantly related to jejunal length ($p < 0.01$). In the twelve jejunostomy patients, the amount of fat absorbed was dependent on fat intake ($p < 0.001$) without an upper threshold, supporting the promotion of a non-limited fat intake for these patients

Thus, fat restriction did not improve energy, fluid or monovalent electrolyte absorption in jejunostomy patients [61, 199, 202]. Since a constant proportion of dietary fat is absorbed [39, 61, 199, 202], jejunostomy patients should be encouraged to take a higher fat diet to increase energy absorption, reduce dietary osmolality and provide essential fatty acids. Whilst this does raise fat excretion, it does not usually increase stomal output nor make it more offensive [61, 199, 202]. However, a high fat diet may reduce absorption of divalent cations such as calcium, magnesium, zinc and copper [199] and malabsorption increases the risk of essential fatty acid [70] and fat-soluble vitamin deficiencies [71, 74] so these should also be monitored and supplemented as required [4, 27].

MCTs (Table 5)

In contrast to patients with a retained colon, the 50% substitution of LCT with MCT in jejunostomy patients [79] increased fat absorption from 37 to 46% ($p = 0.05$), but did not improve overall energy absorption because MCT significantly decreased absorption of protein from 63 to 51% ($p < 0.05$); carbohydrate from 71 to 63% ($p < 0.05$), LCT from 35 to 27% ($p < 0.05$) and increased stoma volumes from 2177 to 2729 g/day ($p = 0.07$) and is therefore not recommended.

Fluid and Electrolyte Management

Jejunostomy patients lose large volumes of fluid from their stoma, which increase after eating and drinking due to loss of digestive secretions secondary gastric hypersecretion, rapid gastric emptying and accelerated small bowel transit. Each 1 L of jejunostomy fluid contains approximately 100 mmol/L of sodium [9] so sodium losses rise with stoma volume, increasing the risk of dehydration and electrolyte disturbances. Patients with less than 100 cm jejunum to a stoma usually have intestinal fluid and sodium losses that exceed oral intake, leading to a constant negative balance that requires correction with long term parenteral replacement, whilst those with more than 100 cm residual jejunum may have lower intestinal losses but still lose considerable amounts of fluid and sodium, which require replacement [9]. Dietary management with a high salt diet, restriction of oral hypotonic fluids and substitution of an oral rehydration solution to decrease stoma losses in conjunction with anti-secretory medication to decrease gastric secretions and anti-motility medications to slow transit and improve absorption may secure intestinal autonomy in those with intestinal insufficiency or reduce parenteral dependency in those with intestinal failure.

High Salt Diet

Patients with intestinal outputs of <1200 mL/day can usually maintain fluid and sodium balance by taking high salt foods, adding salt in cooking or to food after serving, to utilise the coupled absorption of sodium with glucose and amino acids in the jejunum [1, 203].

Restrict Oral Hypotonic Fluids

The jejunal mucosa is very permeable to water and sodium fluxes, which maintain intra-luminal contents iso-osmolar with plasma at approximately 300 mOsm/L with a sodium concentration of about 100 mmol/L [9]. Consumption of hyperosmolar fluids such as fruit juices, fizzy or energy drinks, alcoholic beverages [204] and some ONS supplements increase intraluminal osmolality, leading to movement of water from plasma into the intestinal lumen to restore iso-osmolality [4, 205]. Hypotonic fluids with a sodium concentration of <90 mmol/L like water, tea, coffee, squash, milk, juice, fizzy and alcoholic beverages dilute intraluminal sodium concentration leading to secretion of sodium to maintain luminal concentration at 100 mmol/L [206–208]. The loss of this sodium rich fluid in jejunostomy effluent results in dehydration and sodium depletion [9]. Patients often describe an 'insatiable thirst' and their natural response is to drink more fluid [4], which may mistakenly be reinforced by health professionals, but this literally washes sodium out of the body creating a vicious cycle of chronic dehydration and excessive beverage intake [207–211].

Absorption of sodium from the jejunum can only take place against a small concentration gradient, when the luminal concentration is 90–120 mmol/L [206, 210, 212] and depends on water movement and the presence of glucose and amino acids to promote absorption by solvent drag [203]. A study of fluid and electrolyte absorption in seven patients with <150 cm small bowel to a stoma found that ingestion of 500 mL of water or tea resulted in negative sodium and fluid balance whereas 500 mL of an oral rehydration solution containing 90 mmol/L of sodium led to positive sodium and fluid balance [208]. Patients with marginally high stoma losses in the range of 1200–2000 mL can maintain hydration by restricting oral hypotonic fluids to 1 L to decrease net secretion with substitution of 1 L of an oral rehydration solution containing 90–120 mmol/L sodium to meet fluid requirements and promote jejunal absorption [1, 208, 211]. They should avoid hyperosmolar fluids [213] and adherence with hypotonic fluid restriction may be encouraged by use of smaller cups or glasses, sucking sweets, ice cubes or lollies, self-monitoring of intake and strategies that distract from thirst.

If patients are struggling with severe thirst and marked sodium/water depletion, it may be difficult to replace previous losses with an oral regimen, but equilibrium can be re-established by placing them 'nil by mouth' whilst giving intravenous normal saline for 48 h [1]. This also helps to demonstrate that output is being driven by oral intake. Intravenous saline can then be gradually reduced as oral food and fluids are reintroduced.

Drink an Oral Rehydration Solution

Oral rehydration solutions have been formulated to provide optimal amounts of sodium in combination with glucose to facilitate absorption [1, 4]. A modification of the World Health Organisation's original cholera solution, which contains 90 mmol/L sodium, is made from 20 g glucose, 3.5 g sodium chloride and 2.5 g sodium bicarbonate made up to 1 L with water [214]. Although taste perception changes in patients who are salt and water deplete, some still find this

solution too salty but acceptance can be improved by chilling, sipping through a straw or flavouring with the addition of a small amount of squash or cordial as part of the fluid used to make up the solution. Patients should be discouraged from adding ice or flavouring to each glass as this dilutes the sodium concentration, making it less effective [215, 216]. Alternate solutions include replacing sodium bicarbonate with sodium citrate to increase palatability [211] or giving Dioralyte®, made at double the normal strength (10 sachets made up to 1 L), which contains 120 mmol/L sodium and 40 mmol/L potassium and therefore requires monitoring to prevent hyperkalaemia [217]. Patients should sip 1 L in small quantities throughout the day, perhaps with medications in order to preserve their hypotonic fluid allowance for more pleasurable drinking. It should be noted that many sports drinks have suboptimal sodium-glucose composition so do not provide an effective alternative to oral rehydration solutions [215, 218]. Alternatively, sodium chloride capsules (500 mg) are effective when taken in large amounts (7 g/day) but can cause patients to feel sick and even vomit [211].

It is vital to give individualised and consistent advice to aid patient understanding, motivation and compliance. Chronic dehydration may result in renal impairment so patients should be taught to monitor their urine colour in conjunction with signs and symptoms of dehydration and given management strategies together with health professional contact details for advice. It is equally important to educate health professionals about oral fluid and electrolyte management so that they can give consistent advice and provide appropriate rapid intravenous fluid and electrolyte replacement when required.

Timing of Antimotility Medications

Loperamide and codeine phosphate reduce intestinal motility and thus decrease water and sodium output by approximately 20–30% [1]. Since the intestinal output rises after meals, it is important that these medications are taken 30–60 min before food and at bedtime. If they emerge unchanged in the stoma effluent, then capsules can be opened or tablets crushed and mixed with water, yogurt or put on food [1].

Separation of Food and Fluids

Loss of the ileal and colonic braking mechanisms results in rapid gastric emptying of liquid [20] so taking fluids separately from food may improve absorption. However, a balance study in eight short bowel patients (five jejunostomy; three jejunum-colon) who received isocaloric diets with a constant fluid content and were randomized and crossed over between taking fluid with meals or restricting fluid intake from 1 h before to 1 h after meals, each over 5 days, found no difference in energy, divalent cation, fluid or electrolyte absorption [58]. Whilst some patients anecdotally report a benefit, the advice to restrict fluid intake with meals is not recommended as a general rule [4].

Fibre

Reducing fibre intake may slow transit to allow more time for absorption, but a randomized crossover study in four jejunostomy patients receiving isocaloric diets with variable amounts of fat and fibre, each over 2–3 days found no significant improvement in absorption and a liberal approach to fibre intake was recommended [202]. However, rapid transit does lead to the appearance of undigested foods in stoma effluent and patients anecdotally report a reduction in intestinal output with reduced fibre [217] from bread, pasta, crackers, biscuits or cakes made with white flour, white rice, refined breakfast cereals, small portions of well cooked, mashed or stewed fruit and vegetables with skins, seeds, pips and stalks removed, small portions of pulses if vegetarian and avoidance of nuts and dried fruits. A low fibre diet is recommended to prevent obstructive symptoms in patients with strictures or adhesions [217].

Oral Nutritional Support Supplements

Protein: Polymeric, Peptide or Elemental?

Patients who find it difficult to maintain adequate nutritional intake from diet may increase their energy and protein intake from orak nutritional support (ONS) taken in between meals (Table 6). It was postulated that partially digested proteins in the form of peptides (semi-elemental) or amino acids (elemental) may be more completely absorbed across a reduced absorptive surface than whole protein (polymeric) diets.

In a randomised controlled study, McIntyre et al. 1986 [202] compared absorption of energy, nitrogen, fat and electrolytes from equal volumes of isocaloric, isonitrogenous semi-elemental versus polymeric liquid diet in seven patients with <150 cm jejunum to a jejunostomy. Each diet was taken over 12–14 h, either as a sip feed (five patients) or by slow continuous nasogastric infusion (two patients). Two patients were unable to tolerate full quantities of either diet and their measurements were conducted using 50% of the recommended intake. There were no significant differences in nitrogen, fat or energy absorption and neither diet significantly reduced stoma effluent weight nor consistently affected sodium, potassium, magnesium or calcium losses, suggesting that semi-elemental provides no nutritional advantage over polymeric diet.

Cosnes et al. 1992 [219] investigated the effect of protein hydrolysis on absorption in six patients with a jejunostomy (90–150 cm jejunum), who had been stable on polymeric EN for at least 2 weeks, prior to being randomized and crossed

Table 6 Studies of the effect of ONS/enteral formula protein composition on nutrient absorption in patients with a short bowel

Reference	Subjects	Mean residual small bowel length (cm), (range)	Method	Diet composition	Effect on energy absorption	Effect on nitrogen absorption	Effect on water and sodium absorption	Effect on divalent cation absorption
Jejunostomy								
McIntyre et al. 1986 [202]	7 Jejunostomy (2HPN 1HPF 2NG 2oral)	101 (60–150)	RCT, crossover, each patient acted as own control	Two liquid diets based on body weight and standardized to contain equal amounts of nitrogen, fluid and sodium (constant 100 mmol/d) in each test period • Polymeric (6 g Nitrogen, 1060 kcal, 37 g fat (LCT) and 146 g CHO/L) • Semi-elemental (6.4 g Nitrogen, 1000 kcal, 10 g fat (LCT: MCT 50:50%) and 183 g CHO/L) Each over 12–14 h by sip feed (5) or NG (2) Due to poor tolerance, tests completed on consumption of half quantities in two patients	None	None	None	None for Ca and Mg
Cosnes et al. 1992 [219]	6 Jejunostomy (6 NG)	110 (90–150)	RCT, crossover double blind	Three liquid diets (3325 kcal, 146 g protein, 130 g fat, 395–470 g CHO, 2500 mL and 300 mmol sodium per day) with varying protein hydrolysis • Polymeric (osmolality 580 mOsmol/L) • Mixed polymeric: semi-elemental 50:50% (osmolality 610 mOsmol/L) • Semi-elemental (osmolality 667 mOsmol/L) Each over 22 h/d by NG for 3 days (last 2 days test period). Nil orally except approximately 1 L water. 5 patients received 1–2 L ileocolonic infusion of saline to maintain Na balance	None % Energy absorption Polymeric: semi-elemental 56.8: 57% (NS)	↑ Nitrogen absorption from semi-elemental compared with polymeric 14.3:10.9 g/day P = 0.012	None	None for Ca and Mg

over between exclusive polymeric, semi-elemental or a 50:50 mixture of polymeric and semi-elemental. Nitrogen was significantly better absorbed from peptide (14.3 g/day) than whole protein diet (10.9 g/day), (p = 0.012), but there were no differences in absorption of fat or calories, stool weight or faecal excretions of sodium, potassium, calcium and magnesium. The osmolality of the peptide diet was high (667 mOsm/L) but stool output was increased in only one patient. It was concluded that a semi-elemental diet may be beneficial when nitrogen requirements are high.

Since polymeric ONS are more palatable, lower in osmolality and have a higher energy density than elemental formulae, they are less likely to increase stoma losses and therefore recommended in jejunostomy patients who require nutrition support [4].

Fibre

Rodrigues et al. 1989 [220] investigated the effect of fibre containing ONS on 6-h intestinal transit, energy, water and sodium absorption in six patients with 30–120 cm jejunum (four jejunostomy, one jejunum-colon to colostomy, one jejunal-rectal anastomosis) who fasted overnight and were randomized to drink either 300 mL polymeric diet or 300 mL polymeric diet containing 6 g soy polysaccharide (40% soluble fibre). Soy polysaccharide decreased percentage energy absorption from 20 to 6% in the four patients measured. It delayed transit time in three of four patients from 66 to 166 min (postulated to be due to a delay in gastric emptying, although this was not measured), but increased 6-h wet weight (895 to 917 g) and sodium output (89 to 136 mmol) in four of five patients. Thus, fibre enriched ONS are not recommended [4].

Osmolality

Although ONS provide a ready source of energy, protein and micronutrients, they are hypotonic and many are hyperosmolar, which will increase sodium and fluid movement into the bowel and increase stoma losses. Osmolality is a measure of millimoles of solutes per kg of solvent [221]. ONS osmolality is influenced by particle size and increased by electrolyte, amino acid/peptide or sugar but not fat content. Rud et al. 2019 [222] investigated the effect of ONS osmolality on stoma output, urine production and natriuresis in eight patients with an ileostomy (150–350 cm residual small bowel) who ate their habitual diet and were advised to maintain a constant fluid intake. They were randomised and crossed over to replace 800 mL of their daily fluid intake with 200 mL four times per day of either an iso-osmolar (279 mOsm/kg) or hyperosmolar (681 mOsm/kg) oral supplement, each over 48 h in two study periods. There were no significant changes in stoma output, despite increased fluid intake, but in comparison with the hyperosmolar supplement, the iso-osmolar supplement induced a significant increase in urine volume (470 mL/day, $p = 0.02$) and natriuresis (36 mmol/day, $p = 0.02$), suggesting improved intestinal water and sodium absorption. Whilst iso-osmolar ONS may benefit hydration, their lower energy density will compromise energy intake. In practice, patients may be offered a 1.5 kcal/mL polymeric, fibre free supplement to maximise nutritional intake within a lower volume, but if the higher osmolality increases intestinal losses, then a 1 kcal/mL supplement with a lower osmolality (approximately 300 mOsm/kg) or a lower volume, modular energy/protein supplement may be offered. ONS should be sipped slowly in between meals and their low sodium content necessitates their inclusion within any hypotonic fluid restriction.

Role of Education and Individualised Dietary Advice

Patient education and motivation are important factors in determining the success of the PN weaning [223]. A lack of understanding may lead to sub-optimal management with potential clinical consequences [224] and a study in short bowel patients on HPN, who had not received dietary education, found dietary patterns that were likely to worsen diarrhoea, cause malnutrition (or prevent repletion) and increase parenteral fluid and nutrient requirements [60]. It is recommended that short bowel patients receive education from an experienced multidisciplinary team, using a combination of written information and verbal education to improve understanding of the physiological changes associated with short bowel, the rationale for dietary and pharmacological therapies [223] and intensive dietary guidance on suitable types and quantities of food/beverages, tailored to individual gastrointestinal anatomy, lifestyle, requirements and preferences to aid compliance, which is adjusted in response to changing needs [225].

The effectiveness of personalised nutrition advice supported by a booklet (containing information about the condition, eating/drinking advice, medication use and long-term monitoring), on knowledge and clinical outcomes was evaluated over 3–6 months in 48 patients with intestinal failure [224]. Patient knowledge improved significantly after dietetic intervention with verbal and written advice ($p < 0.001$). There was an increase in oral energy ($p = 0.04$) and fat ($p = 0.003$) intake with an improvement in BMI ($p = 0.02$). Patients on HPN showed a reduction in parenteral energy ($p = 0.02$), nitrogen ($p = 0.003$), volume ($p = 0.02$) and frequency of infusions ($p = 0.003$). This study demonstrated that personalised nutritional advice in conjunction with an information booklet, tailored to individual requirements, significantly improved knowledge and clinical outcomes, highlighting the positive effect of on-going education in stable intestinal failure patients.

Micronutrients

Parenteral multivitamin and multi-trace element preparations are formulated to meet the requirements of most patients receiving PN [45, 226], but abnormal serum micronutrients concentrations continue to be reported [227], highlighting the potential variation in individual requirements with oral intake, nutritional status, underlying illness, sepsis, inflammation, oxidative stress, absorptive capacity and abnormal losses [45]. Patients with short bowel have an increased risk of developing micronutrient deficiencies due to their underlying condition, fat malabsorption, high stoma/fistula or stool losses or inadequate intake. Optimising diet, fluid intake and medications may permit adequate macronutrient absorption to allow PN weaning, but it cannot be assumed that micronutrient intake or intestinal absorption will be sufficient to maintain adequate body stores or function [228].

A study in short bowel patients on HPN found low micronutrient consumption in association with avoidance of foods that may increase stool losses (dairy products, vegetables) and reduced dietary variety [60].

Short bowel patients receiving intermittent PN with a prescribed oral multivitamin and mineral supplement were deficient in vitamin D [74] and had serum concentrations below the reference range for vitamins E [74, 229], A, C [229] and copper [230], although interpretation is difficult as clinical deficiency symptoms were not reported.

A study of 44 patients with intestinal insufficiency and varying degrees of fat malabsorption not requiring HPN (160–250 cm residual small bowel; 17 no colon), found reduced plasma retinol, α- and γ-tocopherol concentrations in 7%, 61% and 32% of patients, which were rarely associated with clinical symptoms, so it was difficult to interpret their significance, but the authors concluded that supplementation may be required [71].

Vitamin D status and bone mineral density (BMD) were measured in 60 short bowel patients (residual small bowel length 89.6 cm) after weaning off PN (80% oral diet, 20% enteral nutrition) [231]. All patients had suboptimal vitamin D status (5% vitamin D insufficiency and 95% vitamin D deficiency), which was significantly correlated with residual small bowel length (B, 0.072, $p = 0.001$) and duration of short bowel (B, −0.066, $p = 0.020$). Only 2 patients had a normal BMD with osteopenia and osteoporosis present in 68.3% and 28.3% respectively. Despite routine oral vitamin D supplementation (1200 IU/day), 86.7% of patients did not achieve satisfactory status, emphasizing the importance of regular vitamin D monitoring, annual BMD measurements [4], advice on diet and sunlight exposure and consideration of alternative methods of supplementation such as intramuscular administration of vitamin D after PN weaning.

A 9-day balance study in five jejunostomy patients (35–125 cm jejunum), stable on HPN found that a high fat (60% kcal), low carbohydrate (25% kcal) diet increased stomal losses of calcium, magnesium, zinc and copper, which in most cases were converted to net absorption by a low fat (30% kcal), high carbohydrate (55% kcal) highlighting the importance of monitoring and supplementation in patients with fat malabsorption [199].

A 5-day balance study in seven short bowel patients (mean 64 (40–110) cm healthy small bowel in continuity with colon) who had been stable on diet mean 2.7 years found normal serum concentrations and positive balance for iron, zinc and copper suggesting that satisfactory status can be achieved from oral diet [232].

In short bowel, guidelines for micronutrient prescription and monitoring are based on expert opinion [4, 226], necessitating the development of local protocols until more robust evidence becomes available. Micronutrient deficiencies may be prevented by regular monitoring during PN weaning and in those stable on diet, with or without intravenous fluid/electrolyte infusions. Key aspects of management include (1) the promotion of a balanced diet, guided by individual tolerance, which may require periodic adjustment as the bowel adapts (2) optimisation of absorption through dietary, fluid and pharmaceutical management (3) the provision of an oral general multivitamin and mineral supplement during PN weaning, which may need to be given in doses above those recommended for healthy individuals to compensate for malabsorption [223] (4) if a deficiency arises, then the route of delivery, dose and duration of supplementation should be guided by the patient's bowel anatomy and individual characteristics [4] in conjunction with manufacturer's guidance.

Conclusion

Nutritional management is a dynamic process that involves overlap or transition between PN, EN and diet, in response to changes in the patient's condition and intestinal adaptation. The consequences of dietary manipulations, not only on nutrient, electrolyte and fluid absorption, but also on overall quality of life and patient autonomy should be taken in to consideration. Dietary manipulations may affect diet palatability, satiety, abdominal discomfort or bloating and passing of wind, faecal consistency and incontinence. Some patients cope with the hyperphagia, large stool volumes, fatigue and chronic dehydration in order to avoid a life dominated by having a central line and the need for parenteral supplements.

Others see parenteral supplements as a place of refuge escaping the demands of constant hyperphagia, large stool volumes and abdominal discomfort.

Pro-adaptive Hormones in the Rehabilitation of Adult Patients with a Short Bowel

Palle Bekker Jeppesen

Key Points

1. Pro-adaptive hormone treatment includes growth factors which aim is to promote and often exceed the normal structural adaptive process after a bowel resection.
2. Pro-adaptive hormonal treatment aims to reduce the symptoms (less stomal output/diarrhoea) and help reduce or stop the amount of parenteral support required (i.e. to reduce the severity of the intestinal failure). Goals may include a reduction in stomal output of more than 1.5 L/24 h, stopping or having more than 2 night off/week of parenteral support and having an improved quality of life.
3. Growth factors may be considered in patients with a short bowel and dependent upon parenteral support and/or:
   (a) Have had a functioning colon in continuity for at least a year to allow intestinal adaptation to occur. If no functioning colon is in circuit then adaptation will not occur and treatment can be considered sooner (at about 6 months) after the surgery that resulted in the jejunostomy.
   (b) Have no defunctioned small or large bowel that can be brought into continuity. Patients who are candidates for surgical reconstruction should have this surgery before growth factor therapy is considered.
   (c) Patients who have been stable on parenteral support for 1 year, with the volume, nutrient and electrolyte content of the parenteral support and oral intake being optimised prior to starting.
   (d) A patient who, with therapy, may be able to stop parenteral support.
   (e) Patients with an unmanageable high output (e.g. >2 L/24 h) and whose quality of life if poor. These are patients who can be weaned off or have days off PS.
   (f) Patients who with treatment may be able to have nights off parenteral support.
4. Growth factors have the disadvantages of both being expensive (though prices may reduce considerably in the future) and there is the fear that they may promote neoplasia (or increase the growth rate if neoplasia is already present).
5. Before growth factor treatment is given a baseline CT thorax, abdomen and pelvis is performed and in patients with a residual colon, a colonoscopy should be performed to detect and remove colorectal polyps.

Introduction

In normal subjects, a wide range of complex neuro-endocrine regulatory systems modulate the highly coordinated processes of appetite-regulation, food intake, digestion and absorption (i.e. assimilation) that ensure sufficient nutrient in- and uptake to meet the metabolic needs and ensure the metabolic homeostasis of life, thereby preserving body composition, function and the overall health.

Thus, a plethora of hormones, mediators and nerve transmissions are involved in securing the optimal intestinal function at all times. In fact, the intact and healthy gastrointestinal tract has a considerable reserve capacity for nutrient assimilation [1]. However, in patients with inadequate oral intake, intestinal diseases or increased metabolic needs, the nutritional homeostasis may be jeopardized, and malnutrition, dehydration or other deficiencies may develop [2]. Short Bowel Syndrome (SBS) patients with intestinal insufficiency (INS) have preserved oral or enteral autonomy and can compensate for maldigestion or malabsorption (i.e. malassimila-

J. M.D. Nightingale (ed.), *Intestinal Failure*, https://doi.org/10.1007/978-3-031-22265-8_41

tion) by hyperphagia, by reduced physical activity and the body may adapt temporarily to this situation of "semi-starvation", even without suffering from organ impairment, by metabolic adaptation [3]. Patients with SBS and intestinal failure (IF) on the other hand need parenteral support (PS) to ensure the adequate provision of nutrients, fluid and/or electrolytes, to prevent permanent organ damage and ensure proper organ functions, avoid diseases and maintain life [4]. Based on the severity of the degree of malassimilation and the ability to compensate for this, SBS patients can be found within a spectrum ranging from mild, moderate and severe INS across a borderline to mild, moderate and severe IF [5].

Although the malassimilation seen in short bowel syndrome patients following intestinal resection is frequently mainly explained by the reduction in the remnant absorptive mucosal surface-area, it may also relate to detrimental pathophysiological changes in GI secretions (e.g. gastric and pancreatico-biliary), transit, blood-flow, mucosal function and even complex inter-organ communications (e.g. gut-brain and gut-liver axes). Depending on remnant bowel anatomy, the alterations in the meal-stimulated neuro-endocrine feedback mechanisms, caused by the associated under- or over-exposure of endocrine sensor-cells distributed throughout the gastrointestinal (GI) tract, may lead to a dysregulation and either impairment or a compensatory improvement of GI functions.

In general, given a more favourable remnant anatomy with more proximal bowel resection and preservation of the ileum and right-sided colon, positive neuro-endocrine feedback mechanisms may contribute to a "spontaneous intestinal adaptation", which is the process that gradually leads towards a restoration of the intestinal absorption to that pertaining before the intestinal resection. In contrast, distal ileal and right-sided colonic resections tend to favour a condition of GI hypersecretion, rapid transit, and a more severe malabsorption with less spontaneous adaptation [6].

Over the last decades, an increased awareness of the relationship between the heterogeneity and pathophysiological characteristics of SBS patients and the detrimental or beneficial neuro-endocrine changes following intestinal resection has emerged. Based on this knowledge and by the prospect of having potent analogues (agonist or even antagonists) of the relevant endogenously secreted GI hormones for clinical use, a paradigm shift from the empirically based general and symptomatic SBS treatments, consisting of off-label use of anti-diarrheal and anti-secretory agents, to an evidence-based, personalized, targeted and "pathophysiological-phenotype-driven" treatment has been recommended [7]. It is to be anticipated that a further understanding of the processes of importance for best possible assimilation will enhance our ability to intervene, when normal GI physiology is disturbed by intestinal resection. Thus, although the complexity of the normal gastrointestinal digestion and absorption far surpasses the complexity symphony performed by an orchestra, an increased understanding of the roles of the individual musicians and especially of the conductor and the main soloists in the performance will be of significant importance.

This chapter reviews the findings of from clinical trials that have aimed to identify, mimic or even surpass the key hormonal players in the spontaneous intestinal adaptation. Currently, these studies have mainly included the use of somatostatin, growth hormone, glucagon-like peptides or epidermal growth factor either as native hormones or analogues. However, since only the glucagon-like peptide 2 analog, teduglutide, has yet been approved as the first evidence-based drug for the long-term treatment of SBS, the effects of this peptide is the main focus of this chapter. Since the use of these pro-adaptive hormones is relatively new, and since more healthcare professionals outside the established centres of experience are likely to be using these agents in the future, some introductory, general suggestions to their use may be relevant.

In this chapter, the basis for the introduction of pro-adaptive factors in the clinical rehabilitation of SBS patients is summarised and an update of current knowledge and suggestions for future efforts is provided. In addition it recommends when a peptide growth factor may be considered in a patient with short bowel associated intestinal failure (SB-IF). To outline the pre-treatment process and the monitoring required, including when treatment should be stopped.

Theoretical and Practical Consideration Prior to Initiating Treatments

Aim of Treatment

The overall aim of any treatment in patients with SBS is to reduce potential SBS- and IF-symptoms and -complications thereby providing the best possible overall health-related quality of life and longevity in these patients.

Due to the large heterogeneity in the SBS population, and since each SBS patient tend to define their individual disease according to their complaints fears and miseries, a focused interview, objective and paraclinical examinations (e.g. haematology and biochemistry) should seek to determine the cause of the most troublesome inconveniences and potentially, in an individualised approach, address the best means for their successful amelioration or resolution.

In general, treatments should maximize intestinal absorptive capacity, at the same time alleviating the symptoms and inconveniences of malabsorption and prevent, minimize or eliminate the need for compensatory hyperphagia or the need for home PS (HPS). Total weaning from PS, with removal of the tunnelled, central line, is the ultimate goal of treatment of

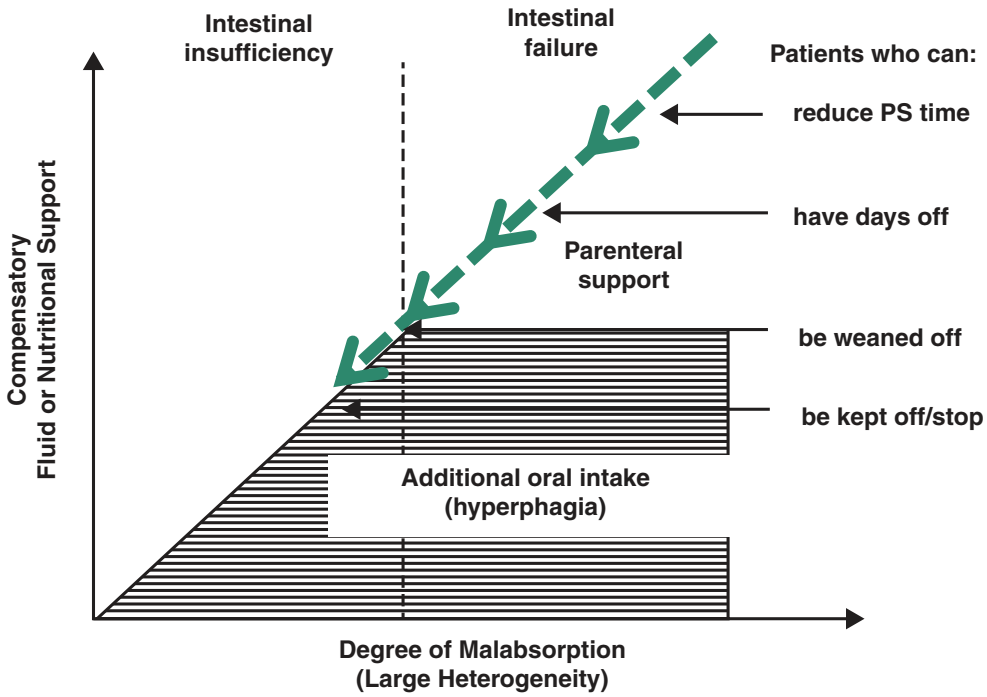

Fig. 1 The benefits/progress of intestinal rehabilitation

SBS-IF patients, but even providing days off and diminishing infusion times may be of significant value to the patients. Evaluation of health-economic benefits should be considered.

Even SBS patients with severe intestinal insufficiency, who struggle on a daily basis to keep nutritional, fluid and electrolyte balances, may benefit by pro-adaptive treatments by gaining a better quality of life and preventing re-admissions due to dehydration and other metabolic disturbances caused by accommodation-induced organ impairments.

The physical symptoms that SBS patients experience may also relate to their gastrointestinal condition leading to SBS or SBS in itself (e.g. diarrhoea, incontinence or stoma problems, abdominal pain), imbalances in body needs leading to organ or system impairments (e.g. malnutrition, dehydration and electrolyte disturbances, insatiable thirst, reduced physical energy level and/or sex drive) or the HPS infusions themselves (e.g. nausea, muscle cramping, headache). The administration of HPS potentially requires daily, timely and skilful adherence, is intrusive and disturbs the sleep pattern of the patients. Infusions are time consuming and restrict the leisure and social activities of the patients. SBS-IF patients are at risk of catheter complications such as catheter related bloodstream infections or even sepsis and thromboembolic events. Catheter dysfunction or accidental tearing out of the catheter may necessitate hospital re-admissions. Chronic organ impairments (e.g. liver and renal failure) may be caused by SBS in itself of by parenteral administrations. The factual or fear of all of the consequences and complications of SBS and PS, as well as the associated signs, symptoms and inconveniences, may eventually lead to significant psychological burden, anxiety and depression [8]. Figure 1 shows the potential benefits and progress of intestinal rehabilitation.

Patient Selection

Successful management of SBS patients is often based on a close dialog informing and teaching the patients about their pathologic conditions, the consequences and the potential options and risks of treatments (benefit-safety). Evaluations and discussions around compliance, adherence and motivation to support therapies may be helpful. It may also be helpful to discuss anticipated outcomes of interventions in order to align expectations to patient needs. Pre-set success criteria may be relevant or justified by high therapy costs.

In order to evaluate effects of new treatments, it is essential that the patients are in a stable condition and already have been optimized according the best available, conventional, individualized care. In all SBS-IF patients, absence in fluctuations in their need for parenteral support, their urine production and body weight will determine their stability, which is required before the initiation of any new treatment interventions.

Although often used in an off-label indication, conventional treatments are likely to be cheaper, and currently their safety profile is often better documented.

In SBS patients with a part of their intestine out of continuity, an attempt for a final restorative surgery should have been performed or rejected by an experienced surgeon in the field.

In SBS patients with a functional colon in continuity, time should be allowed for spontaneous intestinal adaptation to occur, unless an accelerated adaptation is aimed for. Retrospective cohort studies suggest that as much as 75% of SBS-IF patients with a jejuno-ileal anastomosis (Group 3 anatomy) have adapted and are weaned from PS at 5 years following their final surgery [9].

In patients with a jejuno-colonic anastomosis (Group 2 anatomy) the continued, progressive adaptation and PS weaning, at around 50% at 5 years, seems minimal from 2 to 3 years from the final surgery.

Thus, aggressive attempts of weaning from PS seem to be indicated in these two anatomy group of patients. In patients with a jejuno- or ileostomy (Group 1 anatomy) adaptation and total PS weaning is seen in less than 20% of patients at 1 year, and no further adaptation seems to be evident on a group basis from this point onwards. Therefore, an earlier introduction of pro-adaptive agents is reasonable in these patients.

In centres, where metabolic balance studies can be made, a measurement of intestinal energy absorption may be helpful in individual SBS-IF patients, especially in patients with Group 2 and Group 3 anatomy, before and a period of time after the initiation of a pro-adaptive treatment, since it is the provision of the PS of protein-energy and not fluid and electrolytes that may be most critical in these patients.

In SBS patients without a colon in continuity, i.e. patients with a jejuno- or ileostomy (Group 1 anatomy), objective effects of interventions may be demonstrated early following treatment initiation in simple fluid balance studies or by having the patients measuring their urine production and body weight at home.

In general, patients with suspected or active malignancies should not be treated with pro-adaptive agents. This also pertains to patients with a history of malignancies in the GI tract, including the hepatobiliary system and pancreas, within the last 5 years. A colonoscopy with removal of polyps should be performed at the time of starting treatment. Once yearly follow-up colonoscopies (or alternate imaging) are recommended during the first 2 years of treatment. Subsequent colonoscopies are recommended at a minimum of 5 year intervals. An individual assessment, whether increased frequency of surveillance is necessary, should be performed based on the patient characteristics (e.g., age and underlying disease). If a polyp is found, adherence to current polyp follow-up guidelines is recommended. In case of malignancy, the new therapy must be discontinued. In children and adolescents aged 12 years or less, faecal occult blood testing should be performed prior to initiation of pro-adaptive treatments and annually thereafter. Positive tests should lead to a colonoscopy. Colonoscopy is recommended for all children and adolescents after 1 year of treatment, and at least every 5 years thereafter of continuous treatment (https://www.ema.europa.eu/documents/product-information/revestive-epar-product-information_en.pdf).

Cholecystitis, cholangitis and cholelithiasis as well as chronic and acute pancreatitis, pancreatic duct stenosis, pancreas infections and increased blood amylase and lipase levels could occur following treatments with pro-adaptive hormones. In the case of these adverse events, the benefit and need for continued treatment should be reassessed. Additional laboratory and appropriate imaging may be indicated.

Cases of intestinal obstruction have been reported in clinical studies using pro-adaptive hormones. Treatment of patients with a history of chronic abdominal pain and the detection of a narrow stoma should be avoided. In all cases, treatments should be paused until resolution of symptoms and in case of reoccurrence, the indication for treatment and the dose should be reassessed.

It will be important to consider the overall prior medical history of the SBS-IF patient, since the initiation of pro-adaptive treatments in the initial treatment phase may disturb the nutritional and fluid/electrolyte balance. This disturbance may affect any co-morbidity that the patient may suffer from. For instance, patients with a latent cardiac impairment may suffer from overt cardiac decompensation.

Due to increased intestinal absorption, patients receiving oral medication with a narrow therapeutic index may suffer from the consequences of elevated drug levels (e.g. analgesics, anti-coagulants, thyroid or anti-thyroid agents). The prescribing or treating healthcare professionals should be aware of this risk and manage their patients accordingly.

Benefit-Risk Assessment

In the ideal setting, it should always be evaluated, if a drug is so effective that its benefit outweigh its potential risk to patients.

Safety

Short Bowel Syndrome is considered a rare, orphan disease. The care and treatment of SBS patients is often complicated by a large inter-patient and effect-heterogeneity. Thus, in the opinion of the author, the implementation of new pharmacological treatments in SBS patients should ideally, at least initially, be limited to skilled, high volume intestinal failure centres, where sufficient resources are allocated to a dedicated inter- and multi-disciplinary specialist care and surveillance. Thorough effect monitoring and a close post-marketing surveillance are of great importance in order to validate the post-marketing, long-term benefit-risk profile of the specific treatment.

Most of the pro-adaptive agents have multiple physiological effects and are likely to influence both GI mucosal growth and secretions. Therefore, long-term treatments could induce

pathophysiological disturbances in various organ functions and even neoplasia. Since the number of patients included is low and treatment duration is short in the phase 3 programs, multi-national, multi-centre registry studies will be needed to ensure long-term drug safety, when introducing new treatments.

Effect

Although effects or benefit of pro-adaptive treatment may have been demonstrated in groups of SBS patients in randomised, placebo-controlled, phase 3 trials, a large inter-patient and effect-heterogeneity often exist. Therefore, establishment of a clinical meaningful and objectively measurable effect in the individual SBS patient following the initiation of the treatment is the goal.

In the ideal world, the absolute intestinal absorption of fluid, electrolytes and macronutrients in the individual patient may be determined at intervals before and after treatment initiation. This may be done by performing 48–72-h metabolic balance studies, where duplicate portions of oral intakes and faecal and urinary excretions are determined [3, 10]. The use of subjective tools or questionnaires is difficult to implement and objectively evaluate in this orphan condition.

In the real world setting, only few centres have the organisation, logistics and skills to objectivize effects of treatments, but along with conventional standard of care, simple fluid balance measurements with a tracking of changes in urine production, body weight and standard biochemistry should be the minimum for adjusting PS. Subjectively perceived benefits in relation to the treatment with pro-adaptive agents may vary considerably in individual patients, even when patients are allocated according to the various classifications suggested by the ESPEN interest group [4]. Individual effects, that may seem subtle when using conventional measuring tools, may dramatically improve the quality of life in some patients, whereas others, who do not encounter this problem, may find that the treatment has other preferred effects.

Cost Considerations

Since the cost of developing new drugs in orphan conditions is high and the potential patient group is relatively small, the prices of new treatments are much higher than conventional pharmacological treatments. It is also likely, that most patients will require these treatments for the remainder of their life. Therefore, negotiations between health authorities and companies are needed to ensure the right balance, so the barriers to prevent developments that are ethically and scientifically motivated do not become too high, the economic incentives to sponsor this development is fair, and that introduction of these agents do not impair and deprive finances from a well-functioning healthcare system.

The Physiological Basis for Treatment with Pro-adaptive Agents

When discussing the use of pro-adaptive agents in the treatment of SBS patients it is important to emphasize the concept of the intestine as an endocrine organ. Thus, although the enteroendocrine cells only constitutes 1% of the intestinal mucosal cells, a plethora of hormones released in relation to eating ensures the physiological actions required for the optimal digestive process. The gastro-entero-pancreatico-hepatic system is now regarded as the largest endocrine organ in the body [11].

In general, patients with intestinal resection and a jejuno- or ileostomy are characterised by elevated post-prandial, pro-secretory and pro-motility hormones such as gastrin, cholecystokinin, secretin and motilin [12]. This favours rapid propulsion and hypersecretion of gastric acid, bile and pancreatic juice as well as bicarbonate secretion, which in turn may contribute to large stomal losses. A lack of endogenous secretion of more distally secreted pro-adaptive feedback hormones, such as glucagon like peptide (GLP)-1, GLP-2, peptide YY (PYY), oxyntomodulin, and fibroblast growth factor (FGF) 19, may aggravate the accelerated gastric emptying and various hypersecretions, rapid intestinal transit and impaired blood and lymphatic flow as well as mucosal function [13]. Impaired post-prandial secretion of more proximally produced hormones such as glucose-dependent insulinotrophic peptide (GIP) may also contribute to the pathophysiological characteristic of patients with group 1 anatomy.

Patients with group 2 and group 3 anatomies differ by the presence of a part of the terminal ileum and the right-sided colon. Whereas the colon in itself possesses the ability to compensate for small bowel malabsorption by increasing its ability to absorb fluid (up to 5 L/day), sodium (up to 800 mmol/day) as well as energy derived from the fermentation of carbohydrates and protein (up to 4 MJ/day) [14], the terminal ileum and the right-sided colon may also be of significant importance in the hormonal regulation of more proximal GI functions [15]. Thus, the constant hypersecretion of the suggested pro-adaptive distal feedback hormones demonstrated in these patients may also account for the impressive spontaneous adaptation and ability to wean from PS seen in these patients with down to 40 cm of remaining small bowel in the years following intestinal resection. In summary, it is believed that future pro-adaptive treatments in SBS will seek to mimic these effects, potentially by a replacement therapy including a combination of these beneficial feedback hormones.

Overview of Results from Clinical Studies

Somatostatin and Analogues

Somatostatin is widely distributed in the neuroendocrine cells throughout the gastrointestinal tract and in pancreatic D cells. It decreases gastric [16], biliary and pancreatic secretions [17–19] inhibit secretagogue-induced water and electrolyte secretion in the jejunum and the colon [20], stimulate sodium and chloride absorption in the ileum [21], decrease intestinal motility [22] and inhibit the release of hormones that may contribute to the diarrhoea (e.g. VIP, GIP, gastrin) [23]. However, somatostatin could inhibit glucose absorption and pancreatic enzyme secretion, which would impair the macronutrient absorption in patients with SBS. Furthermore, somatostatin reduces splanchnic blood flow [24] and it may reduce the use of amino acids for splanchnic protein synthesis thereby interfering with the physiological process of adaptation to intestinal resection [25, 26].

Dharmsathaphorn et al. were the first to report the acute effects of a 24-h infusion of somatostatin (4 μg/min) in four patients with SBS due to multiple resections for Crohn's disease [27]. Total colectomy was performed in 3 out 4 of the patients and their remnant jejunum was less than 3 m. Having withdrawn all anti-diarrhoeal medications 2 days before admission, patients were placed on a standardised 2000 kcal diet containing 75 g/day of fat. Blood samples, urine and stool collections were obtained for three consecutive 24-h periods before, during and after somatostatin administration. Somatostatin infusion induced a reduction in stool weight in all four patients (from 1892 ± 241 g/day to 1236 ± 254 g/day, on average corresponding to 35%, $p < 0.05$) and a 59% decrease in stool chloride content. Numerical reductions in faecal excretions of fat (9 g/day), nitrogen (1.0 g/day), sodium (30 mmol/day), potassium (7 mmol/day) and magnesium (47 mmol/day) were observed. The urinary volume and electrolytes remained unchanged. Blood glucose levels rose from 25 to 40 mg/dL and fasting and postprandial glucagon, GIP and peptide PP levels were suppressed by the somatostatin infusions. A rebound effect occurred immediately after infusions.

The use of a long acing somatostatin analogue, SMS 201-955 (octreotide), which prolonged the half-life from a few minutes to 3–4 h, was first reported in a woman with Crohn's disease who after colectomy also had a subsequent removal of an ileorectal anastomosis. Four months after the creation of an ileostomy, her output was 4–6 L/day, when on her regular oral intake, and 2–3 L when fasting, and therefore she required PS. In relation to 24-h of infusion of SMS 201-955 (25 μg/h), the ileostomy output decreased from 5300 to 1600 g/day, sodium excretion decreased from 656 to 162 mmol/day and potassium from 48 to 20 mmol/day. In spite of these dramatic effects, the faecal excretion of fat and glucose was not affected. Small bowel transit time was prolonged from 76 to 134 min. Subsequently, the patient was given SMS 201-955, 50 μg subcutaneously twice daily, and her stomal output remained below 2.5 kg/day thereby rendering PS unnecessary [28].

The effect of octreotide was also demonstrated in a 5-year-old boy with an ileostomy placement after an operation due to volvulus. Following unsuccessful treatments with parenteral nutrition for 8 weeks, loperamide, cholestyramine and antibiotics, efficacy of octreotide was demonstrated. Following a phase with continuous analogue infusion followed by twice daily 50 μg subcutaneous octreotide injections, the average ileal output diminished from 1800 g/day to 350 mL/day and was paralleled by reductions in sodium and chloride losses. No side effects were observed.

Rodrigues et al. compared the effects of octreotide to the effects of soy polysaccharide, oral and intramuscular codeine, and loperamide on nutrient fluid and electrolyte absorption in four patients with short bowel syndrome and an end-jejunostomy receiving parenteral nutrition [29]. Following a standardised test meal, the stoma output collected the following 6 h was reduced from 923 ± 213 g to 358 ± 78 g, sodium output from 95 ± 12 to 49 ± 9 mmol, calorie balance increased from 11 ± 6 to 35 ± 8%, and intestinal transit (evaluated as the median time taken to recover 60% of a labelled marker) increased from 64 ± 23 to 205 ± 8 min. However, all four patients found that the subcutaneous octreotide injections were painful, and one patient experienced abdominal pain and distention.

Nightingale et al. studied the effect of octreotide in six SBS patients who all had undergone extensive small bowel resection [30]. Apart from one, who had a jejuno-rectal anastomosis, all patients had end-jejunostomies and a remnant bowel length of less than 70 cm. Two of the patients received codeine and loperamide in relation to participating in the study. The mean daily intestinal output ranged from 3.6 to 6.9 kg, and all patients needed at least 4.5 L of intravenous fluids per day. Following two control days, the patients were given octreotide intravenously through their central catheter in a dose of 50 μg (diluted in 10 mL 0.9% saline given over 10 min) twice daily at 08:00 and 16:00 h for 2 days. This mode of administration was chosen to avoid the painful octreotide injections. When possible, the study was repeated using 100 μg of octreotide three times daily, 30 min before each meal. Treatment with octreotide significantly reduced the mean total intestinal output from 5.13 to 3.30 kg/day (difference 1.83 kg/day, range 0.60–5.01 kg/day, $p = 0.04$). Sodium excretion was reduced from 405 to 248 mmol/day (difference 157 mmol/day, range 56–405 mmol/day, $p = 0.03$) and potassium from 73 to 52 mmol/day (difference 21 mmol/day, range 6–61 mmol/day, $p = 0.05$). A non-significant reduction in faecal energy from 6894 to 5625 kJ/day was observed (difference 1270 kJ/day, range −1092 to

5083 kJ/day, p = 0.20). Increasing the dose to 100 μg TID in three patients did not increase the effect, but the patients preferred this option since it reduced the usual inconvenient postprandial rise in the intestinal output. No side effects were reported. One patient was treated continuously for 1 year without evidence of tolerance occurring and no signs of complications of diabetes, hypothyroidism or gallstones.

Rosenberg et al. investigated the effect of octreotide in doses from 50 μg subcutaneously twice daily to 100 μg three times daily in SBS six patients; two with ileostomies and four with a gastrointestinal tract that was in continuity [31]. Intractable diarrhoea decreased by 73 ± 7% in five of the six patients, but the actual raw-data is not presented in the publication. Although the treatment was very effective in controlling diarrhoea, two patients discontinued treatment within 1 week of commencing treatment due to abdominal cramping and bloating. Two patients were treated successfully as outpatients for 6 weeks. Thereafter the treatment was stopped without the occurrence of diarrhoea. Two other studies were only reported in abstract form. Shaffer et al. performed a randomised placebo controlled crossover trial in six patients with a persistently high stoma effluent (1.3–6 L/day) [32]. After a 2 day control period, the patients received 50, 100 and then 150 μg of octreotide or matching placebo on three successive days. After a 14 days washout, the patients repeated the study with the alternative medication. Octreotide significantly reduced the median stomal volume (2.39 L/day, range 0.62–4.48 vs placebo: 4.03 L/day, range 1.28–5.98, $p < 0.001$), sodium output (153 mmol/day, range 27–271 vs placebo: 311, range 94–594, $p < 0.001$) and potassium output (39 mmol/day, range 8–58 vs placebo: 54, range 23–154, $p < 0.001$). There was a corresponding increase in urine volume (2.09 L/day, range 0.75–6.62 vs placebo: 1.16 L/day, range 0.47–5.13, $p < 0.002$). Body weight was unaffected by the treatment, and no improvements in nitrogen, magnesium, zinc or copper balances were seen. Two patients were followed for more than 2 years on treatment and did not develop any long-term adverse effects or evidence of pharmacological tolerance.

In another abstract, Gilsdorf et al. reported finding in seven SBS patients requiring HPN. Three patients had stomas and in these octreotide, given in doses ranging from 50 to 300 μg subcutaneously in one to three doses, reduced stoma outputs of 5.0, 4.0 and 2.0 L/day to 3.5, 2.5 and 0.6 L/day [33]. Daily bowel movements of up to 20/day decreased in all cases to less than 6/day. Four patients eventually took octreotide in their TPN bags and experienced the same effect as when taken subcutaneously. One patient developed confusion, oedema and a 17 lb weight gain secondary to fluid overload. One had labile blood sugars. All patients complained of dull headaches and nausea which they attributed to octreotide. Thus, three stopped the treatment, whereas three continued the treatment by injecting it into their PS.

These studies were followed by a double blind, placebo controlled balance study by Ladefoged et al. in six SBS patients requiring PS [34]. Five of the six patients had a jejunostomy and less than 225 cm of small intestine, whereas the last patient only had a resection of 30 cm of the terminal ileum. Their stool masses ranged from 2320 to 8125 g/day and their stomal sodium losses ranged from 144 to 601 mmol/day. Four of the six patients were wet weight secretors, and all the patients were sodium secretors. During the study, the patients were maintained on a constant diet composed in accordance with their habitual intake and they received a fixed fluid and sodium intake for all 12 days. After a basal period of 2 days, the patients were randomly allocated to intravenous placebo or octreotide 25 μg/h for 2 days each. After a new basal period of 2 days, the patients were allocated in the same manner to a subcutaneous administration of either placebo or octreotide in a dose of 50 μg every 12 h. In the whole period, double portions of the oral intake was prepared and analysed as was the stools and urine. Infusion of octreotide caused a significant increase in the median wet weight absorption of 1124 g/day (range 347–1854 g/day), $p < 0.005$ and sodium 126 mmol/day (range 52–191 mmol/day), $p < 0.005$, whereas no significant changes in the net absorption of potassium, calcium, magnesium, phosphate, zinc, nitrogen or fat was seen during the infusion of octreotide. Subcutaneous injection of octreotide every 12 h caused similar effects. However, one patient developed symptoms of ileus that resolved after discontinuation of octreotide and conservative treatment. In none of the patients, the improvements in intestinal wet weight or sodium absorption were large enough to make parenteral fluid or sodium supplements superfluous. Four patients opted to continue open label subcutaneous treatment twice daily for 21–28 weeks. In three of these patients, the faecal mass remained below baseline values but in one patient, the faecal mass gradually increased and exceeded baseline values even after doubling the octreotide dose. No side effects were seen.

In an open label study, O'keefe et al. investigated the effect of 100 μg octreotide given subcutaneously TID, 30 min before meals on intestinal absorption after initial 72-h balance studies at days 1–3 that were repeated at days 11–13 [26, 35]. Ten adult SBS patients with end-jejunostomies performed at least a year prior to the investigation were examined. The remaining small bowel was 200 cm or below in all patients, and they all depended on PS (mean PS volume 4.5 L/day, range 1–5.5 L/day and mean sodium provision 387 mmol/day, range 247–982 mmol/day). All patients had received H_2 antagonist therapy until a week before the study and all patients had been given trials of common anti-diarrhoeas. The mean stomal output was 8.1 L/day (range 2.4–20.7 L/day) and sodium losses 510 mmol/day (range 247–982 mmol/day). The study protocol consisted of a 3-day, baseline metabolic balance study, where no

antisecretory or antimotility medications were given. Octreotide therapy was then commenced as 100 μg TID s.c. 30 min before each meal for 8 days before the 3-day balance study was repeated during the same octreotide treatment. After commencement of octreotide, reductions in the stomal fluid were counterbalanced each day by reductions in IV fluid and electrolyte infusions maintaining urine output between 1 and 1.5 L/day. In addition, amino acid metabolism, pancreatic enzyme synthesis and secretion and mucosal protein turnover were measured before and at the end of the 10 days of octreotide therapy. Likewise, mucosal biopsies and hormonal secretions were evaluated before and during stimulation with pentagastrin and cholecystokinin.

The effect of octreotide treatment on stomal output was immediate in all patients, and in spite of a reduction in oral fluid intake, this permitted a significant reduction in the parenteral supplements in all but one of the patients. Thus, on average the stomal losses of fluids and sodium were reduced to 4.8 L/day and 340 mmol/day, respectively (both $p < 0.03$). However, despite increases in net absorption, none of the patients could be weaned from PS. The average parenteral fluid volume and sodium reductions were 1.3 L/day and 118 mmol/day, respectively ($p < 0.03$). In general, the largest effect was seen in patients with the highest stomal losses and highest parenteral needs. No changes in intestinal macronutrient absorption were observed in relation to octreotide treatment.

Octreotide treatment resulted in a significant reduction in the pentagastrin-stimulated acid secretion in all but one of the SBS patients. The exogenous pancreatic excretion of lipase in response to CCK stimulation was significantly reduced before and after 10 days of octreotide treatment, whereas numerical reductions were seen in trypsin and amylase secretion. Although, the time taken to the appearance of carmine dye on average was 12 min longer in comparison with pretreatment values, this was not significant. Mucosal protein turnover and duodenal villus growth rates calculated from isotope incorporation and morphological measurements showed a significant suppression. Plasma concentrations of glucagon, insulin, gastrin and peptide YY all decreased in relation to octreotide treatment. Evidence for improved renal function was obtained from urea clearance with findings of decreases in blood urea concentration and increases in urea nitrogen excretion in the urine. However, although octreotide significantly reduced stomal output and increased fluid balance in the SBS jejunostomy patients, concern was raised that the long-term treatment would interfere with the process of intestinal adaptation. Seven patients continued treatment for over 2 years following the study. Two of these patients died one from septicaemia and the second with intestinal failure associated liver disease. Two patient developed gallstones necessitating a percutaneous cholecystectomy. Mild hair loss was noted by two patients. Two patients complained of occasional abdominal cramps.

In the latest study employing octreotide, Nehra et al. described the use of a long-acting release (LAR) deport, octreotide preparation, sandostatin LAR, in a 15 week, open label trial in eight adult SBS-IF patients [36]. All the patients had been receiving PS for 1–22 years. Three of the patients had a colonic segment in continuity and in all patients the residual bowel was 200 cm or less. Metabolic balance studies and measurements of intestinal transit by radionucleotide scintigraphy employing an egg meal were performed on two separate occasions 15 weeks apart. Following the initial 48-h balance study, the patients received the first 20 mg, intramuscular, Sandostatin LAR injection. This was repeated by self-injection as an outpatient at weeks 3, 7 and 11. The PS was kept constant throughout the study, and patients had fixed habitual like diet during admissions. The average 48-h stool weight was 4.54 g/day (range 2.91–11.16 kg). Sandostatin LAR treatment did not lead to significant differences in body weight, 48-h urine volume, stool weight, faecal sodium or potassium losses or faecal fat excretion. However the depot-treatment significantly prolonged small bowel transit time, whereas the gastic emptying halftime or in the proportion of the meal emptied from the stomach at 2 and 4 h did not change.

According to the ESPEN guideline it is suggested that octreotide is only used in the short term after intestinal resection and in patients with high output jejunostomy in whom fluid and electrolyte management is problematic in spite of conventional treatments. A careful monitoring is recommended to prevent fluid retention in relation to the initiation of treatment as well as potential adverse effects. Although the effects potentially are dramatic in patients with the highest outputs, it is of concern, that sandostatin and analogues have global effects on hormonal secretions and that potential negative interference with the process of intestinal adaptation may be seen following long-term use.

Growth Hormone and Analogs

The concept of “bowel rehabilitation” was introduced by Byrne and Wilmore in relation with treatment with high dose (0.14 mg/kg/day) of growth hormone, glutamine, and a high carbohydrate diet in SBS patients [37, 38]. In eight SBS patients with colon in continuity treated for 5 weeks, wet-weight absorption increased from 1.7 to 2.4 kg/day, and sodium absorption increased from 74 to 113 mmol/day. However, although these patients were receiving PS, it is not clear if they met the criteria for a diagnosis of intestinal failure as defined by Jeppesen et al. [3]. At the same time patients were given a high-carbohydrate diet and oral rehydration solutions as a part of the “rehabilitation-regimen”.

In a subsequent placebo-controlled, double-blind study by Scolapio et al., the effect of growth hormone (0.13 mg/kg/day) and oral glutamine on intestinal sodium and potassium absorption was less than 5 mmol/day [39]. No effects on faecal wet weight excretion were seen.

In a study by Szkudlarek et al., growth hormone (0.11 mg/kg/day) and glutamine, both orally and parenterally administered, tended to decrease wet-weight absorption and increase faecal excretion of sodium and potassium, which reached significance ($p < 0.05$) in comparison with baseline values [40]. However, these findings were accompanied by clinical findings of generalized oedema, increased body weight, a need for diuretics, and a reduction in parenteral saline during treatment. It is believed that the patients were in the process of excreting water and sodium accumulated during the treatment at the time of the post-treatment balance studies 5 days after termination of treatment.

In lower dose studies from Ellegård (growth hormone 0.024 mg/kg/day) [41] and Seguy (0.05 mg/kg/day) [42], no significant positive effects on either wet-weight or sodium absorption were seen.

In the pivotal, randomised, double-blind parallel group study of 41 patients with SBS (mainly with a preserved colon and stool volume less than 3 L/day), who were dependent on parenteral nutrition, the effect of the recombinant human growth hormone, somatotropin (0.1 mg/kg/day for 4 weeks) and glutamine on the need for PS was investigated [43]. The protocol for weaning from PS was based on measurements of body weight, total body water by bioimpedance analysis and measurements of serum sodium, potassium and bicarbonate. A significantly greater reduction from baseline in total parenteral volume occurred in recipients of somatropin plus glutamine or somatropin alone than in recipients of placebo plus glutamine (−7.7 and −5.9 vs −3.8 L/week, respectively). Thus, the effect of somatropin and glutamine averaged 557 mL/day. Balance studies on intestinal absorption were not performed and the results on urinary excretions were not reported [43]. However, it has been reported that growth hormone increases extracellular volume by stimulating sodium reabsorption in the distal nephron and preventing pressure natriuresis [44]. Therefore, when employing bioelectrical impedance analysis during weaning from PS, it should be considered that the effects of growth hormone on fluid balance in SBS patients may also be related to effects on the kidneys and the extracellular space rather than on the intestine.

Results on intestinal energy and macronutrient absorption in studies using growth hormone have been conflicting. In the study by Byrne and Wilmore, the baseline dietary energy intake was 2692 kcal/day, and 1618 kcal/day (~6773 kJ/day, 60%) were absorbed [37]. Thus, according to the parameters that define intestinal failure suggested by Jeppesen et al. [3], the majority of these patients did not need parenteral energy. After 3 weeks of treatment, the intake and absorption were 2367 and 1759 kcal/day (~7363 kJ/day, 74%), respectively, which was a significant improvement in percentage ($p < 0.003$) but an increase of only 141 kcal/day (~590 kJ/day) in absolute amounts. As stated, the "rehabilitation"-regimen included a high-carbohydrate, low-fat diet, which in itself is known to increase energy absorption in SBS patients with a colon in continuity. Supporting the hypothesis that diet alone accounted for the observed benefits, intestinal fat absorption did not improve. In the study by Scolapio et al., where only 2 of 8 patients had colon in continuity, high-carbohydrate diets were provided in both the placebo and treatment arms [39]. Energy absorption was not measured, but no changes were observed regarding nitrogen or fat absorption with growth hormone. In the studies by Ellegård et al. [41] and Szkudlarek et al. [40], no changes were found in intestinal energy or in fat or nitrogen absorption. In the randomized, double-blind placebo-controlled cross-over study by Seguy et al., growth hormone (0.05 mg/kg/day, 9 of 12 patients with colon in continuity) and an unrestricted hyperphagic diet increased intestinal absorption of nitrogen by 14 ± 6% ($p < 0.040$), carbohydrates by 10 ± 4% ($p < 0.040$), and energy by 15 ± 5% ($p < 0.002$), which in absolute terms was 427 kcal/day (~1787 kJ/day) [42]. Fat absorption was unaffected. During growth hormone treatment the mean dietary energy intake was 192 kcal/day (804 kJ/day) higher than during the placebo treatment phase.

In the pivotal study on somatropin, the mean reductions from baseline in total parenteral calories were significantly greater in recipients of somatropin plus glutamine or somatropin alone than in recipients of placebo plus glutamine 5751 and 4338 vs 2633 kcal/week, respectively [43]. Thus, the effect of the combined therapy of somatropin plus glutamine would correspond to an effect of 445 kcal/day (1863 kJ/day). No changes in the dietary energy intake in the three parallel study groups were reported.

In the growth-hormone study by Byrne et al., a weight gain of 5.4 ± 1.2 kg was described in the eight patients after 21 days of treatment [37]. Occurrence of oedema was not reported, but increases in body weight of this magnitude are difficult to explain considering the cumulative effect of approximately 12.4 MJ (590 kJ/day) on the energy balance over the 21 days of treatment. Neither body composition nor urine creatinine excretion was measured. Changes in body weight in the studies by Ellegård et al., [41], Scolapio et al., [39] and Szkudlarek et al., were minor and no changes were seen in urinary creatinine excretion [45]. In the study by Seguy et al., body weight increased 2.0 kg ($p < 0.003$), and the lean body mass, measured by BIA, increased 2.2 kg ($p < 0.006$) [42]. No adverse events to the lower dose growth-hormone treatment were encountered.

In the PS weaning study of somatropin, a dramatic weight loss of 5.2 kg of body weight (from 63.9 to 58.7 kg) was

observed from week 2 (pre-treatment) to week 18 (12 weeks post-treatment) in patients receiving the combined therapy of somatropin plus glutamine. This weight loss closely reflected the anticipated weight loss derived by calculation of the energy deficit obtained by reduction of the parenteral energy support of 1863 kJ/day [43].

In summary, the overall impression is that the effects of high doses of growth hormone were mainly confined to the wet weight absorption and mainly in SBS patients with a preserved colon, whereas the effects on energy absorption were minor. At the lower doses of growth hormone, there may be an effect on energy absorption in SBS patients with a preserved colon, whereas the effect on wet weight absorption was minor regardless of intestinal anatomy.

In 2003, the United States Food and Drug Administration (US FDA) approved Zorbtive® for 4-week treatments in SBS patients. It has not been approved by EMA. The long-term benefits of growth hormone and glutamine on intestinal absorption following discontinuation of treatment remain to be established. The effects of growth hormone are global and not specific for the intestine. The global effects of growth hormone and the presence and severity of adverse events (swelling, fluid retention symptoms, myalgia, arthralgia, gynecomasia, carpal tunnel syndrome, nightmares and insomnia) in relation to high dose growth hormone treatment raises concern especially in relation to a long-term, potentially life-long use of this treatment modality. Trying to reconciliate the conflicting findings in the growth hormone studies a recent Cochrane review concluded: "The results suggest a positive effect of human growth hormone on weight gain and energy absorption. However, in the majority of trials, the effects are short-lived returning to baseline shortly after cessation of therapy. The temporary benefit calls into question the clinical utility of this treatment" [46].

Glucagon Like Peptide-2 and Analogs

Glucagon-like peptide 2 (GLP-2) is a single chain polypeptide of 33 amino acid residues, which is produced by a tissue-specific posttranslational processing of the 160 amino-acid proglucagon molecule in enteroendocrine L-cells. These cells are distributed throughout the gastrointestinal tract with the highest density in the terminal ileum and the colon. GLP-2 is secreted from the intestinal L-cells following meal ingestion. Repeated administration of GLP-2 promotes the expansion of the intestinal mucosa via the stimulation of crypt cell growth and the reduction of enterocyte apoptosis [47]. Exogenous GLP-2 administration inhibits gastric acid secretion and gastric emptying [48, 49] stimulates intestinal blood flow [50–52] increases intestinal barrier function [53] and enhances nutrient and fluid absorption in both preclinical and clinical models [54–56]. GLP-2 has also been suggested to have anti-inflammatory effects [57, 58], and in addition, GLP-2 may decrease bone resorption [59]. The effects are mediated via GLP-2-receptors (GLP-2R), which are G-protein coupled receptors belonging to the class B glucagon-secretin receptor family [60]. GLP-2R expression is primarily found in the gastrointestinal tract and the central nervous system, with limited expression in lung, cervix and vagal afferents [61]. Within the GI-tract the most abundant expression of GLP-2R is found in the jejunum, followed by the ileum, colon and stomach. Different studies have identified expression of GLP-2R in enteroendocrine cells [62], enteric neurons [63] and subepithelial myofibroblast [64]. However, neither crypt epithelial cells nor enterocytes express the GLP-2R and this finding has led to the hypothesis that GLP-2 requires an indirect signal, perhaps functioning through a paracrine mechanism, to induce its effects on intestinal growth. GLP-2R activation results in the release of several growth factors such as IGF-1, EGF and KGF [65].

The biologically active GLP-$2_{1–33}$ is broken down at the alanine residue in position 2 from the N-terminus, catalysed by the proteolytic enzyme dipeptidyl peptidase-4 (DPP-4), and it is thereby transformed into the biologically more inactive metabolite GLP-$2_{3–33}$. Teduglutide is a GLP-2 analog, in which a substitution of alanine with glycine at position two results in a peptide resistant to degradation by DPP-4 and, therefore, has a longer half-life than native GLP-2 [66, 67]. Following subcutaneous (SC) injection, this corresponds to a biological half-life for teduglutide of 2–3 h compared to a half-life of 7 min for GLP-2.

In the first uncontrolled, clinical, "proof of concept" study with native GLP-2 by Jeppesen et al., 8 patients were treated with the empirically derived dose of 400 μg of native GLP-2 twice a day (corresponding to 0.013 ± 0.002 mg/kg/day, a range of 0.011–0.017 mg/kg/day), given subcutaneously for 35 days in an open label study [55]. None of the patients had colon in continuity. Their average wet-weight absorption was 1.2 ± 1.7 kg/day at baseline, and it increased by 420 ± 480 g/day ($p = 0.04$), whereas the effect on sodium absorption did not quite reach statistical significance (33 ± 49 mmol/day, $p = 0.10$). Native GLP-2 treatment improved the relative absorption of energy by 3.5% ($p = 0.04$), and nitrogen by 4.7% ($p = 0.04$). The absolute energy absorption tended to increase by 441 ± 634 kJ/day ([105 ± 151 kcal/day] $p = 0.09$). The effect of GLP-2 on fat absorption was not significant. The improvement in the absolute amount of energy absorbed was obtained in spite of a non-significant decrease in intake of 173 kJ/day, which means that the reduction in the energy malabsorbed (equal to the stomal excretion) was proportionally larger: 617 kJ/day [55].

The first clinical study of the efficacy of teduglutide in SBS was evaluated in an open-label, phase 2, pilot study published in 2005 [68]. In this phase 2, metabolic balance

study, 16 SBS-patients received three different doses of teduglutide for 21 days [68]. The SBS patients were divided into three subgroups based on remnant functional anatomy: end-jejunostomy (n = 10), <50% colon in continuity (n = 1) or >50% colon in continuity (n = 5). The 10 SBS patients with end-jejunostomy received 0.03 mg/kg/day (n = 2), 0.10 mg/kg/day (n = 5) or 0.15 mg/kg/day (n = 3) of teduglutide once daily. The patient with <50% colon in continuity received 0.03 mg/kg/day, and the five patients with >50% colon in continuity received 0.10 mg/kg/day. The doses were chosen to examine dose response in SBS patients over a range of doses expected to provide clinical benefit. It was intended that dietary intake was fixed during the balance studies, and the study did not seek to evaluate the effects of teduglutide on spontaneous dietary intake. Three 72-h balance studies were performed: at baseline; during teduglutide treatment at days 18–21; and after terminating teduglutide treatment at day 39–42. During balance studies, all oral intake, faecal/stomal output and urine was collected, weighed and analysed for energy, nitrogen, fat and sodium and potassium content. Likewise, intestinal mucosa biopsies were done at baseline, day 21 and day 42. The patients took their usual medications such as proton pump inhibitors, codeine or loperamide, and oral and parenteral supplements were kept constant throughout the study.

Compared to baseline, 21 days of treatment with teduglutide increased absolute intestinal wet weight absorption in 15 out of 16 SBS patients. The average increase in wet weight absorption was 743 ± 477 g/day ($p < 0.001$). The overall increase in the relative wet weight absorption was 22 ± 16% ($p < 0.001$), and the magnitude was similar for SBS patients with end jejunostomy (20 ± 18%, $p = 0.007$) and those with >50% colon in continuity (26 ± 16%, $p = 0.023$). In accordance with the increase in wet weight absorption, faecal wet weight decreased significantly compared with baseline in the entire group of SBS patients (711 ± 734 g/day, $p = 0.001$). Since the oral intake and PS were kept constant in this study, the benefits on intestinal wet weight absorption and hydration translated into an increase in urine production in 14 of the 16 SBS patients. The urine weight increased by 555 ± 485 g/day ($p < 0.001$). Furthermore, a significant decrease in faecal energy excretion was observed in the entire group of SBS patients (group 1 = 808 ± 1453 kJ/day, $p = 0.040$), in the subgroup of patients with colon in continuity (group 3 = 1343 ± 916 kJ/day, $p = 0.031$) and in those patients with high dietary compliance (group 4 = 1060 ± 1083 kJ/day, $p = 0.013$). This reduction in energy excretion translated well into both significantly improved absolute energy absorption (group 3 = 1027 ± 798 kJ/day, $p = 0.045$ and group 4 = 963 ± 1290 kJ/day, $p = 0.043$) and relative energy absorption (group 3 = 10 ± 7%, $p = 0.030$ and group 4 = 8 ± 11%, $p = 0.040$). Unfortunately, the results did not translate into a general, significant effect with respect to absolute or relative energy absorption, and it is possible that this is due to variability in dietary intake during the study periods amongst the different groups.

In addition to the metabolic balance studies, the study also examined the possible histological changes in bowel biopsies obtained from the patients. In the jejunum biopsies (obtained from 8 end-jejunostomy patients in group 2) significant histological changes were seen in 7/8 patients. More specifically, an increase in villus height (38 ± 45%, $p = 0.030$), an increase in crypt depth (22 ± 18%, $p = 0.010$) and an increase in mitotic index (115 ± 108%, $p = 0.010$) were demonstrated. Small intestinal biopsies were not obtained from the patients with colon in continuity (group 5), but instead biopsies measuring the colonic crypt depth were obtained in all five group 3-patients, and these showed an increase in crypt depth in 4/5 sets of biopsies. The mean increase in crypt depth (13 ± 22%, $p = 0.330$) was not statistically significant, and neither was the increase in mitotic index (76 ± 112%, $p = 0.170$). Most changes in intestinal absorption and histology related to teduglutide treatment had reversed at follow-up.

Having illustrated that increases in wet weight absorption were paralleled by increases in urine production, the ability to reduce PS according to increases in urine production served as the endpoint in the phase 3 clinical study development of teduglutide.

In each of two 24-week, phase 3, outpatient studies, patients with SBS had their PS and intake of fluids optimized to produce a stable urine output of 1–2 L/day prior to randomization and subsequent efforts to reduce PS requirements while maintaining clinical status and hydration.

The first long-term, multinational, double-blind randomized placebo-controlled teduglutide trail was conducted as a multicenter study in the US, Canada and Europe ("the 004 study"). Eighty-three patients with SBS-IF of various aetiologies were included. Patients with SBS were randomized to teduglutide 0.05 mg/kg/day (n = 35), teduglutide 0.10 mg/kg/day (n = 32) or placebo (n = 16) for up to 24 weeks [69]. The primary efficacy variable in the study was initially the responder rate—that is, the percentage of patients who had a reduction from baseline in parenteral volume of 20–100% at week 20 of treatment and again at week 24. Later on, an expanded graded primary end point was introduced to compare the patients treated with teduglutide versus placebo with respect to a graded response score (GRS) criterion. Secondary efficacy end points included the number and percentage of patients who responded (defined as a parenteral volume reduction of 20–100% from baseline at week 20 and maintained at week 24); the absolute reduction from baseline in parenteral volume and parenteral kilojoules; and the achievement of at least 1 day reduction in the weekly parenteral administration or total weaning from PS. The patients were seen in the outpatient clinic at 2 weeks intervals. The

investigators used a weaning algorithm that allowed PS volume to be reduced by maximum of 10% monthly. The primary efficacy end point of the study, the GRS, was not significantly different from placebo in the teduglutide 0.10 mg/kg/day group. However, it was decided to explore the effect of the 0.05 mg/kg/day dose on the primary end point and these results showed a statistically significant improvement compared with placebo in the GRS ($p = 0.007$). The secondary efficacy end point—the responder rate—was not significantly different between the 0.10 mg/kg/day group and the placebo group, but the responder rate was significantly higher in the 0.05 mg/kg/day dose group compared with placebo (46% (16/35) vs. 6% (1/16)), $p = 0.005$). Three subjects were completely weaned from PS. Two patients in the 0.05 mg/kg/day group became completely independent of PS although they had received this treatment for 25 and 6.5 years, receiving 5.4 L and 3.5 L per week at baseline, respectively. Another patient in the 0.10 mg/kg/day group also became independent off PS at the end of treatment week 24 after having received 4.5 L PS per week for 3.7 years.

None of the active treatment arms resulted in a significant reduction in the number of days on PS, which could be explained by the fact that the algorithm for weaning PS did not specify for conversion of accumulated effects into days off PS and many investigators probably found it easier to just reduce daily parenteral volumes.

In the 0.05 mg/kg/day teduglutide group an observation of significantly more urine production at all time points, in spite of maintaining a constant oral fluid intake and having parenteral volume significantly decreased, was seen. Since urine output increased steadily during the study, this contrasted to the objective of the study protocol, which was to maintain constant urine output by progressively reducing the parenteral volume. Thus, the absolute effect of the teduglutide 0.05 mg/kg/day dose on the reduction in parenteral volume appeared to be underestimated. The concept of "the fluid composite effect" reflects the sum of the reduction in oral fluid intake, the increase in urine volume and reductions in daily parenteral volume. Thus, highlighting the total effect of the 0.05 mg/kg/day teduglutide dose, the fluid composite effect endpoint increased significantly by 816 ± 982 mL/day compared with placebo ($p = 0.03$) at week 20. Highlighting the total absolute effect of the 0.10 mg/kg/day teduglutide dose, the composite effect increased significantly by 489 ± 619, 700 ± 723 and 953 ± 830 mL/day at weeks 12, 16 and 20, respectively (all p-values <0.05) compared to the placebo. Thus, the urine volume increased by ~350 mL/day and the parenteral volume was decreased by ~350 mL/day in the 0.05 mg/kg/day teduglutide dose group, whereas the oral fluid intake decreased by ~350 mL/day and the parenteral volume decreased by ~350 mL/day in the 0.10 mg/kg/day teduglutide dose group. Thereby, it is estimated that the true effect of either teduglutide dose on intestinal wet weight absorption is probably around 700 mL/day (i.e. 4.9 L/week) closely reflecting the effects demonstrated in the phase 2 study.

The reductions in parenteral energy were not significant when comparing the teduglutide groups and the placebo group ($p = 0.11$), but in contrast to the phase 2 study, the oral energy intake and faecal excretions were not measured. It is suggested that the non-significance of the 0.10 mg/kg/day dose vs. placebo could be explained by limitations imposed by the protocol, such as the inability to start reduction of PS until after 4 weeks of initiating teduglutide treatment, the maximally allowed reductions in PS of 10% per month, and a trend towards larger baseline parenteral volume requirements in the 0.10 mg/kg/day group.

The effect on body composition was evaluated by changes in fat mass, lean body mass and total bone mineral content (BMC). Body weight was registered at all appointments and DEXA-scans were performed at baseline and again at week 24. Body weight was significantly increased in both teduglutide groups at various time points compared to placebo and this finding was mainly due to changes in lean body mass. The total bone mineral content (BMC), was significantly higher in both teduglutide groups compared to placebo, but did not result in significant changes in T and Z-scores.

In both teduglutide groups, a significant increase in small bowel villus height in biopsies was demonstrated. A significant increase in colonic crypt depth was demonstrated in the teduglutide 0.10 mg/kg/day group.

Plasma citrulline, an organic compound derived from the amino acid arginine, is used as a biomarker of a reduced enterocyte mass in SBS. Plasma citrulline was increased in both treatment groups compared to baseline and the absolute changes from baseline in plasma citrulline were significantly ($p < 0.0001$) increased after the 24 weeks of treatment in both treatment groups (15.7 ± 12.7 μmol/L in the teduglutide 0.10 mg/kg/day and 10.9 ± 11.3 μmol/L in the teduglutide 0.05 mg/kg/day) compared to placebo (1.9 ± 5.0 μmol/L). Interestingly, while baseline values tended to be lower in the teduglutide 0.10 mg/kg/day compared to placebo group ($p = 0.051$), this group showed the highest increments.

No significant changes in QoL during treatment with teduglutide were demonstrated.

Patients who completed the placebo-controlled study were given the option to enter an open-label, 28-week extension study ("the 005 study") [70]. Fifty two patients were enrolled for continuous treatment of the same dose of teduglutide (25 patients receiving 0.05 mg/kg/day and 27 patients receiving 0.10 mg/kg/day) for a total length of 52 weeks. As in the initial RCT, the primary efficacy end point was a clinical response defined as reduction of 20–100% in weekly PS volume at week 52 compared to baseline.

Throughout the study period a progressive PS volume reduction was reported in the teduglutide-treated groups, greatest in the 0.05 mg/kg/day group. At week 24 (end of Study 004) 46% of the patients in the 0.05-mg/kg/day group and 25% of the patients in the 0.10-mg/kg/day group had achieved reductions of ≥20% of baseline PS volume. These numbers were 68% and 52% in the respective 0.05 and 0.10 mg/kg/day groups. Translated into ≥1 day(s) off PN, this was achieved in 68% of the patients in the 0.05 and 37% in the 0.10-mg/kg/day group. Four patients completely weaned off from PS (3 during study 004 and 1 during the 28-week extension study). Interestingly, 11 of the 19 non-responders at week 24 became responders and achieved reduction of ≥20% of baseline PS volume at week 52. In comparison, 4 of the 24 responders at week 24 became non-responders at week 52 [70].

An increase in fasting plasma citrulline levels from baseline was seen at week 52 of 68% and 86% in the 0.05 and 0.10 mg/kg/day groups respectively. The levels were decreased, but did not return to baseline levels, by 20% and 32% in the respective groups 4 weeks after end of treatment.

A second phase 3 pivotal study (the "020" or "STEPS" study) was subsequently performed using a similar study design but with a modified PS weaning protocol that allowed for earlier (at week 2 vs. week 4) and more aggressive weaning (10–30% vs. 10%) of the optimized PS volume [71]. Forty-three SBS patients were randomized to a 0.05 mg/kg/day dose of teduglutide and 43 patients to placebo for up to 24 weeks. The proportion of teduglutide treated patients achieving a 20–100% reduction of PS at week 20 and 24 was significantly higher compared to placebo (27/43 patients, 63% versus 13/43 patients, 30%, p = 0.002). Teduglutide treatment resulted in a 4.4 L/week reduction in PS volume from a pre-treatment baseline of 12.9 L/week versus 2.3 L/week from a pre-treatment baseline of 13.2 L/week for placebo at week 24. However, placebo-treated patients significantly increased their oral fluid intake by 1.6 ± 3.6 L/week (p < 0.009) in order to maintain stable target urine output of 1.0–2.0 L/day. In patients treated with teduglutide, urine output continued to increase, indicating increased net fluid absorption. Even at the end of the trial, further weaning appeared possible in patients treated with teduglutide. The significant PS volume reduction with teduglutide translated into additional clinical benefits: At the end of the treatment period (at Week 24), the need for PS infusion was reduced by 1 or more days in more than half of the patients in the teduglutide group (53.8%, 21/39) compared with less than one quarter of those in the placebo group (23.1%, 9/39; p = 0.005) [72].

Post-hoc analyses of the 020 study data have revealed that a positive correlation between baseline PS volume and PS volume reduction with teduglutide treatment (y = –0.3870x + 90.0279, r2 = 0.61; *P* < .0001) [73]. Patient were divided in groups based on bowel anatomy (group 1, jejunostomy/ileostomy; group 2, ≥50% colon in continuity without stoma; and group 3, other colon anatomies), and disease features (with inflammatory bowel disease, mesenteric vascular diseases, or other conditions). The absolute effects of teduglutide on absolute PS volume were significantly greater in group 1 patients (reduction of 919 ± 644 mL/day)—not only compared with patients given placebo (reduction of 340 ± 436 mL/day; *P* = .0112) but also compared with teduglutide-treated patients in group 2 (reduction of 355 ± 306 mL/day; *P* = .0066). Teduglutide had an intermediate effect on patients in group 3. A minority of patients with SBS and inflammatory bowel diseases had colon in continuity (10.5% [n = 2/19]), whereas most patients with SBS and vascular or other diseases had colon in continuity (84.4% [n = 27/32] and 67.6% [n = 23/34], respectively). These findings may inform initial parenteral support volume adjustments and management of these severely disabled patients.

Study 021 was an open label long term extension of study 020 in which teduglutide 0.05 mg/kg/day was evaluated for up to 2 years [74]. A clinically meaningful response was defined as a 20–100% reduction from baseline in weekly PS volume. Eighty-eight patients were enrolled; 37 patients had during the 24 week study (study 020) received teduglutide (TED), n = 39 had received placebo (PBO) and =12 had been optimized and stabilized during 020, but not treated with teduglutide (NT). All patients received daily subcutaneous injections of 0.05 mg/kg/day teduglutide (TED). Thus, the study population included three subgroups of TED/TED, PBO/TED and NT/TED. Including the 24 weeks in 020 study, total exposure to teduglutide was up to 30 months for TED/TED and up to 24 months for the NT/TED and PBO/TED subgroups.

A total of 65 subjects (74%) successfully completed the 2 year study period. 28/30 subjects (93%) in the TED/TED group demonstrated a clinical response with a mean reduction in PS volume from baseline of 7.6 (66%) L/week. This number was 3.1 L/week (28 %) in 16/29 subjects (55%) in the PBO/TED group and 4.0 L/week (39%) in 4/6 subjects (67%) in the NT/TED group.

Overall, TED resulted in clinically meaningful reductions in PS requirements, allowing for additional days off PS per week; 25/65 (38%) subjects achieving an additional ≥3 day/week reduction; 13 patients achieved total independence from PS versus 0 patients at the end of study 020.

The effect on parenteral energy supply was reported only in the first of the two phase 3 teduglutide studies. Reductions in parenteral energy at week 24 of 243 ± 450 kJ/day (p = 0.056), 447 ± 1051 kJ/day (p = 0.030) and 912 ± 1333 kJ/day (p = 0.001) were seen in the placebo group, teduglutide 0.10 mg/kg/day group and teduglutide 0.05 mg/kg/day group, respectively, compared with baseline. However, the reductions in parenteral energy were not significant between

active treatment (teduglutide 0.10 mg/kg/day and 0.05 mg/kg/day) and placebo (p = 0.11) [69].

In the 35-day study with native GLP-2 treatment, the overall increase in energy absorption of 15 MJ translated into a significant increase in body weight of 1.2 ± 1.0 kg (p = 0.010) [55]. The study demonstrated positive findings on urine creatinine excretion (0.7 ± 0.7 mmol/day, p = 0.02), which suggests an increase in muscle mass or increase in renal function in relation to GLP-2 treatment.

In both the placebo-controlled clinical teduglutide phase 3 studies, body weights remained stable in spite of PS reductions. Numerical increases in body weight were seen (0.9 ± 2.1 kg, at week 3 [68], 1.4 ± 2.5 kg, teduglutide 0.10 mg/kg/day, and 1.2 ± 2.8 kg teduglutide 0.05 mg/kg/day at week 24 [69], and 1.0 ± 2.8 kg, teduglutide 0.05 mg/kg/day at week 24 [71]. However, none of these reached statistical significance compared to placebo.

Follow-Up Studies

The post-drug consequences of teduglutide treatment were assessed in a descriptive, follow-up study, following the Study 004 [75]. Data were obtained from clinical visits at 0, 3, 6 and 12 months relative to discontinuation. Thirty-seven patients (25 responders, 12 non-responders) were included and classified according to whether their PS volume decreased (DEC), remained unchanged (NEUT) in NEUT/DEC group or increased in INC group.

During the 12 months post discontinuation, in the responders' group, 12 had increased their PS volume (INC) to pre-drug volumes while n = 13 had maintained the same PS volume or had further PS reduction (NEUT/DEC). Of the three patients who weaned off PS while on teduglutide in NEUT, all remained off PS 12 months post-drug. Accordingly, BMI was decreased at 3, 6, and 12 months INC group (P = 001), but not in NEUT/DEC group. NEU/DEC group was characterized by longer median short bowel length (58 cm vs 35 cm), longer median colon length (85 cm vs 58 cm) and more patients with colon in continuity (92% vs 57%) compared to INC group. Also the PS volume reduction while on drug was greater in INC vs NEUT/DEC (−4.7 vs −1.9 L, P = .04). The complication rate was higher in INC (13 total in 3 patients) than in NEUT/DEC (5 total in 3 patients); corresponding to complication incidence rates per person year of 1.5 for INC vs 0.38 for NEUT/DEC (P < 0.01). The complications consisted of multiple hospitalizations in the three INC patients and one bloodstream infection and four hospitalizations in three NEUT/DEC patients.

Other GLP-2 analogues with longer half-lives than teduglutide are currently under development. It is the hope that instead a lyophilized powder that requires daily injections and reconstitution before use, a more ready-to-use product with the potential weekly of monthly injections may be developed. However, in case of adverse events, a short half-life would be desirable.

Other Pro-adaptive Factors and Combinations

As indicated, numerous growth factors may be involved in the postresectional intestinal adaptation, such as such as glucagon-like peptide-1 (GLP-1), oxyntomodulin, peptide YY, neurotensin, insulin-like growth factor-1, hepatocyte growth factor, vascular endothelial growth factor, cholecystokinin, epidermal growth factor, gastrin, insulin, vascular endothelial growth factor, fibroblast growth factors and keratinocyte growth factor. GLP-2 is just one of many endogenously secreted hormones involved in the process of intestinal adaptation following intestinal resection. Therefore, in theory, other hormones, or inhibitors of their degradation enzymes, individually, or in concert with GLP-2, may have positive effects on the intestinal absorption in SBS patients. Results obtained so far have been demonstrated in preclinical studies and in small, open-label, pilot-studies. In mice, inhibiting dipeptidyl peptidase-IV (DPP-IV), which is a serine protease cleaving dipeptides from the N-terminal end with l-proline or l-alanine at the penultimate position (e.g. GIP, GLP-1 and GLP-2), has been suggested as a novel approach to promote adaptation in SBS patients with preserved L-cell secretion [76, 77]. Other peptides such as peptide YY, glicentin, oxyntomodulin and GLP-1 have also been suggested in the treatment of SBS patients. In a small 1-month study, all five consecutive SBS patients with less than 90 cm of small bowel (4 with colon-in-continuity) experienced improvements in stool frequency and form following treatment with the GLP-1 agonist exanatide [78]. PS was stopped successfully in 3 of the 5 patients. Antroduodenal manometry revealed continuous low amplitude gastric contractions during fasting which completely normalized with exanatide. Another pilot study employing the GLP-1 analogue, liraglutide, showed promising results. In an 8-week, open-label, pilot study, liraglutide was given subcutaneously once-daily to eight end-jejunostomy patients, aged 63.4 ± 10.9 years (mean ± SD) and with small bowel lengths of 110 ± 66 cm. Seventy-two-hour metabolic balance studies were performed before and at the end of treatment. Food intake was unrestricted. Oral fluid intake and parenteral support volume was kept constant. Liraglutide reduced ostomy wet weight output by 474 ± 563 g/day from 3249 ± 1352 to 2775 ± 1187 g/day (P = .049). Intestinal wet weight absorption tended to increase by 464 ± 557 g/day (P = .05), as did urine production by 765 ± 759 g/day (P = .02). Intestinal energy absorption improved by 902 ± 882 kJ/day (P = .02) [79].

Likewise, acute effects were observed on intestinal absorption in nine SBS patients (2 with colon-in-continuity) in relation to infusion of native GLP-1, GLP-2 and co-infusion of GLP-1 and GLP-2 [80]. GLP-1 decreased diarrhea and faecal excretions in SBS patients, but it seemed less potent than GLP-2. The combination of GLP-1 and GLP-2 numerically provided additive effects on intestinal absorption compared to either peptide given alone.

Conclusion

The control of function and adaptation following intestinal resection is complex. Thus, the true understanding and development of adequate measurements of the relevant pathophysiological changes in GI function in the individual patients following intestinal resection remains to be resolved. Over the last decades, an increased awareness of some of the key hormones and their functions has emerged. Pharmaceutical companies are now able to provide these pro-adaptive factors and analogues for the clinical use in SBS patients [81]. However, due to the large patient heterogeneity even within recommended SBS classifications, combined with a large effect heterogeneity related to treatments, an individualised approach will be necessary. A wide range of pro-adaptive agents, used singly or in combination, are suggested as potential as future treatments. Since SBS patients are relatively rare, industry interest may be limited. However, physiological findings related to testing these agents in SBS patients may prove relevant for the understanding of human physiology including signalling and regulation of gut-brain and gut-liver axes, appetite regulation and metabolism, which may also benefit other patient groups in the future.

Drug Absorption in Patients with a Short Bowel

Uchu Meade, Nadia Gabriel, Roshni Patel, Maryam Clark, Pritha Singh, Jeremy M.D. Nightingale, and Richard Ng Kwet Shing

Key Points

1. The movement of a drug in the body (pharmacokinetics—absorption, distribution, metabolism and elimination) is altered in patients with a short bowel or small bowel disease due to a reduction in the surface area for drug adsorption, altered gastric or luminal pH (so preventing ionisation), a loss of the specific area where drug absorption takes place and/or reduced drug metabolism within the intestinal wall.
2. Many physicochemical properties influence absorption of an oral drug. These include its: solubility; stability; particle size; dissolution rate; salt form; acid dissociation constant (pKa); lipophilicity; pH of ionisation; polymorphism and molecular weight.
3. A good understanding of the patient's gastrointestinal anatomy and physiology, and the use of basic pharmacokinetic principles should ensure the prescribed medication elicits a pharmacological response.
4. Caution should be used with drugs that are efficacious within a narrow therapeutic range.
5. A knowledge of the biopharmaceutical classification system (BCS) class helps predict absorption of oral drugs. A drug with high solubility and high permeability (Class I) are absorbed quicker and therefore achieve much faster (time to maximum drug concentration (Tmax)) and higher blood concentrations (Cmax) so there is likely to be some absorption even with a very short bowel.
6. Lipid soluble drugs need a long length of bowel to be absorbed so are likely to be poorly absorbed in patients with a short bowel.
7. The formulation of the drug being prescribed must be considered. One that readily forms a solution is optimal but often a medication that by-passes the upper gastrointestinal tract may be the best option (e.g., parenteral (injection/infusion), topical, buccal or rectal).
8. Carefully monitor the patient (sometimes with therapeutic drug monitoring, if available) for both the desired clinical outcome and adverse drug reactions. With appropriate additional qualifications, the core healthcare professions of the nutrition support team should be able to prescribe medication (in most countries).

Introduction

In many countries, with additional qualifications, the core healthcare professions of the nutrition support team (NST) may be legally allowed to prescribe medications. An understanding of how the prescribing of medications for patients with a short bowel (SB) differs from prescribing for patients who have a normal functioning complete gastrointestinal tract (GIT) is critical. The pharmacokinetics of drugs can be altered in SB patients and there need to be strategies that ensure that the desired pharmacological outcome is obtained from the prescribed drug.

This chapter gives a guide on how to better predict the degree of absorption of medications in this heterogeneous group of patients with a SB. Since there is little or no published information on the drug absorption of most individual medicines in patients with a SB (except warfarin, digoxin, cyclosporine, nortriptyline and procainamide [1]), it is necessary to apply basic pharmacokinetic principles to predict the absorption of oral medications (Table 1).

Table 1 Factors that influence drug absorption in patients with a SB (adapted [1, 2])

Physiological factors
Remaining small bowel length
Condition (integrity) of remaining bowel
Intestinal motility (e.g. fast gastric emptying in jejunostomy patients)
Area where drug is normally absorbed (intact and with good integrity)
Perfusion of the bowel
Presence of bile and mucus
Biotransformation through gut bacteria
Physicochemical properties
Formulation of drug (tablet, capsule, elixir, enteric coated etc.)
Rate/extent of drug absorption
Drug solubility (ability to for a solution) and dissolution time/rate
Stability
Particle size
Salt form
Acid dissociation constant (pKa)
Lipophilicity
pH of ionisation
Polymorphism
Molecular weight
Physiological requirement of drug (acid, alkaline, bile salts, enterohepatic recycling, ileal absorption, specific receptors, drug interactions, food)
Binding and localising in tissues

Introduction to Pharmacokinetics

The word pharmacokinetics is formed from two Greek words; *phamakon* meaning drug and *kinetikos* meaning movement [3]. Pharmacokinetics is often said to be the effect of the body on the drug whilst pharmacodynamics is the effect of the drug on the body. Pharmacokinetics follows the movement of medication through the body from intake or administration to excretion [3]. Pharmacokinetics has four main components:

- **A**bsorption (how the drug enters the systemic circulation)
- **D**istribution (where the drug is dispersed once in the circulation, including binding and storage)
- **M**etabolism (how it is transformed or inactivated)
- **E**xcretion (how it is eliminated from the body)

This forms the acronym ADME.

Pharmacokinetics provides a quantitative and temporal concentration profile of the drug in the patient. Clinical teams may use this to predict how likely a drug is to be adsorbed from the GIT of a patient with a SB.

When considering the pharmacokinetics of a drug, the first step is to identify if the drug is acting locally or systemically. Locally acting drugs are applied only to the areas where they are needed. These include nasal sprays, inhalers, eye drops and topical preparations. Topical medication is often prescribed to manage luminal GIT conditions such as ulcerative colitis (e.g. mesalazine or steroid suppositories or enemas). Systemic drugs are those that enter the blood stream/systemic circulation (from oral or parenteral routes) and are delivered via the circulatory system to the targeted site of action. Sufficient amounts of an active form of the medication must reach the site of action to elicit a pharmacological response. The target cells for some medications are within the lumen of the GIT (e.g. loperamide) [3].

Absorption and Bioavailability

The most common route of medication administration is oral, and the most common formulations are solid such as tablets and capsules. Alternatively, intravenous drug administration ensures that the entire dose enters the systemic circulation, with bolus delivery allowing for high drug concentrations to be rapidly achieved or continuous infusion used to give a more even and constant concentration and response. Only the intravenous route can achieve a desired plasma concentration very rapidly [3, 4] thus it may appear a desirable route for SB patients; however, there are disadvantages with this route:

1. Only a limited number of drugs are formulated for intravenous use.
2. Long-term intravenous access and its maintenance is needed for drugs requiring regular use.
3. The patient will require training on the safe administration of drugs and the disposal of used ancillaries.
4. There is a risk of sepsis and venous thrombosis.
5. In England primary care providers are not able to prescribe many drugs formulated for intravenous use and the additional ancillaries needed for safe administration.

Drug bioavailability is the amount of medication that reaches the systemic circulation, for example oral drug bioavailability is the amount of drug absorbed from the GIT. It ranges from 1, meaning 100% of the drug reaches the systemic circulation, to 0, meaning none of the drug reaches the systemic circulation [4]. Oral bioavailability is usually determined in early phase clinical studies and tends to be based on healthy male individuals. The given value for an individual drug is usually available from the pharmaceutical company that manufactures the drug.

The highest concentration is termed the maximum concentration, Cmax. The time that the maximum concentration is reached is Tmax. (Fig. 1) Both Cmax and Tmax are dependent on the rate at which the drug enters and is removed from the body [1, 4]. Drugs that reach their Tmax quickly tend to

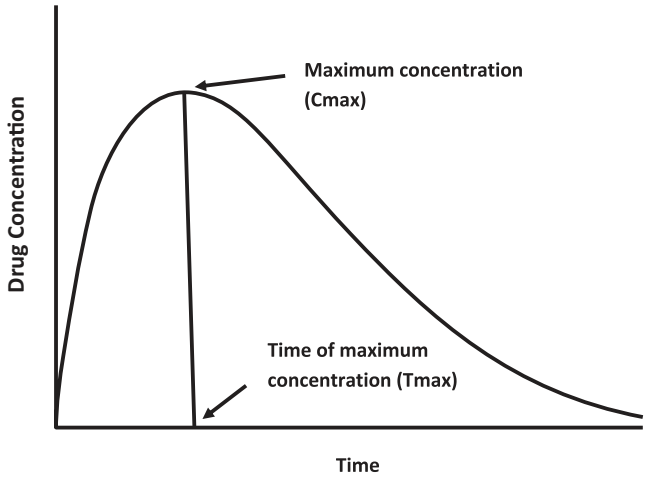

Fig. 1 Drug plasma concentration profile

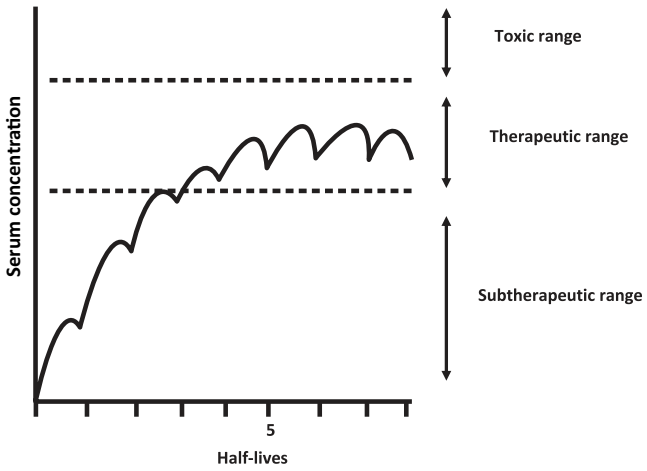

Fig. 2 Therapeutic range of a drug

be absorbed higher in the GIT so are more likely to absorbed in patients with SB (e.g., fluconazole's Tmax ranges from 0.5 to 1.5 h in the fasting state compared to amlodipine's range of 6–12 h post oral administration [5]).

Therapeutic Range of a Drug

The therapeutic range is the concentration range in which the drug is eliciting a therapeutic response [6]. If the amount of drug absorbed is too low then the concentration will fall below the minimum needed to elicit the desired pharmaceutical response and so result in treatment failure, too high and it results in toxic adverse effects (Fig. 2). As patients with SB have numerous additional factors that can alter the drug absorption quite significantly from day to day, drugs with a narrow therapeutic range should be avoided if alternative options are available. Drugs with a narrow therapeutic range are those where small changes in blood concentration can result in serious drug failure very quickly and should be closely monitored for adverse drug effects if prescribed (e.g. warfarin, digoxin, cyclosporine, phenytoin, aminoglycosides and lithium). A higher dose than recommended by the manufacturer, off label/off licensed, (see below) is often needed to compensate for malabsorption of a drug in SB patients. In this case great care must be taken to monitor for adverse drug effects; a list of these are provided by each drug manufacturer. All drugs have a therapeutic range, drugs with a wide therapeutic range are most desirable for SB patients as these have a wider margin of safety.

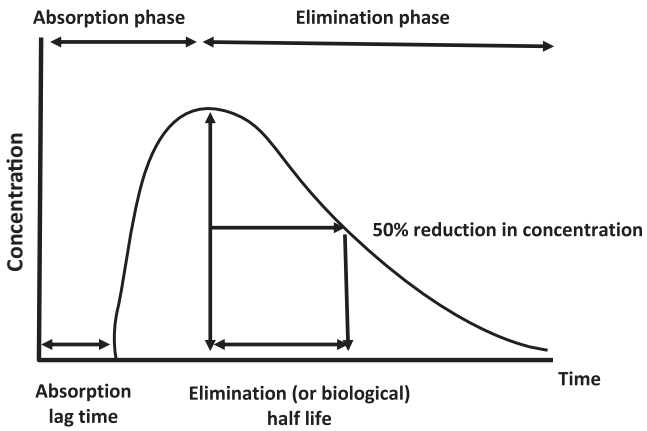

Fig. 3 Area under the concentration-time graph and half-life of a drug

The area under the concentration-time graph (AUC) is a measure of the total systemic exposure the drug measured [7]. The concentration profile before the peak is a measurement of how quickly the drug enters the circulatory system and after the peak would be a measurement of how fast the drug is eliminated from the body. The half-life (T1/2) is the time taken for the plasma concentration of the drug to fall by half [3, 4] (Fig. 3). With regular dosing and any required initial drug loading regimens, in line with the manufacture's recommendations, it takes approximately five half-lives for a drug to reach steady state (Fig. 2). Steady state is when the levels of a drug will stay within the therapeutic range for prolonged periods, if the dosing and the rate of absorption remains unchanged

[8]. Careful consideration needs to be given when prescribing drugs with long half-lives for patients with a SB, as reaching steady state is needed to achieve a pharmaceutical outcome (e.g., the concentrations of antibiotics need to remain within their therapeutic range to ensure optimal treatment).

Drug Absorption from the Gastrointestinal Tract

Formation of a solution is a prerequisite for drug to be absorbed from the GIT. For example, drugs in the solid formulations (tablets and capsules) must first be broken down to allow liberation of the drug from the protective outer casing—called *disintegration*. Once disintegration has occurred the drug can form a solution—called *dissolution*. However, different formulation systems pose challenges. Some capsules and tablets are designed to remain intact for several hours after ingestion and/or only to disintegrate at a specified pH (modified-release/sustained-release preparations) [4]. There are some capsules that have both rapid and prolonged release profiles, and some drugs that once liberated from the main protective capsule or tablet coating, are themselves coated for targeted purposes. For this reason, prolonged release preparations (e.g., enteric coated steroids) are best avoided in SB patients as they are likely to pass through the short length of gut unchanged and without being absorbed.

The rate of gastric emptying is altered in SB patients and so affects the rate of drug absorption. Rapid or increased gastric emptying (e.g., in patients with a high jejunostomy) (chapter "Physiology and Problems of a Short Bowel") may reduce the time available for disintegration and dissolution, and the exposure time to an acidic pH (if the patient is not taking a PPI). For example, when metoclopramide (which promotes gastric emptying) is administered with digoxin, the absorption of digoxin is reduced while the absorption of paracetamol, aspirin and tetracycline is increased. Drugs such as codeine and loperamide are often used in patients with a high output stoma to slow intestinal motility so slowing transit, with the aim of increasing small bowel absorption [9].

Ultimately, the rate of absorption mainly depends upon the time period the medicine is in contact with an appropriate region of cell membrane (Fig. 4). If a medicine does find itself at such an appropriate site that absorption can take place, assuming it has dissolved (is in solution), it can then permeate the cell membrane. In general there are four ways in which medicines can cross the cell membrane. These are via passive diffusion (directly through the lipid membrane); active transport (transporter mediated); facilitated passive diffusion (channel or carrier protein mediated); and pinocytosis (literally meaning cell drinking).

Passive diffusion is where molecules that are small enough can move from a region of higher concentration to a region of lower concentration through a selectively permeable membrane down a concentration gradient. This is the simplest form of transport, not requiring any energy or special transporters. As cell membranes are amphipathic, have both hydrophilic and hydrophobic regions, small lipid soluble molecules diffuse most readily. Most medicines are either weak acids or bases and therefore exist in either an ionised or un-ionised form when in solution. The un-ionized forms are usually lipid soluble and can diffuse readily across the cell membrane. However, the proportion of ionised and un-ionised forms present at any specific region is also influenced by the pH and pKa. Simplistically, medicines that are weak acids are better absorbed in acidic environments and weak bases prefer more alkaline environments, where their un-ionised forms predominate. Strong acids (pKa less than 3) and strong bases (pKa 10 or above) are poorly absorbed as they are fully ionised [4]. pKa is an acid dissociation con-

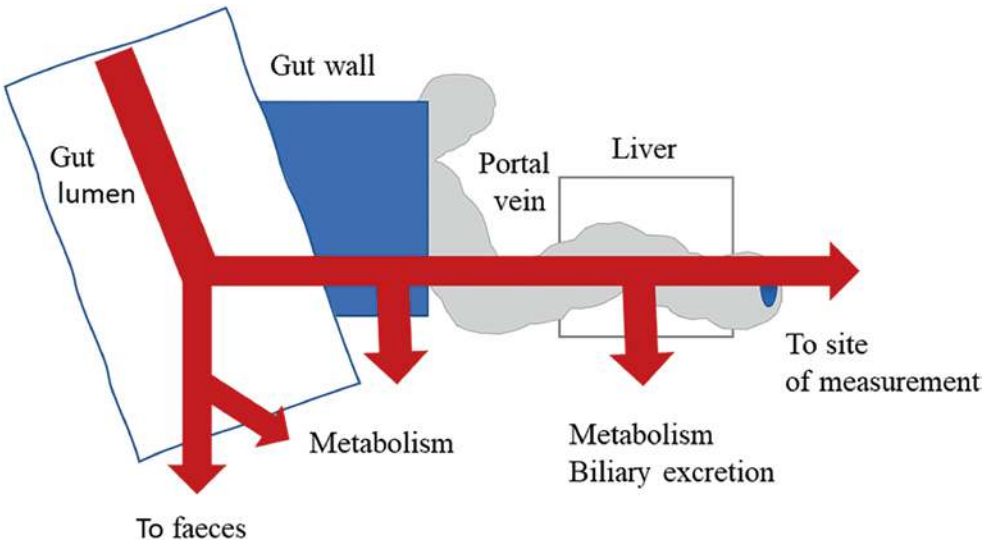

Fig. 4 Factors controlling drug absorption

stant and should not be confused with pH. Absorption will occur at the site in the GIT where the pH is optimal to allow sufficient drug molecules in the non-ionised form to be absorbed into the enterocytes [10]. In reality, the majority of a drug is actually absorbed from the small intestine due to the far greater surface area and epithelia specifically evolved to be more permeable. In relation to gases for inhaled medicines, the same principle applies, but here we refer to the gradient as partial pressures of the gas.

Active transport does require energy and occurs even against a concentration gradient. For molecules to utilise this method, the molecule must attach itself to carrier proteins or transporters found on the membrane surface. The rate of absorption is now dependent on the number of compatible transporters that are expressed on the surface of the membrane and are prone to saturation. Transporters come in many various forms, but the one thing they have in common is that they have evolved to extract those nutrients that we cannot synthesise ourselves. For this reason, most of the medicines that use this method of absorption tend to resemble these nutrients such as vitamins, minerals, amino acids, etc. For the same reason many transporters are only found in certain regions of the GI tract.

Facilitated passive diffusion can apply to those molecules that are not lipid soluble but seem to move through the membranes quite easily, again without the utilisation of energy down a concentration gradient. This is because membranes also contain various channels and carrier proteins that act like small tubes or funnels connecting the outside to the inside. These channels and carrier proteins exist to allow ionised nutrients to be absorbed and so certain medicines can borrow these channels in a similar way to active transporters. The rate of absorption is dependent on the number of compatible channels or carrier proteins that are expressed on the membrane.

Pinocytosis is where external products are engulfed through invagination of the cell membrane to produce a vesicle holding the product inside the cell. This route of absorption is rarely utilised in drug design.

Absorption of drug molecules is also determined by the mucous layer, the expression and regulation of tight junctions, and the presence of trans-porters and enzymes in epithelial cells [10]. The expression of tight junctions differs between the stomach, small intestine and colon thereby affecting the rate of passive paracellular drug absorption within each region. This difference results in a relatively leaky barrier in the small bowel (most leaky in jejunum and less so in ileum), and most efficient epithelial junctions within the gastric and colonic mucosa [10]. The intestinal absorption of a few drugs depends on carrier-mediated transport; levodopa is absorbed via a carrier which usually transports phenylalanine and fluorouracil is absorbed via a carrier which usually transports natural pyrimidines. Calcium is absorbed via a vitamin D-dependent carrier system and iron is absorbed in the jejunum via specific carriers in the mucosa [4].

The most common limiting factor to drug absorption via the GIT is poor aqueous solubility and permeability of a drug molecule. In order for permeation through the GIT membranes to occur, the active ingredient of the drug must first dissolve in gastrointestinal fluids. Hence, drugs which are poorly water soluble will display dissolution rate-limited absorption [11].

The upper small intestine has a relatively high blood flow and contains long villi, which increase the surface area, as well as having an optimal pH for drug absorption. Although drugs can be absorbed in other regions of the gastrointestinal tract, the upper small intestine is the site of most absorption. Minimal drug absorption occurs in the large intestine although some slow-release drugs are absorbed here, as well as drugs such as 5-aminosalicylates where their main target is the large intestine. Patients with a colostomy and an intact small intestine are unlikely to experience significant issues with drug absorption [9].

Studies conducted in rats have demonstrated that drug absorption from the colon is of little significance. The presence of efficient epithelial cell junctions within the colon is one explanation for the negligible paracellular absorption at this site within the gut. Also, due to the colon's active role in water absorption, the colonic contents are highly viscous which leads to decreased dissolution and diffusion through the membrane of the dissolved drug molecules. As a result of this, drugs released in the colon remain exposed to the colonic mucosa for prolonged periods compensating to some extent for the decreased surface area for drug absorption [12]. Consideration should be given when prescribing rectal drug formulations in SB patients if a systemic effect if desired.

Following bowel resection (+/− stoma formation) there is a relationship between remaining small intestine length and drug absorption. Patients with SB experience impaired absorption of macro- and micronutrients as well as fluids and drugs. Another important factor is the quality of the remaining bowel, particularly in patients with underlying disease. Patients with Crohn's disease may experience absorption issues despite having a normal length of remaining small intestine. In Crohn's disease active inflammation reduces villi contact and luminal permeability, and stricturing can prevent tablets and capsules from reaching the necessary absorption sites and in other situations may slow transit allowing more time for absorption [9]. Relieving the stricture in some cases can lead to changes in absorption as the transit times suddenly change, so it is important to always monitor drug efficacy and safety whenever an anatomical change occurs.

Worsening of inflammatory disease can also be a result of reduced bioavailability of oral drugs such as azathioprine and budesonide, therefore leading to increased inflammation, disease progression and further intestine resections. Coeliac disease patients, if untreated have villous atrophy and a reduced functional absorptive area so will have problems in absorbing some medications [9].

Biopharmaceutics Classification System

The Biopharmaceutics Classification System (BCS) is used by: the US Food and Drug Administration (FDA), European Medicines Agency (EMA), and World Health Organisation (WHO) to standardise data relating to the aqueous solubility (disintegration and dissolution) and absorption (permeability) of oral drug formulations made by different manufacturers. The drugs are classified in BCS according to solubility, permeability, and dissolution tests (Table 2). All drugs have had to be classified with this system since 2000.

Solubility: A drug substance is considered "highly soluble" when the highest single therapeutic dose strength is soluble in 250 mL or less of aqueous media over a pH range of 1–6.8 at 37 ± 1 °C. At least three pHs within this range, including buffers at pH 1.2, 4.5 and 6.8, should be evaluated, including solubility at the pH of lowest solubility if it is within the specified pH range and should demonstrate that solubility is maintained over relevant timeframes to accommodate the expected duration of absorption [13].

Permeability: A drug substance is considered to be "highly permeable" when the extent of the absorption (parent drug plus metabolites) in humans is determined to be ≥85% of an administered dose, based on absolute bioavailability or mass balance determination i.e., comparison of bioavailability between intravenous and non-intravenous (in this case oral) routes of administration. Alternatively for permeability non-human systems can be used (such as in-vitro culture methods—e.g., Caco-2 cell lines) [13].

A product is considered rapidly dissolving when no less than 85% of the labelled amount of the drug substance dissolves within 15 min in the following media: 0.1 M HCl or simulated gastric fluid or pH 4.5 buffer and pH 6.8 buffer or simulated intestinal fluid. The BCS Database is open access and can be found on the internet [13]

BCS Class I (high permeability and high solubility) medications are likely to have a lower time to maximum concentration and more likely to be adequately absorbed even in patients with a very short bowel. Examples include metoprolol and paracetamol. See Tables 4, 5 and 6 at the end and the BCS Database (which can be accessed via http://www.ddfint.org) for more examples of commonly prescribed drug's BCS class and Tmax.

Examples of Tmax and biopharmaceutical classification for many commonly used drugs are given in Tables 3, 4, and 5.

Table 2 Biopharmaceutics classification system

Solubility \ Permeability	*High*	*Low*
High	Class I	Class III
Low	Class II	Class IV

Table 3 Common antibiotics and predicted absorption in patients with a SB

Class	ABx	Absorption site	BCS	Tmax (h)
Penicillin[a]	Amoxicillin	Absorbed in the duodenum and jejunum, reduced absorption in ileum, not absorbed in colon [14]	Class IV (high solubility at lowest dose)	1.5
	Flucloxacillin	Unknown	–	–
	Penicillin V	Unknown	Class I	–
Cephalosporin	Cefalexin	Not absorbed in the stomach. Absorbed mainly in upper intestine: mainly in duodenum, reduced absorption in jejunum [15, 16]. (One paediatric study found 10–50% reduction in absorption in children with extensive small bowel resection, but therapeutic range was still achieved) [17]	–	1
Marcolides[a]	Erythromycin	Absorbed mainly in the duodenum [16]. Limited evidence suggesting some absorption in jejunum and ileum	Class II	1[b]
	Azithromycin	Absorbed mainly in the duodenum [18]	Class II	2–3
	Clarithromycin	Absorbed throughout whole GI tract [16]	Class II	–
Quinolones	Ciprofloxacin	Absorbed mainly in upper GI tract/duodenum, limited absorption in jejunum (higher doses maybe needed/consider alternative routes) [16, 19]	Class III	1–2
	Levofloxacin	Absorbed mainly in upper GI tract/duodenum, limited absorption in jejunum (higher doses maybe needed/consider alternative routes) [16]	Class III	1–2

Table 3 (continued)

Class	ABx	Absorption site	BCS	Tmax (h)
Tetracycline	Doxycyline	Mainly absorbed in the duodenum [20]	Class IV	2–4
	Minocylcine	Absorbed in stomach, duodenum and jejunum, but Less suitable for prescribing as per BNF due to higher risk of lupus-erythematosus-like syndrome	–	–
Others	Linezolid	Unknown. (absorption start in stomach and continued in small intestine, maybe limited if administered directly in jejunum) [16]	Class IV	2
	Trimethoprim/ Co-trimoxazole	Unknown. One paediatric study found 10–50% reduction in absorption in children with extensive small bowel resection, but therapeutic range was still achieved [17]	Class IV (high solubility at lowest dose)	1–4
	Metronidazole	Unknown, no studies (well absorbed in the small intestines) [16]	Class IV (high solubility at lowest dose)	1–2
	Rifampicin	Animal studies suggests maximum absorption in the stomach [21]	Class II	2–4 (on empty stomach)
	Isoniazid	Animal studies suggest poor absorption in stomach, mainly absorbed in duodenum, jejunum and ileum [21]	Class III	–

[a] NB: a small study in five children with SBS (>100 cm SB resection) found inadequate absorption of oral penicillin and macrolide to achieve therapeutic concentrations. Author suggested alternative routes of administration [14]
[b] Calculation based on erythromycin ethylsuccinate granules

Table 4 Common antifungal and antivirals drugs and predicted absorption in patients with a SB

Antifungal/antivirals	Absorption site	BCS	Tmax (h)
Fluconazole	Unknown (absorbs well in post-pyloric enteral tubes) [22]. Conflicting recommendations from various guidelines/sources regarding dose adjustments in jejunal administration [16]	Class III	0.5–1.5 (fasting state)
Voriconazole	Unknown (studies show similar absorption in administration via jejunostomy and oral administration) [23]	Class II	1–2
Aciclovir	Upper GI tract—potentially duodenum? (Poor bioavailability even in normal individuals—15–30%) [24–26]	Class IV	–

Table 5 Predicted absorption of drugs commonly prescribed (in the UK) to patients with a SB

Drug class	Drug name	Tmax (h)	BCS class	Comments
Analgesics	Paracetamol [27–29]	0.5–1	I	–
	Codeine Phosphate [27, 30]	1	I	–
	Morphine, liquid [29, 31, 32]	0.25	III	Morphine undergoes significant first pass metabolism in the liver resulting in a systemic bioavailability of approximately 25%
	Oxycodone [27, 33, 34]	1–1.5	IV	This is for immediate release oral formulations
	Fentanyl [27]	–	–	Undergoes significant first pass metabolism in the liver, buccal absorption is used to bypass GIT absorption
	Gabapentin [27]	2–3	III	Absorbed from the proximal small bowel
	Pregabalin [27, 35]	1	I	–
Antiarrhythmics	Bisoprolol [27]	1–3	I	–
	Atenolol [27]	2–4	III	–
	Digoxin [27]	1.5	III	Proximal small bowel
	Amiodarone [29, 36]	4.5	II	The Tmax is recorded when oral tablet administered with food
Anticoagulants	Warfarin [27]	3–6	II	–
	Rivaroxaban [29, 37]	2–3	II	Oral bioavailability increased when taken with food
	Apixaban [29, 38]	3–4	III	–

(continued)

Table 5 (continued)

Drug class	Drug name	Tmax (h)	BCS class	Comments
Anticonvulsants	Sodium valproate [29, 39]	5	I	–
	Phenytoin [27]	2–4	II	–
	Levetiracetam [27]	1–1.5	I	–
	Lorazepam [27]	2	I	–
	Carbamazepine [27]	2–liquid 6–chewable tablets 12–tablets	II	–
Antidepressants	Citalopram [27]	2–4	I	–
	Fluoxetine [27]	6–8	I	–
	Amitriptyline [29, 40]	4	I	–
	Mirtazapine [27]	2	I	–
	Venlafaxine [27]	2	I	–
Antiemetics	Cyclizine [29, 41]	2	I	–
	Ondansetron [27]	1–1.5	I	–
	Metoclopramide [27]	0.5–2	III	–
Antihypertensives	Ramipril [27]	2	I	–
	Doxazosin [27]	2–4	I	–
	Losartan [27]	1	II	–
	Lisinopril [27]	7	III	–
	Amlodipine [27]	6–12	I	–
Antihyperglycemics	Metformin [27]	2.5	III	The effective permeability at the proximal and distal small bowel is similar
	Gliclazide [29, 42]	2–4	II	–
Diuretics	Furosemide [27]	1	IV	Jejunum
	Bumetanide [29]	1–2	II	–
	Bendroflumethiazide [43]	2	–	–
	Spironolactone [27]	1–4	II	–
Sedatives	Zopiclone [29, 44, 45]	1–1.5	I	Time to peak plasma levels has been delayed in cirrhotic patients (from 2 to 4 h)
	Haloperidol [27, 29]	3–6	II	–
	Temazepam [27, 29]	1	II	–
	Midazolam [29, 46]	0.5–1	I	After oromucosal administration midazolam is absorbed rapidly
lipid-lowering medications	Simvastatin [27]	1–2	II	–
	Atorvastatin [27]	1–2	II	–
	Pravastatin [27]	1.5	III	–
Proton Pump Inhibitors	Omeprazole [27, 29]	0.5	II	Proximal to mid–small bowel
	Lansoprazole [27]	2	I	–
	Esomeprazole [27, 29]	1–2	II	Proximal small bowel
	Levothyroxine [27]	2	III	Jejunum
Others	Alendronic Acid [27, 47]	1	III	Better absorbed from jejunum than the duodenum

Table 6 Pharmacokinetics of loperamide formulations [68–72]

Preparation	Onset of action (h)	Half-life (h)	Cost for 2 mg dose (£)
Loperamide syrup 1 mg/5 mL	1	11	0.11
Loperamide capsules	1	11	0.04
Loperamide tablets	1	11	0.05
Loperamide melts	1	11	0.76

Drug Formulations and Routes of Administration for SB Patients

Due to the difficulties of obtaining good oral absorption in SB, alternative routes or methods often need to be considered. When switching from one route of administration or formulation to another, there are potential issues which need to be considered (e.g., with or without food, avoidance of certain foods etc.) and additional monitoring may be needed.

For some medications such as mesalazine, the release profile and therefore the desired effect of the medication differs between brands. For example, Asacol® is released in the terminal ileum and large intestine whereas Pentasa® begins to release from the duodenum, therefore depending on where the desired effect is intended can be affected by the brand of medication prescribed. Brands may also have differences in their licensed indications therefore may not be licensed to be prescribed for the same indications as other brands of the same active drug.

Switching formulations are often made with good reason, for example swapping to liquid preparations can help in administration via an enteral tube and reduce the chances of the tube becoming blocked compared to the administration of crushed tablets. Also, as mentioned above, in SB switching from a modified release to an immediate release formulation allows for better absorption, but switching may lead to dosing changes and potentially more frequent drug administration.

Another difference between various brands of the same active drug or between formulations of the same drug of the same brand are the excipients. Excipients are the constituents of a drug apart from the active substance. These can include fillers, disintegrants, lubricants, colouring, antioxidants, preservatives, adjuvants, stabilisers, thickeners, emulsifiers, solubilisers, permeation enhancers, flavouring, aromatic substances etc., as well as the constituents of the outer covering of the medicinal products, e.g. gelatine capsules [48]. Excipients change when switching from one formulation to another and some of these excipients may not be well tolerated by patients. For example, when switching to liquid preparations, some may contain sweeteners such as sorbitol which can worsen high output stomas, or they may contain alcohol which may not be appropriate for some patients due to their religious beliefs.

Oral bioavailability of medicines can also change when switching from one formulation to another. For example, digoxin tablets and liquid are not bioequivalent therefore dose adjustment may be required. In practice this change is made safer as digoxin levels are closely monitored, however this is not always the case with other drugs. When switching from oral opioids to topical patches adequate pain relief must be maintained. Often a dose reduction is required when switching from oral opioids to patches and this can lead to a subtherapeutic effect [49].

Alternative Routes of Administration in SB Patients

When switching routes of administration (e.g. between oral to oro-mucosal, transdermal, rectal, parenteral, etc.) or formulations of the same drug or to a different drug it is important to ensure the desired clinical effect is still achieved. The switch must be done carefully while understanding the pharmacokinetics of the medication, so the correct dose is prescribed. Once a change is made, monitoring for side effects and efficacy is also important and comes under the prescribing responsibilities.

Oro-mucosal Route

The oro-mucosal route of drug delivery involves two methods, buccal and sublingual.

The buccal mucosa lines the inner cheek and is made of a thin layer of keratinised and non-keratinised epithelia. Drug absorption occurs through the non-keratinised sections of the mucosa. Buccal formulations are placed in the mouth between the upper gums and cheek and absorption into the systemic circulation occurs via the brachiocephalic vein [50].

Some drugs are extracted and metabolised to inactive forms by the liver and sometimes the GIT wall, this is known as first pass or presystemic metabolism. This results in reduced oral bioavailability which can be problematic in patients with SB who already experience reduced absorption after oral administration. Drugs that undergo first pass metabolism include levodopa, propranolol, and verapamil [4].

The advantages of the buccal or sublingual route are that drugs avoid hepatic first pass metabolism as they are absorbed straight into the systemic circulation. The extensive blood supply and permeable membranes make the oro-mucosal route an attractive one for drug delivery. Onset of action is rapid, for example in the case of glyceryl trinitrate in angina. Drug delivery can be better predicted as there is avoidance of numerous pH changes that would be encountered as the drug travel through the gastrointestinal tract. Administration is easy and more appealing to patients in comparison to injections, for example administration of buccal prochlorperazine for nausea and vomiting compared to intravenous cyclizine, which is often used in the UK [51]. If longer term antiemetics are required, buccal prochlorperazine is considered when oral tablets have either not worked or not been well tolerated by patients. In general, using the buccal route can avoid changes in gastrointestinal motility and gastric secretion which can be associated with nausea [52].

Problems can occur however as absorption through this route may be erratic due to the production of saliva which can wash away the drug thereby reducing contact time. Taste

or local irritancy can affect patient adherence. Large, hydrophilic molecules are often not permeable through the membrane and therefore not suitable via this route [51].

The availability of an oro-mucosal formulation option may not automatically mean the drug is absorbed through the buccal or sublingual route (e.g., loperamide and omeprazole). Such preparations result in the disintegration and dissolution only starting in the buccal cavity with the aim of increasing time for absorption and or contact time with the target receptors in the gut, when the drug is in solution [53, 54]. However, drugs such as fentanyl are absorbed directly from the buccal cavity so avoiding first pass metabolism by the liver [55].

Transdermal

The transdermal route of administration is often more desirable to patients as it avoids the oral route altogether, therefore reducing the daily pill burden, reduced GIT absorption issues and potential for GIT side effects of medications is reduced. This route is particularly useful for patients with SB where taking oral medications can cause nausea and vomiting or in whom bowel transit time is too short and therefore the drug is not absorbed. This route of administration is usually in the form of creams, ointments, gels or as patches applied directly to a non-hairy part of the skin which can be hidden under clothing. The pharmacokinetic profiles for medications via the transdermal route provide fewer peaks than with the oral route therefore reducing occurrence of toxicity [56]. Not many drugs can be administered via this route as the drug needs to pass through several layers of skin before it reaches the dermal layer where it can then enter the systemic circulation. The two routes through the skin are intercellularly, usually lipophilic molecules, or intracellularly, usually hydrophilic molecules [56].

For example, in SB, the oral route for opioids is not always effective therefore some patients may be prescribed analgesia via the transdermal route in the form of patches. It is important to note that when switching from an oral formulation to patches, dose modifications may be required. Opioids tend to be the most common class of drug prescribe for SB patients using the transdermal formulation route. Available transdermal preparations, such as fentanyl and buprenorphine, are not suitable for acute pain or in patients whose analgesic requirements are changing rapidly because the long time to steady state prevents rapid titration of the dose. The total daily dose of oral morphine can be switched to an approximate equivalent strength of fentanyl and buprenorphine patches. For example, morphine salt 12 mg daily is approximately equivalent to a buprenorphine 5 μg patch and morphine salt 20 mg daily is approximately equivalent to a fentanyl 12 μg patch. However, when switching due to possible opioid-induced hyperalgesia, the calculated equivalent dose of the new opioid should be reduced by one-quarter to one-half [57, 58].

Another advantage are that formulations of buprenorphine transdermal patches are available as 72-hourly, 96-hourly and 7-day patches. It is important to note the buprenorphine patches come in various brands which all have different pharmacokinetic properties, and this should be taken into account if a patient is to switch from one brand to another [58].

When evaluating the analgesic effect, the patch should be worn for 24 h before making a change to allow for the gradual increase in plasma concentration (e.g. of fentanyl) and previous analgesic therapy should be phased out gradually from the time of first patch application as it can take 20 h or more for the plasma-fentanyl concentration to decrease by 50% [57, 58]. Patients should be warned to remove old patches when placing a new patch as the old patch may continue to provide sub-therapeutic doses of the drug in addition to the new patch and could lead to overdose. In addition changes in temperature have been known to increase drug absorption, with pyrexia, hot bath or sauna or the application of heat to the patch increasing local skin blood flow and hence increase absorption of the drug leading to overdosing [59].

When conventional treatment does not work an alternative analgesia to opioids is a lidocaine patch. However, lidocaine medicated plasters are only licensed for neuropathic pain associated with post-herpetic neuralgia as there is not enough evidence on lidocaine to support neuropathic pain (on its own) or for management of any other pain both acute or chronic but has been used in SB patients. This use is off label/ off license.

Parenteral Administration

Parenteral refers to administering medications without going through the digestive system. The word “parenteral” comes from the roots ‘para-’, or ‘outside of’, and ‘-enteral’ which refers to the alimentary, or digestive, system. The most common parenteral routes of drug administration are intravenous, intramuscular and subcutaneous [60].

The advantages are that it can be used for drugs that are poorly absorbed, degraded, or ineffective if given orally and has predictable pharmacokinetics in SB patients, intravenous administration provides immediate quick onset of action with 100% bioavailability. However, it is invasive, can lead to bruising, bleeding and blood clots at the infusion site. The patient will also need to be trained on how to administer and reconstitute the medication at home, organise repeated visits to a healthcare professional or, if available, a home visit by a healthcare professional may need to be organised to aid

administration and compliance. Intravenous access will need to be installed and maintained. It may also require additional medications and ancillaries to be prescribed such as water for injection, sodium chloride infusion bags, syringes, etc. The patient will also need to adhere to strict aseptic technique, which can be tricky in a home environment. Moreover, considerations need to be made based on the patient's physique as intestinal patients tend to be underweight and malnourished and this can affect the suitability of injecting for example, subcutaneously which is injected into a fatty area of the abdomen or upper thigh and in the muscle if prescribing an intramuscular injection. Other considerations include physical ability and dexterity that may be exacerbated by conditions such as arthritis.

Specific drugs that are often utilised in SB are the somatostatin analogues such as octreotide and lanreotide and are used off label/off license for controlling high output stomas, which are administered as injections. However, care must be taken as the use of octreotide in intestinal failure patients can have disadvantages. The clinical response can be unpredictable, it increases the patients risk of developing cholethiasis, it has been suggested that it may affect intestinal adaptation post-surgery, postprandial hypoglycaemia has been reported and injections can be unpleasant for patients [4]. Furthermore, it has been suggested that macronutrient absorption may be impaired by somatostatin in patients with SB, by inhibiting glucose absorption and pancreatic enzyme secretion hence, somatostatin analogues are only considered for patients when other strategies have not been effective, in reducing a high output [60, 61]. As lanreotide is a more expensive medication and is being used off label/ off-license in this situation and it is often not possible to obtain locally. Therefore prescribing, cost and logistics will rest with the initiating specialised intestinal rehabilitation team, in the UK. These considerations need to be made when trying to manage a high output stoma that is not responding adequately to conventional treatment.

Rectal

While the rectal route is available for some patients, it may not be available for many SB patients due to previous surgical procedures where the rectum has been removed. Rectal drug administration can be erratic and less reliable due to difficulties in drug retention particularly if a patient is suffering with diarrhoea or loose stools. It is also reported that only 50% of drug absorbed via the rectum undergoes first pass metabolism as the upper part of the rectal venous blood supply is connected to the portal system into the liver, whereas the lower part is directly connected with the systemic circulation. This is just an approximation as it may also depend on the formulation of drug used, which tends to be as either a solution or suppository. When considering the rectal route it is important to check if switching is equivalent, for example with carbamazepine, 100 mg tablets are equivalent to 125 mg of suppositories. In general most drugs will not achieve the same plasma levels when equivalent doses are given rectally compared to the oral route, but if oral delivery is proving to be a real concern, then the rectal route can be very useful [62]. Additionally, consider monitoring drug levels when doses have been changed or if there is concern about under or over-dosing [63]. Drugs commonly given rectally for a systemic effect include analgesics (paracetamol), antiemetics (prochlorpromazine) and antibiotics (metronidazole).

Changing the Formulation

Altering a licensed drug formulation can be considered to help improve drug absorption. Often crushing and dispersing tablets in water or opening capsules and dispersing the contents in water before administration are tried. The theory is to start the disintegration and formation of solution sooner.

However, alteration of the dose form can cause risk to healthcare workers. For example, with cytotoxic medications crushing can expose healthcare workers to aerosolization of the powder therefore this should be avoided. Crushing a tablet can cause instability of the medication particularly if it has a coating to protect it from light or the acidic environment of the stomach. This could lead to degradation of the drug or irritation in the body due to release of irritants from the dosage form. Alterations can cause changes in bioavailability and this is important to consider with narrow therapeutic range medications such as digoxin or phenytoin. Also, administration via an enteral tube can increase the chances of the tube becoming blocked [64]. It is always advisable to discuss any consideration to alter a drugs standard delivery method with the local pharmacist.

Classes of Drug Prescribed for SB Patients

Antisecretory Drugs

Acid production may be increased (gastric hypersecretion) in patients with a short bowel SB. High levels of gastric acid can raise the amount of secretions entering the shortened bowel, and interfere with absorption. Drugs that reduce gastric acid secretion reduce jejunostomy output. Omeprazole is readily absorbed in the duodenum and upper small bowel, but if less than 50 cm of jejunum remains, it may need to be given intravenously. Proton pump inhibitors, such as pantoprazole intravenous, are commonly given to patients with a jejunostomy for long term administration; but may increase the risk of osteoporosis, so should maintain an adequate intake of calcium and vitamin D [65, 66].

Antiemetics

Nausea and vomiting is often experienced by patients with SB. All formulations of cyclizine are often prescribed for SB patients, e.g., intravenous, subcutaneous, intramuscular and oral. Cyclizine is licensed for the treatment or prevention of nausea, vomiting and labyrinth disorders including vertigo and motion sickness. It is a class 1 drug in the biopharmaceutical classification which means it has high permeability and high solubility; hence most SB patients will achieve a pharmacological benefit with the oral formulation. However, all formulation of cyclizine can cause euphoric and hallucinatory effects and there have been reports of misuse and abuse of cyclizine. Cyclizine can also damage central and peripheral lines and increase episodes of catheter-related blood stream infections. For this reason, antiemetics such as ondansetron ($5HT_3$ antagonists) are preferred and are as effective as cyclizine (H_1 antihistamine), although more expensive and commonly causes constipation [67].

Antimotility Drugs

When considering other formulations, it is also important to think about whether the new formulation is a better alternative or not. While switching from capsules or tablets to liquids may be easier for enteral administration or in those who find it difficult to swallow, it may not always be suitable. For example, with loperamide for treating high output stomas, an efficacious dose often requires many tablets or capsules, 2 mg are the only strength available in the UK, and patients often complain of seeing capsules being excreted whole into their stoma bags. Switching to liquid loperamide may sound attractive, however the volumes required to achieve the same dose can be significant which could worsen the output. Loperamide liquid may also contain sorbitol that also worsens outputs due to its laxative effect. Often the alternative is to open capsules and dissolve the powder in a small amount of water. This would be an unlicensed form of administration as opening the capsules is not covered in the manufacturers licensing of loperamide capsules. Both options would be unlicensed however by using the capsules, the clinical outcome is more likely to be positive and costs can be reduced. One equivalent dose of liquid loperamide would cost more than double the price of an equivalent capsule dose, see Table 6.

Off Licensed Medicines

An off licence (or "off label") medication is one that is prescribed in a way that is not covered by its product license e.g., indication(s) and dosing regimen(s). A company must have a product license to advertise and sell a medicine, also known as a marketing authorisation. In the UK this is given this by the Medicines and Healthcare Products Regulatory Agency (MHRA), various national regulatory authorities or the European Medicines Agency (EMA) in Europe, and in USA by the Food and Drug Administration (FDA). The licence is often referred to as the label of the drug, hence the term off label. An unlicensed drug has no product license/marketing authorisation.

If the desired pharmacological affect is not being achieved from the prescribed drug, as per its licenced dosing regimen, first it is worthwhile determining if there are alternative drugs that can be used as per their licence before considering off licenced use or using an unlicensed drug to achieve the desired effect. There must be governance in place when prescribing both off licensed and unlicensed medication or routes, to protect the patient and the prescriber. There may be variations in local procedures in prescribing and obtaining off licensed and unlicensed medications. The prescriber holds greater legal responsibilities when prescribing off licensed/unlicensed medications and should monitor the drug's therapeutic efficacy and safety. Cost may be a determining factor in choosing a treatment. There should be clear documentation of off licensed and unlicensed use. This should include a rationale for the choice of drug, governance procedures followed, monitoring, a prescribing plan and documentation of discussions with the patient about risks and benefits [73].

Distal Administration of Medicines

Information on the distal administration of medications is poor and needs further research. Understanding the pharmacokinetics, and the individual properties of a drug help us understand how a drug may be affected by distal administration. As it is unlikely that manufacturers have tested this method during the licensing process, it would be classified as an unlicensed route, and therefore, a clinician recommending this method of drug administration would do so outside of a its license.

There are several factors to be considered if using distal administration; available drug formulations, the manufacturer's intended site of drug absorption, the anatomy of the distal stoma, consequences of potentially bypassing hepatic metabolism, and mechanisms for monitoring the drug's effects (chapter "Distal Feeding and Hydration").

An important element to consider is the distal stoma site location, as this will aid understanding and determine whether the drug will be effectively absorbed/elicit its desired effect. Distal administration of a medicine into an ileostomy or colostomy will differ considerably to a jejunostomy that is in close proximity to the DJ flexure, for exam-

ple. As the latter is further up the GIT, the increased downstream GIT length and surface area will enable a drug to go through dissolution, absorption, and first-pass hepatic metabolism, which may be required for certain pro-drugs i.e. those that require metabolising to be converted to its active form. Distal administration into a colostomy may only be beneficial for drugs that are intended for release into the colon which may be the site of activity.

Knowledge of the available drug formulations is important, so that drug dissolution principles can be considered. A solid tablet or capsule cannot be directly administered via a distal stoma.

Drug efficacy principles are based around improving dissolution in the stomach or faster absorption of the active ingredient throughout the GIT, or both [74]. If the disintegration or dissolution in the stomach is bypassed, for distal administration to be an effective route, the drug needs to be administered in a dissolute form to allow absorption to occur; this may be as a liquid preparation, crushed and dissolved tablets or using the IV form enterally (the latter two options being unlicensed routes).

An awareness of the proportion of remaining small bowel is also important as this will affect the amount of drug being absorbed, and hence undergoing hepatic first-pass metabolism. Where absorption and hepatic first-pass metabolism is expected to be affected, it would be prudent to closely monitor a patient's response to their medication both short and long-term.

It is also important to ensure that patients are monitored for drug effect and/or toxicity. Some drugs have measurable effects, for example, measuring a patient's blood pressure indicates that the antihypertensive prescribed is sufficiently controlling the blood pressure. Other drugs however, do not possess outwardly 'measurable' effects, and so will require another form of monitoring. This is also important in patients who are established on a drug via the enteral route, and then converted to administration via distal route, as this will require re-establishment of clinical effect/benefit, due to a potential shift in absorption site and concentrations.

Drugs that are classified as having a narrow therapeutic index, i.e. narrow window between the effective dose and the dose at which they produce adverse toxic effects, are regularly monitored by blood sampling [75]. This ensures that patients are not put at risk and the dosing is within acceptable limits. However, this requires accurate timing of testing and relying on patients to adhere to monitoring requirements and implementing dose adjustments. This is a useful method to utilise wherever possible if considering administering medication distally. Consulting with local or national hospital laboratories as to what drugs they are able to monitor would be useful especially where the patient is also on high risk drugs, or there are concerns with absorption.

Chyme Reinfusion and Drug Absorption

Chyme is the mixture of the digestive secretions, bile salts, and pre-digested food that is transformed into absorbable nutrients by enzymatic digestion [76]. Medication taken orally would also be present in this mixture, and once in the upper small intestine, drug absorption begins to occur into the portal vein bloodstream to the liver, whereby hepatic first-pass metabolism takes place.

Chyme re-infusion (CR) is a technique used to artificially restore intestinal continuity between a proximal and distal stoma/mucous fistula [76]. The amount of chyme re-infused is an important factor to consider, and this depends on the purpose, or intended outcome, of CR. One purpose is to use CR as the main nutritional source, whereby the majority of the stoma content (chyme) is re-infused. Studies have shown that this is an effective alternative method to parenteral nutrition, with the majority of the patients enrolled in these studies being switched from parenteral nutrition to CR [77, 78].

In some centres or circumstances, only a small proportion of chyme, 50–100 mL for example, is re-infused; the purpose of this is to maintain the distal gut function and reduce atrophic changes; however, the patient will still require nutritional support using an alternative method.

Knowledge of the amount of CR is crucial in understanding how we may predict a drug will perform. Also, we must know what part of the bowel is removed, the bowel length upwards of the proximal and downwards of the distal stomas, and the anatomy of the two stomas.

Patients with a high-output stoma, taking oral medication, will have had careful monitoring and fine dose adjustment to ensure they are receiving a therapeutic drug dose. If they are eligible for a CR device, the drug(s) that were once discarded along with the stoma output will be re-infused, the patient will be re-exposed to the drug, and this extended exposure may impact the plasma drug levels and the dose response curve. A study looking into a novel device mentions how some patients recruited experienced changes to their medication absorption, for example, constipation requiring loperamide withdrawal, drowsiness requiring dose reduction of analgesic/anxiolytic doses, and a flare of trigeminal neuralgia post stoma creation that resolved on initiation of CR, which all indicate that increased drug absorption occurred [78].

Although these are only a handful of patients, they prove the concept that patients should be monitored in the acute phase, and an investment made into observing and adjusting medication doses such that adverse effects are reduced [78].

Box 1: Case Study—Heart Failure/High Output Stoma/Anticoagulation

A 62 year old woman has a high output ileostomy with approximately 2.6 L output over 24 h. She has dry oral mucus membranes, dark rings round her eyes and reduced urine output of 560 mL/24 h.

Events Prior to Reviewing Patient

Recent Medical and Surgical History

- 4th December—Pulmonary oedema secondary to acute coronary syndrome (ACS).
- 7th December—Reduced ejection fraction of 24% and impaired right ventricle (RV) function
- 10th December—underwent percutaneous coronary intervention (PCI) due to ACS, (Troponin 7113 ng/L on 05th December and 3669 ng/L on 07th December).
- 13th December—Developed new right unilateral weakness. CT Head showed a subacute infarct involving middle cerebral artery region.
- 18th December—One week history of pyrexia of unknown origin prompted CT scan of chest/abdomen/pelvis which showed an intestinal ileus in association with a suspected area of bowel ischemia in the distal ileum.
- 19th December—Emergency laparotomy, right hemi-colectomy, small bowel resection and formation of double barrelled ileostomy. Approximately 190 cm of small bowel (SB) remaining from duodenojejunal (DJ) flexure to a small bowel stoma.

Past Medical History

- 11 years ago—Non-ST elevated myocardial infarction (NSTEMI) and PCI
- 8 years ago—Myocardial infarction with a coronary artery bypass graft
- Asthma
- Type 2 diabetes

Current Medication—(No known drug allergies. Simvastatin caused nightmares)

Drug	Dose	Frequency	Route	Alternative for a high output stoma patient
Paracetamol	1 g	Four times daily	Intravenous	Not needed as not using enteral route
Omeprazole	40 mg	Twice daily	Intravenous	Not needed as not using enteral route
Loperamide	16 mg	Four times daily	Oral	Open capsules and sprinkle contents into water. 30–60 min before food
Codeine	60 mg	Four times daily	Oral	Not needed as very small tablets. Could switch to non-sorbitol containing syrup or linctus, 30–60 min before food
Aspirin	75 mg	At night	Oral	Use dispersible tablets, with food
Ticagrelor	90 mg	Twice daily	Oral	Oro-dispersible tablets available which can be dispersed in water or placed on tongue and swallowed without water
Rosuvastatin	10 mg	At night	Oral	Tablets can be crushed and mixed with water for administration
Sertraline	100 mg	At night	Oral	Tablets disperse in water within 1–5 min. They can also be crushed and mixed with food
Bisoprolol	2.5 mg	In the morning	Oral	Tablets can be crushed and mixed with water for administration. Tablets will also disperse in 1–5 min in water
Metformin	1 g	Twice daily	Oral	Consider switching to subcutaneous insulin as Metformin can exacerbate loose stools
Gliclazide	160 mg	Twice daily	Oral	Consider switching to subcutaneous insulin
Losartan	100 mg	Once daily	Oral	Tablets can be crushed and mixed with water for administration
Apixaban	5 mg	Twice daily	Oral	Tablets can be crushed and dispersed in water, glucose 5%, apple juice or puree Switch to Warfarin to allow INR checks and effective monitoring of anticoagulation Therapeutic drug monitoring for apixaban is now available from some specialist centres in the UK
Budesonide/ Formoterol Dry powder inhaler	200 µg/6 µg	Twice daily	Inhaled	Not needed as not using enteral route
Salbutamol 100 µg inhaler	100–200 µg	Four times daily when required	Inhaled	Not needed as not using enteral route

The reason for her high output stoma (HOS) was poor bowel quality despite sufficient small bowel length.

Biochemistry 1st February 2021

Investigation	Result	Normal range
Sodium	160 mmol/L	133–146 mmol/L
Potassium	3.2 mmol/L	3.5–5.3 mmol/L
Urea	15.7 mmol/L	2.5–7.8 mmol/L
Creatinine	63 mmol/L	44–80 mmol/L
Random urine sodium	28 mmol/L	<20 mmol/L indicates dehydration
C-reactive protein	0.8 mg/L	0–5 mg/L
Serum Osmolality	356 mOsmol/kg	275–295 mOsmol/kg. >300 mOsmol/kg can indicate dehydration

Fluid balance chart over last 24 h for 1st February 2021

In	Out
IV = 1000 mL sodium chloride 0.9%	Stoma = 2600 mL
NG = flushes post medication − 60 mL water	Urine = 560 mL
NG = Enteral feed 1000 mL over 24 h	
Total = 2060 mL	**Total = 3160 mL (negative 1100 mL/24 h)**

Physical examination/test	Findings
Abdominal system	Abdomen was flat and non-tender. No abdominal mass noted (if present may indicate tumour or sepsis) and no enlargement of the spleen or liver. Normal bowel sounds. No abnormal findings
Stoma assessment	Stoma pink, warm and healthy, no bleeding or break of skin barrier and no soreness. Stoma protruded approximately 1.5 in. from the skin and had a sealed see-through stoma bag around it. A finger inserted easily into the stoma with no stenosis. Stoma output was dark green/brown in colour and watery
Temperature	Apyrexial. But had been ≥37.8 °C over the last 2 days. (may suggest an underlying infection preventing the stoma output from settling). Regular doses of paracetamol were being taken and this may mask a temperature
Observation chart	Weight 65 kg, height 170 cm. BMI = 22.4 kg/m^2 NEWS = 1. No requirement of oxygen, and was stable with a heart rate of 93 bpm (could be increased due to dehydration or sepsis). Lying blood pressure was normal
Bloods & Urine sodium	Urine sodium was at the low end of the normal range, suggesting a degree of dehydration. Urea was raised and may suggest dehydration but the creatinine is within the normal range suggesting a large amount of protein has been broken down (a bleed or much oral or parenteral feeding)
Peripheral oedema check	Peripheral oedema can prevent optimal hydration. The patient had some pedal oedema which may be due to immobilisation post stroke. Alternatively it can represent excessive parenteral saline or general inflammation
Mucous membrane check	Dry or cracked mucous membranes indicate dehydration The tongue was dry, with no saliva around the teeth or tongue and the patient felt very thirsty
Cramps	No muscle cramps, (Muscles cramps usually reflect sodium depletion but may occur with hypomagnesaemia caused by a HOS)
Fluid balance check	Daily fluid balance checks and daily weight measurement are crucial when managing HOS patients. The fluid balance for the last 24 h showed a negative balance of 1100 mL/24 h
Urine check	Urine output was more than the minimum of 0.5 mL/kg/h. Urine colour was a dark orange

Considerations When Caring for This Patient Cohort

This patient has fluctuating fluid requirements due to both intestinal and heart failure, which depend on the output from her stoma. She may quickly become dehydrated or overhydrated if the incorrect amount of intravenous fluid is given to replace her losses.

According to the British society of gastroenterology (BSG) guidelines for the management of patients with a short bowel, there is further medication optimization which should be done for this patient. This patient is experiencing net loss of fluid and sodium, and so should be prescribed 1 L of an oral electrolyte mix, an unlicensed solution which leads to more sodium being absorbed from the bowel lumen [77]. These guidelines advise that a patient with 150–200 cm normal functioning SB should be able to manage their HOS with optimized medication and electrolyte mix [79, 80].

At this stage she is requiring IV fluids; however, the addition of electrolyte mix could help to reduce and ultimately prevent this requirement.

As the heart starts to fail, renal perfusion reduces. The kidneys respond to this by increasing renin production, leading to aldosterone production, which is consequently followed by sodium and water retention. Arginine vasopressin (AVP) is also released, further enhancing fluid retention, and stimulating thirst [81]. This stimulation of thirst will cause a patient to drink, which in this patient's case is detrimental to her hydration status as it will cause more losses from the stoma if hypotonic fluids are ingested.

It is necessary to consider the absorption of critical cardiac medication in this type of patient. Her anticoagulants and antiplatelet drugs are necessary to prevent another stroke or myocardial infraction. It is advised to look for alternate routes of administration of the medications that can avoid using the bowel, such as transdermal or intravenous or preparations which partly use the bowel such as sublingual or buccal. These drugs may need to be rationalised, such as switching to subcutaneous insulin to manage diabetes rather than metformin, which may cause loose stools. See the last column on the medication table which gives possible alternatives.

Nutrition teams should consider creating a care plan for their patient if they are to be discharged with intravenous fluid. A care plan provides guidance on deciding the volume of fluid required, it utilizes physical assessment skills to follow the plan appropriately.

Daily Monitoring Instructions

- On waking-up please empty your stoma bag and then weigh yourself and record your weight on your daily weight chart.
- Over a 24 h period, measure and record your intakes and outputs on your daily fluid chart.
- Monitor signs of dehydration by noticing whether you feel thirsty, experience any dizziness on standing, pass less urine than usual or whether your urine is darker than usual
- Monitor signs of over hydration by noticing whether you develop any worsening swelling of your ankles or shortness of breath after IV fluid.**Use the information in the following care plan to decide fluid requirements:**

Option A: Adequately hydrated

– Weight is stable – Not thirsty & passing adequate amounts of urine – No worsening ankle swelling	E.g. Give 0.5 L 0.9% saline with 10 mmol $MgSO_4$ three times a week (overnight) over 12 h Monday, Wednesday & Friday

Option B: Dehydration

• Weight loss of more than 2 kg – Feels thirsty, or – Passing less urine which is darker than usual, or – Feels dizzy on standing	E.g. Give additional 1 L sodium chloride 0.9% over 10 h

Option C: Over-hydration

• Weight gain of more than 2 kg – Worsening swelling of ankles, or – Feels short of breath	E.g. Do not give IV fluid until back to dry weight (only use 5% dextrose if any fluid has to be given)

Planned Follow-Up and Monitoring Including Applicable Timeframes

The outcome of additional electrolyte mix measured on any given day reflects the day it is taken. Therefore, 2 days shows two 24 h periods of fluid balance charts, etc., a useful timeframe to make any further changes. The electrolyte mix may need to be stopped if it is simply adding to the fluid loss via stoma output, indicating very poor bowel quality.

It is crucial to re-check the same blood investigations at the next patient review, with a priority to check serum sodium as this was markedly increased due to dehydration.

Distal Feeding and Hydration

Laurence Lacaze, Denis Picot, and Ronan Thibault

Key Points

1. Infusion of feed and fluids and/or proximal bowel content into distal bowel (ileum or colon) via a temporary loop enterostomy or an entero-atmospheric fistula may be used as the sole source of nutrition/hydration as an alternative to parenteral support. It is called 'distal feeding and/or hydration' (DFH).
2. Enteroclysis and chyme reinfusion with special pumps or devices are two techniques for DFH, and can be continued until surgical reestablishment of bowel continuity.
3. Distal feeding improves nutritional status and liver function, and avoids the complications of parenteral nutrition (especially central venous catheter infections and thrombosis).
4. DFH is safe, low-cost and easy-to-use in hospital and at home, providing contraindications (fistula, perforation or stenosis in the downstream small intestine) are taken into account.
5. DFH needs to be integrated into multidisciplinary care, handled by specialized trained teams, and should be included in patient's education to avoid technique failure.
6. Proximal and distal contrast studies of the bowel prior to starting DFH must be performed to ensure there is no disease, obstruction or leak present in the distal bowel.
7. Feed is delivered through a distal feeding tube using a polymeric or semi-elemental enteral nutrition solution, or chyme, and/or hydration by using fluid containing salt.
8. Besides technical issues, the main side effects of DFH may be abdominal pain and disturbed intestinal transit.
9. DFH acts by reducing upper gastrointestinal secretions and motility, increasing intestinal absorption capacity and thus proximal stomal/fistula output, leading to the reduction of the amount of nutritional/fluid parenteral support. These beneficial effects are driven by neural and humoral mechanisms, including the release of gut hormones by the distal small bowel.
10. DFH is making the surgical reestablishment of bowel continuity more likely to be successful (technically easier, faster post-operative recovery of function, lower risk of anastomotic leak).

Introduction

In the course of an intra-abdominal surgical procedure, several clinical situations lead the surgeon to perform a double (loop or double barrel) temporary enterostomy on the small bowel (e.g. Crohn's disease, mesenteric ischemia, peritonitis, fistulae, and anastomosis protection). Entero-atmospheric fistula (EAF) can also arise spontaneously as a post-operative complication of peritonitis or anastomotic leakage. Initially these conditions leads to type 1 intestinal failure (IF), and then become type 2 IF, especially when the stoma/fistula output is equal or higher than 1500 mL/24 h [1], and this lasts until the surgical re-establishment of digestive continuity. All these situations could lead to serious complications resulting in hospital readmissions (40–50%) [2, 3]: acute or chronic dehydration (18–29% of patients) [4, 5], renal failure [6], electrolyte disturbances, micronutrient and mineral deficiencies, and malnutrition, thus increasing healthcare-related costs [7] and affecting patients' quality of life. According to the clinical classification of the intravenous support (IVS) based on daily fluid [8], electrolyte and nutri-

tional requirements provided by parenteral route, in case of IF, most of these patients are in categories 3 and 4, defined by very high hydration and nutrient requirements [9, 10].

After such complicated surgeries, it is recommended to wait for at least three months from the last surgery to perform the surgical re-establishment of digestive continuity and stoma closure. During this time, nutritional support should be effective, at low-risk and sufficient to prepare the patient for this surgery. At this time, the current gold standard therapy indicated for IF patients until the surgical re-establishment of digestive continuity, is parenteral nutrition (PN) and/or hydration (IVS) [1]. However, home PN has its own morbidity and, in the absence of expertise, the risks of infectious, hepatic dysfunction, mechanical, and metabolic complications are increased [11]. PN has been associated with infectious and hepatobiliary (e.g cholestasis, steatosis and fibrosis) complications [12–14]. In many developing countries, PN is not available as it is considered too expensive or there are no home PN homecare providers [15].

Distal feeding and/or hydration (DFH) techniques, namely enteroclysis, and chyme reinfusion (CR), are alternative therapies to IVS for type 2 IF patients. Although IVS has long been the standard of care for IF, the use of DFH in patients with EAF or temporary intestinal enterostoma has been described by many authors for a long time [10, 16–18]. DFH by CR was first described by Etienne Levy in 1977 [16].

The scope of this chapter is to describe the technical principles of enteroclysis and CR, to overview their indications, contraindications and clinical benefits, and to give practical details for their use.

This chapter does not discuss the use of small volume bolus fees given once or twice daily into defunctioned bowel to help maintain anatomical structure and motility before a surgical anastomosis is performed (see chapter Insertion, Types and Care of Enteral Feeding Tubes).

What Is Distal Feeding and/or Hydration?: Definitions

Enteroclysis and CR are the two main techniques of DFH. To be eligible for DFH, patients should have a loop or a double-barrelled enterostoma or two stomas apart of the small bowel or an EAF, with access to the downstream small bowel (Fig. 1). DFH will be feasible only if the downstream small bowel can be catheterized.

Enterocutaneous fistula are aberrant connections between the gastrointestinal tract and the skin or atmosphere. They occur in 75–85% of cases after surgery and in 15–25% spontaneously [1]. Most close under medical treatment. EAF is an enterocutaneous fistula developed in a wound in the abdominal wall with a mucocutaneous continuity where the openings are visible as enterostomies. Closure almost always requires surgery.

Enteroclysis consists in infusing water, electrolytes, and/or enteral nutrition solution through an enterostomy or an EAF into the distal (downstream) small bowel. Fistuloclysis is enteroclysis through an EAF. The term enteroclysis seems preferable to fistuloclysis as it refers to the instillation of a fluid (-clysis) into the small intestine (entero-) regardless of the nature of the orifice, enterostomy or EAF, and the nature of the fluid, hydration, nutrition or both.

CR, also called "re-feeding enteroclysis", consists in reinfusing the chyme collected from the proximal stoma (from the upstream small bowel) through the distal stoma, into the downstream small bowel [9, 10, 14, 19, 20]. The chyme is composed of digestive secretions (including growth factors), nutrients from oral food and/or tube feeding and drugs. CR reestablishes the functional continuity of the anatomically present small bowel through an extracorporeal circulation of the chyme [16]. The CR and enteroclysis could be considered as enteral nutrition tech-

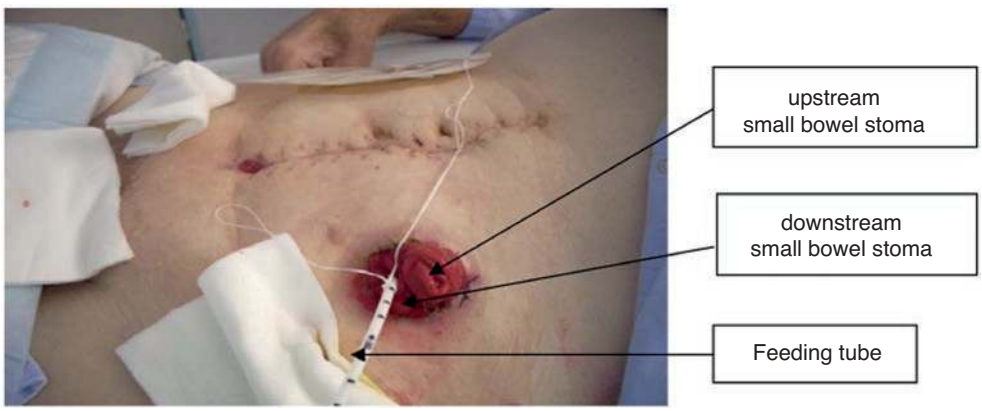

Fig. 1 Example of a temporary double enterostomy [Authorized reproduction from [19]]. The small bowel continuity is disrupted with two small bowel segments exposed to the abdominal wall: the upstream afferent segment, with impaired digestive and absorptive function, and a downstream efferent segment, totally deprived of digestive secretions, bowel flow and succus entericus. The feeding tube is inserted in the downstream small bowel, and is ready for enteroclysis or chyme reinfusion

niques [20]. It means that two options of enteral nutrition could be available in patients with IF. The first, our preferential one, consists in feeding the patient orally with pureed food and reinfusing the chyme into the downstream small bowel. If oral ingestion is insufficient, additional enteral nutrition is infused "en Y" in the CR tube or, rarely, by nasogastric tube or gastrostomy if present. The second is to use enteroclysis to directly infuse the enteral nutrition solution into the downstream small bowel, as is done for enteral nutrition by jejunostomy. The supposed advantages of the first is to keep functional all the digestion functions that prepare food into absorbable nutrients, to increase the intestinal absorption surface area, to restore the enterohepatic cycles of digestive secretions, certain nutrients and drugs and to restore entero-hormone secretions by ileal and colonic L-cells. However, to our knowledge, no study has compared both methods, so that it not possible to recommend one from another. Both methods achieve weaning from IVS by 90% or more. The choice between the two should be made based on the multidisciplinary team expertise and the availability or not of chyme reinfusion devices.

What Are the Indications and Contraindications of DFH?

The European Society of Enteral and Parenteral Nutrition (European Society of Clinical Nutrition and Metabolism) (ESPEN) has defined intestinal failure as the reduction of gut function below the minimum necessary for the absorption of macronutrients and/or water and electrolytes, such that intravenous supplementation is required to maintain health and/or growth [1]. Enteroclysis or CR are indicated mainly in type II IF. The ESPEN IF specific interest group defines three types of IF. Type I IF is defined by an acute, short-term and usually self-limiting condition. Type II IF is defined by prolonged acute condition, often in metabolically unstable patients, requiring complex multi-disciplinary care and intravenous supplementation over periods of weeks or months. Type III IF is defined by a chronic condition, in metabolically stable patients, requiring intravenous supplementation over months or years. It may be reversible or irreversible [1].

In case of temporary double enterostomy or EAF, the IF is type 2. DFH is particularly indicated in patients with type 1 and type 2 IF, and with EAF or double stoma with high intestinal outputs (≥1200 mL/24 h). ESPEN has endorsed repeatedly recommendations for using CR in this setting [21–23] and American Society for Parenteral and Enteral Nutrition (ASPEN) clinical guidelines published in 2016 [24] suggest the use of enteroclysis for enteral nutrition in patients with IF with double enterostomy or EAF. We propose in Fig. 2 an algorithm of decision for the nutrition support of patients with a double enterostoma or EAF.

Many people who have enterostomies have episodes of dehydration that require readmissions to the hospital for short stays during which they receive intravenous rehydration [2–5]. Because of the absorptive capacities of the colon, enteroclysis in the terminal ileal or colonic downstream segment of a mixture of water, salt, and bicarbonate is an alternative to intravenous fluids for hydration [25].

DFH is safe, low-cost and easy-to-use if some practical aspects and contraindications are well taken into account [15, 19]. Indeed, before starting DFH, there is a need to perform GI imaging, i.e. X-ray intestinal radiography or CT enterography to follow the progression of the contrast product. The aim is to ensure that the downstream small intestine is clearly shown and that there is no contraindication to feeding: fistula, perforation, occlusion or stenosis in the downstream small intestine. This will also allow the measurement of the length of the downstream small intestine: indeed DFH can only be offered to patients with a functional small intestine of at least 15 cm. To achieve GI imaging, a tube is introduced into the first 15 cm of the downstream small bowel; we advise to use a 14F polyurethane nasogastric tube or feeding gastrostomy (balloon of 5 mL max), and not a Foley® catheter because of the risk of ischemia if the balloon is inflated to 20 mL. The contrast product should be infused under real time X-ray imaging to check the luminal progression to the right colon [19] (Fig. 3).

DFH needs to be integrated into multidisciplinary care, handled by specialized trained teams, and should be included in patient's education, to avoid technical failure [19, 26]. Enteroclysis or chyme reinfusion are actually part of intestinal rehabilitation, especially for complex management of opened abdominal wounds or patients with high intestinal outputs [23].

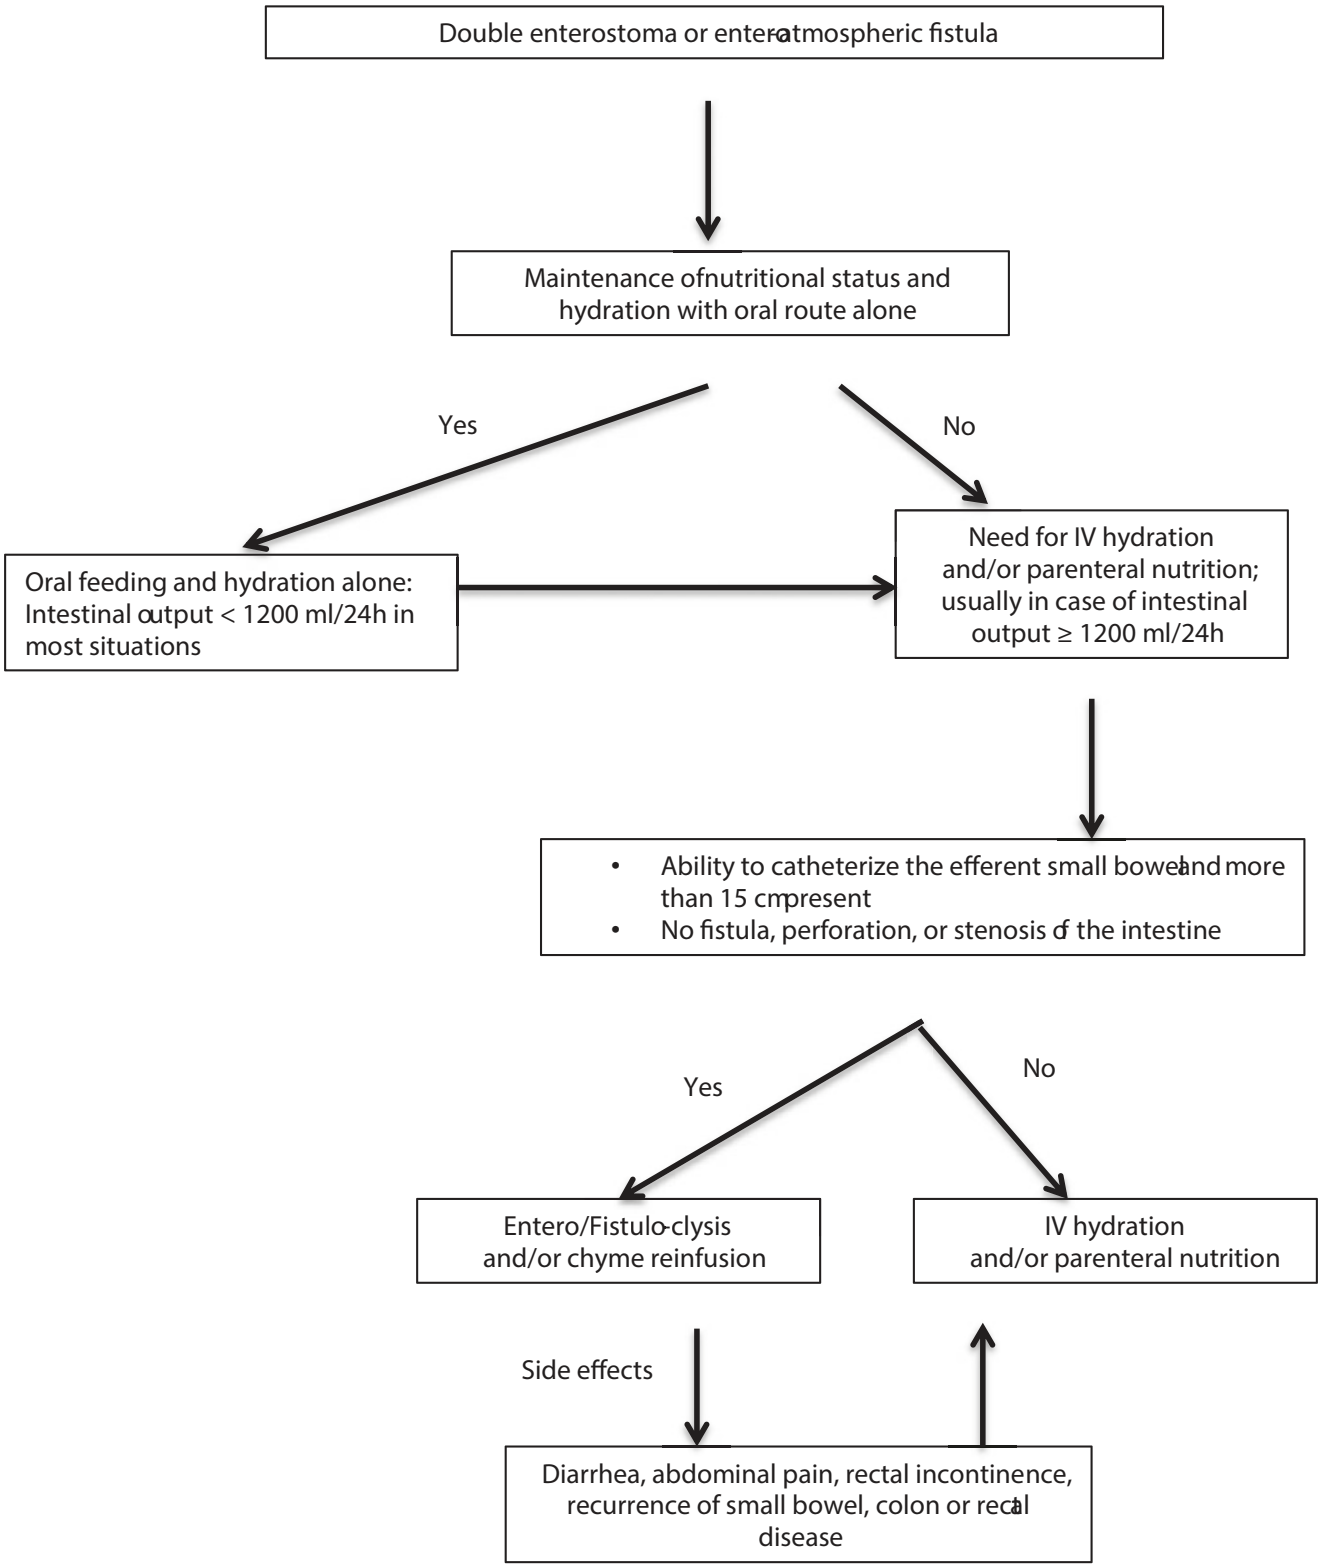

Fig. 2 Proposal for an algorithm of decision for the nutrition support of patients with double enterostoma or entero-atmospheric fistula. Parenteral nutrition would be chosen only if distal small bowel is inaccessible or diseased, or in case of uncontrolled side effects, making the distal feeding contraindicated. In every situation, the patient's agreement must be obtained

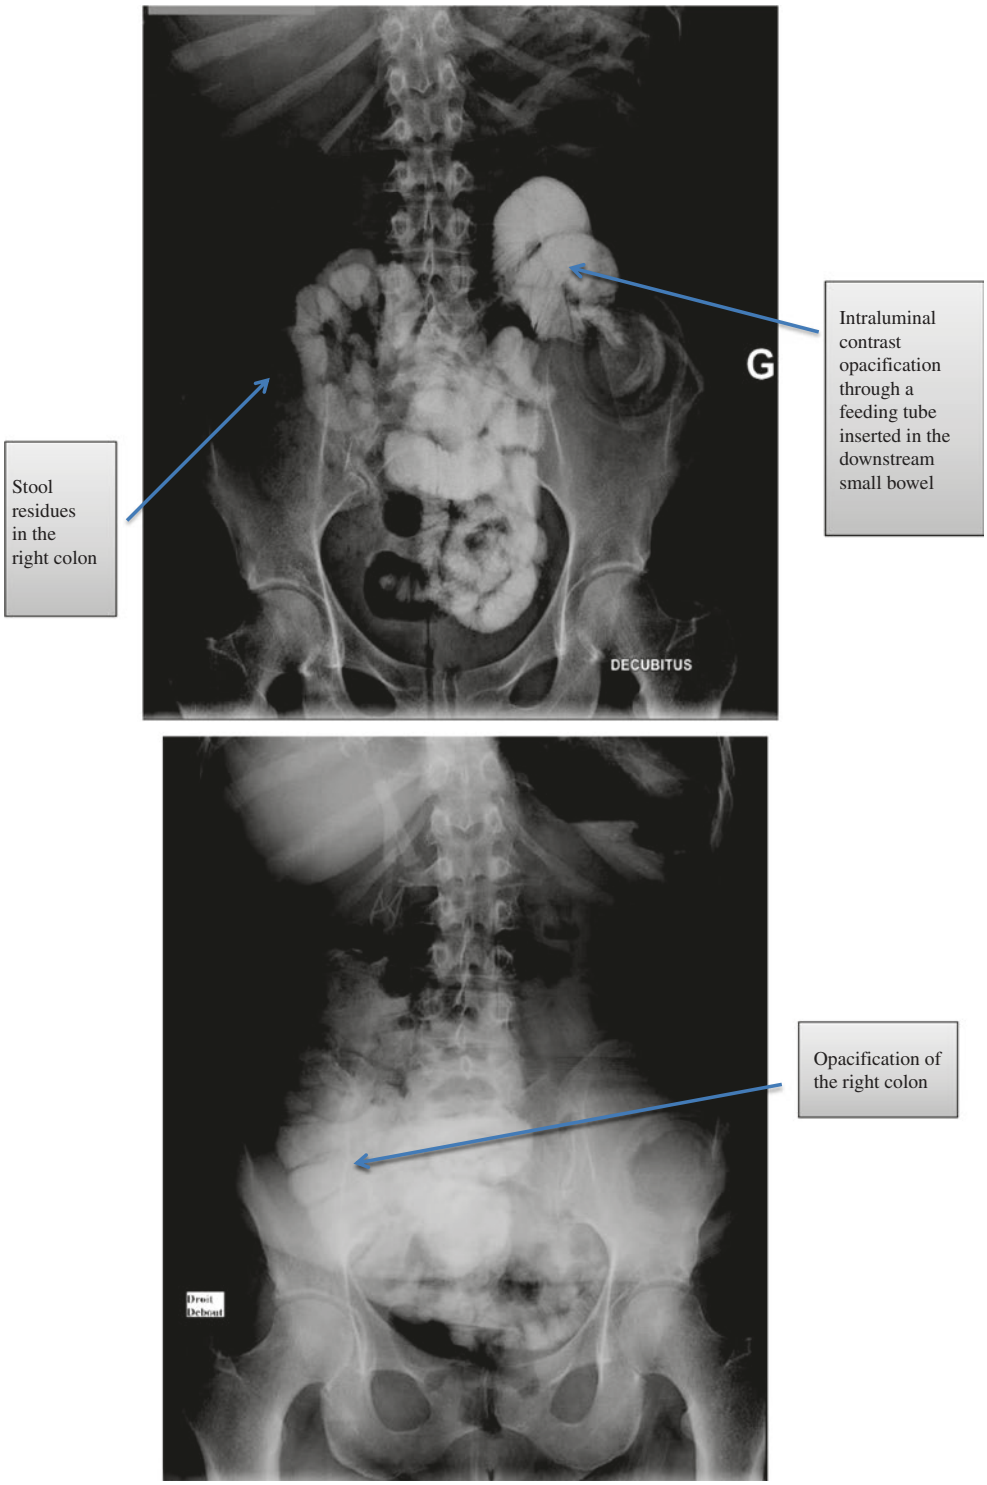

Fig. 3 Opacification of the downstream small bowel through a feeding probe. The presence of fecal residues in the right colon makes the patient at high risk of constipation or subocclusion. The administration of laxatives through the feeding probe is indicated, as well as the stop of anti-motility drugs. In the second image you could observe the progression of the intraluminal contrast into the right colon attesting that there is no proximal intestinal occlusion. The progression should be observed to the rectum (not shown)

Benefits and Side Effects of DFH

Enteroclysis, or chyme reinfusion performed with auto-regulated pumps can be performed until the surgical reestablishment of continuity and stoma closure. One of the first reported benefits of DFH is the reduction of the proximal small bowel output [16]. This is one of the reasons to quickly start DFH in patients with EAF or a high output stoma (≥1200 mL/24 h). DFH contributes to the improvement of nutritional status and liver function, and prevents parenteral nutrition complications, mainly central venous catheter-related infections and thrombosis, and liver complications

Table 1 Summary of the key clinical studies that evaluate the benefits of DFH in patients with intestinal failure

Author	Year	Study design	Patients (*n*)	Type of patients	Type of distal feeding	Main findings
Nagar et al. [15]	2018	Retrospective case series	35	Proximal stoma with a remnant upstream small bowel ≤120 cm	CR	Cost-effective and could effectively substitute PN
Picot et al. [9]	2020	Retrospective case series	306	Double entererostomy or EAF	CR	Improvement of nutritional status, citrulline, plasma liver tests, and feasible at home, weaning from IVS
Wu et al. [29]	2014	Retrospective case series	95	High-output upper EAF, particularly biliary fistula	DFH	Improvement of hepatic and nutritional parameters
Coetzee et al. [14]	2013	Retrospective case series	20	EAF	DFH	Feasible in selected patients with a proximal enteric fistula or stoma. Weaning from parenteral nutrition, reduction of IVS infectious. Adequate nutrition, water and electrolyte balance achieved without the need of PN
Cosnes et al. [27]	1990	Retrospective case series	10	EAF	DFH	Effective nutritional support. Weaning from IVS

CR chyme reinfusion, *EAF* enterocutaneous fistula, *EN* enteral nutrition, *EF* enteroclysis/fistuloclysis, *IVS* intravenous support

[9, 10, 13, 14, 17, 18]. Besides technical issues, the main side effects of DFH are transient abdominal pain, during the first few hours, and motility disorders (e.g. diarrhoea) [18, 19]. Table 1 reports the main clinical studies having evaluated the benefits of DFH in patients with IF.

Enteroclysis

Enteroclysis has many benefits especially in patients with a high-output fistula.

Cosnes et al. [27] performed an enteroclysis of an elemental diet in the distal small bowel in ten patients with a double enterostomy located between 10 and 95 cm from the duodeno-jejunal flexure. The length of the distal limb was 215 ± 58 cm. Five of these patients had undergone small bowel resections of more than 1 m. All patients were receiving parenteral nutrition. The jejunal losses averaged 3 kg/24 h. The enteral nutrition solution provided 31.9 ± 10.5 kcal/kg/24 h in a volume of 2860 ± 803 mL/24 h. Enteroclysis lasted for 39 ± 9 days until intestinal continuity was restored, 20 h/24 h. Patients had an oral diet. The digestive nitrogen absorption balance ($n = 6$) was positive between 5 and 15 g/24 h in all patients, despite nitrogen losses through the upstream segment. Sodium balance was positive in 9 patients, negative in one patient who required intravenous fluids. Downstream intestinal sodium absorption was measured to be between 176–297 mmol/24 h. Parenteral nutrition was discontinued in 9 patients.

Teubner et al. [18] included 12 patients with EAF, dependent on IVS for hydration balance ($n = 2$) or nutritional needs ($n = 10$), during a median of 7 (range 5–7) nights per week. Median length of proximal small intestine from the duodeno-jejunal was 105 (range 45–200) cm and that of the distal small bowel, 120 (range 75–400) cm. Patients had an oral diet. The median fistula losses were 1360 (range 690–3190) mL/day. Enteroclysis was made with a standard polymeric enteral nutrition solution ($n = 3$) or, if intolerance, a semielemental or elemental solution ($n = 4$ each). One patient did not tolerate the enteroclysis. Eleven patients were weaned from IVS after a median of 28 days.

In summary, enteroclysis is a safe technique and can replace IVS to maintain or improve nutritional status and it reduces the complications and costs of IVS and parenteral nutrition.

Chyme Reinfusion (CR)

CR consists in the chyme collection from the proximal stoma and reinfusion through the distal stoma within the downstream small bowel. In many case reports or short series publications, CR was performed with enteral nutrition pumps or sequentially with a syringe [19]. Nowadays, CR could be performed with specifically designed devices or pump [15, 18]. During three decades, Enteromate® pumps have been specifically marketed for automated CR [9, 10, 18]. The advantages were considerable. In a closed circuit, and therefore without unpleasant odor, they continuously adjust the flow rate of the CR to that of the upstream enterostomy, without needing human manipulation to transfer (and/or sieve) the chyme. Portable pumps with adjustable

continuous flow were also available from 2008, allowing CR to be continued at home [9] until the surgery to close the enterostomy or EAF. CR ensures the use of the entire potentially functional intestine and the correction of the IF. CR restores the function of the entire anatomically present bowel prior to the surgical restoration of continuity, including increasing absorptive capacities, restoring enterohepatic cycles and enterokine secretions, and improving trophicity of the downstream bowel. Patients are fed with what they eat. Some patients with a short or pathological downstream intestine still have intestinal insufficiency but it is less severe. Picot et al. published the largest case series studies of CR [9, 10, 28]. It included 306 patients with intestinal failure patients due to temporary double enterostomy (n = 269) or EAF (n = 37). They demonstrate that CR corrects the IF by restoring intestinal absorption. CR decreased intestinal losses by 85% and allowed strong improvements in nitrogen and fat digestive absorption coefficients. Plasma citrulline levels improved and there was a strong reduction in the proportion of patients with plasma citrulline <20 μmol/L. Nutritional status improved, especially in patients with body mass index <20. According to the ESPEN clinical classification of intestinal failure IVS [8], CR allowed 94% (46/49) of patients receiving only fluids and electrolytes, and 88% (142/162) of those receiving parenteral nutrition to stop IVS. The remainders required lower volumes of PN-IVS ($p < 0.001$).

DFH and Liver Dysfunction

Intestinal failure associated liver disease (IFALD) results in part from the interruption of enterohepatic cycles of bile salts (BSs). Under physiological conditions, BSs reabsorbed in the terminal ileum and right colon, return to the liver where they are re-secreted into the bile. In the L-Cells of the ileo-cacecal area, the transcellular flow of BSs stimulates the secretion of FGF19 into the portal blood. In the liver, FGF19 inhibits cytochrome 7-α-hydroxy-4-cholesten-3-one (C4), which controls the activity of 7-α-hydroxylase responsible for BSs synthesis from cholesterol. In case of a high flow enterostomy or EAF, BSs are lost, this enterohepatic cycle is broken, FGF 19 secretion stops, C4 activity increases and the liver secretes BSs in excess. The prospective study RESCUE shows in 12 patients that CR restored bile salt reabsorption and, within a few days, normalized enterohepatic signaling which corrected the hypersecretion of BSs by the liver [29]. Plasma FGF19 levels increased within a few days, C4 levels fall, and plasma alkaline phosphatase (ALP) and gamma-glutamyl-transpeptidase (GGT) activity decreased. The increase in FGF19 correlated with the decrease in C4, the increase in citrullinemia, and the decrease in plasma ALP and GGT activity.

Previous studies have suggested that CR could improve liver tests and function. Picot et al. showed that the number of patients who had one or several plasma liver tests abnormalities decreased from 83 to 40% ($p < 0.0001$) [9].

The retrospective study by Wu et al. [30] included 95 patients with high output EAF located between 10 and 95 cm from the duodeno-jejunal flexure. They were receiving parenteral nutrition. The distal intact small intestine was longer than 100 cm. The authors compared 60 patients with exclusive enteral nutrition (EN) and 35 patients with exclusive enteral nutrition and chyme reinfusion (EN-CR). Patients with EN-CR had greater liver function test improvements and better one year survival than patients with EN. In addition, in the EN-CR group, bile reinfusion and succus entericus from duodenal fistulas resulted in a greater improvement than jejunal chyme.

In contrast, Cosnes et al. observed no change in liver tests during the duration of enteroclysis, despite weaning from IVS [27].

In summary, CR allows to reestablish the small bowel continuity, to correct the intestinal failure, to restore the intestinal function, to normalize the nutritional status, to wean off IVS and to restore the enterohepatic cycle of bile salts that help with the improvement of IFALD.

Future Perspectives

Research is needed to better understand the positive effects of DFH and determine if CR is more beneficial than enteroclysis with an enteral nutrition solution alone. The mechanisms underlying the improvement of intestinal and liver functions are incompletely understood. One hypothesis could be that CR restores several endocrine functions of ileocaecal L-Cells through the effect of signaling molecules. BSs are signaling molecules. The targets of BSs are dedicated nuclear and plasma membrane bound receptors, in particular the nuclear transcription farnesoid X receptor (FXR) [31, 32]. By targeting these receptors, BSs could influence various metabolic and biological processes including BS and glucose homeostasis, hepatic inflammation, intestinal barrier function, trophicity of the intestinal mucosa, regulation of gastrointestinal motor function, and intestinal barrier function.

The choice to perform CR rather than enteroclysis currently depends on the availability of medical devices or equipment specifically designed to perform CR in a closed circuit, without manipulation or odor, convenient, easy to learn by caregivers and patients, feasible at home, inexpensive, and reimbursed by health insurance. New CR devices are in the advanced stages of development and are awaiting approval for hospital and home use and reimbursement by Medicare [33].

Side Effects of Enteroclysis and CR

As reported above, DFH is a safe technique of enteral nutrition if its contraindications, namely intestinal stenosis, occlusion, fistula and perforation, are well respected. The side effects are mainly represented by abdominal pain, diarrhea, or constipation (see below paragraph 'Practical aspects of DFH'). The most frequently reported technical problem is the accidental expulsion of the feeding tube, because of the peristaltic contractions of the small bowel, requiring its repositioning. Its prevention is based on adequate fixation of the tube to the stoma and stopping drugs that slow down intestinal transit [14, 20]. Patients with downstream occlusion, for example due to peritoneal carcinomatosis, cannot be candidates for DFH because of the major risk of complication and the lack of benefits. The other difficulties of DFH are tube displacement/leakage, and diarrhoea with unpredictable absorption. In the latter, despite DFH, the risk that the patient remains dependent to parenteral support seems high, and surely difficult to predict.

Practical Aspects of DFH

Figure 1 shows a double enterostomy with a feeding tube inside the downstream small bowel. Before initiating DFH, i.e. enteroclysis or CR, it is mandatory to perform GI imaging, i.e. X ray or tomodensitometry with luminal contrast, to ensure that there is no contraindication: fistula, perforation, occlusion or stenosis in the downstream small intestine (see above paragraph "What are the indications of DFH?"). The presence of a stenosis or of a bowel perforation contraindicate the use of DFH. The length of the downstream bowel has to be more or equal to 15 cm. Figure 3 shows an opacification of the downstream small bowel through a feeding tube; the fecal residues in the right colon make the patient at high risk of constipation or subacute occlusion. Their prevention consists in the administration of a laxative drug through the feeding probe.

To be sure of well-functioning downstream small bowel, we suggest, two days before starting the DFH, to instill one liter of oral rehydration solution (e.g. World Health Organization water solution with salt and sugar) through the feeding tube. In case of fecal residues or fecaloma in the colon, laxatives must be added. Anti-motility drugs have to be stopped to avoid intestinal occlusion or constipation just after the start of DFH [19].

Before starting DFH, it is important to obtain the agreement of the patient, and especially for CR, regarding the food constraints of ingesting smooth puree meals. For enteral nutrition through enteroclysis, polymeric formulas can be used. If intolerance occurs, they could be changed into semi-elemental formulas [24]. During DFH, if diarrhea occurs, loperamide can be used. In case of abdominal pain, antispasmodic can be used. In selected patients, CR was feasible at home thanks to portable pumps [20]. Picot et al. showed that this was possible for 30% of patients with an enterostomy, and in this study, no patient had to stop CR [9]. However, in France and other countries, home CR is not yet recognized by health insurances as a nutrition support technique, and unfortunately cannot be recommended.

Conclusions

Enteroclysis and CR, the two techniques of DFH, are recommended by international clinical nutrition societies as nutrition support techniques in patients with type 2 IF and a double enterostomy or EAF. DFH has many benefits: it decreases upstream stoma or fistula output, improves intestinal and liver functions, and nutritional status. Consequently the major benefit of these techniques is that it allows IVS weaning, thus can decrease the IVS and PN-related complications, mainly of central catheter-related infections. DFH is safe if the contraindications and a dedicated protocol are respected. It is important to emphasize the need to integrate DFH into multidisciplinary intestinal rehabilitation, under the supervision of dedicated and trained teams of a physician (with a special interest in nutritional support), a surgeon, dieticians, and nurses. Based on these large benefits for health, DHF may become routine practice in an IF patient before a temporary stoma or fistula is surgically closed.

Chronic Abdominal Pain

Peter Paine and Justin Turner

Key Points

1. Pain is an unpleasant sensory and emotional experience associated with or without tissue damage.
2. Pain related to intestinal failure can be due to a surgical catastrophe, inflammatory bowel disease or dysmotility.
3. Psychological support is needed to help manage chronic pain.
4. Due to absorption problems analgesia may need to be given by topical, buccal (including lozenges), or rectal routes.
5. Narcotic bowel syndrome may occur with chronic opiate use for chronic pain and is characterised by gastrointestinal dysmotility and hyperalgesia.
6. Chronic pain should not be treated with opioids; neuromodulator drugs may be beneficial
7. The approach to chronic pain has changed and there is a shift from that of a *cure* focus to a *care* focus with an understanding that chronic pain cannot be cured medically but can be helped.

Definitions

Pain

The International Association for the Study of Pain (IASP) defines pain as

> *an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage* [1]

This global definition allows for all conditions that have pain. For example acute appendicitis and irritable bowel syndrome, where abdominal symptoms are present for both, but the underlying cause and treatment options may be significantly different.

The definition also highlights that pain is an emotional experience and therefore there is a component of pain which is part of a conscious process. Pain is a reported problem and so the way the patient interprets their symptoms and then the way in which they are able to communicate those symptoms will vary. How a person interprets their experience of pain can be altered by mood, activity or distraction.

Acute Pain

Pain is protective. At the time of initial injury for example when you take a hot drink, the burning pain causes you to stop to prevent significant injury to your mouth or oesophagus.

Pain is then protective by preventing further activity and allowing healing to occur. For example if you fracture a bone this will lead to reduced movement and limiting the weight bearing on the bone, allowing for healing.

Post-operative Pain

Surgery is trauma where the normal responses to pain in the short term have been prevented by anaesthesia. This leads at a later stage to a situation where the subsequent responses to pain are to a degree no longer helpful and in fact may be detrimental to recovery. For example abdominal pain following laparotomy leads the patient to minimise movement, which in turn prevents deep breathing. This in turn increases the risk of chest infection and delayed recovery from surgery. Surgical techniques are aimed at minimising the degree of trauma and anaesthetic techniques aimed at improving pain relief to aid in early return to normal physical function.

Chronic Pain

Whilst the IASP global definition for pain is generally accepted, the definition of chronic or persistent pain is not as clearly defined. A pain which persists beyond the time of healing can be considered chronic. However the difficulty with this definition is for some patients, for example osteoarthritis, healing may not be possible. For this reason an alternative definition for chronic pain is a pain which has lasted longer than 3 or 6 months. For many forms of chronic pain the protective nature of pain is no longer apparent and the pain itself becomes disabling. Chronic pain within the general population is common [2].

Intestinal failure patients may have chronic non-GI pain which relates to another problem such as osteoarthritis or vertebral compression fracture. The management of these pains is beyond the remit of this chapter. However consideration needs to be given to the effect of intestinal failure on the medications available to the patient. Equally the medicines used would need to be considered with respect to their impact on bowel function.

Acute on Chronic Pain

A patient with chronic pain still has the risk of developing new medical problems relating to their intestinal failure e.g. a parastomal hernia or a new Crohn's disease inflammatory mass. New pains that have different characteristics in terms of the nature of the pain or location may still need to be investigated. Increased intensity in pain that has been established to be a chronic pain however, a "flare up", is unlikely to benefit from further investigation and the costs, both economic for the service, and emotional for the patient would need to be considered.

Mechanisms of Chronic Pain and the Biopsychosocial Model

An understanding of the pathophysiological mechanisms of chronic pain can be helpful in both characterising the pain, tailoring appropriate therapies and in explanatory models to delimit realistic treatment expectations. These mechanisms need to be considered within a biopsychosocial model [3]. From a holistic perspective, the biological, psychological and social components of the pain experience cannot be fully disentangled, and it is likely that there will be disordered processes in play at all these levels concurrently. It is possible however for one or other of these levels to predominate and therefore they will be deconstructed, albeit somewhat artificially.

Biological

At the more biological end of the biopsychosocial spectrum, pain is largely divided into *nociceptive* and *neuropathic*. Nociceptive pain describes the normal and appropriate function of the pain nervous system in response to potentially damaging stimuli and the reversible adaptive pain hypersensitivity ensuing as a protective mechanism for proper healing. Neuropathic pain however reflects damage and prolonged dysfunction to the pain nervous system itself, whereby pain can occur spontaneously, its threshold may fall dramatically such that innocuous stimuli produce pain (allodynia), and the duration and amplitude of its response to noxious stimuli are amplified. This should be considered as an autonomous disease state of the pain nervous system in its own right [4].

A summary diagram of the pain "hardware" involved following nerve injury or inflammation in chronic neuropathic pain states, and possible sites of abnormal function underpinning chronic pain is shown in Fig. 1. It is quite possible that more than one or indeed all of these levels of abnormal pain nervous function could be in operation at once. It is beyond the scope of this chapter to detail these changes further, but they are outlined in a helpful review article [5].

The structural diagram of the pain nervous system changes however does not convey that endogenous pain modulation is also a *dynamic* process and it is likely that there may be a "tug of war" happening between inhibitory and facilitatory processes and between bottom up and top down sensitisers [6]. A practical consequence of this information on neuropathic pain pathophysiology is that it can be helpful to patients to be given *explanatory models* (together with the use of simplified diagrams e.g. Fig. 2) of the "wiring" of their pain alarm system, including sites of malfunction. In particular, the instantiation of chronic pain within the spinal cord, brainstem and central nervous system can help explain why surgical procedures aimed at a peripheral target (such as adhesiolysis or organ removal) are unlikely to remove the pain. Helpful explanatory analogies here can be made with "phantom limb" pain and with a broken fire alarm, whereby the peripheral element or trigger may be resolved, but the central component perpetuates the pain experience. Such "central mediation" of chronic pain helps to explain why this is not readily fixable surgically and why centrally acting drugs ("neuromodulators" such as antidepressants and anti-epileptics) might be helpful to alter central pain neural function. Indeed, the Rome IV classification has recently recast chronic continuous or nearly continuous abdominal pain as "centrally mediated" and highlighted the problematic association with opiates for this kind of chronic pain and the potential role of neuromodulators [7].

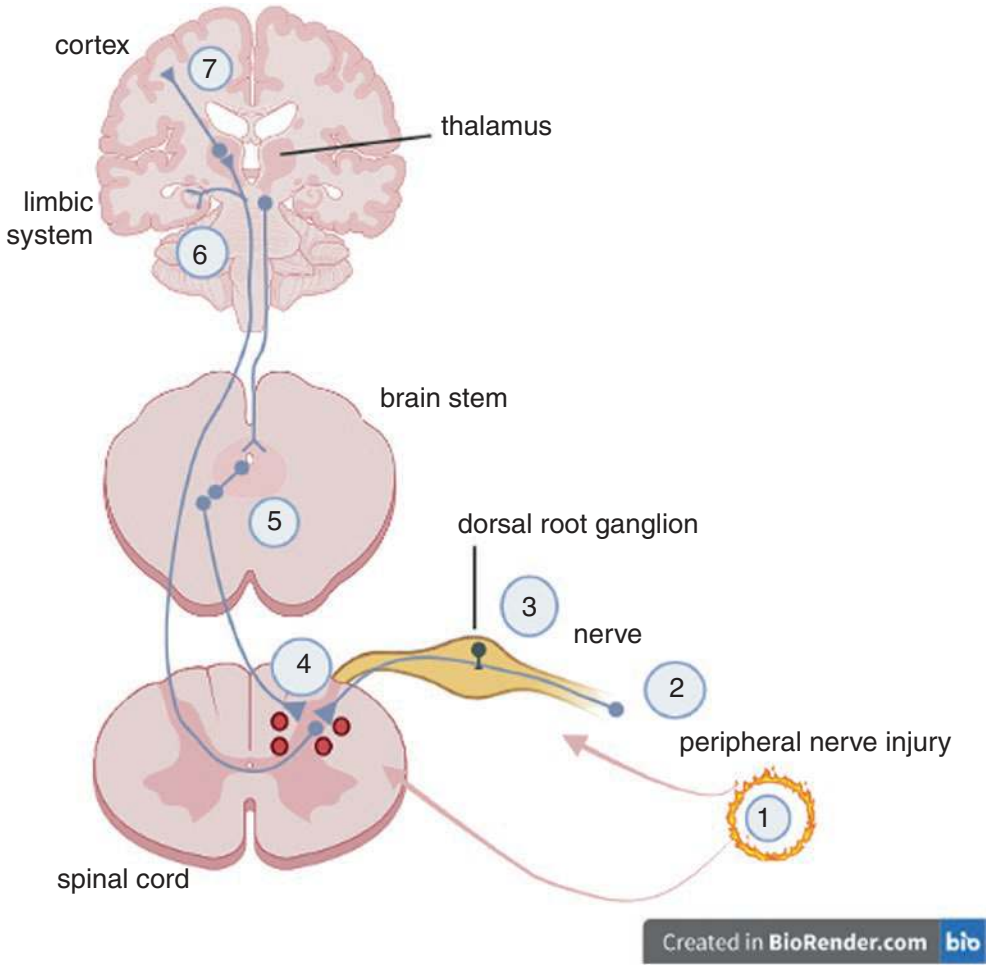

Fig. 1 Sites and mechanisms of chronic post-surgical neuropathic pain. (1) Peripheral sensitisation (distal chemicals), (2) Neuroma at injury site (ectopic excitability), (3) Dorsal root ganglion gene expression (excitability), (4) Central sensitisation (dorsal horn gene expression, inhibitory interneurone loss, microglia activation), (5) reduced Descending Noxious Inhibitory Controls (brainstem), (6) Limbic and hypothalamus (emotion, behaviour, Autonomic Nervous System), (7) Cortex (cognitive-evaluative)

Another important biological concept for understanding and explaining the clinical features of chronic abdominal pain in particular is that of *viscerosomatic convergence* at the level of the dorsal horn of the spinal cord. This can help explain to patients why a previous internal injury is often associated with extreme cutaneous pain sensitivity (allodynia). An example of this is seen in patients with chronic pancreatitis [8]. Furthermore, chronic pain that has been triggered or initiated from the viscera may also be quite diffuse and poorly localised because of the multi-level spinal inputs. Moreover the close association of the viscera with limbic and autonomic areas may predispose chronic visceral pain to greater levels of autonomic upset and fear/anxiety components. Lastly, the role of the microbiome in the bioactive luminal chemical soup in chronic pain is an area of increasing but poorly characterised interest.

Finally, opiate induced hyperalgesia is a specifically important mechanism to consider here. Whilst the clinical aspects of recognising and managing this will be dealt with later, in brief chronic opiate usage likely produces molecular biological changes in pain neural pathways such that the net result is further exacerbation of the underlying chronic pain state [9]. This is a highly counterintuitive concept for both the patients and the team looking after them but is important to recognise and understand that this has a molecular biological basis which appears to be largely reversible by careful controlled opiate reduction and withdrawal [10].

Psychological

Psychological risk factors for patients developing disabling chronic pain include pre-existing anxiety, depression and pain catastrophizing. Pain catastrophizing combines rumination (preoccupation with fear of worsening pain), magnification (amplify the significance of pain) and helplessness (inability to control the pain experience). A dissociative coping style may be a risk factor for opiate abuse [9].

Psychological factors that make patients more resilient and protect from disability with chronic pain include Pain Acceptance which involves activity engagement (engage in activities even if pain is experienced) and Pain Willingness (not attempting to control or avoid pain). Pain self-efficacy which is the confidence to cope with pain and engage with activities despite pain [5].

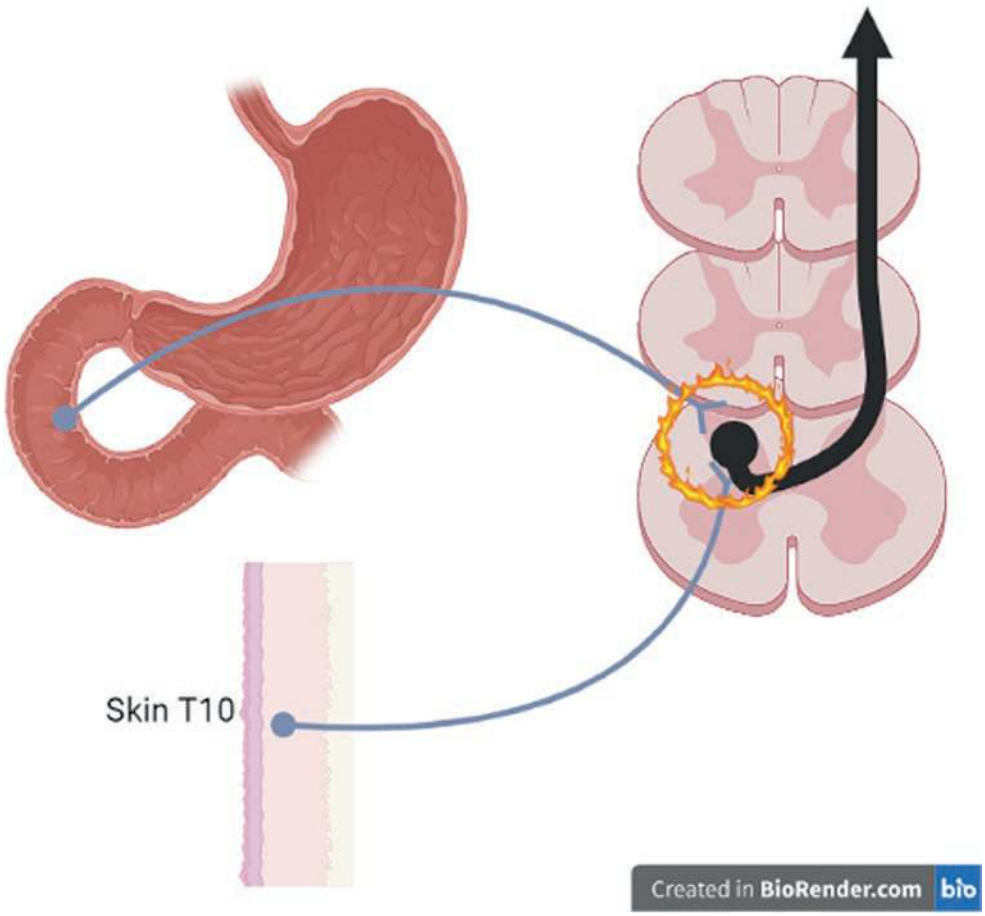

Fig. 2 An example of a simple diagram that can be used with patients to explain concepts such as viscerosomatic spinal convergence giving rise to cutaneous allodynia, central sensitisation in the spinal cord dorsal horn, and increased afferent barrage

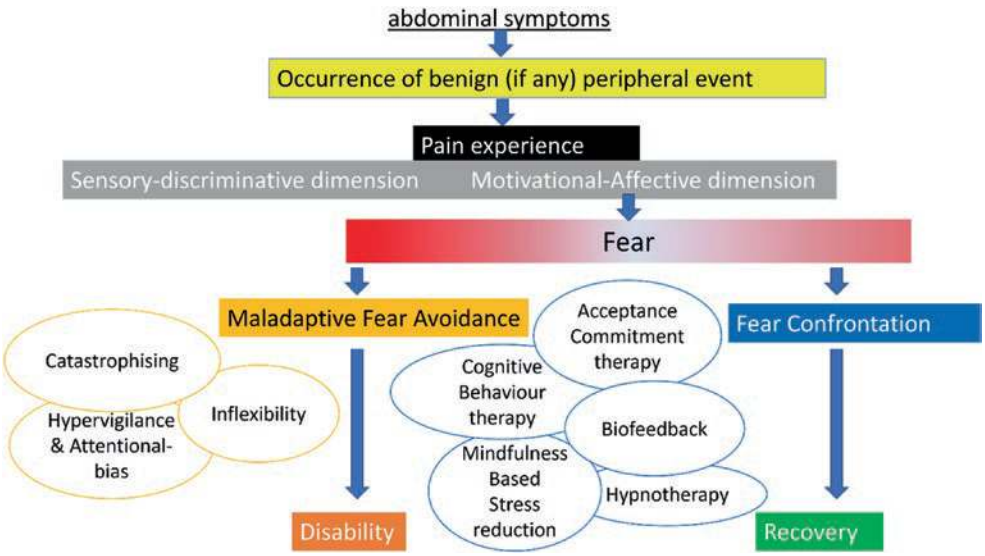

Fig. 3 Psychological factors involved in chronic pain outcomes

Some of the psychological vulnerability and resilience factors associated with outcomes are summarised in Fig. 3, which includes the key concept of maladaptive fear avoidance and both other maladaptive psychological processes and rehabilitative therapeutic approaches [11]. Trauma memory and pain meaning can also be important psychological aspects of the pain experience for a patient and therefore it is essential that clinical pain psychology forms part of any approach to chronic pain assessment and management.

Social

Finally, it should also be recognised that pain behaviours take place in a social context as displays of distress to elicit support. In a similar way to psychological responses, some of these pain behaviours and ways of attempting to elicit support can become maladaptive. At an extreme end of this spectrum are manipulative and deceitful behaviours such as in Munchausen's syndrome or in malingering for secondary financial or emotional gain. More commonly however, maladaptive social dimensions of pain can reflect the values and meaning given to certain expressions of pain within the learnt behaviour environment of the family or culture [12]. Pain behaviours can also sometimes therefore serve as proxies for other kinds of emotional, psychological or social distress when direct expression of these have been suppressed, for example when patients experience bereavement or relationship breakdown. Patterns of maladaptive social interactions with health care providers can also form a sociological vicious cycle exacerbating the pharmacological vicious cycle in the narcotic bowel syndrome [13]. Clear agreed and consistently practiced boundaries and sometimes written contracts can be necessary in some cases where maladaptive social interactions, for example frequent emergency department attendance for injectable opiates, is occurring.

Patients in Pain

Each patient in an intestinal failure unit presents with their own story, their own pain and how they present and manage their pain will be different for each individual Fig. 4. These will include components of nociception, the pain experience with or without nociceptive activation, suffering and pain behaviours [14].

If treatment of pain as a "signal" removes the signal completely then there is no progression to suffering and consequently no need to consider a model of pain as the wider experience described above.

Whilst teams treating patients are often guided to treatments by pain, in chronic pain, it is an unrealistic goal that medical interventions will provide a resolution of the pain [15].

Unfortunately, in chronic pain associated with intestinal failure, treatment of pain as a "signal" very rarely produces absolute relief, and so the aim should be to manage pain as the larger experience and resultant problems.

Treatment of pain in the intestinal failure unit for most patients should be multimodal with medical, psychological and physical therapies considered.

When assessing any patient it is important to firstly exclude new symptoms which may represent new pathology and consequently should be investigated as felt to be clinically appropriate.

The assessment of Chronic Pain should consider the various components of pain, the impact of pain on levels of physical function, psychological well-being, and resultant levels of disability.

Assessment of Pain

The assessment of the components of pain [16, 17] should include:

- ***Pain intensity***—A 11 point numerical rating system (0–10 with 10 being the worst pain) is a repeatable system that is easy to administer.

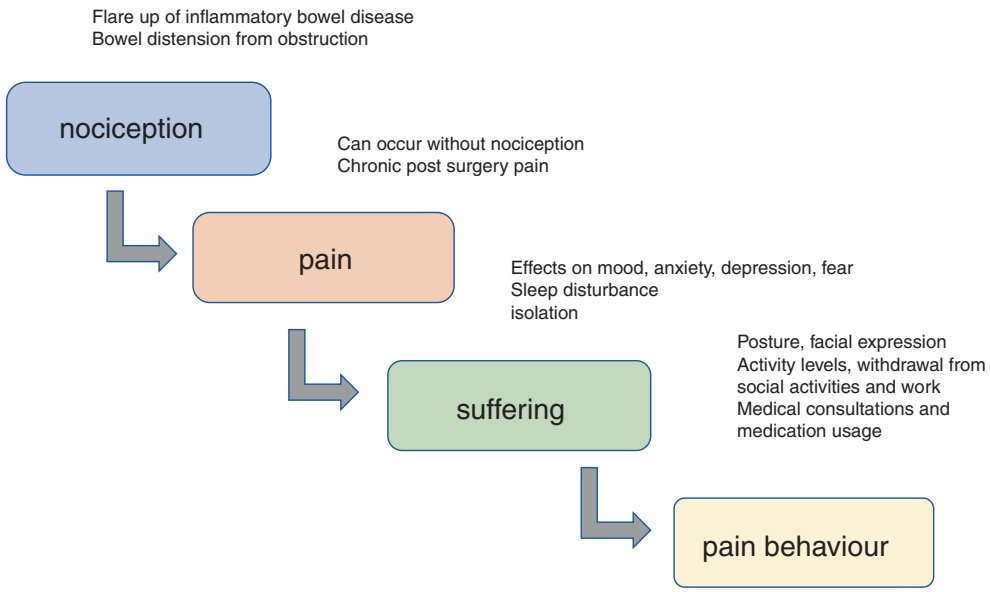

Fig. 4 Components of individual pain presentations

- ***Distribution of Pain***—Both origin of the pain and radiation are useful in assessing possible causes of pain. Pain Diagrams may provide useful information that can be repeated.
- ***Sensory quality of the Pain***—Pain described as colicky in nature and following feed would suggest a mechanism for pain different to a neuropathic pain with burning or stabbing pain, or pain on light touch (allodynia). It is possible to use various scales to assess the descriptive components of pain with standardised questionnaires such as the Short Form McGill Pain Questionnaire.
- ***Temporal Nature of Pain***—Duration of Pain is an important factor since chronic pain in intestinal failure does not exclude the patient from the risk of developing new pathology, for example a flare up of Crohn's disease or development of parastomal hernial. Equally chronic pain which has increased in intensity or flared up is unlikely to need further investigation. Triggers for worsening and improving pain are important to explore, they help suggest a cause for the pain such as ischaemia or obstruction or alternatively they may be linked to changes in psychological or social state. For some patients a Pain Diary is a useful tool to look at intensity overtime.

These aspects of assessment may guide which therapies may be helpful in the management of their ongoing pain.

For the majority of patients on the intestinal failure unit, medical management of their condition has been an ongoing process for a significant length of time.

Aetiology of the individuals' intestinal failure needs to be elicited as well as the amount of functioning bowel. Choices in terms of medications may well vary depended upon the length of small bowel available and transit times through the bowel.

Assessment needs to include a review of previous pain therapies and the reasons particular therapies were found not to have any value. A significant degree of distress occurs if therapies that have previously been found to be unsuccessful are revisited without addressing patients concerns and expectations linked to each therapy. For example patients who have trialled gabapentin and found it to cause recognised side effects such as drowsiness or forgetfulness are unlikely to find it helpful to retry the same medication again.

Current medication usage and the reasons for usage needs to be elicited. Medication route of administration and frequency of dosing need to be clarified. The reasons why particular routes of administration have been adopted also needs to be explored. This is of particular importance when looking at opiates. In our experience many patients will continue to be on opiates. The majority will have started these opiates during an acute exacerbation of pain, but at some stage their pain will have changed from acute to chronic but the opiates remain in place. Reasons for particular routes of administration of opiates needs to be elicited and also why other routes are no longer used. For example it is important, if a patient is using a subcutaneous opiate regime management, to clarify why subcutaneous morphine was prescribed and what prevents use of other routes of administration.

Patient concerns about therapy are also important to review. For a significant group of patients concerns may be about medical desire to reduce opiates, and if this occurs without patient understanding and agreement, our experience is this leads to increasing levels of iatrogenic distress and a poor experience for both the patient and the staff caring for that patient. It is important therefore to understand the patient's perspective on the role of medication. For other patients the awareness that opiates are not helpful in the long term and concerns about addiction are significant and management of those patients will have different priorities.

An assessment of ongoing pain and the potential challenges to management of pain or any change in therapy is not possible without an assessment of the psychological risk factors the patient may have. Patients understanding of what their pain means in terms of further damage (hurt/harm), and pain catastrophizing needs to be explored.

Disability for patients on the intestinal failure unit is multifactorial. Understanding the patient's level of disability and their perception as to how pain plays a part in ongoing disability needs to be explored, to aid in the setting of realistic goals for treatment.

Examination

For some patients on the intestinal Failure unit, examination is complicated by the stoma dressing and wound dressings that are required.

For some of those patients, any pain related to inflammatory irritation to the abdominal wall is best treated by management of the cause of that problem which is covered in other parts of this book.

Examination is important however to look for signs associated with ***neuropathic pain***. These include:

- *Numbness*
- *Dysesthesia* (e.g. tingling, burning)
- *Allodynia*—Pain on light touch

Table 1 Summary of assessment and examination for chronic pain

Pain	Onset, intensity, distribution, quality, duration, triggers
Cause of gastrointestinal failure	Bowel function, previous surgery
Current therapies	Medication dosages, frequency, route of administration other therapy e.g. physiotherapy
Previous therapies	As for current therapies and reason stopped
Past history	Medical, pain, psychological
Psychological factors	Hurt/harm, anxiety, depression
Function	Levels of disability and cause, family and friends, financial pressures
Examination	Inflammation, infection, stoma output, neuropathic signs, nerve entrapment

Table 2 Common themes/phenotypes

Initial cause of intestinal failure	Triggers for pain
Surgical catastrophe	Chronic post-surgical [5, 19]
	Adhesions or Stricture formation leading to obstruction
Inflammatory bowel disease	Ulceration of bowel
	Stricture formation.
	Fistula formation.
	Surgery to remove stricture, which may need to be repeated [20]
Dysmotility	Abdominal distension
	Opiate bowel dysfunction
	Narcotic Bowel syndrome [21]

- *Hyperalgesia*—Increased pain on pinprick
- *Summation*—Increasing pain on repeated stimuli rather than the normal reduction in stimulus
- *Altered Temperature sensation*—Reduced or increased sensation to cold or heat.

It may be possible to elicit pain associated with scars from previous surgery.

If anterior abdominal wall nerve entrapment is considered a possible diagnosis, a specific tender area is located, it is then possible to ask the patient lift their legs and contract the abdominal wall. If this is associated with increased pain this may suggest a nerve entrapment—Carnett's sign [18].

The approach to assessment and examination is summarised in Table 1:

Chronic Pain "Phenotypes" on the Intestinal Failure Unit

Whilst the assessment and examination approach outlined above emphasises an individualised approach, nonetheless we do see common clusters or themes of three main groups of patients presenting with chronic pain on the intestinal failure unit which may be taken into consideration (Table 2).

There tends to be a reasonable degree of overlap in the approaches for the surgical catastrophe and IBD group of patients, but there is a perception that the dysmotility group may present with some particular assessment and management challenges. This may in part reflect more general difficulties in characterising and determining aetiology for the dysmotility patients [22]. This is an emerging and not well evidenced based area currently, and would merit more multi-centre comparative group outcome data as the prevalence of this group of patients in IFU practice would appear to be increasing.

Treatment of Pain in Intestinal Failure Patients

The treatment of chronic pain in all patients on the intestinal failure unit needs to be considered within a biopsychosocial model. No single therapy is likely to provide the solution to a patient's ongoing symptoms.

Therapy for patients with chronic pain associated with intestinal failure therefore needs to be multimodal and interdisciplinary with coordinated care often from multiple medical specialties, nursing care and allied healthcare professionals. The staff on the intestinal unit are key to coordinating the care.

Assessment not only provides the information to guide further therapy but also provides an opportunity to allow the patient to know they have been listened to about their ongoing problems and for some patients this in itself is therapeutic.

For a significant group of patients' psychological factors will play a significant role in their presentation and a full psychological assessment by a clinical psychologist will be necessary and psychological therapies to aid in the ongoing management of pain will be needed.

There are a group of patients in the intestinal failure unit who due to multiple factors including the length of stay in hospital, previous surgeries and recovery, underlying medical conditions who become increasingly de-conditioned and physiotherapy aimed at increasing strength, range of movement and endurance is essential. Occupational therapy assistance with managing ongoing disability may also be required.

Medical Management

It is important to recognise that there are no currently available drugs which can abolish chronic pain completely in all or even most patients. A rule of thumb is that in patients who have some response to analgesics, will find a 30–50% reduction in the intensity of the pain experience useful and are likely to continue that medication. Furthermore, it is clear that in a majority of patients with chronic pain, opiates are ineffective and indeed can be counterproductive and harmful. Non-opiate drugs for chronic pain are often termed adjuvant or neuromodulator drugs. We will deal first with opiate management however, as this appears to be particularly problematic in intestinal failure patients.

The Management of Opiates

For the majority of patients with gastrointestinal failure, due to the chronic nature of the condition it is usually possible to take a considered approach to management of pain and medication changes.

Alterations to therapeutic regimes are more successful with patient agreement and there is less risk of reversion to treatment that the patient believes to be more successful in symptom alleviation whilst the treating team believes it to have a greater risk of harm. For example, ongoing use of subcutaneous opiate injections despite oral intake.

There has been increasing awareness of the harmful and indeed counterproductive effects of opiates on gastrointestinal function and chronic pain management. At the extreme end of the spectrum of negative effects, the "***narcotic bowel syndrome***" has been described. This is a combination of severe opiate induced gastrointestinal dysmotility (including sometimes pseudo-obstruction), combined with opiate induced hyperalgesia. This is described as occurring in a context of a vicious cycle of inadvertent iatrogenic healthcare re-enforcement of dependence on short acting and escalating opiate use, often via the emergency department route [7]. On the other hand, evidence has accrued that "detox" from opiates, especially if sustained, can be associated with a significant improvement (although not abolition) of pain levels and improvement in GI motor function [10]. In the intestinal failure setting, there is some evidence that opiate use is associated with some greater risk of harms, in particular catheter related blood stream infections [23]. Opiates at high doses suppress aspects of immune function including inhibitory effects on humoral and cellular immune responses including antibody production, natural killer cell activity, cytokine expression, and phagocytic activity [24] leading to greater susceptibility to infections. Finally, the risks of opiates in regard to addiction and abuse is well known.

The ideal situation therefore is not to commence opiates for chronic pain in the first place, even if no alternative pain medication is available [25]. However, many patients in the IFU setting will have already been started during acute exacerbations of pain. Unfortunately, often as the pain settles they are not removed due to on-going low level symptoms. Overtime with further exacerbations of pain the opiates are increased. The result is a significant group of patients arriving at a gastrointestinal unit do so with large doses of opiates already on board. The immediate priority in this situation is ***stabilisation*** of the opiate dose and ***optimisation*** of the route.

As the medical profession increasingly recognises the potential for harm of opiate usage in all patients with chronic pain it is understood that opiates play only a small role in the management of ongoing pain and high-dose opiates (equivalent to more than a 120 mg/day) should be discouraged.

In assessing opiate usage in intestinal failure areas of management that need to be explored are:

- ***Route of administration****:* due to various factors including nausea, vomiting, short small-bowel, gastrostomy, patients are prescribed opiates via multiple routes of administration.
  - Intravenous route is preferred by some patients.
  - Intramuscular injection.
  - Subcutaneous injection.
  - Sublingual or intranasal.
  - Oral
  - Transdermal

  The reason why a patient continues to use their opiates via one or other of these routes needs to be explored as does their understanding of potential risks and benefits of that route compared to other routes of opiates.
- ***Frequency of dosing:*** When opiate use becomes prolonged the half-life of all the drugs is at least 3 h and so it seems reasonable to expect opiate usage to be less frequent than this, however some patients are using opiates more frequently and it is important to assess what factors lead to more frequent dosing with opiates.
- ***Dose:*** A significant group of patients in the intestinal failure unit will be on a greater dose of opiates than the upper limit of currently recommended doses.

  This is likely to be multifactorial. For example, during "flareups" of pain or acute admission opiates may have been increased to aid in analgesia at that time, however if the patient has an ongoing chronic pain it is unlikely the opiates alleviate the symptoms completely, once the acute episode settles however due to the ongoing pain the opiate dose often remains unaltered and therefore escalated. The risk is that this happens with multiple admissions.

Pain and perceived improvement in symptoms transiently from dose increases also leads to a reduction in distress for the patient and consequently the treating team. Unfortunately, once the initial improvement abates and pain returns, as does ongoing distress for the patient and then as a result the treating medical team. As the dose increase was effective in alleviating the problems previously, the same behaviour can be repeated, and the result is further dose increases. In the literature on the narcotic bowel syndrome, a "***soar and crash***" phenomenon of escalating doses of opiates is described where the opiate side effects on GI function, opiate induced hyperalgesia and withdrawal side effects on de-escalation are actually driving the dosage prescribing higher and higher [9]. This seems to be a particular problem with the shorter acting opiates.

- ***Aims of therapy:*** Opiates for a significant group of intestinal failure patients, particularly those with slow transit times such as enteric dysmotility, are unlikely to be helpful and so reduction of opiates and if possible removal of opiates can be considered the long-term goal.

  For other patients where slowing transit time is not an issue, opiates nonetheless remain of limited benefit and therefore again dose reduction to recommended limits is necessary and removal of opiates should still be considered.

  Rapid changes are likely to produce withdrawal symptoms which in an intestinal failure unit may be very similar to the symptoms of a flareup of pain. The result being further changes are met with opposition from patients.

  If patients are willing to make multiple changes then this may be an option, however in a reluctant patient in our experience it is better to make gradual changes with the patients' agreement. However, dose escalation or reversion to previous route of administration is discouraged.

Alteration of Opiates Regime and Route

Intravenous opiates The use of intravenous opiates is encouraged in the management of *acute* pain and patient-controlled analgesia systems allow the self-administration of opiates within set parameters. These systems are very useful in the acute pain setting, however in a *chronic* pain setting intravenous opiates are no longer appropriate. The use of lines for opiates which are aimed primarily at on-going nutrition increases the risks of line infection and in our opinion is an unnecessary risk. Bioequivalent doses of opiates can be achieved using subcutaneous injections in the short-term and this can be considered as an alternative route in the shorter term for patients unable or unwilling to manage other routes of administration.

Intramuscular injection Historically this was used for patients with ongoing pain, however as subcutaneous injection is equally effective in the majority of patients this is no longer part of the practice within our intestinal failure unit. Patients who use repeated intramuscular injections to manage their pain are at risk of myofibrosis and muscle contractures and so long-term usage is discouraged [26].

Subcutaneous opiates have the advantage of not requiring an oral route and for some patients allow the use of a syringe driver to allow continuous dosage. The placement of a butterfly allows repeat injections without the need for multiple needle stabs. Whilst this route is used particularly during episodes of vomiting if opiates are required, there is still the potential for developing infections at the site of the needle and so there is still a potential for harm which can be avoided if the opiates are either stopped or the route of administration changed.

For all the routes of administration detailed above it is our practice to inform patients of the potential risks not only of the opiate but also of the route of administration and the potential therefore of harm to the individual from on-going injection therapy and that this risk will increase with prolonged reliance upon each route. One option would be to reduce opiates and then stop the opiates without changing the route of administration, however for many patients the removal of opiates is not at this point an achievable goal and so alteration of mode of delivery is more achievable.

Sublingual and Intranasal Opiates offer a route of administration of opiates that avoids absorption via the intestinal system. For patients with intestinal failure this potentially may be seen as advantageous in allowing opiate administration. These medications are licensed only for palliative care and are designed for pain episodes which are relatively short lived. The speed of onset is relatively rapid, but they are not designed for multiple uses per day. The cost of these medications is relatively high and therefore this needs to be considered when considering their usage. It is our practice to use these only as a potential option for the management of painful dressing change.

Transdermal opiates in intestinal failure represent an ideal route of administration as the absorption of the opiate (fentanyl or buprenorphine) is through the skin and not the gastrointestinal system. They provide continuous opiate release, absorption can however be altered by fever and caution with hot baths is also advisable. It is important to consider the

relative potency of these medications to morphine when considering dosage.

Oral Opiates usage is dependent upon both tolerability by the patient and also bowel transit time. Modified release medications often have a limited role as bowel transit times may be short and so absorption of the opiates is limited. Immediate release opiates however which can be given as a liquid or tablets do appear to be effectively absorbed for many patients on the intestinal failure unit. They allow for medications to be given during flareups of pain, however as the half-life is over 3 h for all these medications our policy is to provide opiates no more frequently than three hourly.

For the majority of patients, the initial goals in management of opiates are ensuring the route of administration is either transdermal or oral or a combination of both.

Table 3 Dose equivalences of commonly used opiates

Oral opiate	**Dose**	**Oral morphine dose**
Codeine Phosphate	60 mg	6 mg
Dihydrocodeine	60 mg	6 mg
Tramadol	50 mg	7.5 mg
Hydromorphone	1.3 mg	10 mg
Oxycodone	5 mg	10 mg
Tapentadol	50 mg	20 mg
Transdermal opiate	**Dose**	**Oral morphine equivalent per 24 h**
Fentanyl	25 μg/h	90 mg
Buprenophine	20 μg/h	50 mg
Approximate dose equivalents for opiates compared to morphine

Opiate Reduction

Due to the absence of supporting data for any benefit from opiates in chronic pain and increasing evidence of harm from high-dose opiates, it is important to engage the patient in discussion about the risks of harm from opiates as well as any benefits.

An explanation of the effects of opiates on the bowel and also the increasing evidence of effects of opiates on hormone production, potential effects on white blood cell function and immunity, as well as paradoxical worsening of pain are among risks that should be discussed with patients. There is evidence from the narcotic bowel syndrome literature that a sustained detoxification from opiates is associated with a reduction (but not abolition) in pain intensity, thought to be due to improved gut function and removal of opiate induced hyperalgesia [9].

Explanation of *gradual* reduction in opiates to prevent withdrawal symptoms, and that it is unlikely that there will be worsening of pain symptoms despite dose reduction need to be clarified.

Also, the potential benefits of improved pain relief during any *acute* episode of pain needs to be explained.

Opiate reduction needs to be considered in two parts—(1) The frequency of dosing and (2) total daily dose of opiates. The frequency of immediate release opiates should not need to be more frequent than every 3 h and for patients with chronic pain and a background of sustained-release opiates, breakthrough doses should be needed less frequently than this. As opiates have only a limited role in chronic pain, dose escalation of sustained opiates based upon breakthrough dosing is of minimal value. Prior to commencing dose reduction, it may be necessary to limit frequency of administration of immediate release opiates and then consider how to achieve dose reduction.

Overall opiate doses should be considered for all, with a reduction of opiates encouraged with patients on higher doses. It is important to start a process of dose reduction but at a rate of reduction that is acceptable to the patient. Table 3 below summarises dose equivalences for commonly used opiates.

There are no evidence-based guides on reduction but in broad terms a reasonable aim is a 10% reduction at agreed intervals, not more frequently than weekly but potentially longer, and no dose increases.

The method of administration will be an important factor in deciding which opiate is used during dose reduction.

It is possible to reduce any opiate gradually and so the preference of patient and the familiarity of staff with a drug on the unit are important factors in deciding which drug to use.

In addiction clinics, methadone is used due to the once daily dosing and some patients in pain clinics find it an effective opiate for analgesia. Unfortunately, due to the stigma attached to the drug from the association with addiction many patients are unwilling to see this as a therapeutic option. Buprenorphine is a partial opiate agonist which has a ceiling effect to the opiate action. This has been used increasingly in opiate reduction and therefore is an option available if a change of opiate is desired.

If opiate rotation or switch is used at the time of change a lower dose (than equipotent) should be used to prevent toxicity at the time of change.

Adjuncts to opiate dose reduction to minimise withdrawal side effects might be considered such as clonidine [9]. Where opiate abuse is suspected, there may be a role for engaging liaison psychiatry drug and alcohol input.

Peripherally acting mu opiate receptor antagonists, including naloxegol and methylnaltrexone may also be useful adjuncts to mitigate against some of the bowel dysmotility side effects of opiates, however they do not appear to help pain symptoms [9].

Neuromodulator (Adjuvant) Drugs

The Rome foundation have reviewed evidence for the use of drugs which have activity in the brain-gut axis for pain and associated symptoms, which have been termed gut-brain "neuromodulators" [27]. In the chronic pain setting these drugs are also called adjuvant analgesics.

Tricyclic Antidepressants

Tricyclic antidepressants (TCAs) are recommended for use in the range of 25–75 mg at night for chronic abdominal pain, with amitriptyline and imipramine more likely to produce anticholinergic and anti-histaminic dose limiting side effects than desipramine and nortriptyline. Their analgesic efficacy is thought to be due to combined 5-HT and NA reuptake inhibition. Muscarinic1 receptor antagonism accounts for side effects of dry mouth, constipation, drowsiness and blurred vision. The constipating side effect can be useful therapeutically in the setting of diarrhoea. Alpha 1 adrenergic receptor antagonism may lead to dizziness, drowsiness and orthostatic hypotension. Histamine 1 antagonism may lead to weight gain which can be helpful in functional dyspepsia. Sodium channel blocking properties can risk arrhythmias and seizures in overdose.

Serotonin Noradrenalin Reuptake Inhibitors

Serotonin Noradrenaline Reuptake Inhibitors (SNRI) may have at least equal benefit as TCAs for chronic GI pain. They have a more favourable side effect profile than TCAs as they are largely devoid of other receptor affinities. Venlafaxine may be more prone to side effects than duloxetine. Duloxetine has equal affinity for 5HT and NA transporters and at lower doses than venlafaxine and so should be the preferred SNRI to use.

Delta Ligand Agents (Gabapentinoids)

Delta ligands (Pregabalin and Gabapentin) have less direct data in chronic abdominal pain but nonetheless are considered of potential benefit, and there is also some data that gabapentin may be helpful in reducing opioid-induced hyperalgesia [9]. They block the alpha2delta subunit of voltage-sensitive calcium channels to reduce excitatory glutamate production. This likely underpins their anticonvulsant, anxiolytic and analgesic actions.

Augmenting Agents

The Rome Foundation working party on neuromodulators also supports a concept of "augmentation treatment" where combinations of different classes of the neuromodulators may give rise to synergistic positive effects. They also provide some data for adding in the atypical antipsychotic quetiapine to a TCA or SNRI at low doses of 25–200 mg. If this approach is considered then awareness of the hazards of serotonin syndrome should be considered and also monitoring for metabolic syndrome and involuntary movements [27].

Other Drugs

Cannabis and cannabinoids act via cannabinoid receptors, the endogenous cannabinoid system is found throughout the body's neural system including the viscera [28]. Cannabis is not currently available in the United Kingdom and there are no cannabinoid treatments licensed in the U.K. for use in chronic pain. Cannabis may be a potential treatment for chronic pain in neuropathic and visceral pain although there is limited evidence of benefit and the value of this reduction in pain compared to risk of longer term side-effects is unclear [29].

Gastrointestinal side-effects that have been associated with cannabis usage include visceral pain with acute heavy cannabis use and in prolonged usage cannabinoid hyperemesis syndrome [30].

Ketamine acts at the *N*-methyl-D-aspartate receptor and it may also act on descending inhibition of pain pathways. It is an anaesthetic drug that has been used at sub-anaesthetic doses to treat resistant chronic pain syndromes. It has been given as short-term infusions and also orally over prolonged periods. There has been limited research into its use in chronic pain and no evidence of improved functionality despite its use. Potential side-effects include memory effects and urological problems although most of this evidence is gathered from recreational ketamine users [31].

Nerve Blocks and Ablation

For some patients' injections may produce an improvement in symptoms which enables reduction in medications and potentially increased levels of function. The aim of a nerve block is to alter the conduction or transmission of pain signals by blocking the nerves involved in carrying the pain signal.

Injections can be diagnostic, using only short-acting local anaesthetic. If injections produce a short-term improvement in symptoms and then symptoms recur this is suggestive that a further block may be therapeutic.

Longer term pain relief can be achieved in some patients using a combination of local anaesthetic and steroid which can produce a longer-term effect. For those with chronic abdominal wall pain this may be possible to consider as an injection to the abdominal cutaneous nerve [18].

It is possible to consider neurolysis for some nerve blocks. This involves the injection of a neurotoxic drug e.g. phenol which may produce longer term effects, however due to the risk of recurrence of symptoms and also more serious and long-term side-effects with neurolysis, this is often reserved for palliative care.

Radiofrequency ablation is increasingly used as a modality of treatment to provide prolonged pain relief. It works by using a high-frequency alternating current to heat tissues to temperatures (above 45 °C) which will cause denaturing of the tissues at the tip of an electrode which is placed near the nerve. This has been used to provide pain relief for patients with abdominal pain although not within an intestinal failure setting.

Splanchnic nerves and coeliac plexus blocks have been used as treatments for managing visceral pain [32].

Spinal Cord Stimulation

Melzack and Wall described the gate theory of pain in 1965. The principal being that transmission of pain signals could be altered by stimulation of other pathways that would stop onward transmission of noxious information and as a result reduce pain.

Spinal-cord stimulation was introduced as a way to alter the experience of pain.

Spinal cord stimulation involves the implantation of an electrode either percutaneously or surgically into the epidural space. A pulse generator is then implanted in the subcutaneous tissue and this then produces the stimulation to the spinal-cord.

Initially it was thought spinal-cord stimulation acted in the dorsal horn of the spinal-cord, however it is thought spinal-cord stimulation also acts via posterior columns of the spinal-cord to recruit endogenous inhibitory pathways. There is also an autonomic effect. However, mechanisms of pain relief are still not fully understood.

Spinal-cord stimulation has been found to be effective in the treatment of neuropathic pain following back surgery, complex regional pain syndrome, neuropathic pain secondary to peripheral nerve damage and pain associated with refractory angina [33].

Medical contraindications to spinal cord stimulation include local or systemic sepsis and ongoing anticoagulant therapy.

However visceral abdominal pain has been treated with spinal cord stimulation, reducing opiate requirements. Potentially this may be a treatment option for some patients with chronic abdominal pain and gastrointestinal failure [34, 35].

Psychological Approaches to Pain

There is considerable evidence that various psychological interventions such as cognitive behavioural therapy and mindfulness training for chronic pain can be effective. There is also data to support hypnotherapy for chronic abdominal pain [9]. The treatment of co-morbid anxiety and depression may indirectly also improve patients coping with chronic pain. Psychological aspects and treatments in general on the IFU are dealt with in greater detail in chapter "Psychological Aspects of Intestinal Failure".

Chronic Pain: A Paradigm Shift

Finally, an optimal approach to chronic pain requires a series of "paradigm shifts" for both the patient and the doctors looking after them. The first element of this paradigm shift is from that of a *cure* focus to a *care* focus. At the most basic and simple level this is an understanding that chronic pain is "chronic" and currently cannot be cured medically.

A second shift is from the *biomedical* model of "test and treat" to a *biopsychosocial* model. On-going fruitless and frustrating cycles of investigations and searches for the "cause" of the pain can be costly, harmful, and counterproductive in preventing patients from moving on with engagement with a chronic pain rehabilitative focus. There is no objective reliable test that can show the abnormal nerve function underpinning chronic pain and so after initial structural evaluations, unnecessary rounds of repeated tests should be avoided. Explanatory models of the pain system and the role of the central nervous system, and eliciting specific clinical features of neuropathic pain, can be helpful as a positive alternative to negative tests.

Since most of these patients are not in the terminal phase of their lives, rather than a *palliative* approach of increasing narcosis, a third shift therefore is to minimise approaches which reinforce dependence and helplessness (avoidant coping) and to improve self-efficacy in patients (active coping), with an aim to promote improved function and coping in the face of on-going chronic pain—a *rehabilitative* approach.

Psychological Aspects of Intestinal Failure

Yoram Inspector

Key Points

1. Attend to the person who has the disease as much as to the disease a person has.
2. Psychological support is normal and essential for most patients with intestinal failure (IF) and especially if needing PN at home.
3. The needs are different if the IF is acute (e.g. mesenteric infarction) or chronic (e.g. Crohn's disease).
4. All patients will go through the 5 stages of mourning (denial, bargaining, anger, depression and finally acceptance) at different rates.
5. Ask the patient how they experience their condition and what do they think about it.
6. Psychopharmacology, Cognitive Behavioral Therapy, Acceptance and Commitment Therapy, Psychodynamic Interpersonal Therapy, Eye Movement Desensitization and Reprocessing, and Gut Directed Hypnotherapy are all useful and helpful for our patients.

Introduction

Reflecting on the title I gave to my chapter, I immediately felt the urge to amend it to:

> ***The Psychological support offered to the person who experiences Nutritional Failure***

This title allows us to acknowledge the reality that IF occurs within the body of a unique human being who needs to recruit all possible psychological resources in order to cope with this extreme condition. As William Osler said: "You have to be interested in the person who has the disease as much as you are interested in the disease the person has" [1]. Each patient faces different challenges and needs and therefore an individually tailored therapeutic approach must be formulated to suit her/his different medical history, life story, personality and their various adaptation capacities. This is one of the most important lessons I have learnt from the last 10 years of providing weekly psychiatric and psychological treatment to the patients of the Intestinal Failure Unit (IFU). The name of the unit was changed around 3 year ago to The Intestinal *Rehabilitation* Unit (IRU). The word *Failure* has been purposefully replaced by *Rehabilitation* in order to provide a rather more hopeful and constructive message to the patients and the medical staff alike. IF, which nearly always involves the need for PN, will affect all domains of one's existence: physical, emotional, social and even spiritual. All these aspects need to be addressed by the multidisciplinary team in order for the treatment to succeed to significantly improve the patient's wellbeing and quality of life.

The Psychiatric and the Psychological Assessment

St Mark's Hospital has a dedicated in-house Psychological Medicine Unit (PMU) that provides psychiatric and psychological treatment and support for patients who suffer from various gastrointestinal diseases and disorders, among which

"Funny little thing about this tummy o'mine,
doesn't wanna work like once upon a time,
I can eat the food but it just sits,
making my tummy hurt and throw a lot of fits!
The food doesn't wanna stay,
I feel like a cow chewing cud all day.
Then there is the pain with no end in sight,
I hurt all through the day and through the night.
Off comes the weight down another size,
God how I miss those burger and fries!
But gone are those foods, this is hard to endure.
What can I have?
Oh, Goody Ensure!!!"
The poet was a patient at the Intestinal Rehabilitation Unit of St Marks' Hospital.
She called herself "a Gastroparesis Fighter".
I want to dedicate my chapter to all the fighters of the Intestinal Rehabilitation Unit of St Mark's Hospital- to all the patients and to all the members of the multidisciplinary team who fight for having a good, happy and fulfilling life alongside intestinal failure.

Y. Inspector (✉)
The Psychological Medicine Unit, St Mark's Hospital, Harrow, UK

J. M.D. Nightingale (ed.), *Intestinal Failure*, https://doi.org/10.1007/978-3-031-22265-8_45

are a large group of patients who cope with IF. The PMU's team meets weekly with the IRU's team to discuss patients with IF who need and/or possibly would benefit from a psychiatric and psychological assessment. Getting to know the background of the patient usually begins in this this joint meeting, when the nurse, dietitian and or the gastroenterologist presents the patient's information to the PMU. This is then naturally followed by the PMU clinician's first meeting with the patient at the IRU after the patient has given consent to the meeting.

The Physical Condition: It Is Not Just in Your Head!

Although I already know something about the patient from the initial team meeting, I do not know him or her yet. To know is to experience. I try to put aside the information and start afresh. After I introduce myself I always tend to add: "Don't worry, the fact that you've been asked to see a psychiatrist and a psychotherapist doesn't mean that you are mad; It means that your gastrointestinal system became a bit mad and if this happens it can madden anyone and as I am allegedly an expert on madness you are seeing me". I have found that this sentence immediately puts a smile of relief on patients' faces as it validates the fact that whatever they experience mentally and emotionally, as extreme as it may be, is a normal reaction to the abnormal situation of the IF.

To consolidate this message, in which I strongly believe, I tend to start my assessment with taking a detailed account of the history of their gastrointestinal disease. When and how did they start suffering from it? How it behaved over the years? I always also endeavor to create the space to speak about the physical pain the disease causes and inquire how the patient manages to live with it. Many gastrointestinal diseases and conditions can involve an acute or severe and enduring IF and each patient has her/his unique journey, an account of which one must listen to carefully. It is important for the mental health clinician who works in the psychosomatic field to fully embrace the physical bodily experience of the patient—"The Body Keeps the Score" [2].

It is not just psychosomatic (the psyche affecting the body) it is also, first and foremost in the case of IF, the impairment of this vital, crucial physical function to which the psyche acutely reacts.

How Does IF Affect The Psyche?

> ***"Losing my colon felt like losing a part of my mind" a patient on the IRU***

As the causes of IF vary considerably, so do its psychological consequences. It is rather different to find oneself needing home PN after gradually losing, over the course of some years, most of one's intestine due to aggressive inflammatory bowel disease, for example, than to be needing the same after an acute mesenteric artery occlusion that was incurred spontaneously. In the first instance one might actually experience relief due to the improved quality of life PN can provide, yet in the latter situation one would perhaps enter a state of shock and grief in reaction to the sudden and brutal loss of one's capacity to digest food. In any case the experience is traumatizing.

The word trauma in Greek means "wound". It is also etymologically related to the word *Trema* which means a mark or a "hole" (used for the dots on dice, for example) as well as the words "tremor" and "tremendous"—indeed, trauma designates an event as beyond the realm of the ordinary. The wound has created a hole that marked you and that has brought about a physical and emotional trembling. Every person who faces IF has experienced trauma along his journey to recovery through PN.

This may seem like stating the obvious, but it is nevertheless crucial to state it: PN is a life-saving therapy in patients with severe IF. Importantly, these patients do not chose PN out of their free will, but it is usually the ultimate remaining option to maintain or improve their nutritional status [3]. This lack of choice means that every patient undergoing treatment necessarily experiences the five stages of the mourning process that was described by the Swiss-American Psychiatrist Elisabeth Kubler Ross [4].

Denial: "I feel fine, this cannot be happening to me"
Bargaining: "I can still do something to change the situation"
Anger: "Why me? It's not fair; how can this happen to me? Who is to blame?"
Depression: "I am so sad, why bother with anything?"
Acceptance: "I can't fight it, I may as well prepare for it; It's going to be okay"

Granted, this should not be understood as some linear ideal chronology by which a patient's attitude always and unvaryingly develops and progresses. It may start and end with any stage - but all the above five stages will at some point in time be encountered. We hope to end with acceptance, yet many researchers have found that depression is the most common emotional response to home parenteral nutrition (HPN) (the most common end result of IF) and can be found in up to 80% of the patients who are commonly overwhelmed with feelings of worthlessness, helplessness and hopelessness [3].

Most of us take for granted our ability to eat spontaneously and be nurtured through our mouth. Imagine that this capacity is suddenly taken away from you; you will obviously feel deprived and deeply frustrated. So much of one's communal

activity revolves around food that not being able to eat in a natural way might give anyone a feeling of being a "second class citizen" in normal society. It is easy to comprehend how having a permanent catheter inserted in a central vein in your neck for feeding can make you feel like an alien.

Many HPN patients suffer as a result of their condition from poor self-esteem and body image.

A constant source of concern for almost all patients was the cosmetic effect of multiple surgical procedures and the actual location of the catheter. Some patients perceived themselves as unattractive or even repulsive, experiencing feelings of embarrassment and shame concerning disfigurement due to scars and weight loss. Such embarrassment and shame often lead to impairment in sexual relationships. Other psychological problems include: changes in dependency (mostly loss of independence), changes in one's ability to travel (which was the activity most disturbed by HPN), the feeling of being a nuisance or burden to others, feeling that one lacks understanding of others as well as perceiving a lack of understanding from others [3].

All the above states are accompanied and even maintained by anxiety. IF and HPN naturally provoke various fears; of the unknown, of catheter infection, of pump malfunction, liver damage or fear of death. Anxiety is composed of two major elements: (1) uncertainty and (2) dread that something irreversible will happen. Any psychological support provided will need to address this anxiety in order to transform overwhelming fear into a constructive life affirming and celebrating attitude. In the treatment section I will reflect on how this might happen. In the assessment—I ask how does it affect you?

How Does the Psyche Affect IF?

The brain-gut axis is a "dual carriage way": What happens in the gut affects the brain through the gut microbiome and the enteric nervous system and at the same time what is happening in the brain is perceived by the gut through the autonomic nervous system. It is not rare to hear from patients who suffer from IF that their gastrointestinal disease erupted following an emotional trauma: An attachment trauma, being bullied at school or other various forms of abuse. Our ancestors thousands of years ago already knew about such a possible linkage: Chapter 22 of the Book of Psalms in the Old Testament opens with the poignant Hebrew words which Jesus quoted on the cross: [5].

> *Eli Eli Lama Azavtani"—"My God My God why have you forsaken me.*

In line 14 of this poem we can find an accurately moving description of what the lonely, abandoned, trapped, traumatized person experiences in his body:

> *I am poured out like water and my bones are out of joint;*
> *My heart melted like wax;*
> *It melted* ***into the midst of my bowels.***

This has been confirmed in modern scientific literature: 62% of women with idiopathic gastroparesis (which often ends with HPN) reported a history of physical or sexual abuse, and physical abuse was significantly associated with abdominal pain, somatization, depression and life time surgeries [6]. Approaching such issues should be undertaken with great sensitivity and at the right timing as childhood and/or adult trauma often is not merely remembered—it is relived. Opening up these wounds can be retraumatizing.

The Treatment-How to be the Second Mouse?

When I need to define what the PMU does, I always write (as mentioned above): "The PMU provides psychiatric and psychological treatment and *support* for patients who suffer from various gastrointestinal diseases and disorders". A mental health clinician suggested to me to omit the word *support* from this description, as according to them it is not suitable to the highly specialized service we provide. The word *support* might be perceived as too broad or unspecified—your aunt or friend can *support* you as well. After reflecting on this issue for a while I told them that while I see their point, I believe that the word *support* is the most important one for me in this definition and would be the last one I would be omit. I went on to talk about the *Supporos* in Greek antiquity—those who *supported* you when you came to heal yourself in the "The Asklepion" the temple of Asclepios - The God of Medicine [7]. After being given a bath with all sorts of aromatic oils and healing plants the patient was sent to "incubate", have a dream at night which will hopefully contain a healing symbolic message from the Gods and in the morning the *Supporos* would come and *support* you physically from both sides (by the way the world *support* is related etymologically to the word *Sub*-from underneath, to *support* bottom up, which is very connected to gastroenterology). Then they would accompany you to stand in front of the image, the sculpture of Asclepios and say: "We Support and God Heals". I said to my colleges that in my view this humility regarding our role in healing and at the same time the crucial role of the humane *support* in this process that is embodied in the *Support* of the *Supporos*, should guide us even more now in our technological age of the 21st and added that Hippocrates the father of scientific medicine was initially a follower of Asclepios and that maybe from this period he came with his important sentence: "You completely cure rarely, you give therapy (makes things better) frequently and you must comfort always. Comfort and support are naturally interwoven.

The question is how to support the patient who is suffering from IF? The first thing I would recommend is: Be the second mouse! This suggestion needs obviously a bit of explanation. It is based on the experiment done with mice presented by the French surgeon Professor Henri Laborit in the French Director Alain Renais's film: Mon Oncle d'Amerique which translates into English as "My American Uncle" in which mice are used as an illustration to the humane condition. What happens in the experiment? It has three stages:

1. A mouse is put in a cage but the door of the cage remains open. The mouse received a disturbing but not a dangerous electrical shock and it immediately escaped through the open door of the cage to avoid further pain. Its health was not affected.
2. A mouse receives the same disturbing but not dangerous electrical shock, but this time the door of the cage is locked. It cannot escape and is **alone!** This **lonely, trapped** mouse starts to become ill-it develops alopecia and a peptic ulcer and vomits blood.
3. Two mice are put in a locked cage and are electrocuted (given same non dangerous electric shock). They cannot escape like in the first stage of the experiment but they are **together- not alone**! They interact with each other, discharge their pain on each other and share it. These mice remain physically healthy!

There is scientific evidence that "stressed mice look like depressed humans. This is actually the subtitle in a fairly recent textbook on *The New Mind-Body Science of Depression* [8]. Which explores fascinating and surprising interlinks between inflammatory processes and depression. Not being alone and interacting with others has a healing potential for depression and according to the above textbook even for inflammation. How then to interact with the patient who is trapped in the "Electrocuted cage of IF"? In order to really help, healthcare professionals need to step into the cage of the IF patient and be ready to be "Electrocuted": Be ready to compassionately take the patient's experience in.

The Word Compassion in Latin Means to Suffer With!

Compassion does not require one to achieve complete understanding of the other's perspective and circumstances, engendering exactly the same feeling; it merely calls on one to imagine what it might be like to suffer in a way that the other is suffering. If achieved, this will engender the corresponding emotion, which can then be conveyed [9]. If you are really ready to "suffer **with**, and have a true genuine rapport with the patient don't worry about being "electrocuted", because you will not be alone, the patient can become your protecting second mouse in the "electrocuted cage of IF".

The remedy to "My God My God why have you forsaken me", in Psalms 22, mentioned above, can be with found in the next poems Psalms 23:"Even though I walk through the valley of the shadow of death, I will fear no evil, for you are **with** me." Again it is about being **with!**

In addition to the core essential healing modality of compassion or "being the second mouse" we have two more additional "specialized", "professional" tools aimed at improving the patient's quality of life and wellbeing: psychopharmacology and psychotherapy.

Psychotropics drugs can help to improve various mental disorders:

The different types of anxieties, depression, post-traumatic stress disorder and mood swings. I encountered all of them at the RIU and if indicated I would prescribe psychotropic drugs to reduce the psychic pain of the patients. Being also a psychotherapist, inspired by the Swiss Psychiatrist Carl Gustav Jung saying: "Man cannot stand meaningless suffering", I know that medications are not enough to address the suffering of a person who suffers from IF. Finding the unique meaning she or he attributes to this radical condition is crucial to their healing and recovery.

Psychotherapy—"The Talking Cure" aims at widening the repertoire of how the person relates to himself and to others, which is helping in getting redeemed from the feeling of being trapped. Psychotherapy aims at creating a sense of self-agency (you can reflect about and influence your life) and at providing tools for affect regulation. Many times it is not only focusing on fixing psychopathology 'it is also a mean to support individual development and growth in every aspect of one's life including the spiritual domain.

There are numerous psychotherapies based on different psychological theories and I will mention just a few of them, the ones we commonly use at the IRU:

Cognitive Behavioral Therapy

A basic assumption of cognitive behavioral therapy (CBT) is the recognition that there is a reciprocal relationship between our cognitive processes (what we think) and our affect (emotional experience), physiology and behavior. Although Cognitive Behavioral treatments for individual disorders differ in both their form and application, they all emphasize the importance of changing cognitions and behaviors as a way of reducing symptoms and improving the functioning of the person.

In CBT we commonly challenge automatic thoughts -The self-critical or exaggerated negative self-statements that go through a person's mind and are accepted as true by the person without testing their accuracy [10]. We put question marks after the exclamation marks-!? For example, if a

patient who is diagnosed with IF thinks that he is a worthless human being because of it, that he is helpless and there is nothing he can do to improve his life and that he is hopeless - the situation will never get better, he will feel deeply depressed and will withdraw from many life affirming activities (thought changes feeling which alter the behavior). The CBT therapist will explore together with the patient the validity of his assumptions which lead to his depressing conclusions and with the technique of "Cognitive restructuring" will help the patient to realize that they can be modified.

The CBT therapist will assess the patient's beliefs about the causes for the IF, the consequences, symptoms experienced, personal and treatment control, chronicity and recurrence and the feeling of anger, upset, anxiety, low mood and fear that accompany their beliefs.

The principal predictors of the above negative feelings in IF patients were:

1. Poorer appraisals of patients' ability to exert personal control over aspects of their condition and treatment
2. The perception that the condition and treatment makes little sense to the patient [11].

Therefore the CBT therapist at the IRU has also a psychoeducational role-they need to be knowledgeable and fully understand what it entails to live with IF in order to help the patient to have a sense of coherence of their illness and discover the meaning they give to their suffering.

Acceptance and Commitment Therapy

This is a "third wave" CBT therapy that has some similarities to the way the Buddhist philosophy approaches pain-with compassion and acceptance. The acceptance and commitment therapy (ACT) model holds that culturally supported attempts to control and eliminate unpleasant experiences result in personal suffering, behavior disorders and lack of vital and purposeful living. ACT attempts to teach clients to accept, rather than control or eliminate painful experiences that are not amenable to first order change. Acceptance is accomplished through teaching the client to see these experiences as conditioned verbal responses, rather than literal truth. ACT emphasizes that the patient approach rather than avoid, valued life goals, even though pursuing such goals may stimulates uncomfortable experience [12].

ACT uses Mindfulness, an approach, a technique which aims at "Consciously bringing awareness to you're here and now experience with openness, interest and receptiveness." It makes no attempt to reduce symptoms, its goal is to create a rich and meaningful life, while accepting the pain that inevitably goes with it. ACT has proven effective with a diverse range of clinical psychiatric conditions [13].

The use of ACT at the IRU focuses on consolidating the commitment to life alongside the IF. We hope that future work may show that ACT is helpful in the treatment of chronic abdominal pain and so provide an alternative to the abuse of analgesics (especially opiates).

Psychodynamic Psychiatry/Psychotherapy

As the name indicates, this type of therapy is engaged with exploring and facilitating the dynamics between all levels and aspects of the psyche—the conscious as well as the unconscious ones. This is how the psychiatrist Glen O Gabbard describes the psychodynamic attitude: "Psychodynamic psychiatrists approach their patients by trying to determine what is unique about each one-how a particular patient differs from other patients as result of a life story like no other. Symptoms and behaviors are viewed only as final common pathways of highly personalized subjective experiences that filter the biological and environmental determinants of illness. Furthermore, dynamic psychiatrists place paramount value on the patient's internal world -fantasies, dreams, fears, hopes, impulses, wishes, self-images, perceptions of others and psychological reactions to symptoms" [14].

In the context of IF the psychodynamic oriented psychiatrist might then be interested in exploring childhood early feeding experiences, relationships with parents siblings, the relationship with the therapist the possible symbolic meaning the patient might attribute to the central venous catheter: An intrusion or maybe a feeding umbilical cord?

Will this encourage regression, separation or individuation? The meaning the patient will give to the HPN might be influenced by his attachment patterns that can be for example reenacted with the medical team caring for him/her or with the psychotherapist.

Psychodynamic Interpersonal Therapy

Psychodynamic interpersonal therapy (PIT) is a form of Psychotherapy [15] that was developed by the Jungian Psychiatrist Robert Hobson. His Unique Conversational Model to Psychotherapy is presented in his Book—Forms of Feelings—The Heart of Psychotherapy [16]. It has been Further adapted by Professor Else Guttery to treat unexplained and or Functional Bowel Disorders [17]. It is now a relatively short term therapy up to 8–10 sessions but what is special about it is that the first session is not restricted to an hour. The therapist allows the patient all the time needed to describe in his own language the physical experience of his gut disorder and waits patiently for the unique metaphors of the patient to organically emerge from the description in

order to create a bridge to the patient's feelings. For example, if the patient is using a metaphor of a volcano to describe bouts of pain it may lead to exploring feelings of rage and anger; speaking about trapped air in the bowel may lead the patient to speak about how he feels trapped in life. This approach frees us from needing to decide is it physical or psychical, as it holistically embraces the gut disorder experience.

Eye Movement Desensitization and Reprocessing

Eye Movement Desensitization and Reprocessing (EMDR) is an eight -phase treatment approach that facilitates resolution of distressing historical events, desensitization of present triggering stimuli, and acquisition of desired behaviors [18]. It is a structured therapy that encourages the patient to briefly focus on the trauma memory while simultaneously experiencing bilateral stimulation of the brain (typically by eye movements), which is associated with a reduction in the vividness of the intrusion of post traumatic flashbacks and the overwhelming emotions associated with the trauma memories. It can be very useful in treating severe avoidance behaviors and phobias.

Gut Directed Hypnotherapy

Hypnotherapy is a NICE recommended treatment for Irritable Bowel Syndrome that can be also a very efficient tool to reduce the intensity of various forms of anxiety that many patients at the IRU are coping with them, to enhance deep relaxation as well as improving self-confidence and esteem [19].

Disordered Eating or an Eating Disorder? And Why Does It Matter?

All the patients who suffer from IF experienced disordered eating. Until PN had been introduced they could not eat normally: vomiting if they have gastroparesis, gut dysmotility or obstruction, or diarrhea due to poor absorption of food as result of a short bowel or intestinal inflammation. However few of them suffered from an Eating Disorder.

An Eating Disorder is a psychiatric disorder in which eating becomes disordered due to psychological and social reasons not due to physiological reasons.

The Eating Disorders are classified into four main categories (see also chapter "Eating Disorders in Adults). Anorexia Nervosa (restricting and binge-purging type), Bulimia Nervosa (purging and non- purging type), Binge Eating Disorder and the Atypical Eating disorder (which has some elements from each of the other groups but does not fulfil the full criteria to any of them).

A "transdiagnostic model" has been suggested by Fairburn [20] who argues that this division should be abandoned as 50% of the patients who suffer from anorexia nervosa will turn into bulimic patterns and because the largest group is actually the atypical one. Moreover, they all share according to Fairburn the same psychological problems:

1. Core Low Self-Esteem
2. Clinical Perfectionism
3. Mood Intolerance
4. Interpersonal difficulties.

One of main issues that maintains the Eating Disorder is that self-esteem becomes totally dependent on body shape and weight. This is definitely not the case with the patients who suffer from disordered eating due to IF. Rarely an Eating Disorder might be unveiled or triggered by IF due to the fact that in addition to PN some patients are encouraged to have a hyperphagic diet to compensate for the malabsorption they experience aiming for 3000 Kcal/day [21].

More often I found myself needing to redeem patients at the IRU from an Eating Disorder diagnostic label that was put on them unjustly in the past. This became commonly the case with young women that developed IF due to gastroparesis and or severe gut motility disorders that was part of a previously undiagnosed Ehrler Danlos Syndrome (EDS). The gastrointestinal manifestations of EDS which appear all along the gastrointestinal track have received little attention despite the observation that they represent a considerable symptom burden on sufferers [22]. In addition to abdominal pain they include: Oral: periodontitis, loss of teeth and bone; Oesophagus: hiatus hernia (33.3%) rarely rupture; Stomach: nausea and vomiting (29–34%), gastric emptying abnormalities (75%) with most frequently a delay in gastric emptying; Small bowel: perforation; Colon: spontaneous colonic perforation, chronic constipation; Rectum and Anus: fecal incontinence, obstructed defecation.

The EDS patients I have seen are mostly young women and nearly all of them had a long and painful "Via Dolorosa" until their symptoms were taken seriously and properly diagnosed. Often as they were young women who struggled to eat they were misdiagnosed as suffering from an Eating Disorder or Somatization-meaning that a psychological conflict or distress is expressed through their bodily symptoms. The risk of ignoring the reality of a physical disorder when the mind of the psychiatrist is already set on a psychological cause for the physical symptoms is unfortunately not an uncommon mistake and can be fatal.

It happened even to "the father of Psychoanalysis "Sigmund Freud:

> "A little girl was sent to him (to Freud) suffering abdominal pains. He diagnosed her as an 'unmistakable" case of Hysteria and "cured" her with psychoanalysis. Two months after he discharged her she died, the cause being abdominal lymphoma. Apparently unabashed, Freud denied all culpability, insisting that he had cured the hysteria which he declared: "had used the tumor as a provoking cause". Dr. Anthony Stevens the Jungian Psychiatrist who discusses this case in his book: An intelligent guide to Psychotherapy [23] says that "clinical arrogance of this degree and magnitude was ill-designed to protect Freud against the kind of missed physical diagnosis of which all psychotherapists live in dread".

The Story of S

The treatment of S. at the IRU and the PMU illustrates the complexities that are at the core of the confusing gray area between Disordered Eating and an Eating Disorder and highlights the importance of taking the time and the patience to make the right diagnosis as it crucial for finding the right therapeutic approach that will improve the wellbeing and the quality of life of the patient. When I first met S. she was 19 years old. Her BMI was extremely low −12 kg/m^2! She presented with recurrent episodes of low potassium due numerous episodes of vomiting especially after eating any amounts of food and at times even after drinking. In her vomit there were lumps of undigested food even from the previous day. She also suffered from continuous feeling of nausea and constant acid reflux and regurgitation. To complicate matters, she had a period of 18 months during which she was a patient in an inpatient Eating Disorders' unit where she was at times under extremely strict 2:1 observation for 24 h 7 days a week. S. passionately insisted that she does not have an Eating Disorder! that she doesn't have a body image problem! and that wants to restore a healthy wait but simply cannot do it physically!

As a specialist for nearly 30 years now in the field of Eating Disorders, I made a conscious choice to firstly fully believe my patients although I know that at times they tend to disguise or hide their disturbed eating patterns. They do not lie about it because they are immoral, they are simply afraid these maladaptive eating habits will be taken away, leaving them with no other coping mechanism to regulate their emotional traumas.

When S. told me that she tried to eat fish and chips numerous times but couldn't hold it in, I knew she did not suffer from Anorexia Nervosa. She did not have a conscious drive toward thinness and did not induce vomiting. On the other hand her initial refusal to receive PN raised again the suspicion that she is "hiding something". So I asked her why are you refusing to receive PN? She answered me straightforwardly:

"I am afraid that if a fire will burst in the ward and I will be connected to the PN pump, I will not be able to escape". Her unexpected surprising answer made sense later when we were able to link it to her feeling of being trapped in the Eating Disorders unit being misdiagnosed with Anorexia Nervosa and to the ongoing feeling of being trapped in her body that is not capable to absorb and food. Her answer reassured what all my best mentors in psychiatry and medicine taught me: Don't assume! First ask the patient what do they think about their condition, they know! they are the one who has the experience! This is true in any specialty of medicine but should especially not be forgotten in mental health where the danger is that the opinion of the person will be disregarded as already he has a label that challenges his capacity to make a sensible judgment.

So What Happened to S? How Did Her Problems Evolve?

Her mother confirmed that when she was one year old she contracted a campylobacter infection in a swimming pool that might have been followed by a post infectious irritable bowel syndrome as since she was a little girl she has complained a lot about "tummy pains" which were diagnosed as "tummy migraine". She also had unexplained bouts of vomiting from a young age. At the age of 3 she had two episodes of a prolapsed rectum. S. who was hyper mobile and very flexible became an outstanding athlete. She won a national competition for under 10 years old in her field. During that time her coach made a thoughtless, unsensitive remark: He told her that she needs to be careful how she eats as she might become too heavy to compete in the team. As her success in her sport was so important to her at that time and part of her identity she took his comment extremely seriously and nearly stopped eating completely. She started obviously to lose weight and when it started to become too much she was diagnosed with Anorexia Nervosa. However; when she was threatened with admission to a hospital and cessation of her sporting activity, she immediately started to eat and restored a healthy weight. This is something that a "true Anorexic" will never do. She recovered very quickly from this period but then at the age of 14 she started to suffer from projectile vomiting up to 3–4 times a day and started to lose weight again.

Although she did not have any Anorexic Ideations at that time she was "accused" of making herself vomit on purpose. When she reported that she vomits "white lumps looking like hard dumplings" she was told that this is imaginary.

When the symptoms continued at some point feeding with a percutaneous endoscopic gastrostomy (PEG) was tried followed by a percutaneous endoscopic jejunostomy (PEJ). During its insertion a bowel peroration occurred

which was followed by peritonitis. Then she was as mentioned above treated in an Eating disorder unit and as this had not succeeded to improve her state she was referred to the IRU for further assessment and PN.

Believing her narrative, taking it seriously as her own experiential truth was the most important initial step to enable her to engage in therapy and regain trust in the medical team that tried to help her. After I explained to her and warmly reassured her that even if a fire would burst in the ward she will not be trapped even if she is connected to the PN pump; thus she agreed to receive the PN.

The traumatized person does not remember the trauma they re-live it!

They immediately enter a Fight-Fight-Freeze mode. They become stupefied with fear (this is the origin of the word stupid) and cannot reflect or think rationally because they are fighting for their life. Creating a secure, safe base within the therapeutic relationship is the most essential component in enabling engagement in the treatment process.

Unfortunately, during the PN S. developed sepsis and it had to stop but as she was already motivated to try and restore a better nutritional state she was willing to see me on a weekly basis as an out-patient at the PMU. Once the right name to her condition was given -a gut motility disorder with delayed gastric emptying/gastroparesis most probably as part of the gastrointestinal manifestations of EDS and she was "redeemed" of being misdiagnosed as an "Eating Disorder patient" she became significantly less anxious, and very motivated to work together .

The psychiatric differential diagnosis of Gastroparesis is complex and in addition to Eating Disorders includes Somatization Disorders, Post-Taumatic Stress Disorder and other Anxiety disorders, Opioid Withdrawal and even Schizophrenia. In addition the Gastroparesis itself in a vicious cycle triggers a Phobia to eat, Panic Attacks and personality changes [24]. The key thing that helps to navigate in this "labyrinth" is to address the uniqueness of each patient-to find his/her "Pin Number". This can be found only through mutual work.

An old Chinese proverb says:

Tell me something and I will forget,
Show me and I will learn,
Involve me and I will understand.

The psychotherapist working with patients on the IRU needs at times to actively involve the patient with psychoeducational material about the brain-gut axis, the links between stress and fatigue and inflammation etc. With S. I had to speak with her a lot about the importance of maintaining a stable safe potassium level, about its influence on the regular heart rhythm; we had to think creatively about what she can absorb and when and how to be more "jazzy" and improvise with what she can eat. As she was no longer afraid to be disbelieved she came regularly to the meetings and was able for the first time to have a life outside hospital whilst maintaining a safer bodily state and a stable potassium level.

At the end of each session she gave me a little animal made of paper. I realized that she is a master of Origami work. Then she showed me her drawings which were absolutely amazing in their originality and delicacy. I then discovered that she dreams to be an illustrator for children's books. She did not believe that she will be able to be accepted to an art or an illustration school or class. I actively encouraged her to do that. It was not hard for me to do as I was deeply moved by her images. I told her: "Just show them your work and you will be accepted". Exactly this happened! She started to study illustration in a professional highly regarded art school and kept herself nurtured and physically safe as much as possible.

When she was discharged she gave me this picture (Fig. 1) that she drew:

For me this moving symbolic image of hope and fragility is her self-portrait. It is also what life with IF is about: The

Fig. 1 Picture drawn by patient

paper boat can represent her fragile body that carries her motivation represented by the fisherman in the yellow coat and hat who patiently waits to find, to bring something from the depth of the lake. In German the word lake is SEE and the word Soul is SEELE. The lake and the soul are connected. She doesn't give up on the connection with her soul. The yellow color symbolizes the sun, consciousness, joy and humor.

S. was only one of the many patients at the IRU who humbled, inspired and thought me each day about courage, resilience and about how with the right motivation and support IF stops being an obstacle for living life to the full.

Part VI

Outcome of Intestinal Failure

Home Enteral Nutrition in Adults: Indications and Outcomes

André Van Gossum, Asuncion Ballarin, Marianna Arvanitakis, Xavier Hébuterne, and Jeremy M.D. Nightingale

Key Points

1. The use of Home Enteral Nutrition (HEN) is increasing throughout the world.
2. The prevalence of HEN is variable at about 100–1400/millions inhabitants in Western countries.
3. HEN is indicated in patients who are at high nutritional risk or malnourished, who are unable to meet nutritional requirements by the oral route and who have a functional gastrointestinal tract.
4. Dysphagia due to neurological disorders or head-and-neck cancer are the main indications for HEN.
5. Most (80%) of HEN is through a gastrostomy tube. Some are by a naso-gastric tube or rarely a jejunostomy.
6. Survival on HEN depends upon the prognosis of the underlying disease.
7. The objectives of HEN must include nutritional targets (e.g. achieving/maintaining a pre-determined body weight), quality of life, ethical issues and the criteria for stopping.
8. The initiation and monitoring of HEN should be performed by a multidisciplinary nutrition support team in collaboration with the community/family/caregivers.

Introduction

The use of HEN started in the early seventies in response to the interest and need for ambulatory care. For the majority of the patients, enteral nutrition is initiated during their hospital stay and then continued at home. Procedures and funding for home parenteral nutrition (HPN) preceded that of HEN in many European countries [1]. Globally, HEN is used for patients with oral failure (OF) but having a functional gut. On the contrary, home parenteral nutrition (HPN) is indicated in patients with severe chronic intestinal failure requiring intravenous supplementation to meet nutritional or fluid requirements [2].

The use of HEN progressively increased around the world after the introduction of the percutaneous endoscopic gastrostomy (PEG) technique [3], the availability of commercially-designed enteral formula and the development of home care services.

HEN must be considered as a medical treatment. Before starting HEN, not only nutritional needs but also prognosis, quality of life and ethical issued have to be discussed and regularly evaluated [4]. Although HEN can be initiated by any medical team, it is highly recommended that the route of administration, timing and composition of feeding, organization or services are best made by a multidisciplinary nutritional support team (NST).

OF is often unrecognized, partly because it is not thought of and partly because these patients are looked after by a myriad of medical specialties. This contrasts to IF which usually recognized because these patients tend to be under the care of appropriate specialists and have more immediate problems. It is paradoxically more difficult to recognize and treat the problems of OF than IF.

J. M.D. Nightingale (ed.), *Intestinal Failure*, https://doi.org/10.1007/978-3-031-22265-8_46

Epidemiological Data

The incidence and prevalence of HEN is not known in many countries but when reported is increasing [5–7]. There are few national registries that try to record all patients receiving HEN (BANS in UK or NADYA-SENPE group in Spain), [7, 8] but still are likely to give an under-estimate as registration is not compulsory (perhaps only a third were registered in UK) [7]. In the USA, information comes primarily from Medicare and Medicaid Services [6]. Many other hospital/university centres in different countries report their own case-series.

There is no standardization in the way in which incidence (new cases/registrations), prevalence (one-day point and annual occurrance) and outcome data are presented. Most prevalence data are per 10^6 inhabitants (or population). Comparison between these data sets can be difficult to interpret.

During the nineties, it was estimated that the number of patients receiving HEN was ten times higher than those on HPN [9–11]. For example, in the UK, the one-day prevalence of HEN in 1998 was 200–267 patients/10^6 inhabitants and for the region of Nice in France, the annual incidence of HEN was 99 patients/10^6 million inhabitants [12, 13]. In 2017, the Spanish Home Enteral Nutrition Registry reported a prevalence of 102/10^6 million inhabitants [14]. It is estimated that 18,232 people (284/million population) received home HEN in the UK in 2013 [15]. In Italy the incidence was 406 ± 58 patients/million inhabitants/year for patients living at home and 319 ± 44 for patients living in a nursing home in 2012 [5]. In USA. 437,882 patients (1385 per million U.S. inhabitants) were receiving HEN in 2013, which was a large increase from 1992 (415 per million) [6, 9].

In some countries, HEN reports combine oral supplements and enteral feeding (via a tube) [16]. For example in New South Wales (Australia), the HEN population of participating hospitals was approximatively 7600, with 81% oral nutritional support and 19% tube-fed patients [17].

It is estimated that 10% of nursing home residents in the USA are receiving HEN [8].

Indications for HEN

HEN is indicated in patients who are at high nutritional risk or malnourished, who are unable to meet nutritional requirements by the oral route and who exhibit a functional gastrointestinal tract [18]. They should have a life expectancy of more than a month [18]. Short term or predicted short term enteral nutrition for 4–6 weeks is usually via a naso-gastric tube [18]. According to the ESPEN Guidelines, an inadequate nutritional state is confirmed if patients cannot eat for a week or if the energy intake is less than 60% of estimated requirements for 1–2 weeks [19].

There are three major underlying physiological reasons for HEN to be needed: dysphagia, anorexia (OF) and intestinal failure. Dysphagia and anorexia cause a reduced intake, and intestinal failure results in reduced absorption. Some patients may have several reasons for needing HEN (e.g. anorexia and moderate intestinal failure) (Table 1).

Globally, neurodegenerative, and neurovascular diseases account for 50–60% of the indications. Dysphagia due to head-and-neck or upper GI cancer is the second most common indication. In the recently published experience in Poland, the primary diseases for a total of 4586 patients were 54.5% neurological, 33.9% cancer (20.2%—head and neck, 11.7% gastrointestinal, 2.5% gastroenterology and 1.5% inherited diseases [14]. In the UK in 2015 (3216 patients) 42.9% had cancer (mostly head and neck), 39.6% central nervous system and mental health problems, 9.0% non-malignant gastrointestinal disease and 8.4% others [7] (Table 2).

Table 1 Clinical features that lead to the need of HEN

• Swallowing disorders because of neurological diseases
• Dysphagia because of malignancies (mostly head and neck cancer or upper GI tract)
• Cancer-related cachexia
• Chronic malnutrition related to chronic obstructive pulmonary disease/chronic heart disease or chronic infections (i.e. cystic fibrosis)
• Malabsorption/maldigestion because of liver, pancreas or intestinal disorders

Table 2 Common underlying disease for which HEN is given to new adults in the UK in 2009 [19] and Poland 2007–13 [20]

UK classification		UK *n = 3282*	Poland *n = 456*
CNS and mental health (*n* = 1226)	Cerebrovascular disease	649	137
	Motor neurone disease	197	17
	Multiple sclerosis	122	17
	Parkinson's disease	109	7

	Dementia	48	18
	Cerebral palsy	36	74
	Anorexia nervosa	26	1
Cancer (*n* = 1226)	Head and neck	673	23
	Oesophageal	239	
	Oropharyngeal	183	
	Gastric	45	19[b]
Non-malignant gastrointestinal (*n* = 291)	Dysphagia (unknown cause)	58	
	Crohn's disease	20	4
	Dysmotility	15	
Other (*n* = 205)	Cystic fibrosis	24	6

[a]Includes spinal injury
[b]Labelled as abdominal cancer

Most adults are over 60 years though those with cerebrovascular disease tended to be older; 66% were aged 71–90 [7]. Head and neck cancer patients tend to be younger and have HEN due to dysphagia (69%), disease-related malnutrition (19%) or gastrointestinal obstruction (3%) [7].

Physiological Reasons for HEN

Dysphagia

Dysphagia is the major reason for a patient to receive HEN. It may be secondary to a neurological problem (usually cerebrovascular disease), a vegetative state, a head and neck cancer, or a rare benign cause. In most cases dysphagia will remain a permanent problem; in some cases it is temporary, for example, during radiation therapy or chemotherapy or prior to removal of an upper gastrointestinal cancer.

Anorexia

Anorexia represents a growing indication for HEN and defines a patient without dysphagia who cannot take adequate nutrition by mouth to meet his or her nutritional requirements. Some patients may have associated increased energy requirements (cancer or rarely AIDS patients). Anorexia is generally found in very old patients, is secondary to an acute or chronic illness (surgery, infection, dementia or psychological disorder) and is associated with the problems of undernutrition. Active dietetic support is needed for these patients; if sip-feeds are unsuccessful, enteral feeding in the hospital may be given for 3–4 weeks. If voluntary intake improves significantly during this time, enteral nutrition can be stopped; if not, there is a high chance that long-term HEN will be needed.

Intestinal Failure

In the case of intestinal failure, oral intake is insufficient regardless of the gastrointestinal problems that have led or will lead to undernutrition. A patient with chronic diarrhoea may be a candidate for enteral rather than parenteral nutrition if the daily stool weight is less than 500 g and the daily faecal fat less than 20 g (72 mmol). There are many diagnoses responsible for maldigestion (e.g. chronic pancreatitis or previous gastrectomy) or malabsorption (e.g. short bowel, small bowel dysfunction or HIV/AIDS). Patients with more than 200 cm of small intestine remaining and a functioning colon may need a period of enteral support. Long-term enteral support may be needed in patients with a jejunostomy and 100–200 cm of remaining small intestine [21].

Persistent Vegetative State

Persistent vegetative state (PVS) is a clinical condition of complete unawareness of self and the environment, accompanied by sleep–wake cycles, with either complete or partial preservation of hypothalamic and brain stem autonomic functions [22]; there is no interaction between the patient and others, and the patient is doubly incontinent [23]. Some authors argue that physicians are not obliged to provide nutritional support in this condition because there is no clinical benefit although physiological functions can be maintained [24]. Others strongly disagree with this attitude on the basis that every human being has the right to food and water, even in situations in which medical interventions can be ethically withheld [25]. The physician needs to explain all outcomes to the family and then, in some countries, let them decide. In the UK, an application to stop the feeding has to be made to the High Court. If the family wishes to care for their family member at home, it can be argued that the medical profession must provide both the means by which food and water can be given, and the feed itself (Chap. 53).

Reasons Not to Give HEN

Before starting HEN, the absence of contraindications must be checked (Table 3) and the criteria for starting confirmed (Table 4) (Fig. 1).

The success of HEN depends on patient selection, safe placement of a feeding tube/device, suitable nutrients and administration system, adequate education about enteral feeding, and regular monitoring. The European and international guidelines advice against initiating tube-feeding in patients with severe dementia. Orlandi et al. challenged this issue reporting a series of 585 consecutive patients of the mean age of 85 ± 7 years [26].

Table 3 Contraindications to HEN [18]

1. A life expectancy estimated to be less than 1 month
2. The existence of severe functional disturbances of the bowel, gastrointestinal obstruction, gastrointestinal bleeding, severe malabsorption or severe metabolic imbalances
3. Patients and/or their legal careers who do not agree to a HEN program or are unlikely to comply with and/or if there are organizational/logistic problems which cannot be overcome

Table 4 Criteria for proposing that a patient be started on HEN

Oral failure and a functional/usable gastrointestinal tract
Ability to tolerate enteral nutritional therapy in the hospital (for at least 7 days)
No other medical or surgical problems—ready to be discharged
A clean and safe home
Patient or carer able to perform all enteral procedures safely

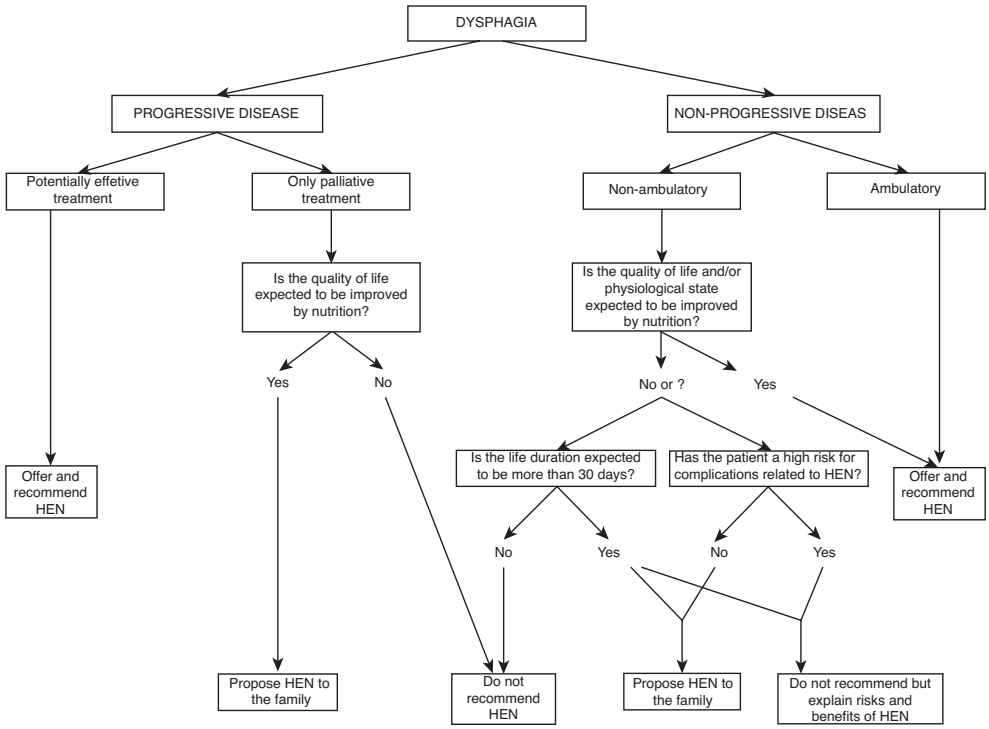

Fig. 1 Algorithm for starting HEN

Table 5 Items to address before the patient can discharged (adapted from [18])

• The quantity of EN, and which brand should be administered
• Total amount of fluid administrated
• Duration of administration, during day or night
• The use of the enteral feeding pump and what to do in case of dysfunction of the pump (if a pump is used at all)
• Whether the patient is allowed to have oral intake next to HEN (any restrictions?)
• Personal care, impact of HEN on daily life (shower, swimming, party, holiday)
• Who will take care of the administration of the EN (patient, family, [home care company] nurse)
• How to secure the tube adequately
• How to administrate medications through the tube
• Who will change or reinsert the tube in case of dislocation
• What to do in case of blocked tube:
– Who to contact in case of material or physiologic complications (material: dislocation, blocked tube and/or breaking material) and physiologic complications (diarrhea, constipation, aspiration, change of weight, dehydration)
• How often the patient should be evaluated, by whom and where

Interestingly, Velapati G et al. described a series of 72 patients who presented with malnutrition due to bariatric surgery [27]. They reported that HEN was safe and effective leading to avoidance of parenteral nutrition in most cases.

Before discharging the patient at home, a checklist must be completed for assuring a good quality of care at home (Table 5) [18]. A Canadian survey underlined that 74% out of 390 adults on HEN did not have any record of visiting a community registered dietitian up to 6 years after tube placement [28].

Mode and Method of Delivery

The most common tube inserted is a gastrostomy, usually done endoscopically (percutaneous endoscopic gastrostomy (PEG)). In the UK in 2015, 80% of HEN patients were fed via a gastrostomy, 10% via a nasogastric tube, 6% via a jejunostomy and 3% by a nasoduodenal or nasojejunal tube [7]. In Spain in 2012, 45.3% were fed by a nasogastric tube and 29.4% by a gastrostomy [8]. In Poland in 2018 a gastrostomy tube was used most commonly (PEG 65.3%, other gastrostomy 11.6%), 14.3% had a naso-gastric tube, 7.0% a jejunostomy, 0.6% a naso-jejunal tube and 0.2% a gastro-jejunostomy (PEGJ).

Feeding through a tube may be by a continuous infusion (with pump assistance), intermittent drip, or a bolus technique. Bolus feeding involves 4–6 feeds a day of 200–400 ml given by a 50 ml syringe over 15–60 min [18]. Overnight feeding tends to be over 10–12 h using a static or mobile pump. In Poland 74.4% had feed given as a bolus, 17.6% by gravity flow and only 8.0% through a pump [29]. In most countries feed is currently given with the aid of a pump. However in the USA Medicare will provide reimbursement for a pump if: The administration rate is less than 100 ml/h,

if circulatory overload, if increased aspiration risk/pneumonia or if diarrhoea, dumping syndrome, gastrointestinal reflux, vomiting or blood glucose fluctuations [30].

The feed may be polymeric (with or without fibre) or increasingly consist of homemade blenderized food.

Outcome of HEN

Data about the complications of nutritional support are often given as the proportion of patients developing a specified complication though it is better (as for PN) to be per EN feeding days.

Fourteen percent of those who had a stroke returned to oral feeding, thus it is important to assess continually a patient's ability to swallow as it may improve and allow tube feeding to be stopped [31].

Survival

Folwaski [29] et al., in Poland, described a series of 4586 HEN patients in 2018. The median overall survival on HEN was 354 days but 615 days for neurological diseases and 209 days for cancer patients (Table 6) [29]. Ruggeri et al. reported a mean survival of 22.1 weeks in cancer patients with dysphagia who received HEN [32]. A retrospective Italian study found a median duration of HEN of about 196 days [17]. Regarding the underlying disease, duration was 261 days for neurovascular diseases, 251 days for neurovegetative disease, 118 days for head and neck cancer, 82 days for abdominal cancer, 788 days for head injuries. In this series, only 7.9% of the patients resumed oral nutrition; the median survival was 9.1 months. The median survival and the rate of complications were similar between those with or without dementia [26].

Cawsey et al. reported a series of 727 adult patients [33]. Median duration of HEN for cancer patients was 122 (range, 1–1259) days, duration for neurological disorders was 187 (range, 1–1752) days, and duration for GI disorders was 161 (range, 1–1849) days.

Table 6 Outcomes of adult HETF during 2015 [7] in UK and 2018 in Poland [29]

		UK	Poland
	n	%	%
Continuing	6270	70	48.5
Died	1436	16	40.2
Return to oral diet	1039	12	5.3
Lost to follow up	131	2	4.7
In hospital	14	<1	
Withdrawn/refused	14	<1	1.2

Table 7 Outcome of patients on HEN (follow-up 18–65 months) [34]

	Full oral nutrition *n* = 51 (%)	Continued HEN *n* = 19 (%)	Died *n* = 93 (%)	Stopped for other reasons *n* = 20 (%)
Neurological disease	16	13	65	6
Head and neck cancer	33	5	54	8
Digestive disease	49	3	26	22
Post-traumatic dysphagia	14	43	0	43
Anorexia (elderly)	30	6	58	6
AIDS	0	0	100	0
Other	50	25	17	8

Table 8 Survival at 1 month, 1 year and 5 years [35]

	n	1 month (%)	1 year (%)	5 years (%)
Neurological disease	148	83	41	21
Digestive disease	76	90	59	49
Head and neck cancer	64	88	37	24
Dementia	54	54	20	3
Anorexia	32	81	56	21

The overall probability of survival was 44% at 1 year and 29% at 5 years in one study (Table 7) [34], and similar results of 80, 42 and 25% at 1 month, 1 year and 5 years respectively in another (Table 8) [35].

There is a low mortality for cerebral palsy, cystic fibrosis and multiple sclerosis. However it is higher for patients with motor neurone disease, dementia and malignancy (30–60% in the first year. Patients who had a cerebrovascular accident and were over 75 years were 3–4 times more likely to die while on HEN than those patients aged less than 65 [31]. Patients with small bowel malabsorption needing HEN are uncommon, but at 1 year 82% were alive, 43% had 'complete rehabilitation', and 45% had stopped HEN and resumed an oral intake [36].

In a retrospective cohort study of 253 older patients with dysphagia in Japan 180 patients were randomised to PEG and EN feeding and 73 to TPN. The PEG group had a significantly longer survival time (median, 317 vs 195 days); but a significantly higher incidence of severe pneumonia (50.9% vs 25.5%); however the incidence of sepsis was significantly lower (10.9% vs 30.9%) [37].

Quality of Life

While the health-related quality of life for patients with gastrostomy tubes is poor (usually due to severe physical disability) compared to that of the general population, the

majority of patients and carers rated the gastrostomy 'positively' [38]. The recorded quality of life for most patients in the UK receiving HEN is poor. 72% in UK were living alone at home. 42% were able to manage independently but most needed total 37% or some help 22%. Only 10% were housebound and 15% bedbound. 25% were in residential care. Those with cerebrovascular disease had a greater need for total help (82%). Only 4% managed independently, 70% required nursing home care. Those with head and neck cancer are relatively independent and active, 96% were in their own home, 75% were independent and only 4% needed total help and 20% some help. 73% achieved full normal activity, 25% a limited activity and <2% were housebound or bed bound. 24% of these patients returned to oral feeding alone, 61% continued and 14% died [7].

Complications

The overall HEN-related complication rate such that hospital admission was required was 0.3–0.4 per patient per year (with little difference between the diagnoses); this was half that of patients receiving HPN [9]. Readmission to hospital in the USA for non-HEN problems was less common for patients with neuromuscular disorders of swallowing (0.9/year), than with cancer or small bowel disease (both 2.7/year) [36].

Nine percent of patients receiving gastrostomy tube feeding developed aspiration pneumonia and in this event most needed hospital admission [39]. Aspiration is less likely to occur with a PEG than with a nasogastric feeding tube [40]. To reduce the risk of aspiration pneumonia a nasogastric tube's position is checked before each use and it is replaced with similar checks if it becomes displaced ("falls out"). Although in a healthy person with no dysphagia it is very difficult to inadvertently pass a tube into the lungs, this can easily be done in patient with neurological disease or reduced consciousness as they do not cough/become hypoxic as soon as the tube is misplaced.

Tube malfunction, breakage, site infection and a blocked tube all occur (Chaps. 33 and 54).

The poor clinical outcomes of HEN suggests that better selection of candidates for HEN will be needed and this will be helped by studies focusing on the quality of life and prognostic factors. Each case needs to be carefully discussed with the patient and family, and there needs to be an awareness of the aims and potential benefits before a decision is made to start HEN.

Home Parenteral Support for Adults

Laura Cohen, Francisca Joly, Simon Gabe, and Jeremy Woodward

Key Points

1. Improved availability and safety of home parenteral support (HPS) has led to a significant (two- to fourfold) increase in its usage and indications over the last two decades.
2. The most common reasons for HPS are surgical complications, Crohn's disease and mesenteric infarction.
3. Complications include those due to the venous access, the non-physiological route of delivery, and the pharmacological composition of the PN and are often difficult to separate from the effects of the underlying intestinal failure.
4. Long-term survival is possible on HPS, and most deaths on treatment are due to the underlying disease. Less than 25% of deaths are due to HPS-related causes, most frequently IF-associated liver disease (IFALD) and catheter-related blood stream infection (CRBSI).
5. Some patients maintain a good quality of life on HPS whereas others carry a significant burden of symptoms and interference with daily activities.
6. Failure of HPS (for reasons of impending loss of vascular access, IFALD or unmanageable/intolerable complications of intestinal failure) can be managed by intestinal transplantation. Early detection of IFALD or those at high risk and treatment with pre-emptive isolated intestinal transplantation is preferable to allowing end stage liver disease to develop, that then requires combined liver and intestinal transplantation.

Introduction

It is currently just over 50 years since the first demonstration of successful life support using sole intravenous nutrition in beagles by Stanley Dudrick [1]. Given that intestinal failure (IF) was a rapidly terminal condition at this time, the first use of parenteral nutrition in humans followed shortly afterwards, with patients learning how to manage their own parenteral nutrition at home from the early 1970s [2, 3]. Over the intervening half century, it is surprising how little has changed in the basic principles of intravenous nutrition and its delivery. However, with greater understanding of the complications and risks involved in home parenteral nutrition (HPN), and subsequent developments in nutrient composition, monitoring and support of patients, HPN therapy has become safer and more efficient. As a consequence the indications for HPN have broadened, it has become more widely available, and new challenges in its use have inevitably arisen.

In this chapter we address the need for HPS, the economics of its use, the requirements for establishing HPS, the practical avoidance of its complications and developing changes in HPS provision. The term home parenteral support

J. M.D. Nightingale (ed.), *Intestinal Failure*, https://doi.org/10.1007/978-3-031-22265-8_47

(HPS) is used except where the data or information relates only to parenteral nutrition (PN) when the term home parenteral nutrition (HPN) (which excludes those who receive parenteral fluid alone) is used.

The Need for HPS

Long-term PN and fluid support as an inpatient in hospital is not a valid option for most patients with intestinal failure. In order to retain any meaningful quality of life, this treatment needs to be available in the home environment. HPN may be required for only a limited period of time where there are surgical options available for the restoration of sufficient intestine in continuity ('type 2 intestinal failure'), or it may be required indefinitely ('type 3 intestinal failure') [4, 5]. Whilst a useful classification in clinical use, the distinctions between type 2 and type 3 IF are not always clear given the heterogeneity of conditions requiring PN support and the increasing medical and surgical options for treatment, including intestinal transplantation.

HPN is expensive [6, 7] with costs that escalate when nursing care is required for the connection and disconnection of infusions. Nevertheless, in most westernised health economies it is still more cost effective to provide PN at home rather than in hospital where capacity for inpatient treatment is in high demand. It is this cost differential (rather than concern for improving quality of life) that has largely driven the use of HPN for increasingly short periods of time whilst awaiting restorative surgery.

Organisational improvements that have led to increased efficiency, support and safety in HPS provision, have enabled a significant increase of HPS use in many countries over the first two decades of the twenty-first Century. In the UK for instance, the number of patients receiving HPN has increased from around 10 per million population in 2000 [8] to 40 per million in 2015 [9]. However there remain significant differences in HPN prevalence between countries—for instance in 2013, Spain reported 4.2 cases per million [10] whereas there were approximately 79 per million in the USA [11]. Interestingly, in the USA, HPN prevalence has actually dropped from 157 cases per million in 1992 [11], possibly due to an increase in availability of home enteral nutrition support or due to issues related to charging and benefits associated with the healthcare system.

Indications for HPS

HPS is indicated for the long-term support of any condition where enteral feeding is either impossible or inadequate. A pathophysiological definition (rather than the above 'func-

Table 1 Indications for home parenteral nutrition (HPN) (adapted from [5])

Pathophysiological group	Mechanism of intestinal failure	Examples
Short bowel	• Reduced absorptive surface area	• Intestinal resection due to:
	• Increased fluid losses	• Mesenteric infarction arterial or venous, volvulus, Crohn's disease, radiation enteritis, trauma
	• Secondary reduced oral intake to control losses	• Congenital intestinal malformation, gastroschisis, atresia
	• Rapid gastrointestinal transit	
Intestinal fistula	• Bypass of gastrointestinal absorptive mucosa	• Iatrogenic due to surgical bowel injury
	• Increased fluid losses	• Trauma
	• Secondary reduced oral intake to control losses	• Crohn's disease
	• Metabolic demands due to associated sepsis or inflammation	• Tumour
		• Infection (TB, actinomycosis)
Intestinal dysmotility	• Intolerance of oral/enteral feeding due to symptoms	• Chronic intestinal pseudo-obstruction either primary (visceral myopathy or neuropathy) or secondary to a wide variety of underlying medical conditions or medication use
	• Small bowel bacterial overgrowth	
	• Increased fluid secretion in obstructed segments	
	• Increased GI losses due to vomiting, diarrhoea or gastric drainage	
Mechanical obstruction	• Reduced oral intake due to symptoms and lack of absorption	• Obstructing tumour of the GI tract
	• Increased fluid secretion in obstructed segments	• Obstruction due to peritoneal disease including tumours or adhesions
	• Increased GI losses due to vomiting, diarrhoea or gastric drainage	

(Continued)

Table 1 (continued)

Pathophysiological group	Mechanism of intestinal failure	Examples
Extensive intestinal mucosal disease	• Inefficient nutrient absorption or nutrient and fluid loss from mucosal surface	• Refractory coeliac disease, Crohn's disease, common variable immunodeficiency with chronic noroviral infection, tufting enteropathy, microvillous inclusion disease

tional' classification of IF types) identifies five main types of indication [5] (see Table 1). In the UK, the British Artificial Nutrition Survey (BANS) [9] has kept comprehensive data on the usage of home enteral and parenteral nutrition since 1996. Short bowel remains the commonest indication, but has dropped from 44% of patients receiving HPN in 2005 to 34% in 2015, largely accounted for by a proportionate reduction in patients with Crohn's disease. In the UK, malignant bowel obstruction and dysmotility disorders contribute approximately equal proportions of existing HPN patients, however the UK-BANS registry collects separate data for 'point' prevalence (on a specified census date) and 'period' prevalence (between two time points). Patients with malignancy generally have a shorter life expectancy than those patients with dysmotility and therefore contribute approximately a quarter of new HPN registrations compared to around 7% for chronic intestinal pseudo-obstruction. Ovarian cancer is the commonest malignant indication for HPN in the UK.

The proportion of new HPN registrations for malignancy in the UK has doubled over the last 10 years and a similar trend is apparent in other national registries such as Canada [12] and Spain [10] where malignancy now comprises the commonest indication in adults.

Establishing a Patient on HPN

A hospital providing an HPN service requires a comprehensive and integrated nutrition support team that comprises nutrition nurse specialists, medical staff with appropriate expertise and training, pharmacists, and dietitians. The team will require close links with vascular access and community homecare teams [13].

To be suitable for receiving parenteral nutrition at home, a patient requires a stable PN prescription with regard to nutrient and electrolyte composition and volume [14]. This may take several days or weeks to establish as volume and electrolyte losses can vary from day to day in patients with high output fistulae or proximal stomas. Much will depend on their ability to limit hypotonic fluid intake. It is crucial to ensure that the patient fully understands the importance of this as it is not uncommon for patients to comply with such fluid restrictions in hospital only to take hypotonic fluids *ad libitum* when at home, resulting in rapid readmission with acute kidney injury. The clinician is often best advised to allow the patient to set a fluid regimen in hospital that they will be able to comply with in order to maintain the same at home, even if this is at the expense of a larger PN fluid volume.

Whereas hospital PN is often run over 24 h for patients with type I IF, patients generally prefer shorter infusion times at home so that they can feed overnight, allowing them to be active during the day. There is some evidence to suggest that this cyclic PN is also preferable from a metabolic viewpoint [15]. In some countries such as the UK it is traditional not to add lipid to all of the PN bags but to provide the patient's full lipid requirements in just 1–3 bags each week. Initial reasons for this were that daily lipid containing feeds were found to clog central venous catheters (and required ethanol flushes to clear). Subsequent evidence suggested that parenteral lipid is associated with hepatotoxicity, although this evidence is largely limited to the former use of soy-based 'intralipid' as the main parenteral nutrition lipid source [16]. Indeed, many patients describe symptoms of nausea and headache after receiving lipid-containing infusions, but not after aqueous bags. The mechanism of such symptoms requires further study. As a result, clinicians have attempted to reduce the lipid component of the PN. Whilst this can be achieved by providing a smaller amount of lipid on a daily basis in every PN bag, it risks physical instability and shorter shelf life of the PN mixture.

The downside of reducing the lipid content of the PN is that a higher proportion of calorie requirements are then provided by simple carbohydrate, and (especially given the pressure by patients to reduce infusion times) it is possible to exceed the body's glucose oxidation capacity. This can result in de novo lipogenesis in the liver which is associated with steatosis, inflammation and fibrosis through increased local generation of reactive oxygen species [17]. Clearly a balance needs to be achieved for each patient regarding lipid frequency and the overall PN infusion times. At the moment, the underlying cause of IFALD is not established and it is likely to be multifactorial.

Reducing the infusion time of PN needs to take place whilst still in hospital in order to confirm tolerance—particularly in the elderly or those with myocardial compromise where high fluid infusion rates may not be tolerated.

Prior to discharge on HPN, the prescription needs to be stable on a day-to-day basis but also to have proven physicochemical stability to ensure suitable shelf life for weekly or fortnightly deliveries to take place. Pharmaceutical tables of stable additive ranges now allow for this to be calculated without recourse to 'trial and error', but may limit the quanti-

ties of electrolytes or trace elements that can be provided. In practice this requires a hospital pharmacy to have the capability for 'scratch' or 'bespoke' bag compounding.

Patients need a suitable central access device for infusion of HPN. Increasingly patients are being discharged initially with 'PICC' lines (Peripherally Inserted Central venous Catheters), although these are associated with an increased risk of thrombosis and require extension sets to allow patients the ability to access them [18]. Therefore, such devices would be used only as a temporary access until a tunnelled central line can be placed. A tunnelled, cuffed CVC should be considered to be the central venous access device of choice. However, other options that can be considered are implantable ports (portacaths) and even using an arterio-venous fistulae. Some patients prefer implanted subcutaneous 'portacath' devices that require needle access. These have the advantage of permitting activities such as swimming and exercising and may be more cosmetically satisfactory—they may therefore be more popular with younger and fitter patients. However there is no evidence that infection rates are lower with such devices, they have a limited lifespan depending on how often the membrane is punctured for access and associated infections may be more severe and difficult to treat than for tunnelled central lines [19, 20]. In addition, a small number of centres preferentially use surgically created arterio-venous fistulae for PN access for their patients [21].

Before discharge on HPN patients will have to find space for a large enough refrigerator to hold the bags for weekly or fortnightly deliveries. Standard domestic specification refrigerators are inadequate as they rarely have uniform temperature distribution (bags might freeze at the back, yet be too warm at the front) or have adequate responsiveness for temperature fluctuations outside the necessary limits. They will also require dedicated space for ancillaries and for sterile connection and disconnection of their feed. Patients will need to be educated to handle the settings of their infusion pump (which may be different at home from that in hospital) and be able to know what to do in case of unexpected events such as inadvertent disconnection, refrigerator failure or pump faults. There is good evidence to suggest that patient education is able to reduce central venous catheter infection and hospital readmission rates.

In many countries, dedicated homecare nursing for feed connection and disconnection is not available and patients or their family members need to be trained in sterile procedures in order to do so themselves. This can substantially delay discharge (by an average of around 3 weeks), and economics currently dictate that where suitable community nursing support is available, patients return home with twice daily visits for connection and disconnection and are trained to manage their PN themselves whilst at home.

HPN provision is often undertaken by specialised homecare companies with dedicated compounding facilities, cold-chain delivery capability and 24 h telephone support availability for problem solving.

While this model of delivery and providing PN for use at home may be ideal, it is costly for healthcare services and requires considerable infrastructure. In some countries (e.g. Poland) the PN components are delivered to patients who are trained to mix the components together into an infusion bag and then subsequently infuse this directly. It may be viewed that the risk is higher regarding bacterial contamination but if infused immediately and a 0.2 μm filter is used on infusion (this is standard anyway) then infections may not necessarily occur. In addition, the issues relating to stability of the PN over time are much less of an issue. As less infrastructure is required, this is a cheaper way of delivering HPN.

Supporting HPS

The support of patients on HPS requires close communication between the hospital nutrition team and the homecare support team [22]. Liaison prior to discharge will co-ordinate the first delivery of feed and homecare nursing visit. One of the clear advantages of patients learning to manage their own PS at home after discharge is that there is ongoing regular (usually twice daily) contact with nursing staff who can instantly report any problems back to the hospital nutrition team or the homecare delivery team. Despite having achieved electrolyte stability prior to discharge it is often necessary to recheck blood tests shortly after the patient returns home. It is important to ensure that wherever possible patients do not become dependent on nursing support at home—for economic and logistical reasons as well as the benefits for patients in having a greater degree of freedom and confidence to manage their own PN.

When patients are able to manage their own connection and disconnection and are therefore liberated from twice daily nursing visits, they need to be confident of 24 h back up arrangements and to be aware of whom to call in case of problems arising. At this stage, the homecare delivery driver often plays a role in reporting back quantities of unused feed or ancillaries which can give the hospital team an idea of compliance with therapy and early warning of problems. Home healthcare providers have identified significant benefits in providing continuity in delivery drivers in order to foster trust with patients which provides an additional safety net of support.

As well as having an overall umbrella of care and support, the hospital nutrition team should arrange a clinic follow up appointment within the first month after discharge and thereafter at regular intervals dependent on clinical stability (Table 2).

For patients on long term HPN, in addition to regular anthropometric assessment and adjustment of feed nutrients,

Table 2 Outpatient check list with multidisciplinary team (doctor, nurse, dietitian and pharmacist)

Review and treat underlying diagnosis
Assess symptoms (e.g. diarrhoea, vomiting, abdominal pain etc.)
Assess hydration/nutrition status
Assess the vascular/enteral access and catheters/enteral tubes
Review catheter care regimen
Review wounds/stomas
Check for complications (e.g. CRBSI, thrombosis, liver, bone or kidney disease)
Assess surgical plans (if any) and bowel mapping status
Review deliveries and storage of equipment, ancillaries and feed
Review medications and PN prescription, consider stopping/changing HPS (e.g. nights off feed)
Assess the goals of the nutritional support
Consideration of transplantation/links to other units or services
Review the psychological state, coping mechanisms, ways of improving the quality of life
Put information onto local or national register (eBANS in UK)

monitoring from the hospital clinic should include a baseline bone density scan and liver ultrasound (to determine the presence or absence of gallbladder and stones, liver texture and degree of steatosis), and intermittent measurement of micronutrients and trace elements.

Renal and liver function tests should be performed regularly as well as checking magnesium, zinc, haematinics (B_{12}, folate, ferritin/iron studies) and vitamins (vitamins A, D, E are the most easily measured). A lipid profile is valuable occasionally to ensure that triglycerides are adequately cleared from the circulation. A CRP should also be checked at the same time and measuring a spot urinary sodium concentration can be helpful to assess hydration status. Generally patients are followed up every 3–4 months, depending on their stability ("Monitoring of Parenteral Nutrition at Home" chapter). However a survey from the ESPEN-HAN working group in 2008 showed that there was considerable variability in the follow-up frequency and the type of blood tests performed for these patients [23].

Manganese accumulation and subsequent neurotoxicity is a rare complication in this patient group. It is excreted in bile (and a degree of cholestasis is not uncommon with HPN), and the quantity present in proprietary trace element admixtures was previously excess to requirements. It is also sensible to optimise selenium and iron quantities in the PN according to blood measurements.

Voluntary patient advocacy groups such as PINNT (Patients on Intravenous and Nasogastric Nutrition Therapy) [24] in the UK and the Oley Foundation in the USA [25] are a key element to supporting patients on HPN. They can provide shared experiences and open up routes of communications for new patients on HPN to talk to others with experience of living with the condition, as well as useful practical advice and tips on aspects such as travelling and insurance.

Living with HPS

The impairment of quality of life on HPN should not be underestimated by clinicians. Although many patients adapt their lifestyles extremely well to manage the burdens of their chronic condition and treatment, many experience ongoing and long term difficulties. The ability to adjust will depend on the prior illness experiences of the patient, their stage in life and expectations, and the degree of family and community support available. Tragically, many patients with short bowel syndrome are young, previously fit and well and experience a sudden catastrophic mesenteric vascular insult that results in a high output proximal stoma and the need for life long HPN. Many will have ongoing symptoms such as thirst, hunger, pain, nausea and vomiting as well as a high stoma output risking dehydration and acute kidney injury and socially embarrassing noise and leakage from the stoma itself. Some patients will have additional gastric venting tubes or enteral feeding tubes to cope with as well. These will have profound psychological consequences and affect physical intimacy with partners and their relationships.

On top of these issues are the need for central venous access which may be visible to others and can limit physical activities, and poses a worry of infection. Overnight parenteral nutrition can lead to disturbed sleep, waking with pump alarms (occlusion or air in the line), and nocturnal polyuria due to the altered diurnal fluid delivery.

Social consequences also include mealtime embarrassment and exclusion, especially if patients are unable to eat, the need to take large amounts of paraphernalia with them when away or visiting friends restricting travel and holidays. Medical insurance cover can be problematic, and security arrangements at airports and borders need to be addressed given the excess baggage and fluid requirements. Often the patient advocacy groups are best placed to advise patients of these issues and also they often have information relating to holiday insurance as well that is helpful to patients.

Tools have recently been developed to attempt to quantify the quality of life impact on patients needing HPN—the HPNQOL [26] and the PNIQ (Parenteral Nutrition Impact Questionnaire) [27]. Surveys generally show a significant detriment to quality of life [28] that tends to improve over time, but is affected markedly by the age of onset and nature of the underlying disease and the number of nights over which HPN is required. Patient-related outcome measures (PROM) may be the best approach and the PNIQ was developed on that basis. However, more studies are required using this tool to see if it is effective.

Complications of HPS

Many complications of long-term parenteral nutrition are consequent to its non-physiological route of delivery that bypasses enteroendocrine regulation of metabolism and gut function (Table 3). These can aggravate or be difficult to separate from the effects of intestinal resection in those with a short bowel [29]. Such metabolic complications include the lack of co-ordinated incretin stimulation of insulin secretion to match intravenous carbohydrate delivery, and altered levels of other gut hormones such as oxyntomodulin and ghrelin which influence glucose and lipid metabolism and regulation of energy intake. Gastrointestinal effects of reduced oral intake include cholestasis and high risks of gallstone formation due to lack of cholecystokinin secretion. This is exacerbated by interruption of the enterohepatic cycle and altered bile acid pool. Impaired epithelial barrier integrity and reduced villus height result from a lack of luminal nutrients and consequent reduced secretion of GLP-1 which has trophic effects on the mucosa. Malabsorption may be increased by rapid intestinal transit due to reduced secretion of PYY, GIP and GLP1 from distal intestine or colon that act to slow motility. Patients with short lengths of residual intestine are prone to overabsorption of oxalic acid from the colon—thought to be due to preferential complexing of divalent cations with malabsorbed free fatty acids—and lead to renal calculus formation.

The composition of PN compromises the physiological form of the nutrients in order to provide physico-chemical stability in a complete mixture. The lipid component in particular has been problematic in view of its delivery as lipid micelles rather than chylomicrons. Initial formulations required a high phospholipid:triglyceride ratio for emulsification and led to phospholipid accumulation in the reticulo-endothelial system. Abnormal lipid accumulation in the reticulo-endothelial system can also rarely result in 'sea blue histiocytosis' syndrome causing hepatosplenomegaly, thrombocytopaenia and bleeding [30]. Original soy-based lipid formulations contained significant amounts of phytosterol and contributed to intrahepatic cholestasis and steatosis by direct inhibition of the liver Farnesoid X receptor [31]. Delivery of >1 g/kg/day of soy-based lipid emulsion has been identified as a risk factor for advanced IFALD [16]. Newer lipid preparations with a higher omega 3:6 fatty acid appear to be better tolerated and metabolised and can reverse cholestasis associated with soy-based lipid [32]. Hepatotoxicity is still probable although the effects of the PN and the underlying cause of intestinal failure are difficult to dissociate—the increased risk of IFALD associated with 'ultrashort' intestine (<20 cm to stoma) may be due to the anatomy or the associated need for more calories to be delivered intravenously [33].

Metabolic complications of HPN also relate to the inflexibility of a fixed composition of the feed unregulated by enteroendocrine signals that affect not only overall energy intake through satiety and hunger regulation but can also alter the volitional intake of specific nutrients under normal physiological circumstances. There is therefore little opportunity with HPN for 'fine-tuning' nutrient intake, absorption and disposition on a day-to-day basis. As a result, nutrient deficiencies and/or excesses may occur. Impaired salt and fluid balance can lead to fluid overload, fatigue, or acute or chronic kidney

Table 3 Complications of HPN

Complication	Related to	Mechanism	Frequency
Sepsis	Catheter care, gut disease	Catheter related blood stream infection (CRBSI)	CRBSI 0.35–2.27/1000 catheter days
Thrombosis/stenosis	Catheter tip position, PN composition, coagulation abnormalities	Vein damage, high osmolality solution	0.027–0.082/1000 catheter days
Gallstones	Pigment gallstones	Gallbladder stasis, biliary sludge	38% at 20 years of HPN, 76% of these have complications
IFALD	Sepsis, drug therapy, pre-existing liver disease or PN composition	Excess macronutrients, copper or manganese; deficiency of choline, taurine, carnitine, essential fatty acids	Variable frequency 15–40% May be more common if ultrashort bowel 3–26% of deaths on PN
Renal impairment	High gut fluid losses, sepsis, medication	Dehydration, repeated kidney injury, excess oxalate absorption, CRBSI related glomerulonephritis	eGFR <60 mL/min—15% at 5 years
Osteoporosis	Young when starting PN, low BMI, underlying disease	Chronic high acid load, vit D and K deficiency, reduced physical activity, low sunlight exposure, smoking/alcohol, chronic inflammation and medication	Osteopenia occurs in 13–57%, osteoporosis in 18–44% of long-term HPN patients
Anaemia	PN composition, disease, remaining gut anatomy	Inadequate iron, folate, B12 or copper	Common
Reticulo-endothelial dysfunction	Gut absorption and PN composition	Phospholipidosis "Sea-blue histiocytosis"	Rare
Neurological dysfunction	Gut absorption and PN composition	Manganese toxicity; thiamine or B12 deficiency	Rare

injury. The aetiology of muscle 'cramps' is poorly understood but this is the commonest symptomatic complaint of patients receiving HPN and is thought to relate to membrane electrolyte imbalance. Magnesium and calcium deficiency can lead to painful muscle spasm and tetany. Trace elements are often required as the catalytic centres of enzymes or to form tertiary protein structures—zinc for instance is required in over 10% of human proteins and deficiency can profoundly affect protein synthesis. Copper deficiency can result in microcytic anaemia resembling that of iron deficiency, and copper has previously been shown to precipitate with some amino acid mixtures used in PN [34]. Excess manganese can result in neurotoxicity through basal ganglia deposition [35]. Selenium is required in glutathione oxidase and is fundamental for redox balance—deficiency is not uncommon in HPN patients.

Vitamins are also provided in PN, with the usual exception of Vitamin K which might interfere with attempts to therapeutically anticoagulate. In some patients with a short bowel who require warfarin anticoagulation, vitamin K deficiency can be a difficult problem to overcome. As fat soluble vitamins can now be provided in a form that is miscible with aqueous solution, the removal of lipid from HPN formulations is less likely to result in their deficiency. However, vitamin D deficiency is common in HPN patients, particularly those with significant fat malabsorption, likely due to interruption of the enterohepatic cycle. Bone density can be adversely affected, leading to osteoporotic vertebral and long bone fractures and skeletal deformity. However, metabolic bone disease in patients receiving HPN is undoubtedly multifactorial and not solely related to vitamin D deficiency [18]. Aluminium toxicity was previously implicated due to high levels found in casein hydrolysates and has been prevented by using alternative amino acid sources. The optimal PN solution pH of 5–5.5 (that maintains calcium phosphate in solution, prevents lipid micellar aggregation and prevents toxic Maillard reactions between glucose and amino acids) may also contribute a significant renal acid load. Whilst not demonstrating overt metabolic acidosis this could lead in the chronic state to buffering through bone loss [36].

Remaining complications of HPS relate to the need for central venous access that provides a potential portal for bacterial and fungal bloodstream infection ("Prevention, Diagnosis and Management of Catheter-Related Blood Stream Infections" chapter), and can be compromised by thrombosis or stenosis of large veins up to and including the vena cava ("Central Vein Thrombosis" chapter). As well as threatening future access for PN, the latter can lead to venous hypertension in the draining territories with resulting facial swelling and headaches (from intrathoracic vein occlusions) or resistant peripheral oedema of the legs. Large collateral vein formation can present a surgical hazard, and reduced rates of venous return can affect cardiac and renal physiological responses.

Changes in HPS Provision over Time

Since the introduction of HPN as a possibility for selected patients in the 1980s, there have been considerable advances in the equipment and homecare service that have occurred over time, to the benefit of patients. Regarding equipment, previously the pumps were large, noisy and had to be connected to the mains electricity supply, now they are much smaller, portable and able to run on batteries. In addition, the PN infusion needed to be attached to a drip stand at home, which was cumbersome but now the whole system (PN infusion and pump) will usually fit into a backpack that can be carried or pulled on wheels, making this much more convenient at home or when travelling. Regarding the tunnelled CVCs, these were initially placed surgically by cut-down into the subclavian vein and the method used (with a purse string to secure) usually resulted in loss of the vein once the CVC was removed. Now a minimal access approach means that the CVCs can be placed under local anaesthetic with or without sedation. The jugular veins are preferably used as well as there are fewer complications that occur when using this approach (e.g. pneumothorax). These minimally invasive techniques mean that central venous access is maintained for longer. Also, the homecare service has developed over time in many countries, allowing more patients with comorbidities to receive HPN safely, with a specialist nursing service allowing patients to receive HPN who are not able to do the connections and disconnections themselves. Finally, with the digital revolution it is becoming possible for data relating to the infusions (volume, time, pump infusion pressures) to be collected securely on a platform that may enable the early detection of complications [37].

A large single centre survey over a period of 36 years has demonstrated that since the 1980s, the mean age of patients receiving home parenteral support increased from an average of 31 to 52 years [38]. In addition, the percentage of patients receiving home parenteral support due to surgical complications increased (3.4–28.8%). This clearly demonstrates that older patients with more comorbidities are being offered home parental support. While this has affected long-term survival when analysed by era, overall life expectancy remains good (55% 10 year survival for non-malignant aetiologies). In addition, the frequency of complications for patients on home parenteral support has been reducing over the last 30 years (catheter-related bloodstream infections [71% to 42%], CVC thrombosis [36% to 5%] and IFALD [10% to 2%]) [38, 39].

Life Expectancy on HPN

Sustenance by parenteral nutrition can provide long term survival in patients who would otherwise succumb rapidly to the nutritional and hydrational depletion of intestinal failure. The wide heterogeneity of underlying causes of intestinal failure, patient ages and comorbidities make unselected mortality figures difficult to interpret. However, it is clear that the majority of deaths of patients on HPN result from the underlying disease rather than complications of the HPN itself.

Unselected survival data demonstrate a 1 year survival of 86–95%, a 5 year survival of 66–82% and a 10 year survival of 55–71% [39–43]. Outcomes depend on age (better when young) and underlying disease (better with Crohn's disease or pseudo-obstruction than other causes of intestinal failure) (Table 4). HPN related complications are responsible for 13–22% of deaths with approximately equal proportions due to liver disease and catheter related bloodstream infection. Nearly two thirds of deaths occur within 2.5 years of commencing HPN [40]. Some studies have demonstrated an inverse association of survival with length of residual intestine for patients with short bowel [43–45], whereas others have not [42] although in the latter case survival was shorter in those with a stoma compared to those without.

Evolving Considerations in HPS

With increasing ease of establishing patients on HPS in the community, and the possibility of educating and training patients in their own homes rather than in the hospital, the use of HPS has increased significantly over recent years. This is reflected in the number of patients receiving HPS and also the nature of the indications. As a result new challenges are emerging:

Use of HPN in advanced malignancy It was previously impractical to consider using HPN for patients with advanced malignancy (even if there was no other route of nutrition available) as patients required prolonged admissions for HPN establishment. With limited life expectancy this would mean spending a large proportion of their remaining time in hospital. Homecare nursing and HPN training at home have now facilitated early discharges, and this allows the possibility of feeding such patients parenterally at home. The downsides of HPN remain, as described above, and may further impair quality of life which is already adversely affected by the underlying disease. There is also very limited evidence to suggest that life is prolonged by HPN at all even in the presence of complete bowel obstruction [46]. However palliative benefits include maintenance of performance status and the energy and wellbeing to allow patients even in the last weeks of life to put their affairs in order and adjust to their situation. Nutrition support may also empower patients to make decisions regarding their end of life, including choosing the time of stopping PN. The balance of benefits and burdens of HPN is therefore highly individual and needs careful consideration by an experienced multi-professional team and a well informed and supported patient [47].

As the key aim of HPN in this setting is to preserve quality rather than length of life, it follows that patients with good performance status at initiation are most likely to benefit. This is unusual in patients with advanced malignancy and therefore by using this as a selection criterion, the number of potential candidates for HPN is small. It is most often used in the setting of malignant bowel obstruction. Ovarian cancer and appendiceal or colonic tumours causing 'pseudomyxoma peritonei' [48] can be associated with a survival of many months or even some years despite widespread peritoneal metastasis. Such patients may outlive many who are commenced on HPN for 'benign' indications demonstrating that decisions made on this distinction are artificial and potentially discriminatory. Prognosis nomograms have been

Table 4 Percentage survival on HPN based upon IF aetiology from St Mark's Hospital [39]

		Percentage survival (%)						
Aetiology	Number of patients	1 year	5 years	10 years	15 years	20 years	30 years	35 years
Surgical complications	244	83	65	50	50	18	–	–
Crohn's/IBD	242	95	77	68	52	30	15	15
Malignancy	62	33	0	–	–	–	–	–
Mesenteric infarction	183	88	61	46	43	35	29	–
Intestinal dysmotility	93	92	79	70	60	45	45	–
Radiation enteropathy	53	80	28	18	9	9	–	–
Volvulus	15	71	71	71	71	71	71	–
Scleroderma	21	80	52	33	17	–	–	–
Congenital	10	100	88	88	88	88	88	–

developed in order to aid appropriate patient selection [49], but unfortunately these have not been adequately validated. Needless to say, more data is required on the outcomes of patients with advanced malignancy started on HPN.

HPS in the elderly and with additional organ dysfunction With the possibility of long-term survival, some patients started on HPS may reach old age and have to cope with its associated burden of accrued co-morbidity. The ability to provide HPS in care home settings also allows the possibility of offering it to more elderly patients. This brings additional challenges as older patients may lose the ability to manage their own infusions, to comply with fluid restriction and medications (which may be poorly absorbed due to the underlying intestinal failure) and require more nursing assistance. However, it is the advent of additional organ dysfunction that most complicates the use of HPS in the elderly.

Loss of cardiac reserve makes fluid and salt balance more precarious with an increasingly narrow therapeutic window between fluid overload and inadequate renal perfusion. The duration of PS infusion may need to be increased as well as reducing the volume or sodium content in order to compensate. It is unclear whether there are additional benefits of central veno-dilatation by using loop diuretics in this circumstance.

Renal failure may also compound fluid and electrolyte balance in patients with HPS and increase the risk of complications such as osteoporosis due to acidosis. Maintenance of renal perfusion may be challenging and the long term effects of significant central volume depletion during the day with restoration by overnight PS infusion are unclear. However, in patients with high stoma or fistula losses the omission of even one infusion due to mechanical line or pump issues may result in acute kidney injury. Repeated such insults can lead to permanent renal failure. Additional risks to the kidney in HPS patients arise from CRBSI sepsis causing hypoperfusion or infection related glomerulonephritis.

Venous access may be severely limited for haemodialysis, and the lifestyle detriment of requiring two separate intravenous organ support modalities may be unacceptable. Volume management may be challenging and even require daily dialysis to remove excess fluid in those who do not have high volume stoma losses (which can be unexpectedly advantageous). The outcomes of renal transplantation in patients requiring HPN are not reported but this scenario usually leads to consideration of a combined intestine and kidney graft when feasible.

Similarly, the effect of long term HPS after liver transplantation is still unclear, and is again usually avoided by the use of a combined graft. Where isolated liver transplantation has been used in this setting it is usually in children who are likely to wean from HPS in the near future, but sequential liver and intestinal grafts have been undertaken.

HPN and diabetes The carbohydrate load of HPN may result in hyperglycaemia in patients with impaired glucose tolerance or overt diabetes, and can be difficult to manage. Oral hypoglycaemics may be contra-indicated or poorly absorbed in patients with intestinal failure. Rebound hypoglycaemia after stopping the PN infusion may require a slow 'ramp down' rather than sudden cessation. With overnight infusion there is a risk of uncontrolled hyperglycaemia and the use of insulin as a bolus regimen with corrective doses may risk hypoglycaemia or further nocturnal disturbances for blood sugar monitoring. Currently, glycaemic control is either achieved through subcutaneous basal-bolus insulin regimens or the addition of insulin to the PN solution. By combining insulin with the PN, the risk of unopposed insulin (for instance with unexpected PN pump failure) is mitigated. Although used in this way routinely in some countries such as the USA, there is still reluctance to do so in others due to the potential for incomplete mixing or insulin adsorption to the container and giving set [50]. In the future, the use of continuous glucose monitoring devices and closed loop algorithms for subcutaneous insulin infusion devices will significantly improve the safety of HPN in diabetics.

HPS in performance athletes With the growth of paralympic sports there are now athletes who are dependent on HPS who wish to compete in endurance sports [51]. This highlights the problems associated with the inflexibility of day-to-day variation in requirements, particularly with regard to fluid and sodium intake due to excessive loss in sweat and breath rather than the gastrointestinal tract. There is also the desire to alter body composition and provide suitable amino acid sources for muscle building. Experience in this area is currently limited. In our practice we meet the requirements through a complex additional PN bag regimen that can be provided for the athlete's use on training days and infused over a short time course after the exercise.

Failure of HPS

HPS can be considered to have failed when central venous access is no longer achievable, when it is associated with life threatening CRBSI or organ dysfunction (such as IFALD or renal failure), or when it becomes unmanageable due to gastrointestinal fluid losses or unacceptable quality of life. In these situations intestinal transplantation with or without

other organs (liver, stomach, pancreas, colon) can be considered.

The indications and optimal timing of intestinal transplantation have changed considerably due to significantly improved outcomes and greater experience of the management of such patients with and without transplantation. Complete loss of vascular access is rare and new techniques for recanalization and stenting have improved access for central venous catheters—however it is currently unclear how sustainable these are for the long term and at present such measures may be seen as merely providing the temporary central access required for the transplant operation to go ahead.

Recent evidence of improvement in IFALD related hepatic fibrosis after isolated intestinal transplantation has driven a move towards 'pre-emptive' intestinal transplantation. Around 90% of patients in our unit currently survive 5 years or more after isolated intestinal transplant in this setting compared to less than 40% in whom a liver containing graft is required due to advanced IFALD [52]. Early detection of IFALD therefore leads to better post-transplant outcomes and more appropriate allocation of donor livers that are in short supply. Unfortunately, ultrasound elastography ('fibroscan') and liver blood tests have proven to be unreliable tools for the detection and assessment of IFALD and liver biopsy is currently still required. Given the rapidity with which advanced liver disease can develop in patients with 'ultra-short' intestine (less than 20 cm to a stoma), many now consider that sub-total enterectomy should be followed by intestinal transplantation as soon as feasible and before the development of complications. This is supported by a European study of patients on long-term HPN which demonstrated that IFALD and desmoid tumours threatening the mesenteric vasculature (requiring major intestinal resection) were at that time the only two 'standard' indications that could potentially achieve better outcomes after transplantation than without [53]. Transplantation purely for quality-of-life indications remains a disputed indication as the issues that affect quality-of-life change once a transplant has been performed. The benefit of stopping PN support may be adversely affected by the presence of a stoma, fear of rejection or other factors.

The Future of HPS

HPS use will undoubtedly continue to evolve with improved safety and quality as national services become more organised, along with advances in the establishment and maintenance of central venous access and improvements in composition (particularly the lipid component). Financial and logistical (for instance nursing support) constraints are likely to limit the expansion of HPN provisions even in wealthy countries. However, the outcomes of isolated intestinal transplantation are already excellent and with continued improvement it is likely that it will begin to supplant long-term HPS in suitable candidates as it more cost effective and has the ability to improve quality of life. Further and ongoing systematic study of the symptoms of intestinal failure and the burdens of HPS in comparison with intestinal transplantation will be required.

Home Enteral and Parenteral Support for Children

Theodoric Wong and Gabriela Jiménez-Arguedas

Key Points

1. Dietary foods for special medical purposes are classified into three categories: nutritionally complete foods with standard nutrient formulation, nutritionally complete foods with a nutrient-adapted formulation specific for a disease, and nutritionally incomplete foods.
2. EN is indicated when energy and nutrient requirements cannot be met by regular food intake in a patient with at least a partially functional gut.
3. Fifty percent of patients receiving home enteral nutrition (HEN) have neurological or genetic reasons and about 25% have digestive diseases.
4. There are three types of patient with IF needing PN. Type 1 have a loss of intestinal function for less than 2 weeks (e.g. acute gastroenteritis or post operative ileus); type 2 for less than 28 days (e.g. intestinal atresia or uncomplicated gastroschisis), and type 3 long term.
5. Reasons for HPN include necrotising enterocolitis (NEC), atresia, intestinal resection/short bowel syndrome as well as enteropathies (e.g. tufting enteropathy and microvillous inclusion disease).
6. Survival of patients receiving HPN has steadily improved from around 50% in the early 1990s to 90% in 2008–2013.

Home Enteral Nutrition

Definition of Enteral Nutrition

The term EN in paediatrics is often recognized as referring to liquid feeds (e.g. formulas). Currently, dietary foods for special medical purposes as defined by the European legal regulation directive 1999/21/EC of March 1999 [1] is classified into three categories: (a) nutritionally complete foods with standard nutrient formulation, (b) nutritionally complete foods with a nutrient-adapted formulation specific for a disease and (c) nutritionally incomplete foods. EN can be encompassed by all three of these categories.

Prevalence of HEN

The use of home enteral nutrition varies across the world. This is due to availability of enteral equipment (e.g. feeds, tubes, pumps and syringes), trained community support and access to regular reviews by clinicians. The lack of consensus in HEN eligibility criteria has meant that reported data are not comparable. However, the general trend has been an increase in the use of HEN in developed countries (Table 1). The prevalence varies between 1.4 per 100,000 to 69.5 per 100,000 [2, 3]. These studies have large time gaps between them, geographic as well as patient demographic differences making them difficult to compare.

Indications and Considerations for HEN

EN is indicated when energy and nutrient requirements cannot be met by regular food intake in a patient with at least a partially functional gut. Every possible effort should be made to ensure that those patients who have no mechanical

Table 1 Showing the comparison of the prevalence of HEN in different countries

Country	Total/prevalence of HEN	Reference	Date completed	Age group
New Zealand	Total: 630 69.5 per 100,000	Jelleyman 2013	2013	<15 years
Spain	Total: 529	Gomez-Lopez 2010	2007	Paediatric
Poland	Total 525 1.375 per 100,000	Szlagatys-Sudorkiewicz 2012	2010	Paediatric
United Kingdom	Total: 1336	BANS 2011	2010	<16 years
	7.9 per 100,000	Pironi 2007	2003	<16 years
Italy	3.47 per 100,000	Diamanti 2013	2009	0–18 years
	0.84 per 100,000	Pironi 2007	2005	<18 years

Table 2 Examples of aetiology of HEN patients

Insufficient oral intake
Oral motor immaturity or dysfunction
Neurologic impairment
Maldigestion and malabsorption
Type II/III intestinal failure including short bowel syndrome
Cystic fibrosis
Inflammatory bowel disease
Chronic liver disease
Increased nutritional requirements
Cyanotic heart disease
Burns
Metabolic diseases

issues be fed orally where possible and have any psychological barriers are looked at and managed accordingly.

There is no strict consensus as to when HEN would be indicated. Generally speaking, this is determined by (a) anticipated length on EN, (b) financial considerations of provision of EN and (c) ability of family/community support for EN. This decision should ideally be made at the start of starting enteral nutrition and not in an unanticipated fashion.

Setting goals such as target weight, target volume, target calories or resolution of symptoms (e.g. lack of diarrhoea or vomiting) will allow healthcare professionals and patient/families to know what to expect over a particular timeframe.

Clinicians have mainly used clinical judgement when deciding whether a patient requires HEN. That is usually patients with insufficient oral intake and those who present with wasting and stunting [4, 5]. There are also patient groups who, due to their medical diagnoses, are more likely to require HEN than others (e.g. patients with neurological disorders, feeding disorders and intestinal failure) (Table 2). In one study, about 50% of patients on HEN have neurological or genetic reasons and about 25% were due to digestive diseases [3].

Enteral Access Devices

Enteral access devices such as nasogastric tubes (NGT) has had a long history and were first described by Hunter in 1790 [6]. The selection of an enteral access device is an important step and requires evaluation of the following [7]:

- patient's disease.
- past surgeries and current anatomy.
- gastric and intestinal motility and function.
- intended length of therapy.

Normal gastric emptying with no obstruction or fistula is required for a gastric placed enteral access device. Direct small bowel feeding maybe appropriate for patients with gastric outlet obstruction, gastroparesis and in those with known gastro-oesophageal reflux disease (GORD) and aspiration of gastric contents.

Nasoenteral Tubes/Devices

Although the tubes/devices are often described according to access point and/or entry point in the gastrointestinal tract, their only difference is the material, the length (cm) and the diameter (Fr sizes) of the tube/device. The materials can be polyvinyl chloride (PVC), silicone or polyurethane. PVC tubes use are generally short term (3–5 days) whilst the silicone/ polyurethane tubes/devices can be used for up to 8–12 weeks. The length of the tube/device should be selected according to the age of the patient and anatomy so that the access point (stomach or jejunum) can be reached. The diameter of the tube should be selected also according to the age and size of the nasal passage (if this is the route of entry).

Methods for tube insertion are detailed elsewhere [8] but all tubes/devices should be inserted only by trained staff or caregivers because of the risk of misplacement and oesophageal or pulmonary perforation [4]. Confirming the position of the NG tube is essential not only on insertion but also on subsequent use. Radiology is the recommended method but has the drawback of radiation exposure. Other methods of confirmation of placement such as pH of aspirates or auscultation for "bubbling," when air is flushed down the tube are unreliable [4, 9].

There are a number of methods that can be employed for the placement of nasojejunal tubes. They include a "blind" bedside insertion with the use of a prokinetic agent such as metoclopramide or erythromycin, use of weighted/magnetic tubes [10], string tie on the end of the tube, fluoroscopic and endoscopic placement. Despite the use of these techniques, the success rates have not surpassed 75–80% [11]. Radiological confirmation of position would still be required in most of these methods.

Complications of Nasoenteral Tubes

Complications associated with nasoenteral tubes are less frequent since the introduction of fine-bore tubes. Passage maybe facilitated with guidewire. Currently available tubes are more flexible and less likely to cause erosions, oesophagitis or strictures.

Tube related complications include blockage, dislodgement, nasopharyngeal discomfort and trachea-oesophageal fistula. Blockage can occur when the tube is not properly managed, for example: leaving drug remnants, having a viscous formula, using gravity and not a pump, a small lumen or yeast colonization. Up to 24% of neonates have a NGT for feeding with oesophageal and gastric perforation in low birth weight babies seen in 4% of cases [9].

Tube misplacement may occur in patients who have lack of gag, swallow and cough reflexes, for example in children on mechanical ventilation or altered consciousness but may also occur in an otherwise well child. Reinsertion of guidewire, with the feeding tube in situ, is not recommended.

Gastrostomy Tube/Jejunostomy Tube

As a general rule, when EN is expected to be long term, feeding via a gastrostomy, or in certain situations enterostomy, should be the preferred route [4]. Gastrostomy allows access directly into the stomach and enterostomy directly into the small intestine. This allows the patient the option of being free from having tapes on the face, which can cause skin breakdown and pain on removal. The presence of a tube in the oesophagus is also thought to be a hindrance to oromotor skills development.

There is much debate is as to the minimal time on EN to justify gastrostomy insertion but generally should not be for less than 12 weeks, and in many cases should be longer. Percutaneous endoscopic gastrostomy (PEG) technique, initially described by Gauderer et al. [12] has largely replaced open gastrostomy placement via laparotomy. Absolute contraindication for PEG insertions include: (1) inability to perform UGI endoscopy (laryngeal or oesophageal stricture) and (2) uncorrectable coagulopathy. Relative contraindications could be: failure to transilluminate abdominal wall, patient's comorbidity (portal hypertension, severe gastritis or gastric ulcer, massive ascites, peritonitis, peritoneal dialysis, peritoneal metastases, left ventriculoperitoneal shunts) and terminal illness with limited life expectancy [4].

Many centers also now use laparoscopic assisted placement of gastrostomies to allow direct visualization. This is thought to be a safer method avoiding inadvertent colonic injury.

Gastrostomy feeding appears to have better outcomes compared to NGT feeding with better comfort and less irritations, ulcerations, bleeding, displacement or clogging. Improved nutritional adequacy and reduced rate of GOR and aspiration pneumonia are also seen [13, 14].

In patients with high risk of aspiration or a dysfunctional stomach, a long term jejunal access should be considered i.e. gastrojejunal tube, jejusnostomy tube or surgical jejunostomy. A surgical jejunostomy is a part of the intestinal tract brought out to the surface of the skin and requires intubation by a tube for delivery of enteral nutrition. They are fashioned to bypass any upper GI anatomical or mechanical issues.

Complications of Gastrostomy Tubes

Initial one piece system PEGs can be exchanged to low profile devices (with removable attachments to the device). This should only be done once the gastrostomy tract is matured and this may take from 6 to 12 weeks. As with nasoenteral tubes, gastrostomies can present with blockage or dislodgement. Dislodgement might cause catastrophic complication of peritonitis if dislodged into the peritoneal space.

Local complications like pain around site and skin irritation can be seen in patients who have a tight fixation, infection or leakage. In these cases, fixation needs to be checked; infection treated and consideration of the use of PPI for leakage. Granulation tissue, also known as hypergranulation tissue, has been reported in up to 44–68% of patients with gastrostomy tubes [15]. It presents as a red, spongy, proliferation of tissue that produces exudate and bleeds easily [16]. It can be removed using silver nitrate or cauterisation. Application of a steroid ointment (hydrocortisone/dexamethasone/betamethasone) with antibacterial agent might help to reduce granulation tissue.

Leakage of nutrients or gastric juice can occur with a large stoma. This can be improve by replacement with a smaller tube size. In severe cases, feeding needs to be stopped and parenteral nutrition considered in order to reduce the stoma size and heal the surrounding skin.

Enteral Feeds

Formulations

EN can be offered as liquid ready-to-feed formulations or powdered preparations that are mixed with cooled boiled water before feeding. Products available for children can be categorized as either "enteral feeds" or "supplemental feeds" [4].

Current medical enteral feeds are designed to be nutritionally complete when taken as the only source of nutrition to meet caloric requirements. The nutrient composition of enteral feeds should be age adapted [17]. Most of the newborn formulas have energy density start at 0.67 cal/ml. The energy density can be increased to beyond 1 kcal/mL depending on tolerance and age. Feeds with a high energy density (1.5 kcal/mL) are used in children with increased energy requirements, however, it may not always provide sufficient fluids to meet requirement.

Supplement feeds ("sip feeds") may be provided in addition to normal food to increase energy and nutrient supply when required. Supplements contain a concentrated source of energy, protein, and other selected nutrients, but do not need to provide all of the nutrients in a balanced composition.

Most formulas are cow's milk (protein) based and is usually referred to as polymeric feeds. Protein molecules (usually casein) can be broken down into smaller less antigenic units by heat treatment, enzymatic hydrolysis and also final ultrafiltration to separate larger molecules. When the degree of hydrolysis is >50% then the formula can be referred to as extensively hydrolysed. The size of the protein is usually less than 1000 Daltons. Partially hydrolysed or extensively hydrolysed formulas are usually the first line specialized feeds in those patients with cow's milk protein intolerance/allergies. It can also be used in those children with short bowel syndrome when expressed breast milk is no longer available.

Note that some formulas might use porcine enzymes to break down proteins and so might not be halal. A lot of commercially available hydrolysed formulas not only manipulate the protein component of the formulas but also the percentage of long chain fatty acids (e.g. higher medium chain triglyceride) and carbohydrate source (i.e. lactose free) and so the effects from the formula might not be purely from the protein component.

Elemental feeds are those feeds that have amino acid as their source of nitrogen. Elemental feeds are usually prescribed when infants cannot tolerate hydrolysed formulas for due severe cow's milk protein reactions. Prescribers should also be cautioned that some elemental formulas might use soya as their protein source. This might continue to cause reactions in those infants who are susceptible.

High osmolality feed (such as elemental feeds) can induce diarrhoea, so iso-osmolality (300–350 mOsm/kg) is preferable. This is particularly important in patients with transpyloric continues feeds. Fibre and its fermentation products (short-chain fatty acids) have potential beneficial effects on intestinal physiology and the prevention of both diarrhoea and constipation [18].

For those patients (e.g. with short bowel syndrome) where there is no commercially available feeds to complement the absorptive capacity of the gut, a modular feeds might be required. This involves providing the individual macronutrient and micronutrient components in a special combination that the gut can tolerate and absorb. This should only be done in specialized units where there is technical dietetic experience in managing these patients.

Blenderised Diet

Blenderised diet refers to using everyday foods and atomising them into a puree consistency. There has been an increased interest and shift towards blenderised diets as this is seen by parents and caregivers as more natural than commercially available formulas in providing nutrition. Studies have also shown improved stooling, weight and height gain in patients with intestinal failure who transition to Blenderised tube feeding (BTF) [19]. Other benefits such as improve gagging and retching in children post fundoplication [20] has also been reported.

In another study, blenderised tube feeding analysis found that the samples provided 50% less energy and macronutrient values than prescribed and had higher water content [21].

Good candidates for blenderised diet are:

- children who are on bolus feeding via their gastrostomy.
- stable growth and otherwise healthy.
- with a motivated family.

Patients who are contraindicated for BTF [22] are:

- those with acute illness or immunosuppression.
- gastrostomy tube size of less tan 10 Fr.
- fluid restricted.
- continuous feeding.
- jejunstomy tubes.
- multiple food allergies.
- lack of resources.

Blenderised tube feeding is labor intensive and requires additional food storage space and equipments which might not be covered by medical insurance. Blenderised diets should be discussed with a qualified dietitian to ensure that caloric and nutrient requirements are met. Often blenderised diets are used in conjunction with formulas, at least initially.

Organization of HEN

Discharge Planning

In order for discharge to take place, there are a number of requirements must be satisfied prior. They consist of:

Table 3 Example of some HEN equipment required

Pump, Stand, Frame, hooks	Feed bags/bottles/containers, sets, syringes, connectors
pH indicator strips	Tape and dressings
Disinfectant wipes	Gloves

- Training; this includes practice of basic hygiene, setting up of pump and giving sets, making up of feeds (if required), NGT testing and/or reinsertion (if applicable).
- Suitable home environment (to clean water, secured electricity)with available storage space
- Community support (usually nursing as well as medical) for troubleshooting.
- Home care company who is able to supply feeds and consumables (Table 3).

If possible, a multi-disciplinary meeting should take place with parents/caregivers, community services and hospital staff prior to discharge to discuss what has been achieved during the admission, what is to be expected after discharge and clear guidance as to who to contact in what circumstances.

Ongoing Review

Patients on long term HEN should be reviewed on a regular basis. Issues that should be looked at during these reviews include issues with managing EN at home, tolerance of EN, nutritional and growth status of the child on HEN, whether HEN could be weaned and adequacy of community support. Goals should be set with the caregivers at each review and this could be used as a measure of progress or lack of it.

Weaning patients off HEN might require a multi-disciplinary approach with the skills of nurses, dietitians as well as speech and language specialists. The central goal is to be weaned off tube feeding in the quickest possible time whilst maintaining nutritional and growth status. For those children who are at school, a comprehensive plan that offers input from the school is also vital for success.

Home Parenteral Nutrition for Children

The survival of children on HPN has increased significantly over the last 20 years to the point that death is the exception rather than the norm. Even so, the provision of HPN is not entirely risk free. A lot of the improvements in HPN survival come from a team approach in training children and families in recognising early signs of complications and line infection and getting prompt treatment.

The prevalence of type III intestinal failure in the paediatric population varies between countries. The UK experience has been that it had risen from 4.4 per million in 1993 to 16.6 per million in 2012 [23]. Other centres have had similar experience [24]. Although the prevalence has increased but the long term survival and rates of significant complications have decreased.

The criteria for offering Home parenteral nutrition (HPN) are the following:

- Requiring inpatient PN for at least 3–6 months
- Not requiring any imminent further surgery
- Clinically stable (e.g. without fluctuating electrolyte requirements)
- Suitable PN formulation
- Suitable long term venous access
- Suitable home setting (both physical and social)
- Contract of engagement for ongoing reviews

Aetiology and Classifications

Currently, a combination of aetiology and intestinal function help to predict and describe those patients who might require HPN. In children, aetiologies that are commonly seen requiring HPN include: necrotising enterocolitis (NEC), gastroschisis associated with other aetiologies, atresia, intestinal resection/short bowel syndrome as well as enteropathies such as tufting enteropathy and microvillous inclusion disease just to name a few.

In the last 10 years, intestinal function/failure has been classified into three main groups [25]. Type 1 pertains to loss of intestinal function for less than 2 weeks. Patients in this category might require iv fluids and/or short term parenteral nutrition during their illness. Aetiologies which might be in this category could include acute gastroenteritis or post-operative ileus. Type 2 pertains to the requirement of PN for less than 28 days. Typically patients in this category might have intestinal atresia(s) or uncomplicated gastroschisis with prolong dysmotility. Type 3 intestinal failure are those who are might benefit from HPN due to the need for prolong PN. The concept of permanent intestinal failure refers to those patients with aetiologies which are unlikely to ever become independent of PN. This will include patients with ultrashort intestinal length and enteropathies such as microvillous inclusion disease. The definition of ultrashort has changed through the last decade with patients now surviving with little or no small intestinal length, where previously a length of 30 cm has been proposed.

Clinical Stability

Patients who have ongoing intensive nursing needs are unlikely to benefit from being sent home with PN. These

patients might include those with large variable daily stomal output and require close fluid and electrolyte monitoring. Stability of bespoke PN might be influenced by the electrolytes added to the PN. Traditionally, calcium and phosphate are the minerals that are looked at closely as precipitation can occur.

Those patients with ongoing repeat line infections and requiring definitive line care management are also not eligible to be discharged home on HPN. See below with respect to line care.

PN Formulation

Paediatric HPN are usually tailored made (bespoke). This is due to HPN patients often have electrolyte and macronutrient requirements that are not standard from the recommended guidelines to account for stomal/stool, renal losses or altered metabolic demands.

Although this must be common knowledge, consideration for PN composition should include the following macronutrients: amino acid, carbohydrate and lipid source. Whether all macronutrients are to be provided with each infusion will depend on clinical need of the patient and local practices (e.g. some units might have lipid free nights). In addition to macronutrients, electrolytes, trace elements and vitamins supplementation would need to be considered. Although guidelines (e.g. ESPGHAN 2018) exist for providing the maintenance requirement, they do not take into account the pathology of the individual patient and each patient will need careful review as to whether guideline recommendations for electrolytes or micronutrients suit that of the patient to ensure toxicities and deficiencies are avoided. Biochemical monitoring is often used to assist in this determination.

Having mentioned the above, there is guidance when formulating HPN.

From an energy point of view, lipid should represent about 25–40% of non-protein energy, and linoleic acid should be 1–2% of total energy. The maximum lipid utilization rate is about 3.3–3.6 g/kg/day [26]. The maximum infusion rate of glucose through a central vein should be 1.0–1.5 g/kg/h; if it is greater than this glycosuria may occur [26].

Ingredients that generally require special attention are: calcium and phosphate (as they might precipitate out of solution and greater amount will be required for premature infants), cation and anion imbalances, trace elements and vitamins contributing to longevity of formulated bag. Before supplying PN as formulated, manufacturers need to certify the stability of and shelf life of the composition.

Infusion

Currently, there are a number of presentations of PN bags for administration into the patient. (1) Separate lipid and aqueous bags, (2) separate chambers (roll in one) and (3) all in one bag. The infusion requires a portable pump. These pumps are usually light weight, allow programming of different settings (e.g. maximum infusion rates or maximum pressure to deliver infusion) and allow delivery of PN without constant need to be plugged into a power source after charging.

The infusion is prescribed as ml/h over a set number of hours (e.g. 50 ml/h over 12 h). When the hours of PN infusion is condensed, this is termed cycling of PN. Most units aim to cycle PN over 12 h. There are several rationale behind this is for (1) for practical reasons, 12 h free from PN would allow relatively normal activities to be performed during the day such as schooling and work. (2) reduce the total time that the liver is exposed to glucose from the PN. This has been suggested to provide a beneficial role in minimizing IFLAD [28].

There needs to be caution not to become too fixated on achieving a12 h infusion time as some patients who cannot tolerate any oral/enteral intake may develop dehydration and electrolyte disturbances. In some patients, sudden cessation/increase of a glucose infusion precipitates hypoglycaemia/hyperglycaemia. In these patients, it may be beneficial to include a stepping up and down regime depending on glucose tolerance. The stepping up or down rate of infusion is generally half the full rate for 30–60 min at the start or prior to the cessation of PN infusion.

Early morning vomiting is not an uncommon symptom voiced by patients and family who have overnight PN. The exact reason for this is unknown but maybe related to large fluid shifts in the body over a short period of time. Other causes for vomiting should be sought before diagnosing it to be PN related vomiting.

PN Administration

Aseptic non touch technique (ANTT) has largely replaced the use of sterile gloves to prepare the person for connection and disconnection of PN at home. The main principles of the ANTT is that sterile products are used and the sterile part of the product does not come into contact with anything that is not sterile, thus preventing contamination from occurring [27]. The identification of key parts e.g. the tip of a syringe, and these should be kept sterile so that the use of sterile gloves and/or a sterile field is not required [27] (chapter "Nursing Care of Patients Receiving Home Parenteral Support").

Table 4 Equipment required for HPN

Pump (with clamps, leads, backpack, wheels, admin set)	Towel dispenser	filters	Sharps container
Drip stand	Soap dispenser	IV caps/ bungs	Waste bags
Fridge (thermometer)	Extension cords	Towel	Hand wash/soap
Collapsible trolley	Dressing (for line site, line end)	Needles	
Blue procedure tray	Elasticated tubular bandage	Dressing pack	
Blue clamps	Gloves and aprons	Syringes	
Patient thermometer	Wipes (chlorhexidine)	Tape	

The delivery of PN will require certain basic equipment to be available in the home (Table 4). These can be procured from the hospital or from the home care companies.

Storage of PN

Stability of PN is a major consideration and factors such as temperature variability will affect the chances of precipitations or of the browning effect of carbohydrate within PN. To increase the longevity of PN, refrigeration is often required (especially for bespoke bags) while off the shelf multi-chamber bags (standard bags) can often be stored at room temperature for a long period of time. Refrigerators will need to be able to accommodate the number of bags for each delivery from the manufacturing company and this might be in access of 2 week's supply of PN bags. The PN fridge should not have any other food or beverages in it as the opening and closing of the fridge will contribute to temperature fluctuations.

Home Care Company

Every country will have different national/regional procurement laws and policies. In essence, the responsibility for the PN prescription lies in the nutrition support team looking after the patient and the home care company's responsibility will be to deliver the PN and other associated consumables. Some home care companies also offer nursing services to compliment the PN delivery service. In the UK, the current setup with HPN is that each patient needs a unique high cost drug number and the services need to be commissioned locally. There is a list of approved providers from which the hospitals can choose or be assigned with. Hospitals will need to take into account different factors such as previous service performances, responsiveness to issues arising and geographical constrains when choosing a particular provider. Some hospitals have elected to choose from a selected number of providers and rotating the providers for each new patient. The advantages of doing so is to distribute risks of relying on only one provider but this might not match suitable companies with suitable patients.

Venous Access

Home parenteral nutrition cannot be delivered without central venous access and the maintaining of their integrity (i.e. Free from breakage or infection) has been the cornerstone of the delivery of parenteral nutrition.

Line care begins even before the line is inserted. Considerations include:

- Position of venous access (e.g. stoma site & vascular anatomy).
- Type of access (e.g. peripherally inserted central catheter, port or skin tunnelled lines).
- Number of lumens.
- Thrombotic risk (patients with coagulopathy).
- Previous line infection and preventive measures (skin washes prior to insertion).
- After line care (regular skin washes, line locks and frequency of use).

There are some general principles/recommendations that are to be adhered to [29]:

- Avoid using the femoral vein for central venous access.
- Where possible, ultrasound guidance is used for placement of central venous access to avoid multiple attempts of cannulation.
- Use the minimum number of ports or lumens essential for the management of patient.
- Promptly remove the central venous catheter when no longer required.

Integral to reducing catheter related blood stream infection (CRBSI) is also the selection of appropriate hubs for central venous access [30]. Catheter hubs which allow turbulent flow and easy wear and tear at the access points are to be avoided.

In addition to good line care, good skin care should also be incorporated into any HPN protocol to reduce the risk of skin contamination. These can be in the form of skin washes such as octenidine and the use of chlorhexidine gluconate impregnated sponges/patches applied to the skin exit site [31].

With adherence to these principles, the rate of CRBSI has decreased over the years with reported rates of 2–3 per 1000 catheter days [32]. Local data from Birmingham Children's

Hospital suggests that this could be further decreased to 0.2 CRBSI in 1000 catheter days with the aim to achieve 0 CRSBI infections in the HPN cohort.

Home Setting

A home assessment will need to take place prior to discharge. This is to assess a number of different factors:

- Cleanliness and hygiene of house and rooms.
- Enough space to house the child and equipment.
- Access for deliveries and emergency escapes.
- Number and relationship of family members who will reside at the same address.

In general, the house should not be overcrowded both with people and belongings. This is so that PN could be place on and taken off without chances of contamination.

The space available for storage should be large enough to hold at least 2 weeks' worth of ancillaries and equipment as well as a PN fridge. Proximity of handwashing facilities to the place of PN being put up/taken down.

Nutrition Support Teams and Intestinal Rehabilitation Programs

Nutritional support teams (NST)/intestinal rehabilitation programs (IRP) have been the cornerstone of nutritional care for patients with intestinal failure. Although the composition of team members vary in their title, in essence the skill mix that is required are:

1. Parenteral nutrition: detailed knowledge of PN composition, stability (and aseptic manufacturing knowledge and managerial skills if making PN on site), medication interactions with PN, procurement of PN (if it is not made in house).
2. Caloric requirement, nutrient selection, body composition determination.
3. Nursing, Line care, organisation and continuing support of home PN provision.
4. Medical overview of progress, medication review.
5. Social and psychological support of families.

It is difficult to pinpoint the exact reasons as to why a NST/IRP would produce benefits to patients with intestinal failure and on HPN. What is clear though from a number of studies is that the benefits can be seen in a number of different outcomes. They include decrease mortality whilst on HPN, earlier achievement of enteral autonomy, improvement in intestinal transplant success rates, decrease in CRBSI, improved mortality and morbidity related to IFALD [33].

Long Term Management

Growth and Nutrition

All children receiving long-term parenteral nutrition at home need to be regularly reviewed by the multidisciplinary team in the specialist centre.

A number of studies have documented the growth of patients on HPN. These in general have been much poorer than the general population [34] especially during the first 2 years of life [35, 36]. It has also been shown that perhaps these growth and developmental abnormalities persist even when parenteral nutrition has been weaned off [37]. It is uncertain as to the reasons for this but it has been postulated that this might be related to e.g. nutrient insufficiency, constitutional short stature.

The current methods of measuring growth and nutrient sufficiency have many flaws. The use of weight and height measures might be inaccurate due to variation in equipments, body fluid fluctuations and technical problems with children not being still when they are measured. Anthropometric measures can supplement weight and height measurements to give a better picture in terms of progress and these include mid arm circumference and tricep skin folds.

Biochemical measurements do not often reflect actual macro/micronutrient status until late in the piece. Even so, clinicians often measures full blood count, electrolytes, liver functions, trace elements and vitamins to guide them in PN prescriptions. As a guide, children receiving long-term PN as inpatients should have weekly measurements of blood count, urea, sodium, potassium, calcium, magnesium, phosphate and liver function tests and monthly copper, zinc and selenium measurement until they are stable. In those patients who are stable, 2–3 monthly biochemical estimations should be sufficient. 6 monthly measurements of fat-soluble (ADEK) vitamins is advised. Yearly liver/gallbladder ultrasound as well as B group and C vitamins and thyroid function need to be checked [26].

Outcome

Survival

The Survival of children on HPN has steadily improved from around 50% in the early 1990s to 90% in 2008–2013 (Table 5). Much of the improvement in survival has been attributed to the understanding of the benefits of early use of enteral nutrition, more aggressive PN weaning practices, multi-discipline nutrition support teams getting involved early on [38, 39].

Weaning and Stopping Parenteral Nutrition

The ability to wean patients off parenteral nutrition is dependent on a number of factors. Patients with congenital mucosal

	1987–1997	1998–2007	2008–2013
Number of patients	15	45	46
Outcome:			
Full EN	6 (40%)	23 (51%)	24 (52%)
Full EN after liver transplant		(2)	(1)
Full EN after bowel transplant		(1)	(1)
Continues HPN	2 (13%)	7 (16%)	18 (39%)
Overall Survival	*53%*	*67%*	*91%*
Died	7 (47%)	15 (33%)	4 (9%)
IFALD (on transplant list)	5 (4)	5 (1)	2(1)
Post transplant	0	3	2
Sepsis	0	3	0
Underlying diagnosis	2	4	0

diseases such as tufting and microvillous inclusion disease will take years to come off PN completely, if at all. Those patients with short bowel syndrome secondary to bowel resection are more likely to come off PN but this is dependent on a number of factors e.g. total small bowel length, associated intestinal dysmotility and bowel dilatation [40].

As there is no marker for intestinal failure (unlike in liver or renal failure), the only way is to challenge the gastrointestinal tract's function until symptoms appear or the appearance of unabsorbed substances in the stool (faecal reducing substances, pH, faecal fat globules and alpha 1-antitrypsin). When there is malabsorption of particular components, changing the relative composition of them in the enteral feed to achieve the same caloric provision might be necessary e.g. via a modular feed.

Quality of Life on HPN

There are a number of disease specific quality of life (QoL) instruments in paediatrics such as that for biliary atresia and liver transplant but there is currently no such instrument for paediatric intestinal failure or HPN. Despite this, a number of centres have produced some qualitative measure of paediatric patients on HPN. These studies have found that the QoL is reduced and in domains such as physical and cognitive functioning in 13–24 months old and physical health and social functioning in the 2–6 years old [41]. Abdominal pain and stool frequency >3 times per day was associated with higher parental stress. Longer time interval since the last bowel operation and hospitalisation was associated with lower parental stress level [42].

Children with IF and their parents also might have common themes of concerns such as thoughts about living with illness, restricted life, social support and interactions, identity and the future [43]. This affirms what has been found earlier that this group of patients have psychological distress with high parental social integration but attachment is negatively affected [44].

Clearly there is much need to have a universally agreed QoL instrument to allow better description of paediatric intestinal failure patients on HPN and their parents/caregivers' QoL.

Transition of Paediatric HPN Patients

With the increase in the number of paediatric HPN patients as well as the better survival of these patients, it is inevitable that more patients will graduate into adult services.

It is imperative that both paediatric and adult services are equipped in making sure that not only the medical needs are met for these young persons but their educational and psychosocial needs are being met. It is in this light that NICE has produced guidance [45] to assist healthcare professionals in delivering a unified approach to transitioning for young persons. The important points are:

- The transition process is to set young persons to develop independence to meet their healthcare, educational and psychosocial needs.
- Transition should begin no later than 13/14 years of age.
- Young person's needs and views are to be taken into account in individualised plans.
- Joint statement (paediatric/adult/young person) for vision of transition in writing.
- Transition should be developmentally appropriate.
- A key worker should be identified to lead this process with the young person.
- Process should encompass before, during and after move to adult services.

With respect to young persons with intestinal failure, the following are examples of some goals that are to be agreed as a marker for readiness for transition into adult services:

- Young person understands their underlying medical condition.
- Physically allowing, be able to manage home PN independently.
- Know and administer any medications/feeds independently.
- Discuss aspirations, issues or concerns independently.
- Knowledge of access to help (medical, psychological or social) when required.

Home Parenteral Support for Patients with Incurable Advance Cancer

Mani Naghibi and Federico Bozzetti

Key Points

1. Patients with incurable advanced cancer may be considered for home parenteral support (HPS) if they have intestinal failure (IF) or significant nutrition deficiencies from bowel obstruction (partial, intermittent or complete), enterocutaneous fistula(s), a short bowel, dysmotility or severe mucosal disease (often following chemotherapy or radiotherapy).
2. The patients with the best survival and quality of life on HPS are those with higher performance status and low serum markers of inflammation (C-reactive protein <10 mg/L and albumin >32 dg/L).
3. Some guidelines (e.g. ESPEN) suggest selecting patients with an expected prognosis of 2–3 months or greater but this is challenging in practice.
4. All patients who may be considered for HPS should have an early multidisciplinary team (MDT) review by the nutrition support team (NST), oncologists and palliative care teams. The desired aim(s) of starting PN and the plans for withdrawal (either at the end of life, or any time after commencing) should be discussed.
5. Patients who require HPS support for bowel obstruction should be considered for a venting gastrostomy placement (20F or larger) in order to palliate vomiting and, if wanted, to allow eating and drinking of a limited diet. Abdominal interventions do risk the tumour growing along any medically or surgically created tract, although this is less clinically relevant in the palliative phase and symptom control should take priority.

Introduction

When a malignant disease reaches a stage where curative treatments are no longer available, or amenable, this is termed 'incurable' or 'palliative' cancer. The term palliative is not clearly defined in the medical literature, although 'palliative care' is defined by the World Health Organisation (WHO) as "the approach that improves the quality of life of patients and their families, facing the problems associated with life-threatening illness, through the prevention and treatment of pain and other problems, physical, psychosocial and spiritual" [1]. For this reason the use of parenteral support (PS) for patients with incurable cancers does not fully meet the definition for palliation, as one of its main aims is to also increase survival length.

In this chapter we will explore the effect on survival and quality of life for patients with incurable cancer when treated with PS and consider tools available to optimise patient selection. We will also consider the health economics of this treatment.

Cancer, Nutritional Status and Outcomes

Involuntary weight loss is often present as a symptom of cancer. Depending on the site of the cancer, between 31% and 87% of patients have involuntary weight loss [2–5]. In pancreatic cancer, it has been shown that 85% of patients have weight loss at diagnosis, with 30% displaying severe weight loss of greater than 10% in the preceding 6 months [2].

Weight loss correlates with stage of cancer, as well as the clinical outcome [6]. Malnourished cancer patients have a poorer response to medical oncology treatments [7–9]. There is also evidence that malnutrition negatively influences length of hospital stay, readmission rates, symptom burden and quality of life in cancer patients [10].

The causes of weight loss in patients with cancer vary by the primary site and metabolic activity of the tumour, but common themes are reduced intake through inflammatory

J. M.D. Nightingale (ed.), *Intestinal Failure*, https://doi.org/10.1007/978-3-031-22265-8_49

and cytokine driven loss of appetite [11–13] or obstructed gastrointestinal tract, increased resting energy expenditure in some cancers [14–16], insulin resistance leading to increased gluconeogenesis [17] and lipolysis [18, 19].

Cancer cachexia differs from simple starvation, as it encompasses weight loss despite sufficient or excess supply of nutrients, which can be via natural or artificial routes. Cachexia is a complex multifactorial syndrome that leads to progressive functional impairment [20].

The pathophysiology of cancer cachexia is characterised by reduced food intake and abnormal metabolism. The hallmarks are anorexia, early satiety, weight loss, muscle wasting, anaemia and in the late stages, oedema. The definition of cachexia overlaps with other diagnosis such as sarcopenia and malnutrition, and can be distinguished from them by the presence of a disease process, which may be benign or malignant.

The current understanding of cancer cachexia has led to its classification into pre-cachexia, cachexia and refractory cachexia [20]. To combat the progression of cachexia early supplementation of nutrition need to be combined with therapies that can slow or stop the metabolic process contributing to its development. The term refractory cachexia is being challenged, as multimodal treatments in cancer, including nutritional supplementation, are showing reversal of cancer cachexia previously termed refractory.

Many cancers induce inflammation, causing peripheral and centrally mediated catabolism and appetite suppression, with inverse correlation of survival length in those with higher markers of inflammation [21]. A systematic review of the use of non-steroidal anti-inflammatory drugs (NSAIDs) in cancer cachexia, identified 13 trials, of which 11 demonstrating stabilisation in weight or lean body mass where NSAIDs were used, though the studies were small with risk of false positives [22].

These findings suggest that we may be able to manipulate the processes leading to weight loss associated with cancer, with potential for effective utilisation of nutrient intake to positively influence clinical outcomes including response to anti-cancer medical and surgical treatments.

The ability to alter the type of nutrients supplied to cancer patients may also play a role in improving utilisation of energy. Waterhouse and Kemperman in 1969 [23] demonstrated that fat is metabolised more efficiently than carbohydrates in cancer patients. The mechanism for this may be the increased inherent reliance on mobilisation of fatty acids, from fat deposits, as the major source of energy in any semi-starved state. Further studies have also observed improved fat metabolism in cancer patients [14, 24, 25]. For example, lipid clearance, after intravenous administration of short chain and medium chain triglycerides, has been found to be more effective in malignancy patients, compared to healthy controls [26].

Cancer and Intestinal Failure

The cause of intestinal failure (IF) in patients with cancer is most commonly bowel obstruction (BO), followed by fistulation, short bowel resulting from surgery, infarction or dysmotility. BO is estimated to occur in 10–28% of colorectal cancers and 5–50% of ovarian cancers [27].

When IF occurs in the context of palliative cancer, life expectancy is dramatically reduced. Without parenteral support the immediate cause of death would be dehydration rather than tumour progression or, if hydration is maintained, malnutrition. Commencement of burdensome PN would be neither ethical nor acceptable in most patients with incurable cancer. The challenge is, therefore, to optimally select patients with end stage cancer in whom the benefits outweigh the drawbacks of treatment. However, the proportion of patients suitable for HPS treatment in end stage cancer is still unknown.

Prevalence of HPS for Incurable Cancer

Table 1 summarises the published data for prevalence rates across the world for PN use in cancer patients. These data can be challenging to evaluate and compare directly with each other as the prevalence rates are expressed differently (i.e. period prevalence vs. point prevalence) and from varying time periods. Nevertheless, despite these limitations, it is clear that the practice of HPS therapy for incurable malignancy is common in economically developed countries, but varies considerably, even between countries with comparable health systems.

In those countries with published data, the lowest appear to be in the UK [28, 29] and highest in Italy and North America [30, 31], with evidence of increasing prevalence in all reporting countries [31–33].

HPS in Incurable Cancer Patients

HPS is defined as ‘total’ when the intravenous administration of nutrients represents the exclusive (or the near-exclusive) way of feeding the patient. In cancer patients this happens most frequently due to gastrointestinal obstruction from the tumour or due to metastatic peritoneal invasion. In such cases the obstruction may be incomplete, where it worsens when patient attempts to eat and is associated with early satiation, nausea, vomiting, abdominal distension and pain.

In this context a randomised control trial (RCT) is considered to be unethical. If the incurable cancer patient is suitable for HPS therapy, randomising to non-HPS, when

Table 1 Prevalence of malignant conditions as indication for home parenteral nutrition

Study	Country	Total HPS patients	Number of HPS patients with cancer	Proportion of HPS with cancer (%)	Period or point prevalence (years)	Data source

Smith et al., 2011 [28]	UK	523	42	8	*Point* prevalence 31/12/2010 (Percentage of new registrations during 2010—14%)	British Artificial Nutrition Survey (BANS) database
Howard et al., 1995 [39]	USA	4520	2122	47	Period prevalence (1985–1992)	North American Home Parenteral Nutrition database

the deleterious effects of a prolonged starvation in malnourished subjects are well known and as the benefits of HPS have been demonstrated, would not be ethical. The control group for such a study may be those who are hypo/aphagic due to incurable cancer, qualify for HPS, have been offered HPS, but have chosen, for personal reasons, to decline. This would allow for observational studies, but precludes randomisation. To date this group has not been studied.

HPS is 'supplemental' when the patient is able to maintain a limited oral intake of nutrients, and the PN is given in parallel to meet requirements. In cancer patients this occurs secondary to low grade gastrointestinal obstruction, severe uncontrolled anorexia, or due to high stoma or fistula output.

In 5–23% of cancer patients the main cause of death has been reported as cachexia [40–43] and weight loss of cancer patients is proportional to the severity of anorexia or to the reduction of nutrients' intake or to the persistence of a negative energy balance. There is now a growing bulk of evidence showing that a PN support for incurable cancer patients can improve survival and is able to improve not only the body weight but also the lean tissues.

Outcomes: Survival Length

The survival of 'healthy', non-cancer individuals undergoing extreme starvation, but not dehydration, is approximately 2 months, as observed in the tragic events of the Leningrad siege [44], Warsaw ghetto [45] and Irish hunger strike [46], where the longest length of survival was 2.4 months (73 days). The longest length of survival of cancer patients undergoing a total or almost total nutrients deprivation is similarly reported to be approximately 2 months in hospitalized patients [47] and only 17–29 days in patients followed at home [48, 49], though the survival is often shorter due to predisposing weight loss even before the onset of bowel obstruction. Since the 1990s International Consensus [50] has existed to support the use of HPS in advanced hypo/aphagic cancer patients if the expected survival due to the cancer is approximately greater than 2 months, in combination with other favourable factors outlined in Table 2.

Most of the studies on HPS in advanced cancer patients are retrospective, with small case series leading to inherent limitations that come from small patient numbers, with wide confidence intervals that lead to data which is not clinically reliable. Naghibi et al. (2014) systematically reviewed these

Table 2 American and European guidelines regarding parenteral nutrition therapy in palliative malignancy

American Society of Enteral and Parenteral Nutrition (2009) [51]
1. Must be physically and emotionally capable of participating in their own care
2. Should have estimated life expectancy of >40–60 days
3. Require strong social and financial support, including a dedicated in home lay carer
4. Must have failed trials of less invasive medical therapies such as appetite stimulants and enteral feeding
European Society of Enteral and Parenteral Nutrition (European Society of Clinical Nutrition and Metabolism) (2009)[a] [10]
In intestinal failure and incurable malignancy, long-term PN should be offered, if:
1. enteral nutrition is insufficient
2. expected survival due to tumour progression is longer than 2–3 months
3. it is expected that PN can stabilise/improve performance status and quality of life
4. the patient desires this mode of nutritional support
There is probable benefit in supporting incurable cancer patients with weight loss and reduced nutrient intake with "supplemental" PN

[a]Updated in 2016 with further narrative guidance

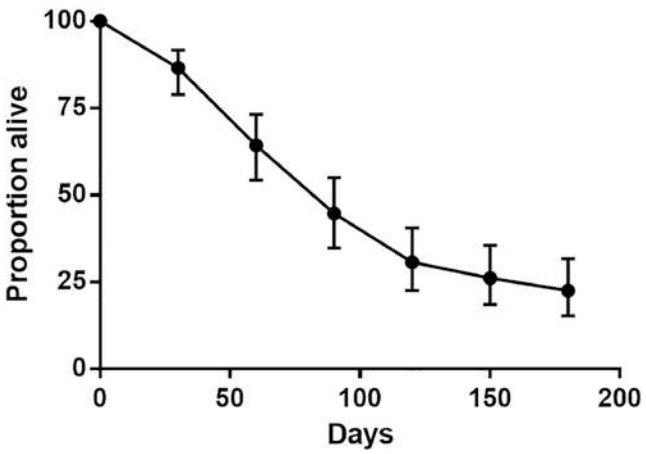

Fig. 1 Proportion of patients alive at monthly intervals during the first 6 months, with corresponding 95% confidence intervals (n = 244)

studies and applied random effects modelling to meta-analyse the data, incorporating 12 studies and 244 patients in the final meta-analysis of survival length (Fig. 1) [52]. This demonstrated 3.9 months and 2.8 months mean and median survival, respectively. In this systematic review it was also demonstrated that higher performance status at baseline of HPS therapy for advanced cancer patients is predictive of longer survival (Fig. 2).

Only a few studies in this patient group have been carried out prospectively [45, 53, 54]. The largest prospective study is by Bozzetti et al. (2014) on 414 incurable cancer patients treated with HPS, reporting a comparable survival length of

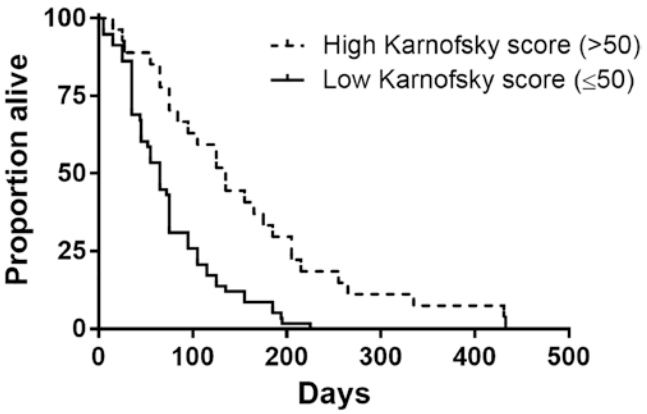

Fig. 2 Kaplan Meier survival curves, based performance status (measured by Karnofsky performance score) (p = 0.01)

4.7 months and 3.0 months mean and median survival, respectively [54].

These studies have lead to two main considerations: first, if we accept a threshold of 3 months as the longest potential survival in patients undergoing total starvation, HPS will prolong survival in over half of patients (though likely to be a higher proportion); second, while this patient population is heterogeneous and several factors can finally affect the length of survival, large multi-centred and international retrospective and prospective studies have resulted in similar survival lengths.

Quality of Life and Body Composition

Data on quality of life (QOL) for incurable cancer patients treated with HPS are scanty and difficult to interpret. QOL can only be assessed by the person who is experiencing the factors studied, hence, retrospective studies of QOL scores completed by clinicians or family members are not validated methods, which currently make up the majority of the data in this field.

A prospective QOL study by August et al. (1991) reported that in 14 patients (82%) both patients and their families perceived their therapy as beneficial or highly beneficial [55]. Their Nutritional Support Team agreed with this assessment in 11 patients, but did not share this perception in three patients. These three patients had a short duration of HPS (less than 25 days) or minimal rehabilitation.

In another prospective study [45] investigating the QOL in 69 incurable cancer patients using the validated cancer QOL tool, Rotterdam Symptom Checklist questionnaire, variables were collected at the start of HPS and then at monthly intervals. Results showed a median survival of 4 months (range 1–14) and QOL parameters remained approximately stable till 2 months before death.

Table 3 Prospective studies on the effects of HPS on QoL measured through validated scores in malnourished advanced cancer patients on chemotherapy

Author	#PTS	Mode of sHPS	Methods	Results	Comments
Finocchiaro 2002 [58]	70	27 Kcal + 1.1 gAA/kg/d	TIQ at >2 months	QoL: =48%, ↑31.5%, ↓20.5%	Evaluated 27 patients
Culine 2014 [61]	437	Usually overnight 26 Kcal + 1.1 gAA/kg/d	FACT-G day 1–28	↑ Physical, functional, emotional, familial/social status	Responsiveness to therapy may affect QoL
Seys 2014 [57]	221	Overnight	FACT-G day 1–28	↑BW and global QoL in 68% and 59% of pts. (and sub-score physical, functional and emotional)	Regimen of NPS ill-defined; No statistical analysis; Responsiveness to therapy may affect QoL
Vashi 2014 [60]	52	Cyclic, total oral + PN Kcal and AA: 25–30 and 2 g/kg/d	EORTIC QLQ-C30	↑Global QoL index at 1–3 mos	Small sample, loss of patients; Responsiveness to therapy may affect QoL; Assessment of requirements unpractical
Girke 2016 [59]	23	–	EORTIC-QOL-C30 day 1–28	↑Emotional/social domains = muscle strength, physical activity, BMI ↓ phase angle	Nutritional regimen not assessed; Large drop out of patients
Cotogni 2017 [63]	111	21 Kcal + 0.8 g AA/Kg/d	EORTIC QLQ-C30 monthly for 1–4 months	↑Global QoL, physical functioning, role functioning, emotional functioning, appetite loss and fatigue scores	High attrition rate due to death 49/111 completed at 4 months
Obling 2017 [62]	47 random HPS VS	Overnight, 2–4 times/week, 10 Kcal + 0.5gAA/Kg/d × 3 months	Bioelectrical impedance analysis and EORTIC QLQ-C30	↑ at 3 months of FFM and overall QoL	Loss of patients during the study

These studies are also in keeping with QOL assessed by Orrevall et al. [56], where structured interviews were carried out with incurable cancer patients and their family members. This study reports both positive and negative aspects. The positive aspects were centred around the sense of relief and security in both patients and relatives because the nutritional needs were being met through HPS. The burden of treatment did have reported negative effects on the patient and family social life, but the salient summary was of positive effects out weighing the negative.

Given HPS in context of incurable cancer is often for a short period of time, this leads to few patients and/or family members fully training in the care of HPS. Hence, HPS treatment is accompanied by up to twice daily visits by trained nurses, who often give emotional support and security to patients in addition to the technical procedures that they carry out. The security felt by patients and family members on HPS may be, in part, be related to this close relationship with a health professional.

As regards the QOL of patients receiving supplemental parenteral nutrition, multiple studies [57–61], using validated methods (Therapy Impact Questionnaire, Fact-G, EORTC-QOL-C30) have also reported an improvement in quality of life (summarised in Table 3). These findings were also observed in the RCT by Obling et al. which found that PN also increased fat-free mass [62].

Table 4 Karnofsky performance status

Score, %	State of health
100	Healthy, no symptoms or signs of disease
90	Capable of normal activity, few symptoms or signs of disease
SO	Normal activity with some difficulty, some symptoms or signs
70	Caring for self, not capable of normal activity or work
60	Requiring some help, can take care of most personal requirements
50	Requires help often, requires frequent medical care
40	Disabled, requires special care and help
30	Severely disabled, hospital admission indicated but no risk of death
20	Very ill, urgently requiring admission, requires supportive measures or treatment

Patient Selection

In the above mentioned international prospective study by Bozzetti et al. (2014) three prognostic factors for survival at the multivariable analysis were identified [54]; performance status, as measured by Karnofsky performance Status (Table 4), Glasgow Prognostic Score and presence of tumour metastasis. The prognostic value of these variables coupled with type of primary tumour, was subsequently validated on

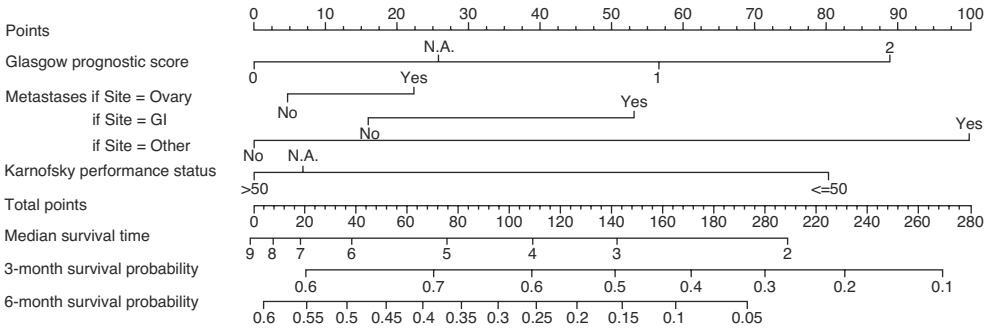

Fig. 3 Cox model based nomogram for predicting 3-, 6-month and median length of survival. Score are added up for each patient factor and the total points correspond to survival estimates at the bottom of the figure

a separate series of patients [64] and led to the construction of a prognostic nomogram (Fig. 3).

It is worth noting that a sub-analysis of patients with so-called 'refractory' cachexia according to an International Consensus [20], showed a 3- and 6-month survival of 29.4% and 8.4%. These figures were 31.7% and 12.2% for patients without vital organ involvement, 27.1% and 5.9% for those with vital organ involvement. These figures would suggest such patients can still benefit from HPS therapy, and we would advise multidisciplinary team assessment of performance status as the most predictive of favourable outcome for these patients.

In these incurable patients HPS was generally withdrawn a few days before death. In one third the main reasons for stopping HPS treatment was tumour progression (73%), patient choice (20%) and HPS central venous catheter complications (CVC) was the least common cause (6%). The cause of death was vital organs failure (46%), progressive wasting (34%) and HPS CVC complications (1%) and unknown in the remaining patients.

Ethical Considerations

Both the decision to commence HPS, as well as to withdraw it, should directly involve the patient, which requires the patients be aware of their diagnosis and their prognosis to express informed consent. However, the conveyance of the information can be challenging and there are considerable variations between countries, within countries, cultures and health systems. There has been a trend for increased direct involvement of the patient over the last few decades, with evidence that a greater proportion of patient would welcome this information. Clinical experience suggests the presence of a multidisciplinary team, involving palliative care practitioners to fully explore the alternatives of not accepting this high burden treatment to be highly valuable.

In the 1990s, in Southern Europe, only 25–38% of patients were aware of their cancer diagnosis at an advanced stage and studies suggested less than half of these wanted to be given more information [65–68]. A survey of over 2000 patients with metastatic cancer, carried out in Italy in 1999, found that 39% believed it to be 'difficult to cure' and 47% considered their disease 'severe' [69]. In Spain only 12% of patients with a terminal diagnosis knew about their short-term prognosis [70]. More recent studies suggest there is evidence that these practices and attitude have changed significantly. In a multicentred Italian study, Costantini et al. [71], reported that 87% of patients were aware of their cancer diagnosis, although 49% of those with metastatic cancer were of the opinion that they have curable disease.

Family members may sometimes be responsible for the patient's ignorance regarding their diagnosis and prognosis. In some cultures, those surveyed (73%–84%), reported a wish not inform the patients in a straightforward manner about the state of disease advancement [65, 70].

The Council of Europe (European Treaty Series, Chapter III, Article 10, Convention for the Protection of Human Rights and Dignity of the Human Being with regard to the Application of Biology and Medicine) came into force on 1st December 1999, states that 'everyone is entitled to know any information collected about his or her health. However, the wish of an individual not to be so informed shall be observed.' One third of physicians in Europe, questionnaire at the turn of the millennium, believed that patients never want to know the truth [65], while an equal percentage believe that informed consent is necessary to respect patient autonomy [72].

While adequate information should always be given to patients when actively or implicitly requested, there is much uncertainty about the true comprehension of the communication. Indeed, the ability of the patient to actively negotiate in a decision with the caregiver requires four intact cognitive functions: (1) the ability to clearly understand the information relevant to the decision; (2) the ability to fully appreciate the situation and the consequences of alternatives approaches; (3) the ability to elaborate and weigh the information rationally in the context of a coherent set of values and goals, and (4) finally, the ability to communicate or transfer choices to the physician regarding care.

A self-report survey measuring 'desire for death' distributed to 92 incurable cancer patients with a life-expectancy of less than six months demonstrated substantial fluctuations in this score over time, within various intervals of time (hours to 1 month) [73]. Therefore, the assessment of a patient's will to live (and consequently to accept a HPS program which primarily aims to prevent an early death from starvation) may be repeated several times during the assessment and only if the answers are consistent should this information be utilised to determine whether to initiate or withdraw a life-sustaining treatment.

It is noteworthy that a study carried out in a Canadian palliative care centre in the mid-1990s reported the presence of cognitive deficit in 44% of patients at the moment of hospitalization and in 55% at time of death or upon hospital discharge [74]. Asking for informed consent by anticipating some situations before they occur is also fraught with difficulties. Coppola et al. (1999) have shown in 2536 patients that there was no constancy in the choices of preferences regarding life-saving treatments expressed in advance, both verbally and in writing [75]. Specifically, the desire to undergo artificial nutrition as a life-sustaining procedure ranged from a very low percentage of subjects by Coppola et al. (1999) to about 70% of patients by Pearlman et al. (2000) [75, 76]. Many factors would contribute to this variability; the context, manor of communication, symptom burden, chance of treatment success conveyed and cultural/religious background of the patient, clinicians attitude and background society will have varying effects.

A survey of the UK based intestinal failure clinicians in 2013 [77], showed that clinicians would support HPS for incurable cancer more often for improvement of QOL rather than increased survival time alone. While the attitude of intestinal failure clinicians influences the treatment advanced cancer patients receive, the attitude of oncologists, gastrointestinal surgeons, gynaecologists, palliative care teams and other clinicians who meet incurable cancer patients is also paramount to referring patients to intestinal failure services, and this is, as yet, unstudied.

Withdrawing of HPS can be a difficult task and should be discussed with the patient and relatives prior to the start of HPS. Should the patient's condition change causing a deterioration of general status the composition and frequency of PN may change or treatment withdrawn. Reassurance should be given that this joint decision will be taken with the direct involvement of the patient and family with the multidisciplinary team. HPS complications such as medically resistant ascites or pleural effusions, central line blood stream infections and thrombosis related to the HPS therapy should also trigger treatment cessation discussions.

Health Economics

The costs of medical therapies are relevant when considered in the context of a health economy with limited financial resources. When comparing the cost of treatments, the absolute costs may be misleading because of the variable impact of treatments on survival length and QOL. Incremental cost effectiveness ratio (ICER) is currently the most prevalent measure of the cost of a treatment per quality adjusted life year, allowing for direct comparison of a wide variety of treatment with variable impacts.

In addition to allowing comparison of different treatments, ICERs also allow for thresholds to be set when treatments are assessed for economically viability. While there is debate about the existence of a fixed ICER thresholds used by the National Institute of Clinical Excellence (NICE) in England and Wales, there is evidence that £30,000/QALY is often used as a cut off threshold [78, 79]. It has been demonstrated that treatments associated with ICER over £30,000/QALY only have an 8% probability of approval [80]. Comparable thresholds are used in several other countries, but controversy exists about the threshold that should be used, for example, in the Netherlands a threshold of up to Euros 80,000/QALY has been proposed according to severity of disease [81].

In health systems where thresholds are used, when the ICER for a desired treatment is above the threshold, the justification for that treatment needs to be strong, with increasing justification needed with higher ICERs. In an example only directly relevant to England and Wales, criteria have been set by NICE for appraisal of 'end of life' treatments that exceed £30,000/QALY. These are: a limited number of patients expected to require the treatment, the treatment should be expected to extend life by greater than three months, the extended survival length is experienced at a QoL anticipated for a healthy individual at a similar age and health economic assessment models would need to be carried out.

The only detailed analysis of the health economics of *benign* indication HPS was carried out in the UK in the study of Richards and Irving in 1996 [82] and did not include any patients with incurable cancer. In their model they calculated the absolute cost of HPS over the first year to be £44,288 with a corresponding ICER of £85,825/QALY. The ICER value reduced to £68,975/QALY after 4 years due to the health economic concept of 'discounting' with longer survival (initial set up cost only needed once, QOL slowly improves in conditions such as inflammatory bowel disease and short bowel on commencing HPS, thereby the ICER is reduced over time).

The health economic assessment of HPS treatment for *incurable cancer* in the UK was carried out in 2013 [52]

showing the ICER for this circumstance is higher at £176,587/QALY. The shorter survival lengths for such patients means that 'discounting' does not apply. To allow for comparison with the benign cost estimates, inflation would need to be taken into account. With uplifting to 2013 prices, due to inflation, the ICER for the first year of benign treatment corresponds to £135,610/QALY, (inflated to 2013 prices, applying 2.9% inflation per year – UK Office of National Statistics). Hence the ICER for incurable cancer patients remains higher, but comparable in the first year at £176,587/QALY.

The multi-variant analysis of incurable cancer HPS therapy costs also suggests that selection of patients with favourable factors for longer survival, better quality life, in combination with reduced PN costs (frequency, complexity, independent of nursing at home) would bring the ICER costs significantly lower [52].

This ICER health economic model is the dominant method used currently in health economy, but this model may not be the most appropriate to appraise all treatments. Several experts have stated a preference for Willingness to Pay (WTP) in setting the thresholds [83]. Research recently commissioned by the UK Department of Health [84] estimated the threshold of WTP to range as high as £70,000/QALY.

Despite the high health economic costs of this treatment, there are special circumstances for supporting the use of this expensive treatment to extend life, such as giving individuals valuable time to reach a short term goal (e.g. impending birth of child or other life events of equal magnitude), which could have long-lasting positive effects on the family and on the image of a health system that has a compassionate attitude towards the care of the terminally ill patients.

Monitoring of Parenteral Nutrition at Home

N. M. Clermont Dejean, N. Somlaw, D. Brundrett, and J. P. Allard

Key Points

1. The haematological and biochemical monitoring of patients receiving parenteral nutrition at home should be individualised and may change with their clinical condition.
2. Routine blood tests include sodium, potassium, chloride, bicarbonate (as a measure of acid-base balance), calcium, magnesium, phosphate, urea or blood urea nitrogen (BUN) /glomerular filtration rate (GFR), creatinine, liver function tests (albumin, bilirubin alanine transaminase (ALT), aspartate tranaminase (AST), alkaline phosphatase, gamma glutamyl tranferase (GGT), international normalised ratio (INR)), glucose, blood count, ferritin and C reactive protein (CRP)) and are performed every 1–4 months depending upon the stability of the patient.
3. At discharge from hospital patients should have their prothrombin time (INR), cholesterol and triglyceride, Haemoglobin A1c, vitamin D & B_{12} and folate concentrations checked. These are rechecked every 6–12 months. If the triglyceride concentration is elevated a fasting level is taken.
4. Baseline vitamins A&E, zinc, copper, manganese and selenium concentrations are checked initially then every 6–12 months.
5. If the CRP is raised (>25 mg/l), transferrin saturation is used as a measure of iron status. In the presence of sepsis or inflammation, do not measure zinc, copper, selenium or vitamins A, D or E.
6. Urine sodium concentration is useful for assessing sodium balance in patients with a jejunostomy and a 24-hour urinary oxalate collection for assessing the risk of renal stone formation in patients with a short bowel and colon in continuity.

Introduction

Home parenteral nutrition (HPN) is a life-saving treatment that allows patients with intestinal failure to return in the community while receiving appropriate nutrition. Monitoring HPN is important for multiple reasons. It ensures that treatment goals are met, it helps to prevent, recognise and treat complications arising from HPN, it allows an audit of outcomes and more importantly it secures and improves patient's quality of life.

Guidelines and Studies on Monitoring

A series of guidelines (1–7) have been published and cover the topic of monitoring patients on HPN. Most of them recommend that a multidisciplinary team with experience with HPN be responsible for the monitoring and that patient care be assigned to a particular person in the group. The core members of the team include a gastroenterologist, a surgeon, specialist nursing, dietitians and pharmacists. The guidelines also emphasize the fact that monitoring should be guided by outcomes that will have been set with the patient prior to initiation of the treatment. In addition to these goals, impact on quality of life, morbidity, anthropometric measures and incidence of complications related to HPN should be considered. A study by Dreesen (8) conducted in an international

cohort of 300 HPN patients, all with benign disease, showed that the most important outcome indicators for patients were incidence of catheter related infection, survival and quality of life.

The monitoring regimens found in the major international guidelines (1–6) propose different frequency and timing of monitoring based on the consensus reached by their authors. None of these guidelines are based on randomized controlled trials and a study has yet to show the impact of the different regimens on patient outcome.

The current literature (1–6) outlines a similar biochemical monitoring between articles which includes extended electrolytes (sodium, potassium, chloride, phosphate, magnesium, calcium), glucose, HbA1C, liver function test (albumin, bilirubin, aspartate aminotransferase(ALT), alanine aminotransferase (ATL), alkaline phosphatase (ALP), gamma-glutamyltransferase (GGT) and International Normalized Ratio (INR)), renal function test (creatinine, glomerular filtration rate (GFR), urea, bicarbonate), complete blood count, trace elements (zinc, copper, manganese, selenium), iron, ferritin, folate, lipid panel (triglycerides, cholesterol), vitamins (vitamin A, B12, D, E) and Dual-energy X-ray absorptiometry bone scan (DEXA) and C-reactive protein (CRP). Regular clinical assessments are also recommended with monitoring of anthropometric measures including weight, height, mid upper arm circumference, triceps skinfold measurement, mid arm muscle circumference and grip strength. Evaluation of fluid status, oral intake, mood and quality of life are recommended to be part of the assessment.

Interestingly, in a study conducted by Smith et al. in 2002 (9), affiliation with organizations that provide patient support and education was a factor that improved HPN patients' outcomes by improving the quality of life index, lowering depression scores and decreasing the cumulative incidence of catheter-related bloodstream infections over 18 months. The authors suggested that contact between these organizations and patients be facilitated by the HPN programs.

When comparing clinical practice to guideline recommendations, Wengler et al. found in 2005 that of 42 studied European centers, most varied from the recommendations found in the literature (10). 92% of the centers had a multidisciplinary HPN team and in most of these centers the main responsibility for monitoring a patient was assigned to one member of the team. After hospital discharge, 81% of centres continued to monitor patients' skills for HPN administration, with 31 centers organizing home visits carried out either by the HPN team, a home care agency, a community nurse or a general practitioner. After more than 1 year of HPN, stable patients continued to be monitored by the discharging hospital in 73% of centers, a local hospital in 12% and a general practitioner in 11%.

From this report (10), 28 centers had written guidelines for monitoring practices and 23 of those had developed their own local guidelines. The interval for clinical assessment of patients ranged from 1 to 6 months with more than half the centers reporting a range of 2–3 months. At each visit body weight and anthropometry were monitored in all centers. Less than half took blood pressure and pulse at every visit; 88% of centers evaluated the state of hydration and 74% inquired about oral intake. 86% checked the mood of their patients at every monitoring visit.

For laboratory tests, between 95 and 81% of centers measured haematology, biochemistry for liver function, creatinine, electrolytes, magnesium, calcium, phosphate and glucose at every visit. 48% of centers also monitored triglycerides, cholesterol and albumin. Trace elements and analysis of vitamins and folic acid took place at every visit in 19% and 14% of centers respectively. Other centers also monitored these variables regularly but not at every visit. In some cases it was only done if a problem arose. More than 60% of the centers requested BMD once or twice a year and quality of life was assessed in 10 of the 42 centers; 6 of which used the SF 36 questionnaire. The other 4 had their own local questionnaire. In case of complications, patients contacted the HPN in 76% of centers and if admission was needed it was arranged in the HPN-teaching hospital in 95% of cases. When distance was an issue patients were directed to the local hospital. In Scotland, the HPN managed clinical network studied the frequency and adequacy of monitoring in their patient group with their results indicating that length of time on HPN was found to be inversely associated with frequency of monitoring without an increase in complication rates (11).

Core Monitoring

Hospital patients need to be metabolically stable on a parenteral nutrition prescription before being discharged home. Based on the previously mentioned literature and clinical experience, core monitoring for HPN patients is summarized in Tables 1 and 2.

After discharging a new HPN patient initially, blood work should be considered every 1–2 weeks for the first 2 months. If stability is achieved, the interval can be lengthened to monthly for 3 months and then every 3 months (see details in Table 1). Assessment of trace element and vitamin status should be done annually in the stable patient and more frequently in situations that require closer monitoring such as in severe malnutrition or increased losses, when deficiencies or toxic levels are suspected or when a deficiency or toxicity has been diagnosed and is being treated. Clinical interpretation of plasma vitamin and trace element results can only be done with knowledge of the patients CRP level. The effects of the acute phase response on micronutrient levels have been well described by Duncan et al. (12). In patients at risk

Table 1 Suggested laboratory monitoring practice for stable Home Parenteral patients

	Baseline	Monthly for 3 months	Every 3 months	Yearly
Electrolytes	X	X	X	–
Glucose	X	X	X	–
Liver function test	X	X	X	–
Albumin	X	X	X	–
INR	X		X	–
Renal function test	X	X	X	–
Complete blood count	X	X	X	–
Lipid panel	X	–	X	–
Iron and ferritin	X	–	–	X
Vitamin D 25-OH and PTH	X	–	–	X
Vitamin A, E, C	X	–	–	X
Vitamin B12 and folate	X	–	–	X
Trace elements	X	–	–	X
DEXA scan	X	–	–	X
24 hr. urine collection for oxalate	X	–	–	X

Suggested core monitoring based on clinical experience and current guidelines (1–6)

Electrolytes include sodium, potassium, chloride, magnesium, phosphate, calcium. Liver function test include aspartate aminotransferase (ALT), alanine aminotransferase (ATL), alkaline phosphatase (ALP), bilirubin. INR = International Normalized Ratio. Renal function test include creatinine, GFR, BUN. Lipid panel includes triglycerides and cholesterol. Trace Elements include zinc, copper, manganese, selenium and chromium. DEXA = Dual-energy X-ray absorptiometry bone scan

Table 2 Suggested clinical monitoring for Home Parenteral patients

	Baseline	Between 1 and 3 months after discharge[a]	Every 3–6 months[a]	Yearly[a]
Anthropometry	X	X	X	X
Calculation of nutritional requirements	X	X	X	X
Vital signs	X	X	X	X
Physical examination	X	X	X	X
Fluid balance and evaluation of fluid status	X	X	X	X
Oral intake	X	X	X	X
Mood	X	X	X	X
Quality of life	X	–	X	–
CVC examination	X	X	X	X

Suggested clinical monitoring based on clinical experience and current guidelines (1–6)

Anthropometry includes weight, height and body mass index calculation. Evaluation of quality of life should be done with recognized and validated tools (see chapter "Home Parenteral Nutrition for Adults"). *CVC* central venous catheter

[a]Evaluation done in person during clinic or with telehealth

of oxaluria and kidney stone such as those who have steatorrhea and colon in continuity, 24-hour urine oxalate should be monitored every 3–6 months initially, and then yearly, while on a low oxalate diet (see chapter "Nephrolithiasis and Nephrocalcinosis"). Bone density should be assessed at baseline and yearly thereafter (see chapter "Bone and Joint Disease").

Clinic visit should be organized within the first 3 months after discharge. After this initial assessment, future appointment schedule will depend on the stability of the patient. The intervals should range between 3–6 months and eventually yearly. If a patient lives far from the center responsible for monitoring it is possible to rely on technology with the use of tele-health for clinical assessments (13). Evaluation of quality of life should also be done yearly with a validated tool (see chapter "Home Parenteral Nutrition for Adults"). At every clinic visit, weight, anthropometric measures, oral intake, fluid status, central line patency, medications, physical signs of nutritional deficiency, the need for continuation of HPN as well as the symptoms linked to the underlying disease which led to the need for HPN should be assessed (Table 2).

Monitoring of Complications Related to HPN

Besides metabolic complications associated with the administration of parenteral nutrition (PN), long term HPN support is associated with central venous catheter complications, parenteral nutrition associated liver disease, and bone disease. Close monitoring of HPN patients as recommended above may reduce this risk. In addition, patients should be provided with information regarding these complications and how to monitor themselves at home.

Monitoring of Blood Glucose

Self-monitoring of blood sugar at home is not a routine practice in non-diabetic patients whose blood glucose is well controlled before hospital discharge if there is no difference between inpatient and home regimen. However, if there is a significant change in the amount of glucose infused and/or cyclic infusion occurs at home or patient relies on PN as the sole source of carbohydrate (e.g. ultra-short bowel), then blood glucose should be monitored 4–6 hourly (14, 15) to assess risks of hyperglycemia and/or rebound hypoglycemia (16). If these occur, reducing infusion rate by half in the first 2 h of infusion and the last 2 h of infusion as well as a diabetic team review should be considered. Monitoring of blood glucose in non-diabetic patient can be discontinued when the results show consistently normal levels although it is important to be aware that previously stable patients may go on to

develop hyperglycaemia (17). On the contrary, in diabetic patients who require either intravenous insulin in PN or subcutaneous insulin injection, the monitoring is indefinite, but frequencies and subsequent managements should be based on clinical judgement.

Monitoring for Catheter Infections

Catheter related blood stream infection (CRBSI) is one of the most serious complications in patients receiving PN. Signs and symptoms of this infection include fever, chills, hypotension, elevated white count, and, sometimes, elevated liver function tests. There are also other catheter related infections with fewer systemic symptoms, which can eventually progress to blood stream infection. Exit site infection is commonly detected by redness and purulent discharge at the exit site of the catheter. Tunnel infection usually present with redness and tenderness along subcutaneous tract of tunnelled catheter. Tenderness, induration and/or necrosis of skin overlying the implanted device are presented in pocket infection (18). HPN patients and their carers must be educated to identify the potential signs of a CRBSI, an exit site infection or a tunnel infection and know the importance of seeking medical advice should symptoms occur. If a blood stream infection is suspected, blood cultures from both catheter and peripheral vein should be obtained immediately. Although the current clinical guideline for catheter related infection does not define how to manage PN in this situation, it is recommended to temporarily discontinue PN when CRBSI is suspected or confirmed, and administered broad spectrum antibiotics (14). The practice of withholding PN is based on one study showing that continuing PN after a positive blood culture resulted in longer hospitalization (19).

For more details on diagnosis and management of catheter complications please refer to chapter "Prevention, Diagnosis and Management of Catheter-Related Blood Stream Infections".

Monitoring for Hepatobiliary Complications

Long-term HPN may result in intestinal failure-associated liver disease, also known as PN-associated liver disease (PNALD). The clinical presentation of PNALD varies from asymptomatic transient elevated liver function tests that improve with modifying PN prescription (e.g. reduction in total parenteral glucose or lipid energy, or a change in lipid emulsion), to cirrhosis (20). Thus, as recommended in Table 1, it is necessary to have serial measurement of liver function tests in every patient on PN to monitor and detect early, any elevations in liver enzymes or bilirubin. Patients who have sudden or persisting elevations should be further investigated with blood cultures to eliminate a central venous line infection and an abdominal ultrasound to assess for hepatobiliary complications, depending on the clinical situation.

For more details on diagnosis and management of hepatobiliary complications please refer to chapter "Intestinal Failure Associated Liver Disease".

Metabolic Bone Disease Monitoring

Long-term HPN increases the risk of bone loss on top of pre-existing individual's risk factors (e.g. lack of exercise, postmenopausal, etc.). Factors associated with intestinal failure and HPN are multiple and include suboptimal vitamin D levels and low calcium absorption or intake, high amino-acid load, electrolyte imbalance, aluminum contamination, and cyclic infusion (21, 22). The prevalence of vitamin D insufficiency and deficiency is well documented in patients on home parenteral nutrition, even in those receiving additional oral and IV supplementation (23, 24). Thus, annual or biannual bone mineral density testing (DEXA Scanning) should be considered and PN modification, high dose vitamin D supplementation and other managements should be addressed accordingly.

For more details on diagnosis and management of metabolic bone disease please refer to chapter "Bone and Joint Disease".

Weaning off Parenteral Nutrition

The fate of the intestinal failure patients is determined by types (acute, prolonged acute, or chronic) and aetiologies (short bowel, dysmotility, fistula, mechanical obstruction, mucosal disease, etc.) and treatments of each individual. In general, it is widely accepted that intestinal adaptation in surgical short bowel syndrome reaches maximum extent within 2 years after the last bowel resection in adult. Prior to the era of novel growth factor therapies, if elimination of PN is not accomplished in the first 2 years, the probability of permanent PN requirement is 94% (25). Several factors influence the success of PN weaning in this group of patients. Length of remaining small bowel, the presence of colon and ileocecal valve in short bowel play important roles in weaning of PN because of the impact on nutrients and fluid absorption. Residual disease in the remaining small bowel also determines the outcome of weaning in patients with inflammatory bowel disease and radiation enteritis. Other factors that may be associated with the success of PN weaning include use of novel medications (Glucagon-like peptide-2 agonist (GLP-2 agonist), recombinant human growth hormone), age of the patient, duration of time on PN, and nutritional status prior to

weaning (26, 27). Weaning will also be more rapid if growth factors are used (e.g. GLP2-agonist), requiring closer monitoring, initially on a weekly basis until patients are more stable in their weight gain and hydration status. Individualized plans to reduce or stop PN should be established in all patients except for those with a predicted short term survival, such as intestinal failure from inoperable malignant bowel obstruction, and patients with ultra-short bowel syndrome. The aim is to provide the minimum amount of parenteral support to maintain an acceptable nutritional status and prevent dehydration.

Transition from PN support to oral and/or enteral nutrition requires the effort from both patient and multidisciplinary team. Patient' motivation and compliance should be assessed. General education about their underlying diseases, physiological changes of remaining small bowel, as well as, dietary and pharmacological therapies should be reinforced. Furthermore, patients have to understand that the process of PN weaning generally requires life style modifications which include increasing daily oral food intake, modification of daily fluid intake, taking more supplements and medications, and switching some intravenous medications to other formulations.

Optimization of diet, fluid intake, and medications is necessary and should be achieved before weaning of PN. Clinicians in PN team should establish caloric requirement of individual patients based on their resting energy expenditure, activity factor and malabsorption factor. Serial measurements of body weight and actual caloric intake by food diary or food recall should be assessed to confirm if nutritional status is optimized. Adequacy of hydration can be addressed by fluid intake and output records. A pragmatic approach to monitor hydration in clinical setting is daily urine more than 1 L. However, if urine output is not easily measured, urine sodium >20 mmol/L and serial measurements of blood urea nitrogen (BUN), serum creatinine and electrolytes are also useful. Enteral balance (oral fluid intake minus stool output) more than 500 mL per days is suggested by the expert (26), however, it is not a good parameter in short bowel with high ostomy output.

Reduction of PN can be done by either decreasing the days of infusion per week or decreasing the daily infusion volume equally throughout the week (10–30%). Most patients prefer the former because of psychosocial benefits and a potential reduction in catheter infections. However an assessment of the patient's fluid dependence needs to be made before this option is discussed. If this method is chosen, in order to maintain adequate hydration, the PN free nights should not be consecutive. Some patients may require intravenous hydration instead of PN on those days, which can be administered during the day, allowing for a good night sleep.

An optimal interval for making PN reduction decision should be also individualized and based on feasibility of monitoring and PN modification by PN team. Once a week reduction is possible but need close monitoring especially from hydration perspective. During the process of weaning, patient should be monitored, as mentioned above, to ensure adequate nutrition and hydration on weekly basis until stable. This interval of laboratories monitoring should be based on reduction regimen. Besides modification of calories and fluid in PN solution, electrolytes especially magnesium, potassium, and phosphate should be of concern. Antidiarrheal medications and oral vitamins plus trace elements should be adjusted and serum levels of trace elements and vitamins closely monitored. 1–6 mg intramuscular or subcutaneous vitamin B12 supplement is required in patients with history of gastrectomy or distal ileal removal when multivitamins is discontinued together with PN (in UK 1 mg hydroxocobalamin is given intramuscularly every 3 months). Some patients will maintain weight with withdrawal of parenteral macronutrients but overtime may develop micronutrient deficiencies despite oral micronutrient supplementation and will need an ongoing plan to support their micronutrient status parenterally.

A trial of PN discontinuation is considered when PN infusion has gradually been reduced to 3 days or less per week. Weaning of PN is not equal to elimination of all parenteral support. Some patients with a high stomal output require intravenous hydration to prevent fluid and electrolyte imbalances when PN is reduced or terminated.

Conclusion

Monitoring of HPN patients is extremely important in order to maximize the benefits of receiving HPN while reducing complications. This requires a multidisciplinary PN team that has the expertise and experience in following these patients as well as protocols to monitor and avoid or treat promptly any complications. Weaning should be attempted in most patients, in order to improve quality of life and reduce HPN associated complications. This also requires continuous monitoring that needs to be more intensive if growth factors like GLP2-agonist are used.

Quality of Life

Ashley Bond and Simon Lal

Key Points

1. QoL reflects a complex interplay of physical and psychological health. It is influenced by a person's independence, position within their environment, social relationships and social standings.
2. QoL in IF may relate to the underlying disease, having a short bowel, medication or needing parenteral support.
3. QoL involves a physical and psychological assessment. It also includes assessing how daily activities have been affected (including employment), eating/drinking, socialising and often stoma/wound management.
4. The SF-36, Euroqol, HPN-QOL, SBS-QoL, PNIQ and HPN-PROQ have and still are used to assess quality of life.
5. HPS patients who require the greatest number of nights per week (and greatest volumes of PS) consistently report the worst QoL which may improve when the PS requirements can be reduced.
6. Patients with a short bowel are mainly affected by thirst.
7. Patients with poor social networks and those of working age who had ceased employment are particularly at risk of depression and anxiety.
8. HPS-dependent patients with SBS and their family members, described restrictions on activities of daily living and physical functioning, highlighting that patients' lives were dominated by their condition.
9. Transplant recipients score better than HPS patients in ability to holiday/travel, fatigue, gastrointestinal symptoms, stoma management or bowel movements. However they have more psychological issues which in addition to being post traumatic, partly relate to fear of graft rejection and the consequences of severe immunosuppression.

Introduction

Patients with a reduction in gut function to the point that they require home parenteral support (HPS) are said to have type 3 intestinal failure (IF) [1]. The overarching aim of HPS is to enable long term survival, while also maintaining, wherever possible, quality of life (QoL). There is no doubt that the requirement for HPS can be burdensome and time-consuming, requiring a significant degree of adjustment for patients and their families [2–5]. Thus, not only may activities of daily living be affected, patients can also encounter sleep disturbance as well as emotional reactions of fear, anger, disbelief or depression [6]. Economic and social restraints associated with the need for HPS can lead to a further restriction of leisure activities and employment opportunities, elements of life that many people may take for granted [7–9]. HPS is frequently life long and, whilst preserving life, it is associated with inherent risks of complications such as catheter related bloods stream infection, thrombosis, biochemical instability and liver disease [5, 10–12]. Readmission to hospital with complications associated with HPS can further impair a person's QoL, as can worry over the development of such complications [13]. Frequent hospitalisation is seen in this cohort of patients which in turn will, of course, have a negative impact upon wellbeing [14–16].

Maintaining QOL has been identified to be of key importance to patients when dependent on HPS [2]. The World Health Organization has defined QoL as 'an individual's perception of their position in life in the context of culture and value systems in which they live and in relation to their goals,

expectations, standards and concerns' [17]. QoL reflects a complex interplay of a person's physical and psychological health and is influenced by an individual's independence, position within their environment, social relationships and social standings. Tools or questionnaires that are used to evaluate QoL can be grouped into generic measures, thus applicable across a wide range of conditions, and disease-specific measures.

QoL Assessment Tools

General

Across the available literature, the generic Short Form-36 (SF-36) has been the most commonly used tool for QoL measurement in clinical trials [2, 18]. An advantage of a generic tool is that it allows for comparisons and summation from a wide range of studies examining different disease types; for example, a comparison between the QoL of those living with chronic IF and those with end-stage renal failure, both of whom require life preserving therapies that impact upon daily activity and also share the need for long term central venous access [2, 19]. The EuroQoL is also frequently utilised to evaluate QoL and cost-utility; this is a relatively simplistic tool that is often used in conjunction with a second measure such as SF-36 [2]. However, neither EuroQoL nor the SF-36 specifically address the unique issues for patients living with chronic IF, such that disease-specific tools have subsequently been developed, particularly given the more recent and evolving need to evaluate the impact of novel therapies such as growth factors on the QoL of HPS-dependent individuals.

HPS Specific

The first attempt to derive a disease specific tool was by Baxter et al., who developed the HPN-QOL after validation in U.K. patients [20]. The questionnaire contains multi and single-item scales for functional and symptomatic assessment. The functional scales cover general health, ability to holiday or travel, physical function, ability to eat and drink, employment and sexual function, amongst others; for these scales, a high score indicates a high level of functioning. The symptom or problem scales, in which a high score represents high severity or more problems, include body image, fatigue, sleep pattern, pain, stoma presence or absence and body weight. Two questions relate to nutrition teams and the availability of specific equipment related to HPN, in which a high score represents a good outcome [20]. The largest study using HPN-QoL included 699 patients across 14 countries and demonstrated that QoL scores were significantly associated with HPN duration (better after longer-term dependency), underlying disease (better in Crohn's disease and mesenteric ischemia) and living status (worse for those living alone) and, after adjusting for the other factors, with the number of HPN infusions per week [20]. A smaller single centred assessment using HPN-QoL analysed 193 patients and their care givers, demonstrating that those with intestinal dysmotility reported the lowest quality of life [21].

The Parenteral Nutrition Impact Questionnaire (PNIQ) was developed and validated in the U.K. to measure patient reported QoL and lived experiences of HPS [9, 13, 22]. An initial series of semi-structured qualitative interviews with HPS-dependent patients were used to identify the impact of HPS on need fulfilment and then to create a needs-based model and item response theory to design the final version of PNIQ. The tool comprises 20 questions, specifically related to the impact of HPS on QoL. Each question has a dichotomous response of 'True' or 'Not true', with scores summated up to give a total score ranging from 0 (good quality of life) to 20 (very poor quality of life). In contrast to HPN-QoL, PNIQ tests patients' response to HPS and QoL independently of the underlying disease. Notably, PNIQ can typically be completed in under 10 min by the patient without assistance, making it a useful tool for QoL assessment in routine day-to-day clinical practice [13, 23].

The HPN patient reported outcome questionnaire (HPN-PROQ) was developed as a disease specific tool in order to allow patients to identify and address lifestyle concerns they may wish to discuss with their clinician and these, in turn, may lead to more in-depth conversation about psychosocial feelings and QoL [24]. HPN-PROQ consists of 23 HPN related questions, each with a 5-point Likert response scale as well as questions from HPN-QoL. This includes items relating the number of HPN nights, medical devices used in the administration of HPN and the organisation of the service delivery in the community. In addition, questions also specifically assess perceived QoL. The HPN-PROQ provides a way to help foster patient-clinician communication about lifestyle adaptation and QoL [24]. The tools are summarised in Table 1.

Short Bowel

More recently, the short bowel syndrome (SBS)-QoL tool was developed primarily for self-administration specifically in those living with SBS, with or without HPS-dependency. The SBS-QoL relies on Visual Analogue Scale assessment with scores summated to a maximum value, with a recall period of the preceding 7 days. Due to its disease specific nature, SBS-QoL has been particularly used to evaluate the impact of growth factor therapies such as glucagon-like peptide-2 (GLP-2) on HPS dependency and SBS-related symptoms [25, 26].

Table 1 Key features of available HPN or CIF specific QoL measurement tools

QoL measurement tool	Key features
HPN-Qol	• Developed using classical test theory • Scales for functional and symptomatic assessment, with questions also relating to nutrition teams • Assessment of nutritional team support and HPN related equipment
SBS-QoL	• Developed using classical test theory • Visual analogue scale assessment • Disease specific tool for short bowel syndrome
PNIQ	• Developed using item response theory • Dichotomous response questions • Evaluates impact of PN on the individual
HPN-PROQ	• 5-point Likert scales and items from HPN-QoL • Aimed at encouraging dialogue with provider

Factors Affecting Quality of Life for HPS-Dependent Patients and Their Family Members

When viewed in isolation, the available disease-specific QoL tools identify a number of factors that influence an HPS-dependent person's QoL, such as the number of infusions per week, underlying disease and mechanism. However, it is important to recognise that, at any one time and for any individual, QoL represents a complex interplay of social, medical and psychological issues. Nonetheless, identifying common influential factors in cohorts of patients with a specific disease can of course be informative both for research and day-to-day clinical practice.

Effect of Infusion Time/Amount

As noted, there is a clear correlation between frequency HPS requirements and duration of infusion and QoL. Patients who require the greatest number of nights per week consistently report the worst QoL, as evidenced in studies using PNIQ and HPN-QoL, which demonstrated an association between worsening QoL with an increasing number of infusion days [13, 16, 20]. Patients have also reported an improvement in their QoL when a reduction in PS requirements is achieved [26], with Nordsten et al. demonstrating an improvement in SBS-QoL with a reduction in daily PS volumes [16].

Effect of Peptide Growth Factors

The associations between PS frequency and duration of infusion and QoL are important since therapeutic strategies, such as GLP-2 analogues, have the potential to reduce requirements and thus improve QoL. While the GLP-2 analogue, Teduglutide, has been shown to effectively reduce PS requirements in a large randomised controlled study [27], it is noteworthy that initial post-hoc analysis of these data did not demonstrate an improvement in SBS-QoL compared to placebo [26, 27]. However, when considering these initial data, it is important to recognise that QoL was not the primary outcome of the studies, which were also of relatively short duration and, as such, may have been underpowered to achieve an effect on QoL. Indeed, more recently, Jeppesen et al. reported that Teduglutide resulted in volume reduction that was significantly associated with improvements in SBS-QoL [28]. The strongest association was observed with 80–100% PN volume reduction and the effect on QoL was particularly notable in the IBD cohort [28]. A study in 2020 reported that those with the highest baseline PS requirements derived the greatest improvements in QoL from the use of teduglutide [25], which may be expected given that patients with the largest PS requirements report the worst baseline QoL [16].

Eating and Amount of HPS

The ability to eat and maintain oral intake has been described as key goal for HPS-dependent patients [29], which is of course relevant when interpreting the effect of enterohormonal therapies such as Teduglutide on QoL. In a similar fashion, the interplay between intestinal anatomy, HPS requirements and QoL likely explain the finding that patients with less than 50 cm of remnant small bowel report a poorer QoL compared to those with longer bowel lengths, even when adjusting for confounders of age, sex, body mass index and education [16]. It must be recognised that those with shorter remnant small bowel are likely to have greater HPS requirements. However, the additional detrimental effect of a high stoma output and voluminous diarrhoea may also play a part in impairing QoL in those with shorter bowel lengths, which may also explain the association between citrulline levels and QoL reported in patients with SBS, with citrulline acting as a surrogate marker for small bowel mass and function, as well as HPS requirements [29].

Duration of Illness and of Receiving HPS

The length of time an individual has received HPS, as well as the duration of any pre-morbid condition can also influence QoL. Thus, it was recognised more than 20 years ago that those with relatively sudden onset intestinal failure, such as following an acute mesenteric ischaemic insult, may experience an abrupt deterioration in QoL, compared to those already suffering with long term chronic conditions such as

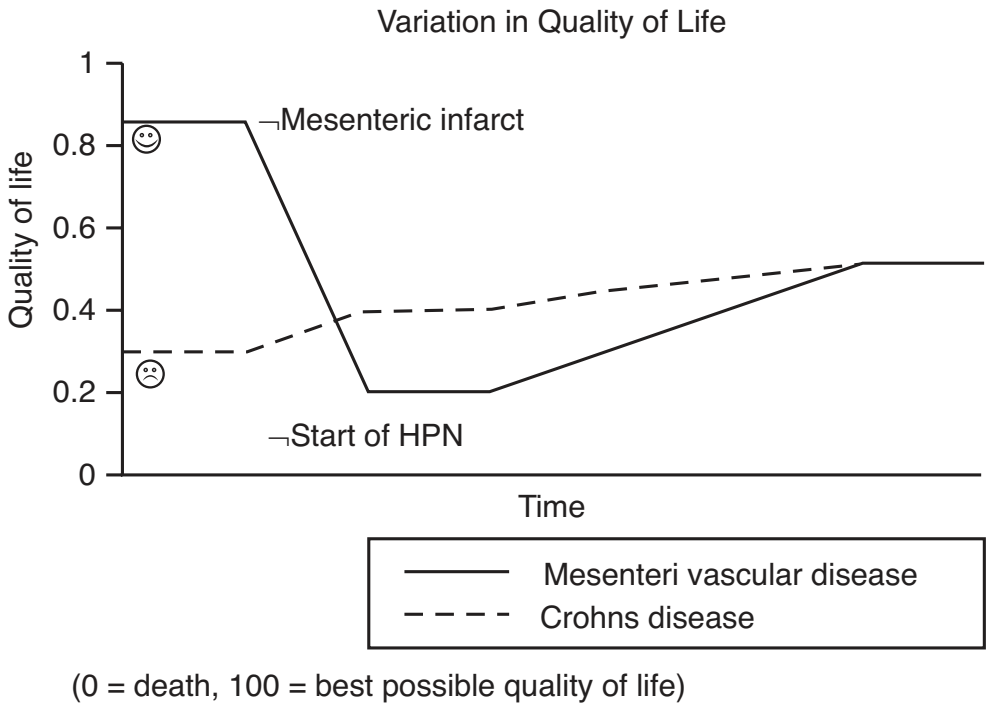

Fig. 1 Quality of life of HPS patient secondary to Crohn's and mesenteric ischaemia and variation with time

Crohn's disease (Fig. 1). In keeping with this, Burden and colleagues more recently demonstrated that those suffering from surgical complications leading to intestinal failure reported a poorer PNIQ score compared to HPS-dependent patients with chronic inflammatory bowel disease [13]; this effect may be explained by the sudden onset of intestinal failure that occurs in patients with surgical complications. Indeed, patients with acute, type 2 IF resultant from surgical complications, typically present after multiple operations and, after prolonged periods of in-patient stay, are discharged home to recuperate on HPN [30, 31] and such patients are often devastated by a relatively rapid deterioration in their QoL [13]. Moreover, better overall HPN-QoL scores were reported in patients with HPN duration longer than 24 months compared to patients with shorter duration [20] and other studies have similarly demonstrated the same pattern of improving QoL with over time [26, 32].

Dysmotility

The reported QoL of HPS-dependent patients resultant from gastrointestinal dysmotility seems to vary according to the tool used. While there has been a report of increased distress secondary to gastrointestinal symptoms and problems with eating in those with underlying dysmotility compared to patients with SBS, this did not seem to have an impact on overall QoL [14, 21]. Baxter et al. used HPN-QoL to demonstrate that patients with GI motility disorders had a lower QoL when directly compared to those with Crohn's or mesenteric ischaemia [20]; however, this was not the case when PNIQ was used to evaluate QoL [13]. This discrepancy may reflect the fact that PNIQ solely evaluates the impact of HPS on QoL, while tools such as HPN-QoL also take into account underlying gastro-intestinal symptoms and patients with gastro-intestinal dysmotility receiving HPS will often continue to have very troublesome symptoms, including pain, nausea and vomiting. Therefore, tools which assess symptom impact as well as HPS impact will likely report lower QoL scores.

Employment

The ability to work and maintain a living will ultimately have a significant impact on an individual's and families' quality of life, as with all chronic conditions. One consistent finding is the positive impact on wellbeing that employment has. Ablett et al. reported patients with poor social networks and those of working age who had ceased employment were particularly risk of depression and anxiety [33]. The number of days per week on HPN and the desire of the patient to return to employment have also been found to be significantly associated with the ability to maintain employment [34]. When compared to HPS-dependent patients receiving an above minimum wage, those paid minimum wage or below had a significantly lower reported QoL [13].

Activities of Daily Living

When using a qualitative, non-interventional interview approach to assess QoL in HPS-dependent patients with SBS-IF, novel themes and drivers can be identified. A recent qualitative assessment of HPS-dependent patients with SBS and their family members, described restrictions on daily life, actives of daily living and physical functioning, highlighting that patients' lives were dominated by their condition. The most burdensome symptoms reported by patients was thirst. In addition, patients described the emotional aspects of living with SBS, specifically with difficulties socialising and maintaining relationships. Patients also described coping mechanisms and adapting their lives around their condition, acknowledging the life sustaining element of the treatment. Family members also described the impact of living with an individual on HPS, reporting that they worried about their relative's condition with some also being affected by the obligations of HPS and the impact it had on QoL. Relatives also reported the importance of achieving a night off from infusions, which is an important consideration for clinicians [35].

Advanced Malignancy

Quantitative and qualitative evaluation of the impact of HPS in those with advanced malignancy and palliative needs have revealed insightful results. Notably, the PNIQ score of patients with advanced cancer was comparable to that of patients with inflammatory bowel disease in a large U.K. study, suggesting that HPS has a similar effect on the QoL of those with benign and malignant conditions [13]. Sowerbutts et al. used longitudinal interviews to assess QoL of patients with ovarian cancer and malignant bowel obstruction, along with their caregivers. Patients considered HPS as an essential element of their condition as a whole. Although it inferred some negative aspects, many considered it as a "lifeline" that allowed them be at home. Negative aspects reported included the loss of normality and the effect it could have on the social aspect of mealtimes. On the whole, many felt HPS was worthwhile because of the extended time they had at home with their relative [36].

Impact on Family Members and Carers

More recent larger studies have further evaluated the impact of HPS on family members and carers. Beursken-Meijerink et al. assessed QoL and distress using the HPN-Qol and the Caregiver Strain Index (CSI) and found that the caregivers of those with dysmotility experienced a higher burden when compared with caregivers of patients with SBS, due to increased demands on time and perceived strain. A multinational, cross-sectional survey from 2021 assessed the impact on caregivers of adult patients receiving parenteral support for short-bowel syndrome. Caregivers reported an overall negative effect, with a reduction in the ability to work full-time. They also reported an impact on daily activities and their ability to participate in recreational activities. When asked about the impact of caregiving on emotions, most caregivers reported worrying about the health of the patient [37]. The health status of the caregiver also appears to be an important factor, with French et al. (unpublished) reporting family members with a poor health status more likely to perceive a moderate to very severe subjective burden when living with an individual dependent on HPS [38].

Intestinal Transplantation

Intestinal transplantation can be considered in patients with unique circumstances of extremely poor QoL (see chapter "Intestinal Transplantation") but, given the risks associated with transplantation, QoL alone should be scrutinised by a multidisciplinary team if used as a single factor indication for transplant [39].

It is difficult to directly compare the QoL of patients of patients receiving HPS with patients who have undergo an intestinal transplant. However, using HPN-QoL as the assessment tool, Pironi et al. made comparisons between people receiving long term HPS for benign disease and those who had undergone intestinal transplant; notably, transplant recipients showed a significantly better score in the domains related to ability to holiday/travel, fatigue, gastrointestinal symptoms, stoma management or bowel movements and the numerical rating scales of quality of life. Furthermore, HPS-dependent patients reported poorer scores for employment and for emotional function [40].

Pither et al. reported QoL scores measured using SF-36 improved in approximately half of the patients compared to their status at listing for transplantation, no change in around one third, and a minority experienced a decline [41]. In a parallel paper, Pither and colleagues evaluated psychiatric disorders in patients pre- and post-transplantation and found that 10 of 14 patients still had a single psychiatric disorder after transplantation and 3 of 14 had also acquired a second psychiatric diagnosis with suicidal ideation in 2 cases. Notably, depression resolved in only 1 patient after transplantation and a further patient without a history of psychiatric issues before being transplanted, developed a double psychiatric diagnosis (anxiety with depression) during the post-operative course [42]. The authors highlighted in their conclusion that the additional stress of transplantation can impact psychological wellbeing, detailing the importance of mental health support during rehabilitation. A further study found that patient personal financial

pressures are greater following intestinal transplant which may affect the morbidity associated with organ graft receipt [43]. A similar effect was reported by Abu-Elmagd et al., whereby a number of domains improved post-transplant, but recipients reported worsening of levels of depression and financial obligation worries [44]. A systematic review published in 2016 reported that post-transplant QoL improved with time since transplant and there is a need for large and longitudinal studies to explore any improvements to QoL and other areas of daily living over time in more detail [45].

When considering QoL as a sole indication for transplantation, it is, of course, important to take survival into account. A prospective 5-year study compared survival of patients with uncomplicated HPN to those with any indication for transplant and found that the probability of survival of individuals considered possible candidates solely on the basis of low acceptance of HPN was 100%; the authors concluded that while desmoids and IF-related liver failure were clear indications for life-saving intestinal transplantation, other indications should be considered on a case-by-case basis [11]. Clearly, the risk: benefit ratio may change as survival following transplantation improves but, for the time being, QoL as a sole indication needs to be carefully considered on an individual basis with the patient and wider multi-disciplinary team, highlighting the risks following any transplant.

The Patient's Requirements

Carolyn Wheatley, Monika Malickova, Joanne Shepherd, and Steven Brown

Key Points

1. Patients prefer to have their care at home but not all will want to self-care.
2. The patient must feel part of the decision-making processes involving their care.
3. Many have body image issues in addition to physical weakness.
4. While there is feed and ancillaries (equipment and consumables) delivered to the home, the home should not look like a hospital.
5. The patient/carer/parent/guardian needs to understand the underlying medical condition and the reasons for the type of feeding (enteral or parenteral nutrition) and the challenges (including complications) that may occur. It is helpful to have a short medical summary that includes contact details.
6. The aim at home is to be able to return to doing all/most of the activities that were previously done (includes washing/dressing, driving, sport/leisure activities and going on holidays.
7. Patient groups and associations can give very useful support and helpful advice? to common problems.

Introduction

The route to home artificial nutrition is complex and the reasons why it is required are diverse. Navigating this route to successful discharge and home treatment can be challenging. Increasing numbers of patients—both adults and children, are now able to live with varying degrees of independence in their own homes whilst receiving artificial nutrition. Some individuals are immediately dependent on it from birth, whilst for others it is the failure to thrive that subsequently leads to awareness that it is urgently needed. Both adults and children may encounter medical and surgical complications that necessitate artificial feeding during their lifetimes, which then becomes a life-saving home therapy. While many patients are fortunate to have homecare as an option, we know through the network of patient groups, that the availability of homecare varies around the world.

Home is always the goal—it's where people want to be, both those receiving the treatment and their parents, partners and families. For many this will be a welcome relief from long and possible frequent episodes of hospitalisation, but for others it may mean a life of intense routine and isolation. Acceptance that life is dependent upon a specialised treatment, aseptic procedures, complex routines and mechanical equipment can be hard to comprehend. Those able to self-care may find adjusting a little easier, but this should not be assumed. Children will naturally be dependent on their parents/guardians for their care initially.

During treatment, and at intervals along the way, everyone will need the support of family and friends. Whilst they are life-saving treatments, they can be both demanding and a burden [1]. Patients understand these are likely to be needed long-term, and that a desired lifestyle choice may need changing or modifying. An adult may resent being dependent on others for their care and all those involved in home treatment will need to place their trust in the hands of a highly specialised medical team whose skills will allow them to integrate the therapy into their home and personal lives. Additionally, for those who have a homecare service and community support, it will be necessary to determine who is responsible and how this all fits together to provide the necessary support for all concerned.

Patients, parents and carers are fully aware that home nutritional support will not cure their underlying condition, but instead allow them to live with it. In the initial stages, and possibly for the duration of their therapy, both children and

adults may experience situations and emotions that are psychologically challenging. These experiences can be difficult to explain and are partly due to the subjective effects of both the nutritional support and the underlying illness(es).

There are pros and cons to having hidden conditions and tubes. Invisibility may mean the patient is perceived as 'normal', however, the need for artificial nutrition is often poorly understood by society at large, so many patients can find themselves alienated in a world that does not always comprehend things it cannot see.

Recently, patient groups and associations worldwide have made excellent progress in forging links. It has proved invaluable to learn of the variation in treatment options and homecare. We are now able to appreciate the inequity in both care and services.

Despite difficult, and possibly prolonged periods of hospitalisation, homecare is a natural step for many. However, the journey to going home can be a long one, if it's even an option. There are some patients fighting for their treatment options, parents advocating for their children, and carers, who for a variety of reasons, are also seeking appropriate treatment and choices.

Care in Hospital

Once the decision has been made to commence artificial nutrition, parenteral or enteral, the patient or carers are likely to experience some degree of apprehension. They will be aware that this treatment is only commenced when all other avenues have been exhausted. As the patient may have experienced disappointment following previous treatment failure, doubts may surface. The patient and carers may wonder 'can we afford to place our trust in yet another treatment which may not have a positive outcome?' Often the families and carers involved are juggling work, childcare and education so they want the right decision made for their loved one to expedite improved nutritional status and hopefully discharge.

Weight loss or failure to thrive, has both clinical and physical impacts on the body. People may experience poor body image in addition to the physical weaknesses this imposes. Observing the body wasting away or failing to develop properly, despite all attempts to correct it, can leave the patient with low self-esteem, feeling worthless and defeated. In certain circumstances the individual may lapse into a period of denial, and this state of mind may adversely affect the outcome of their treatment. Parents and carers may feel helpless despite the encouragement and support they provide; their desire to make things better is not always that simple.

Prior to Insertion of Venous Access Device/ Feeding Tube

To support the patient and provide them with all relevant information, it is important to ensure enough time is set aside to discuss all aspects of the process. To facilitate the acceptance of change, the patient needs to feel empowered [2]. Where the parents or carers of a young person are making the decisions, they need equal time and opportunity to discuss it and ask questions. Indeed, the parents/carers will need to explain this to their child and it will be them who they turn to if they have questions. Everyone needs the opportunity to discuss any fears or concerns with the medical team. It is vital that the patient feels part of the decision-making processes [3], as it is their body. Verbal communication needs to be as informal and open as possible. Educational resources, where possible, should be made available in different formats such as film or reading material—as not everyone processes information in the same way.

As soon as the need for a feeding device is identified, the preparation should begin, it should not be rushed nor overlooked. No concern or question should be belittled. Anxieties require discussion and need to be systematically worked through to quell any fears. The patient or carer may benefit from time spent familiarising themselves with the equipment. This juncture is crucial to the acceptance of what will change their life forever—not only will they have a visual and constant reminder that they are now different, but their state of mind may be altered. There are several child-friendly educational resources available, which will certainly aid acceptance for a child. These are also useful for siblings.

At this crucial point of acceptance, the patient and/or their family may need some psychological support to navigate the change. Support should be provided by healthcare professionals who have experience of intestinal failure and artificial nutrition. Some intestinal failure units have acknowledged the benefit of having this support integrated into their service and, as a result, have psychologists as part of the nutritional care team [4].

Dependent upon the patient's state, appropriate anaesthetics should be administered to ensure equanimity during the procedure. For those who have undergone many surgical procedures during their illness, another procedure, no matter how minor, may cause distress. When feeding devices are being replaced, it is important to ask the patient or carer about previous experiences that could impede the smooth operation of the next procedure. They are experts in their own health and procedures. It is important to stress that discomfort and soreness may be present after the insertion. Knowing something is normal and expected can be reassuring.

A positive result for the patient is full acceptance and correct management of their feeding device.

After Venous Access Device/Feeding Tube Insertion

Patients and carers will notice that shortly after nutritional support has commenced the nourishment has a positive impact on the body and mind. Possibly, the initial and most obvious sign of improvement will be a healthier looking patient and weight gain. It may be slow, but the much-needed nutrition will fuel the body. It will become apparent that the patient is more attentive and shows a greater ability to concentrate.

Everyone will be pleased to see the improvements, and this will hopefully contribute to acceptance of the device and the need for artificial nutrition. Patients may previously have been told they looked thin and unwell. Following treatment, it can be satisfying to be told how well you look. Often, it's not until things improve that there is recognition of how bad things were beforehand. However, underlying conditions must not be forgotten during this phase. For parents of tube-fed children weight gain will be welcome, but they will also be keen to know if their child is progressing in other ways too.

For the patient the presence of a feeding device may be both welcomed and feared. It will alter body-image and may not be the only medical attachment they have. Even patients who accepted the need for the device prior to its insertion, may find that the physical presence alters how they feel. They may require support from psychologists with experience of intestinal failure and artificial nutrition; ideally one connected to the nutrition team.

Equipment Management

Tubes and central lines require strict care and observation to ensure they remain patent, safe and infection free. The presence of a feeding device will bring restrictions in terms of clothing, activities and possibly raise questions about sports and swimming. Children may be restricted, and parents may be concerned about normal development milestones that could compromise a feeding device e.g. tummy time, crawling, rolling over and a lot of tossing and turning at night.

All patients have personal feeding regimes, many patients are restricted by feeding tubes and central lines, pumps and equipment—it is unrealistic to assume that all patients stay in bed for the duration of their feed.

For many, as they are starting to regain control of their life, confidence will return and they will be heartened by their improved appearance. A former dislike to weighing scales may vanish as they are now displaying signs that 'this treatment' is working.

Conversely, there are patients who find themselves on artificial nutrition with no time to prepare or adjust; it happens quickly—an accident or sudden health change. For these patients, acceptance takes longer or may not happen. Additionally, not all patients feel better and have complications that add to their medical issues; it's not always a blessing.

A skilled medical team with carefully planned follow-up appointments for the patient, should be in place to not only monitor the clinical parameters but also the psychological aspects of living with home artificial nutrition. They will have seen the 'unexpected' emotions before and their expertise can be used to address these and, if necessary, refer patients, parents and carers for additional support [5].

Training Programme

It is essential that the patient, parents and carers understand the training programme which has been devised for them and appreciate the importance of taking one step at a time. We recognise that the training for parenteral and enteral procedures are different and require different training programmes. Also, there are large variations in training locations. At one time it was always carried out in hospital but in some countries, it's done in the patient's home. There is also variation between the adult and child training.

A training programme should ideally be outlined in advance, providing information on where it will be done and who will be trained. Everyone concerned should be informed; if self-caring is the goal then this should be made clear with goals and clear timelines. For those who will self-care, it will be a one-to-one training progamme. For those who are reliant on parents or carers, an amended programme will be needed. Preferably more than one person will be trained to care for the patient, particularly for children. The best laid plans often need to change, usually at short notice. At no time should day-to-day living cause issues if a sole parent or carer became detained or delayed; feeding and the care of the patient should never be compromised.

Where children transition into adulthood and still require artificial nutrition, transferring skills to create independence and autonomy, should be discussed with the parents and carers as soon as it's considered appropriate. Where possible independence should always be the goal.

Where homecare nursing services are used to train patients, a clear outline of the plan and timescale should be apparent. Sometimes people are eager to take over their own care; whilst others nearing the end of their training may feel uneasy about losing visits from nursing staff. It's essential that no patient, parent or carer should feel that once training ends they are on their own. The availability of a support network must be certain.

Everyone will learn at their own pace; it may be necessary to reiterate certain aspects of the procedures to ensure people understand what they are doing and why. It can be an overwhelming process for some; others will pick it up easily, it's about ensuring the patient is competent and capable of performing the procedures.

Individuals may form a close bond with those who are teaching them; it's a very personal time and during training, people often share their feelings and seek reassurance that it's all going to be okay.

Following initial training, everyone should have the opportunity to ask questions or express their concerns. Also, as new products are introduced, it's preferable if everyone is taught how to use and integrate them. Often basic information is sent out via the homecare companies and patients, but parents and carers are left wondering what to do with them. At all times during the need for artificial nutrition, healthcare professionals should be vigilant to ensure patients, parents and carers are continually reviewed and updated [6].

Life at Home

Going home can be a satisfying feeling, however this may be combined with feelings of anxiety, fear and excitement.

Often, long periods of hospitalisation will have been endured and it may take time to adjust to life on the outside. It will be challenging for all concerned; there will be so much to adjust to; feeding equipment, ancillaries, routines and procedures all to be done in a completely different environment. Home is not a hospital, but it will need to accommodate all the essential elements of the home artificial feeding. Preferably home should not resemble a hospital but the amount of storage required may mean several adjustments need to be made. Some people will dedicate a spare room for this and keep it all stored centrally. Others will need to use every bit of space they can find to fit it all in. The practical aspects of being at home can be a challenge.

Some people receiving home artificial nutrition may have a reduced capacity for oral intake. It will vary between people and for an array of reasons. Adjusting and accepting to this may be difficult for some people and psychological support should be offered to aid the adjustment period. Family life includes food and drink; for being unable to enjoy it or take part has the potential to cause distress, not only to the person receiving artificial feeding but to family and friends. A large portion of social interaction is based around food and drink, birthdays, christenings, weddings and religious events; life with a limited or no oral intake is challenging. Identifying this is important and support should be offered as part of the clinical care. Support groups can help with empathy but often a higher level of care is required.

Babies and young children: For families taking home a baby or small child; while it's exciting, there may be a lack of support from the usual channels, i.e. health visitor, GP, baby clinic and the most natural network of other new families. Home can suddenly feel isolating and lonely. Whilst the goal is to give families the best possible quality of life, the burden of care on the parents is enormous [7]. The only network they may have is medical. It's preferable to balance medical with conventional support.

Children and young adults will start or return to school, college or progress onto university. All aspects of their care and personal needs should be considered; life must go on to provide normal education and development; systems need to be in place to support them on this journey.

Adults at home: Adults may be returning home to find life has carried on without them. How they integrate back into family life, work, friendships and hobbies may be overwhelming depending on how much they are able to participate.

For some people, they are returning home to be on their own, this can be isolating; it's very different to the hustle and bustle of hospital life. Those with partners or other family members at home may find that their loved ones must give up work or education to become full-time carers and the combination of the feeding, medical conditions and daily life may leave little time for activities outside the home. Many people cope extremely well with the immense changes that have occurred. But these coping mechanisms, which partly depend upon the effects of their underlying condition and its treatment, are not automatic and they take time to evolve.

Needs of the carers at home: Consideration should be given to the mental health and emotional needs of the patients; but let us not forget the parents and carers. Everyone will have their own set of challenges, this will fluctuate with health changes and day-to-day living. To make life at home as manageable as possible, focus needs to be on the whole person and not just the feeding.

As we know, patients often return to hospital, it's upsetting when it happens, people truly don't want to be in hospital but often know it's the best place to be. Frequently

admissions cause further emotional turmoil for everyone; once at home it's where people want to stay. Sadly, when life at home starts to settle, fate often dictates that it's time to pack your bags and be re-admitted; often not knowing how long it will be until everyone is back at home.

Feeding

Food is everywhere—television commercials, magazines, advertising hoarding and it is also a key component in celebrating any major event. Eating and drinking are accepted social pastimes and exclusion from these can cause social isolation, leading to depression, social anxieties and loneliness.

Eating and drinking will be advised for each patient depending upon their personal circumstances. Some patients will have upper allowances of what they can consume orally. These allowances should be monitored in the hope that they can be increased, and, for some patients, dietitian involvement can have key benefits. Where limits are set; self-control must be steadfast.

When it comes to the actual process of setting up the feeds, how this affects family or home life will vary from one situation to another. Being part of a normal household may bring unexpected pressures, particularly with timings. Initially, accommodating the feeding into other people's lifestyles may be problematic and adjustments will be required. Those who can self-care will determine how best to accommodate it. If the patient needs a carer to set the feed up, then the timing and availability of their support network will need careful consideration and planning. In some countries, where patients cannot carry out their own procedures, a nursing service may be available. While this is good as the patient can go home, it can be restrictive in terms of rotas and the capacity of the nurses. For example, up to a 2-h window may be given—the nurse will be arriving at some point during that slot. If nursing support is required, sometimes twice a day, then the patient and family may have restricted freedom of movements and feeding time options.

Feeding the patient is the priority; in practice how this works while people juggle their daily commitments can mean a major impact on day-to-day living. In some instances, a child may need more than one parent or an additional carer to assist for logistical reasons; their playfulness, feeling tired or unwell may hamper the parent or carers from being able to perform the procedures safely.

Some people, both adults and children, will need supervision or assistance during the night both in terms of practical help—toilet needs, responding to pump alarms, changing feeding containers/topping up feeds as well as safety needs—for example, failure of equipment, such as tubing leaks, or symptoms of infection requiring immediate hospitalisation. Independent patients may need help with personal hygiene or medication.

The common belief that parenteral feeding at home is administered while the patient is asleep is not necessarily correct. Each patient will have their own sleeping patterns and may not wish to retire to bed early just because it is time to commence feeding. Some patients are electing to feed during the day to try and eliminate frequently disturbed nights due to regular trips to the bathroom. Feeding patterns will not be constant and the time for connecting will fluctuate. As part of the teaching process, the patient should be assured that it will be a natural occurrence for feeding time to vary from those that they have become used to in hospital. Patients, parents and carers should be encouraged to take control of the feeding regimes in terms of timings. Life must go on, families and couples need quality time together, this may be outside the home, so feeding must be adapted to ensure this takes place. Where possible, patients, parents and carers should ensure that the treatment does not rule their lives. The aim of the therapy should be to enable the individual to live life to the fullest and to meet their personal goals.

Equipment

There are various aspects of equipment management that need to be considered for home artificial feeding.

Ancillaries and storage: Initial deliveries of ancillaries may be overwhelming. Patients, parents and carers may not fully appreciate the number of essential items they will be receiving. It may be mentioned that a lot of boxes will be sent but it's not until you see it in the home environment that reality dawns. Storage space may be a significant issue. Ancillaries need to be stored safely yet easily accessible for use, as well as being rotated and used in date order. Keeping curious people out of medical fridges or little people away from interesting medical supplies may be a challenge.

Type of pumps and equipment used in the home: Despite increased awareness of ambulatory feeding pumps, some patients are using hospital-style static pumps in the home environment. These pumps need to be attached to heavy hospital-style cumbersome drip stands. This is across both feeding treatments; enteral and parenteral. However, sadly there are many patients who do not even have a static pump to infuse their feeds. Gravity feeding is still favoured by some countries and healthcare professionals. Mobility is improved where ambulatory equipment is available. This applies within the home—being able to go up and down stairs independently or move freely is a huge confidence

booster. Pumps are evolving which enhance the patient's quality of life; allowing them to feed outside the home and not be dependent upon a power supply to power the pump.

All options should be discussed with the patient, parents and carers. Pumps should be reviewed in line with lifestyles. While we advocate that ambulatory pumps should be considered, backpacks may not be viable for all patients. It will be dependent upon their personal well-being. The development of wheel rucksacks should be welcomed to meet the changing needs of patients, whether that is adults or babies and toddler patients who are learning to crawl or walk and need to be given confidence from an early age [8].

Dedicated parenteral nutrition fridge: There are large variations in how parenteral nutrition is supplied and subsequently stored by the patient. Some feeds are supplied as multi-chamber bags while others are cold-chain bespoke compounded solutions. For those who have cold-chain feeds, the storage facilities should be between 2 and 8° and a dedicated fridge is desirable. Some patients are not given fridges, some need to purchase their own while others have access to anything between domestic fridges and pharmacy quality fridges. Some patients will struggle to accommodate a large fridge and it may need to be 'squeezed' into the home somehow. Ensuring it's not tampered with is also vital, the internal temperature must be maintained to ensure the safety of the parenteral nutrition.

Patients, parents and carers should be asked about their lifestyles and the most appropriate equipment supplied. This should also be reviewed, as they may not necessarily know what the alternatives are. Healthcare professionals need to ensure they support their patients with choices, while being clinically safe, about equipment and ancillaries that could either hamper or enhance their feeding experience.

Deliveries/Supplies to the Home

For the patient to carry out their essential medical treatments they need the relevant ancillaries, and prescribed medication/solutions. There may be various options available to the patient, but some may be time consuming and difficult, especially if we consider that patients are unwell and have varying levels of mobility, particularly when attached to their feed. Gathering supplies from local pharmacies or surgeries and collecting nutritional fluids from hospitals, for example, is less than ideal.

Although homecare companies do not operate in all countries; in an ideal world, all patients should have a reliable service that will minimise stress by delivering complete supplies directly to their home [9]. The delivery times and frequency should be tailored to local resources in conjunction with the instructions from healthcare professionals as they arrange these services for their patients. A desirable goal would be for a homecare company to supply all relevant medical items related to the patient's needs. Centralising contact and distribution would make life much easier for patients, parents and carers. One call, one delivery, one monitoring and checking process.

Where homecare companies operate, there should be a good relationship between the prescribing hospital, the company and the patient. It should be clear how the service will operate, who to contact and how and where the lines of responsibility rest. Where the patient, parent or carer has been given a homecare service, it should meet their expectations and enhance their home feeding regime. They should deliver what's promised, when it's promised and in good condition and be fit for purpose [9]. Ancillaries and fluids should be supplied as expected; any omissions or replacement should be made known to the patient in advance of the delivery. For some patients, it's a struggle to determine what they can have and how many. The lines of approval for ancillaries is often unclear and the importance of a consistent service cannot be underestimated.

This is an area where the patient, carer or parent can feel 'out of control' of the means to sustain their life. They put huge trust in the homecare company and it can be a source of anxiety if errors and mix-ups occur. Whilst a consumer can look at a food and drink item and use their senses of vision, smell, taste etc. to assess the quality, freshness and safety; with medicinal products and ancillaries the consumer is trusting the provider. When errors occur, thoughts as to what other undetectable errors have occurred can be a source of anxiety. Due to the lines of responsibility between the hospital, homecare company and patient, follow-up of errors and ensuring appropriate action is taken can be difficult for the patient themselves to facilitate.

During the COVID 19 pandemic many homecare services were under as much pressure as the hospital services around the world. Homecare services need to be protected and safeguarded to ensure the supply of essential medical nutrition during usual and unexpected crises. Communication with patients/families/careers is vital for reassurance. Information needs to be given to those dependent on homecare deliveries and supplies. Homecare enables people to remain at home unless clinical care is specifically needed in a hospital.

Hospital Follow-Up

All patients, parents and carers understand the need for follow-up and clinic appointments at the hospital. Not only is it necessary to review and monitor their nutritional status but also their on-going underlying condition(s). The frequency

will vary depending on the needs of the individual patient. In addition to follow-up and clinics, some patients may be frequently admitted to hospital to manage various aspects of their needs. While necessary, this is very disruptive to family life, work life, schooling and education. It's upsetting when loved ones are re-admitted, often with no knowledge of how long they will be an in-patient. While the patient is in hospital, life at home doesn't stop; school, work and social occasions continue regardless. Each admission brings familiar emotions, often difficult and painful.

At home, the patient, parent and carer assume the roles of some of the healthcare professionals as they need to monitor and respond to the changing situations at home. Ill-health, raised temperatures, pain, sickness—each need appropriate action. When do you stop trying at home and decide to contact the hospital? Self-diagnosis is common and accepted for those with long-term illness and treatments but knowing when to seek help can be confusing and worrying.

Continual support must be given to the patient, parents and carers, and they must feel secure in the knowledge that advice is available 24 h a day just as it was in the hospital. Contact numbers must be given, but more importantly, where there is an answer machine, they should be checked regularly or provide clear and precise instruction on how to gain access to a person able to provide support. The nurse is generally the team member that the patient turns to in a crisis, therefore their availability and accessibility is paramount to the patient's sense of security.

Unfortunately, many of the problems faced by patients at home appear to occur late in the evening or at weekends. Most patients prefer to deal with their own team members who have knowledge and an understanding about them, which eliminates the need to go over old ground before any help can be offered. Hopefully, the hospital supervising the care will have someone known to the patient on call or at least they can be contacted for expert advice. It's important to realise that most people on home artificial nutrition are experts in their own conditions and care. Many are more than happy to discuss this and work with healthcare professionals to ensure the right treatment options are planned and administered. Patients, parents and carers will be fully aware of all the complications that can arise.

Large units with specialised knowledge in intestinal failure care for many patients receiving home parenteral nutrition. This may pose problems as the distance between home and the hospital may be considerable; requiring the need for a car, for example. However, this does not deter many patients and they elect to stay under their care despite the distance involved. For some a shared care policy can add a reassuring back up for unexpected events.

When a child needs to transition to adult services, there is usually a clear pathway already defined. It's essential that children are not seen as small adults, they have specific needs and when transitioning careful attention must be paid to the emotional and psychological support, not only for the patient but the parents.

Relationships

The need for home artificial nutrition can start at any point in someone's life; unexpectedly—following a trauma or accident or because of a long-term illness which may change over time. As there are various types of artificial nutrition, oral supplements, enteral and parenteral feeding, it is not unusual for some patients to have progressed from one to another based on their personal needs. No matter when artificial nutrition is introduced into a family unit it will have profound effects. If we consider the numerous types of relationships we have in our lives starting from an early age—parents and children, children and siblings/school friends, friends we socialise with, work colleagues, personal relationships—long-term relationships: life evolves as do relationships.

Children should be encouraged to ask questions about relationships as they develop. Altered body image, along with peer pressure, may leave them confused with potential for low self-esteem. As a child approaches puberty and then transitions to adulthood, it can be extremely daunting without the right support.

New personal relationships may be hard to contemplate—long-term ones may be just as difficult to re-establish. Consideration and understanding for all concerned should ease people through these testing times. It often helps to discuss these emotions with either the hospital team or other patients, people who have faced these challenges many times before. Partners and parents often need to adopt the role of the carer, even if this would not be a natural fit for them, which can alter previous relationship frameworks. It's imperative that personal relationships are maintained, but in practice, marriages and partnerships may be put under considerable strain. Other family members will be affected, and their needs may be overlooked. Child and sibling carers' needs are not always met.

Established relationships may be already strained during the diagnosis, admission and treatment phases. Bearing in mind, always, that the underlying condition may still be present and active, the treatment may feel like another set of issues to contend with. All aspects of the need for artificial nutrition will fluctuate and need careful understanding along the way.

In an ideal world we would hope that other people would be more accepting of illness and medical treatments, but sadly we know that this is not always the case. Whilst family and friends may find they can accommodate additional needs such as the use of a wheelchair easily, planning for unseen

conditions and disabilities may not be so easy. For example, strain may be placed on relationships with family and friends who don't make allowances for the need to be home in time to commence feeding. There may be time when activities are planned which the patient finds it difficult to participate in. Feeding regimes can make spontaneity difficult, thereby excluding the patient or adding stress to their life.

When the patient is in hospital, friends and family realise that attendance at social events such as weddings and celebrations is impossible. However, once home, expectations of family and friends might exceed the patient's ability to organise their healthcare needs to attend such events. It might be very difficult for the patient to attend, especially if the event is organised without the patient's needs in mind, but family and friends may not see these difficulties and may view it as the patient being difficult or unreasonable.

Self-confidence can be easily knocked by thoughtlessness or when constant rejections are made, leading to friendship/relationship breakdown. The treatment becomes the obvious obstacle, which can lead to diminished enthusiasm for trying again. Negotiating the relationship maze may be tricky for some, easier for others and it may change throughout the life of the patient.

Talking about sex and relationships should be part of the overall care of the patient, it should be managed by the right people and support offered to those who need it. Sadly, access to psychologists may be patchy. In many places mental health services are not established or funded sufficiently to enable this. However, the mind should be supported as much as the body is; we should never assume patients will just cope [4].

It is assumed that there are fewer psychosocial and sexual problems where low level or implanted feeding devices are used [10]. However, this will vary from patient to patient. Let us not forget that the feeding device may not be the only medical attachment they have, stomas are often present for many, along with scars and dressings.

Education and Work

It can take several weeks, if not months before usual routines or lifestyles can be re-established. The prospect of starting/returning to school or work may need to be reconsidered and based upon feeding regimes and health, adjustments may be required.

School/Education

The safety of the patient, in any setting, must be the priority. For a child at school or in education determining what help they may need, what information needs to be shared and whether any special arrangements need to be put in place, must be discussed and agreed prior to the child returning to school. Obviously, this should be reviewed at frequent intervals. Mainstream school and education should be encouraged unless they have specific needs that cannot be met in these environments.

Work

For those on artificial feeding who will hopefully embark on a career when completing education, their chosen pathway may be already influenced based on their health and feeding. Young adults should be encouraged to grow and prosper and venture into the world with confidence; it goes without saying that support networks should be in place throughout their adventure in life.

For an adult patient, depending upon the type of career the patient has, it may be possible to return with minor or no modifications. For some, the prospect of returning to full-time employment or an established career may not be possible; every effort should be made to ensure the patient has an opportunity to consider all options.

In some instances, partners and parents become a carer for the patient—personal careers and ambitions are set aside to support their loved one. While they often do this freely and unconditionally; it frequently leaves people feeling burdened with the routine and responsibility of home artificial nutrition and the medical needs of the patient.

The perception that ambulatory equipment is a given to easier employment is misleading. We need to consider the many 'health and safety' aspects of offices and companies; they will accommodate medical and special needs much more widely nowadays, but these should not be assumed, just like a child at school, they should be discussed and planned. A recent survey by PINNT showed that adult patients on home artificial nutrition reported that their ability to work was moderately to severely affected [11].

Travelling and Holidays

Planning is key—any time away from home on artificial nutrition requires close attention to detail! Where patients are visiting other countries, it's good to try and establish links for added support, even determining if there is any help in terms of fluids, compounding or healthcare, where possible.

Most patients want to travel, if not for themselves then for the benefit of their friends and family, it's something most people take for granted. Often, it's not the distance you travel but the personal journey you take.

Travelling and holidays are enjoyable and fun; for example, it is often during a holiday that the thought of a fun pas-

time such as swimming is considered. Patients will have at least one feeding device. Currently there is no consensus on swimming.

Travel is also necessary in many aspects of life. For patients who have lifelong artificial nutrition, travel does not just mean a 'week in the sun' but may be required in employment and to visit friends and relatives. At times, travel may be required at short notice, such as the sudden illness or death of a member of the family and the perceived barrier to travel, the artificial nutrition can be especially difficult. Ensuring patients and their parents and carers can travel is crucial to quality of life.

Patients travel via various modes of transport, some find packing the car easier and less stressful, others want to fly. Cruising is becoming increasingly popular with patients, especially no-fly cruises. Several destinations can be enjoyed in one trip, there are medical facilities on-board and storage—especially for parenteral nutrition, and it may be easier to arrange.

Due to heightened security around the world, especially in airports, navigating the strict security systems may be worrying for many. It comes back to planning; making all the right pre-travel arrangements and having the right paperwork should ease the stress and aid a swift and safe transition through the airport.

Where patients have a homecare provider, it's useful to find out what help and assistance they provide with arranging travel or a holiday. There are variations in services, it's always good to ask well in advance of travelling. Some homecare companies have a deadline for requests.

The first trip away can be the most daunting. It is best for the patient to start by talking to their usual healthcare professionals to seek advice. Deciding where to go and when are possibly the most important issues to address. If the chosen destination is warm, the patient may need to consider extra fluids to ensure they do not suffer any effects from dehydration. If the patient is staying in their own country access to their usual support networks should be available to them. However, if they elect to go further afield, there are different aspects to consider. While the basic planning will be the same for both enteral and parenteral patients, for those transporting cold-chain parenteral nutrition it may be more complex.

Patients, parents and carers need to take great caution when travelling, make lists, check and re-check, never forget the basic principles that have been learnt, always take safety stock too. Feeding can be done anywhere providing the procedures and safety aspects are maintained.

Support Groups/Patient Associations

The best support for patients, parents and carers in terms of adapting to life and facing the future on home artificial nutrition, is to meet and talk to others in similar positions. Patient groups and associations have been established in many countries, and often it's a case of locating them and providing information to the patients as part of their discharge planning. For many patients a large proportion of their energy is channelled into maintaining an image of expected well-being. It becomes a natural part of being ill to maintain an outwardly positive facade.

Some groups and associations have been established for many years, others are in the early stages of becoming established. Their remits may vary but fundamentally they all provide a vital support network to patients in their own country or locality as well as setting up International networks. Almost all problems experienced by a new patient have been encountered and resolved by a previous patient. It is reassuring to know that there are others in similar situations who can frequently offer support.

Advice and assistance are tailored to the needs of patients, family and carers. Each group will provide the support and advice they know their members need. Many will campaign for products and services that, if available, would enhance the quality of life for the patient.

Via the patient groups network, we can identify that there is a distinct inequity in both services and products for those on home artificial nutrition. Some patients are fighting for basic care and services, while others don't realise the wealth of choice they have available to them.

In the UK, the patient group PINNT, is a core group and founder member of the British Association for Parenteral and Enteral Nutrition (BAPEN); this well-established relationship has been beneficial for all concerned. If we truly believe all aspects of home artificial nutrition should be managed by multi-professional teams then surely the patients and carers should be part of that. We hope to see this model adopted in more countries.

In addition to groups and associations, modern communication methods provide different models of support via social media. Most are very useful and credible, but caution should always be applied when using social media due to its faceless nature.

Conclusions

Home artificial nutrition provides patients with an essential treatment that can be carried out in their own homes. Often these treatments have saved lives and brought individuals back from the depths of illness, but not provided a cure. All age groups, who receive home artificial nutrition, have been through some very challenging times and no doubt will face further difficulties in the years ahead [12].

Feeds and formulations are continually evolving and feeding lines and tubes are improving all the time. These changes contribute to better outcomes for those receiving the treatments, meaning that many patients are thriving on artifi-

cial nutrition. These improvements also mean that the number of adults who have been on artificial nutrition all their life and have a prognosis of lifelong artificial nutrition is growing. This provides new challenges for healthcare, for example, in a patient with parenteral nutrition, this might mean taking a very conservative approach to preserving venous access, given that the patient will need lifelong access. Many patients, parents and carers develop an inner strength and good coping mechanisms. Life presents its ups and downs and they continually endeavour to overcome each of them in their own unique way. Don't ever assume it's easy; it's an emotional rollercoaster.

Homecare is growing, and we would like to see greater equity for all patients who need these life-saving treatments at home. When faced with illness or trauma, they should not be using their energy to fight for the right to live but channel their energy and personal resources into achieving improved health and an acceptable quality of life.

Patients constantly face the problem of projecting a positive and healthy exterior with no visible signs of the pain and suffering they may be experiencing from their underlying condition(s). Artificial nutrition has enabled patients to manage this, along with their lives to an acceptable standard. The permanent links with hospitals and healthcare professionals are accepted as part of their normal life and the patient becomes an active member of any healthcare team. Their continued support in addition to that of the homecare provider, partners, friends and family is essential to maintain the status quo and it is important for them to remember that each patient is an individual who must be treated accordingly.

Everyone should have access to appropriate healthcare and support that treats them holistically rather than as a sum of their parts.

Nutritional Support Services

Simon Lal, Simon Gabe, and Jeremy M.D. Nightingale

Key Points

1. Patients with type 1 (short term) intestinal failure (IF) are managed by a hospital multidisciplinary nutrition support team (NST). By keeping careful data a NST should be able to justify itself in terms of quality of care and cost savings.
2. Patients with type 2 (medium term) IF and those re-admitted to hospital with complications associated with type 3 (long term) IF should be managed by a specialised multidisciplinary team on a dedicated Intestinal Failure/Rehabilitation Unit (IF/IRU) in order to achieve an optimal outcome.
3. Core members of the IF multidisciplinary team (MDT) should include gastroenterologists, IF surgeons, specialist nurses, dietitians, pharmacists, interventional radiologists, microbiologists and psychologists/psychiatrists.
4. A ward dedicated solely to the management of patients with type 2 and 3 IF concentrates clinical expertise and can obtain the lowest central venous catheter-related complication rates, while also promoting patient, family and carer support.
5. IF/IRUs should continuously collect data and undertake quality improvement activity on type 2 and 3 IF outcomes, including mortality, surgical and catheter/metabolic complication rates, unplanned re-admissions, waiting times for admission, length of stay and patient quality of life.
6. IF/IRUs should work to national and international guidelines and audit their outcomes.
7. There should be close working relationships between IF/IRUs and intestinal transplant services with regular MDT meetings to overview patient selection and follow-up.
8. The organisation of hospitals specialising in IF/rehabilitation care in a country can be developed into a formal network to harmonise patient care.

Introduction

There are three types of IF [1, 2]. Type I IF (short term) is a common, short-lived and usually self-limiting condition, occurring in approximately 15% of patients in the perioperative setting after abdominal surgery and comprising the vast majority of all cases of IF on general hospital wards [2]. Indeed, more than 90% of patients requiring PN following surgery do so for less than 30 days [3]. Such patients should be managed by hospital NSTs to ensure appropriateness of PN and minimise their risk of PN-related complications [4].

Types 2 (medium term) and 3 (long-term) IF are rarer and more complex conditions [1, 2]. Type 2 IF is a prolonged acute condition, characterised by metabolic instability, whereby patients require intravenous nutrition for weeks or months [1, 2]. Type 3 IF is a chronic condition occurring in metabolically stable patients who require long term, sometimes lifelong, PN; type 3 IF may be reversible or irreversible [1, 2]. Patients with type 2 IF and those re-admitted to hospital with complications associated with type 3 IF should be managed by specialised MDTs on a dedicated IF/IRU in order to achieve optimal outcomes [5, 6].

Nutrition Support Team

If healthcare staff are not skilled and experienced in giving clinically assisted nutrition and hydration (CANH) serious life threatening complications can occur; with enteral nutrition (EN) aspiration pneumonia and local gastrostomy problems; with PN catheter-related blood stream infection (CRBSI), central vein thrombosis and IF associated liver disease (IFALD).

Many disciplines with different, but essential skills (Table 1), are involved in the safe administration of CANH particularly parenteral support (PS) and these staff need to communicate regularly with each other to give co-ordinated planned care. This is most commonly and effectively done by combining the specialist skills of different disciplines into one NST that works closely together. The composition of a NST team is variable in different hospitals but core members are a clinician, nutrition nurse specialist (NNS), dietitian and pharmacist [7, 8, 11] and they will do a NST inpatient round 2–5 times a week. Gastroenterologists have largely taken on the role of leading an NST because they can achieve access to the gut via endoscopic techniques and they manage patients with intestinal problems. However, some teams are run effectively by a non-gastroenterologist such as a general surgeon, chemical pathologist, anaesthetist or endocrinologist. The most important starting member of a new NST is the NNS who allows safe PN using aseptic techniques [12, 13]. The NNS achieves the administration of safe PN with a low rate of CRBSI initially by personally caring for the central feeding catheters and later by teaching others to put up and take down a PN bag [9]. The techniques used to do this involve strict asepsis (non-touching of key parts) and may be different to the clean techniques used by other disciplines to care for Hickman-type lines. Once PN can be administered safely in a hospital, attention can be directed to the nutritional/fluid requirements with the dietitian and to the composition/compounding of the PN bags with a pharmacist. Thus the traditional NST core membership consists of a clinician, NNS, dietitian and pharmacist though other specialists may be involved particularly when the team works with type 2 and 3 patients (e.g. chemical pathologist, microbiologist, radiologist) (Table 1). A NST improves the quality of patient care largely though education that improves nutritional assessment, appropriate nutrient delivery and reduces mechanical, infective and metabolic complications [9, 14]. The rate of CRBSI should fall to much less than 10/1000 catheter days (ideally nearer to 5/1000 days) after an NST had been formed [13, 15].

Table 1 Members of a nutrition support team [7–10]

Essential member	Roles
Clinician	Overall responsibility, co-ordinated care, may insert enteral and intravenous feeding tubes. Liaises with the patient's primary team. Prescribes the parenteral feeding solution
Nutrition nurse specialist	Teaches and supervises care of tubes and catheters and recognises and manages complications. Places or assists in placement of enteral and parenteral feeding catheters. Acts as the patient's advocate, who also trains patients/carers to manage at home
Dietitian	Nutritional assessment, calculates requirements, designs feeding regimen and monitors nutritional and fluid status. Can also act as a patient advocate
Pharmacist	Responsible for providing enteral feeds and sterile PN nutrition solutions (may include compounding). Optimises composition and advises on compatibility/stability issues and drug/nutrient interactions

NB: the roles may overlap and all are involved in monitoring progress
All the core personnel need cover for all their roles in of case time away (courses, holiday, sickness, etc.)

Other Staff in the Extended NST and Needed for IF/IRUs [10, 16, 17]

Stoma care/tissue viability nurses.
Upper or lower intestinal surgeons (± plastic surgeon).
Social worker.
Physiotherapist.
Occupational therapist.
Psychiatrist/psychologist.
Interventional radiologist.
Microbiologist.
Speech and language therapist.
Other specialists as necessary (e.g. haematologist, urologist, gynaecologist etc).
Community workers (e.g. dietitians and nurses).

Most hospitals in the UK have a NST [18]. While they may be involved with seeing all types of patient needing nutritional support, they are likely to manage many with type 1 IF. Table 2 gives an example of the types of patient referred to the NST for PN.

The overall aim of a multidisciplinary NST team is to provide safe up-to date appropriate nutritional and fluid support to an individual patient, who is malnourished or at risk of

Table 2 Reasons for 117 patients being given PN by an NST in its first year after formation [19]

	n (%)
Short term—type 1	
Ileus	17 (15)
Chemotherapy/GVHD	12 (10)
HIV	4 (3)
Medium term—type 2	
Fistula/anastomotic leak	35 (30)
Small bowel obstruction	28 (24)
Long term—type 3	
High output stoma/short bowel	18 (15)
Other	3 (3)

malnutrition, in a co-ordinated fashion. In many of the patients the care also will involve treating over hydration (usually due to excess intravenous saline) or dehydration (often due to a high output stoma or fistula).

The NST can be "totally responsible (complete autonomy)" in which the team assesses the nutritional and fluid requirements of the patient, established the access for feeding, writes the prescription, monitors progress and manages any complications. It is easier if the team is also responsible for the medical management of the patient but this is not always practical. An alternative way of working is to be "consultative (or supervisory)" and to see patients and advise upon their management. This is more difficult and less efficient as it relies upon good communication with the primary medical team, who need to act upon the advice offered. Often a team will work in a totally responsible way on some wards (e.g. medical gastrointestinal and surgical wards) and in a consultative capacity on others (e.g. ITU, haematology and oncology). At least one member of an NST must see all patients needing PN daily.

The team may perform some procedures itself. Some teams insert all central parenteral lines themselves with or without ultrasound and/or X-ray guidance. Others may insert the peripherally inserted central catheters (PICC) themselves and ask radiologists, surgeons or anaethetists to do other central lines. There is no evidence that the place a central feeding line is inserted relates to the subsequent occurrence of CRBSI providing the insertion is performed using an aseptic technique. Most enteral tubes will be inserted by the gastroenterologists (naso-jejunal (NJ), percutaneous endoscopic gastrostomy (PEG), PEG with a jejunal extension (PEGJ), or percutaneous endoscopic jejunostomy (PEJ)), some will be inserted in a radiology department and others in theatres by surgeons.

An NST needs to establish good links with the local community staff who will care for patients needing enteral feeding. There needs to be clear information/guidelines about the care and contact details if there are problems. When this works well patients will be discharged home more quickly and emergency admissions can be prevented.

The NST is likely to undertake a large educational role both teaching (undergraduates and postgraduates in medicine and nursing, all healthcare workers and many carers/patients) and writing guidelines/policies and setting standards. These are likely to be about nutritional assessment, indications and management of EN and PN. The NNS may teach and establish link nurses on the relevant wards.

The UK NICE guidelines recommend that all hospital trusts have a nutrition steering committee (NSC) to co-ordinate the nutritional care within a hospital and in addition to the NST this includes catering and dietetic services [8] (Fig. 1). In the UK, a freedom of information request in 2017

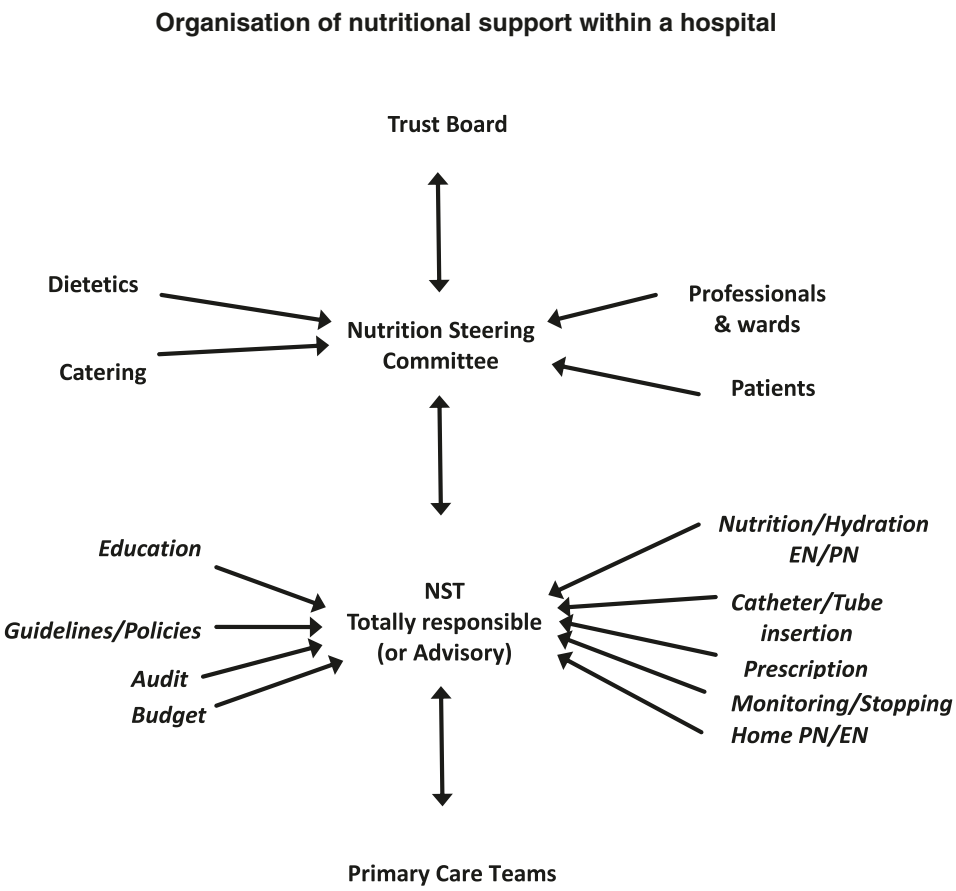

Fig. 1 Organisation of nutritional support within a hospital

showed that 80% of Trusts have a NSC [18]. Core members of the NST are members of and will report to the NSC which oversees their actions and reports directly to the Trust Board (see Fig. 1). Some members of the NST may become involved in the hospital catering.

The Setting Up and the Continuation of a Hospital NST

The process of setting up a team is slow and involves changing the culture of an organisation to one that realises the importance of such a team and questions why it does not have one. This process involves making many presentations to management and healthcare workers. This can be done simply using three questions; where are we now, where do we want to be and how do we get there? In addition a strengths, weaknesses, opportunities and threats analysis may be used (SWOT analysis). In making a business case alternatives need to be proposed and these include doing nothing, having a fully functioning salaried team with backup, or in-between situations (e.g. employing a nutrition support nurse only).

In a hospital with no NST, there is likely to be a problem of unrecognised malnutrition which may be poorly treated with high complication rates and high rates of PS bags being wasted. There may be no or few policies / guidelines and care is likely to be fragmented and uncoordinated. To demonstrate the poor current situation background local data needs to be collected; this may include looking at the prevalence of in-patients who are undernourished or at risk of becoming undernourished and determining how many of these are unrecognised [20] and the staff knowledge of undernutrition and its treatment [21]. The rate of CRS, waiting time for venous access for PN, waiting time for NJ or PEG tube placement, and the number of wasted parenteral feeding bags is relatively easy to obtain. The number of PEGs inserted, their appropriateness and the 30 day mortality rate following placement may also be audited.

The two key steps in setting up a NST are to establish a Nutrition Steering Committee (NSC) which reports directly to the Trust board and to appoint a NNS who can perform and teach the aseptic techniques to safely set up and take down a parenteral feeding bag.

The continuation of the NST at first will depend upon it keeping good audit data. As a minimum it must record details of all patients seen and data about every episode of CRBSI and every other complications of parenteral support (PS) [22]. It should present infection data per 1000 catheter days; percentage of infections is not such a good indicator as it gives no indication of the duration of the feeding before an infection occurred. There should be a clear definition of what a CRBSI is (definite and probable). It may also have data about wasted PN bags, central vein thrombosis and IFALD, and PEGs not inserted and PS not deemed appropriate.

While the employment of a NST involves costs these can be offset by showing quality benefits and cost savings. In terms of PS, the savings come in avoiding giving PS (using EN instead) and in reducing complications especially CRBSI [13]. Additional cost savings can be made by an NST reducing the number of PEGs that are inserted [23] and preventing PN bags from being wasted.

The NST must have plans for backup staff to cover holiday, study leave and sick leave.

Intestinal Failure or Intestinal Rehabilitation?

As described in this book, IF occurs in patients who require nutritional support to survive and there are established types of IF (types 1–3). However, for patients/relatives the feeling that they have a failing organ is not a helpful perception especially if this is a long term or indefinite situation (type 3 IF). Being treated in an IRU by specialists in intestinal rehabilitation implies both hope and specialism. Consequently, some units around the world (England, North America, Columbia and the Middle East) are adopting this terminology that includes rehabilitation (rather than failure) within their names to become an IRU with doctors and other healthcare professionals specialising in the various elements of intestinal rehabilitation. Small changes like this can make a big difference to patients and relatives.

Referral to a Specialised IF/IRU

Specialised units caring for patients with IF are usually called intestinal failure units (IFU). However, the teams offer positive ways of helping patients manage with a life threating condition.

In the U.K., a service specifications outlined referral recommendations for specialised IF care [24] (Table 3). Patients with type 2 IF include those requiring prolonged PN support; the duration of support can vary but, in general, patients needing more than 28 days of PN tend to cross the threshold from having type 1 to 2 IF. However, if the referring team have difficulties managing the patient's medical and/or surgical IF needs prior to 28 days, then earlier referral is appropriate. Intestinal rehabilitation teams should proactively manage patients referred on any waiting list through regular contact with referring teams in order to optimise the patient's condition prior to transfer and to make pre-emptive admission and discharge plans. This may include multidisciplinary contact by a nurse, dietitian and/or physician/surgeon and can involve the use of telemedicine. Any urgent non-IF

Table 3 Referral indications for specialised intestinal rehabilitation care [24]

PN with complications or PN whose duration is causing concern
• More than two episodes of catheter related blood stream infection
• Uncontrolled high output stoma despite standard management
• Central venous thrombosis with associated access problems
• Persistent metabolic complications (e.g. liver or renal dysfunction, diabetes)
• Significant associated psychiatric co-morbidity
IF with intra-abdominal sepsis, fistulation and/or open abdomen
• Recurrent/persistent severe abdominal sepsis
• Complex fistulation requiring surgical reconstruction
• Dehisced abdominal wound or open abdomen needing reconstruction
• High output enterocutaneous fistula despite standard management
• Need for distal limb feeding
• Surgery in a patient with radiation enteritis or inherited connective tissue disorder
• Persistent IF with significant comorbidity
IF occurring in patients requiring intestinal reconstruction
• Surgery for severe intestinal dysmotility
• Intestinal lengthening
Surgical re-appraisal
• Severe intra-abdominal adhesions/potentially hostile abdomen
• IF due to encapsulating peritoneal sclerosis
Establishment on HPN
• Short bowel syndrome
• Uncontrolled high output stoma or fistula
• Severe intestinal dysmotility or mucosal disease leading to malabsorption unable to meet needs via enteral nutrition
• Advanced malignancy with loss of intestinal function

related confounding medical issues should be optimised prior to transfer, where it is safe and appropriate to defer transfer to the IF/IRU. If required, direct transfer to the intensive care may be needed in exceptional circumstances for clinical stabilisation prior to admission to the IF/IRU ward. It is incumbent on the intestinal rehabilitation service to minimise waiting times for transfer where possible; such an approach can mitigate the risk of IF-related morbidity and mortality prior to transfer [25].

IF/IRU Multidisciplinary Team

A broad and experienced MDT (Table 1) is required to manage the complex needs of patients with types 2 and 3 IF. Core clinical members involved in day-to-day patient care include specialist gastroenterologists (with experience in nutrition support), IF surgeons (usually with a colorectal background), specialist nurses, specialist dietitians, specialist pharmacists, interventional radiologists, microbiologists and psychologists/psychiatrists. Patients should be given every opportunity to make informed decisions about their care and treatment, in partnership with their MDT. Subsequent treatment and care should take into account the patients' needs and preferences.

. Depending on the patient's individual requirements, the core MDT may require access to additional specialised services, such as urologists, gynaecologists, pain management teams, plastic surgeons, physiotherapists, clinical biochemists, occupational therapists and social services [1, 5].

Adoption of a cohesive multidisciplinary approach to intestinal rehabilitation care is integral to successful intestinal rehabilitation outcomes. The 'Sepsis-Nutrition-Anatomy-Plan' approach is a tried and tested means to manage the patient with complex IF needs and can form part of the MDT's core standard of care [1, 5].

IFU/IRU Environment

There is a learning curve for the MDT managing patients requiring long term PN, and this affects patient outcomes [26]. Indeed, since then, evidence has confirmed that lack of team experience can have an adverse experience on the survival of patients with type 3 IF [27]. For example, it is clear that the reported incidence of CRBSI rates varies hugely between different centres and that experienced teams with established CVC care protocols achieve the lowest CRBSI rates for both outpatients and inpatients [28, 29]. This was recently further evidence based in a large multinational study of 2194 HPN-dependent patients from 65 centres which demonstrated that the risk of death on HPN and the occurrence of a CVC infection were both negatively associated with the number of patients included in the study by the individual HPN centre; again, the implication of these findings is that centres managing larger cohorts, with therefore likely greater IF experience, can achieve better outcomes [30]. A challenge now is to share best practice between established IFUs and emerging teams in the same and other countries in order to standardise the care delivered so that optimal outcomes can be achieved in all centres.

In the U.K., dedicated IFUs were established in Salford and London in the late 1970s. Both services and the teams' experience have grown over time; the IFUs commenced as small, 4–5 bedded units and have grown to current establishments housing more than 20 beds each. These units have ring-fenced beds within the hospital solely for patients with type 2 or those readmitted with type 3 IF. A clear advantage of such dedicated units includes the ability to concentrate multidisciplinary expertise into one area within the hospital. A key component to day-to-day patient care includes nursing expertise to manage large laparostomy wounds and long term central venous catheters (CVC). Meticulous care is required to achieve wound healing and optimal surgical outcomes, while maintaining a low CVC infection rate, so as not to add to the patient's metabolic

instability with an additional focus of infection. Thus, by concentrating intestinal rehabilitation nursing expertise on one ward within a hospital allows teams to achieve very low in-patient catheter infection rates on such units as compared to patients receiving PN on general hospital wards. While quality improvement measures, including the introduction of a nutrition support team, were shown to reduce the catheter-related infection rates in patients with type 1 IF receiving PN on general hospitals ward to a low level of around 0.7 per 1000 [4], this figure was still greater than 17-fold higher than the 0.04 in-patient catheter-related infection rate reported for patients with type 2 and type 3 IF cared for on a dedicated IFU in the same hospital in Salford [29].

Beyond very tangible clinical outcomes such as catheter infection rates, dedicated IF/IRUs also benefit patients and families by providing an environment for patient-to-patient peer support. Patients can stay in hospital for a number of months, often a significant distance from home and, therefore, appropriate facilities also need to be offered on the IF/IRU to improve patient outcomes and enhance patients' and families' experiences. Access to social areas, overnight accommodation for families and catering facilities help patients and their visitors interact, so promoting the peer support that is fundamental in helping individuals live with chronic and rare conditions. A quiet area or room that allows psychological counselling, along with more specialised facilities such as cold storage for PN and bioelectrical impedance equipment for dietetic assessment, can also help focussed delivery of care by the MDT. In the past, both U.K. units dedicated an area for training patients to administer PN while in-hospital. However, with an increasing service demand and associated pressure on in-patient beds, patients are now trained at home by home care nursing teams with no detriment noted to CRBSI rates [28].

Out-Patient Follow-Up

Patients with type 3 IF require regular review in the outpatient setting by the MDT, not only to ensure safe and tailored delivery of PN support, but also to optimise patient and family psychological wellbeing. Thus, the outpatient MDT largely mirrors that delivering inpatient care, with dietetic and pharmacy review, physician and surgical input, as well as nursing and psychological support. While patients may require regular hospital attendance for physical examination, there has been an increasing desire by patients to avoid long distance travel, such that established IFU MDTs now offer the option of telemedicine (with telephone or video consultations) [31]. Notably, this approach has not only been offered for medical review, but also for dietetic, nursing and psychology review where necessary with positive feedback from patients, particularly through avoiding the need to travel [31]. Following the recent Covid-19 pandemic this has become much easier to perform for both the healthcare staff and patients.

It is also, of course, vital that all intestinal rehabilitation teams offer 24-h access to specialist advice and admission to the dedicated IF/IRU when required. Patient guided self-management using appropriate education material reduces complication rates and anxieties related to HPN complications; both U.K. units have also found that the use of novel personal health records or e-portal systems supports this approach by allowing patients and other hospital teams access to clinical records as well as secure ways of patients interacting with their clinical team while at home [32]. Using these systems patients can ask questions from the team as well as upload images, results or correspondence. In addition, some personal health record systems enable easier communication between different healthcare professionals, especially when transferring information between multiple care providers [33].

As survival improves, an increasing requirement for transition from paediatric to adult centres has been recognised in most countries. Again, considered and early outpatient MDT involvement in these processes is mandatory to manage patient and parent expectation, minimise risk and also, ultimately, achieve autonomy for the patient in managing his/her own long term healthcare needs.

Quality Outcomes

It is the responsibility of all IF/IRUs to collect data on outcomes of type 2 and 3 IF, including mortality, re-fistulation rates, CRBSI rates, CVC thrombosis rates, unplanned re-admissions, waiting times for admission and length of stay. Progressive teams are also encouraged to embrace quality improvement methodology to address any issues that may arise; examples of successes of this approach include practice changes to reduce admission waiting times and in-patient lengths of stay [34], as well as PN wastage [25]. It is now equally incumbent on intestinal rehabilitation teams to evaluate the quality of life of patients with IF. We aim that completion of a needs-based QoL tool that takes patients minutes to complete, will now be routine practice for patients with type 3 IF in the U.K. [35]. While established tools such as the hospital anxiety and depression scale can currently be used for in-patients, a more dedicated patient-reported outcome measure is required for patients with type 2 IF. Ultimately, all recorded clinical and quality of life outcome measures should be part of a national IF registry, allowing continued monitoring of intestinal rehabilitation service provision.

Home HPS Care Providers

In the UK there is a PN framework contract with commercial companies that compound, dispense, and deliver the PS bags. They are responsible for supplying all equipment (fridge, pumps, drip stands, working surface etc) and ancillaries (dressing packs, flushes etc). They have to ensure they meet quality, time, cost and professional standards. In addition, an increasing number of patients have the feed set up and taken down by the companies trained nursing staff.

Intestinal Transplantation

Around the world there are very different approaches to the timing and position of intestinal transplantation in the management of patients with IF. This can relate to the availability and success of HPN and transplant services in different countries and healthcare systems. Both services are costly for any healthcare service and some countries do not offer either service. In countries that offer both long term HPN and intestinal transplantation, there will be established criteria that need to be met for intestinal transplantation (chapter "Intestinal Transplantation").

Unlike heart, lung and kidney transplantation, there is much less awareness of the possibility of intestinal transplantation in the general public, patients and even healthcare workers [36]. The staff working in an IFU/IRU need to be aware of the indications for transplantation and should also be aware of the patient journey undergoing an intestinal transplant in order to start this conversation. At a practical level, this may be easier where an IF/IRU is co-located in the same hospital as an intestinal transplant centre. For IF/IRUs that are not co-located with an intestinal transplant centre, it is important that there are close working relationships with the regional or national transplant service that involves systems for regular MDT meetings to overview patient selection and follow-up.

IF Networks Within and Between Countries

In 2001 a patient survey in the UK by the patient advocacy group PINNT suggested that patients appreciated expert care in specialised centres with high reputations, but found the distances involved in attending these units for routine care, unforeseen problems or emergencies excessive. Patients want care that leads to an improved quality of life. However, in view of the fact that severe IF is a rare condition, there has to be a balance between centralising the expertise required for specialised services and providing more accessible services with potentially less expertise.

Consequently, in 2007 a national review was undertaken by the NHS which resulted in the publication in 2008 of 'A Strategic Framework for Intestinal Failure and Home Parenteral Nutrition Services for Adults in England' [10]. There was significant geographical variation seen in the management and prevalence of both type 2 and type 3 IF. In addition, there was no consistent coding to identify patients with type 2 IF and the costs were high to manage these patients. It was proposed that a network of specialist hospitals differentiated by their skill sets would be best to cater for the population of patients with IF in England. A specialised definition set was also developed which included standards that should be met by the service [24].

Recently, in England a network comprising HPN centres (predominantly care of type 3 IF), Integrated Care (IC) centres (caring for patients with both types 2 and 3 IF) and National Reference Centres has been developed. In 2021 the IC and National Reference Centres were appointed with the HPN centres appointed later in 2021. The whole network (HIFNET—Home parenteral nutrition & Intestinal Failure NETwork) will work to common protocols and standards to help to unify practice across the country to the overall benefit of patients.

This approach to develop a network of units or hospitals within a country by the NHS is unique and we believe that it will help to set a standard globally as well. There is very significant geographical variation in both the prevalence of IF and the management of the condition, which would benefit from harmonisation.

Networks between countries are more difficult to organise but the European Society of Enteral and Parenteral Nutrition (European Society of Clinical Nutrition and Metabolism) (ESPEN) and the American Society for Parenteral and Enteral Nutrition (ASPEN) have been instrumental in helping to facilitate this by developing guidelines for these conditions [5, 6, 37–40]. In addition, ESPEN developed special interest groups in both acute and chronic IF enabling international cooperation, surveys and studies. The BAPEN special interest group (BIFA, the British Intestinal Failure Alliance) has also developed guidance and top tips that have been widely disseminated (www.bapen.org.uk/about-bapen/bapen-special-interest-groups/bifa).

Appendix

Key Education Topics for Members of a NST [41]

1. Understand the role of a hospital nutrition support team (NST) in giving good quality, safe nutritional care.
   - Consists at least of a clinician, nutrition nurse specialist, registered dietitian and pharmacist.
   - Advises and manages the care of patients needing clinically assisted nutrition and hydration.

2. Include nutritional/fluid status into every patient's clinical notes and state where appropriate a nutritional/fluid care plan.

Basic Physiology

3. Understand how appetite/food intake is regulated. This includes neurological, hormonal and psychological mechanisms.
4. Understand the processes of digestion and absorption (for macronutrients, water, minerals and vitamins), including the importance of colonic fermentation. Know the volumes of the gastrointestinal secretions in health. Know the variable length of the 'normal' small intestine.
5. Know how the estimated daily requirements are derived and appreciate that they vary with rest, physical activity, illness and during life.
6. The essential components of a diet are macronutrients (carbohydrate, fat and protein), water, minerals (includes those often referred to as electrolytes (Na, K, Cl, Mg, P) and trace elements (e.g. Se and Zn)) and vitamins. Know the daily requirements for water and key minerals in health and in illness (including post-operatively).
7. Understand how inflammation and specific diseases (including sepsis, trauma, burns and cancer) and their treatments influence nutritional status and needs by affecting:
   - intake, digestion and absorption
   - requirements
   - losses of water and electrolytes (e.g. from the gut or urine)
8. Know the effects of acute and chronic malnutrition on physiological (especially muscle), biochemical, immunological and mental processes.
9. Understand the processes of adaptation (hyperphagia, structural and functional adaptation) that may occur in patients with a short bowel (especially when the colon remains in continuity).

Problems of Malnutrition

10. Be aware of the effect of malnutrition on clinical outcomes (including complications, length of stay and readmission rate) via mechanisms including:
    - muscle strength (thus mobility and respiratory reserve),
    - wound healing and the risk of pressure ulcers
    - resistance to infection

Problems of Under and Over Hydration

11. Dehydration may cause acute and chronic kidney injury and death. Over hydration (especially saline excess in surgical patients) delays recovery, increases mortality, complications and the duration of the hospital admission.

Recognition/Detection of Patients Who Are Malnourished or at Risk of Becoming So

12. Appreciate the methods and importance of formally assessing nutritional status and the limitations of relying on the initial clinical impression alone. The assessments include:
    - Detecting those currently malnourished from the calculation of BMI, percentage weight loss and mid arm muscle circumference. A measure of muscle function (e.g. grip strength or sit up to squat (SUSS) test) may help. Other tools may be used and include subjective global assessment (SGA), malnutrition universal screening tool (MUST) and the global leadership initiative on malnutrition (GLIM).
    - Detecting those at risk of becoming malnourished from the current nutrient intake and the illnesses' predicted course.
13. Recognise intake (oral) failure (inability to get food into the gut) due to poor dentition, poor appetite, head/neck cancer/trauma, neurological disease (e.g. stroke, cerebral palsy, motor neurone disease, multiple sclerosis) and psychological disorders (e.g. dementia, depression and anorexia nervosa).
14. Recognise the symptoms and signs of typical and atypical eating disorders (and other psychological problems) and know how/when to obtain help from eating disorder specialists.
15. Recognise digestive and absorptive (intestinal) failures. Digestive failure is due to gastric or pancreatic disease and absorptive (intestinal) failure due to short gut, intestinal fistula, obstruction, dysfunction or mucosal disease.
16. Identify patients at risk of developing refeeding problems (e.g. low phosphate) when food (especially carbohydrate) is introduced to a malnourished patient. Know the principles to prevent and treat this.

Recognition of Patients Who Are Dehydrated or Overhydrated

17. Recognise the clinical symptoms, signs and observations (e.g. weight, fluid balance, postural blood pressure, urine sodium concentration) of over and under hydration.

Treatment (Nutrition and Fluid)

18. Appreciate that giving nutritional support to malnourished patients improves the quality of life, morbidity and mortality. Some diseases (e.g. COPD, CCF, IBD and

cancer) and surgical procedures have a better outcome if nutritional status is improved or normalised.

19. Know how to calculate fluid requirements (including an intravenous infusion regimen for a patient taking nothing by mouth) and know how to take into account losses (e.g. nasogastric aspirate, small bowel stoma/fistula output). Be able to monitor fluid balance with daily weight and fluid balance charts; and sodium balance with a urinary sodium concentration (especially important in patients' with a small bowel stoma/fistula).
20. Know the indications and goals for nutritional/fluid support. Have knowledge of the routes (oral, enteral and parenteral) of giving nutritional support and the advantages and disadvantages of the different forms of nutrition/fluid support.

Problems of Treatment

21. Have knowledge of the problems that can occur with enteral nutrition (e.g. mal-positioned enteral tube, leakage, blockage or associated diarrhoea) and with parenteral nutrition (e.g. catheter-related blood stream infection, central vein thrombosis/stenosis, intestinal failure associated liver disease and metabolic bone disease).

Ethics

22. Know and understand how to apply the principles of the ethical and legal aspects of providing, withholding or withdrawing nutrition and hydration treatment. This includes autonomy, beneficence, non-maleficence, justice and mental capacity.

Ethical and Legal Aspects of Nutritional Support

Andrew Rochford

Key Points

1. Artificial nutrition and hydration constitute medical treatment.
2. Nutrition support should be considered in people who are malnourished or at risk of malnutrition.
3. The first question should be 'what are we trying to achieve'? If in doubt, a trial of clinically assisted nutrition and hydration with clearly agreed objectives may be appropriate.
4. It is essential to consider the pre-existing wishes of the patient and adhere to the core ethical principles of autonomy, non-maleficence, beneficence and justice.
5. Decisions should be made as a multi-professional team and clearly communicated and documented.

Introduction

The number and proportion of people aged 60 years and older in the world population is increasing. In 2019, the number of people aged 60 years and older was one billion. This number will increase to 1.4 billion by 2030 and 2.1 billion by 2050. This increase is occurring at an unprecedented pace and will accelerate in coming decades, particularly in developing countries [1]. It is important to acknowledge that millions of people globally are malnourished and face food insecurity on a daily basis. This represents its own ethical and social challenge but is beyond the scope of this chapter.

Although life expectancy is rising, healthy life expectancy (i.e., the number of years we can expect to live in good health) is declining with increasing incidence and prevalence of conditions such as cancer and dementia. For example, in the United Kingdom (UK) it has been estimated that 1.3 million people aged over 65 are malnourished or at risk of malnutrition. One third of people in this age group are found to be at risk of malnutrition when they are admitted to hospital, and the same proportion are discovered to be at risk on admittance to a care home [2]. The use of a validated nutrition screening tool such as the Malnutrition Universal Screening Tool ('MUST') is essential to identify nutritional risk and enable action to be taken at the earliest opportunity to reverse or delay the progress of malnutrition. There is also an increasing drive to encourage patients to self-screen with clinically validated tools such as the Patients Association Nutrition Checklist [3].

However, it is not simply ageing that challenges the legal and ethical provision of Clinically Assisted Nutrition and Hydration (CANH). The number of patients living with chronic disease and long-term conditions that compromise their nutritional intake is also increasing. The number of patients on home enteral tube feeding (HETF) is on the increase worldwide due to advances in technology, development of percutaneous endoscopic gastrostomy (PEG) techniques, and the shift in care provisions from acute to community settings. For example, in the UK in 2015 72% of HETF patients registered as part of the British Artificial Nutrition Survey (BANS) were living in their own home [4]. While the significance of home enteral nutrition in meeting the nutritional requirements of patients with poor swallowing reflexes and those with poor nutritional status is not in doubt, differences exist in terms of funding, standards, management approaches and the level of infrastructural development across the world [5].

The provision of CANH often presents an ethical challenge to many clinicians; in the context of changing health and social demographics, this challenge is set to increase. The subject is incredibly emotive for patients, relatives and carers, and staff as the provision of food and water represent the most basic requirements for life.

Ethical Position

Biomedical ethics is underpinned by four main tenets:

1. *Autonomy*—respecting and supporting autonomous decisions
2. *Non-maleficence*—avoiding the causation of harm
3. *Beneficence*—a group of norms pertaining to relieving, lessening, or preventing harm and providing benefits and balancing benefits against risk and costs
4. *Justice*—ensuring fair distribution of benefits, risks and costs [6].

These should not be seen as a set of rules but rather perspectives that should be used to frame and facilitate discussion in order to reach consensus (Fig. 1). Important principles to help guide these discussions are the *sanctity of life* and the preservation of *dignity*. The sanctity of life means that the life of a patient is valuable in itself and does not depend on their social or economic achievements. However, the principle of the sanctity of life does not mean that life should be preserved at all costs. For instance, it need not oppose withdrawal or withholding of treatment in particular cases. Neither does the principle of the sanctity of life mean that a patient's autonomous wish to refuse treatment may be overridden. The preservation of dignity means that, at all times, the patient should be treated with respect [7]. These principles are internationally recognised and underpin all aspects of clinical practice. Furthermore, these principles are interrelated, and this should be taken into account when considering their application.

The principle of autonomy recognises the right and the capacity of a person to make a personal choice. People may refuse support even if the refusal is difficult to understand by others and may change their mind at any time with regard to consent [8]. Autonomy does not mean that a patient has the right to obtain every treatment they wish or request, if this particular treatment would not be medically indicated.

When making decisions about the appropriateness of a medical intervention clinicians must balance the benefits (beneficence) and risks of harm (non-maleficence) from the intervention. It is important to note that potential harm may not only be physical but can also be psychological or involve infringement on a patient's privacy or liberty. In some cases, there will be a conclusion that treatment will not yield or may no longer yield any benefits and/or the risks of harm outweigh the anticipated benefits. In other words, the medical intervention is inappropriate or disproportionate. This situation is described as "therapeutic obstinacy" (or unreasonable obstinacy). In such cases, the clinician may legitimately decide, in their dialogue with the patient, not to implement the treatment or to withdraw it [9].

There is no obvious means of measuring whether medical interventions to provide CANH are disproportionate. Even though there are medical criteria from evidence-based medicine, which can be used to evaluate risks and benefits, whether or not treatment is proportionate will be assessed in the light of the patient's situation as a whole. Clinical decisions are the result of a reconciliation between the will of the patient and the assessment of the situation by a healthcare professional taking into account all the ethical tenets.

Religious and Cultural Context

Eating and drinking are not simply essential for maintaining nutrition and hydration. They are important for pleasure and social interactions – food and mealtimes are a way we connect with others and can often be an expression of our cultural identity.

The provision of oral nutritional support should therefore be the preferred method of choice for any patient with inadequate food and fluid intake to meet requirements, unless they cannot swallow safely, have inadequate gastrointestinal function or if no benefit is anticipated, for example in the last days of end-of-life care [7].

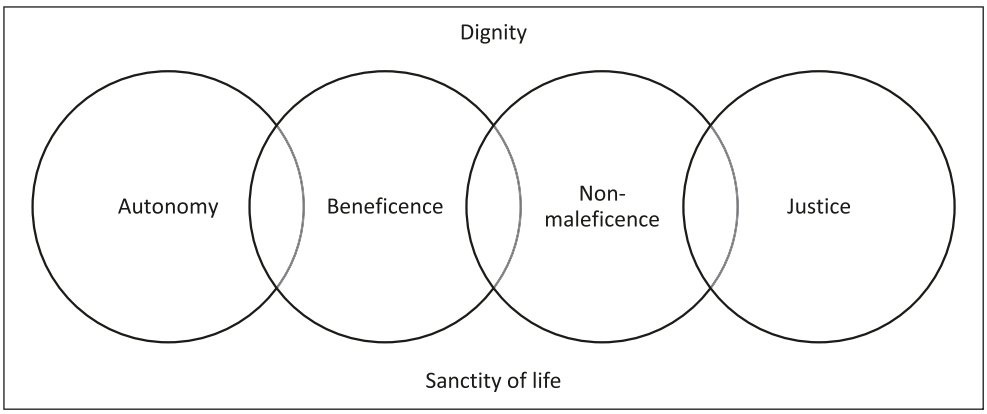

Fig. 1 Ethical considerations for clinical care

Modern society is an amalgam of different religious, ethnic and cultural backgrounds, and beliefs. Attitudes to end-of-life care and the sanctity of life vary widely between different groups. Additionally, medical staff will inevitably judge patients according to their own morals and beliefs. It is beholden on all those involved to respect these views and wherever possible take account of them in a sympathetic and understanding manner [8].

The ethics of refusing or withdrawing nutrition and hydration from sick or dying patients has a substantial history with theological discussions dating back more than 400 years; this suggests that there has always been a significant ethical dilemma to the provision of CANH.

Table 1 Factors encouraging CANH [11]

Party involved	Factors encouraging CANH
Relatives	• Unwillingness to accept terminal prognosis • Belief in cruelty of dying process if ANH not administered • Need to demand interventions to avoid guilt
Clinicians	• Lack of familiarity with palliative care techniques and evidence • Length of time needed to educate families • Desire to avoid controversial decisions • Fears of litigation
Others	• Fear of regulatory sanctions if ANH not provided (nursing homes) • Extra time and staff needed to assist with oral feeding

Legal and Regulatory Position

Generally, in law, the term 'child' is used to refer to people under the age of 18. The law treats a child's consent to treatment differently from a refusal of consent. This is because it assumes that healthcare professionals who propose treatment do so for good reasons [7]. The provision of nutrition and hydration to children and adolescents may differ from adults; in this section we will focus on the legal and regulatory position in adults.

The provision of food and drink by mouth is seen legally as basic care whereas the provision of CANH is considered a medical treatment in many, but not all countries. The competent patient has the right to participate in decision making and to refuse treatment although a doctor is not obliged to give treatment which they consider futile or against the patient's interests. There is often a delicate balance between professional judgement and patients' rights which on occasion has been legally challenged. The ethical principle of autonomy underpins the legal process of consent as it is the patient's consent that makes invasive medical treatment lawful. Clear guidance has been provided by the British Medical Association and the Law Society regarding gaining consent in the UK (see Box 1).

Box 1 Best practice guide for gaining consent [10]

A person should be able to:

- Understand in simple language what the medical treatment (or research intervention) is, its purpose and why it is proposed.
- Understand its principle benefits, risks and alternatives.
- Understand in broad terms what will be the consequences of not receiving the proposed treatment.
- Retain the information for long enough to make an effective decision.
- Make a free choice without pressure.

In the acute setting, the ethical challenges around providing CANH frequently involve patients who lack capacity with increasing pressure for clinicians to prescribe CANH for a number of reasons (see Table 1). However, healthcare professionals should not be tempted to underestimate the patient's capacity to make a decision and should make every attempt to assist this process.

The legal and regulatory position on the provision of CANH varies in different countries and often within different states. It. Is therefore paramount that appropriate advice is sought where there may be doubt or confusion.

Patients Who Lack Capacity

The provision of nutrition and hydration is a basic human right. It is only in circumstances where a person is unable to eat and drink for themselves or adequately maintain their required nutrition and hydration where medical intervention may need to be considered and the principles of biomedical ethics applied.

Someone's capacity may be affected by cognitive impairment which may be permanent (e.g. dementia) or temporary (e.g. delirium), a learning disability, or a mental health problem. There may be other clinical reasons which affect people's capacity, for example sedation or anaesthesia. It is important to recognise therefore that decisions regarding the provision of CANH may need to be assessed over a period of time.

The Mental Capacity Act 2005 (MCA) is a statute in force in England and Wales [11]. It sets out a legal framework for determining mental capacity and making decisions on behalf of people aged 16 and over who lack the capacity to decide for themselves and provides a good reference with which to frame discussion in this section.

The MCA specifies that any act done, or decision made, for a patient who lacks capacity, and does not have a valid

and applicable advance decision to refuse treatment, must be done or made in their best interests. This means that a decision-maker must consider all relevant circumstances, including any wishes, feelings, beliefs and values of the patient. The MCA provides very useful guidance on how to determine capacity (summarised in Box 2).

Box 2 Best Practice Guide for Assessing Capacity

The MCA says that a person has capacity if they are able to:

- Understand the information relevant to the decision.
- Retain that information.
- Use or weigh that information as part of the process of making the decision.
- Communicate their decision (by talking, using sign language or any other means).

The MCA requires that the decision should be that which, objectively, is in the best interests of the patient [12]. Decision-makers must start from the strong presumption that it is in a patient's best interests to receive life-sustaining treatment, but that presumption can be rebutted if there is clear evidence that a patient would not want CANH provided in the circumstances that have arisen.

If the patient does not have capacity and cannot make their own decisions about what to do, then their voice will have to be relayed by others. It is imperative that the collection of information and opinions should be respectful, unhurried and comprehensive, as well as carefully documented. Legally, family members cannot give consent to or refuse treatment on the patient's behalf unless they have been formally appointed as a health and welfare attorney. Although not the decision-maker, they do have a crucial role in providing information about the patient as part of the best interest's assessment [7].

Mental Health

Patients with mental health disorders cannot have treatment imposed on them simply because the treating clinicians think it is medically justified. Patients may have capacity to make some decisions but not others and so the standard of practice around informed consent still applies. Equally, patients with mental health disorders may lack capacity in the same way as anyone else in which case treatment will be deemed legal if it is in the patient's best interest.

Under carefully specified circumstances, CANH may be considered a medical treatment for a mental health disorder. For example, in eating disorders such as Anorexia Nervosa, malnutrition contributes to the psychiatric burden of the illness and in extreme cases CANH may need to be enforced to support treatment of the underlying mental health disorder. However, in all situations the ethical principles of providing CANH should be carefully considered and applied.

Best Interests

In making a best interests decision about giving or continuing life-sustaining treatment, there is always a strong legal presumption that it will be in the patient's best interests to prolong their life. This presumption can be nullified if there is sufficient evidence to suggest that the patient would not want to have the treatment proposed in the given circumstance, the treatment itself would be overly burdensome for the patient, or the treatment would not provide the patient with an acceptable quality of life. However, it is imperative to highlight that these judgements must be made from the patient's perspective and not those of healthcare professionals.

There have been a number of high profile cases relating to CANH (see Table 2) that provide insight into the legal challenges that exist around best interest decisions.

Legal proceedings in England have highlighted that best interests means more than 'best medical interests.' Healthcare professionals making decisions must look at a patient's welfare in the widest sense—not just medical but social and psychological. They must consider the nature of the medical treatment, what it involves and its prospects of success. They must ask what the patient's attitude to the treatment is or would be likely to be; and they must consult others for their view of what his or her attitude would be. [1]

[1] *Aintree University Hospitals NHS Foundation Trust v James* [2013] UKSC 67 at paragraph 39.

Table 2 Examples of high profile court cases relating to CANH

Legal case (country)	Background	Outcome
Tony Bland (England)[a]	Tony Bland was a football supporter who was crushed in the Hillsborough disaster which reduced him to a persistent vegetative state. He had been in this state for three years. His brain stem was still functioning, so technically he was still alive but he was not conscious and had no hope of recovery The hospital with the consent of his parents applied to the courts to discontinue all life-sustaining treatment and medical support measures, including the termination of CANH	The court ruled that there was no duty to treat if treatment was not in the best interests of the patient. Since there was no prospect of the treatment improving the patient's condition the treatment was deemed futile and there was no interest for Tony Bland in continuing the process of artificially feeding him upon which the prolongation of his life depended
Vincent Lambert (France)[b]	Vincent Lambert sustained serious head injuries in a road-traffic accident in 2008, which left him tetraplegic and in a state of complete dependency In 2011 his condition was characterised as minimally conscious and in 2014 as vegetative He received CANH via a gastrostomy In 2012 his carers observed increasing signs of what they believed to be resistance on his part to daily care In early 2013 the medical team initiated a procedure provided for by French law on patients' rights and end-of-life issues (known as the "Leonetti Act"). The patient's wife Rachel Lambert was involved in the procedure, which resulted in a decision by his doctor to withdraw CANH. The courts ruled this as appropriate in April 2013. However, the parents and other family members appealed and won an injunction ordering the hospital to resume CANH In January 2014, there was a further application to discontinue CANH which was upheld but family members appealed to the European Court of Human Rights in Strasbourg	The Grand Chamber of the Strasbourg Court upheld the right of to die with dignity by ruling that there would be no violation of Article 2 (right to life) of the European Convention on Human Rights if artificial nutrition and hydration were to be withdrawn from a patient in a persistent vegetative state
Terri Schiavo (USA)[c]	At the age of 26 Terri Schiavo had an out of hospital cardiac arrest and suffered a hypoxic brain injury. After almost three months without recovery, she was declared to be in a permanent vegetative state. Her clinical condition remained unchanged despite intensive rehabilitation effort over the next two years Schiavo's husband and legal guardian argued that Schiavo would not have wanted prolonged artificial life support without the prospect of recovery, and in 1998 elected to remove the gastrostomy tube. Schiavo's parents disputed her husband's assertions and challenged Schiavo's medical diagnosis, arguing in favour of continuing CANH There then followed a prolonged series of legal challenges presented by her parents, which ultimately involved state and federal politicians up to the level of President George W. Bush After a a seven-year (1998 to 2005) period Schiavo's gastrostomy tube was finally removed	The "Terri Schiavo case" actually refers to a series of cases. Fundamentally, the case involved a dispute between family members over what the patient's wishes would have been for such a situation The Schiavo case involved 14 appeals and numerous motions, petitions, and hearings in the Florida courts; five suits in federal district court; extensive political intervention at the levels of the Florida state legislature, Governor Jeb Bush, the U.S. Congress, and President George W. Bush; and four judicial reviews in the Supreme Court of the United States

The MCA has outlined a helpful checklist (see Box 3) that can be used to help decision making when determining best interests.

Box 3 A Proposed Checklist for Determining Best Interests [13]

- Do not discriminate or make assumptions on the basis of the person's age, appearance, condition or behaviour
- Consider whether the person will at some time regain capacity, and if this is likely, whether the decision could be postponed
- Encourage participation by doing whatever is possible to permit or encourage the person to take part
- Cannot be motivated by a desire to bring about the person's death where the decision relates to life-sustaining treatment
- Consider all the relevant circumstances by trying to identify the things the person lacking capacity would take into account if they were making the decision themselves
- Find out the person's views, including their past and present wishes and feelings, and any beliefs or values that might influence their decision if they had capacity. This should include consulting family, carers and anyone granted a lasting power of attorney.

Advance Decisions

An advance decision is a decision by a person to refuse particular medical treatments at a time in the future when they may be unable to make such a decision. It is sometimes referred to as a living will or advance directive. It might say, for example, that an individual would not want to be given CANH if they were ever in a permanent vegetative state.

An advance decision is legally binding in English law and can be applied to adults who wish to refuse life-sustaining treatment. It is therefore considered a surrogate for the patient's autonomy should they not be able to express their own wish. An advance decision only applies where it is in writing, witnessed, and verified by a statement by the person to the effect that it is to apply to that treatment even if life is at risk [7]. However, even if not all the legal criteria are followed, an advanced decision can be considered as an expression of a patient's feelings and should be taken into consideration when making best interest decisions.

In England the MCA recognises that some patients may also have appointed a Lasting Power of Attorney, who can make decisions relating to personal health, financial and property matters when the patient becomes incapacitated. If the patient has no relatives and lacks capacity, consideration should be given to appointing an Independent Mental Capacity Advocate, particularly if Deprivation of Liberty Safeguards are being considered [13].

Oral Feeding Dilemmas

If possible, the provision of adequate food and water taken by mouth should be the aim for all patients. When considering the provision of CANH the first question should be 'what are we trying to achieve?' If there is any doubt it is recommended that a trial of treatment is provided. A good example would be in the case of an acute stroke where the prognosis may be uncertain in the short term; however, without the provision of CANH the recovery and outcomes would be poorer. In contrast, for patients in an advanced stage of a progressive neurological disease such as Alzheimer's dementia it has been shown that tube feeding does not prolong life and causes more complications than benefits.

For many patients maintaining independence with eating and drinking for as long as possible remains important; and mealtimes continue to provide a key opportunity for social interaction and enjoyment as well as nutritional intake. Unintentional weight loss in the frail elderly is associated with higher rates of mortality, institutionalisation, adverse health outcomes, decline in functional status, and overall poorer quality of life. A careful weight history is therefore paramount when considering the provision of CANH. The mechanisms of weight loss are multi-factorial, but the prevalence of malnutrition often increases with disease progression; for example, in the later stages of dementia more than two thirds of all those living with dementia are likely to be at risk of malnutrition [14]. There is evidence that meal-time adaptations such as providing assistance and an appropriate environment for eating can slow the rate of unintentional weight loss, however, as disease progresses it is unlikely that malnutrition can be reversed and simply slowing nutritional deterioration through adapted oral intake should be seen as a positive outcome.

Many patients with oral feeding difficulties have communication or cognitive disabilities which affect understanding, retention and processing of verbal and written information and communication of needs. It is therefore imperative that appropriate measures have been taken to enable participation in discussions and decision making around long term nutrition and hydration. Ideally, discussions and decisions about the provision of CANH for patients with progressive conditions should be made in advance of the point of clinical deterioration where CANH is being considered. It is recommended that decisions to provide CANH should be reviewed every

6 months (or every 12 months where the patient has been in a stable condition over a long period of time) and more often if the clinical situation has changed significantly [7].

The term 'feeding at risk' or 'risk-feeding' is currently used to refer to oral feeding when people continue to eat and drink despite a perceived risk of aspiration. This approach is appropriate for patients unsuitable for tube feeding who have an unsafe swallow that is unlikely to improve and is often seen as a strategy that affords comfort, dignity and autonomy for patients [15].

Many patients will require assistance to eat and drink. The majority of carers prepare all the meals for the person that they care for and 60% of carers express worry about the nutrition of the person they support [16]. Carers may need training and support to ensure that they are using the correct techniques and are complying with guidance regarding preparation of consistency and the modification of food and fluid. If an individual is 'feeding at risk' then this decision needs to be documented with clear guidance for carers and healthcare professionals on how to assist the person with eating and drinking.

Enteral Nutrition

All clinicians have a morale and professional duty to monitor and review the nutrition and hydration needs of their patients. For example, in the UK the General Medical Council states:

> *Malnutrition and dehydration can be both a cause and consequence of ill health, so maintaining a healthy level of nutrition and hydration can help to prevent or treat illness and symptoms and improve treatment outcomes for patients. You must keep the nutrition and hydration status of your patients under review….. If you are concerned that a patient is not receiving adequate nutrition or hydration by mouth, even with support, you must carry out an assessment of their condition and their individual requirements. You must assess their needs for nutrition and hydration separately and consider what forms of clinically assisted nutrition or hydration may be required to meet their needs* [17].

When patients fail to meet or maintain their nutrition and hydration needs orally other routes of administration should be considered. Enteral nutrition is commonly provided temporarily via Nasogastric tubes (NGT) and over a longer period via gastrostomy tubes placed either endoscopically (PEG) or radiologically (RIG). The placement of a gastrostomy tube has recognised risks of mortality and morbidity but there is a lack of high quality clinical evidence in the benefit of gastrostomy feeding in certain population groups. A Cochrane Systematic Review of PEG versus NGT feeding demonstrated no significant difference in mortality rates between the two groups. Furthermore, there was no significant difference between risk of aspiration although there was a lower risk of reflux oesophagitis in patients with a PEG. There was also no significant difference in outcomes relating quality of life, patient satisfaction, inconvenience of maintaining the intervention by nurses, and functional ability [18].

Decision making in these circumstances is often complex and involves many steps; decisions may evolve as the patient's condition changes requiring re-referral and re-assessment. It is often appropriate to seek a second opinion from members of the nutrition support team regarding the most appropriate long-term course of action.

It is important that clinicians consider all the ethical perspectives outlined in Fig. 1 for each individual patient. There may well be conflicting views held within the multi-professional team as well as between patients, relatives and care givers. Particular care needs to be taken for patients with functional gastrointestinal disorders where additional psychological and/or psychiatric evaluation may be required to explore the principles of non-maleficence and beneficence in more detail. Similarly care should be taken for patients with learning disabilities. It has been estimated that approximately 36% of patients with learning disabilities in the UK living in community settings have swallowing difficulties [19]. In many countries it is illegal to discriminate against patients with learning disabilities on the basis of that disability. It would also be considered ethically inappropriate to insert a gastrostomy tube for the convenience of the caregiver. Where there is doubt about clinical outcome and/or long-term nutrition and hydration requirements a trial period of feeding via NGT is recommended.

When tube feeding is continued outside hospital there is an ethical duty to ensure that the patient, carergivers and the community health team are adequately instructed in the technique and possible complications.

Parenteral Nutrition

Home parenteral support (HPS) is arguably more accessible than ever before. For example, the National Framework Agreement for Home Parenteral Nutrition in England allows suitable patients to be discharged within 5 working days once they are stable on their HPS regime; acknowledging that gaining clinical stability may take several weeks in hospital. Over the last 5 years there has been a greater than 200% increase in new HPS patients. In 2015, the major underlying diagnosis for new patients with 'gastrointestinal obstruction' treated with HPS was malignancy (69%) [20].

For most patients requiring HPS the ethical considerations are identical to other forms of clinical nutrition support and the decision making process should be similarly robust. Although it should be highlighted that HPS is an expensive healthcare intervention, and its provision may place a significant economic burden on healthcare services

where resources are limited. This does, therefore, raise a question surrounding the ethical position of justice and resource allocation in such cases.

It is generally accepted that the significant risks and burdens of HPS outweigh the benefits in patients who have an expected survival of less than 2 months. However, it is often extremely difficult to predict the length of survival and quality of life for patients being considered for HPS and there may be palliative benefits in providing HPS to patients with a shorter prognosis but with a good performance status. It is therefore paramount that informed decisions are made regarding prognosis and performance status. It is recommended that a recognised measure such as the Eastern Cooperative Oncology Group (ECOG)/World Health Organisation (WHO) performance status is used.

Feeding at the End of Life

There is limited evidence for recommendations regarding nutrition in end-of-life care due to the challenges in undertaking intervention studies in this population. However, in the terminal phase of illness the inability or unwillingness to eat often creates significant anxieties for relatives and carers. It is important for healthcare professionals to support understanding that both the social significance of eating and the atmosphere created around eating may be more important at the end of life than the nutritional content of the food itself [21].

In the dying phase, a patient's desire for food and drink lessens. Good mouth care rather than attempting to feed a patient becomes a more appropriate intervention. It is important at this stage to consider the appropriateness of continuing either enteral or parenteral nutrition and attention to patient comfort and dignity should take precedence. The discontinuation of intravenous fluids must also be considered, as at this late stage it may only serve to exacerbate pulmonary oedema, peripheral oedema and increase secretions, which the semi-conscious patient is unable to manage. Clear reasons should be identified and recorded for withdrawal of nutrition and hydration and good communication between healthcare staff, relatives and carers is essential.

In end-of-life situations, the assessment of "overall benefit" plays a particularly important role in determining the suitability of a treatment whose purpose may change (shifting from a curative to a palliative purpose for example). In these situations, the prolonging of life must not in itself be the sole aim of medical practice, which should attempt just as much to relieve suffering. The difficulty of any medical decision at the end of life is to ensure that the patient's autonomy and dignity are respected and that a balance is struck between the protection of life and the person's right to be relieved of suffering if possible [22].

Withholding and Withdrawing Treatment

People with preserved cognitive function who are unable to eat or drink must be involved in decision making (with all the necessary support). Their perception of the process resulting from absence of food will be different from those with impaired cognitive function. It is commonly believed that death from lack of nutrition or hydration is distressing or painful for the patient. This may be true for some, especially those with better cognitive function. However, appetite is often severely reduced in terminal disease and the sensations of hunger and thirst are suppressed. For those who are severely cognitively impaired, there is little evidence that hunger or thirst are perceived significantly. Indeed, patients may resist efforts by carers to offer food or fluids. These rejections may be no more than reflex responses. The dilemma of whether to 'force feed' such patients by mouth or with clinical assistance then arises [7].

In England the law regards withholding and withdrawing treatment as the same. There is no requirement for decisions to withdraw CANH to be approved by the court, as long as there is agreement upon what is in the best interests of the patient, the provisions of the Mental Capacity Act 2005 have been followed, and the relevant professional guidance has been observed [23]. There are, however, certain situations e.g. persistent vegetative state or when there is conflict between professional judgement and the wishes of legal guardian or family, when the courts need to be involved before any action is taken (see Table 2 for some examples).

There is legal guidance that can be helpful in supporting decision making about the provision of CANH in patients who are not imminently dying (see Box 4).

Box 4 Suggested Questions to Support Decision Making Regarding the Provision of CANH [24]

- What is his/her current condition?
- What is the quality of his/her life at present (from his or her perspective)?
- What is his/her awareness of the world around him/her?
- Is there any (or any significant) enjoyment in his/her life? If so, how can this be maximised?
- Does he/she experience pain and/or distress and if so, is it appropriately managed?
- What is his/her prognosis, if CANH were to be continued?
- Is there any real prospect of recovery of any functions or improvement to a quality of life that he/she would value?
- What is the prognosis if CANH were to be discontinued?
- What end-of-life care would be provided?

The General Medical Council's guidance states that a second clinical opinion should be sought where it is proposed, in the patient's best interests, to stop or not start CANH and the patient is not within hours or days of death [25]. There is sufficient evidence that the provision of parenteral nutrition is best provided by specialist nutrition teams and there is some evidence that the provision of enteral tube feeding support has less complications and better outcomes if managed through a specialist nutrition team. It is therefore appropriate that the opinion of nutrition support teams may be sought to assist in decision making around the provision of CANH.

It is important to highlight that in some countries CANH does not constitute treatment but is considered a form of care meeting the patient's basic needs, which cannot be withdrawn unless the patient, in the terminal phase of an end-of-life situation, has expressed a wish to that effect.

Multi-Professional Working and Best Practice

Communication and decision making surrounding CANH often takes time and requires considerable skill. A multi-professional approach is essential but within a multi-professional team there may well be differing moral, ethical, religious and cultural opinions and beliefs. A study of the dynamic challenges facing a multi-professional team discussing the provision of CANH has shown that decision making is not a singular decision but frequently involves many steps with the potential for anonymity of decision-making to emerge [26]. Decisions are rarely made in a single meeting and are constantly evaluated in different settings and clinical situations. Decisions are frequently made across at least four inter-dependent axes (as shown in Fig. 2).

The Royal College of Physicians (RCP) has published guidance to support conversations for ethically complex care [27]. The College recommends six guiding principles for ethical decision making which are:

- Respect for patients
- Duty of care
- Equity of care
- Accountability and transparency
- Inclusivity
- Reasonableness

Furthermore, the guidance recommends a stepwise, question-based approach to ethical decision making that is founded on the work of Jonsen, Siegler and Winslade [28] (shown in Fig. 3).

For more complex situations, the RCP recommends using the Ethical Care Decision-Making Record (ECDMR) which is available to download at https://www.rcplondon.ac.uk/projects/outputs/conversations-ethically-complex-care. This provides an excellent framework that will ensure robust and appropriate documentation of the decisions made.

Fig. 2 An illustrative model of the decision-making axes upon which clinical information can be weighted to make decisions [26]

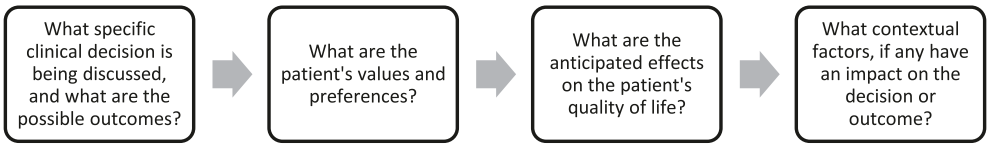

Fig. 3 A four-question approach to facilitate and support conversations for ethically complex care

Conclusions and Recommendations

In many countries CANH is regarded in law as medical treatment and should therefore be considered in the same way as any other medical intervention. The application of the principles of biomedical ethics is paramount. Patients, relatives and carers cannot demand treatment, but patients can refuse treatment. For patients who lack capacity there is clear guidance for healthcare professionals to support best interest decision making. There is a lack of high-quality clinical evidence, but it is recommended that decisions are made on a case-by-case basis involving a multi-professional team with experience of providing CANH. As patients approach the end-of-life priority should be given to supporting quality of life over and above nutritional intake and may involve supporting patients, relatives and carers to 'feed at risk' in preference to the provision of CANH.

Part VII

Problems of Treatment

Enteral Nutrition

Timothy Bowling

Key Points

1. Enteral nutrition is most commonly given to patients with "intake (oral) failure" (inability to get food into the gut) due to poor dentition, poor appetite, head/neck cancer/trauma, neurological disease (e.g. stroke, cerebral palsy, motor neurone disease, multiple sclerosis) and psychological disorders (e.g. dementia, depression and anorexia nervosa).
2. Enteral tubes are used for patients with inadequate or unsafe oral intake, and a functional, accessible gastrointestinal tract.
3. Complications of enteral tube feeding may be mechanical (tube insertion, the tube blockage/displacement etc), feed delivery, metabolic/biochemical or gastrointestinal related.
4. The risk of aspiration of the feed from an enteral feeding tube may be reduced by elevating the head of the bed to 30° or more, feeding for less than 24 h a day, using a lower osmolality feed and considering a tube with its tip beyond the duodeno-jejunal flexure.
5. There is always a risk of a naso-gastric feeding tube being inserted inadvertently into the lung. In patients with reduced conscious level or reduced oro-pharyngeal sensation a post procedure chest X-ray may be done in addition to testing the pH of aspirate.
6. Diarrhoea with enteral tube feeding is most commonly due to medication (especially anti-biotics).

Introduction

Undernutrition is common in the hospitalized patient, as has been described elsewhere. When a patient is unable to meet their nutritional requirements by oral intake with or without oral nutritional supplements, enteral feeding will be required, providing there is a functioning and accessible gastrointestinal tract. The management should be by a multi-professional nutrition team, including (as a minimum) a doctor, dietitian and nutrition nurse specialist. Indications for enteral tube feeding are listed in Table 1. Access to the gastrointestinal tract can either be via a nasogastric or nasojejunal tube or by an enterostomy. This chapter will mention the routes and feed delivery; but mainly deals with the complications of enteral feeding.

Table 1 Indication for enteral feeding

Patients with a functioning stomach and/or intestine
• Impaired swallow, e.g. stroke, motor neurone disease, Parkinson's disease
• Altered level of consciousness, making oral feeding impossible
• Ventilated patients
• Dysphagia with oro-pharyngeal/oesophageal obstruction, i.e. head and neck and oesophageal cancer
• Gastric outlet obstruction: Mechanical (tumour, pyloric stricture) or functional (stasis). These situations will require jejunal feeding (see below)
• Severe pancreatitis (gastric or jejunal)
Supplement inadequate oral intake
• Cystic fibrosis
• Hyper-catabolic states, e.g. burn injury, decompensated liver disease
• Facial injury
• HIV wasting
• Psychological/psychiatric reasons, e.g. anorexia nervosa

Routes for Enteral Feeding

The following options are available:

1. Nasogastric tube (NGT)
2. Nasojejunal tube (NJT)
3. Gastrostomy
   (a) Percutaneous Endoscopic Gastrostomy (PEG)
   (b) Radiological Inserted Gastrostomy (RIG)
   (c) Surgical
4. Jejunostomy
   (a) Endoscopic (PEJ or PEGJ)
   (b) Radiological (RIGJ)
   (c) Surgical

Nasogastric Tubes

NGT are recommended for those requiring tube feeding for no longer than 4–6 weeks. They are safe, cost effective and less invasive than alternatives. There are two types of NGT: Fine bore tubes designed for administration of feed; and wide bore tubes (e.g. Ryles) designed for aspiration. The latter can cause oesophageal damage, such as ulceration and stricture, if left in for a prolonged period, and should not normally be used for feeding. Fine bore tubes are usually easy to insert and safe, even in patients with oesophageal varices. They should not be inserted in patients with obstructive pathology in the nasopharynx or oesophagus, or in patients with basal skull fractures.

NHS Improvement issued guidance in 2016 for safe placement and position checking of nasogastric tubes [1]. The guidance highlighted the unreliability of certain tests—such as the "whoosh" test and testing for acidity with litmus paper - and instead recommended testing with pH indicator paper as the first line check (pH $\leq$ 5.5). Higher pH suggests either the position could be wrong, i.e. in the respiratory tract, or the patient could be on acid suppressing therapies, such as a proton pump inhibitor. It recommended checking X-ray images as the second line test, although not for routine use. The single greatest cause of harm resulted from misinterpretation of X-ray images. The National Patient Safety Agency (NPSA) issued a safety alert in March 2011 focusing on safe interpretation of X-ray images [2]. Tube placements should be checked at least once daily and before administering each feed or medication. However, there has to be an element of pragmatism in this. Provided that the initial placement was appropriately confirmed and no other signs of dislodgement (such as retching or coughing) are present, repeat radiography would not usually be needed as long as the external length of tube remains unchanged [3].

Nasojejunal Tubes

These are most commonly placed endoscopically. However, specifically designed self-propelling nasojejunal tubes will spontaneously cross the pylorus in 70–80% of patients with normal gastroduodenal motility, especially with a concurrent intravenous bolus of metoclopramide [4]. If the stomach is atonic, nasojejunal tubes usually require endoscopic placement. The distal end must be placed beyond the duodenojejunal flexure or it will invariably pass retrogradely back into the stomach. There are other systems that can facilitate transpyloric passage, for example an electromagnetic device on the end of the tube can be tracked by a bedside imaging system to help ensure correct placement [5]. Plain abdominal X-ray is required to verify placement, unless placed under screening. NJT come as single, double or triple lumen. Double or triple lumen tubes are recommended for patients who require simultaneous gastric decompression and small bowel feeding.

Gastrostomy

A gastrostomy is usually preferred if tube feeding is likely to be required for greater than 4–6 weeks. It can be placed endoscopically (PEG); radiologically (RIG); or occasionally surgically. There are a number of different types of PEG/RIG tubes in terms of size (9 FG–30 FG); internal fixator (flange, balloon) and material, including more cosmetically acceptable "button" gastrostomies. If the anatomy prevents insertion by one method then other methods will often be limited by the same problem.

PEG insertion is usually straightforward. Although not a sterile procedure, antibiotic prophylaxis 30 min prior to the procedure is recommended [6]. Table 2 lists the contraindications to PEG insertion. It should be noted that many of

Table 2 Contraindications to PEG insertion

Absolute	Relative
• Inability to pass endoscope due to obstructing pathology in oro-pharynx or oesophagus[a] • Obstructing gastric outflow pathology • Significant ascites • Gastric varices	• Severe obesity (due to technical difficulties accessing the stomach)[a] • Uncorrected coagulopathy • Portal hypertension/ascites • Active gastric ulceration/malignancy • Gastroparesis • Gastrectomy (total or partial)[a] • Severe kyphoscoliosis (may be difficult to access stomach)[a] • Impaired respiratory reserve, e.g. motor neurone disease • Current peritoneal dialysis

[a]May be achievable if done under radiological guidance to locate stomach

the "relative contraindications" to endoscopic placement can be overcome if insertion is done under radiological guidance.

PEG's and RIG's can be easily taken out, but care is required. If removed within 2–3 weeks of insertion a formal tract may not have formed, with consequent risk of spillage of gastric contents into the peritoneal cavity leading to peritonitis. This also means that it is not possible to re-insert a feeding tube down the same track, as it will not find its way into the gastric lumen. Therefore if the PEG/RIG does come out in the first few weeks of insertion the stoma site should be covered, antibiotic cover instituted and, if nutritional support is still required, an alternative, e.g. NGT, used until the wound has healed. After 2–3 weeks removal presents little risk of peritonitis or sepsis. However, closure is rapid, so if replacement is required this must be done within 4–6 h using a fresh PEG/RIG or, temporarily, a balloon gastrostomy or Foley catheter. Elective removal is usually undertaken endoscopically. Alternatively, the tube can be cut close to the skin allowing the internal fixator to pass spontaneously through the gastrointestinal tract. There are a few reported incidents of obstruction, e.g. at the ileocaecal junction, and therefore some experts are wary of this method of removal [7]. This should not be undertaken if there is known small intestinal pathology, such as strictures.

Jejunostomy

Percutaneous endoscopic gastrojejunostomy (PEGJ) are "extensions" that attach to a PEG and can be passed endoscopically beyond the duodeno-jejunal flexure. PEJ is similar to PEG but requires a direct puncture into the small intestine. Insertion techniques are not straightforward, but in expert hands successful placement can be achieved in 70–80% [8]. For most hospitals, where such expertise may not be available, and where post-pyloric feeding is required, a surgically-placed jejunostomy for post-pyloric feeding is often preferred, except in a patient too unfit for a general anaesthetic.

Removal of PEGJ/PEJ's have similar cautions as those described for PEGs.

Surgical jejunostomies are most commonly needle catheter jejunostomies inserted subserosally to reduce the risk of leakage, but tend to be fine bore, and prone to block if poorly managed. Other tubes such as Foley catheters can be used but are not recommended because of leakage and difficulties in connecting with feeding equipment. Increasingly, jejunostomies are inserted per-operatively to allow for early post-operative feeding, especially in those whose nutritional status is sub-optimal at the time of surgery. Although complications can occur, the advantages of improved post-operative nutrition usually out-weigh the risks [9].

Delivery of Enteral Feed

Feed can be administered as a bolus or continuously. Continuous feeding is usually over 16–18 h; bolus feeds are typically 100-500mls of feed over 15–60 min at 3–6 h intervals. Bolus feeding into the stomach is more physiological. Although there is a perception that it predisposes to aspiration, diarrhoea, bloating and dumping syndrome compared to continuous feeding, there is no clinical evidence to indicate that this is the case. With jejunal feeding, the loss of the stomach reservoir means patients with post pyloric tubes should be fed continuously. Further detail on delivery and formulation of enteral feeds is dealt with elsewhere.

Complications of Enteral Feeding

Complications of enteral feeding can be divided into mechanical, ie related to the tube; gastrointestinal, ie related to the delivery of the feed; and biochemical/metabolic, ie related to the content of the feed. Table 3 lists these.

Mechanical Complications

Naso-Enteric Feeding Tubes

Inadvertent Removal

The most commonly encountered problem with NGT is inadvertent removal, either by the patient or by accident, e.g. snagged on clothing, vomiting. If this is a recurring problem and feeding is still required, either a PEG can be considered

Table 3 Complications of enteral tube feeding

Mechanical	Insertion	Nasoenteral—nasal damage, intra-cranial insertion, pharyngeal/oesophageal pouch perforation, bronchial placement
		Enterostomy—bleeding, pain, peritonitis, pneumoperitoneum, intestinal/colonic perforation, gastrocolic fistula
	Post-insertion	Nasoenteral—tube displacement/removal, blockage, bronchial administration of feed, erosions, strictures Enterostomy—stoma infection, blockage, displacement, leakage, over-granulation, buried bumper
Feed delivery	Gastrointestinal	Nausea, fullness, diarrhoea, constipation
	Pulmonary	Aspiration, pneumonia
Metabolic		Refeeding syndrome, hyperglycaemia, fluid overload, electrolyte disturbance

or a "nasal loop" or bridle can be attached, thereby making accidental removal far less likely—18% for bridled tubes compared to 63% for non-bridled tubes in one study—with the bridled group more likely to meet their recommended nutritional requirements [10]. Bridle systems are commercially available and although their unit cost is relatively high, this is more than offset by the avoidance of repeated NGT placements +/− X-rays to verify placement.

Tube Blockage

Tube blockage may occur if crushed medication is inserted into fine-bore tubes, if the tube is not flushed adequately, or if there is precipitation of protein in the enteral feed. Precipitation of enteral feed occurs because the iso-electric point of protein is between pH 4.5 and 5.3, and at this pH, protein precipitates causing tube blockage [11]. Many elixir medications have a pH of 5 or less [12] and thus may cause protein precipitation and tube blockage.

To prevent tube blockage a feeding tube should be flushed with sterile or boiled water at least before and after a feed or medication. Obstructed tubes may be unblocked with water, a variety of solutions including fizzy drinks, pineapple or cranberry juice, alcohol or powdered pancreatic enzymes. If enteric-coated pancreatic enzymes are used they need to be dissolved in a sodium bicarbonate solution before being administered (e.g. the contents of one Creon® capsule can be dissolved in 10 ml of 8.4% sodium bicarbonate).

Malposition

Malposition of a naso-enteric feeding tube, especially when inserted blind, occurs in about 2% of insertions. When placed into the airways, with subsequent intrapulmonary infusion of an enteral diet, this can be fatal if not recognized. Intracranial placement has also been reported. Other complications arising from tube malposition include pneumothorax, intrapleural infusion of enteral diet and oesophageal perforation [13].

Localised Trauma

Physical complications of naso-enteric tubes may be due to the size, material and pliability of the tube used. Polyurethane naso-enteric feeding tubes are preferable to polyvinylchloride naso-enteric feeding tubes, as they are softer, less traumatic and easier to aspirate the gastric contents. Intubation with a naso-enteric tube can cause discomfort for patients, and depends to some extent on the type and size of tube used. In general, the larger the tube the greater the discomfort [14].

Although many problems are less common with the softer, more flexible fine-bore tubes, complications due to the physical presence of the feeding tube can occur. Nasopharyngeal discomfort persisting after intubation may be due to reduced saliva production, due to mouth breathing and absence of chewing. Patients can develop a sore mouth, difficulty with swallowing, and a sensation of thirst and dry mucous membranes. Simple measures such as mouthwashes, sucking ice cubes or using artificial saliva may help alleviate discomfort. Nasal erosions and occasionally an abscess can occur from pressure of the naso-enteric tube on the nasal alae. If the sinus tracts or Eustachian tubes are blocked by the naso-enteric tube, acute sinusitis or secondary otitis media infection respectively may occur. The mucous membranes of the larynx can be irritated causing hoarseness. Excessive pressure against the oesophageal wall may cause ulceration with subsequent stenosis. The risk of oesophageal ulceration is increased in the presence of severe gastro-oesophageal reflux and oesophagitis. Fine bore tubes do not appear to jeopardise the integrity of oesophageal varices. However, large bore tubes should be avoided where varices are known to exist. Rarely, tracheo-oesophageal fistula may develop with large-bore naso-enteric tubes as a result of pressure necrosis of the oesophagus and trachea.

Enterostomy Feeding Tubes

Complications can arise from the insertion procedure itself or related to the enterostomy. A more detailed review can be found elsewhere [15].

Insertion Related Complications

- Complications of endoscopy, such as cardiopulmonary compromise resulting from sedation, hypoxia, arrhythmias and hypotension; upper gastrointestinal haemorrhage and oesophageal perforation all have similar rates of occurrence as with other diagnostic and therapeutic endoscopies. The risk of pulmonary aspiration and subsequent chest infection is greater, as a result of the case mix of those requiring a PEG, who are often older, more frail and have, by the definition of needing a PEG, significant co-morbidity, usually affecting the ability to swallow and gag. Further detail of endoscopic complications can be found elsewhere [16].
- **Pain:** This is common within the first 24 h. If severe, it is important to exclude peritonitis or tube displacement into the anterior abdominal wall.
- **Haemorrhage**: This is unusual if the clotting screen is within normal limits. As malnutrition can lead to vitamin K deficiency, the prothrombin time/INR should always be checked prior to procedure, and corrected if necessary.
- **Peritonitis**: This can develop from infection introduced during the insertion process. Pre-procedure antibiotics mitigate against this complication [6].
- **Pneumoperitoneum**: There will always be some free air after PEG insertion Pneumoperitoneum is usually self-limiting. It only needs to be a cause of concern when intra-abdominal air is worsening or when it is found in the presence of signs of peritonitis, portal and/or mesenteric venous gas, systemic inflammatory response and/or sepsis.

- **Gastrocolic fistula** due to the interposition of the colon between the anterior abdominal wall and stomach is a rare complication. It is often not clinically apparent and can be found by chance, for example during a colonoscopy. Measurement of the anterior abdominal wall thickness on the PEG after insertion can be an indicator. For example measurements over 3 cm in a thin individual should raise concern of interposed tissue between the stomach and anterior abdominal wall.
- **Injuries** to small and large intestine, spleen and liver have all been documented. They are rare, but should be considered when there is otherwise unexplained haemodynamic compromise or signs of peritonitis following insertion.
- Surgical or anaesthetic complications need to be considered in surgically placed enterostomies or those placed under a general anaesthetic. Further discussion on these issues is beyond the remit of this chapter.

Tube-Related Complications

- **Stoma infection:** This is a common complication, and even with prophylactic antibiotics occurs in up to 5% in the first 30 days after insertion [6]. The risk is increased both from insertion factors, eg excessive traction on the internal bumper, and host factors such as diabetes, malnutrition and underlying malignancy. It usually resolves with appropriate antibiotics and proper stoma care. It is not usually necessary to remove the enterostomy or stop feeding unless severe ulceration or wound breakdown occurs.
- Less commonly an abscess in the anterior abdominal wall can develop, especially if there is spillage of feed and gastric contents through an immature stoma tract. This will cause localized pain. The management is usually to stop the feed and give antibiotics.
- Necrotising fasciitis is a very rare complication, and more likely when there is systemic compromise, for example poorly controlled diabetes. This usually requires surgical debridement.
- **Tube blockage:** This is a common problem, and arises either because of thick consistency of feed or medication. It can be minimized if flushed with water before and after each feed/medication. The management is the same as for a blocked nasoenteral tube (see above).
- **Peristomal leakage and tube displacement**: Although the reported incidence of peristomal leakage is 1–2% [17], this complication is probably much more common, especially early after PEG placement. Tube displacement through the gastric wall in the immature stoma tract is a common precipitant to peristomal leakage. This is more likely to occur in a confused patient who may pull on the enterostomy. Correct siting of the internal end should be checked either radiologically or endoscopically, and corrected if necessary. There should not be excessive traction on the external bolster compressing the abdominal wall too tightly, and this should be loosened if necessary. Barrier creams and skin protectants should be applied. Antisecretory therapy, such as proton pump inhibitors, to reduce gastric acid secretion can help. Replacing the original PEG tube with a larger one should be avoided as this may cause the tract to enlarge and exacerbate the leakage. If leakage persists, it is often necessary to remove the PEG and resite a new one elsewhere.
- Displacement of a PEJ or PEGJ back into the stomach is a common problem, and this should be suspected if the patient complains of the symptoms that led to the need for post-pyloric feeding in the first place, including fullness and vomiting with feed.
- **Buried bumper**: This is migration of the internal fixator into the gastric/anterior abdominal wall leading to tube blockage. It is a late complication, usually months or years after placement, and diagnosed when the enterostomy cannot be rotated or pushed inwards. Removal can often be done endoscopically, but on occasions requires surgery.
- **Tumour tract seeding**: There are some case reports of PEG's inserted where there are oesophageal or oropharyngeal tumours, with neoplastic seeding in stoma tracks [18]. Where the PEG is inserted as part of palliative care, this is unlikely to be of relevance in the patient's lifetime. Where an enterostomy is required as a bridge for definitive treatment, a radiological procedure avoids the risk of tract seeding, and some experts advocate this.
- **Overgranuation**: Can occur at the stoma site and bleed and/or become painful. This is treated with steroid cream or silver nitrate.
- **Mortality**: There is a 30 day mortality of about 10% following PEG insertion, and 40% following a RIG. The difference is explained by the case mix for the two procedures, with the sicker and more co-morbid individuals more likely to have a RIG [19]. Careful case selection can minimise these figures.

Complications Relating to Feed Delivery

Gastrointestinal Problems

Nausea and Fullness

Nausea and fullness can occur in 10–20% of patients, with the pathogenesis being multifactorial, including smell, diet osmolality, altered gastric emptying, rapid infusion of feed and psychological factors [20]. Management has to be individualised, depending on the circumstances of the particular patient.

Diarrhoea

Diarrhoea occurring in the enterally-fed patient is a common problem, with a reported incidence ranging from 6–60%, more frequent in the critical care setting. This huge variability is a reflection of the heterogeneity of patients and case-mix in the various studies and of the definitions used for diarrhoea. Patients range from critical care to community-based elderly, all with varying degrees of comorbidity and polypharmacy. The definitions of diarrhoea are even more variable—at least 33 quoted in the literature [21]. Many studies utilise consistency, frequency, stool volume and stool weights either alone or in many different combinations. Some studies have developed diarrhoea scores; others just cite "inconvenient" bowel activity and several have no definition at all. What this all means is that it is difficult to truly determine from the literature how much of a problem there is with diarrhoea in the enterally-fed patient.

Contaminated feeds and feeding equipment can lead to the introduction of exogenous pathogens into the gastrointestinal tract. Enteral feed provides an excellent growth medium for bacteria, and once contaminated bacteria will rapidly multiply. A variety of micro-organisms have been cultured from enteral feeds including *Enterobacter* spp., *E. coli*, *Klebsiella* spp., *Proteus mirabilis*, *Salmonella enteriditis*, *Pseudomonas* spp., *Staphylococcus aureus* and *epidermidis*, *Streptococcus faecalis*, *Acinobacter* spp., *Citrobacter* spp. and yeasts. Although enteral feeds are sterilized, as soon as the bottles or cans are opened, there is a risk of bacterial colonization of the feed, through a variety of routes, which is exacerbated by handling, type of delivery system, prolonged hanging time and ascending spread of bacteria up the giving set [22]. Contaminated feeds reportedly cause not only diarrhoea, but also sepsis, pneumonia and urinary tract infections [23]. Gastric acid is an important protection against infused exogenous pathogens, and therefore inhibiting gastric acid secretion allows bacterial overgrowth. Those on antacid medication are therefore at an increased risk of infected enteral feeds and the clinical consequences that can follow. To mitigate risk, containers and giving sets should be changed at least every 24 h [23].

Many gastrointestinal diseases may cause diarrhoea, and these need to be considered, investigated for and dealt with where appropriate. Also to be considered are metabolic causes, such diabetes and thyroid dysfunction. Medications are frequently implicated in causing diarrhoea. The most common are antibiotics, probably due to their effects on colonic flora and short chain fatty acids. Antibiotic usage therefore should be scrutinised and stopped if possible. Other drugs include osmotically-active medications, primarily relating to sorbitol, which is present in many elixirs, and which is frequently given to many patients on enteral feeding for ease of swallowing. There are many other medications which list diarrhoea as a potential side effect. Therefore all medication, prescription and otherwise, should be considered and, if appropriate, stopped [24].

Other aetiological factors have been proposed as relevant to enteral feeding related diarrhoea [25]. Hypo-albuminaemia has been associated but is probably only as a surrogate for a sick patient with a sick and leaky gut. There is no evidence to implicate lactose intolerance or diet osmolality, both of which have been proposed in the literature. It has been suggested from healthy volunteer studies that intragastric feeding is more likely to lead to diarrhoea than post-pyloric feeding, because of different neurohumoral responses resulting from the two methods of feeding, with consequent effects on colonic water flows [26]. However, no clinical studies have been undertaken to test this hypothesis.

Diarrhoea is distressing for patients and their relatives, time-consuming for nursing staff and can add to potential problems such as infected pressure sores and altered fluid and electrolyte balance. It may also delay patient discharge and increase hospital costs. Loperamide at standard dosage (2-4 mg once to three times daily) is often very effective. The addition of codeine phosphate (30–60 mg up to four times daily) can also be of benefit [27].

The role of colonic flora, short chain fatty acids, fibre and pre/probiotics in relation to enteral feeding diarrhoea remains unclear. There are a lot of interesting data on the analysis of colonic flora and the changes observed during enteral feeding. However, the true clinical relevance of such manipulations remains unresolved [26]. There are some clinical data to suggest that including fibre in enteral diets reduces diarrhoea [28]. Therefore, a trial of a fibre-containing feed is worth trying, especially when enteral feeding related diarrhoea is not responding to anti-diarrhoeal medication [29].

Enteral feeding is unphysiological. Bolus feeding is better in this regard than continuous feeding for gastric feeding, but unless the bolus is substantial (more than 500 kcals over 20–30 min) the normal post-prandial neurohumoral responses do not get activated, and this may be of relevance to enteral feeding diarrhoea [30]. There are practical arguments for and against these two forms of feeding, such as ease of administration, patient comfort and convenience and staffing input, which often take precedence over clinical applications. If diarrhoea is a significant problem and is not responding to anti-diarrhoeal medication, then a critical look at the method of feeding is advised. Post-pyloric continuous feeding is more physiological and could be considered, although there are no clinical studies comparing this with gastric feeding and the incidence of diarrhoea. Very occasionally, when diarrhoea is incapacitating and cannot be eased by any of the above, parenteral feeding can be started.

Constipation

Constipation, often with resulting overflow diarrhoea, can be a problem with enteral feeding, although is much less

common that enteral feeding related diarrhoea. It has been suggested that constipation is due to a lack of dietary fibre in many enteral feeds. There is currently, however, little conclusive evidence that using fibre-enriched enteral feeds increase stool frequency and weight. The lack of improvement in constipation by adding fibre to enteral diets may be partly due to the manufacturing process which alters the physicochemical properties of the added fibre. The viscosity of the feed is kept low by using fine rather than coarse fibre. However this reduces the water holding and bulking properties of the feed. Furthermore, due to the requirement of having a small particle size renders the fibre highly fermentable, reducing the amount of fibre available to bulk faeces. A recent meta-analysis has not demonstrated a clear benefit of fibre supplementation in the treatment of either constipation or diarrhoea [29]. However, given the theoretical benefits of fibre and the intuitive view that it should be part of a nutritional regime, many experts would use a fibre-enriched enteral feed in patients with constipation.

Pulmonary Complications

Reflux of feed is almost invariable. Many studies have identified evidence of this, for example pepsin in alveolar aspirates is found in more than 90% of patients being nasoenterally fed [31]. The development of aspiration pneumonia is therefore a potential complication in all patients being tube fed into the stomach or small bowel. Aspiration of feed can occur without obvious evidence of vomiting, particularly in those patients with poor mental status and an absent swallow reflex. Such regurgitation is often a clinically silent event until signs of pneumonia develop. Those at particular risk are the elderly, those with dementia or neurological disease affecting their swallow and gag reflux, and those in critical care on ventilators and with impaired consciousness.

To reducing the risk of pulmonary aspiration, elevating the head of the bed to 30° or more, to help aboral progression of feed by gravity, and feeding for less than 24 h a day, for example over 18–20 h, have been shown to improve aspiration risk [32]. High osmolality feeds of 560 milliosmoles or greater can significantly delay gastric emptying, and so it is probably preferable to use iso-osmotic feeds in patients at risk from aspiration.

There has been much interest in gastric residual volumes for patients primarily in the critical care setting and a presumed association with risk of aspiration. On critical evaluation, there is no clear link between amount of residual and aspiration risk, and 500 mL residuals appear to be no more hazardous than smaller amounts [33, 34]. Current evidence would therefore not support review of residuals only if these are less than 500 mL per 6 h [35].

As with gastric residuals it has also been presumed that bolus feeding increases the risk of aspiration compared to continuous pump feeding. Studies have given mixed results, with some demonstrating benefit with pump feeding [36] and others showing no difference [37].

There is no evidence that enterostomy feeding has any less risk than nasoenteral feeding. There have been a number of controlled trials comparing postpyloric to pre-pyloric feeding, with meta-analyses giving conflicting results [38–40]. It is commonly the case that nasoduodenal tubes can reflux back into the stomach, so to minimise risk of retrograde displacement and aspiration risk, postpyloric tubes should be placed beyond the duodenojejunal flexure (Ligament of Treitz). Pro-motility drugs (e.g. metoclopramide or erythromycin) can be tried to reduce the chances of aspiration in those patients most at risk, although evidence of benefit from meta-analysis is weak [41].

In terms of evidence, the only strategy clearly demonstrated to improve aspiration risk is feeding for no more than 20 h per day and with patients propped up by 30° or more [31].

Metabolic/Biochemical Complications

Artificial feeding of patients may cause a variety of metabolic problems, including deficiencies or excess of fluid, electrolytes, vitamins and trace elements. Over-hydration occurs frequently, particularly if enterally-fed patients are also receiving supplementary intravenous nutrition or fluids.

Hyponatraemia is a common problem when enteral nutrition is given to sick patients. It is often accompanied by the development of oedema and is usually due to a combination of enteral tube feeding and excessive use of IV fluids along with the adverse effects from malnutrition and severe illness. Patients end up with excess body water and a very high total body sodium (the low plasma levels being due to dilution effect). As a consequence, rather than administering further sodium in feeds or IV fluids, treatment should usually entail fluid restriction. Generous amounts of potassium to encourage cell membrane sodium exchange may be helpful. Hypernatraemia can also occur but is usually due to dehydration and/or excess water loss, e.g. through diuresis, rather than as a direct consequence of enteral tube feeding.

Between 10–30% of tube fed patients are hyperglycaemic and may need oral anti-diabetic agents or insulin, before and during feeding. Rebound hypoglycaemia may also occur in tube-fed patients if feeding is stopped abruptly, especially if they are on anti-diabetic therapy.

Deficiencies or excesses of many other electrolytes, vitamins and trace elements can occur but which can usually be avoided by careful monitoring. Basic haematological and biochemical parameters should be measured before starting

nutritional support, and then monitored regularly during such support, with appropriate supplementation given when necessary, especially for those on prolonged enteral feeding.

Refeeding Syndrome

The refeeding syndrome was reported among those released from concentration camps following the Second World War. Oral feeding of these grossly malnourished individuals often resulted in fatal diarrhoea, heart failure and neurological complications including coma and convulsions. Milder symptoms were later reported by Keys et al. during the refeeding of healthy volunteers with a mean weight loss of 23% after starvation [42].

Severely malnourished patients appear to be at particular risk of developing the refeeding syndrome (chapter "Refeeding Problems"), who's features include:

- Salt and water retention leading to oedema and heart failure, which may be exacerbated by cardiac atrophy,
- Hypokalaemia due to rapid cellular uptake of potassium as glucose and amino acids are taken up during cellular synthesis of glycogen and protein,
- Hypophosphataemia due to increased phosphorylation of glucose,
- Rapid depletion of thiamine, a cofactor in glycolysis, leading to Wernicke's encephalopathy and/or cardiomyopathy, and
- Hypomagnesaemia due to cellular uptake of this mineral.

In severe nutritional depletion, atrophy of the gut mucosa and impairment of pancreatic function may predispose to severe diarrhoea following oral or enteral refeeding, precipitating further electrolyte and mineral imbalance.

It is difficult to give a precise definition for the refeeding syndrome since many otherwise well-nourished patients, refed after only a few days starvation, will show a modest change in biochemical values, e.g. a fall in serum potassium and phosphate concentrations, without displaying any symptoms. There is a spectrum or gradation in the features of this condition from such asymptomatic cases to those with severe malnutrition who are at risk of overt and even life-threatening symptoms. The cut-off point at which the 'refeeding syndrome' can be said to be present is, therefore, somewhat arbitrary. The full blown syndrome should be defined by the presence of symptoms, but that biochemical changes of sufficient degree to pose a potential risk should be acted upon without delay in order to prevent the clinical features developing.

Common factors involved with the pathogenesis of the refeeding syndrome include the severity of the underlying malnutrition, overaggressive nutritional support in the early stages without adequate supplements of phosphate, thiamine, potassium and magnesium, and associated conditions that exacerbate micronutrient, electrolyte and mineral deficiencies, e.g. alcoholism, gastrointestinal disorders, and poor or eccentric diets.

Although phosphate is just one of the components affected, hypophosphataemia has far reaching consequences on the functioning of various organ systems. During starvation, phosphate and potassium are lost from the cell in proportion to the breakdown of glycogen and protein, potassium being the main intracellular cation balancing the negative charges on proteins. There is, therefore, no clinical deficiency of these electrolytes until catabolism is abruptly reversed and resynthesis of glycogen and protein begins, creating a sudden demand for inorganic phosphate for phosphorylation and ATP synthesis and for potassium to balance the negative charges on protein and glycogen. Magnesium, being involved in ATP synthesis, is also taken up by the cells. Upon the introduction of carbohydrate, insulin is released into the blood stream and there is a shift of metabolism from fat to carbohydrate. Acute thiamine deficiency may be precipitated, especially in patients suffering from chronic alcoholism, since diminished thiamine reserves are rapidly used up, as carbohydrate metabolism is accelerated. Excessive infusion of glucose may also cause hyperglycaemia leading to osmotic diuresis, dehydratation and hyperosmolar non-ketotic coma. The production of fat from glucose due to lipogenesis can result in hypertriglyceridaemia and/or a fatty liver.

Refeeding problems primarily occur after feeding commences, and can be regarded as an iatrogenic condition. With awareness of its existence and careful management, its development is usually preventable. NICE and other authorities recommend that generous amounts of potassium, magnesium and phosphate supplements should be given alongside initiation of feeding, which should start at around 10 kcal/kg/day in very high risk groups [42, 43]. Thiamine and other B vitamins must also be given intravenously starting before any feed is commenced, and continuing for at least the first 3 days of feeding. Feeding rates can then be gradually increased over the next few days to full calorie requirements by day 8. Thereafter, regular monitoring, especially of the refeeding electrolytes (phosphate, potassium and magnesium) is essential, although the frequency required will depend on the stability of the patient. A more in depth description of the management of refeeding syndrome can be found in reference [43] and chapter "Refeeding Problems".

Prevention, Diagnosis and Management of Catheter-Related Blood Stream Infections

Simon Lal, P. Chadwick, M. Gompelman, and G. Wanten

Key Points

1. Catheter-related bloodstream infections (CRBSI) represent the most common serious and life-threatening complication for patients receiving home parenteral support (HPS).
2. Development of CRBSIs occurs mostly following microbial migration along the contaminated or colonized central venous catheter (CVC) surface into the bloodstream (usually from the hub).
3. Skin-derived flora causes most catheter related infections; therefore adequate hand hygiene and aseptic catheter handling techniques are most important for CRBSI prevention.
4. CRBSI should be suspected when patients receiving HPS present with fever (especially if within an hour of setting up an infusion), are unwell or have been involved in events that may be associated with a catheter infection (e.g. catheter fracture, attempts at restoring patency, etc.).
5. Paired qualitative (using differential time to positivity (DTP) or paired quantitative (using pour plates)) blood cultures from a peripheral vein and from the catheter are required for the diagnosis of a definite CRBSI.
6. When central blood cultures are positive and no peripheral cultures can be taken (or vice versa), this can be classified as a probable CRBSI providing the symptoms and clinical picture is suggestive of a CRBSI.
7. For uncomplicated CRBSIs it is recommended that an attempt to salvage the CVC is made, by means of treatment with antibiotics since repeated catheter loss ultimately will lead to a failure to obtain adequate and reliable central venous access. Catheter salvage is not recommended for candida infection.
8. Once a CRBSI is suspected and while blood cultures results are awaited, empirical therapy should be commenced with a CVC antibiotic lock plus a systemic antibiotic, adjusted thereafter according to microbial sensitivity.
9. If salvage fails or the patient has recurrent CRBSI, the CVC should be removed and other sources of infection should be considered.
10. Fluid (or parenteral nutrition) during salvage is given by a different catheter (often into a peripheral vein).
11. After a CRBSI the aseptic techniques in setting up/taking down an infusion should be reassessed, and possible environmental contributors identified.
12. Central blood cultures should be taken at least 48 h after completion of therapy to confirm successful treatment.

Introduction

Patients with chronic intestinal failure depend on parenteral nutrition to maintain health and preserve life. Catheter related complications, particularly blood stream infections, are a significant cause of morbidity and mortality in patients on HPS. Dedicated intravenous catheters managed with rigorous aseptic protocols are vital in preventing complications and obtaining good long-term outcomes in patients dependent on HPS. Similarly, robust arrangements for the early recognition and treatment of catheter-related complications, including catheter-related blood stream

J. M.D. Nightingale (ed.), *Intestinal Failure*, https://doi.org/10.1007/978-3-031-22265-8_56

infection (CRBSI), help to prevent progressive loss of venous access.

Pathogenesis of CRBSI

The use of a central venous catheter (CVC) is associated with the risk for microbial colonization and subsequent serious infections, including CRBSI. Several factors have been implicated in the pathogenesis of CRBSI:

Colonization and Contamination of the Central Venous Catheter

The catheter itself can be involved through several potential routes [1]:

- Colonization of the catheter tip and/or extraluminal subcutaneous tract by skin-derived flora
- Colonization of the catheter lumen through microbial contamination
- Hematogenous spread of microbes onto the catheter surface from other foci of infection
- Colonization of the catheter lumen through contaminated infusate.

The most common routes for contamination of CVCs are migration of skin-derived flora from the insertion or exit-site of the catheter into the cutaneous catheter tract, and along the extraluminal surface of the catheter with subsequent colonization of the catheter tip, or via direct contamination of the catheter hub by contact with hands, contaminated fluids or devices. Less common causes of CRBSI are hematogenous seeding or infusate contamination [2]. Microbial contamination, colonization and subsequently biofilm formation on catheter surfaces can occur within 24 h after insertion [3].

Biofilm Formation

Microbial contamination of the catheter leads to the development of microbial consortia associated with the CVC surface and surrounded by a self-produced polymer matrix, termed a 'biofilm'. Biofilms typically consist of 3 components: the biofilm-growing microorganisms, the planktonically (nonaggregated) growing organisms and the integrated host component, such as fibrin, platelets or immunoglobulins [4]. Biofilms have the capability to seize and concentrate a number of environmental nutrients in their extracellular matrix. In addition, biofilms facilitate the resistance to antimicrobial factors by several mechanisms, such as down-regulation of cell division and by acting as a diffusion barrier. Finally, there is a potential for dispersion through detachment, allowing for an enduring bacterial source population [5]. When harbored within a biofilm, pathogenic bacteria are, to some degree, protected against host defenses and antimicrobial compounds. The stability of this environment allows the bacteria to grow on the surfaces of indwelling medical implants or devices such as catheters or infusion ports [3, 6]. Since these devices are in direct contact with the bloodstream, the surface becomes coated with bloodstream components that act as a conditioning film to which microbes can attach [7]. Within days of adherence to the catheter cell wall, multiple bacterial layers are usually formed and microcolony aggregation occurs. An extracellular matrix of exopolysaccharide (EPS) forms an antimicrobial glycocalyx or "slime" layer [8]. Bacteria in a biofilm communicate cell-to-cell through molecular signals, a phenomenon that is termed 'quorum sensing' (QS) [9]. Many proteins and virulence factors are produced by bacteria in response to QS and thereby create a chronic, low-grade immune response [8]. A substantial proportion of the intimately connected microbial population lives in a down-regulated state because of the low nutrient and oxygen content within the biofilm. In addition, host responses that comprise the actions of granulocytes, immunoglobulins and antimicrobial therapy will likely have diminished effects since they fail to penetrate the biofilm [10].

Infection Prevention

Type, Choice and Site of Central Venous Access Device

The choice, type and exit-site location of the central venous catheter (CVC) plays an important role in occurrence of catheter colonization and the risk for developing CRBSI and is best determined by a multidisciplinary HPS team, where the opinion of the patient or his/her caregiver should also be taken into consideration [11]. The first choice for placing the CVC is in the upper caval vein with the tip placed as near as possible to the level of the right atrial-superior vena cava junction, via the internal jugular or subclavian vein and preferably on the right side. A left-sided approach, with a more intimate contact between the venous vascular lining and the catheter, is associated with a higher risk for thrombotic complications [12]. Femoral vein access routes potentially have more risk for catheter colonization, bloodstream infections and symptomatic thrombosis, though this has only been proven in the case of short-term and non-tunnelled catheterization [13, 14]. Subcutaneously tunnelled or totally implanted devices are preferred above non-tunnelled devices because of the lower rate of infections due to the specific protection from extraluminal contamination and fewer complications related to self-administration of HPS [15]. If pos-

sible, a single lumen is device is preferred over a multiple lumen catheter because of the lower infection rate. Also, infection treatment itself is more complicated in the multi-lumen situation [16, 17]. In selected patients, for example for those with recurrent CRBSI, the creation of an arteriovenous fistula has been proposed as a valuable alternative [18].

HPS Training

Careful management of CVCs, that are dedicated solely for HPS administration according to a well-established protocol, is key for the prevention of CRBSI. As such, CRBSI rates are the main quality indicator for any HPS support program. To establish this optimal care, the patient and caregiver need to be well trained and educated in all fields of CVC care. Since adequate training in this respect is of major importance for the prevention of CRBSI, training programs in many centres have been intensified in recent years. Attention is more focused on the teaching of patients and their caregivers on how to manage their CVC themselves and encompasses more rigorous aseptic protocols that are performed at the patients' home instead of in the hospital environment, thus reducing length of hospital stay [19–21]. However, so far, CRBSI rates remain the lowest whenever the care is under control of a highly trained nurse [21]. More modern forms of training programs that include video education of both staff and patients may be another measure that lowers catheter related infection rates and improves problem-solving capacities and quality of life [22]. On the other hand, a recent study was more pessimistic and suggested that, when compared with usual care, video education may lead to an increased number of patient calls without improvements in CRBSI rates [23].

Hand Hygiene, Antiseptics and Central Line Care

Adequate hand hygiene with appropriate use of disinfectants before and after touching the CVC (and non-touching of any key parts) by those who perform the HPS care is the cornerstone for preventing healthcare related infections in general [24]. The preferred antiseptic for catheter exit site and certain parts of the catheter (hubs, stopcocks and sampling ports) is chlorhexidine 2% [25]. Intravenous administration sets should be changed every 24 h when parenteral nutrition (PN) is used [15]. In general, the use of in-line filters, needle free connectors and routine replacement of catheters are not advised as infection prevention measures since there is no definitive proof that these measures reduce the incidence of CRBSI [26]. Antimicrobial-coated access devices only seem a valuable option in short-term PN care [15].

Dental Care

The various medications and therapies that are being used by patients with intestinal failure receiving HPN may affect their oral health status. Concerns exist that some CRBSIs arise from poor oral health or recent dental treatment and for this reason some experts recommend parenteral antibiotic prophylaxis prior to dental care according to the infective endocarditis (IE) dental prophylaxis guidelines [27]. However, further study is needed to establish whether there is a true relation between dental treatment and CRBSI and clear guidelines on appropriate prescription of antibiotic prophylaxis specific for patients on HPN are required.

Catheter Lock Solutions

Catheter lock therapy is a technique for disinfecting the catheter lumen and involves the dispension of locking solutions in the catheter lumen for extended periods of time while the catheter is not in use. Several lock-solutions have been developed and are being used for the prevention of CRBSIs, while others primarily serve to prevent occlusions. Unfortunately, although this strategy may seem promising, several of these catheter lock-solutions carry some associated risks and special attention should be given to problems that can arise, such as the development of side effects based on toxicity and allergies, as well as antimicrobial resistance. An overview of the most commonly researched or used catheter lock solutions is provided below:

Anticoagulant and Fibrinolytic Lock Solutions

These types of catheter-lock solutions are especially relevant in the setting of haemodialysis, since in these patients blood is aspirated through the catheter and anticoagulants are required to prevent catheter clotting and occlusion. However, this does not apply to the HPS setting, since blood is only withdrawn from the catheter in cases of a severe infection. There is some evidence that heparin and citrate may promote catheter colonization and biofilm formation [28]. Therefore, the use of anticoagulants as a catheter lock therapy to prevent CRBSI is not advised in the HPS setting.

Ethanol

Although ethanol lock therapy (ELT) is relatively inexpensive, readily available and seems to reduce the rate of CRBSI in high-risk HPN patients (i.e. patients with a history of prior CRBSI), the reduced CRBSI rate cannot be generalized to all HPS patients [29–31]. Therefore, and due to the concerns that exist, particularly the effect of ethanol on catheter structure, integrity and systemic toxicity, use of ELT is currently not advised [26, 32].

Antibiotic Locks

Results from in vitro studies demonstrate stability of antibiotic locks while maintaining high concentrations for prolonged periods of time [33–35]. However, evidence is lacking that prophylactic use of such antibiotic locks reduce the incidence of CRBSIs in HPS patients, while this strategy is associated with an increased risk for the development of microbial resistance, especially in the case of long-term HPS requirement [15]. Additionally, the biofilm that develops on the intravascular catheter is relative resistant to antibiotic penetration and this necessitates much higher blood levels of antibiotics to reach sufficient therapeutic efficacy than can be achieved by antibiotic lock therapy [36].

Taurolidine

Taurolidine, a derivative of the amino acid taurine, is non-toxic for humans and is rapidly metabolized into the amino acid taurine, water and carbon oxide. An irreversible reaction of its downstream methylol metabolites with the bacterial cell wall leads to diminished microbial adhesion to catheter surfaces, and hence, biofilm formation. Taurolidine displays a broad spectrum of antimicrobial activity against Gram positive and Gram negative microbes as well as yeasts and also neutralizes bacterial endo- and exotoxins [37, 38]. Experience with taurolidine as a catheter lock therapy is growing and the use of this compound as part of diverse available formulations has become common practice in several centres over the last years. Several randomized controlled trials (RCTs) have been conducted and all of them showed that the use of taurolidine locks is significantly associated with a lower incidence of CRBSIs without obvious adverse effects and development of bacterial resistance when compared to heparin locks [39]. Since the previous trials cold not discriminate between the beneficial effects of taurolidine and/or detrimental effects of heparin, more recently a European multicenter RCT was conducted that compared taurolidine 2% to sodium chloride 0.9% as a catheter lock solution in HPS patients. In this study, use of taurolidine resulted in a decreased CRBSI risk by more than four times with a favourable safety profile as compared to saline, without adversely influencing microbial susceptibility [40]. Whether taurolidine as a catheter-lock solution should be considered in all patients or only those with a high infection risk is still a matter of debate, not least because of the financial implications of this strategy.

Novel Preventive Strategies

Staphylococcus aureus Eradication

Although not new, strategies focussing on the eradication of the skin bacterium *Staphylococcus aureus* are currently under research in the HPN population [41]. It is known that eradicating *S. aureus* with mupirocin ointment in nasal carriers results in a statistically significant reduction in *S. aureus* infections (RR 0.55, 95% CI 0.43–0.70). Nevertheless, there is a wide variety between centers and the prevalence and clinical outcomes of CRBSIs caused by *S. aureus* in the HPN population appears in some centers not as poor as in other patient groups [21, 42–45]. Hopefully, in the near future it will become clearer if the benefits also outweigh the potential risks for eradicating *S. aureus* in the HPN population.

Novel Catheter Lock Solutions

The inhibition of biofilm formation still appears the most attractive strategy to prevent catheter-associated infections. In recent years, the emphasis has been on the development of non-toxic and preferably antibiotic-free antiseptic agents that disrupt the biofilm, like taurolidine; these rely on matrix degradation, destabilization or anti-virulence compounds that target the most tolerant microbes inside the biofilm. For example, a recently developed novel non-antibiotic, heparin-free solution containing nitroglycerin (NTG) demonstrated *in vitro* activity against a broad spectrum of microbes with high efficacy and ability to eradicate biofilm formation, with a potency similar to that of heparin. This compound appeared safe and well-tolerated when administered in cancer patients who had peripherally inserted central catheters (PICCs) [46–48]. Altogether, a better understanding of biofilm formation at the molecular level may help to develop novel approaches for the prevention of CRBSI.

Diagnosis

There is a wide variation in the incidence of reported CBRSI rates, even amongst internationally-recognised HPN centres, with a systematic review published in 2013 reporting a range of 0.38–4.58 per 1000 catheter days amongst 39 studies reviewed [44]. Since the publication of this systematic review, a case series from the U.S.A. reported a much higher CRBSI rate of 11.5 per 1000 catheter days occurring in 101 adults newly discharged home on PN [49], while a much larger series from the U.K. published in 2017 reported the lowest published CRBSI rate of 0.22 per 1000 catheter days in 279 patients newly discharged on home parenteral nutrition (HPN) [21]. This variation in CRBSI rates between different international centres may, to a limited degree, reflect differences in patient cohorts studied since a number of patient-related factors, such as the presence of a stoma and/or opiate use, have been associated with CRBSI occurrence [45]; however, differences in catheter care protocols between centres is likely the most significant factor accounting for the extremes in CRBSI rates.

Another factor that may influence reported CRBSI rates is the criteria used for CRBSI diagnosis. A number of organisations have proposed criteria for the diagnosis of bacteremia affecting patients with indwelling venous catheters,

including the Centre for Disease Control and Prevention (CDC), Infectious Disease Society of America (IDSA) and the European Society of Enteral and Parenteral Nutrition (European Society of Clinical Nutrition and Metabolism) (ESPEN) [15, 50, 51]. The current ESPEN guidelines are based upon the CDC criteria and recommend that a CRBSI is diagnosed by a 'positive culture of the catheter (on removal), or paired blood cultures from a peripheral vein and the catheter (when left in place) with isolation of identical organisms (both species and antibiograms) from cultures of catheter segments and blood drawn from a peripheral vein in a patient with clinical symptoms of sepsis and the absence of another source of infection.' Once drawn, international guidelines further recommend that blood samples from central and peripheral veins undergo quantitative and/or qualitative analysis in the laboratory. Quantitative methods, such as pour plates, are thought to have the best diagnostic accuracy and are recommended by international organisations, but may not be widely used [50, 52–55]; if quantitative methods are used, then the diagnosis of a CRBSI should be made if the colony count of microbes grown from the catheter hub blood sample is at least threefold greater than the colony count from the peripheral blood [50]. Qualitative methods include assessment of differential time to positivity (DTP), which has reasonable accuracy and is more widely available in most hospitals; a positive CRBSI is diagnosed if the growth of microbes from the catheter hub blood sample occurs at least 2 h before any microbial growth is detected in the peripheral blood sample [56]. Quantitative and qualitative blood cultures rely upon careful sample labelling, with equal volumes of blood instilled into blood culture bottles (within 10 min) and that the samples are then handled identically. The samples require prompt transport to and processing within the laboratory (within 4 h of being collected).

Failure to follow standardised guidelines utilising quantitative or qualitative paired cultures can lead to CRBSI misdiagnosis, inappropriate antibiotic usage and potentially unnecessary catheter removal. Indeed, a retrospective study from Denmark demonstrated that simply adopting a clinically-based approach to diagnose CRBSI (for example, based on the presence of clinical symptoms, elevation of biochemical blood tests and a positive peripheral or central blood culture) rather than using quantitative or qualitative methods may lead to significant over-diagnosis by 46% [57]. Thus, consistent approaches to the CRBSI diagnosis are clearly important to allow meaningful comparisons between different centres, not least because CRBSI rate is deemed a surrogate marker of the quality of care provided by HPS centres and the outcome indicator considered to be the most important by HPN-dependent patients [58].

New methods to diagnose CRBSI have been evaluated but have not yet proven to be of clinical benefit. For example, plasma immunoglobulin levels against flagellin and lipopolysaccharide were not found to differentiate between non-bacterial febrile illnesses and CRBSIs in a small study of children with intestinal failure [59] while other methods aimed at making a rapid diagnosis, including real time PCR, have been explored but currently do not appear to be adequately sensitive to be used in this setting [60]. Further work is required to develop and evaluate the role of novel techniques aimed at rapidly diagnosing CRBSIs, while ensuring consistent methodology so that meaningful comparisons of CRBSI rates can be made between different IF centres.

Management

Current international guidelines recommend that infected CVCs are salvaged wherever possible because repeated catheter loss can ultimately lead to failed venous access which, currently, can be an indication for a small bowel transplant [26]. Thus, once diagnosed, attempts should be considered to treat the CRBSI with antibiotics without resorting to CVC removal. Of course, salvage should be only attempted if deemed clinically appropriate such that immediate CVC removal is recommended if the patient is at clinical risk with septic shock, where any attempt at CVC salvage may be felt to compromise the safety of the patient [21, 26, 45]. In addition, if patients have a CVC tunnel infection, a metastatic infection (e.g. endocarditis, osteomyelitis) or a septic thrombosis associated with the CRBSI, salvage is also not generally recommended because of the relatively low chance of success and, in these circumstances, CVC removal is advised [26, 45]. While tunnelled catheters can be readily salvaged, some experts also describe successful salvage of infected implanted ports; however, in the authors' experience and according to European guidelines [26], successful salvage of these devices is rare and most implanted ports have to be removed if infected [16, 26]. If removed, reinsertion of any long term CVC should not take place until after completion of a course of appropriate systemic antibiotics and, thereafter, once repeat blood cultures are negative [26].

For uncomplicated CRBSIs, current guidelines advise that systemic antibiotics with appropriate microbial sensitivity based on blood culture results, alongside antibiotic CVC lock therapy, should be used for 2 weeks [26]. Two recent papers evaluating very large series since the 1990s, from Salford in the U.K. and the Mayo Clinic in the U.S.A., have demonstrated high CVC salvage rates of HPS-associated CRBSIs of 72.5% (180 CVCs salvaged of 248 CRBSIs) and 70% (325 CVCs salvaged of 465 CRBSIs) respectively, with low associated mortality (U.K. 1.7% inpatient episodes of CRBSI and U.S.A. 3.5% overall mortality from CRBSI in the HPN population) [45, 61]. Coagulase negative staphylococci were the most frequent isolate in both series and had the greatest successful salvage rate of 79.8% in the U.K. paper and 77.8% in the U.S.A. paper [45, 61]. CVCs infected

with Gram negative or polymicrobial bacteria could also be salvaged at high rates [45, 61]. Notably both papers demonstrated that more than half of all CVCs infected with potentially highly pathogenic organisms, such as *S. aureus,* could also be safely salvaged [45, 61]. This is despite guidance from the Infectious Disease Society of America (IDSA) recommending that CVCs infected with *S. aureus* should be removed [62]. Most international authorities recommend that CVCs infected with fungi should be removed [15, 26, 50, 51] and this was the practice in recently published papers from the U.K. [21, 45]; the Mayo group actually reported successful treatment of fungal CRBSIs, albeit at a very low rate (14.2%) [61]. An ECHO should be performed if there is a prosthetic heart valve, pacemaker/ICD, persistent bacteraemia and/or pyrexia 72 h after initiation of appropriate antibiotic therapy and/or with S aureus infection.

There remain some methodological differences between institutions in CVC salvage protocols. For example, some [21, 45] but not all [61] centres advocate routine use of thrombolytics within the CVC salvage protocol theoretically to remove any associated intraluminal thrombus, although the evidence-base for this approach is limited [26]. Furthermore, the duration of antibiotic therapy has varied according to the underlying organism and according to institution protocol. Although international guidelines recommend a course of 14-days antibiotic treatment for all organisms, recent evidence suggests that 10-days [21] or even 7-days [61] may be equally effective for less virulent organisms such as Coagulase negative staphylococci [21]. Similarly, methods used to confirm salvage success have varied between different institutions. The Mayo group defined catheter salvage 'as the process of treating an occurrence of CRBSI appropriately with antibiotics without removing the central venous catheter', while the Salford group confirmed salvage success through negative repeated sets of peripheral and central blood cultures and pour plates 48 h after completion of antibiotic therapy [45]. The latter approach supported in a subsequent publication from the same group which revealed that negative cultures following antibiotic salvage could predict the absence of re-infection in 96% of patients over the following 1-year [21].

Current guidelines do not recommend the routine screening for CRBSI occurrence in the absence of suspicion of a catheter-related infection. However, clinicians may have a low index of suspicion for a CVC infection or colonisation if patients are transferred from general hospital wards with a high incidence of infection to a dedicated IFU. Indeed, a recent study screened a large number of patients newly diagnosed with type 2 IF with central and peripheral blood cultures on admission to an intestinal failure unit and found that 19% of had a colonised or infected catheter that had been contracted but not recognised in the referring hospital [21]. A successful CVC salvage rate of 91% was achieved in this cohort after antibiotic therapy and the subsequent in-patient catheter-related BSI rate for those admitted with a CVC on the IFU was very low at 0.042 per 1000 catheter days, over a total of 23,548 in-patient catheter days [21]. Thus, since there is a risk that continued PN infusion may serve as an infective milieu, identification of central venous catheter infection or colonisation is clearly important in patients with acute IF to attempt to reduce the risk of the associated morbidity resultant from subsequent CRBSI development in already metabolically-unstable individuals [21].

After a CRBSI the patient/carer's aseptic technique in handling should be reassessed. If recurrent CRBSI another source of infection should be sought (e.g. teeth, wounds, nails, urine etc). 70% Isopropyl alcohol port protectors may be used. The prophylactic use of antimicrobial locks (e.g. taurolidine) can be used for recurrent CRBSI, but ethanol locks are not recommended. For all (especially nursed) patients a root cause analysis is recommended to try and identify possible contributory factors.

Central Vein Thrombosis

Cristina Cuerda and Yaser Naji

Key Points

1. Acute central vein thrombosis is a medical emergency requiring an urgent Doppler ultrasound and/or venogram.
2. Thrombolysis can be given directly into the clot.
3. Early treatment may prevent later venous stenosis/occlusion.
4. Chronic venous stenosis can be treated with angioplasty and stenting.
5. The cause of the thrombosis should be determined.
6. When 2 of the 4 major supra-diaphragmatic veins have been lost there should be consideration for a small bowel transplant.

Introduction

Home parenteral support (HPS) is administered through central catheters of different type (tunneled, ports, peripheral inserted central catheters (PICCs)). Even though thrombotic complications of the catheter are less frequent than catheter-related infections, they cause a significant burden in these patients and may lead to catheter replacement and loss of venous access that may compromise the administration of parenteral nutrition in the long-term.

In this chapter we will review the incidence, etiology, diagnosis and the strategies for the prevention and treatment of this complication.

Incidence and Etiology

Thrombotic complications of the catheter are a dynamic process with varying severity from the appearance of the fibrin sheath at the tip of the catheter, intraluminal blood clot, mural thrombosis to venous thrombosis [1].

The fibrin sheath does not usually affect catheter function and can occur within 24 h after catheter placement and often develops within two weeks. Intraluminal clots usually cause catheter occlusion. Mural thrombosis is a blood clot that adheres to the vessel wall and can occlude the tip of the catheter but does not completely occlude the vein. Central venous thrombosis (CVT) occludes the vein and is the most significant thrombotic complication.

CVT is a severe complication that is responsible for the loss of central venous accesses in patients on home parenteral support (HPS) and may be an indication for small bowel transplantation if it affects two or more of the central venous vessels (subclavian, jugular or femoral) [2].

The pathogenesis of CVT is multifactorial and includes the following: (a) vessel injury during the procedure of insertion, (b) venous stasis due to indwelling of the device and damage to the endothelium caused by infusion of parenteral nutrition with a high osmolality, and (c) mechanical rubbing of the catheter against the vessel wall.

Venous thrombosis can develop soon after catheter insertion or delayed in patients with long-term catheterization. The former cause is probably related to the damage to the endothelium of the vein during the insertion and may be decreased using ultrasound guidance [3]. Other important factors are the proper selection of the vein (the right internal jugular vein is the preferred one due to its direct direction to the right atrium *vs.* the left-sided catheters), the catheter (less thrombogenic material, lowest calibre and single-lumen), and the correct location of the tip of the catheter (in the lower third of the superior vena cava, at the atrio-caval junction, or in the upper portion of the right atrium) [3–6]. PICCs are associated with a higher risk of CVT than tunneled or chest ports in some studies [7, 8], but not in others [9, 10]. The risk

Table 1 Risk factors for venous thrombosis

Catheter
• Material (polyvinylchloride and polyethylene are more thrombogenic than silicone and polyurethane)
• Number of lumens
• Diameter of the catheter
• Location of the tip of the catheter
• Traumatic insertion (previous catheterizations)
• Infection
• Ethanol lock (pediatric patients)
• Type of catheter (PICC associated with more thrombosis than tunneled or chest ports)
Patient
• Underlying disease (cancer)
• Thrombotic diathesis
• Previous thrombosis
• HPS, chemotherapy, thoracic radiation
• Immobilization

for thrombosis is also higher in patients with cancer, thrombotic diathesis, previous thrombosis, multiple catheterizations, catheter infection, or treatment with chemotherapy [11, 12]. In recent studies it has been described an increased risk for thrombosis associated with ethanol lock therapy in the pediatric HPN population [13, 14]. In children with intestinal failure on long-term HPS low levels of anticoagulant proteins (antithrombin, protein C and S) and elevated factor FVIII activity have been described, likely reflecting liver insufficiency and chronic inflammation [15]. The main risk factors for venous thrombosis are summarized in (Table 1).

CVT may be clinically manifest or subclinical. Most of the data on the incidence of CVT in patients receiving home parenteral nutrition (HPN) comes from retrospective series with large patient numbers but only report clinically manifest thrombosis. In these studies, the incidence of CVT is around 0.02–0.09 cases/catheter/yr. or 0.06–0.12/1000 catheter-days [16–23]. Some retrospective cohort studies have shown a decrease in the incidence of this complication over the years, probably due to changes in the catheter management and patient selection [12]. Paediatric patients seem to have higher incidence of CVT than adults [15, 24].

The incidence of subclinical CVT with a routine diagnostic imaging in patients on HPS is much more unknown. In a cross-sectional study in 42 adult patients on HPN with a mean dwelling time of 37 weeks, the authors reported 26% of clinical obstruction of the upper venous system, 51% of radiologic thrombotic changes of the vessels wall and/or catheter tip and 66% of catheter dislocation from the original place, although this study is quite old and probably does not reflect the current practise [25]. In a prospective study including 30 consecutive patients receiving intravenous feeding (16 of whom had cancer), venography was performed in the 24-h period prior to catheter removal. The percentage of thrombosis found was 33%, but only one patient had symptoms [26].

However, in a recent prospective study of the HAN-CIF ESPEN group in 62 patients, the incidence of CVT with serial Color Doppler Duplex Sonography evaluations for 12 months after catheter insertion was 0.045/catheter/year, quite like that referred in retrospective studies [27]. In this study all the catheters were inserted with ultrasound guide or radiologic control and the catheter tip was in the atrio-caval junction or in the lower third of the superior cava vein in all the subjects.

Diagnosis

The diagnosis of venous thrombosis may be suspected in patients with symptoms due to interrupted venous return (pain, swelling, erythema, positional headache; patients often say they have a sensation of having a swollen head and neck) and signs (oedema, non-pulsatile raised jugular venous pulse and if chronic visible collateral vessels usually on the upper anterior chest wall) in the territory drained by the vein in which the catheter is located. Due to its low specificity (14%), the D-dimer test is not a useful method in screening for deep vein thrombosis of upper extremities [11]. The gold standard method for diagnosis is venography, but it is invasive and requires exposure to intravenous contrast and radiation (Fig. 1). The preferred method for screening is Doppler ultrasonography, which may be employed in both symptomatic and asymptomatic thrombosis as it is a non-invasive method with high sensitivity (97%) and specificity (96%)

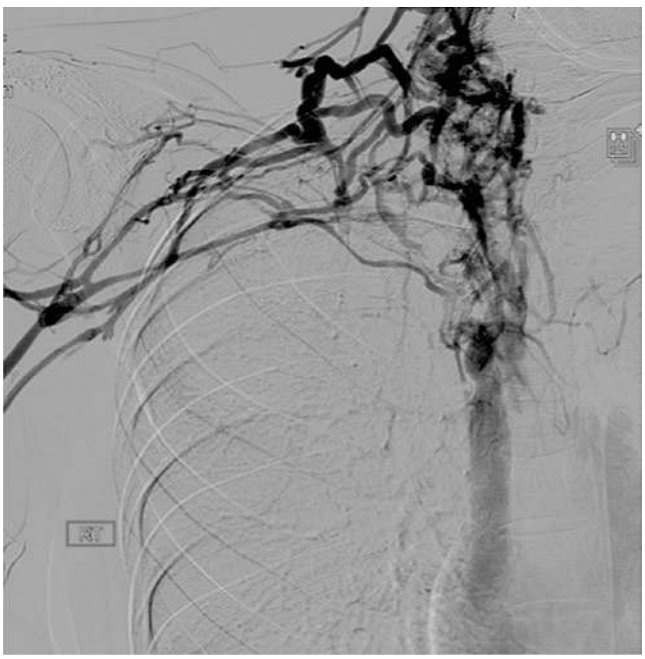

Fig. 1 Right upper limb venography showing occluded right brachiocephalic vein with extensive collaterals

compared to venography in upper extremity deep venous thrombosis [4]. Duplex ultrasound can accurately detect CVT involving the jugular, axillary, distal subclavian and the arm veins. Constrast venographic imaging is required for indeterminate duplex findings and to evaluate the deep central veins and pulmonary arteries.

Alternative strategies such as serially performed ultrasound, spiral CT or MRI may be useful and of potential interest, but are not yet validated [28].

Complications

The main complications of venous thrombosis are infection, pulmonary thromboembolism and post-thrombotic syndrome [1, 11]. Also, intracardiac thrombus has been described in patients on HPS [29].

The infection of the thrombus leads to a septic thrombophlebitis that is a serious complication that requires catheter removal. On the other hand, catheter infection facilitates the development of thrombosis due to the adherence of the components of the thrombus to the *biofilm*. Pulmonary thromboembolism is symptomatic in 4–14% of patients with venous thrombosis of the upper limbs and is asymptomatic in 15–36%, sometimes delayed months or years after catheter withdrawal. Although the post-thrombotic syndrome has been described only in 5% of patients with deep thrombosis of the upper limbs, it may be more frequent in patients on HPN. In the study of Barco et al., 20.7% of the HPN patients with venous thrombosis developed vena cava syndrome [12]. In a retrospective study of 527 patients, including 138 children found an incidence of superior vena cava or inferior vena cava syndrome of 0.02/catheter/year [16]. Moreover, CVT causes loss of central venous accesses and may compromise the administration of HPS in the long-term in these patients.

Prevention

To prevent CVT it is very important to minimize the damage to the vein wall during catheter insertion, recommending using ultrasound guided catheterization, choosing a catheter with the smallest caliber compatible with the infusion therapy, and placing the tip of the catheter at or near to the atriocaval junction [3, 5]. All the risk factors relating to the patient and catheter, previously discussed, should be considered. A thrombophilia screen may be done.

Several drugs have been used in the prevention of CVT, including heparin (in the catheter lock, inside the HPN bag, or administered subcutaneously) and oral anticoagulation (vitamin K antagonists). Also, these studies may be done in primary and secondary prevention of CVT. They have been summarized in several meta-analysis and systematic reviews, but the results are difficult to analyze as they often include a mixed population (cancer and benign disease), hospitalized and at home, different types of catheters, and there are differences in the diagnosis of thrombotic complications (with routine diagnostic imaging or with clinical endpoints) [30–38]. Based on the current evidence the use of routine prophylactic anticoagulation is not recommended in patients with central catheters in different guidelines [39, 40]. In the same direction, ESPEN guidelines do not recommend routine thromboprophylaxis with drugs (heparin, warfarin) for all adults on HPS based on the risk/benefit balance (grade of evidence low) [5].

At least 5 old, randomized studies in patients receiving parenteral nutrition (none receiving HPN) used unfractionated heparin in various doses added in the bag or intravenously and found a trend through less thrombotic events in the venogram [41–45]. However, the safety of heparin prophylaxis due to the risk of bleeding, thrombocytopenia, bone disease, among others, presumably outweighs the risk of thrombosis in many cases.

Regarding HPS adult patients, there are only retrospective and prospective studies, but no large, randomized, controlled clinical trial that evaluates the role of thromboprophylaxis.

Studies on the effectiveness of warfarin in preventing thrombosis in HPN patients are limited and most have used low-dose warfarin (1 or 2 mg/day), which does not increase the INR. One of the factors that may influence the effectiveness of warfarin prophylaxis is vitamin K intake in these patients [46]. Three studies evaluated warfarin prophylaxis in HPN adults. In a prospective non-randomized trial of 2 mg of warfarin given to 23 HPN patients, the incidence of venous thrombosis was 1 in 1617 catheter days compared with 1 in 251 days prior to the study [47]. In a retrospective review of 47 HPN patients with HIV/AIDS, the thrombosis rate was 0.016 per patient per month in 9 patients receiving 1 mg/day warfarin compared with a rate of 0.09 thromboses per patient per month in 38 patients on no prophylaxis [48]. Finally, in a retrospective review of HPN patients who already had 1 thrombotic event, the use of therapeutic warfarin resulted in a significantly decreased thrombosis rate (1 in 18 patient months vs. 1 in 184 patient months) [49].

In a retrospective study in children on HPN, prophylactic anticoagulation with low molecular weight heparin or warfarin significantly decreased catheter-related thrombosis and occlusion [50].

In general, therapeutic warfarin has been associated with a 0.4%–2% annual risk of non-intracranial hemorrhage and an annual intracranial hemorrhage risk of 0.1–0.9%, depending on the INR target range [51]. In a study with patients on HPN the annual incidence of major bleeding was 4.3% for patients on anticoagulants versus 1.8% for those off anticoagulants, heparin-induced thrombocytopenia occurred in 0.6% and heparin hypersensitivity in 2.5% of the patients [12].

In two recent surveys on the current practice of experienced centers on HPN (one in UK, and the other one in the HAN-CIF ESPEN group) most of the centers used warfarin for the prevention of CVT only in patients with previous CVT or other venous thrombotic events [52, 53].

Based on current evidence, the decision to use anticoagulation therapy to prevent venous thrombosis requires an assessment of the risk of thrombosis, bleeding risk with anticoagulation therapy and patient compliance, on an individual basis.

Treatment

Treatment of CVT depends on the chronicity of the condition, the underlying cause, and the clinical presentation [54]. Acute CVT is a medical emergency and its adequate treatment can prevent loss of venous access. BAPEN has recently pubished guidance papers for the appropriate treatment of this relevant catheter complication [55, 56].

The treatment will include thrombolysis if within 14 days of onset of symptoms followed by anticoagulation; otherwise anticoagulation only will be used. There should be an early discussion of the patient with the vascular radiological team. It is important not to remove CVC immediately, as it may be dangerous. However, it may be necessary if thrombolysis is not successful. If there is a residual central venous stenosis then balloon venoplasty can be considered (with or without stenting) and subsequently antiplatelet therapy should be given for 3–6 months, with anticoagulation after this. Figure 2 summarizes the treatment of acute CVT.

Anticoagulation

This is the mainstay of treatment for acute CVT in addition to endovascular procedures as catheter-directed thrombolysis (CDT), pharmacomechanical catheter-directed thrombolysis (PCDT), or percutaneous mechanical thrombectomy (PMT). Endovascular procedures have proven to be effective in improving patient's outcomes [57].

Anticoagulation will prevent progression of the thrombus and preserve patency of the collaterals. Unfractionated heparin is used initially as a bridge until full anticoagulation with warfarin is achieved, with a target INR between 2.0 and 3.0. Unfractionated heparin can be replaced with low molecular weight heparin which is helpful for those patients who can be managed in an outpatient setting [58].

Anticoagulation does not lyse an already existing clot that has formed after CVT. The residual thrombus will impede blood flow and the inflammatory reaction to the thrombus can cause significant narrowing or occlusion [59].

The time on anticoagulant treatment should be individualized, and long-term anticoagulation must be considered, with any decision to cease determined on a case-by-case basis involving discussions with an expert in intestinal failure/parenteral support.

Thrombolysis

Systemic thrombolysis has been proven to cause partial clot removal in randomized clinical trials but is associated with 3–4 times increased risk of major bleeding when compared with anticoagulation alone [60–62].

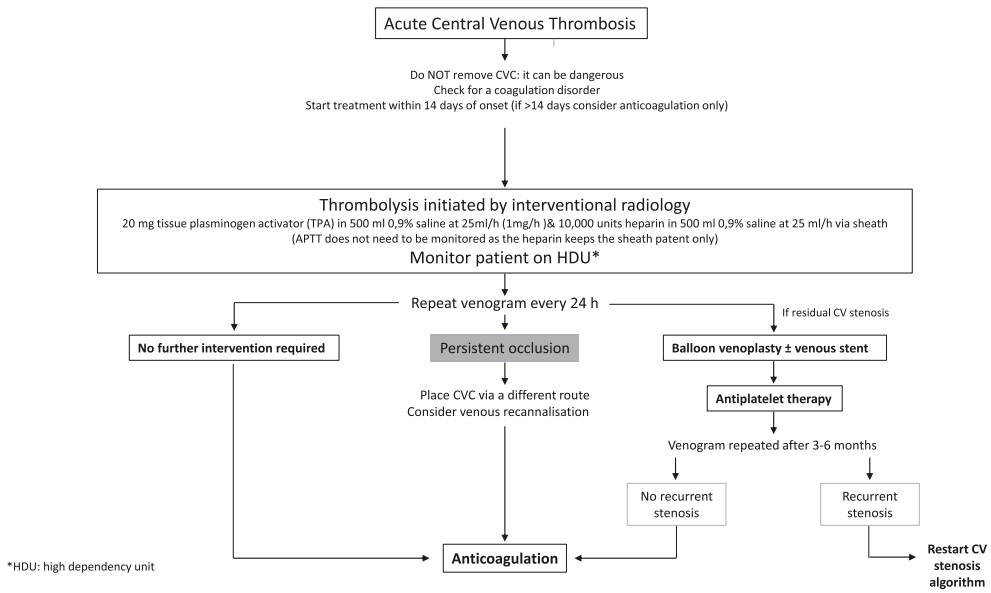

Fig. 2 Algorithm of acute central venous thrombosis treatment. (Modified from [56])

Catheter-directed thrombolysis (CDT) is a procedure where a fibrinolytic drug is infused, over 6–24 h, directly into the thrombus using a catheter with many side holes, that is positioned directly into the clot under fluoroscopy guidance. This ensures that a smaller dose of the fibrinolytic drug achieves a higher intra-thrombus concentration of the fibrinolytic drug, when compared with systemic administration of the drug. This will result in reduced treatment time and hospital stay as well as less bleeding complications. Underlying venous strictures, which might be the precipitating factor for CVT, can be identified and treated at the same time after dissolving the clot [63, 64] (Fig. 3a–d). Heparin is

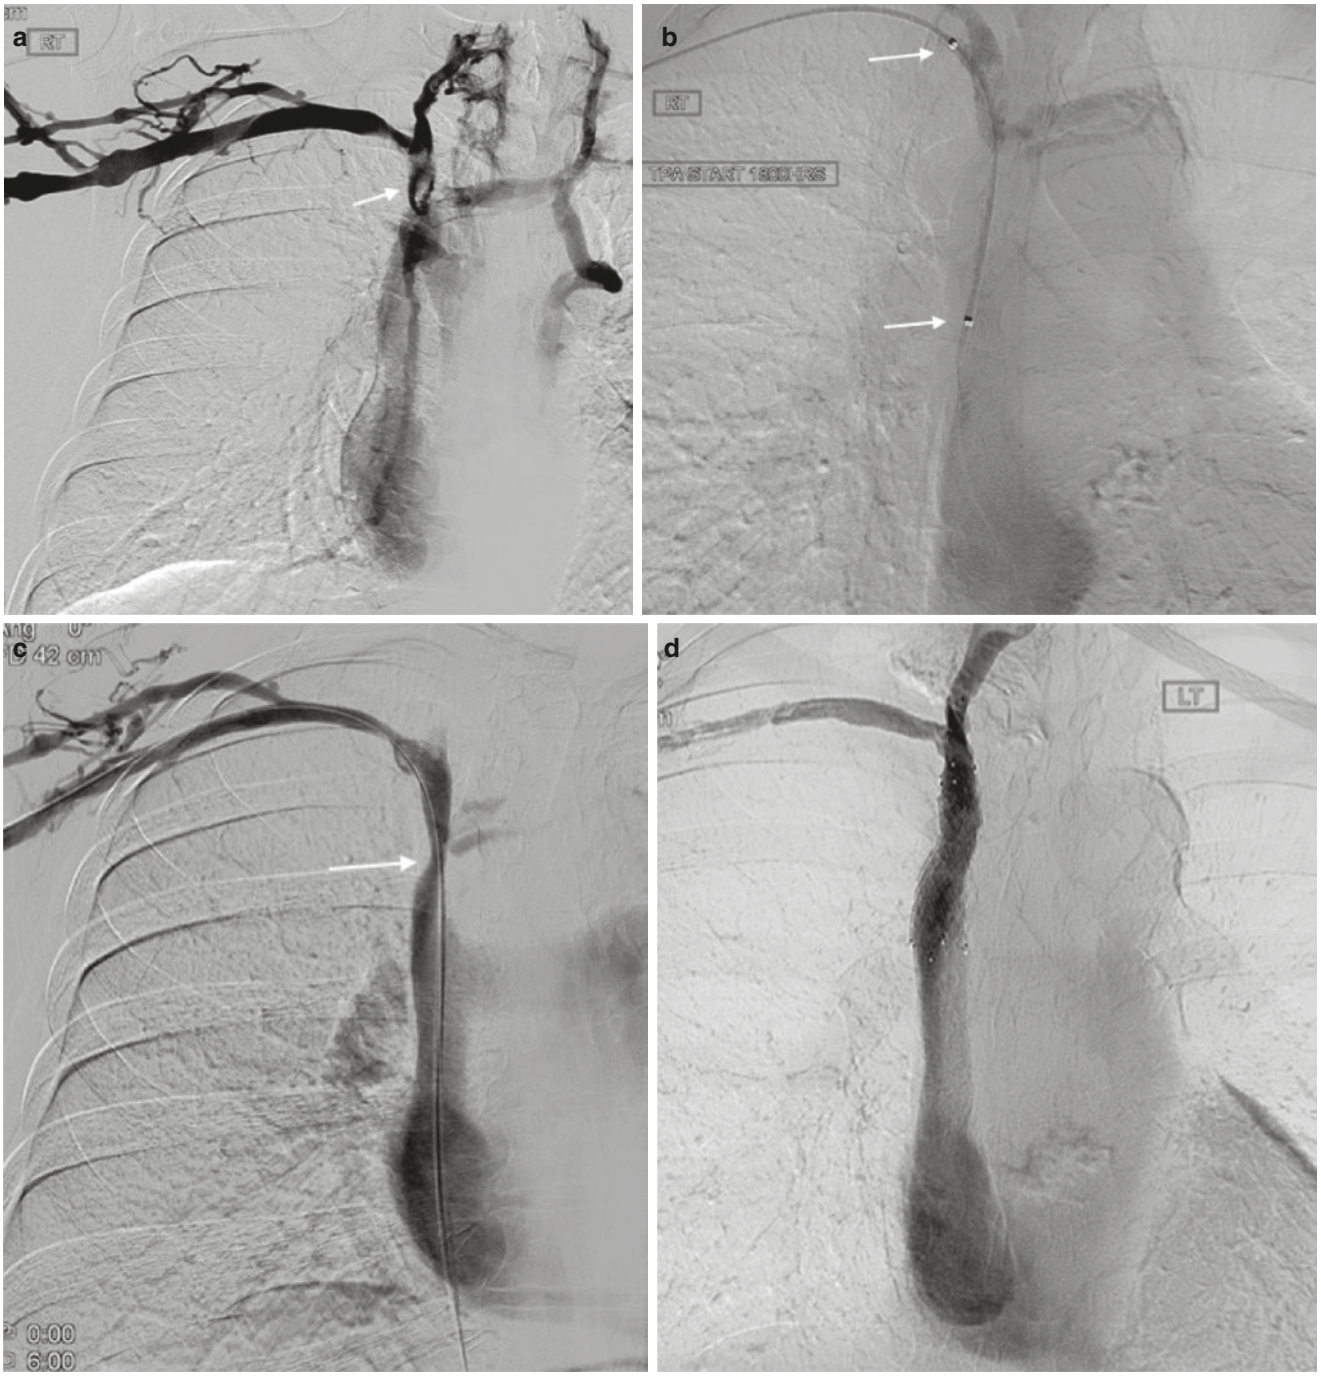

Fig. 3 (**a**) Right upper limb venography showing a thrombus in the form of filling defect in the right brachiocephalic vein (arrow). (**b**) Catheter-directed thrombolysis. A catheter with multiple side holes (identified by two radio-opaque markers on the catheter "arrows") is introduced so that the holes are present within the thrombus. (**c**) Thrombolysis check venography 24 h post initiation of catheter-directed thrombolysis shows complete resolution of the thrombus and an underlying significant stenosis at upper SVC (arrow). (**d**) Self expanding metal stent deployed at site of stenosis

infused at the same time, through the side arm of the vascular sheath, to prevent venous thrombosis around the sheath and the catheter [58].

A successful rate of clot lysis is expected in 80–90% of patients after 1–3 days of the thrombolytic treatment if the thrombus is less than 2 weeks old [64].

Cases should be individually assessed to address the factors that might increase the risk of bleeding, which is a potential serious side effect of CDT. Those factors include active or recent bleeding, recent major surgery or trauma, recent haemorrhagic stroke, or bleeding-prone lesions in critical areas like the central nervous system, and uncontrolled hypertension [65, 66].

The incidence of major bleeding is estimated to be 2–4% only with infusions of recombinant tissue plasminogen activator at low doses (0.5–1.0 mg/h) [67–69].

The addition of a mechanical thrombectomy device to intrathrombus administration of the fibrinolytic drug is called pharmacomechanical CDT (PCDT). Devices like AngioJet (Possis Medical Inc) and Aspirex (Straub Medical) have been widely used. Retrospective studies have suggested that PCDT can further reduce the dose of fibrinolytic therapy needed to lyse the clot as well as treatment time [70, 71].

Thrombolysis restores venous flow early on, prevent endothelial damage and subsequent long-term complications like stenosis and occlusions which are detrimental to patients on parenteral nutrition [72–74].

When thrombolysis restores venous patency, and if there is an underlying significant venous narrowing, endovascular treatment options include percutaneous transluminal angioplasty (PTA) and bare metal stents (BMS). Several studies have demonstrated variable success rates for all these procedures [75–79].

The most common complication of thrombolysis is puncture site oozing or bleeding. This is usually responsive to manual compression or extrinsic compression using bandages. Allergic reaction to the fibrinolytic drug can occur and is more likely to happen with Streptokinase.

Balloon Angioplasty

Balloon angioplasty is usually performed for chronic venous narrowing/occlusion. Noncompliant high-pressure balloons with diameters from 8–16 are needed to dilate the narrowing or occlusion in the central veins. These balloons have a higher rated bursting pressure (up to 18 atm.) compared with the standard balloons. If a significant residual narrowing (>30%) is still present post balloon angioplasty with persistent filling of the collaterals, insertion of a bare metal stent is advised to prevent recurrence of CVT [80].

PTA for central venous disease has a technical success rate of 70–90% [75, 78, 79, 81–83]. One of the largest studies for PTA demonstrated a cumulative patency rate of 76% at 3 months, 62% at 6 months, and 53% at 12 months [84].

Repeated interventions with PTA might be needed for central venous disease to maintain patency for a long duration [82, 83].

Stenting

Bare metal stents (BMS) will provide mechanical support and are indicated if the following conditions: (1) significant residual stenosis (>30%) after PTA (2) dissections or circumscribed perforations after PTA (3) post recanalization of venous occlusions. Stents can migrate, shorten, fracture, or get luminal instent narrowing due to intimal hyperplasia, which will require frequent ballooning. As no proven advantage has been noticed in BMS over PTA, stent deployment should be restricted to the above-mentioned indications [82–84]. Primary and cumulative patency rates of BMS at 3 months are 63–100% and 72–100% respectively, 42–89% and 55–100% at 6 months, and 14–73% and 31–91% at 12 months [78, 79, 82–93]. Flexible, self-expandable bare-metal stents are preferred as they can conform with the tortuosity of the veins and enough radial strength for most venous occlusions [94]. In patients with Paget-Schroetter syndrome (venous thoracic outlet syndrome), stent insertion across the first rib/clavicle is a contraindicated due to high rate of stent fracture and occlusion [95].

Covered stents (CSs) might have the advantage of reduced endothelialisation and in-stent stenosis while still provide the mechanical effect of the BMS. The disadvantages of CSc are occlusion of collateral veins, accidental cover of nearby veins like the internal jugular or the contralateral brachiocephalic vein and the high cost [96].

In cases with chronic occlusion of the central veins, the combination of catheters and glide wires is tried first to cross the occlusion. This is followed by prolonged ballooning with or with stent insertion. If conventional wire manipulation was unsuccessful in crossing the lesion, sharp recanalization using the back of a stiff wire, or a thin-gauge needle can be attempted [95]. If the occlusion could not be crossed with this technique, a longer sheath is advanced as close as possible to the occlusion and angled or straight glide wires (Terumo) with glide catheters are usually successful in crossing the occlusion [96]. If not, a second venous access in performed from the right common femoral vein under US guidance and a glide catheter and wire are used to negotiate the occlusion from below. More aggressive techniques like using the back end of a stiff wire or a thin trocar needle and trocar cannula can be used to cross tough and fibrotic lesions [58] (Fig. 4a–e).

Cases with complete occlusion of the central veins, including those who will require access from brachial / subclavian and femoral veins, and even those in whom thin needles are needed to cross the occlusions are not associated with higher complication rates [97].

Fig. 4 (**a**) Left upper limb venography confirms an occluded left brachiocephalic vein (arrow) with multiple bridging collaterals. Crossing the lesion with an angled glide wire was unsuccessful. (**b**) A long sheath with an angled glide wire were advanced form the left upper limb venography puncture site (straight arrow) and a curved catheter (curved arrow) was introduced into the upper SVC for a right common femoral vein puncture to help in crossing the occlusion. (**c**) The occlusion was crossed, and an 8 mm diameter balloon is used to dilate the track before stent deployment. (**d**) Two self-expanding metal stents deployed at site of occlusion and dilated using a 10 mm diameter balloon. (**e**) A feeding line was inserted from a separate left subclavian vein puncture and through the stents. Note that the tip of the feeding line was kept at lower SVC / upper part of right atrium to reduce the risk of catheter-induced venous narrowing (arrow)

Complications of Balloon Dilatation and Stenting

PTA and stent insertion for venous narrowing or occlusions are considered safe procedures [83, 97–100]. Puncture site bleeding, which is usually mild even in patients who are anticoagulated, can be easily managed with manual compression. Venous perforation, which can happen during sharp recanalization is not associated with serious comorbidities and serious bleeding is rate, as there is low or zero flow at the site of perforation [82, 83, 100].

Recanalization and stenting for chronic venous occlusion is associated with severe pain and adequate pain management is needed. Most of the cases will be performed under general anaesthesia but the pain might persist for few days after stent insertion [82, 83].

Stent can migrate especially if under-sized. If they migrate to the heart or the pulmonary circulation, they should be removed as soon as possible [100]. Increased venous return that can occur after venous recanalization of major central veins has been reported to cause pulmonary oedema [101]. Stent thrombosis can happen, which can be treated with thrombolysis or anticoagulation. In stent stenosis, due to endothelial hyperplasia can be treated with repeated balloon angioplasty rather than an additional stent insertion [100]. Over dilatation of the SVC can cause arrhythmia or even cardiac arrest [102].

Surgery

Extrinsic venous compression causing chest outlet syndrome (Paget-Schroetter syndrome) can be surgically treated with resection of the anterior part of the first rib or clavicle. After successful thrombolysis, if a residual narrowing over the anterior part of the first rib is seen, a venogram in neutral and abducted positions should be performed. If venous flow is imbedded in abducted position only, this would confirm a chest outlet syndrome, and surgical treatment should be considered before balloon venoplasty or stent insertion. This approach will ensure long term patency of the treated vein [74, 102–105].

Surgical thrombectomy is an invasive procedure, needs general anaesthesia and can be complicated with pneumothorax, brachial plexus injury, and is usually attempted in thrombolysis refractory cases [72].

Part VIII

Surgical Treatment of Chronic Intestinal Failure

Surgery for Patients with a Short Bowel and Tissue Engineering

Mattias Soop, Laween Meran, Jeremy M.D. Nightingale, and Jon S. Thompson

Key Points

1. Surgery for patients with a short bowel is either to manage the complications resulting from the resection (e.g. abdominal wound, gallstones or renal stones) or to use surgical procedures to maximize the function of the existing intestine.
2. The vast majority of surgical procedures to improve absorption involve standard techniques such as recruiting additional intestine into continuity, relieving obstruction or tapering massively dilated segments.
3. Less common surgical techniques involve lengthening and tapering the bowel or slowing the passage of chyme through the small intestine.
4. Various procedures to slow intestinal transit have been attempted but long term efficacy and benefit have not been demonstrated.
5. The longitudinal intestinal lengthening and tapering (LILT or Bianchi) procedure may increase the absorption surface of the remnant bowel, but can only be performed on a dilated small bowel and is rarely technically possible in adults.
6. The serial transverse enteroplasty (STEP) procedure is technically less challenging than the LILT procedure, and is now more used in both children and adults.
7. Small bowel mucosa may be grown and placed in a synthetic or biological scaffold; however, work continues to form a neural network. In future a tissue engineered graft may be an option to small bowel transplantation.

Introduction

There are two important roles for surgical procedures in the management of patients with a short bowel. One is the management of complications related to the massive intestinal resection and the resulting pathophysiology. The other is to employ surgical procedures therapeutically to maximize the function of existing intestine.

Surgical Management of Complications

Approximately 50% of patients with a short bowel will require re-operation after their initial time in hospital [1]. These procedures are most frequently required for intestinal problems and cholelithiasis. Gastric acid hypersecretion is no longer a commonly encountered, probably [2] as most patients are given proton pump inhibitors. The important aspects of management are shown in Table 1.

Table 1 Surgical management of complications

Intestinal problems

Intestinal Problems

Two-thirds of re-operations in patients with a short bowel are for intestinal problems. Many are related to the underlying intestinal disease or to mechanical challenges to the intestine from adhesions or hernias, requiring further resection or management of obstruction or fistula. During these procedures an important goal is to preserve as much of the intestinal remnant as possible. There are several strategies that can be used to preserve intestinal length when further intestinal disease occurs in patients with short intestinal remnants. These include employing intestinal tapering for dilated segments, stricturoplasty for strictures and serosal patches for strictures and perforations to avoid resection [3] (Fig. 1). If resection is necessary, minimal resections should be performed whenever possible. An end-to-end anastomosis is preferred when maintaining length is the goal.

Whereas normally a surgeon might discard a few inches of intestine to avoid another anastomosis, this should be given careful consideration in patients with a short bowel where each additional centimetre of bowel becomes important. Such consideration will take into account the length of bowel already in continuity, the relative gain of the additional segment(s) as well as the type of bowel under consideration: jejunum, ileum or colon. The colon is often thought of as an organ absorbing only water and sodium. However, the colon and rectum also absorb energy in the form of short-chain fatty acids resulting from the microbial metabolism of polysaccharides [5].

Cholelithiasis

As discussed in chapter "Gallstones in Intestinal Failure" cholelithiasis eventually occurs in approximately half of patients (adults and children) with a short bowel requiring parenteral support [3, 5–15]. These patients have a significantly increased risk of developing cholelithiasis (about 75%) when the remnant length is less than 120 cm, total parenteral nutrition (TPN) is required and the terminal ileum is resected [14, 15]. Furthermore, these patients have more complicated biliary tract disease and increased postoperative morbidity and mortality rates [11, 14]. In one study, 40% of these procedures were performed as an emergency, with a complication rate of 54% and mortality of 11% [11]. Delay in diagnosis may contribute to this poor outcome, particularly because of the confounding effect of Intestinal failure associated liver disease (IFALD). Thus, the diagnosis should be suspected and ultrasonography performed liberally to permit early diagnosis. The significant morbidity of symptomatic cholelithiasis in these patients has led to recommendation of prophylactic cholecystectomy, even before cholelithiasis develops [11, 14]. This is particularly appropriate in patients with benign conditions and anticipated long-term survival. While cholecystectomy may not be advisable at the time of the initial massive resection, it should be considered at the time of other abdominal operations in those patients who have developed gallstones [15].

Abdominal Wall Protection

Many enterocutaneous and, even more so, enteroatmospheric, fistulas severely worsen a patient's quality of life [16] by causing frequent leakages under the skin appliance of the fistula bag, destruction of the surrounding skin with associated chronic pain, and the requirement for very lengthy and frequent procedures for fistula dressings. Resection of the fistula is sometimes indicated on the basis of this indication alone, even in cases where there is no scope for a significant increase in absorptive capacity. A clinical observation is that the improvement in quality of life when such a fistula is resected and converted into a conventional stoma, even if high-volume, is very significant.

Occasionally, patients with fistulas develop chronic cavities in the abdominal wall, resulting in accumulation of infected fluid. When it is not possible to control such cavities by drainage procedures, the patient may need to stay nil by mouth. Resecting such fistulas, or diverting them proximally, will often resolve the chronic abdominal wall sepsis and allow patients to resume an oral diet.

Surgical Therapy for Patients with a Short Bowel

The goal of surgical therapy is to increase intestinal absorptive capacity by either improving absorption by existing intestine or by increasing the area of absorption (Table 2). Absorption can often be improved by recruiting additional intestine into continuity, relieving obstruction, or slowing intestinal transit. Intestinal lengthening is feasible in selected patients but obviously the most significant increase in length is achieved by intestinal transplantation (chapter "Intestinal Transplantation").

Adjunctive procedures for surgical therapy of patients with a short bowel should not be performed at the time of initial resection [17, 18]. They add potential morbidity in patients who are already quite ill. Furthermore, intestinal adaptation, in patients with retained ileum and/or colon, will often result in sufficient improvement in absorption to obviate the need for additional therapy. This is particularly true in children, where additional growth occurs. Adaptation may avoid the need for PN in almost half of patients [19, 20].

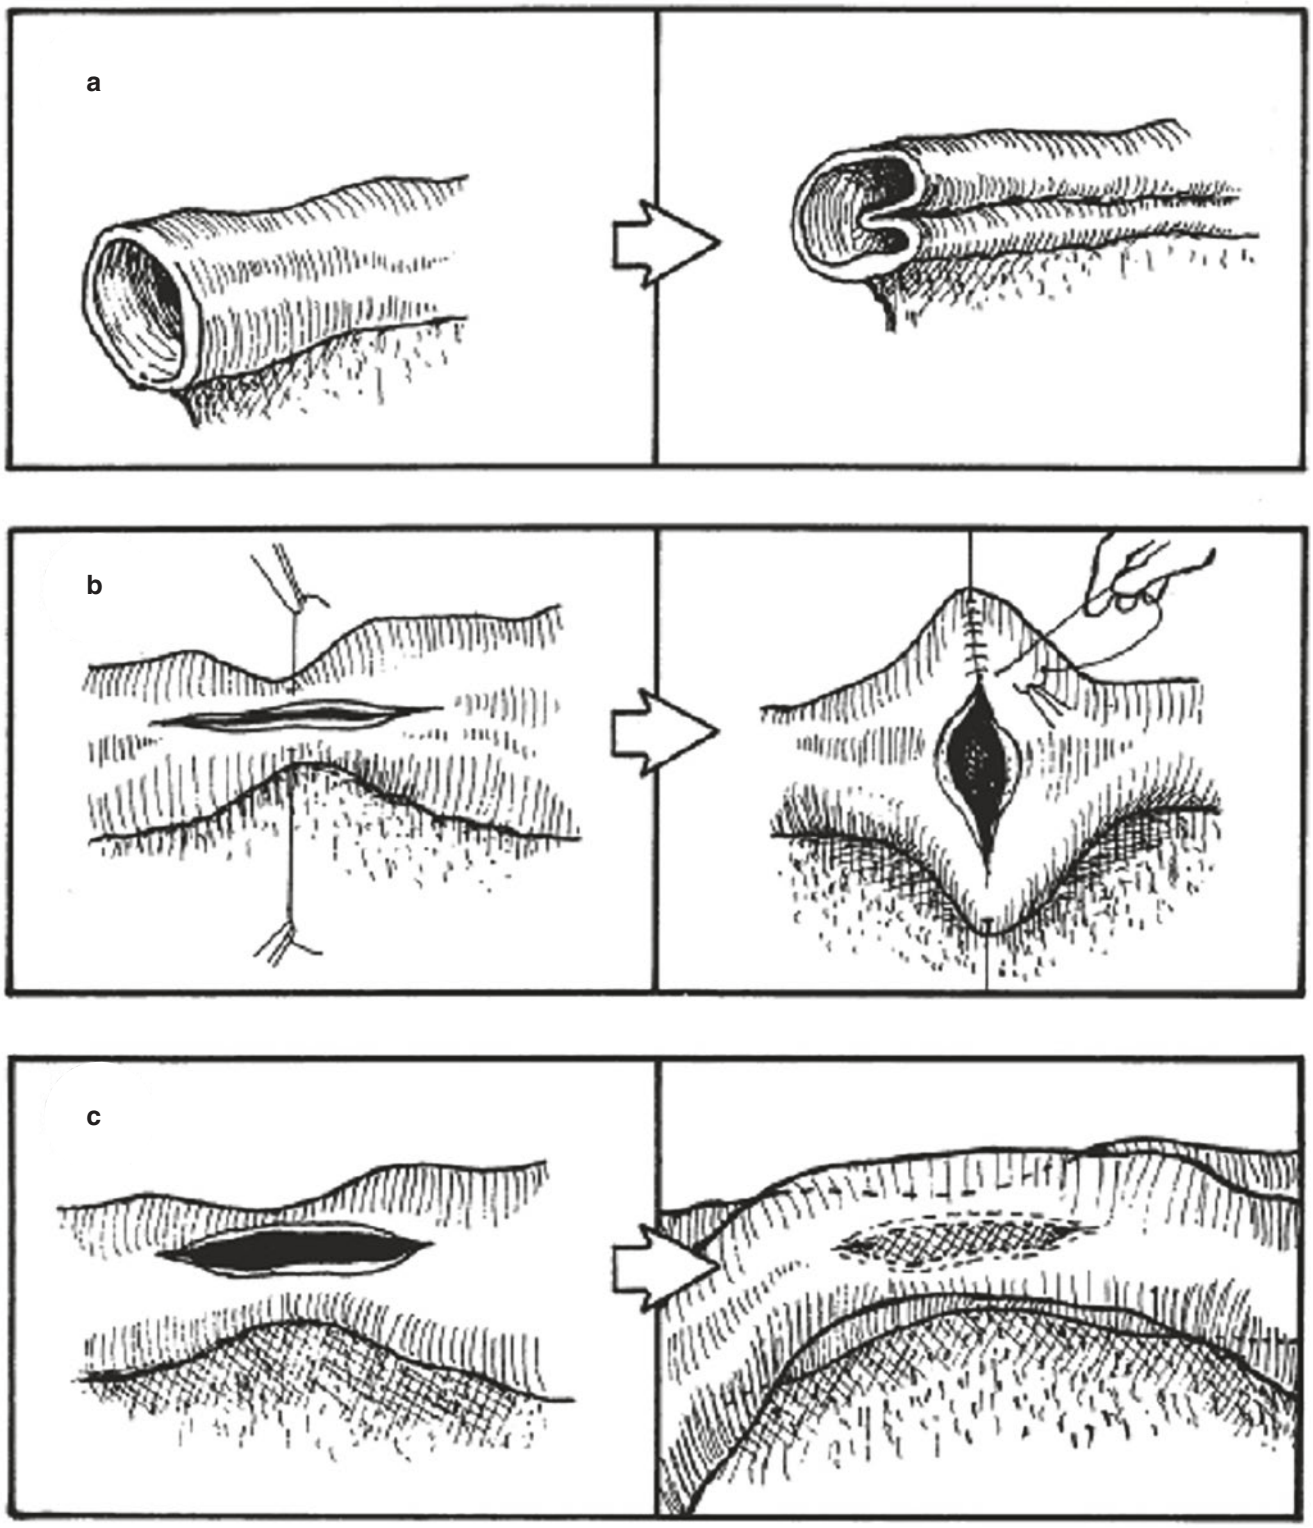

Fig. 1 Techniques for preserving intestinal length include tapering of dilated segments rather than resection (**a**), stricturoplasty for strictures (**b**), and serosal patches for strictures and perforations (**c**). (Reproduced with permission from Thompson [4])

Such adaptation may take longer than previously thought; a substantial proportion of patients continue the adaptive process beyond 10 years [20].

Moreover, there is evidence to suggest that performing such procedures (e.g. colon interposition and serosal patching), at the initial resection may diminish the degree of adap-

Increase intestinal length
• Intestinal lengthening

tation that occurs [19, 21]. Thus, surgical therapy for patients with a short bowel should only be undertaken after the initial adaptive period and even then with specific objectives.

The nature of nutritional support is the primary factor to be considered when surgical therapy for patients with a short bowel is contemplated. Patients supported by enteral nutrition (EN) alone should be considered for operation only if they demonstrate worsening malabsorption, are at risk for receiving parenteral nutrition (PN) or have other symptoms related to malabsorption. Patients who are stable on PN should undergo surgical therapy only if this would permit them to discontinue or significantly reduce PN. Patients who develop significant complications from PN will eventually require either combined liver–intestine or solitary intestine transplantation.

Optimising Intestinal Function

Recruiting any additional intestine into continuity with the gastrointestinal tract is an important objective in managing patients with a short bowel. Intestinal absorptive capacity can be increased and transit time prolonged. Recruiting downstream intestine may simply entail exchanging a more proximal jejunostomy for a more distal colostomy or actually closing a stoma. However, occasionally other intestinal segments are available. For example, continuity has been restored using an ileal segment previously used as a urinary conduit in a patient with a short bowel; this ameliorated diarrhoea and steatorrhoea [22].

Many patients have stomas created at the time of massive resection [23]. Whether or not intestinal continuity should be restored at a later time will depend on several factors, including length of intestinal remnant, status of the ileocaecal valve and colon and the overall condition of the patient. While some patients function well with very short intestinal remnants, generally at least a metre of small intestine is required to prevent severe diarrhoea and perianal complications [23, 24]. Only 20% of the patients with an initial stoma had intestinal continuity restored at a later time [23]. Moreover, only one-third of the patients in whom continuity was maintained at initial resection had a satisfactory long-term outcome. In addition to improving absorption, maintaining intestinal continuity eliminates the inconvenience of the stoma. This has more than psychological advantages since patients with a stoma are more likely to have catheter-related blood stream infections (CRBSI) [25]. Furthermore, malabsorbed carbohydrates that reach the colon are metabolized to short-chain fatty acids by colonic bacteria [26]. Short-chain fatty acids improve fluid and electrolyte absorption, are absorbed as additional energy and may be trophic to the intestinal remnant [26, 27].

There are also a number of potential risks inherent in restoring intestinal continuity. Bile acids cause secretion of fluid in the colon and may exacerbate diarrhea. Thus, there may be more perianal complications and resultant dietary restrictions. 60% of patients in one study had dietary restrictions with intestinal continuity compared to 33% with a stoma [23]. Also, calcium oxalate kidney stones occur more frequently because of absorption of unbound oxalate from the colon (chapter “Nephrolithiasis and Nephrocalcinosis”). In another study no patients with a jejunostomy had nephrolithiasis compared to one-fourth of patients with a short bowel and an intact colon [13].

Predicting the functional outcome after restoring intestinal continuity in individual patients with short remnants is difficult. In general, Carbonnel et al. [28], found that a jejuno-ileal anastomosis is equivalent to adding 80 cm of small bowel and a jejuno-colic anastomosis equivalent to 25 cm of small bowel in terms of improved energy absorptive function compared to a jejunostomy. Patients with a marked increase in stomal output in response to feeding will not do well unless a significant amount of small intestine is recruited distally. As adaptation to a short bowel is a process that continues for several years, sometimes beyond a decade [20], it is not necessary to await completion of this process until surgery to restore intestinal continuity is undertaken.

Assessing the effect of the distal bowel on absorption has been evaluated by using an external reinfusion apparatus [29] (chapter “Distal Feeding and Hydration”). This technique is somewhat cumbersome and requires access to the distal remnant. A smaller reinfusion device that resides in the stoma bag itself has been introduced with favorable results [30]. The potential roles of chyme reinfusion are in evolution, and include evaluation of the effects of restoration of continuity on bowel absorption and function; trophic feeding of the distal gut to prepare this for re-anastomosis and improved recovery; and in some cases a replacement of parenteral support altogether.

The proximal intestine may become markedly dilated secondary to chronic obstruction and/or structural adaptation in patients with a short bowel. In adults this is usually due to obstruction secondary to stenosis. A useful approach in these

patients is simply to relieve the obstruction. Stricturoplasty may be efficacious [19]. Dilated bowel is less frequently due to obstruction in children and may be a variant of intestinal pseudo-obstruction. The resultant stasis and bacterial overgrowth further aggravates malabsorption. These large diameter segments of intestine have low contraction pressures that result in poor propulsion [31]. Therefore, tapering dilated segments should improve motility in these patients.

Intestinal Tapering

Intestinal tapering has been reported in at least 27 children with a short bowel and dilated intestine [19, 31, 32]. Absorptive function, growth and development improved in all cases. Patients had bacterial overgrowth but only one-fourth had an associated mechanical obstruction [19]. All had transient functional improvement but 2 of 11 required further procedures for recurrent malabsorption. Many patients experienced a prolonged postoperative ileus. Segments ranging from 15 to 35 cm in length were tapered on the antimesenteric border. Tapering can be accomplished by either resection or simply turning in the redundant tissue. Overlapping the redundant intestine results in more normal intestinal structure and function than tapering by longitudinal transection and is the preferred approach [33].

Slowing Intestinal Transit

The earliest surgical therapeutic attempts for patients with a short bowel involved using techniques to retard intestinal transit [34]. These have included antiperistaltic segments, artificial valves, colon interposition and other approaches (Fig. 2). These procedures are most appropriate in patients with sufficient intestinal surface area but rapid intestinal transit. Massive intestinal resection results in markedly shortened intestinal transit time, which contributes to malabsorption and diarrhoea. The evolution of pharmacological agents that slow gastrointestinal transit, including glucagon-like peptide analogues (chapter "Pro-adaptive Hormones in the Rehabilitation of Adult SBS Patients"), has reduced the role of these operations.

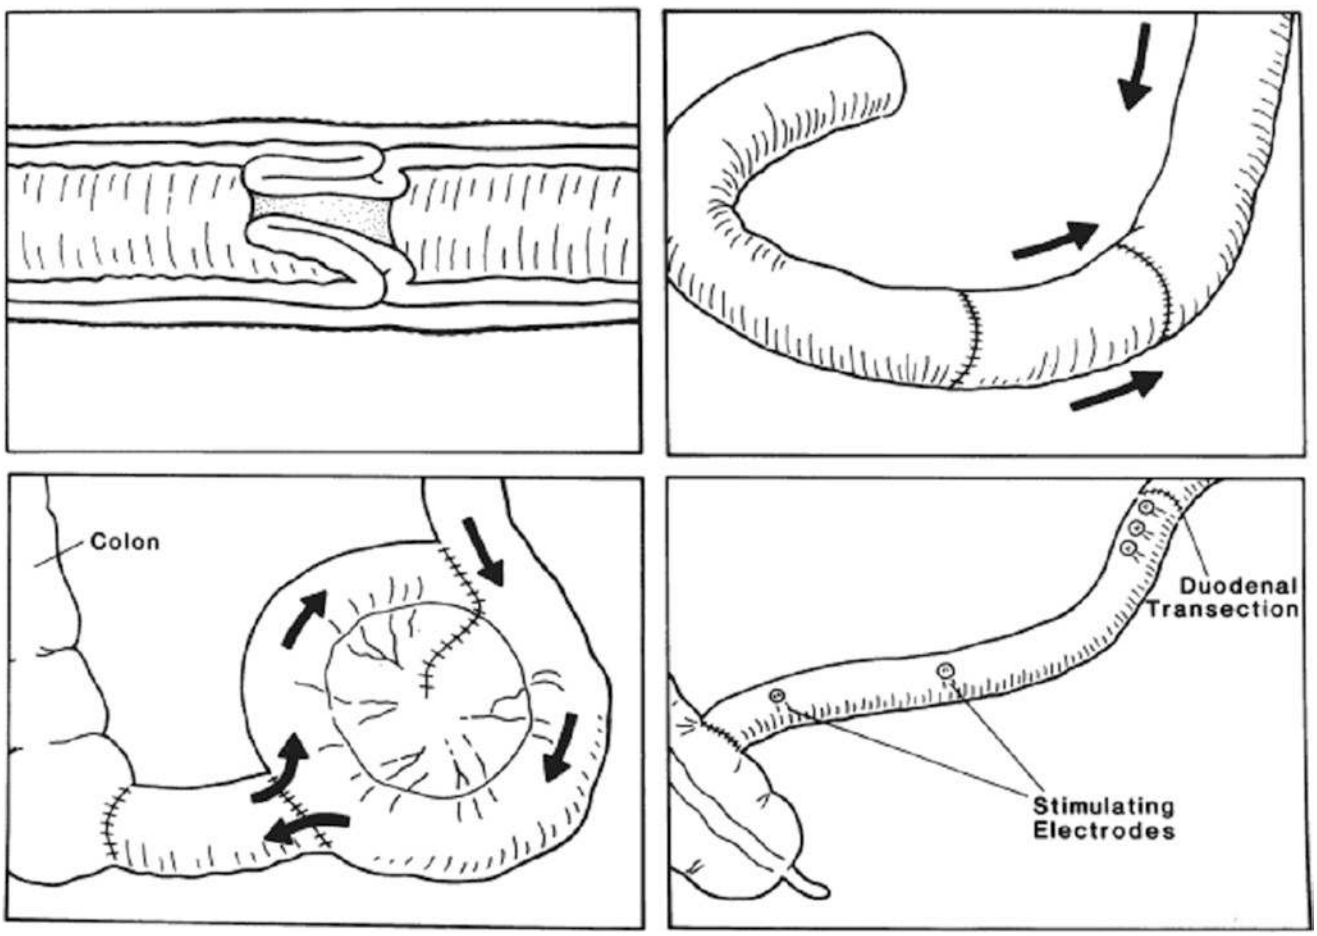

Fig. 2 Techniques for slowing intestinal transit: intestinal valve (upper left), antiperistaltic segment (upper right), recirculating loop (lower left) and intestinal pacing (lower right). (Reproduced with permission from Thompson [4])

Antiperistaltic Segments

Reversing segments of intestine to slow intestinal transit has been studied extensively. The antiperistaltic segment acts as a 'physiologic valve' by causing retrograde peristalsis and disrupting the motility of the proximal intestine. The disruption of the intrinsic nerve plexus slows distal myoelectrical activity [35]. Although retrograde peristalsis has been demonstrated radiologically, this finding does not always correlate with improved function [36]. Antiperistaltic segments slow intestinal transit, improve absorption, reduce weight loss and prolong survival after intestinal resection in some experimental studies but others report no beneficial effect [37–39].

These conflicting results may be partly explained by the different lengths of antiperistaltic segments used. While the ideal length of the antiperistaltic segment is not clear, lengthy segments may produce significant obstruction and short segments may be ineffective. In one study an intestinal valve was more effective than an antiperistaltic segment in prolonging transit time after resection, but neither procedure improved absorption [40].

Antiperistaltic segments have been used clinically in more than 80 patients, the majority being adults [19, 41–46]. Slowed intestinal transit and increased absorption occurs [45]. They benefit half of the selected patients with a short bowel who have rapid transit but adequate remnant length. The outcome in individual patients is difficult to predict and subsequent surgery was frequently required [44]. Transient obstructive symptoms and anastomotic leak are potential problems [39, 42]. While the length of the segment has varied from 5 to 15 cm in these reports, the ideal length of the reversed segment seems to be approximately 10 cm in adults and 3 cm in children. In one study a reversed segment that initially increased absorption could not be demonstrated radiologically 6 months later [45]. Furthermore, initial manometric abnormalities in the proximal intestine may resolve with time which may explain loss of function over the long term this procedure [46]. Another limitation of this procedure is that patients with shorter intestinal remnants may not be able to afford to sacrifice a 10-cm segment for reversal.

Intestinal Valves and Sphincters

The terminal ileum and ileocaecal valve may be important in retarding intestinal transit of nutrients and preventing reflux of colonic contents. The presence of colonic contents in the small intestine may alter motility and may contribute to bacterial colonization of the small intestine and further malabsorption. An intact ileocaecal valve permits survival in children with only 11 cm of small intestine remaining, whereas those who lost their ileocaecal valve required at least 25 cm of small intestine for survival without PN [47].

Intestinal valves and sphincters have been created by a variety of different techniques. These include constricting the intestine externally, denervating segments of intestine and increasing intraluminal pressure by intussuscepting intestinal segments [48–55]. Thompson et al. generally creates a sphincter similar to that employed in the continent ileostomy procedure but only 2 cm in length [19]. The effect of valves and sphincters on intestinal motility is complex, involving several different mechanisms. They create a partial mechanical obstruction, prevent retrograde reflux of colonic contents and disrupt the normal motor pattern of the small intestine, converting jejunal motor activity to a pattern more similar to the ileum [51, 54, 55]. While intestinal valves and sphincters have been shown to lengthen transit time, increase absorptive capacity and prolong survival in several experimental studies, results have been inconsistent [49, 50, 52, 54, 55]. Effective valves usually cause some dilation of the proximal intestine and may result in obstructive symptoms. Necrosis of the valve, complete obstruction and intussusception are potential complications. Valves may lose the sphincter function with time [49].

Clinical experience with intestinal valves and sphincters has been limited with approximately 25 cases reported [19, 48, 51, 56]. Intussuscepted valves have been reported in six patients with a short bowel [19, 48, 51]. Four patients improved markedly, one remained unchanged and the other had an obstruction necessitating take down of the valve. However, in one long-term study ileocolic nipple valves were lost in one-third of patients followed for more than 5 years [56]. As described below, nipple valves have recently been utilized to cause dilation of the intestine to permit subsequent intestinal lengthening [57].

Colon Interposition

Isoperistaltic and antiperistaltic colon interposition will retard intestinal transit. Isoperistaltic transposition is performed proximally and functions by slowing down the rate at which nutrients are delivered to the distal small intestine [21, 58]. The antiperistaltic colon interposition is placed distally, similar to the reversed small intestinal segment, but has the advantage that none of the small intestine remnant is used. In addition to the effect on transit time, interposed segments absorb water, electrolytes and nutrients [59]. Experimental studies demonstrate that isoperistaltic colon interposition, either proximal or distal to the small intestinal remnant, resulted in slower transit time, less weight loss and increased survival without producing intestinal obstruction [58–60]. While one investigator also demonstrated prolonged transit time with isoperistaltic colon interposition, no significant improvement in body weight or intestinal absorption was found [21]. The length of colon interposed seems to be less critical than with reversed segments. However, results with antiperistaltic colon interposition have been less consistent [61, 62].

The use of colon interposition has been reported in ten patients. Isoperistaltic interposition was performed in nine of these patients, of whom eight were infants less than 1 year of age [63–67]. The length of colon interposed varied between 8 and 24 cm. All patients were dependent on PN and had intestinal remnants ranging from 15 to 63 cm in length. Four infants were weaned off PN within 4 months and survived. Diarrhoea improved in one infant who subsequently died of pneumonia. Three patients did not improve and subsequently died of sepsis or hepatic failure. An adult patient had transit time prolonged from 10 to 25 min and a 50% reduction in PN [65]. Thus, isoperistaltic colon interposition has shown some promise as a therapeutic alternative. In a single report of antiperistaltic colon interposition, an infant eventually died after initial increase in weight and slowing of intestinal transit time [67].

Recirculating Loops

Theoretically, intestinal pouches and recirculating loops would prolong transit time by permitting repeated or prolonged exposure of luminal nutrients to the intestinal absorptive surface [68, 69]. However, these procedures have been associated with high morbidity and mortality rates in experimental studies and do not clearly improve absorption or survival rates after massive resection [70, 71]. The results of few anecdotal clinical reports using recirculating loops have not demonstrated clear benefit [72–74]. The three adults were followed for 7, 10 and 24 months. Two died and increased absorption was not clearly demonstrated. Cywes [75] previously created a proximal jejunal pouch with a distal 4-cm antiperistaltic segment in an infant. After 3 months transit time was prolonged, but improved absorption was not demonstrated.

Retrograde Electrical Pacing

Retrograde electrical pacing has also been investigated as a means of prolonging transit time [76–78]. This promotes peristalsis in a reverse direction and also alters the motility of non-paced intestine, presumably through a hormonal mechanism [78]. In experimental studies, postcibal retrograde pacing improved absorption of water and minerals after intestinal resection [76, 77]. In addition, weight loss and faecal fat and nitrogen excretion were decreased. Intestinal pacing has been used clinically in only one patient with a short bowel, but the pacemaker failed to stimulate the intestine [79]. In humans, the natural pacemaker potential frequency is similar throughout the length of the small intestine. Intestinal transection does not alter the pacemaker frequency of the distal intestine [80]. Because the pacemaker frequency cannot be increased above the natural rate in the intact intestine, it may not, in fact, be feasible to entrain the intestine to achieve retrograde pacing in humans [81].

Increasing Intestinal Length

Longitudinal intestinal tapering and lengthening (*LILT*), which has the attraction of not only tapering the dilated intestine but also using the redundant intestine for additional length, was initially described by Bianchi in 1984 [82]. Dissection is performed longitudinally between the blood vessels on the mesenteric border of the intestine, allocating vessels to either side of the intestinal wall (Fig. 3). A relatively avascular plane can be developed because these vessels enter the intestine from either side of midline. The intestine is then transected longitudinally with clamps or a

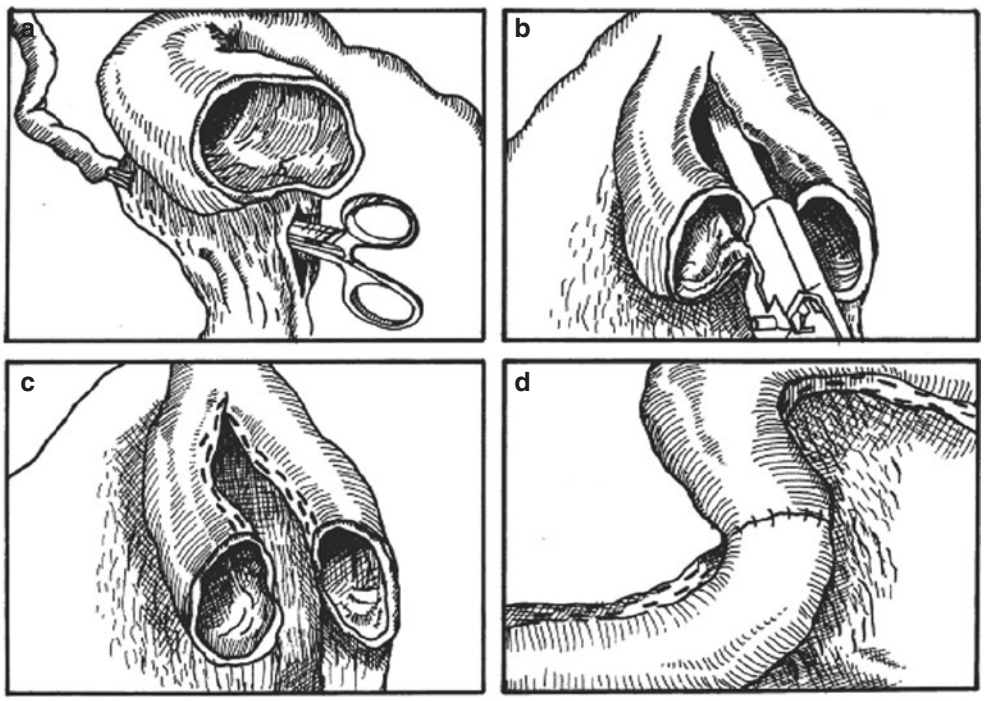

Fig. 3 Longitudinal intestinal tapering and lengthening (LILT). Dissection longitudinally between the blood vessels on the mesenteric border (**a**) permits the stapler to be used to divide the bowel longitudinally (**b**, **c**). The two parallel segments are then anastomosed end-to-end (**d**). (Reproduced with permission from Thompson [4])

stapler. The resultant parallel intestinal segments are then anastomosed end-to-end so that the initial dilated segment becomes a segment of one-half the diameter and twice the length. In the short-term this procedure disrupts motor activity and alters the hormonal response to resection [83]. However, long-term patency and function of divided segments has been demonstrated with resultant improved absorption.

The Bianchi procedure has been reported in more than 50 children ranging in age from 1 day to 19 years [57, 83–85]. Bacterial overgrowth and complications of TPN were present frequently. Significant improvement in nutritional status occurred in approximately 90% of patients in these reports. Segments as long as 55 cm have been tapered and lengthened. Complications have been reported in 20% of cases. In one patient in whom a 25-cm segment of proximal intestine was divided longitudinally, one-half of the divided segment became ischaemic and required resection. Intestinal motility is slow to return in these patients and gastrostomy tubes are frequently used. Death is rare but has occurred in the youngest (days/weeks old) and may be due to sepsis related to an anastomotic leak. Thus, although intestinal lengthening is beneficial in selected patients with a short bowel, the procedure should be applied cautiously because there is the risk of jeopardizing the divided segments. The vascular anatomy must be favourable and the intestinal diameter of the segment to be tapered should be at least 4 cm.

The serial transverse enteroplasty (STEP) procedure was described by Kim et al. in 2003 [86]. This procedure does not require separation of the leaves of the mesentery, and can therefore also be applied to adults. Instead, the dilated intestine is lengthened by partially dividing the bowel from alternate sides with a cutting stapler instrument (Fig. 4), leaving a channel 2.5 cm in diameter and some 70% longer than the original segment.

At least 111 children have undergone the STEP procedure [87]. Of 97 children with long-term follow-up, 11 died and 5 had an intestinal transplant. Thirty-seven achieved nutritional autonomy [88].

Data on outcomes of STEP in adults are scarce. The Nebraska group published a detailed case series in 2010, reporting outcomes in 20 adults who had bowel lengthening, of whom 15 had the STEP procedure [87]. Overall, mortality was nil and four patients (20%) required a reoperation, in all cases for obstruction. At long-term follow-up, 59% had regained nutritional autonomy. Cleveland Clinic reported overall outcomes of 420 cases of autologous gastrointestinal reconstruction for intestinal failure, 14 of whom were children [89]. Among the 420, 68 underwent the STEP procedure. Interestingly, 12 of those also underwent STEP on their colon. Nutritional autonomy was regained by 44 (72%) of 61 long-term survivors [89].

At present intestinal lengthening can only be applied to a fairly select group of patients. They must have a short remnant and an intestinal diameter greater than 4 cm. Thus, there has been recent interest in sequential procedures, first employing a distal valve or sphincter to dilate the proximal bowel and then performing the lengthening procedure [57]. Alternative methods to increase blood supply to isolated seg-

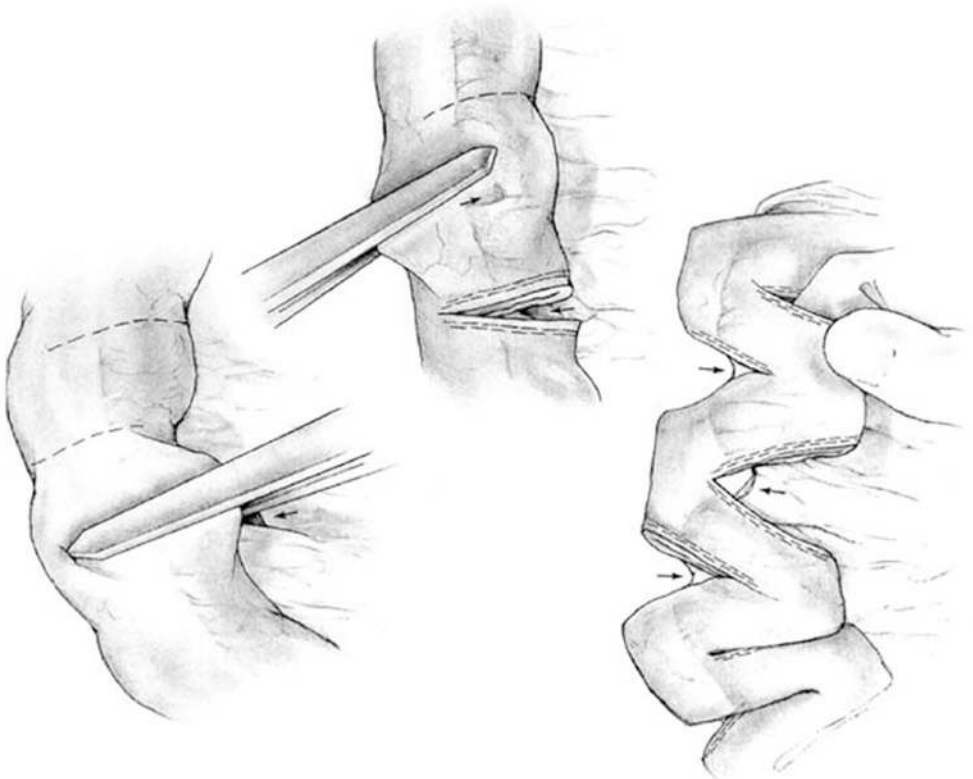

Fig. 4 Serial transverse enteroplasty procedure (STEP). Direction of insertion of the cutting stapler instrument indicated by smaller arrows. (Reproduced by permission from Kim et al. [86])

ments (e.g. from liver or omentum) and thus, permit repeated lengthening have also been investigated [90].

The STEP and LILT procedures are both accepted procedures for non-transplant surgical management of children with a short bowel, and the outcome of the STEP procedure may be more favourable [91, 92]. Long-term outcomes were recently compared in a systematic review of studies including 782 children, reporting nutritional autonomy in 52% of patients following LILT, and 48% following STEP [93].

Spiral intestinal lengthening and tailoring (SILT) is a novel technique described in children by Morabito, which requires less manipulation of the mesentery than the LILT procedure, and does not alter the orientation of the muscle fibers as with the STEP procedure [94–96]. In brief, incisions are made in the dilated bowel at 45–60° to the longitudinal axis. The bowel segment is then stretched longitudinally over a wide catheter with the same diameter as the desired new lumen. The incisions are now closed with bowel in its new, narrowed configuration. This promising technique awaits validation in other centres.

Other Techniques

While the surgical techniques are summarised in Table 3, there are other potential techniques for expanding the intestinal surface area take advantage of the regenerative capability of the intestine.

Intestinal regeneration will occur in full thickness intestinal defects patched with a variety of surfaces, including adjacent serosal surfaces. Whether or not sufficient mucosa can be produced by intestinal patching to significantly increase intestinal absorption remains unclear [18]. Further experimental study is necessary to assess the safety and efficacy of this approach. Clinical experience with intestinal patching to increase absorptive surface in patients with a short bowel has not been reported. This remains a useful technique, however, for managing intestinal defects and strictures when it is desirable to avoid resection.

Table 3 Surgical options for patients with a short bowel

Remnant length	Clinical condition	Surgical options
Remnant >120 cm	Normal diameter	Optimize intestinal function
	Enteral nutrition	
	Dilated bowel with bacterial overgrowth, stasis	Treat obstruction
		Intestinal tapering
Remnant >90 cm	Rapid transit	Recruit additional length
	Need for PN	Reversed intestinal segment
		Artificial valve
		Colon interposition
Remnant 60–90 cm	Normal diameter	Optimize intestinal function
	Dilated bowel	Intestinal lengthening
	Need for PN	
Remnant <60 cm	Complications of PN	Intestinal transplantation

Intestinal Tissue Engineering

Introduction

Tissue engineering is an evolving scientific discipline that combines stem cell biology and biomaterials science to construct human organs. The unifying philosophy within the field of tissue engineering is that the human body's innate regenerative responses can be applied and induced in the laboratory, to reconstruct functional human tissue for transplantation. Bioengineering of tissues with simpler functions such as the skin and cornea are established in clinical practice [97, 98]. Successful clinical applications of more complex organs have also been demonstrated in a few case reports of trachea and bladder reconstruction [99, 100]. There have been great advances in pre-clinical studies of bioengineering organs including oesophagus, skeletal muscle, liver and lung [101–106]. Tissue engineering of small bowel is particularly relevant for patients with a short bowel. Here we discuss the recent advances and strategies in development for intestinal tissue engineering solutions in short bowel syndrome.

Intestinal Stem Cells

The intestinal mucosa has one of the fastest self-regenerating rates of all mammalian tissues. Self-renewal is driven by intestinal stem cells (ISCs), positioned at the base of intestinal crypts. As ISCs divide, they give rise to daughter cells which then proliferate and migrate upwards towards the crypt-villus junction. Here, they terminally differentiate into the absorptive or secretory lineages before reaching the villus tip, where they are shed into the lumen [107].

Early attempts to establish the in vitro expansion of ISCs were extremely difficult without first inducing genetic transformations, which limited their clinical translation potential. In 1992, Evans et al., first demonstrated primary adult intestinal crypt cultures that consisted of both epithelial and mesenchymal cells [108]. However, only short-term cultures lasting up to 2 weeks were possible using this method and multipotency was somewhat variable. In 2007, Barker et al., made the landmark discovery that ISCs were marked by the Wnt target gene *Lgr5* [107]. The increasing knowledge in ISC biology paved the way for the establishment of intestinal organoids in vitro (Fig. 5) [109]. Sato et al., showed that both mouse and human intestinal organoids could be cultured in a

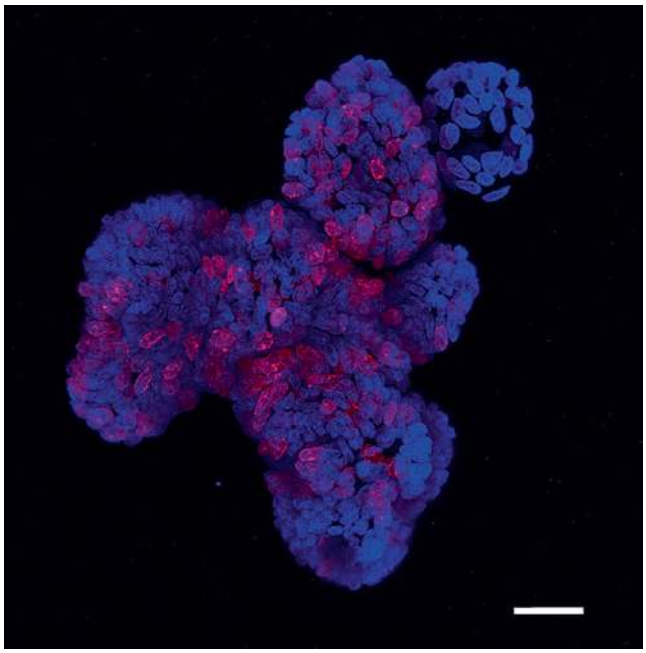

Fig. 5 Whole mount immunofluorescence staining of a human jejunal organoid. Proliferative cells are marked in magenta by 5-ethynyl-2′-deoxyuridine (EdU), whilst non-proliferating cells are marked in blue by 4,6-diamidino-2-phenylindole (DAPI)

three-dimensional matrix with an unlimited expansion potential whilst maintaining multipotency of all differentiated intestinal epithelial cell types [109, 110]. This was a key milestone in the field with significant research applications, particularly for intestinal tissue engineering [111, 112].

Sources of intestinal cells include induced pluripotent stem cells (iPSCs) and embryonic derived stem cells (ESCs). iPSCs are generated by forced expression of genes in differentiated adult cells such as fibroblasts [113], and have been used to generate intestinal epithelium of all lineages in vitro [114, 115]. Furthermore, they have been used in pre-clinical intestinal tissue engineering studies where human iPSCs grafts were transplanted in rats to demonstrate both structural and digestive functional competence in vivo [116]. An advantage is that donor cells can be non-invasively obtained from autologous sources such as skin biopsies, rather than requiring endoscopy.

In contrast, ESCs are derived from totipotent cells of the blastocyst stage of the early mammalian embryo (i.e. less than 8 weeks after fertilization) and are capable of unlimited, undifferentiated proliferation in vitro [117]. Human ES cell lines (commercially available) have also been used to form intestinal tissue when engrafted in the kidney capsule of NSG mice. After 6 weeks in vivo, the cellular grafts contained most of the intestinal epithelial, mesenchymal and smooth muscle cell types found in the developing gut [115]. However, the derivation of ESCs from human embryos is associated with substantial ethical impediments, which may hinder their translation into clinical studies.

Scaffold Biomaterials

Scaffolds are an essential component in tissue engineering as they act as a physical platform and support network, guiding three-dimensional cell growth. Scaffold composition should ideally mimic the natural extracellular matrix (ECM) that exists in vivo as closely as possible [103, 118–120]. Biodegradability of the scaffold is also an important consideration to ensure structural competence once anastomosed to native structures. Both synthetic and biological scaffolds have shown promising results in pre-clinical animal studies.

Synthetic intestinal scaffolds have been derived from biodegradable polymers and are moulded or printed into the intestinal shape. The great advantage of synthetic scaffolds is the potential to develop an "off the shelf" product that is widely available and can be manufactured in large scale production lines. However, these polymers do not retain any of the natural nanotopography of the native intestine, nor any bioactivity, which in turn affects cell behaviour such as loss of pluripotency [120].

Biological scaffolds are derived directly from the ECM of native organs through a process of decellularization, which describes the process whereby an organ is perfused with a series of chemical and biological solutions to remove all cellular and immunogenic material [112, 118]. Bioactivity of important growth factors (such as vascular endothelial growth factor) is maintained after decellularization [121]. Most promisingly, human intestinal decellularized scaffolds (Fig. 6) have been formed and are shown to have preserved microarchitecture of the crypt-villus axis and retained biological activity, therefore offering the most biomimetic substrate for intestinal tissue engineering [112]. Whilst this

Fig. 6 False coloured scanning electron micrograph of human small intestinal decellularized scaffold. Epithelial cells have been stripped off to reveal the underlying extracellular matrix. Crypts are present as depressions on the mucosal surface, whilst villi protrude upwards (coloured in violet/grey at their tips)

strategy still relies on the availability of donor organs, the study also showed it was possible to use colon scaffolds as substrates for jejunal mucosal reconstruction which would provide an alternative source of tissue [112].

Bioengineering Human Intestinal Grafts

There is great momentum in the research field to define the optimal combination of human intestinal cells and scaffolds for transplantation studies [116, 119, 122–126]. Most recently, patient derived jejunal ISCs were expanded and combined with human decellularized small intestine and colon scaffolds to form intestinal grafts which demonstrated digestive and absorptive function in vitro. When transplanted ectopically in mice, the human jejunal mucosal grafts survived and differentiate appropriately, maintained structural competence in vivo and demonstrated evidence of neovascularization [112]. These data support ongoing studies into larger animal transplantation studies using ISCs/iPSCs and biological scaffolds. A second evolving unique strategy being explored by Sugimoto et al., is to transplant small intestinal organoids into a segment of denuded colon, in order to repurpose it into functional small intestinal tissue. This strategy offers a scaffold-free technique of creating small bowel for patients with short bowel syndrome with promising results in small animal models [127].

In the next 10–15 years, tissue engineering advances will enable us to adapt engineering strategies and personalise grafts for an individual patient's needs. The most significant hurdle will be ensuring that intestinal grafts display enteric nervous function post-transplantation. It is likely that a combination of iPSC and ISCs based approaches, together with hybrid biological and synthetic scaffolds will offer the best strategy for first-in-man studies using this technology.

Intestinal Transplantation

Lisa M. Sharkey, Stephen J. Middleton, Irum Amin, and Andrew J. Butler

Key Points

1. There are 4 types of intestine-containing transplant (often these are all grouped under the umbrella term of 'intestinal transplant')—isolated intestinal graft, liver plus intestine, modified multivisceral (stomach, pancreaticoduodenal complex and intestine) and Multivisceral (includes stomach, pancreaticoduodenal complex, liver and intestine).
2. An intestinal transplant is considered for the complications of intestinal failure/parenteral nutrition (e.g. liver disease), or in the context of extensive evisceration for desmoid or other benign abdominal tumours.
3. For an isolated small bowel graft the 5 year patient survival is as high as 80% in some centres and the chance of these patients being off parenteral support is 93%.
4. Problems of immunosuppression include increased risk of infection, nephrotoxicity, neurological side effects and increased risk of malignancy
5. Rejection occurs in 30% and graft-versus-host-disease in 10%.

Historical Perspective

Transplantation of the small intestine, either alone or as part of a cluster of organs has been undertaken for more than a century, but patient survival for more than a few days was not achieved until the late 1980s when Grant *et al.* reported what is accepted to be the first example of a successful small bowel transplant [1]. This group made the observation that this success was associated with the presence of a chimeric population of immunocompetent cells in this patient which led to the proposal that engagement of the host and donor immune systems promotes a degree of tolerance by the recipient for the graft. Other centres have reported evidence of graft tolerance such as the observation of regulatory T cells in the transplanted intestinal lamina propria [2].

Under normal circumstances, lymphocytes circulate between the peripheral lymphatic tissues such as the spleen, lymph nodes and the gut. This process continues after small bowel transplantation but there is interplay between host and transplanted lymphocytes which cycle through the transplanted and host trafficking sites [3–5]. Under suitable immunosuppression this can be a benign process where tolerance prevails. However, inadequate immunosuppression can lead to proinflammatory lymphocyte behaviour and graft rejection or less commonly GVHD [6, 7]. Efficacy of lymphocyte-depleting agents may arise at least in part from the generation of "prope-tolerance" encouraged by the replacement of depleted host immunocytes with a new population that emerges in the environment consisting of both host and donor tissues such that there is an enhanced degree of tolerance of donor tissues as self. In 1995 Campath 1H, a monoclonal anti-CD 52 antibody, was first used for a multivisceral transplantation in Cambridge, UK. This depletes both T and B lymphocytes and seems to promote a greater degree of tolerance which, together with the advent of the more potent calcineurin inhibitors such as Tacrolimus in the early 1990s, led to a decade when the use of intestinal transplantation became exponential. An increase in serious infections tempered enthusiasm and highlighted the delicate balance between preventing rejection and avoiding infection. Attempts to improve tolerance and reduce infections by concurrent splenic transplantation gained some traction for a brief period but has not stood the test of time.

Over the last decade there has been a more cautious policy in most transplant centres and in general survival figures

are now reasonable with a few centres still achieving results similar to those of liver transplantation. The incorporation of a liver in the cluster of transplanted organs was initially believed to be largely responsible for inducing graft tolerance. It is now clear that it greatly increases the overall risk of the procedure and is associated with a reduced survival compared with that associated with procedures that do not contain a liver. Consequently, patients on parenteral nutrition, particularly if they have a very short small bowel remnant, should be carefully monitored and referred early to a transplant centre before significant liver disease develops.

Indications and When to Refer for Intestinal Transplantation

The current indications for intestinal transplantation in the UK as published by NHS blood transfusion and transplantation are summarized in Table 1. These have gradually broadened over the last 15 years as the risks and benefits of these procedures have become more understood and the survival chance a little more predictable. However, there remains a need for a fully validated system to estimate survival chance of patients who are considered as candidates, both with their existing problems and in the event of transplantation. The same applies to the effect of transplantation on quality of life. Some patients find their quality of life enhanced after intestinal transplantation, but others do not, and may even find a reduction. Currently it is not possible to predict which patients will do well from this perspective. Attention should be given to the likely impact of transplantation on aspects of life that the patient considers of greatest importance to them, but always in the context of the other effects of their likely post-transplant condition. This area remains very challenging.

As seen in Table 1, loss of central access sites for parenteral nutrition is an indication for IT. However, it is critical that the patient has sufficient venous access to allow adequate operative and post-operative support. For example, many patients will require temporary renal replacement therapy, intravenous nutrition, management of complex sepsis, multiple surgical procedures and other invasive procedures during their post-operative recovery. They will therefore require suitable venous access sites to be available over a long period of time and continued attrition of these is to be expected. Even after hospital discharge it is usual for patients to require intermittent re-admission [8], over the long term, with serious intercurrent illness when they require good central access to receive appropriate treatment.

Others may have recurrent sepsis or inadequate nutritional support resulting in a steady decline, and slow growing tumours such as desmoids can present a particular timing difficulty due to their unpredictable growth rate and tendency to be more advanced than indicated on cross sectional imaging.

Table 1 Current indications for intestinal transplantation in the UK (Source: NHS blood and transplant, https://www.odt.nhs.uk/transplantation/small-bowel/

Irreversible intestinal failure, plus
1. Life-threatening complications of parenteral nutrition (a) Progressive intestinal failure-associated liver disease (IFALD) or non-IFALD • Assessed by biochemistry and biopsy • Combined intestinal and liver transplant is best considered in the presence of advanced liver disease (portal hypertension or advanced fibrosis)
(b) Severe sepsis • More than one life-threatening episode of catheter-related sepsis for which no remediable cause can be identified • Endocarditis or other metastatic infection
(c) Limited central venous access • Venous access limited to three major conventional sites in adults (above and below the diaphragm) and two major conventional sites above the diaphragm in children • Conventional central venous sites are defined as internal jugular, subclavian and femoral veins
2. Very poor quality of life thought likely to be correctable by transplantation
Patients with indications for extensive surgery involving partial or complete evisceration
1. Surgery to remove a large proportion of the abdominal viscera considered untenable without associated multi-visceral transplantation (e.g. extensive desmoid disease, extensive critical mesenteric arterial disease)
2. Localised malignancy considered amenable to curative resection requiring extensive evisceration (e.g. localised neuroendocrine tumours). Particular caution should be exercised in this group and patients should be discussed in a multidisciplinary multicentre forum (e.g. National adult small intestinal transplant forum, NASIT)
Patients requiring transplantation of other organs where exclusion of simultaneous intestinal transplantation would adversely affect patient survival
1. Where the transplantation procedure is expected to preclude the possibility of future intestinal transplantation (e.g. loss of venous access or further human leukocyte antigen sensitisation)
2. Where the need for subsequent intestinal transplantation is considered likely and the risk of death is increased by excluding the intestine from the graft
Examples include predictable problems related to administering immunosuppression (e.g. line sepsis), or continuing severe intestinal disease such as diabetic visceral neuropathy, or ultra-short bowel syndrome, which may cause fluid, electrolyte and acid base balance problems that would damage an existing or planned renal graft
Special considerations
Transplantation of additional organs for feasibility reasons Renal transplantation Adults and children with corrected GFR of <45 mL/min/m^2 are evaluated for the possibility of simultaneous renal transplantation

In addition to these factors, consideration should be given to the escalation of surgical complexity. If transplanted early enough, liver disease associated with intestinal failure often resolves. The requirement of a liver as part of the cluster of transplanted organs is associated with a much lower survival rate than non-liver containing grafts. Unfortunately, intestinal failure associated liver disease can develop insidiously and reach an advanced stage with few if any signs for the attending clinician to become alerted to its presence (see below).

Therefore, it is necessary to avoid premature listing for transplantation when the patient does not fulfil criteria and would be exposed to the risks of transplantation unnecessarily, but also avoid undue delay when the patient's condition has deteriorated to a point which significantly reduces his/her chances of survival.

Assessing the Potential Transplant Recipient

The importance of the patients' pre-operative condition and the adverse effect of comorbidity on operative and post-operative survival are now well established. Not only must patients be in a suitable physical condition but their mental state is also of critical importance. Many patients already have mental illness arising in the context of their protracted physical morbidity and the additional burden of the transplant process often deepens any existing tendency toward depression and anxiety. Patients frequently spend several months in hospital after the transplant and have long periods on the intensive care unit. These stresses are often associated with loss or reduction in their support network of friends and family, due to geographical constraints.

There needs to be careful multi-disciplinary consideration as to the suitability of each patient in the broader context of their general condition and likelihood of surviving what is one of the most challenging medical procedures performed in the modern era. Some centres achieve this with multidisciplinary meetings, and in the UK there is a National Adult Small Intestinal Transplantation forum (NASIT) at which all potential candidates are reviewed prior to listing for transplantation. This has also proven to be a valuable opportunity for the exchange of ideas and experiences between centres and is attended by representatives from intestinal failure units as well as transplant centres.

Medical Assessment

The majority of candidates have experienced multiple thrombotic events, either causing bowel loss or complications of vascular access. A comprehensive thrombophilia screen is necessary but even if no defined pro-coagulant condition is identified these patients should be considered as functionally pro-thrombotic.

Some patients will have developed anti-human leucocyte antigen (HLA) antibodies, as a consequence of pregnancies, blood transfusions or previous transplants and are described as "sensitised". Knowledge of previous of sensitising events is mandatory and a full tissue type and HLA antibody screen performed. If there are anti HLA antibodies this will influence waiting time for organs [9] and may preclude transplantation. Once listed it is important to avoid unnecessary sensitising events (e.g. blood transfusions).

Details of the immune status of the host to infections such as Cytomegalovirus, Epstein Barr Virus, Toxoplasmosis, Varicella Zoster, Herpes simplex, HIV, Hepatitis B, C and E and Mycobacterium tuberculosis are important for the heavily immunosuppressed post-operative environment. Knowledge of previous infections particularly if multi-drug resistant will allow better selection of anti-microbial therapy and patients should receive appropriate vaccination against the endemic infections they are likely to be exposed to during and after transplantation. Knowledge of the immune status to CMV and EBV can influence donor and recipient matching and prophylaxis after transplantation.

Assessment of liver pathology in patients with IF is critical. Normal liver function tests do not exclude underlying fibrosis or cirrhosis, and features of portal hypertension can be absent even in the presence of cirrhosis, due to reduced splanchnic blood flow. Patients at particular risk for advanced fibrosis are those who are 'ultra-short' [10] (residual SB length less than 20 cm), or those with a second hepatic insult (alcohol, viral hepatitis, previous non-alcoholic fatty liver disease). Transient Elastography (Fibroscan®) has not been validated in this group of patients and may be misleading. Liver biopsy is currently the gold standard for liver assessment in this context. It is important that the biopsy is of sufficient size and length and is interpreted by an experienced liver pathologist.

Patients with moderate or moderate to severe fibrosis would not necessarily require a liver as part of their graft. Patients with established cirrhosis will usually require a combined intestine/liver graft, even in the absence of portal hypertension as patients often do not manifest the clinical or radiological stigmata of chronic liver disease. Timing of transplantation may be informed by the patient's United Kingdom model for end stage liver disease (UKELD) or model for end stage liver disease (MELD) scores but these have not been validated in IFALD. In any case with IFALD, careful and nuanced judgement by an experienced transplant centre is required.

Surgical Assessment

At referral, knowledge of the current anatomy including a detailed appraisal of the vasculature and previous surgical

history is needed. Previous histopathology can be helpful, particularly if liver pathology (e.g. IFALD) or dysmotility is expected.

Examination focuses on stomata, enterocutaneous fistulae, surgical incisions, drain sites and anthropometrics. Abdominal wall scarring results in reduced compliance and abdominal domain, limiting the size of potential donors. Ascites increases the size of the abdominal cavity and therefore the availability of potential donors.

Assessment for peripheral vascular disease is essential in any transplant; if present it is a marker of reduced long-term survival.

Radiological Assessment

Interpretation of current and previous images with a dedicated radiologist experienced in the challenges of intestinal transplantation is essential.

The corner stone of radiological assessment is triple phase CT. This is the most useful modality to assess gastrointestinal and vascular anatomy. Assessment of the arterial supply to the remaining abdominal organs, degree of aortic calcification and patency of venous structures within and outside the abdomen are essential.

Many patients will have compromised central venous access which impacts per-i and post-operative care. Ultrasound, CT, MRI and/or conventional venography are used for venous mapping. Venous reconstruction (using interventional radiology or surgery) may be required to allow transplantation.

Nuclear medicine EDTA GFR (nGFR) can be performed to determine the need for simultaneous kidney transplantation in borderline cases [11]. DEXA scanning is necessary given the high incidence of pre-existing metabolic bone disease in this cohort.

These are the minimum tests that all potential candidates require, individual circumstances may dictate further testing such as MRCP, CT chest and head.

Anaesthetic Assessment

Cardiopulmonary testing in our institution involves ECG, lung function test, trans-thoracic echocardiography and some form of cardiac stress test in higher risk patients (those with 1 or more cardiac risk factors).

Assessment by an anaesthetist experienced with the operation is essential. Consideration of the peri and post-operative morbidity and mortality and the projected long-term survival is fundamental [12].

Many candidates are considered for transplant because of impaired vascular access. For liver containing grafts vascular access above and below the diaphragm is required. For non-liver containing grafts two central veins are adequate. Limitation of access to a single central vein considerably increases the peri and post-operative risk, but does not necessarily exclude the patient from consideration.

The functional status of the patient is of great importance as many are deconditioned. A program of prehabilitation is desirable to improve post-transplant morbidity.

Psychological Assessment

The pre-operative psychiatric and psychological assessment of patients deserves special mention. A number of patients have died as a consequence of the development or deterioration of mental health disorders. The engagement of patients with the appropriate mental health support in the preoperative period is of critical importance. Not only for post-operative management but to be as certain as possible that patients have the mental capacity to provide fully informed consent. Institutionalised behaviour including chronic opiate use and poor social support impact on outcomes and in extreme cases may preclude listing. A supervised pre-transplant opiate reduction plan will have a positive effect on post-operative pain management and graft function.

Nutritional Assessment

Weight loss (and loss of lean body mass) is frequently seen in the first 3–6 months post-operatively. In our series 90% of patients lost weight, which was ≥20% of their pre-transplant weight in one third [13]. In paediatric recipients, height and weight parameters improve over the first year post transplant [14, 15]. Therefore, attention should be given to the optimization of both the lean body mass and energy stores of the patients with appropriate involvement of the nutrition team. The presence of sarcopenia can be judged by CT scans of the abdomen, from measurements of psoas muscle mass, or total abdominal muscle mass. Bedside anthropometric measurements (including mid-arm muscle circumference, triceps skinfold thickness and handgrip strength) are useful as they can be performed serially to monitor progress.

Table 2 Example assessment checklist

System being assessed	Minimum measurement tools	Additional testing/intervention needed in some	Cut off criteria[a]
Cardiac	12 lead ECG, echocardiogram, stress testing (dobutamine stress echo or MPS scan)	Angiography	– Inducible ischaemia not correctable by intervention – Moderate to severe impairment of LV systolic function
Respiratory	Pulmonary function tests including transfer factor	CPEX	– FEV1 < 1.5 L – TLCO <50% predicted – AT <8 mL/kg/min
Renal	eGFR If eGFR <60 mL/min for Nuclear medicine EDTA GFR	MAG3 renogram (split function)	GFR <45 requires consideration for concurrent renal graft
Psychiatric	At least one assessment by a psychiatry consultant experienced in transplant assessment	Intervention with CBT or other therapy and reassessment	Psychiatric opinion regarding suitability for Tx
Drug and alcohol	Active use of recreational drugs		– Equivalent total morphine dose per day <100 mg – Any alcohol intake (for liver-containing grafts) in past 6 months
Dietetic	Basic anthropometrics (BMI, MAMC, TSF, HGS)		BMI <18
Anaesthetic	At least one assessment by an anaesthetic consultant experienced in transplant assessment	Prehabilitation plan (strength, aerobic and respiratory capacity)	

MPS myocardial perfusion scan, *CPEX* cardio-pulmonary exercise testing, *FEV1* forced expiratory volume in 1 s, *TLCO* total lung transfer factor measured by carbon monoxide exchange, *AT* anaerobic threshold, *CBT* cognitive behavioural therapy, *BMI* body mass index, *MAMC* mid-arm muscle circumference, *TSF* triceps skinfold thickness, *HGS* handgrip strength
[a]Not prohibitive, requires MDT discussion of overall risk

Treatment for reduced bone density should be promptly initiated and managed by a metabolic bone disease specialist.

Summary of the Assessment Process

Patients who are selected as candidates for transplantation will in most cases have already undergone a rigorous multidisciplinary review as part of the selection process. The subsequent preparation for transplantation should be thorough and provide a convenient summary of all comorbidity which should be quantified and monitored. This involves a comprehensive and sequential evaluation of each body system and should include a careful psychiatric and psychological review. Any abnormality should be fully investigated and corrected if possible and irreversible comorbidity or other risk factors these should be detailed in a special preoperative summary to allow them to be appropriately factored into the management of the patients during and after transplantation. Even minor disorders that would under normal circumstances pose little risk to patients or challenge for clinicians can develop into serious life-threatening complications during the operative and post-operative period. An example checklist for listing is shown in Table 2.

The death of patients can often be traced back, with root cause analysis, to a relatively minor disorder which led to a sequence of ever increasing morbidity. The under appreciation of this phenomenon is probably the commonest mistake made by clinicians when assessing patients for intestinal and in particular multi-visceral transplantation.

Types of Intestinal Containing Grafts

There are a variety of different intestinal containing grafts and the most commonly performed examples are described below and in further detail in Table 3 and Figs. 1, 2, 3 and 4: Any transplant that contains a transplant intestine meets the definition of ‘intestinal transplant’.

Table 3 Types of intestine-containing grafts

Type of graft	Organs transplanted	Proximal enteric anastomosis	Advantages/disadvantages	Impact of graft failure
Isolated small bowel transplant	Small bowel (+/− pancreatico-duodenal complex, colon)	Jejuno-jejunal Duodeno-jejunal	Limited exenteration Splenic preservation	Return to PN, potential retransplant at a later date
Modified multivisceral	Stomach, pancreatico-duodenal complex, small bowel (+/−colon)	Gastro-gastric Oesophago-gastric	More extensive evisceration including splenectomy Stomach inclusion with increased risk of aspiration, gastroparesis and anastomotic leak	Urgent re-transplant
Liver small bowel	Liver, pancreatico-duodenal complex, small bowel (+/−colon)	Jejuno-jejunal Duodeno-jejunal	Splenic and gastric preservation	Urgent re-transplant
Multivisceral	Liver, Stomach, pancreatico-duodenal complex, small bowel (+/− colon)	Gastro-gastric Oesophago-gastric	Extensive evisceration with loss of stomach and spleen	Urgent re-transplant

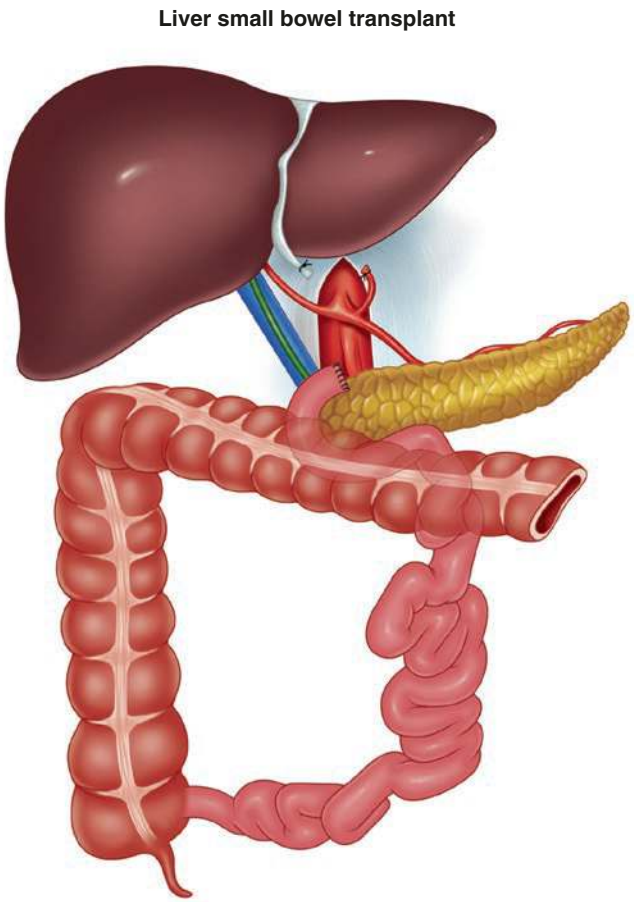

Fig. 1 Combined liver/intestinal transplant (native stomach and pancreatico-duodeno-splenic complex left in situ)

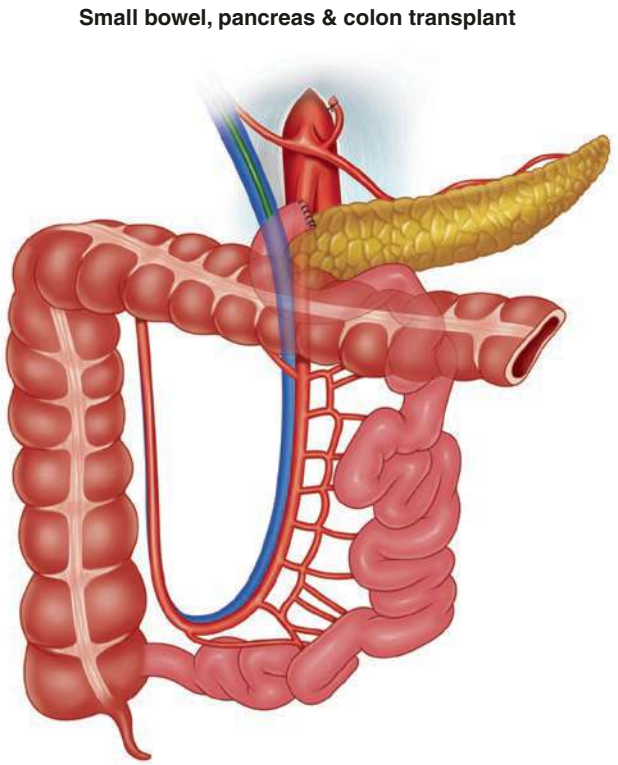

Fig. 2 'Isolated' intestinal transplant (which usually includes small bowel, pancreas and colon)

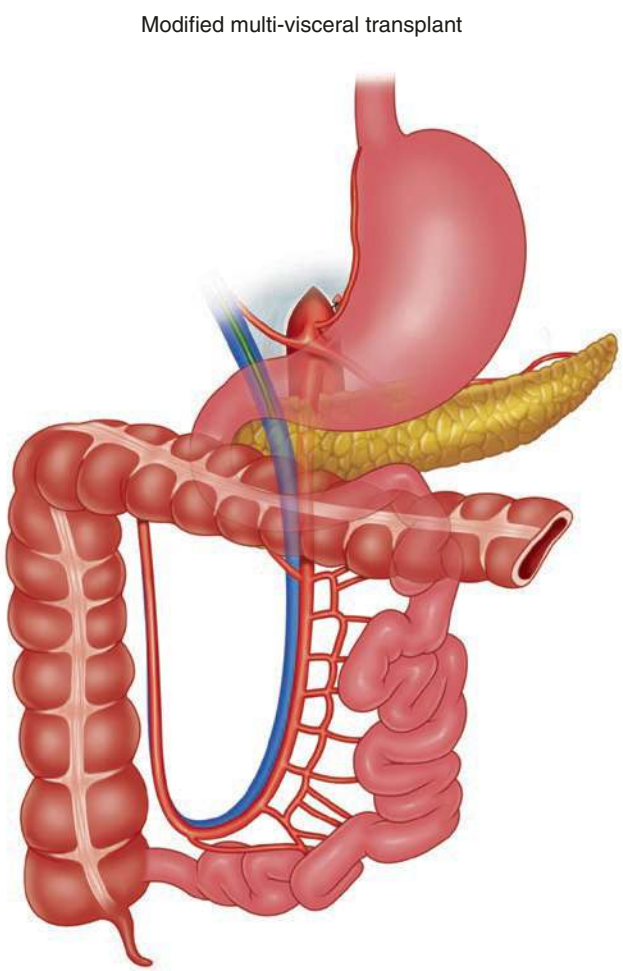

Fig. 3 Modified multivisceral transplant (graft includes stomach, pancreaticoduodenal complex, small bowel and colon with native liver left in situ)

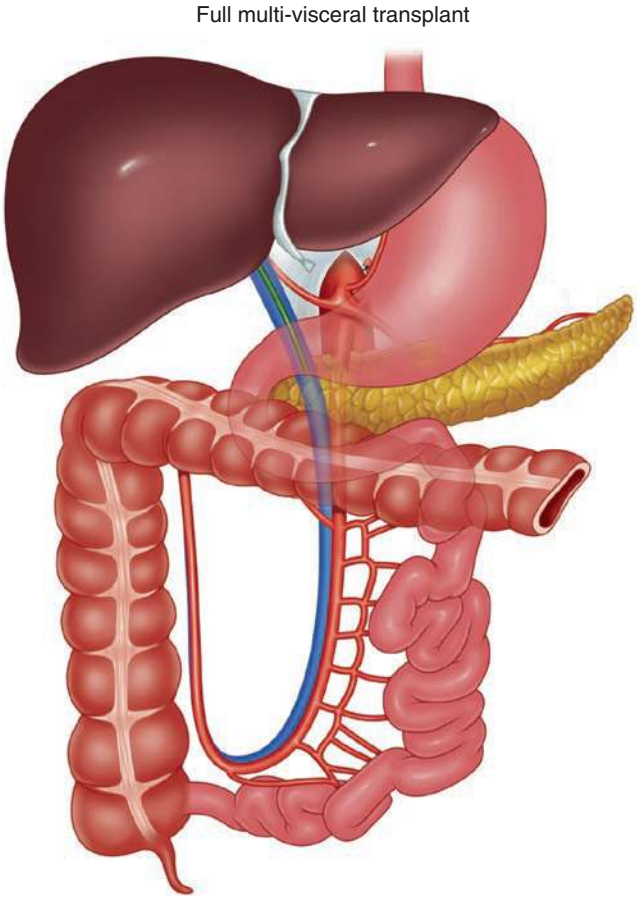

Fig. 4 'Full' multivisceral transplant: replacement of stomach, pancreatico-duodenal complex, small bowel, colon and liver

The Transplant Procedure

The intestine is particularly sensitive to ischaemia reperfusion injury. In order to minimise the cold ischaemia time (<6 hours) the donor and recipient procedures are performed simultaneously.

Donor Selection

Most donors are DBD (donation after brain death) and are selected on the basis of blood group, HLA type, size, viral status and logistics. A small number of living donor intestinal transplants have been performed.

Blood group compatibility is necessary. If the donor and recipient blood groups are compatible but not identical there may be a period of passenger lymphocyte syndrome with haemolysis for up to 6 months [16]. This is addressed by using donor blood group blood when transfusion is necessary post-op. HLA matching is not routinely undertaken, as there is not yet good published evidence to suggest it affects graft survival, but avoidance of donors to which recipients have pre-existing high level anti HLA antibodies is desirable. In some centres donors and recipients are matched according to CMV and EBV serological status to attempt to reduce CMV disease [17] and possibly EBV driven PTLD.

Organ Retrieval (Procurement) Procedure

After an appropriate organ donor has been identified and prior to arrival of the retrieval team the donor bowel is pretreated with anti-fungal and anti-bacterial agents to reduce the number of resident luminal micro-organisms It is not current practice to pre-treat the donor with lymphocyte depleting agents although this has been undertaken by some centres in the past, with no obvious benefit observed.

After the donor procedure has started the organs are assessed for anatomical anomalies and other pathology that would make the organs unsuitable. Once the organs are

deemed appropriate this is communicated to the implanting team and the recipient is anaesthetised and the explant procedure is started.

The specific extent of dissection is dictated by the nature of the graft required [18]. In the situation where a full multivisceral graft is required then the liver, stomach, pancreas, small bowel and colon are prepared in such a way that the donor organs can be removed *en bloc* with a common vascular pedicle. In circumstances where the liver is not required as part of the graft then the block is dissected in such a way that it can be split readily and quickly after cross clamp, thus minimising the cold ischaemia time involved [19]. When no further dissection is necessary this is communicated to the implanting team. If the implanting team are not sufficiently advanced the donor team will delay cross clamp until the recipient operation has progressed further. For this reason the duration of the donor procedure is very unpredictable. It is critical that the other transplanting teams (thoracic and abdominal) need to be aware that there may be delays.

At cross clamp the organs are flushed with preservation solution at 4 °C and rapidly removed and packed in more of this solution. Removal of the thoracic and abdominal organs is undertaken simultaneously. As a result of the extensive dissection prior to cross clamp in these retrievals the intestinal block is often the first to be explanted.

At this point the organs are transported to the recipient centre.

The Recipient Procedure

The recipient procedure involves the removal of the diseased native organs, preparation for implantation of the graft, graft implantation and reperfusion and abdominal closure.

Once the recipient is anaesthetised, central venous access is established to facilitate anaesthesia, for veno-venous bypass (to allow inferior vena cava (IVC) cross clamping or reduce haemorrhage) and allow intra-operative haemofiltration (for metabolic stability). For patients with severe portal hypertension requiring a liver containing graft, very substantial blood loss is expected. Embolisation of the recipient superior mesenteric artery (SMA) and or the coeliac artery (CA) prior to starting the explant procedure results in reduced blood loss and improved haemodynamic stability [20, 21].

The technical challenges of the explant procedure can be very variable. In rare circumstances there is little dissection required to prepare for implantation, most of the native organs having been previously explanted. In most circumstances the recipient will have had multiple previous laparotomies resulting in unclear intra-abdominal anatomy, dense adhesions, enterocutaneous fistulae, intra-abdominal collections and various stomata. Explanting desmoid tumours and other slow growing neoplasms present a particular set of issues including involvement of the abdominal wall and other organs (including the liver and ureters). The involvement of neighbouring organs may require complex strategies (e.g. ureteric reconstruction or auto-transplantation of the native kidney).

Once the necessary native organs have been explanted the vascular inflow and outflow for the graft are prepared. Usually this involves dissection of the infra renal aorta in preparation either for suturing of the Carrel patch or aortic conduit. The venous outflow is either via the IVC or native portal vein or Superior mesenteric vein (SMV).

Isolated Intestinal Transplant (IT)

An isolated small intestinal transplant (not including pancreas or colon) allows the donor pancreas to be utilised as part of a simultaneous pancreas and kidney transplant or pancreas alone transplant. In this situation the arterial inflow is via the SMA and venous drainage is via the superior mesenteric vein (SMV). This may necessitate vascular reconstruction (often using donor iliac vessels) with a potential increased risk of vascular complications. For this reason many units favour inclusion of the pancreas in intestinal grafts.

This facilitates colon inclusion and often negates the need for vascular reconstruction.

Under these circumstances, arterial inflow is via the CA and SMA on a single Carrel patch. This is either sutured directly to the abdominal aorta of the recipient or via an aortic conduit (donor thoracic aorta). Venous outflow is via the portal vein (PV), anastomosed to the recipient PV or SMV (portal drainage) or recipient IVC (systemic drainage). Pancreas inclusion preserves the middle colic vessels and may reduce vascular complications. The proximal enteric anastomosis is to the most distal part of the native foregut. Many units routinely include the colon as part of the graft in order to improve fluid balance and potentially minimise deterioration in renal function [22, 23].

Modified Multivisceral Transplant

A modified multivisceral (MMV) graft requires a larger explant procedure and includes resection of residual small bowel, pancreas, spleen, duodenum and part or all of the stomach. It is essential that the hepatic artery is preserved and if possible, the left gastric artery (allowing a pouch of native stomach to remain). This allows a gastric-to-gastric

proximal anastomosis (a lower risk anastomosis than oesophago-gastric).

As part of the implant procedure a pyloroplasty is necessary to allow gastric emptying. Some transplant centres perform simultaneous gastric fundoplication to reduce the risks of reflux and aspiration pneumonia. Arterial inflow and venous outflow is as for IT.

Liver Small Bowel Transplant and Full Multivisceral Transplant

Liver containing grafts include either a full multi-visceral transplant (including a stomach) (MVT) or a liver small bowel transplant (LSB).

If there are concerns that either the arterial supply/venous drainage of the native stomach (before or after explant) is inadequate or there is compromised gastric motility then a full MVT will be required.

Preservation of the native stomach reduces the magnitude of the explant procedure and also facilitates splenic preservation This is associated with a reduction in sepsis and (anecdotally) the risk of GVHD. For both LSB and MVT the arterial inflow is via the CA and SMA on a single Carrel patch and venous outflow via the hepatic veins. Where the native stomach and native pancreatico-duodenal complex are preserved, the venous outflow from these organs is achieved by a portocaval shunt (either spontaneous, e.g. lienorenal shunt, or constructed at the time of transplant).

At reperfusion extreme fluxes in potassium (from the preservation solution) may cause cardiac arrhythmias and even cardiac arrest. This is usually reversible with CPR.

After completion of the implant and immediately prior to closure most units form a stoma to facilitate graft monitoring. The type of stoma used is variable (and some units choose to avoid a stoma [24]). Our preferred option is a Bishop Koop stoma. This allows access to the graft ileum and colon for surveillance biopsies and keeps the transplant colon in continuity to improve fluid balance. It allows stoma reversal avoiding a full laparotomy.

Abdominal Closure

Abdominal closure must be achieved without causing abdominal compartment syndrome. This is particularly important immediately after transplant because of graft oedema from ischaemia reperfusion injury. If the abdominal domain of the recipient is adequate primary closure is undertaken, if not other techniques may be required:

Use of Prosthetic Materials

Biological and non-biological meshes have been used. They are readily available but have a number of disadvantages.

Abdominal Wall Transplantation (Composite Tissue Allograft)

These are vascularised composite allografts with a number of important considerations in their use [25, 26].

- At implantation the graft is vascularised using microsurgical techniques either directly to the recipient inferior epigastric vessels or indirectly to the arm vessels in a temporary manner
- The teams using this technique have suggested that the donor skin can act as a marker for rejection (a rash) which may help with patient management.

Rectus Abdominus Fascial Grafts

Some centres have used rectus abdominus fascia as a non-vascularised graft [27, 28] (Fig. 1).

Tissue Expansion

Pre-operative insertion of tissue expanders has been described. There are a number of issues that have limited their use.

The Postoperative Course

Post-operative care is frequented by medical and surgical challenges. Some of these are common to all solid organ transplant recipients, however many of these occur with greater frequency in recipients of intestinal transplants. In addition, these patients can present/demonstrate almost unique pathologies that challenge diagnosis and management. The resolution of these conditions, which occur in most areas of specialist medicine, usually require resort to basic principles of the underpinning medical sciences [29].

Induction immunosuppression is given at the time of reperfusion of the graft and may consists of a lymphocyte-depleting antibody and methylprednisolone. Our practice is to give Alemtuzumab (Campath-1H), but some centres use anti-thymocyte globulin, a polyclonal preparation of lytic anti-lymphocyte antibodies or IL-2 receptor blocking antibodies, such as Basiliximab. Maintenance immunosuppression is initially with tacrolimus and a reducing course of steroids, with the introduction of an antimetabolite (usually Mycophenolate mofetil) within the first 2–3 months, depending on individual circumstances.

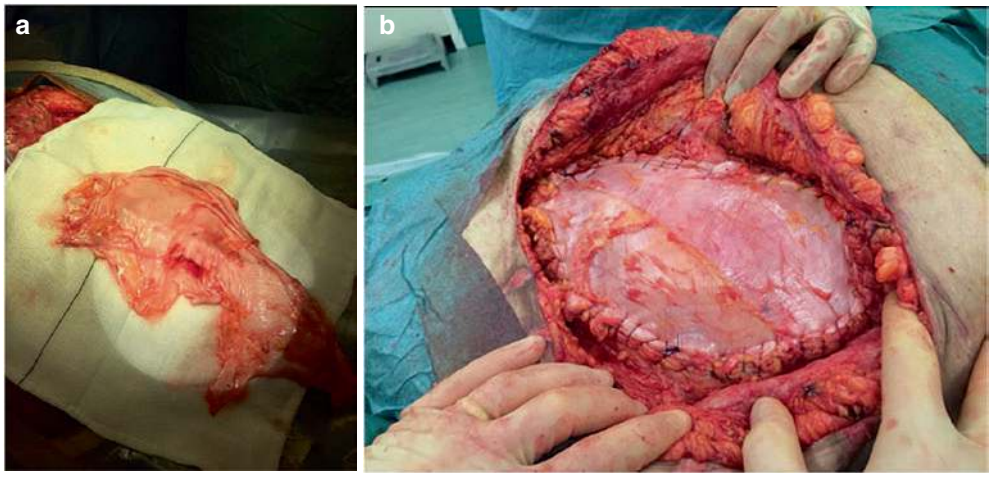

Fig. 5 Donor abdominal wall fascia—pre- (**a**) and post-implantation (**b**)

Mucosal integrity can be compromised in the early phase by ischaemia-reperfusion injury, so broad spectrum antibiotic cover is given for at least the first week, then as necessary for infectious complications. Antifungal and antiviral prophylaxis are given for variable durations post-transplant, depending on the transplanting centre and patient's overall risk.

Most intestinal transplant units have their own protocols for monitoring and management. Key aspects of this include graft surveillance for rejection, monitoring and treatment of infections, nutritional rehabilitation, psychological care and a supported discharge. A wide range of team members are involved, but the transplant specialist nurses are vital for patient support. It is a mistake to try and operate this type of facility without adequate staffing and it is often difficult for those not directly involved to appreciate the number of staff required to provide adequate care for such a brittle and complex group of patients.

The median length of stay in Cambridge is 57 days, the US transplant centres report an overall median length of stay of 49 days (adults and paediatrics). Initially patients are on ICU or high-dependency units and may need to return to a level 2 or 1 unit if complications develop. It is important that patients are advised of this possibility; to avoid feeling this is a 'backwards step'.

All patients will be on parenteral nutrition immediately post-transplant. Nutritional requirements at this stage are very high due to an intense catabolic state and the PN script will reflect this. A feeding jejunostomy tube is often placed at the time of surgery, and this can be used for feeding once the stoma starts working (usually within the first week). Over 90% of patients are weaned off PN by the time of discharge and over 95% are free of this long term.

The international intestinal transplant registry (ITR) last presented their data in 2019. In this report, just over 4100 patients had received an intestine-containing graft worldwide. Patient survival curves for adult and paediatric transplant recipients are depicted in Fig. 5. UK-specific results are published annually at https://www.odt.nhs.uk/statistics-and-reports/organ-specific-reports/

Post Transplant Complications: Surgical

The usual range of surgical complications occur after transplantation but in addition there are some that require particular consideration.

Vascular Complications

Some patients have a history of arterial or venous thromboses [30] and will have an ongoing need for anticoagulation post-op. Despite this, some still develop thrombotic complications, in the most severe circumstances this can results in graft loss or the need for retransplant.

Management of thrombosis may be surgical (thrombectomy) or conservative.

The balance between bleeding and thrombosis in these patients is challenging. From a surgical perspective, bleeding is preferable to graft thrombosis and loss but it can have catastrophic consequences e.g. intracerebral haemorrhage. In intestinal transplantation the vascular anastomoses are wide with limited risk of stenosis. Vessel 'kinking' and extrinsic compression occur more frequently. In our series this particularly affects the donor SMA presenting with ischaemic enteritis [31].

The development of a mycotic aneurysm is a very unusual but potentially catastrophic vascular complication [32] (Fig. 6). The patient usually exhibits a fever with no obvious

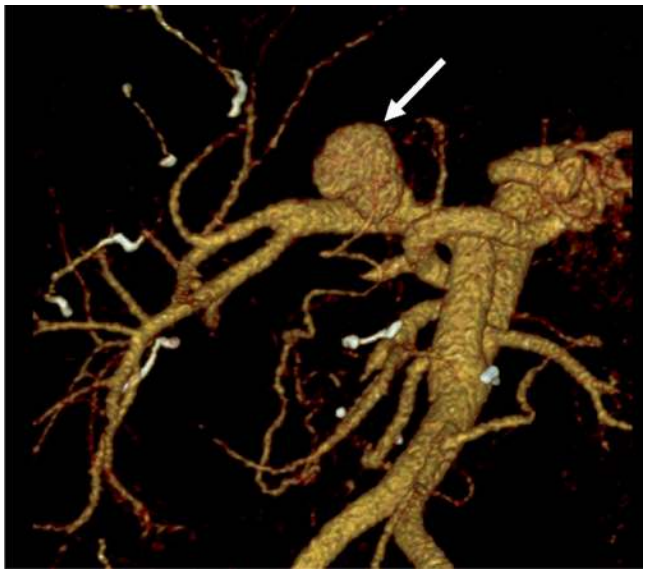

Fig. 6 Mycotic aneurysm of donor aortic conduit (arrow)

cause and a contrast enhanced CT demonstrates an aneurysm. Management is difficult and involves appropriate antimicrobial agents, interventional radiology [33] and may require surgery to excise the infected tissue and replacement with a vascular homograft.

Enteric Complications

Enteric Leaks

Enteric leaks can be either anastomotic or non-anastomotic. Diagnosis can be difficult in immunosuppressed patients. Prompt diagnosis relies upon a high index of suspicion and appropriate use of imaging (oral and iv contrast enhanced CT).

The oesophago-gastric anastomosis is at particular risk of leak and may be associated with Candidal infection. Management has traditionally been surgical (revision of the anastomosis) but successful use of endoscopic 'vac sponge' has been recently described [34].

The aetiology of spontaneous perforations is less clear. They happen relatively early after the transplant and may be associated with unrecognised ischaemic reperfusion injury.

Enterocutaneous Fistulae

These may be either iatrogenic (associated with surgical or radiological interventions) or 'spontaneous'. Iatrogenic fistulae may follow enterotomies at laparotomy. Surgical intervention early after transplantation is extremely challenging. The transplanted bowel is oedematous and friable and densely adherent to itself and the surrounding tissues.

Radiological placement of drains to treat post-operative collections is helpful but may result in perforation. Particular care is needed to avoid the pleural cavity as this may result in empyema and the potentiation of an enteric fistula.

'Spontaneous' entereocutaneous fistulae may also occur. These have been associated with intraperitoneal sepsis (often fungal) and graft ischaemia.

Volvulus

The transplanted small bowel has relatively few peritoneal attachments to the retroperitoneum and this may result in internal herniation and the potential for volvulus and subsequent infarction.

Stoma Complications

Endoscopic graft surveillance early after transplant *may* contribute to the development of stomal prolapse. Parastomal hernias are common. Immunosuppression and poor nutrition result in poor wound healing. The transplanted bowel is oedematous at the time of stoma formation and this may require the use of a larger fascial defect. Stoma reversal is usually undertaken at 6 months to 1 year but may not be possible if there is insufficient distal colon or the patient has a history of anorectal dysfunction [35].

Chyle Leaks

Chyle leaks may present following commencement of enteral feeding. Diagnosis is made by inspection of drain contents and confirmed by measurement of triglyceride concentration. Resolution is achieved with conversion to a medium chain triglyceride (MCT) diet as MCTs are absorbed directly into the portal bloodstream, rather than via the (disrupted) lymphatics [36], and/or bowel rest with parenteral nutrition.

Post Transplant Complications: Medical

Whilst most of the medical complications occurring in the post-transplant period are not unique to these types of grafts, many occur at higher rates than in other solid organ transplants. Of particular concern due to the morbidity and mortality incurred, and therefore discussed in detail here, are acute cellular rejection, graft versus host disease, post-transplant lymphoproliferative disorder (PTLD) and infections. Other significant complications including haematological, neurological and psychiatric, are outlined in brief. The typical medication list of a post-transplant patient is seen in Table 4.

Overall graft and patient survival has been improving over time. Data is collected from all centres for an international registry and the latest output from this registry is shown in Fig. 7.

Table 4 List of typical medication a post-transplant patient will be taking

Medication	Reason for taking	Duration
Tacrolimus[a]	Immunosuppression	Lifelong
Mycophenolate mofetil	Immunosuppression	Lifelong
Prednisolone	Immunosuppression	Reducing course, some may need to continue low dose lifelong
PPI	Gastric protection	6 months
Magnesium supplement	Manage hypomagnesaemia	Often only for 6–12 months
Fluconazole	Fungal prophylaxis	1 year
Valganciclovir/Aciclovir[b]	Viral prophyalxis	12 months/3 months
Penicillin	Splenectomy prophylaxis for some patients	Lifelong
Co-trimoxazole[c]	PCP prophyalxis	Lifelong
Anticoagulation	If pre or post-transplant thrombosis	Lifelong
Loperamide, codeine	Reduce stomal output	According to symptoms

PPI proton pump inhibitor, *PCP Pneumocystis jirovecii* pneumonia
[a]May be converted to ciclosporin or sirolimus
[b]Aciclovir if both donor and recipient CMV seronegative, otherwise valganciclovir given
[c]Alternatives are atovaquone, dapsone or pentamidine

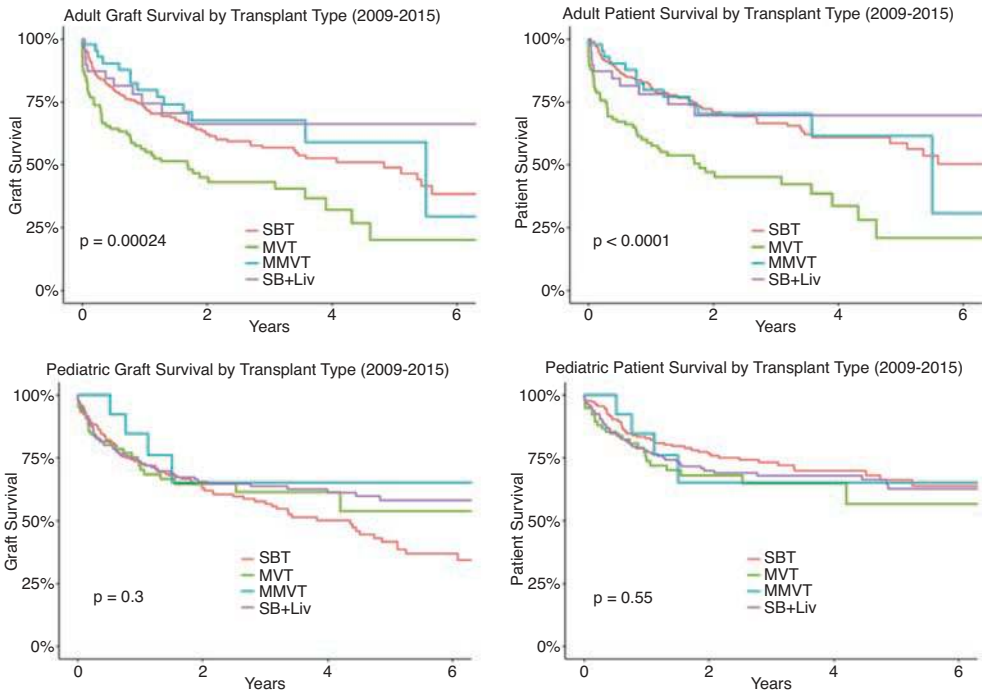

Fig. 7 Adult and paediatric patient and graft survival. Reproduced from the International intestinal transplant registry with permission

Acute Cellular Rejection

This is the most common type of rejection in intestinal transplant recipients and affects 30–40% in the first year [37]. In brief, the mechanisms involve donor antigen presentation to recipient CD4+ T cells, with co-stimulatory signals, resulting in activation of the CD4+ T cells. This results in IL-2 secretion which activates CD8+ (cytotoxic) T cells. These infiltrate the graft and cause tissue damage.

The intestine is more likely to reject, due to the increased numbers of antigen-presenting cells in the gut (intestinal epithelial cells express MHC Class II molecules, in addition to gut-resident 'professional' antigen-presenting cells such as dendritic cells and macrophages in mucosal layer). The classical presentation is with abdominal pain, fever and increased stomal output. However, it can rapidly progress to bacteraemia and septic shock as the damage to the mucosal layer disrupts the usual barrier function. Bacterial translocation can readily occur from the gut lumen into the bloodstream so concurrent broad-spectrum antimicrobials are usually given in addition to augmented immunosuppression.

Diagnosis is by endoscopic evaluation of the graft and histopathology. The early endoscopic findings are mucosal oedema (leading to loss of normal vascular pattern), progressing to ulceration and areas of mucosal/villous loss (Fig. 8). The histological criteria for diagnosis were defined

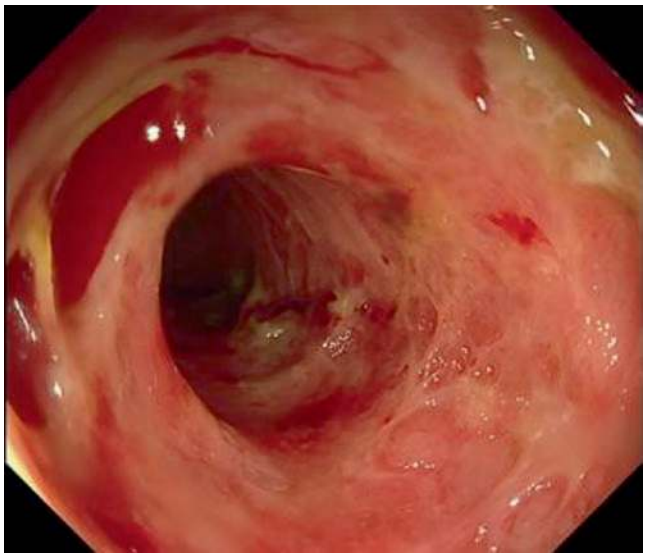

Fig. 8 Endoscopic appearance of severe rejection of the ileum, with mucosal loss, contact bleeding and reduced motility

at the VIII International Small Bowel Transplant Symposium in 2003 [38]. Histologically the early findings are of an increase in the number of apoptotic bodies in the crypts (expressed as the number of bodies per 10 adjacent crypts). With increasing severity, lamina propria inflammation is seen, then architectural distortion and mucosal ulceration. Infections can mimic the symptoms and early histological findings of ACR so it is important to screen all patients for bacterial pathogens and viruses (particularly adenovirus, rotavirus, CMV).

First line treatment of ACR is with pulsed methylprednisolone (500 mg–1 g per day for 3–5 days). Following this it can be difficult to determine the patient's trajectory. Endoscopic and histological features can take 2–3 weeks to improve. It is critical that escalation to second line treatment is timed appropriately. The authors' view is that if a patient is clinically well and a repeat endoscopy 1 week after the index scope does not appear to be worsening, then first line care should be continued. If the patient is deteriorating or the endoscopic appearances are clearly worsening, escalation to a second line agent is needed (Alemtuzumab, Anti-thymocyte globulin, Basiliximab). Graft removal may be necessary in refractory cases, followed by immediate or delayed relisting depending on the patient's clinical state and graft type [39].

Graft Versus Host Disease

Graft versus host disease (GVHD) after solid organ transplant is mediated by immunocompetent donor T lymphocytes moving out of the graft and mounting an immune response against native tissue. It can be considered the opposite process to graft rejection, but again occurs more frequently in patients receiving intestine-containing grafts, affecting around 10% of patients [40–42]. This is due to the large burden of reactive lymphocytes in the mucosa-associated lymphoid tissue and mesenteric lymph nodes.

Fig. 9 Typical skin rash of graft versus host disease (plaster depicts biopsy site)

Any native organ is potentially a target for GVHD, though the most common site is the skin. A maculopapular rash usually starts on the trunk (Fig. 9). Biopsy may show interface dermatitis. If there is a sex-mismatch between the donor and recipient, then fluorescence in-situ hybridisation (FISH) can demonstrate the presence of donor lymphocytes within the inflammatory infiltrate.

Other target organs can include lung, eyes, native GI tract or bone marrow. Involvement of the bone marrow leads to cytopenias and unfortunately the prognosis with bone marrow involvement is especially poor. An adjunct method for diagnosis and monitoring of GVHD uses the detection of peripheral T cell chimerism, the detection of reactive donor T cells within the circulating blood. This can be quantified as a percentage of total circulating lymphocytes and used to guide response to treatment.

Management approaches to GVHD differ between units. Some advocate an increase in immunosuppression, initially with pulsed methylprednisolone, to suppress the graft response. If this approach is used, the risk is of increased infectious complications. Others propose that reducing the immunosuppression (cessation of tacrolimus and antimetabolite) may allow the host immune system to counteract that of the graft. Using this latter approach mandates very careful graft monitoring for rejection and reintroduction of immunosuppression at the earliest signs of graft dysfunction.

Post-Transplant Lymphoproliferative Disorder (and Other Cancers)

Post-transplant Lymphoproliferative disorders (PTLD) is the most common *de novo* malignancy occurring after transplantation of the intestine, in both adults and children. It occurs

in around 15% [43, 44] usually within the first 12 months post-transplant. The site (s) affected are often the intestinal graft or mesenteric nodes, but can be extra-intestinal. PTLD is associated with EBV infection in the majority of cases and the development of an EBV viraemia should prompt investigation for possible PTLD.

^{13}FDG-PET CT scanning can be very useful in the work-up of possible PTLD, by identifying sites and giving a guide as to the burden of disease. However, definitive diagnosis requires a biopsy of affected tissue. The histology can vary, from polymorphic lymphoid proliferations, to aggressive monomorphic PTLD or Hodgkin's-like tumours.

Management of PTLD is with a cautious reduction in immunosuppression and Rituximab, a chimeric antibody to CD20, a B cell surface marker. There is some evidence that Ganciclovir has activity against EBV *in vitro*, but not *in vivo*. EBV-specific Cytotoxic T cells are available commercially in some areas and have been used for PTLD following haematopoietic stem cell transplant and PTLD after intestinal transplant. For refractory cases, chemotherapy is necessary. In general, the outlook is good, with reported survival after PTLD at 1 year of 91% and 75% at 5 years [44] of those affected.

All solid-organ recipients are counseled about increased risk of other malignancies, particularly non-melanoma skin cancer. 50–75% of Caucasian transplant recipients will be affected by skin cancer within 20 years of transplant. Risk factors include fair skin, UV exposure, older age and cumulative exposure to immunosuppression. Patients are therefore advised to adhere rigidly to guidance recommending high factor sunblock and protective clothing.

Cytomegalovirus

Cytomegalovirus (CMV) is the most common viral infection after intestinal transplant. Rates are highest in recipients who are naïve to CMV themselves but receive organs from seropositive donors [45]. Intestinal transplant centres may use universal prophylaxis or a pre-emptive strategy to manage risk of CMV infection. Some centres will also list CMV seronegative recipients for matched (also CMV negative) donors.

Manifestations of CMV infection include asymptomatic viraemia, CMV syndrome (fever, malaise and cytopenias) or tissue-invasive disease. Diagnosis is by quantitative PCR-based detection of viral DNA and histological examination of suspected end-organs involved.

Universal prophylaxis is usually with ganciclovir (intravenous) or valganciclovir (oral). Treatment of confirmed disease is also with one of these agents, at higher doses. Dose adjustment is required for renal dysfunction. Ganciclovir resistance is an emerging problem and should be suspected if there is a failure of clinical response within the first 2–3 weeks. Alternatives include foscarnet and cidofovir and newer agents include maribavir and letermovir. Adjunctive therapies are used variably, and include CMV immunoglobulin, lefluonamide and adoptive transfer of CMV-specific T cells.

Neurological Complications

Calcineurin inhibitors (CNI's) such as tacrolimus cause tremor and myoclonic jerks. This is usually dose-related and responds to a lowering of the blood level. CNI's can also cause Posterior Reversible Encephalopathy Syndrome (PRES) which presents in a variable way, with symptoms including headache, visual disturbance, confusion and seizures. Underlying mechanisms are not fully understood, but possibly include cerebral auto-regulation failure. Characteristic imaging features are of vasogenic oedema in the occipital and parietal lobes, best seen on T2-weighted FLAIR MRI head sequences. Patients respond to a change in immunosuppression and the prognosis for recovery is good [46].

In patients who have received an isolated intestinal graft, the donor portal vein that accompanies the graft, is usually anastomosed directly onto the inferior vena cava, effectively forming a porto-systemic shunt. If there is moderate liver fibrosis (perhaps the indication for transplant), then a hepatic-like encephalopathy can occur, with asterixis, confusion and raised ammonia. Management is with laxatives and non-absorbable antibiotics such as Rifaximin. Occasionally this can occur in the context of essentially normal liver function if there is a high burden of small bowel bacterial overgrowth due to stasis. It is of value to exclude reversible causes of stasis such as anastomotic strictures [47].

Haematological Complications

Many of these patients have pro-thrombotic tendencies which have led to their needing an intestinal or multivisceral transplant (mesenteric arterial thrombosis leading to short bowel, venous thrombosis associated with central venous catheters for parenteral nutrition, extensive porto-mesenteric thrombosis associated with cirrhosis). The transplant itself involves the addition of new vascular anastomoses, therefore, for most patients anticoagulation is continued, even in the early post-operative period.

Drug-induced leucopenia or myelosuppression is common [48], as many of the necessary drugs have this side effect. In particular, the antimetabolites such as azathioprine and mycophenolate, and antimicrobial agents ganciclovir and co-trimoxazole are common culprits. Minimising the doses, using alternative agents, or supporting counts with

Granulocyte colony stimulating factor (GCSF), are strategies for overcoming this problem depending on the clinical condition of the patient.

Transplant-Associated Thrombotic Microangiopathy (TA-TMA) is a multisystem disorder characterized by a microangiopathic haemolytic anaemia (MAHA), thrombocytopenia and end-organ damage affecting the kidneys and/or brain. There are no absolute diagnostic criteria but supportive findings include red cell fragments, thrombocytopenia and raised lactate dehydrogenase. In the transplant population, the most common causes are calcineurin inhibitors and sirolimus [49]. Management involves a change in immunosuppression and plasma exchange or eculizumab, a complement-blocking antibody, for refractory cases.

Renal Complications

Intestinal transplant recipients are at particular risk of developing chronic renal failure (CRF) and this must be taken into account during the assessment and listing process. In a large US study of almost 70,000 transplant recipients (but only 228 intestinal grafts), the cumulative incidence of developing CRF (defined as an estimated glomerular filtration rate of ≤29 mL/min/1.73m^2 body surface area), was 14.2% at 3 years and 21.3% at 5 years [50]. A more recent analysis of all adult intestinal transplant recipients in the US included 843 patients and showed alarming 1, 5 and 10-year cumulative incidence of CRF (defined as eGFR <29 mL/min, chronic dialysis or need for renal transplant) was 3.2%, 25.1%, and 54.1% respectively [51]. A smaller case series from the UK showed a median decline in GFR of 40% in the first 3 months after transplant [11]. The mortality rate for those developing CRF after transplant was sixfold higher than those who maintained renal function.

It is critical to preserve renal function pre transplant, as this study also showed that each 10 mL/min/1.73 m^2 increase in GFR pre transplant was associated with a reduced risk of CKD by 7.6%. This is especially important in patients with short bowel who may have high stomal fluid losses. In the UK it is recommended that all patients referred for intestinal transplant assessment are also considered for simultaneous renal transplant [52] if their baseline GFR is <45 mL/min/1.73m^2. Although it increases the time and complexity of the transplant procedure, short term outcomes for those who receive combined grafts are similar to those without [53].

Psychological Considerations

There are no studies evaluating mental health in intestinal transplant recipients. Studies on quality of life have reported disparate results [54], which likely reflects the heterogeneity of the patients. The need for ongoing nutrition support, frequency of hospital admissions and need for interventions strongly influence the self-reported quality of life outcomes for patients. The neuropsychiatric side effects of corticosteroids are well known. Patients who have been dependent on opiates pretransplant may need continued support with this and involvement of a multidisciplinary pain team is extremely helpful. Recent data from the team in Oxford showed lower quality of life metrics in patients being assessed for transplantation compared to patients stable on home parenteral nutrition, but improvement following transplant to levels comparable to this stable HPN cohort [55]. The effect was seen using generic and disease specific measurement tools.

In the UK, two recipients of intestinal transplant set up a support group for all adult and paediatric patients. They provide valuable emotional support to patients and families on every step of their journey, supply care packages to patients who are in hospital and are actively involved in raising awareness and fundraising.

Transition of patients transplanted as children who are now entering adolescence must be carried out in a meticulous, planned way. This time is associated with graft loss and significant morbidity if not conducted properly. The key requirements are a staged handover and multiple joint clinics between the paediatric and adult teams.

Conclusions

Significant advances have been made in the medical and surgical management of patients receiving an intestine-containing transplant. Survival rates are now similar to those on home parenteral nutrition (HPN), thus intestinal transplant should be at least *considered* for all patients with permanent intestinal failure, particularly for those HPN patients in higher risk groups. The development of end-stage IFALD severely disadvantages patients and Intestinal Rehabilitation teams need to develop processes that are more proactive in diagnosing and monitoring IFALD so that timely referral for transplantation can be considered. It is also crucial that patients who are losing vascular access are referred early enough to still be candidates for transplantation.

Aside from Intestinal Failure, the indications for transplant are expanding and with this it is crucial that multidisciplinary decision-making continues and there are robust reporting systems to the appropriate body for the evolving indications (for example, the advisory groups of NHS Blood and Transplant in the UK and the international Intestinal Transplant Registry https://www.odt.nhs.uk/odt-structures-and-standards/clinical-leadership/advisory-groups/; https://tts.org/irta-resources/irta-resources-main).

As patient and graft survival rates improve, surgical techniques are advanced and medical prevention and management of complications continue to improve, the time is approaching when intestinal transplant can be offered as an alternative to HPN. All clinicians caring for patients with intestinal failure should be aware of the possibility of intestinal transplant and be able to discuss this with their patients. Local teams will also need to be involved in the acute management of sick transplant recipients (Box 1). Referring and transplant centres must continue to work cooperatively to optimize outcomes for all patients with intestinal failure. Establishing a dedicated forum for clinicians to present and discuss their patients and learn from each other's experiences in a cooperative and supportive environment is of particular value.

Box 1 Actions to be Taken When an Intestinal Transplant Recipient Is Admitted Unwell to a Non-Transplantation Hospital

1. Contact the appropriate transplant centre without delay for advice and possible transfer
2. Undertake a full infection screen, including culture (and microscopy) of blood, urine, sputum, stoma effluent/stool, EBV/CMV–PCR, chest and/or abdominal imaging as guided by symptoms. Common seasonal viral infections can present as a severe illness in these patients and trigger graft rejection
3. If infection is suspected (usual) commence broad-spectrum antimicrobial therapy without delay, with advice from microbiologists. This usually includes: meropenem, vancomycin, AmBisome®, ganciclovir. If there is evidence of pulmonary infection, consider high-dose co-trimoxazole, which is active against *Pneumocystis jirovecii*. Advice should be sought from the transplant centre (24/7 on call service available). Many of these patients are colonised with multi-resistant micro-organisms, details of which can be obtained from their transplant centre
4. Be aware of the possibility of tacrolimus nephrotoxicity and neutropenia associated with valganciclovir and co-trimoxazole (patients may already be taking these)
5. Fluid balance: patients will be prone to salt and water depletion. They should be aware of their normal body weight, assess sodium and water balance with spot urinary sodium and osmolarity respectively (urine dip stick for specific gravity is a helpful initial guide)
6. Graft rejection is difficult to diagnose so patients should be transferred to an appropriate transplantation centre as soon as possible. Suspect rejection if there is a change in stoma output, abdominal pain, fever and/or vomiting
7. These patients are likely to develop unexpected complications which often present in an unusual manner and transfer back to the transplant centre is usually the best option

Acknowledgements The authors would like to thank all members of the transplant team, colleagues in referring centres, our patients and their families.

Glossary[1]

Allograft Transplant between two genetically different members of the same species.

Allogeneic Of different genetic make up and therefore capable of inducing rejection.

Antigen A protein molecule that is capable of inducing an immune reaction. In transplantation antigens on the surface of graft cells are the trigger to the immune system of the recipient-inducing rejection.

Carrel patch Full thickness cuff of aorta incorporating the orifices of the coeliac and superior mesenteric arteries to facilitate the arterial anastomosis.

Cell surface markers Antigenic determinants on the surface of cells. In some circumstances these act as binding sites and linkage with a matching determinant is important to allow an immune reaction to proceed. Cell surface antigens have been defined by a number of international workshops that have generated the Cluster of Differentiation (CD) nomenclature.

CD3 The CD3 antigen is composed of five invariable chains and is closely associated with the T-cell antigen receptor. It is expressed on 70–80% of normal peripheral blood lymphocytes and plays a significant role in signal transduction during antigen recognition.

CD4 The CD4 antigen is transmembrane glycoprotein expressed on T helper/inducer cell populations. It is expressed on approximately 45% of peripheral blood lymphocytes and it is involved in the co-recognition of MHC class II antigens in association with the T-cell receptor.

CD8 The CD8 antigen is a two-chain complex expressed on T cytotoxic/suppressor cell populations. It is expressed on 13–48% of peripheral blood lymphocytes and it is involved in the co-recognition of MHC class I antigens in association with the T-cell receptor.

CD25 The CD25 antigen is the low affinity inter-leukin-2 receptor. It associates with the common (CD132) and high affinity (CD122) chains to form the high affinity IL-2 receptor complex. CD25 is expressed on activated T and B lymphocytes and activated macrophages and its expression on lymphocytes is upregulated on activation. Interleukin-2 receptor antagonists are used as induction immunosuppression in certain patients.

CD28 The CD28 antigen is expressed on most mature T-cells and antibody-producing B-cells (plasma cells). It is involved in signal transduction and cell activation events.

[1]This glossary provides definitions of immunological and transplant-related terms, which may be unfamiliar to some readers.

CD44 The CD44 antigen is expressed on leucocytes, erythrocytes and weakly on platelets. The molecule has a functional role in cell migration, leucocyte homing and adhesion during lymphocyte activation.

CD52 The CD52 antigen is present on mature T and B lymphocytes and is the target for Alemtuzumab induction immunosuppression.

Chimerism The presence of donor cells in recipient tissues or bloodstream.

Graft-versus-host disease A reaction in which lymphoid cells in a graft are capable of migrating to recipient tissues and stimulating an inflammatory immune reaction. This is an important feature in bone marrow transplantation but can also occur in intestinal transplantation because the gut contains large numbers of lymphoid cells capable of migrating.

Haplotype A set of genetic determinants located on a single chromosome.

Heterotopic A graft placed in an abnormal anatomical position.

HLA Cell surface proteins encoded by the highly polymorphic major histocompatibility gene in humans. The HLA/MHC proteins are highly involved in antigen presention to T cells.

Natural killer cells Cells capable of reacting against foreign proteins without undergoing prior sensitization. They act as immune scavengers and are important in both cancer (in eliminating abnormal cells) and in transplantation where they may be able to initiate rejection.

Orthotopic A graft placed in its normal anatomical position. In intestinal transplantation the proximal end of the small bowel would therefore be connected to the duodenum and the distal end to the ilio-caecal junction.

Tolerance The specific absence of a destructive immune response to a transplanted tissue in the absence of immunosuppression.

Abdominal Wall Repair in Intestinal Failure

Akash Mehta and Ciaran Walsh

Key Points

1. Even when surgery of the abdominal wall appears simple it may still be very high tariff in an IF patient.
2. Reduce hernia formation in midline wounds by using a small bites closure technique with 2/0 slowly absorbable monofilament suture with self locking knots.
3. Avoid the need for extensive abdominal wall repair surgery by avoiding laparostomies whenever possible. If truly needed then have a plan to close them early with the use of mesh mediated or other graduated fascial traction techniques.
4. Put complex cases through a preoperative planning meeting including a multidisciplinary team with radiology and plastic surgeons present as well as IF and AWR surgeons.
5. Plan carefully with intestinal and abdominal wall mapping. Do not be afraid to perform the abdominal wall surgery in stages. An IF patient's priority is their intestinal integrity and nutritional autonomy. The AWR can follow so align the surgeons and the patient's expectations and priorities.
6. Use a prehabilitation program.
7. Time the surgery correctly and give correct time to the surgery (enterotomies are the devil incarnate).
8. Choose your mesh type carefully on a case by case basis.
9. Consider preoperative botulinum toxin injection to oblique muscles to try and prevent the need for irreversible muscle cutting components separation or to augment it

Closing the Abdomen

The ideal abdominal closure technique should promote optimal and timely tissue healing, provide adequate protection to the viscera, act as a barrier to infection and have sufficient tensile strength in the short and long term to produce good abdominal wall function. It should be reproducible, efficient, and have a low incidence of complications. It should be as aesthetically pleasing as possible and should not impinge on stoma formation or function. All of this needs to be aligned to the context of the surgery being performed and therapeutic priorities in elective and emergency surgery whether by open or minimally invasive techniques. There is ongoing discussion and debate on the best way to close the abdomen in nearly all circumstances [1].

Primary Wound Closure

The problem with closing the abdomen is that it comes at the end of the operation and may not be regarded as part of the operation. The entire focus, often for many hours, has been doing the intended intraperitoneal surgical procedure. However, abdominal closure decisions and techniques are critical and include how best to close, whether to close permanently or temporarily or not to close at all. These decisions may have lifelong consequences for the patient.

Different techniques are needed for different situations. First time midline incisions in elective open surgery, elective open re-operative surgery with or without a hernia and/or stoma, elective minimally invasive surgery and emergency surgery in an unstable patient may all need to be closed differently. Data from randomised controlled trials in elective surgery may not apply to the patient in front of you who by definition was in an exclusion group for such trials for some reason whether that be having a stoma, an emergency procedure, being morbidly obese or septic.

J. M.D. Nightingale (ed.), *Intestinal Failure*, https://doi.org/10.1007/978-3-031-22265-8_60

Apart from a bowel injury and an enteric fistula, arguably the most important long-term complication of inadequate abdominal wall closure is incisional hernia; the occurrence of which is often used as an arbiter of the quality and appropriateness of a closure technique. Sadly, incisional hernias are common and may significantly impair quality of life or lead to life threatening emergency presentations [2, 3]. Furthermore, they will often recur after they have been repaired and represent a significant burden on the health economy as well as on the individual patient.

Incisional hernias often occur after a surgical site infection (SSI). Every effort has to be made to use a surgical site infection bundle allied to a closure technique that is least likely to result in a wound infection and a subsequent incisional hernia.

For elective surgical closure of elective midline incisions current clinical evidence supports fascial closure with continuous slowly absorbable sutures, using a small bites technique placed 5 mm apart with a 5 mm width using self-locking knots with an overall suture to wound ratio of at least 4:1. This opinion is based on multiple studies from Israelsson's team in Northern Sweden [4–7], and supported further by the Dutch multicentre, randomised controlled STITCH trial [8], as well as a recent meta-analysis [9] and European guidelines [10].

Closure does not only refer to fascial closure. Detailed attention to the lipocutaneous tissues overlying the deep fascia is also important. It is important to prevent dead space and pay careful attention to superficial tissues with careful use of dermal and subcuticular sutures possibly augmented by vacuum dressings [11], whilst avoiding fat stitches and skin staples where possible.

In reoperative and emergency settings, and in different incision types, things are less clear. In re-operative surgery, even in the elective context, using involved wound closure techniques may be less well advised when performing enteric surgery with a higher risk of septic complications. The small bites technique may have benefits in the context of emergency laparotomy as regards acute wound failure, but this needs to be taken in the context of other priorities in many of the severely ill and unstable patients having these operations. In this context incisional hernia prevention may not be the key priority. Alternative techniques such as the Cardiff (Hughes) technique may be preferred for closing abdomens when patients are at high risk of incisional hernias such as after complete abdominal wound dehiscence or after laparostomy [12, 13]. Attention also needs to be paid to subcutaneous and skin closure techniques in these alternative settings and these may need to be different and may include leaving areas of the superficial wound open to heal by secondary intention or to augment the closure with a Vacuum dressing.

Stoma Wound Closure

Optimal fascial closure techniques in isolated stoma closure surgery are uncertain [14]. The incidence of incisional hernias in this cohort is likely between 5–40% depending on study bias, duration of follow up and whether assessed by CT scan or clinical exam alone [15].

Recent prospective randomised data trial data suggest a possible benefit from prophylactic biologic mesh in preventing incisional hernia at the stoma site [16]. Concurrent parastomal hernias are common in this group and how they should be dealt with is uncertain as is the technique of fascial closure when they are absent. It is uncertain whether the fascia of a stoma wound with an associated hernia should be closed differently from one without a hernia. A small bites fascial closure technique with self-locking knots may be an effective and possibly cheaper option than using prophylactic biologic mesh but awaits formal trial. It is certainly the case that the anterior rectus fascia needs to be carefully identified and incorporated in the suture bites. As regards the superficial wound closure at stoma sites there is Level I evidence in favour of purse string closure of the superficial wound rather than primary skin closure in terms of reducing surgical site infection [17]. There is also some small cohort-based data to suggest a role for negative pressure wound therapy applied to these stoma closure wounds [18].

Delayed Primary Closure of the Abdomen

Occasionally it is either not possible or not wise to close the abdomen primarily at the index laparotomy. In such an instance the surgeon may choose to fashion a laparostomy. There is no doubt that laparostomies at the time of emergency surgery have saved lives but equally they are to be avoided whenever possible. In the setting of an emergency laparotomy for an abdominal catastrophe and a damage limitation laparotomy the formation of a laparostomy may well be appropriate. If a laparostomy is performed there must be a definite closure plan to achieve delayed primary fascial approximation. Laparostomies are fistulogenic; moreover, they create a big problem for the future with the formation of an enormous incisional hernia. These hernias are difficult to repair with good outcomes and low morbidity. In essence therefore delayed primary closure of a laparostomy helps prevent a very large incisional hernia and may well prevent intestinal failure (IF) due to an enterocutaneous fistula (ECF) or an entero-atmospheric fistula (EAF).

The key to facilitating delayed primary closure is to prevent the abdominal contents from sticking to the parietal peritoneum at the index laparotomy. This permits the two laterally retracted halves of the midline fascia to be brought together without

shearing and damage to the abdominal contents when the midline fascia is sequentially and progressively approximated and closed at subsequent surgeries. The technique most commonly employed is that of mesh-mediated fascial traction combined with negative pressure wound therapy. In this technique a synthetic mesh (most commonly polypropylene) is sutured around the edges of the fascial defect over a large, fenestrated, non-adhesive plastic sheet (covering the abdominal contents and extending all the way into the flanks). A long slit is made in the middle of the mesh and then the two halves of the mesh are sutured together in the midline and a vacuum system applied on top of the mesh. This makes for an easy to manage wound system in the intensive care unit, prevents well-meaning but potentially damaging wound inspection and manipulation outside of theatre and helps reduce some wound oedema whilst preventing lateralisation of the fascial edges. In the course of sequential planned returns to theatre, the two halves of the mesh are sutured together with a greater degree of tension. Each time the patient is returned to theatre on a planned basis over the coming days this mesh is tightened over the plastic sheeting until gradually the two fascial edges become opposed. Ultimately the plastic sheeting and mesh can be removed completely, and the fascia sutured together to reconstitute the linea alba. In this way the mesh-mediated fascial traction has performed a staged and delayed primary closure of the midline wound, prevented a huge incisional hernia and possible development of IF due to an EAF. It must be stressed that none of this is possible if the non-adhesive plastic sheeting (either home-made or commercially available) is not wrapped around the bowels at the time of the first emergency laparotomy.

For the IF surgeon, quite often one's first encounter with a patient with an open abdomen occurs days or weeks down the line, with or without associated small or large bowel stomas and with or without an enteric fistula. The laparostomy is semi-mature at this point and the bowel loops will have adhered to the parietal peritoneum, the fascial edges retracted laterally and staged primary closure is not possible in this scenario. In this situation the subsequent management will depend on the presence or absence of an ECF/EAF and will be modified according to the presence or absence of stomas, particularly high output jejunostomies. In the absence of a fistula the key abdominal wall management strategy is simply to protect the bowel and avoid a fistula. In the authors' opinion, there is no place for an expensive biologic mesh as a glorified wound dressing. Best care is often with a wound manager system that sits around and over the wound and keeps it in a moist environment permitting wound granulation and shrinkage whilst the abdominal contents are protected. If a suction device is to be used in the gutters of such a system to remove accumulated oedema fluid, then great care must be taken to ensure it does not come in contact with the bowel and cause a fistula.

If the patient has an ECF/EAF at this stage then the management is different and is covered in Chap. 5 on the management of ECF's. Skin care is critical in acute abdominal wall failure and will be covered elsewhere in the book in chapter on ECF's.

Occasionally, a patient may be taken back to theatre at this stage for an attempt at skin/subcutaneous closure, or alternatively placement of a bridging polyglactin (Vicryl) mesh to protect the bowel loops, permit granulation and even subsequent skin grafting. This is aimed at bowel protection rather than any attempt at fascial approximation. It should be emphasised that during such procedures no attempt should be made at adhesiolysis or manipulation of the intestinal cocoon. The benefit of the absorbable polyglactin mesh approach is that when the patient is brought back to theatre many months later for definitive surgery, one finds that instead of paper thin laparostomy skin intimately attached to underlying bowel loops, there is in fact a rind that permits safer entry into the peritoneal cavity and helps reduce the risk of this most tricky part of the laparostomy take down and incisional hernia repair, namely peeling the laparostomy skin off small bowel loops with a scalpel.

Abdominal Wall Repair in IF Patients Without an Incisional Hernia

This situation might simply be someone with a very proximal stoma or ECF without an abdominal wall hernia or it might be a relaparotomy in someone with radiation enteritis or a short bowel syndrome after multiple previous laparotomies, possibly including a prior incisional hernia repair, stoma reversal or both. Even when surgery of the abdominal wall appears relatively straightforward, the effect of previous surgery and radiotherapy in particular on the abdominal wall blood supply requires careful thought. Previous incisions may have damaged the epigastric vessels that supply the mid-abdomen lipocutaneous pedicle (Huger Zone 1) via their perforators and non-healing of the wound may be a problem as a result [19].

The principles of primary wound closure previously described need to be applied but with the additional care to factors that delay or prevent abdominal wound healing. Occasionally an abdominal wall has been operated on so many times that it is failing as a functional unit yet there are no true hernias. There may be areas of poor-quality skin from previous infected wounds or repairs and in these situations, it is strongly advised to involve plastic (i.e. reconstructive) surgeons in the decision making to prevent even further complications if further surgery is proposed. It is often just as important to review old operation notes (often from other hospitals), CT scans and the microbiological history in these

cases as it is in cases with difficult large incisional hernias that require repair.

Abdominal Wall Repair in IF Patients with Incisional Hernias

Incisional hernias are a common complication of abdominal surgery [2], as are further recurrences after their repair. Hernia complexity is related to patient comorbidities, hernia size, dimensions and features of the hernia including loss of domain, previous repair history including previous mesh choice and site as well as clinical context including contamination, tissue characteristics and the nature of the clinical presentation [20–25]. In the context of IF, complexity is likely to be high for many reasons including comorbidities and contamination with or without fistulation or concomitant stomas. Abdominal wall failure accompanying intestinal failure requires an experienced multiprofessional team to get best results for both abdominal wall and IF outcomes.

Fundamentals of Incisional Hernia Repair

Abdominal hernia repair needs to be both durable and dynamic with a functional abdominal wall that provides visceral protection, strength and function with a low complication rate and outcomes that provide an improved quality of life for the patient. There are good quality data showing that suture repair without mesh augmentation is associated with a higher recurrence rate [2, 26].

The most important dimension of an incisional hernia as regards recurrence is its transverse diameter [20, 25]. Historically, and occasionally also today in rare and extreme cases, if the opposing edges of the fascial defect cannot be brought together, despite all adjunctive measures, tips and tricks, the gap between them can be bridged by a piece of mesh. This is suboptimal and midline fascial closure is critical. Bridging is to be avoided if at all possible to prevent hernia recurrence as well as other complications including a lack of abdominal wall function [27]. When a hernia repair technique alone is insufficient or inappropriate then one may need to employ abdominal wall reconstruction techniques. The definitive abdominal wall surgery and the IF surgery may need to be staged. The important thing is that cases are discussed preoperatively by a team of people with different skill sets who can plan the best surgical approach based on history, clinical findings, CT scan information, allied to the patient's priorities, wishes and choices.

It must be borne in mind that hernia recurrence in an IF patient may well not be the main priority. Intestinal continuity and nutritional autonomy are the key priorities to be achieved with a minimum of abdominal wall morbidity.

Fundamentals of Abdominal Wall Reconstruction

The term Abdominal Wall Reconstruction (AWR) refers to techniques used to correct the musculo-aponeurotic integrity of the abdominal wall when a straightforward hernia repair with fascial reunion cannot be achieved. This may involve importing tissue into the defect from elsewhere or manipulating the abdominal wall musculature by releasing incisions with separation of the different components of the myofascial package to permit greater movement of one muscle or fascia on another and ultimately permit fascial apposition and reunion. These approximated fascial edges are then reinforced with mesh. The principles of mesh material choice will be much the same as in incisional hernia repair, but the choice of mesh size and site of placement will depend on the technique used. With smaller defects chemical or pharmacologic release or separation with botulinum toxin may be all that is required as an adjunct to a hernia repair or in addition to surgical muscle or fascial releases. In more severe cases with tissue loss a muscle graft may be required to fill the defect and in the most extreme cases where there is abdominal wall failure an abdominal wall transplant may be performed usually as part of a multivisceral transplant for end stage intestinal failure. Regardless of technique the objectives of abdominal wall reconstruction are restoration of abdominal wall integrity, protection of intra-abdominal viscera and the prevention of herniation [28].

Evolution of Abdominal Wall Reconstruction

The sublay mesh technique, based on retromuscular and preperitoneal repairs of ventral hernias as described by Jean Rives and Rene Stoppa, in 1965 and 1966 respectively, has increasingly become the gold standard approach to bigger or more complex ventral hernias (Fig. 1).

Rives, in performing the retrorectus dissection, may possibly have been setting out to create a suitable plane in an extraperitoneal location for mesh placement excluded from visceral contents; however, in doing so he performed a *myofascial* release of both recti permitting some medialisation and approximation of the two halves of the linea alba. There had been published work on myofascial release in ventral hernia repair since 1916 [29–32], and these papers were arguably the foundations upon which was built the landmark paper by Ramirez describing his components separation technique [33]. He described the division of the external oblique muscle and development of the avascular plane between the external and internal oblique muscles to permit one to slide on the other and that, when combined with the Rives-Stoppa retrorectus dissection, permitted significant medialisation of the recti to repair bigger defects.

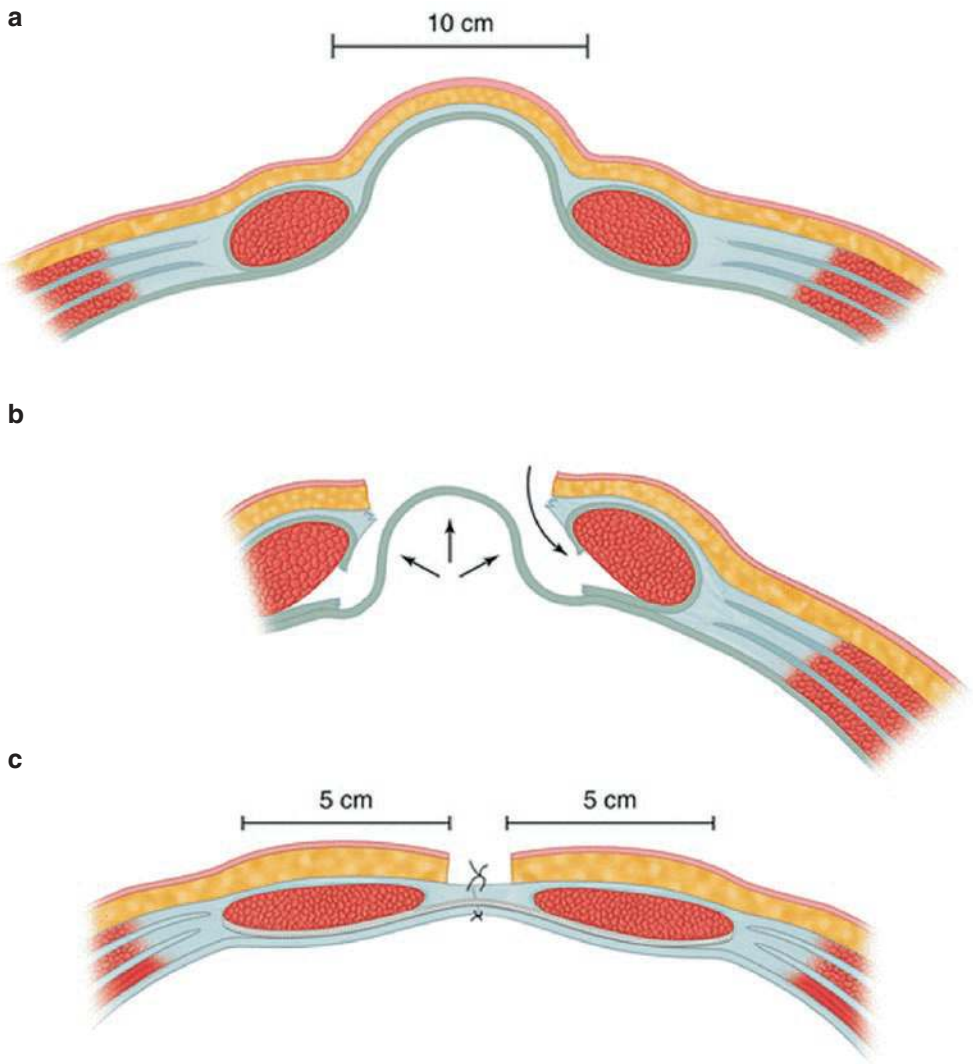

Fig. 1 Rives-stoppa retrorectus mesh repair of midline hernias. (**a**) Midline incisional hernia; note the substantial retraction of the rectus muscles. (**b**) Opening and development of the retrorectus space after incision of the posterior rectus sheath. (**c**) Primary fascial closure with retrorectus mesh reinforcement; note the elongation and medialisation of the rectus muscles

The importance of the concept and popularisation of components separation cannot be overstated. Prior to the publication of Ramirez' paper in 1990 [33], and the development of components separation techniques, ventral defects which could not be closed by en-bloc mobilisation of the abdominal wall were repaired by insertion of a bridging synthetic mesh, exposing patients to potential mesh infections, fistulisation and high hernia recurrence rates. Defects with inadequate soft tissue cover were repaired using autologous tissue transfers (e.g. free or pedicled tensor fascia lata flap), which, although providing coverage, did not actually reconstruct the abdominal wall or its function, leading not only to high hernia recurrence rates, but also significant morbidity related to the donor site. Components separation, in contrast, does not just "close the hole" without the need for a donor site, but restores abdominal wall anatomy and function, by achieving a tension-free re-approximation of the linea alba, restoring the normal anatomical relationship of the abdominal wall muscles and offsetting the lateral pull of the oblique and transverse muscles.

Although truly revolutionary as a concept in the repair of major abdominal wall defects, Ramirez' technique does have some limitations and disadvantages:

- The morbidity associated with the raising of often quite substantial lipocutaneous flaps (seroma formation, skin necrosis, etc)
- The inability to fully close the posterior sheath in large ventral hernias
- The limitations in mesh size being defined by the linea semilunaris bilaterally

To address these limitations, various techniques have been developed and popularised, some of which are modifications of Ramirez' original procedure, whilst others represent completely new avenues and aspects of the core concept of components separation.

Modifications to Ramirez' components separation are all aimed at preserving the integrity of skin/subcutaneous fat/fascia complex to preserve the perforators which form the blood supply to the skin [19].

An endoscopically assisted technique for incision of the external oblique aponeurosis and development of the avascular plane between the external and internal oblique muscles was developed which allowed for direct, minimally invasive access to the external oblique aponeurosis and the inter-oblique plane without the need for development of lipocutaneous flaps [34]. A similar modification, termed the perforator-preserving component separation, also involves direct access to the external oblique aponeurosis just lateral to the semilunar line, reducing the need for raising large lipocutaneous flaps [35].

As stated, Ramirez' component separation involves a "standard" Rives-Stoppa retrorectus dissection. This means that the space available for mesh placement is limited to that of the retrorectus space, between the two semilunar lines. In larger ventral hernias, sufficient mesh overlap of the visceral sac is therefore difficult or even impossible to achieve. A preperitoneal, retrofascial approach was developed which allowed for the creation of a large preperitoneal plane for placement of a widely overlapping synthetic mesh. This method, developed and popularised by Heniford, was first described in 2006 [36, 37]. Following on from work by Carbonell in 2008 [38], Novitsky and Rosen published the novel technique of posterior components separation (PCS) utilising transversus abdominis release (TAR) [39], as opposed to Ramirez' anterior components separation (ACS) utilising external oblique release.

Posterior components separation creates a large retromuscular space allowing for sufficient mesh overlap combined with medialisation of abdominal wall compartments without raising lipocutaneous flaps. This technique again involves an initial standard Rives-Stoppa retrorectus dissection with mandatory identification and preservation of the neurovascular bundles just medial to the semilunar line on each side. Key to the TAR approach is the fact that the transversus abdominis muscle fibers extend medial to the semilunar line in the upper abdomen (Figs. 2 and 3). The key is to go through the posterior rectus sheath medial to the linea semilunaris to identify and go through the transversus abdominis muscle to access the front of the transversalis fascia and develop the plane between the front of the transversalis fascia and the back of the transversus abdominus muscle (Figs. 4 and 5). A key to understanding the versatility of this approach is understanding the origins and insertions of the transversus abdominis muscle; in particular its superior origins are from the costal margin thus by getting behind the transversus abdominis one gets up behind the ribs. The dissection is followed past the xiphoid process to the fascia diaphragmatica (the transversalis fascia covering the diapragm) in the preperitoneal plane and inferiorly into Retzius' and Bogros' space with identification of Cooper's ligaments. These are key points because it means this technique is not limited by the bony costal margin and one can get a mesh

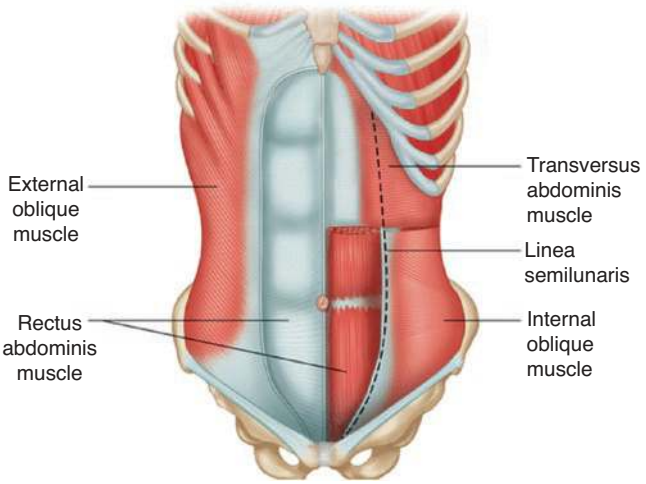

Fig. 2 Sections of the anterior abdominal wall showing the transversus abdominis muscle extending medial to the semilunar line in the upper abdomen

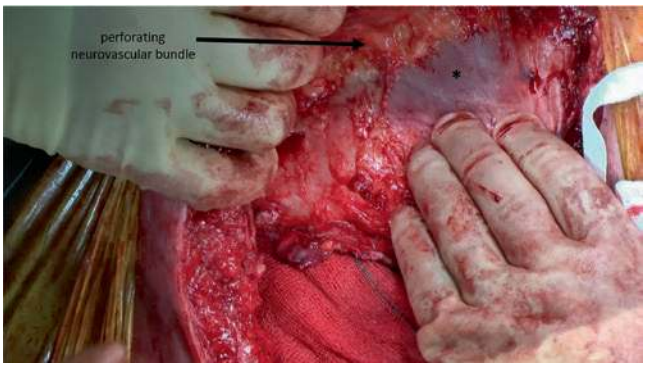

Fig. 3 Intra-operative photograph after completion of full retrorectus dissection upto the semilunar line, clearly showing the muscle fibers of the transversus abdominis (*) extending medial to the semilunar line under the posterior rectus sheath

Fig. 4 Division of transversus abdominis muscle fibers exposing the underlying transversalis fascia

under the costal margin right up to the central tendon of the diaphragm, all the way out laterally and posteriorly to the paravertebral muscles and inferiorly into the pelvis. This gives this approach a far wider range of hernia repair possibilities including rooftop incisional hernias, Mercedes incisional hernias, Inverted T incisional hernias, superior and inferior lateral flank incisional hernias, stoma site hernias, complex multi-incision incisional hernias as well as midline ventral hernias.

The traditional top-down TAR may be augmented or replaced by the bottom-up TAR, described, taught and popularised by Miguel Ureña in Madrid where the incision of the posterior rectus sheath is commenced at the arcuate line and then extended upwards [40]. This technique can be particularly useful when there is a concomitant lateral defect or scar that needs to be circumvented and one can approach it from above and below.

A stepwise description of PCS-TAR is provided in the case study at the end of this chapter.

The favourable combination of good long-term outcomes and decreased post-operative morbidity associated with PCS-TAR have led to a rapid broadening of its applicability [41], leading to descriptions of its use in the treatment of giant ventral hernias following laparostomy formation [42], the treatment of parastomal hernias (by performing a modified Sugarbaker procedure, lateralising the stoma limb in the retromuscular space and reinforcing this with a large retromuscular prosthesis) [43], the treatment of lateral hernias [44]; and even as a salvage procedure for recurrent ventral hernias after a failed anterior component separation technique [45].

Although the reconstruction of the abdominal wall (AWR) in patients with intestinal failure (and often concomitant abdominal wall failure) is inherently different from the treatment of ventral hernias, the surgical principles which have evolved since the early twentieth century have been successfully applied to the practice of AWR in IF. In particular, the Rives-Stoppa procedure remains the mainstay of AWR in these patients, frequently augmented by further myofascial release, either via anterior or posterior component separation (Figs. 6 and 7).

Principles of Mesh Use in Incisional Hernia Repair and AWR

Both hernia repair and AWR techniques involve augmentation with a mesh to reduce recurrence. There are truly endless types of mesh of different materials and configurations. The nature of the mesh used, whether a permanent synthetic mesh, biologic mesh or synthetic absorbable mesh will depend on many factors including hernia grade, site, dimensions and complexity. In the context of intestinal failure, contamination in particular is an important factor and will have a large bearing on mesh choices for abdominal wall repair as will both Crohn's disease and prior radiotherapy. This is an area where using a synthetic absorbable or biologic mesh may need to be considered rather than one's normal first choice of a synthetic macroporous polypropylene mesh. Intestinal failure patients with complex hernias are likely to have travelled a long road with septic episodes and possibly multiple courses of antibiotics prior to their abdominal wall repair. Part of mesh choice is reviewing their microbiological data with regards to resistant organisms as well as detailed previous review of surgical operation notes, review of prior septic sequelae including abscesses and ECF's, up to date CT scans and a clear idea in the surgeon's head of what they are trying to achieve for the patient. The ideal location for the mesh is in the retromuscular plane [46], lying extraperitoneally in front of the transversalis fascia (or peritoneum below the arcuate line) and behind the rectus muscles such that the anterior fascia can be closed primarily above this, thus reconstituting the linea alba in the case of midline incisional hernias. In general, one should avoid using coated synthetic meshes intraperitoneally in the context of IF patients and in Crohn's in particular. One always wants this repair to be the patient's last abdominal operation. In the context of Crohn's disease in particular one may need to temper this ambition and make choices regarding the repair, including mesh choice, with an understanding of the nature of Crohn's disease and the possible need for further surgery. In cases where major IF surgery and major AWR surgery are both required in a staged fashion the mesh choice at the time of the initial IF surgery may depend on the need to bridge the fascial defect at the time of that IF surgery and in this context a biologic mesh may be appropriate. Synthetic absorbable meshes are not usually used for bridging in this context.

Abdominal Wall Transplantation

Severe intestinal failure patients that ultimately require intestinal or multivisceral transplantation will often have extremely damaged abdominal walls and true abdominal wall failure. One of the most important challenges in intestinal and multivisceral transplantation is achieving a successful abdominal wall closure [47]. A tension-free primary closure is the aim but can be very problematic. In most cases a components separation technique is required. If those options are not feasible the patient may benefit from a concurrent abdominal wall transplantation [48]. An abdominal wall composite vascularized allograft transplant utilising direct orthotopic vascularisation can be considered [49]. This is the ultimate abdominal wall reconstruction and is beyond the scope of standard abdominal wall surgeons and is firmly in the realms of transplant surgeons. The abdominal wall graft may be a full-thickness vascularised abdominal wall transplant, a partial-thickness vascularised graft or a partial thickness non-vascularised rectus facia graft. Vascularised and non-vascularised rectus fascia may be effective when there is inadequate healthy muscle/fascia but sufficient skin cover. Temporary 'remote' revascularisation of the allograft has been performed in some cases onto the recipient's forearm vessels when there is a long anticipated cold ischaemia time (>5 h). Preliminary data suggest that in full-thickness grafts, abdominal wall skin rejection might be an early predictor of intestinal rejection.

Loss of Domain

This is a greatly misunderstood concept in relation to abdominal hernias. It means the abdominal contents have prolapsed out into the hernia sack and have lost their place and right of residence or domicile within the abdominal cavity proper. They have lost their original domain and now reside in a second abdominal cavity, outwith the normal confines of the abdomen proper [50]. If they are able to reduce spontaneously when the patient lies flat or can be gently coaxed back in there is therefore room within the abdominal cavity proper for them to reside and there is not a loss of domain (regardless of the size of the hernia sac when the patient stands). If they do not reduce on lying flat, then there is a loss of domain which is to be distinguished from incarceration or irreducibility of a hernia. Loss of domain does not refer to the size of the hernia defect or neck. There may be a small defect with a huge sack or a huge defect with a huge sack. Both will look impressive clinically when the patient stands up. Both will have a loss of domain if the contents do not return into the abdomen when the patient lies down. The degree to which they return determines the degree of loss of domain. Neither will be associated with a loss of domain if their contents return to the abdomen proper when the patient lies flat.

In the presence of significant loss of domain, forcing the abdominal contents back in and pulling the abdominal muscles together at surgery would result in a marked and deleterious increase in intra-abdominal pressure with possible respiratory complications and abdominal compartment syn-

drome possibly with multiorgan failure. In order to try and calculate how much is too much different volumetric assessments such as those described by Sabbagh and Tanaka have been used [51–53]. There are differences between these assessment methods and careful CT assessment and measurement is required but a useful rule of thumb would be that if more than 20% of the abdominal contents are outwith the abdomen proper then there is a significant and clinically relevant loss of domain.

One approach to overcome loss of domain might be to resect colon and/or omentum to make space for the return of the hernia contents but this is less likely to be an attractive option, particularly in IF patients. Another option is to employ adjuncts to prepare the abdominal wall before and during surgery including botulinum toxin injection into the oblique muscles and stretching the abdominal cavity by preoperative air insufflation (progressive preoperative pneumoperitoneum).

Adjuncts in Abdominal Wall Reconstruction

Botulinum Toxin

Botulinum toxin injection into the abdominal wall oblique muscles has a role in the management of the abdominal wall in the context of ventral and incisional hernia repair as well as abdominal wall reconstruction. It may even have a role in the management of the open abdomen and mesh-mediated fascial traction. It was first described by Hurtado in 2009 [54]. The concept has grown in popularity and has been used in different ways by different groups [55–59].

The Botulinum toxin is injected into the three lateral muscles on either side in the preoperative period. This is done by an ultrasound guided technique at a number of points, commonly three, in each muscle with the patient either awake or sedated as a day case or an ambulatory procedure 4–6 weeks before the hernia surgery. The fundamental concept is one of preoperative pharmacologic muscle relaxation and lengthening in order that the midline may be approximated and come together more easily. In midline ventral and incisional hernias, it may be used to augment a Rives-Stoppa repair so that a hernia defect that could not have been repaired in this way due to an inability to achieve medialization and reconstruction of the linea alba can in fact be done. The repair is thus downstaged. By injecting Botox into the oblique muscles in the preoperative period one can both make this repair easier by facilitating medial travel (medialization) of the two sides or one can potentially complete a Rives-Stoppa repair with appropriate tension-free medialization in a case that would otherwise not have been possible and therefore prevent the morbidity of an adjunctive component separation. This concept of downstaging an abdominal wall repair from a bilateral component separation to a Rives-Stoppa repair needs careful consideration on a case by case basis. Whilst the primary goal is undoubtedly the reconstruction of the linea alba by bringing together the two recti it may be necessary in certain hernia configurations to perform a bilateral TAR not just to facilitate medialization but to get a mesh under the costal margins and diaphragm with sufficient “underlap”, especially in patients with lateral defects, stomas and parastomal hernias. These considerations may be modified if the intestinal failure is related to Crohn’s disease as one is reluctant to use synthetic mesh in this context and downstaging a bilateral TAR to a Rives-Stoppa procedure in this context has the additional benefit of being able to use a synthetic absorbable mesh rather than a permanent synthetic mesh in Crohn’s patients.

Another potential role of preoperative Botox is in very big transverse defects of 20 cm or so where one can use Botox to try and help prevent the need for bridging. A further use is in the context of loss of domain, where it will help reduce tension and permit stretching of the abdominal wall in the postoperative period and thus help keep intra-abdominal pressures down.

Progressive Preoperative Pneumoperitoneum

Originally described by Ivan Goñi Moreno from Buenos Aires in 1947 [60], progressive preoperative pneumoperitoneum (PPP) has now gained more popularity but not widespread acceptance as an integral part of an advanced abdominal wall service for hernia patients with a significant loss of domain. In essence and in its simplest form air is gradually instilled into the peritoneal cavity via an intraperitoneal catheter starting approximately 1 week before the hernia repair surgery. Day on day more air is added and gradually stretches the abdominal cavity and makes room for the abdominal contents to return from the second hernia cavity into the abdominal cavity proper at the time of the subsequent hernia repair operation. The aim is to reduce the risk of abdominal compartment syndrome and respiratory complications postoperatively. It is readily apparent how preceeding PPP with botox injection to the oblique muscles would make sense in order to stretch up the abdominal cavity, but some surgeons prefer to use it in isolation. It can be extremely successful in the management of large hernias with significant loss of domain [61, 62], but patients for PPP need to be selected carefully as it is not without its complications including visceral perforation, puncture of solid organs, air embolism, pulmonary embolism, bleeding with haematoma of the abdominal wall, subcutaneous emphysema, mediastinal emphysema and pneumonia [63]. It may well be the case that more severe IF patients who need corrective abdominal wall surgery may in fact be poor candi-

dates for this technique again highlighting the need for truly complex cases to be discussed preoperatively in a multiprofessional forum with IF surgeons, abdominal wall and plastic surgeons.

Obesity

Intestinal failure is not the preserve of the undernourished. The commonest cause of an enterocutaneous fistula is misadventure at the time of surgery and obese patients are not immune. Moreover, obesity is intimately linked to hernia formation [64]. Surgery in acute IF in obese patients brings a lot of unique challenges. Stoma formation can be very difficult due to a dense, fat and shortened mesentery that needs to be delivered through a deep abdominal wall. This often leads to poor quality stomas with skin and subcutaneous erosive and infective complications that cause abdominal wall complications that in turn cause problems for subsequent abdominal wall repair surgery. The catabolism associated with type II IF due to an abdominal catastrophe associated with sepsis, with or without proximal stomas or an ECF/EAF, in an obese patient will likely cause significant weight loss. When they subsequently come to abdominal wall repair, either at the time of their corrective IF surgery or at a later staged operation, it is likely that they will have a significant slack pannus, unhealthy scarred subcutaneous tissues and skin and possibly tissue loss as well as incisional and peristomal hernias. This adds a different dimension to their surgery and often requires the input of a plastic surgeon. Planning and execution of the required excision of unhealthy skin and subcutaneous tissue with or without an associated laparostomy may be even more complicated if prior stoma formation has led to damage to inferior and/or superior epigastric vessels that provide the blood supply to the rectus muscles as well as the overlying skin and subcutaneous tissues via the associated perforator skin blood supply. A wide panniculectomy may be needed to remove redundant unhealthy subcutaneous tissue and skin with a suboptimal blood supply. Vascular mapping preoperatively or intraoperative fluorescence angiography may be required to prevent complications due to an impaired blood supply of the lipocutaneous tissues.

Data on abdominal wall reconstruction in obese patients in the absence of IF suggest that a body mass index greater than or equal to 30 kg/m^2 is associated with significantly higher rates of wound healing complications but not with higher rates of hernia recurrence. It appears that concomitant panniculectomy affects wound morbidity but not hernia recurrence rates in complex AWR not specifically related to IF [65, 66]. Thus, careful surgical planning is critical as is an appreciation of the integrity and quantity of skin and subcutaneous tissues. Superficial remodelling is not an aesthetic bonus in this group but rather a key part of their abdominal wall surgery in order to prevent hernia recurrence and abdominal wall morbidity including wound infection, seroma and abscess formation.

Pre-operative Planning and Intestinal Mapping

The reconstruction of a failed abdominal wall differs significantly from repair of even complex ventral hernias and, in the context of surgery for intestinal failure, requires appropriate consideration and planning. The anterior abdominal wall defect is often large, there is quite often enteric contamination with (low-grade) abdominal wall sepsis, and the abdominal wall can have multiple defects due to fistulae and/or stomas. All these issues should be taken into consideration when planning the abdominal wall reconstruction phase of the surgical procedure. The importance of good quality axial imaging, case planning and multiprofessional discussion supported by high quality radiology cannot be stressed enough. Not just the defect but the relationship of the defect(s) to fistulae and/or stomas should be considered at this stage. Abdominal wall MDT meetings have much to offer in standard AWR practice [67], but in the context of concomitant IF are critical. Ideally, the MDT discussion should involve plastic/reconstructive surgeons as well to assess for and mitigate the degree of tissue loss which is often greater than it appears and to consider the necessity of a panniculectomy as well as the need for a flap transposition rather than components separation.

As described in more detail elsewhere in this book, elective surgery for intestinal failure needs to be considered one of many steps in a multidisciplinary management strategy for what are often extremely complex patients. The management strategy for patients with intestinal and concomitant abdominal wall failure should address the management of sepsis, wound care, nutritional support and optimisation (including the management of high fistula/stoma outputs), intestinal mapping, prehabilitation and surgical planning.

Intestinal Mapping

The anatomy of the digestive tract and abdominal wall is often significantly disrupted in patients with intestinal failure. These changes will often affect decisions regarding nutritional support, the likelihood of spontaneous fistula closure and, ultimately, the proposed strategy for definitive surgical procedures. Crucial information regarding the current anatomy of the digestive tract may often be gained by meticulous perusal of operative records. This will also often yield valuable information on what, if any, attempts were made at abdominal wall closure, whether mesh was used, and, if so,

what type and in which plane and position. This information is often difficult to ascertain by radiological examination alone, and sometimes the radiologic appearances of the abdominal wall may be at variance with the surgery suggested by prior operation notes. Further mapping of the intestinal anatomy is based on imaging; in most centres, the mainstay of this mapping is a CT of the abdomen and pelvis with intravenous and positive oral contrast (supplemented with arterial phase scans for patients with a history of mesenteric ischemia). In addition, contrast-enhanced studies of those sections of the digestive tract which are out of circuit and not amenable to oral contrast enhancement, are often warranted, especially to assess the patency and length of distal bowel when distal limb feeding is being considered and to rule out any distal obstruction which might need to be addressed prior to or during definitive surgical management. In Crohn's disease, full restaging of the disease (both of the small bowel and the colorectum) should be considered. Contrast enhanced CT will also provide an assessment of the maximum dimensions of any abdominal wall defect, the presence of any clinically occult defect (e.g. parastomal hernias), any loss of domain, the degree of tethering of bowel to the anterior abdominal wall, the degree of abdominal wall sepsis, the width, thickness and quality of the rectus muscles as well as the bulk and thickness of the abdominal oblique muscles. Taken together, the information gathered from these various sources forms a comprehensive map of the patient's patho-anatomy which can be used to guide further management and optimisation, as well as to enable adequate planning of the definitive surgical procedure (s). It can be very helpful to amalgamate all the information from different sources and schematically represent these in one single anatomical diagram, which has been useful for other healthcare professionals involved in the care of the patient, in determining the challenges to enteral nutrition and to inform patients about their own anatomy and what further surgery would involve. It has also proved useful in planning surgical procedures and is described in more detail in Chap. 5.

Prehabilitation

Prehabilitation encompasses all of the aforementioned considerations regarding nutrition and wound care, but goes beyond these principles in formulating a pathway (quite often personalised) to enable the team and the patient to work towards their common goal of offering the patient a definitive procedure with the highest possible chance of success with the lowest possible risk of complications (this applies both to the restoration of intestinal continuity and the abdominal repair/reconstruction components of the procedure). Although individualised, basic components of such a prehabilitation "programme" should include the following:

- Exercise and cardiovascular fitness
- Smoking cessation
- Nutritional assessment and optimisation
- Controlled weight loss (ideally to a BMI of less than 30)
- Acceptable diabetic control (measured by HbA1C levels with a cut-off point frequently agreed at 7.3% or 56.3 mmol/mol)
- Anaemia correction
- Psychological well-being and preparation, expectation management, shared decision making on priorities and what the patient considers a good outcome
- Assessment of superficial abdominal lipocutaneous tissues if significant weight loss from when catabolic and what to do with pannus
- Analgesics and opiate review and weaning to provide headroom for perioperative analgesia as not just abdominal pain but also back pain if significant herniation

Surgical Planning

Serious consideration needs to be given to whether or not it is appropriate to perform a formal abdominal wall reconstruction at the time of the definitive restoration of intestinal continuity. It may be more appropriate to bridge the abdominal wall defect with a synthetic absorbable (e.g. Vicryl) or biological mesh without disruption of the retrorectus and retromuscular planes; and perform the definitive abdominal wall reconstruction (possibly with a synthetic mesh) as a staged procedure rather than as part of the restoration of intestinal continuity. This staged approach would allow for "downstaging" of the modified VHWG classification from a grade III to a grade I/II defect [22, 21], and does not "burn any bridges" by avoiding disruption of the retrorectus and retromuscular planes. Moreover, in some patients undergoing restoration of continuity, a temporary stoma may be formed, which will need to be reversed at a later stage, and a case could be made to postpone the abdominal wall reconstruction till that time. Finally, the very nature of these procedures entails a relatively high risk of enteric leak, either from anastomoses or from enterotomies, which could necessitate further surgery, and thereby a re-opening of the reconstructed abdominal wall. Conversely, bridging the abdominal wall defect almost guarantees development of a ventral hernia and, with it, the need for future surgery, which could have been avoided by a single-stage approach. Moreover, the current mindset regarding the use of synthetic mesh in contaminated wounds is different from that of the past: the use of light/medium weight macroporous polypropylene mesh is associated with relatively low rates of mesh infection and mesh excision [68]. However, the majority of the data supporting this stems from series of patient without gross contamination of the abdominal wall, thereby excluding a significant subset of IF patients.

Ultimately, as described eloquently in a 2018 review [69], the decision on whether or not to perform a single-stage or staged approach in IF surgery depends on a number of factors:

- The primary indication for the operation: it must always be borne in mind that the primary goal of IF surgery is hardly ever reconstruction of the abdominal wall; it is restoration of intestinal continuity and nutritional autonomy. If primary fascial closure can be achieved without any formal AWR, this is the preferred approach.
- The likelihood of the patient requiring a re-operation, either unplanned (e.g. bleeding, anastomotic/enteric leak) or planned (e.g. reversal of a temporary stoma).
- The degree to which the operating team is comfortable performing the abdominal wall reconstruction.
- In case of a staged abdominal wall reconstruction, the likelihood that the clinical scenario will be more conducive to successful AWR by delaying (e.g. less contamination, patient optimisation, etc): although a case could be made that there will be less contamination by delaying the AWR, it would be less likely that the patient would be more optimised than they are at the time of restoration of continuity, bearing in mind the aforementioned pre-operative approach to patients with IF. Moreover, it must be borne in mind that the inflammatory response often seen in the postoperative phase following IF surgery could lead to further intra-abdominal adhesions, thereby not necessarily decreasing the risk of contamination from inadvertent enterotomies made during a staged abdominal wall reconstruction.

These factors will be different for every clinical situation and therefore a purely algorithmic, "one size fits all" approach would be inappropriate. In essence, the decision-making will come down to a consideration of the complexity of the intestinal procedure versus the complexity of the abdominal wall reconstruction.

In general, a patient undergoing a low-complexity "simple" restoration of continuity (e.g. reversal of a proximal jejunostomy) and requiring a simple abdominal wall reconstruction (e.g. a Rives-Stoppa repair without the need for additional component separation) would not likely stand to gain much from a staged approach and it would be considered appropriate to perform the AWR at the same time as the restoration of continuity. In contrast, a patient with multiple complex enterocutaneous fistulae in a previously fully dehisced abdominal wall will be undergoing a high-risk intestinal procedure with a complex abdominal wall reconstruction, and simply bridging the abdominal wall defect with a mesh (Vicryl or biologic) and performing a deferred formal AWR with a synthetic mesh would be considered appropriate. However, even this decision is not straightforward and different surgeons would come to different, and equally justified, decisions. In general, it must be borne in mind that a patient with an ECF or more particularly an EAF who ends up with intestinal continuity and nutritional autonomy is a success story regardless of the recurrence/occurrence of an incisional hernia.

Once a decision has been made, taking the aforementioned factors into consideration, due attention must be had for preparing the abdominal wall for reconstruction (whether simultaneous with the restoration of intestinal continuity or as a staged approach) with adjuncts which may facilitate rectus abdominis medialisation and linea alba reconstruction. The two most commonly used adjuncts, intramuscular botulinum toxin injection and progressive pre-operative pneumoperitoneum (PPP), are described elsewhere in this chapter. It is worthwhile pointing out the ability of these adjuncts, especially botulinum toxin injection, to potentially "downscale" a complex abdominal wall reconstruction from a component separation to a "simple" Rives-Stoppa repair, which is yet again another factor to be considered in the aforementioned balancing of the complexity of the planned AWR in deciding on a single-stage versus staged procedure.

Abdominal Wall Reconstruction Leading to Intestinal Failure

Even outside of the context of intestinal failure, abdominal wall reconstruction for a large ventral/lateral hernia can be a complex procedure, with demands placed both on the technical skills of the operating team as well as their dynamic decision-making capabilities.

Inadvertent bowel injury during abdominal wall surgery is not inconsequential. Various reports have found an increased risk of major morbidity after enterotomies and/or unplanned bowel resections, with one report demonstrating a significantly increased risk of ECF formation in patients with an inadvertent bowel injury during AWR compared to patients without bowel injuries (7.3% vs. 0.7%, respectively) [69]. Recently published data from the American Hernia Society Quality Collaborative (AHSGQ) showed that inadvertent full-thickness bowel injuries are recognised in 1.9% of patients undergoing ventral hernia repair, the majority (85%) being small bowel injuries [70]. These tend to occur more frequently in larger hernia defects, recurrent hernias (especially with previous mesh in situ), a history of abdominal wall infection and higher degrees of wound contamination. Unsurprisingly, bowel injury was associated with an increased risk of surgical site infections; specifically, enterocutaneous fistulae were more common amongst patients with an inadvertent bowel injury (4% vs. 1%). Also, there was a higher reoperation rate in the bowel injury group, with an assumed higher rate of hernia repair failure and ultimately hernia recurrence [70].

Case Study

A 57-year-old otherwise fit and healthy male patient was admitted with sigmoid diverticulitis. Initially, he was managed conservatively but developed increasing abdominal sepsis and ultimately underwent an emergency laparotomy. A purulent pelvic collection was washed out but no obvious visceral perforation was seen and no resections were performed. His abdomen was left open due to gross small bowel oedema and a second look laparotomy was planned with a view to delayed closure. At this second look laparotomy, abdominal wall closure was still not possible and a laparostomy was maintained. During his protracted stay in hospital, this patient developed an entero-atmospheric fistula (EAF) in his laparostomy wound. He was ultimately transferred to a tertiary Intestinal Failure unit where his nutritional status and overall condition was optimised, combined with mapping of his intestinal anatomy. His mapping diagram is shown in Fig. 8 and a representative CT image in Fig. 9.

He was established on distal limb feeding using chyme reinfusion and was discharged home, completely avoiding the need for parenteral nutritional support. He was ultimately planned for reconstructive surgery and a multidisciplinary recommendation was made to attempt abdominal wall reconstruction simultaneous with the restoration of intestinal continuity, in view of the relative low complexity of the intestinal procedure as well as the patient's overall fitness and marked conditional and nutritional improvement.

Just prior to commencing laparotomy, the retracted edges of the rectus muscles were palpated and marked (Fig. 10). At laparotomy, a full adhesiolysis was performed and the fistulating small bowel segment resected with a primary small bowel anastomosis. The sigmoid colon, although moderately affected by diverticular disease, was health and therefore a decision was made not to perform a sigmoid colectomy. The abdominal wall reconstruction phase of the procedure was initiated by identifying the medial edge of the rectus muscle

Fig. 9 Axial CT image showing large midline defect with small bowel fistula in laparostomy

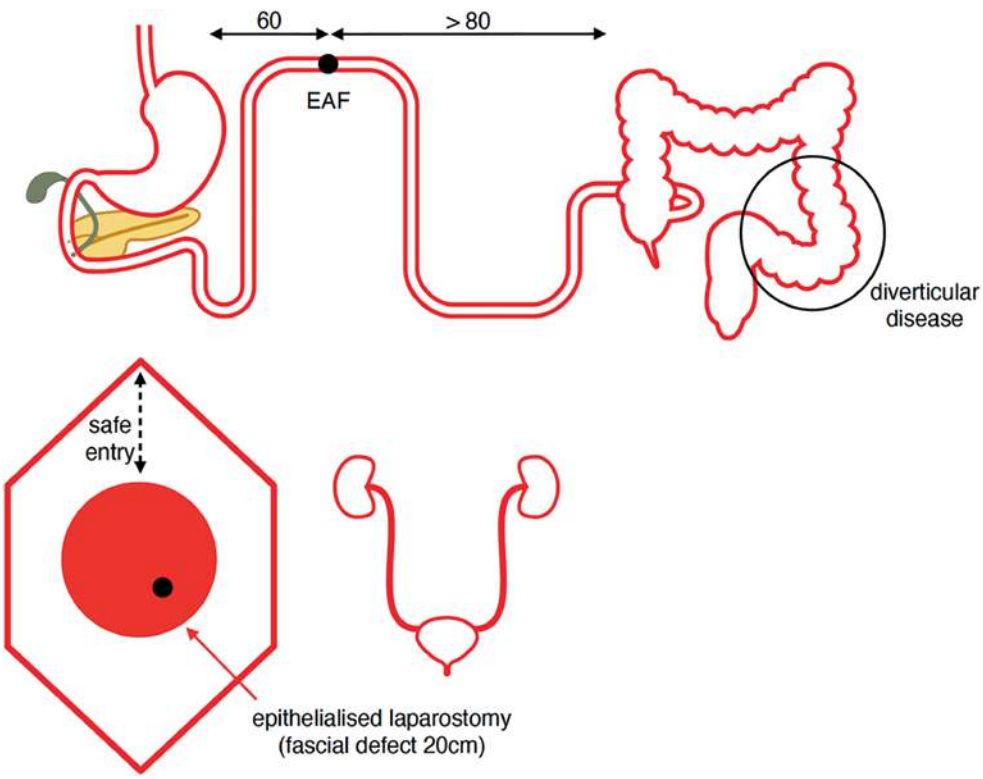

Fig. 8 Initial intestinal + abdominal wall anatomy of patient with an EAF in a laparostomy wound

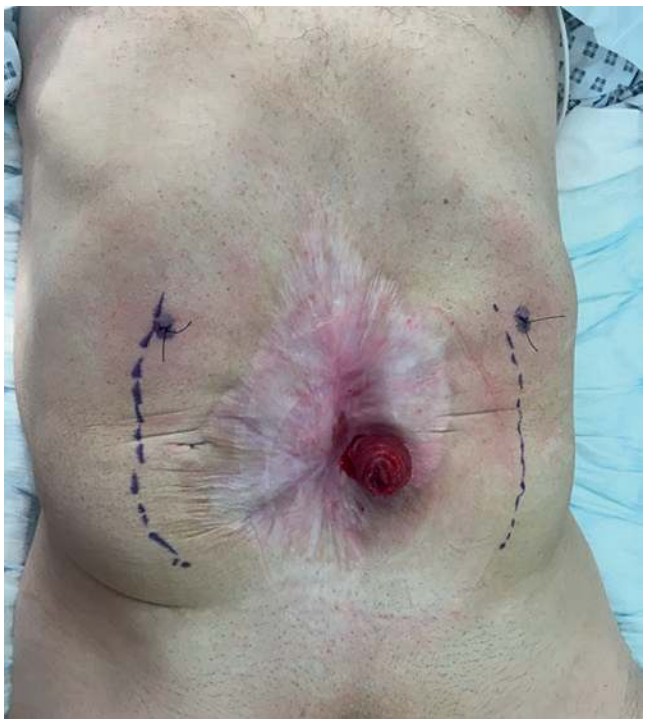

Fig. 10 Pre-operative state of the abdomen with a prolapsing enteric fistula in an epithelialized laparostomy wound; the edges of the retracted rectus muscles have been marked

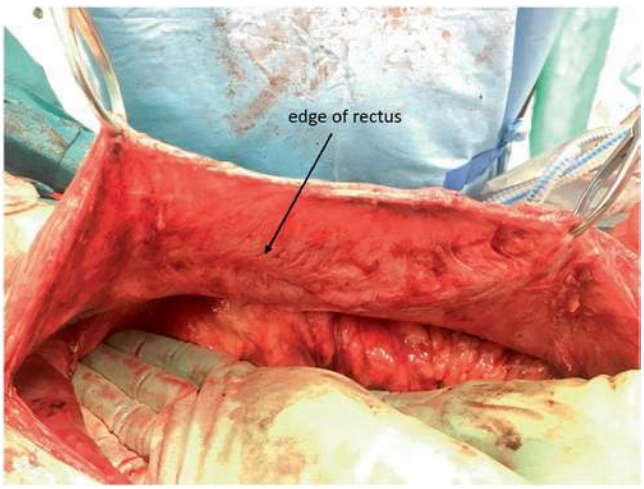

Fig. 11 Intra-operative identification of retracted edge of rectus muscle

(Fig. 11). The retrorectus plane was opened and further developed laterally till the perforating neurovascular bundles at the semilunar line were visualised and preserved (Fig. 12). As in this patient the arcuate line was very clearly visible

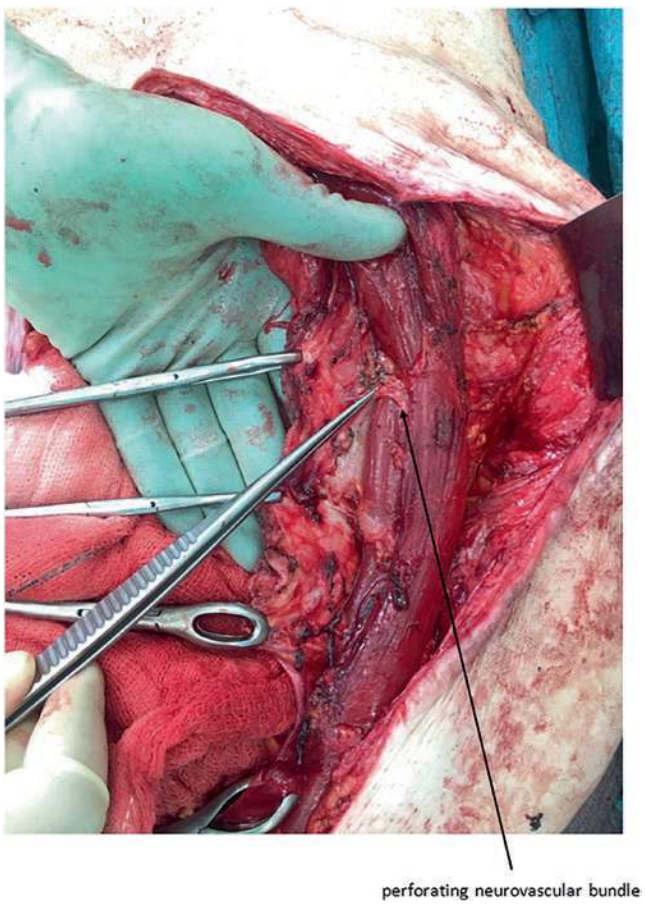

Fig. 12 Retrorectus dissection completed with visualisation of neurovascular bundles. Note the importance of medial traction on the posterior rectus sheath and the importance of visceral protection by placing a large surgical swab over the abdominal viscera

(Fig. 13), a decision was made to perform a bottom-up TAR. The incision of the posterior rectus sheath was therefore commenced at the arcuate line and extended cephalad, always keeping 5-10 mm medial to the neurovascular bundles, thereby exposing the muscle fibers of the transversus abdominis muscle extending medial to the semilunar line (Fig. 14). After division of the transversus abdominis muscle, the underlying transversalis fascia was exposed (Fig. 15) and blunt dissection was initiated in the plane between the transversus abdominis muscle anteriorly and the transversalis fascia posteriorly (Fig. 16). This blunt mobilisation of the visceral sac was extended cephalad beyond the xiphoid process, caudally into Retzius' space and laterally into the flank, exposing the iliopsoas muscle. After completing this same procedure on the contralateral side, significant medialisation had been achieved to allow for easy, tension-free closure of

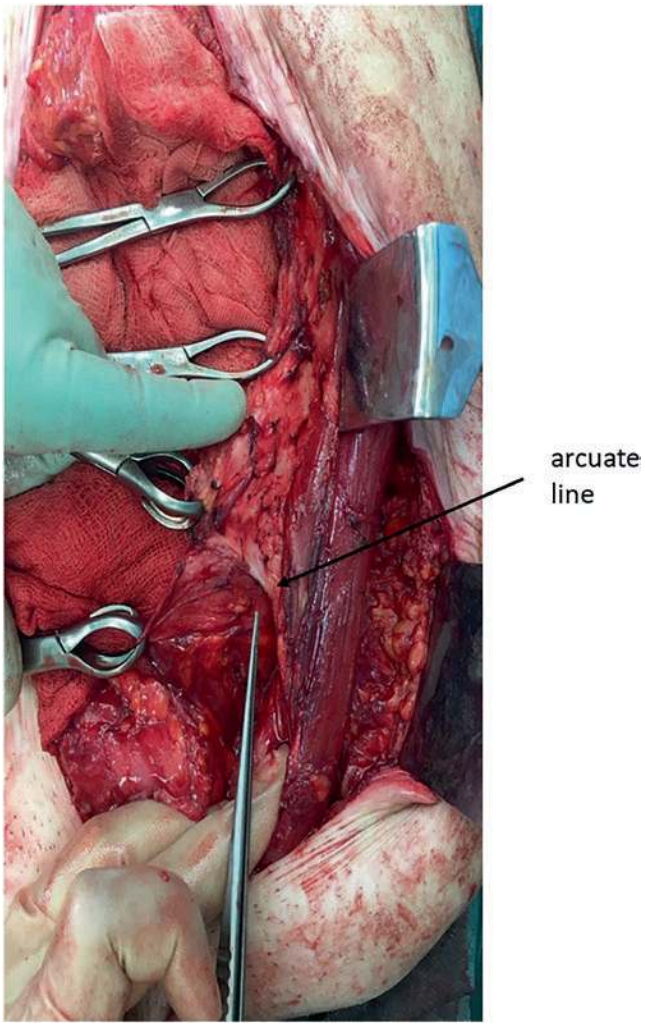

Fig. 13 Arcuate line clearly identified as starting point of bottom-up TAR

the posterior sheath (Fig. 17) and placement of a large synthetic absorbable mesh in the retromuscular space (Fig. 18). Though quite substantial medialisation of the anterior rectus sheath had been achieved as well, midline fascial closure

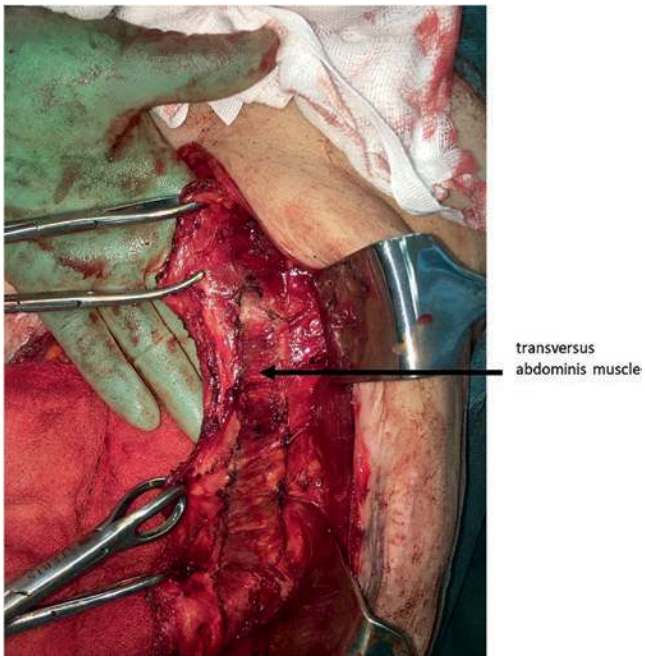

Fig. 14 Transversus abdominis muscle fibers clearly visible after opening the posterior rectus sheath medial to the semilunar line

was not feasible; therefore, the edges of the anterior sheath were medialised as far as possible and secured to the underlying mesh, thereby reconstructing the linea alba and closing the abdominal wall "cylinder" (Fig. 19).

Postoperatively, this patient made an excellent recovery with only a superficial wound infection. He was discharged home on the 18th postoperative day and at review at 6 months, was nutritionally autonomous with a well-healed laparotomy wound without any clinical signs of a hernia. His postoperative anatomy is shown in Fig. 20.

This case highlights the importance of a multidisciplinary approach to complex abdominal defect in intestinal failure. It also illustrates the fistulogenic natures of laparostomies and how every effort should be made to avoid leaving a patient with an open abdomen.

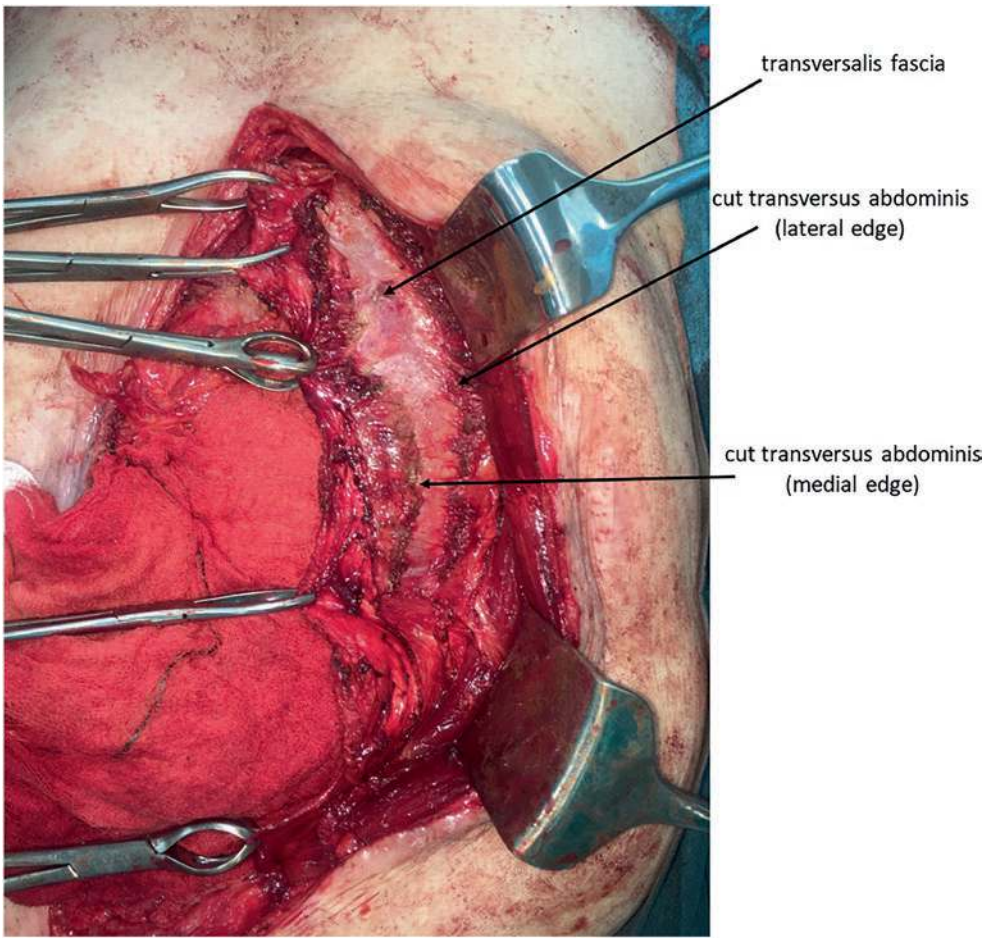

Fig. 15 Exposure of the transversalis fascia after division of the transversus abdominis muscle. Note again the importance of medial traction in exposing the transversalis fascia

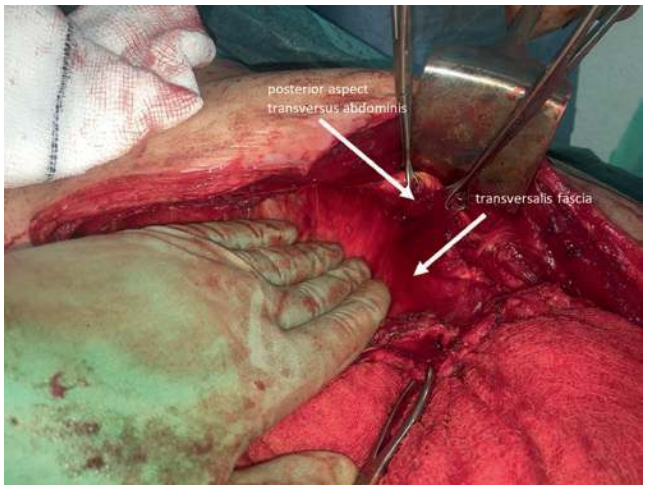

Fig. 16 Development of plane between posterior aspect of transversus abdominis muscle and transversalis fascia after division of the transversus abdominis muscle medial to the semilunar line. Note the importance of close dissection to the posterior aspect of the transversus abdominis muscle and exposing its bare fibers to develop the extratransversalis rather than the extraperitoneal plane

Part IX

Pancreatitis

Intestinal Dysfunction and Failure in Acute Pancreatitis

John A. Windsor and Stephen A. McClave

Key Points

1. Acute pancreatitis is commonly is secondary to alcohol excess, gallstones or occasionally hyperlipidaemia.
2. A third of patients have a severe illness and may deteriorate over several days/weeks.
3. Severe acute pancreatitis is associated with a breakdown of the intestinal barrier, an increase in gut permeability, dysregulated immune responses, and dysbiosis and there develops an adversarial relationship between pathogenic bacteria and the host.
4. Intestinal dysfunction occurs early and is a key driver of disease severity. Infected pancreatic necrosis, organ failure and non occlusive mesenteric ischaemia are the main determinants for a poor outcome.
5. Citrulline and intestinal fatty acid binding protein (iFABP) are promising serum markers of intestinal injury.
6. Most patients can be given nutrition orally or via a nasogastric tube. However some need jejunal feeding but if insufficient or not tolerated then parenteral nutrition should be given.
7. Early aggressive enteral feeding should be avoided in patients who have persisting splanchnic vasoconstriction (e.g. ongoing volume and/or vasopressor requirements) as it can worsen the ischaemia leading to bowel perforation.
8. Although jejunal feeding has been traditionally advocated to rest the pancreas, nasogastric feeding has been shown to be safe and effective in the majority of patients.

Acute Pancreatitis and Determinants of Severity

Acute pancreatitis is one of the most common gastrointestinal diseases requiring hospital admission. While the majority of patients have a mild, self-limiting course with no sequelae, up to a third of patients develop significant complications. These patients usually have a prolonged hospital admission, often require admission to intensive care units and a third may die [1].

While there are many aetiological factors, including gallstones, alcohol and hyperlipidaemia, the clinical, biochemical and radiological presentation of acute pancreatitis is remarkably similar. This suggests a common disease mechanisms. Studies of intra-acinar events show that premature activation of pancreatic proteases, calcium influx and activation of the NF-kB pathway are important early events [1]. Local inflammation ensues and the attraction and activation of macrophages and neutrophils stoke the flames of inflammation further.

Patients usually present with abdominal pain associated with an elevated blood amylase or lipase levels. The pancreas on contrast enhanced CT scanning during the first week will either demonstrate an oedematous pancreas or areas of hypoperfusion, which is termed pancreatic necrosis. Necrosis can also occur alongside the pancreas and is termed peripancreatic necrosis.

Acute pancreatitis is complicated by a wide range of local and systemic complications. The local complications of acute pancreatitis have been defined on the basis of morphological features and duration by CT scanning [2]. A collection within 4 weeks of the onset of acute pancreatitis that is not associated with any pancreatic necrosis is called an 'acute fluid collection' If associated with pancreatic necrosis it is an 'acute necrotic collection' (ANC). When these persist beyond 4 weeks these are characterised by a reactive fibroinflammatory wall and are called pseudocyst and walled-off-necrosis (WON), respectively. All of these collections can

J. M.D. Nightingale (ed.), *Intestinal Failure*, https://doi.org/10.1007/978-3-031-22265-8_61

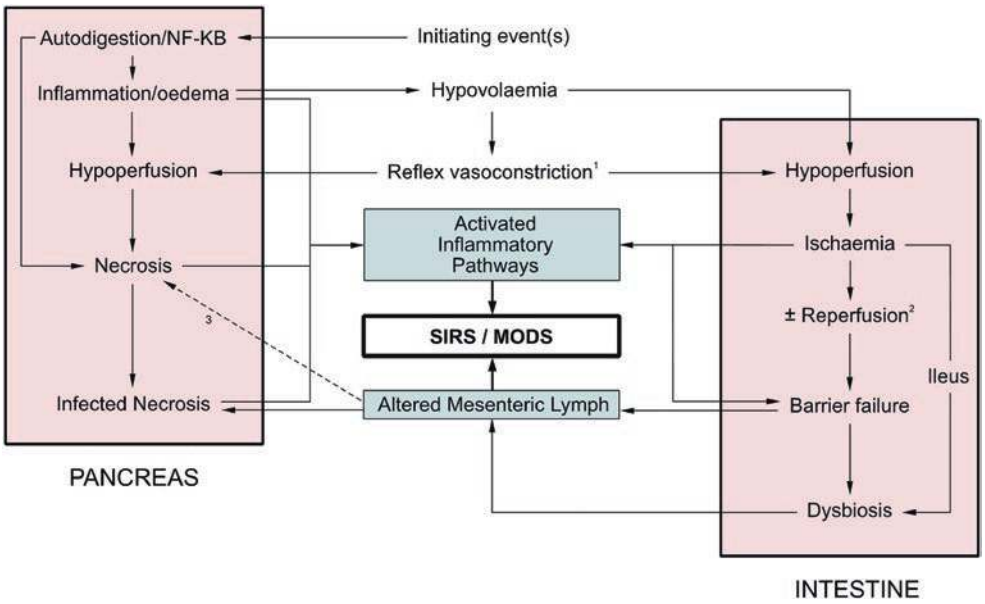

Fig. 1 The locoregional events in the pancreas and the intestine contribute to the development of systemic inflammation and organ dysfunction. (Adapted from [7])

become infected, often from an intestinal source, and this often heralds a downward clinical course.

The systemic complications of acute pancreatitis are analogous to that seen with severe sepsis, major trauma, hemorrhagic shock and other acute diseases. There is a systemic inflammatory response (with a compensatory anti-inflammatory response) driven by complex cytokine cascades. There is also end-organ dysfunction, which can lead to organ failure [2]. When organ dysfunction or failure is present for more than 48 h this is defined as 'persistent' organ failure, rather than 'transient'.

The two most important determinants of acute pancreatitis severity are infected pancreatic necrosis (as ANC or WON) and persistent organ failure [3], and the intestine has an important role in the development of both. These determinants are the basis for a validated classification of severity [4], which is useful for prospective trials and retrospective audits. The Determinants Based Classification (DBC) defines 4 categories of severity based on these two determinants: mild AP (no local or systemic complications), moderate AP (sterile local complication and/or transient organ dysfunction), severe AP (infected pancreatic necrosis or persistent organ failure) and critical AP (both infected pancreatic necrosis and persistent organ failure). The recent modified DBC has highlighted that severe AP with infected pancreatic necrosis has a very different morbidity and mortality profile than severe AP with persistent organ failure [5]. The former has high morbidity and a lower mortality because of improvements in the treatment of infected pancreatic necrosis. The latter is the opposite and reflects the ongoing challenges of treating multiple organ failure, where no specific treatment exists and management amounts to no more than organ support, while the disease takes its course.

A better understanding the fundamental pathophysiology of acute pancreatitis is required to reduce the morbidity and mortality of severe and critical acute pancreatitis. It is the pathophysiological events that are driving the diseases once the patient is admitted to hospital, usually 24–36 h following the onset of pain, that provide potential targets for effective treatment. The locoregional events that occur within the pancreas and the intestine are closely linked and serve to highlight the role of intestinal dysfunction in the outcome of acute pancreatitis (Fig. 1).

Intestinal dysfunction and failure is common, occurring up to 60% of patients in the intensive care unit [6] and this contributes to disease severity. This chapter will focus on the cause, effect, prevention and treatment of intestinal dysfunction and failure in acute pancreatitis. Important new insights and implications for management will be highlighted.

Causes of Intestinal Dysfunction and Failure in Acute Pancreatitis

The intestine is not an innocent bystander in severe AP, but is both a victim and a culprit. Intestinal dysfunction in AP has an important role in the development of the systemic inflammatory response syndrome (SIRS) and multiple organ dysfunction syndrome (MODS) [7].

Acute pancreatitis is characterised by retroperitoneal edema, 'third space' fluid loss, and hypovolaemia [8]. The physiological response to this is the prioritisation blood flow

to vital organs at the expense of splanchnic blood flow. The increased sympathetic outflow that accompanies circulatory shock causes vasoconstriction of the mesenteric post-capillary veins and venules via alpha-adrenergic receptors. This causes 'auto-transfusion' of up to 30% of the total circulating blood volume, so improving the cardiac output and perfusion of other vital organs [9]. Vasoconstriction of the mesenteric afferent arterioles also occurs but this effect is mediated by the renin-angiotensin axis rather than the sympathetic nervous system [10]. The resulting increase in systemic vascular resistance helps to sustain the systemic blood pressure but results in low perfusion through the splanchnic bed.

The intestine, and other splanchnic organs, can adapt to low perfusion states by extracting up to 90% of the oxygen from the blood. This protective effect is has limits because prolonged extraction rates over 70% lead to regional ischaemia [11]. Resuscitation does not provide immediate relief, as the splanchnic region is the last to be reperfused [12]. Indeed, patients who appear to be adequately resuscitated, without clinical evidence of hypovolaemia, may continue to have intestinal ischaemia [13].

The importance of maintaining the barrier between luminal content and the systemic circulation has long been emphasized. It has been found that intestinal barrier dysfunction was present in almost 60% of patients with acute pancreatitis, and that increases in gut permeability correlate with markers of severity and the risk of organ failure and death [14, 15]. The intestinal barrier has several functional and structural components, which include the intestinal microflora, intestinal motility, digestive enzymes, unstirred water and mucous layer, glycocalyx [16], epithelial and endothelial layers, mucosal associated lymphoid tissue and the gut-liver axis. The most important element of the barrier is the epithelial layer which is a single layer of columnar cells arranged into villi and crypts. Microvilli line the apex of the cell and help provide a barrier to microbes. Tight junctions encircle the apical pole which help prevent the passage of molecules, including lipopolysaccharide and other bacterial proinflammatory mediators.

The intestine is particularly susceptible to ischemia because of the anatomy of the villus microcirculation. The countercurrent arrangement of veins around a central arteriole allows for arteriovenous shunting of oxygen and causes anoxia of the villus tip [17]. Ischemia causes hypoxanthine to accumulate and ATP is depleted through inadequate oxidative phosphorylation. In addition, xanthine dehydrogenase is converted to xanthine oxidase. When blood flow is restored xanthine oxidase converts hypoxanthine to xanthine with the liberation of the superoxide ion. The superoxide ion leads to the formation of further oxygen free radicals that injure intestinal cell membranes by lipid peroxidation [18]. Oxygen free radicals are also chemoattractant for neutrophils, and along with other mediators initiate migration of activated neutrophils into the re-perfused tissue. Thus, intestinal reperfusion causes further damage through oxidative stress and inflammatory mediators [19, 20]. Jejunal mitochondrial dysfunction occurs early in experimental acute pancreatitis [21] and could be a treatment target.

There are a number of other important mediators of intestinal injury. Phospholipase A_2, found in high concentration in the intestinal mucosa, plays an important role in mucosal injury and translocation [22]. It is excessively activated in intestinal ischaemia and is released under the partial control of TNF-a [23]. It generates proinflammatory lipid mediators such as platelet activating factor that stimulates endothelial cells and neutrophils, enhancing neutrophil-mediated tissue injury. It also generates arachidonic acid to liberate eicosanoids that cause direct tissue injury. Nitric oxide (NO) has both protective and injurious effects on the intestinal barrier [24]. Under normal conditions it is an antioxidant and signalling molecule that helps to maintain intestinal perfusion. But during ischaemia and reperfusion, NO is converted to cytotoxic nitrites by superoxide radicals. One such nitrite, peroxynitrite, activates poly(ADP-ribose) synthetase by breaking single strands of DNA. This nuclear enzyme then depletes enterocyte NADH and ATP and increases intestinal permeability [25]. The large concentrations of NO liberated from the intestine during ischaemia and reperfusion are probably due to an upregulation of inducible NO synthase (iNOS). Blockade of iNOS prevents the increased intestinal permeability [26] and mesenteric vascular hyporeactivity [27] caused by endotoxin. It also limits bacterial translocation during intestinal ischaemia and reperfusion [28].

In summary, intestinal ischaemia and reperfusion results in oxidative stress which damages cell membranes, with the direct insult to the intestine being triggered through activation of NFk-B and release of lysosomes (containing several proteases which degrade elastin, collagen, and fibrinogen) [14]. This injury to the intestine leads to increased permeability, the extent of which correlates with disease severity and is predictive of mortality [14]. Slowing of gut motility early after intestinal ischemia/reperfusion injury results in small intestinal bacterial overgrowth (SIBO), alteration in the microbiota [29], and bacterial translocation. The translocating bacteria can lead to infection of necrotic pancreatic tissue, an important determinant of mortality [3]. The early phase of inflammation is driven by molecular sensing of tissue damage, as the initial injury is characteristically sterile. But the increase in intestinal permeability and bacterial overgrowth can lead to secondary infection and endotoxemia [29], most often noted in severe AP after the first week.

Effects of Intestinal Dysfunction and Failure on the Severity and Prognosis of Acute Pancreatitis

Local pancreatic inflammation and the development of necrosis and infected necrosis are, in themselves, potent drivers of SIRS [20]. To this the development of intestinal ischaemia, injury and dysfunction adds significant further impetus towards the development of SIRS and MODS. Several models have been suggested to explain the role of the intestine in the development SIRS/MODS [30] covering the spectrum of acute and critical illness, and they are not mutually exclusive.

'Gut Starter' Model

This model focuses on the role of the neutrophil, which is primed as it passes through the mesenteric circulation during ischaemia and reperfusion of the intestine. These continue to circulate around the body in this primed yet inactive state until they are provoked by a second insult such as exposure to endotoxin [31]. Priming of the neutrophil is initiated by mesenteric lymph rather than portal blood and it is the lipid fraction generated by phospholipase A_2 that appears to be most important in priming neutrophils [32]. Neutrophils primed in this way exhibit an increased oxidative burst, augmented release of proteases and cytokines [33], and reduced apoptosis [34]. Neutrophils mediate damage by enhancing the ischaemic effect, releasing of oxygen free radicals and proteases, and amplifying the inflammatory response. Thus, neutrophils becoming potent mediators of SIRS/MODS when activated.

'Gut Motor' Model

In contrast this model focuses on the role of the intestinal barrier in the development of SIRS and MODS [30, 35]. In health, with an intact intestinal barrier, there is a dynamic symbiotic relationship between the intestinal microbiome and the host [30, 36]. There is ongoing crosstalk signalling between the commensal bacteria in the gut and pattern recognition receptors (PRRs) on the surface of the intestinal epithelium [37, 38]. The PRRs are Toll-like receptors (TLRs) and Nucleotide-binding Oligomerization Domain (NOD)-like receptors (NLRs) on the surface epithelium and within the cytoplasm of the epithelial cell. Commensal bacteria do not have the machinery to adhere to the intestinal epithelium, so parts of the commensal organisms (flagella, polysaccharides in the cell wall, or LPS endotoxin) serve as Microbial-Associated Molecular Patterns (MAMPs) which bind to the family of PRRs [37]. The depletion of IgG anti-endotoxin antibodies is a feature of severe acute pancreatitis [39]. This ongoing binding and crosstalk signalling maintains important aspects of barrier function. The crosstalk signalling between PRRs and the MAMPs cause Paneth cells to release anti-microbial peptides (Defensins and Trefoil proteins), goblet cells to produce mucus, intestinal epithelial cells to produce tight-junction proteins, and the dendritic cells to influence immune signalling in the submucosa [38]. In the presence of the commensal bacteria, appropriate immune responses result, as naïve T-lymphocytes are stimulated to mature into T-regulatory cells and Th2 cells of the humoral immune system. Butyrate production as a result of commensal organisms fermenting soluble fiber to short-chain fatty acids has an independent effect on this process, stimulating and enhancing barrier function, competitively excluding pathogens, inhibiting NFk-B production, and supporting appropriate immune responses [37].

Many of these processes are altered with acute pancreatitis. There is a breakdown of the intestinal barrier, an increase in gut permeability, dysregulated immune responses, and dysbiosis and there develops an adversarial relationship between pathogenic bacteria and the host [30, 36, 37]. Tight junctions are breached, enterocytes undergo increased apoptosis, endothelial repair mechanisms are compromised, and microbes penetrate the intestinal wall [37]. Cross-talk signalling between PRRs and MAMPs are replaced by signalling with products of stressed cells and necrosis called Danger-Associated Molecular Patterns (DAMPs) [35]. Virulent pathogenic bacteria, which emerge through quorum sensing, have the capability to bind to the intestinal epithelium directly. As a result of this binding, the pathogens themselves serve as Pathogen-Associated Molecular Patterns (PAMPs). The shift in binding from MAMPs to DAMPs/PAMPs induces differentiation of naïve T-cells to Th1 and Th17 lymphocytes (instead of Th2 and T-Regulatory cells), which has a proinflammatory effect [35]. Binding of the DAMPs and PAMPs to the PRRs leads to dysregulated immune responses, which are considered to be the basis for 'gut-origin sepsis' [30, 35]. With breakdown of the intestinal barrier there is thinning of the mucus layer which allows activated pancreatic enzymes to autodigest gut epithelium [40]. This facilitates further passage of luminal content into the portal venous and mesenteric lymphatic systems, including the pancreatic proteases [41] and lipoprotein lipases [42]. This translocation activates immune cells down-stream from the intestinal mucosa (i.e. Peyer's patches), macrophages in the lamina propria of the gut, mesenteric lymph nodes and Kupffer cells in the liver. These activated immune cells release inflammatory mediators that drive the onset of SIRS and MODS even without a focus of infection [38].

Emergence of a virulent pathobiome results in disappearance of over 90% of commensal bacteria, loss of biodiversity, antibiotic resistance, and an increase in systemic infectious complications [37]. Evidence of a shift in the gut microbiota is seen in severe AP, with an increase in pathogenic bacteria of the Enterobacteriaciae and Firmicutes family, and a decrease in the beneficial Bacteroidetes and Lactobacillus organisms [43]. Pathogenic Enterococcus of the Firmicutes phyla is increased, while the Acinetobacter of the Bifidoacterium phyla is decreased [43]. The extent of these gut microbiota modifications predict the severity of pancreatitis and the occurrence of systemic complications [40]. Coupled with the changes in the microbiota are an overexpression of proinflammatory cytokines and chemokines and a parallel decrease in Paneth cell-related antimicrobial peptides (Defensins and Trefoil peptides) [29, 43].

'Gut Lymph' Model

The role of mesenteric or gut lymph in the promotion of SIRS and MODS has received recent attention [42, 44–46]. This route from the intestine to the systemic circulation has been largely overlooked. Lymph draining from the injured intestine in acute and critical illness undergoes profound compositional changes and drains directly into the systemic circulation (i.e. bypassing the liver) and immediately upstream of the organs that fail most often, the heart, lungs and kidneys [47]. Toxic lymph activates TLRs and neutrophils at these distant sites promoting SIRS/MODS. Confirmation of the 'gut lymph'model in patients has been impeded by the difficulty in accessing mesenteric lymph for investigation, but there are a number of compelling animal studies which support this as an important disease mechanism. For instance, when animals with mild acute pancreatitis were subjected to mild intestinal ischaemia there was a marked decrease in pancreatic perfusion, an increase in the histological severity of acute pancreatitis and this effect was mediated by mesenteric lymph [48]. In another animal model of moderately severe acute pancreatitis ligation of the thoracic lymph duct prevented cardiac failure, independent of hypotension [49].

Clinical and Radiological Evidence of Intestinal Dysfunction and Failure in Acute Pancreatitis

The most common clinical evidence of intestinal dysfunction in patients with acute pancreatitis is seen with *feeding intolerance* [50]. Most guidelines indicate the need for early nutritional support, and have usually advocated naso-jejunal feeding [51], even for those with mild to moderate severity [52]. Although controversial, the latest evidence suggests that ward patients can be allowed *ad libitum* oral access to fluid and food for up to 96 h after admission [53]. If they are unable to tolerate sufficient intake to meet their calculated requirements then enteral nutrition is provided, initially via a nasogastric [54], but this tube can be advanced to the duodenum/jejunum, if required. If enteral nutrition fails to meet requirements, because of feeding intolerance, then supplemental parenteral nutrition may be required. Feeding intolerance is usually reported by patients as abdominal pain and bloating, nausea and/or vomiting. It can be reasonably predicted using a nomogram based on the Gastrointestinal Cardinal Symptom Index on day 2 and the aetiology of acute pancreatitis [55]. Patients requiring mechanical ventilation will not be able to report symptoms, making the diagnosis of intestinal dysfunction more difficult. But clinical signs will be apparent with a reduction or absence of bowel sounds, increased abdominal girth and a tympanic percussion note.

The clinical diagnosis of an ileus is strengthened by the presence of radiological features indicative of intestinal dysfunction, but this depends on the stage of the disease. The early features of small bowel distension with increased gas may be due to aerophagia when a patient is in severe pain. The classical features of an *adynamic ileus* may develop over several days, with distension of multiple loops of small and large bowel with air-fluid levels on an erect film. Classical descriptions of acute pancreatitis, before the advent of cross sectional imaging, included two radiological signs, usually in the left hypochondrium: 'sentinel loop' and 'colon cut-off'. These were taken as diagnostic features of acute pancreatitis itself, and are examples of a localised ileus in proximity to the inflammatory pancreatic phlegmon. Much more commonly, these features are seen on cross-sectional imaging, with contrast enhanced CT scanning which provides additional information about wall thickness, adequacy of mucosal perfusion, and presence of free peritoneal fluid. The presence of an ileus is a predictor of local infection in patients with acute necrotizing pancreatitis [56].

With severe and critical AP intestinal dysfunction can progress to non-occlusive mesenteric ischaemia (NOMI) and this occurs most often in patients within the ICU environment [57]. Initially the clinical symptoms and signs are that of ileus. Radiologically the development of NOMI is seen as *pneumatosis intestinalis*, or the presence of gas within the wall of the intestine, reflecting a loss of the intestinal barrier. This can be extensive and reversible, but further progression to transmural necrosis can result in intestinal perforation, peritonitis and death. Biomarkers for the early detection of reversible NOMI are urgently required [45, 58].

Clinical Assessment and Measurement of Intestinal Dysfunction and Failure in Acute Pancreatitis

The clinical assessment of intestinal dysfunction is limited to clinical and radiological methods because there is no reliable biomarker [6]. All the symptoms and signs are non-specific in relation to acute pancreatitis. A scoring system would be helpful for both clinical management and interventional studies, but of the14 scoring systems published to date, few have been adequately validated and none have been widely recommended or adopted.

The 'modified gastrointestinal failure' (mGIF) score is an excellent example of a clinical scoring system designed to assess intestinal dysfunction and failure in patients with severe acute pancreatitis [59]. Table 1 indicates the components of the scoring system, which includes clinical symptoms (feeding intolerance, intrabdominal hypertension and abdominal compartment syndrome) to which is added endotoxin concentration and CT findings. When measured within the first 3 days, this score strongly predicts the risk of infected pancreatic necrosis, MOF and mortality. Independent prospective validation of mGIF is warranted. When the mGIF score is combined with the SOFA or APACHE II scores the prediction of prognosis was even more accurate than with either score alone [59]. There is an argument for incorporating a measure of intestinal dysfunction and failure into scoring systems for MODS/MOF [60].

Another approach to the assessment of intestinal dysfunction in acute pancreatitis is the use of nasogastric tonometry, which combines CO_2 from the gastric lumen with bicarbonate from peripheral arterial blood to calculate a pHi. This has face validity because it is known that severe acute pancreatitis is associated with ischaemia of intestinal mucosa. The first pilot study showed that gastric intramucosal pH of <7.25 in the first 48 h was highly predictive of mortality [61]. Subsequent studies have shown that prolonged intestinal mucosal acidosis is associated with MOF after 24 h [62, 63]. Gastric tonometry has been used as an endpoint to monitor the response to resuscitation in critically ill patients. An early study found that the patients in whom resuscitation failed to correct a low pHi over the first 12 h had a higher mortality rate [64].

Several serum biomarkers of intestinal dysfunction have also been investigated. A recent meta-analysis on intestinal barrier dysfunction in patients with acute pancreatitis a number of tests of intestinal barrier function, including those that assess epithelial integrity, barrier function and bacterial translocation [65]. These are summarized in Table 2. A systematic review of potential biomarkers of intestinal ischaemia, irrespective of aetiology, revealed that the best diagnostic accuracy (by diagnostic odds ratios and area under the curve) were D-lactate (10.75, 0.86), glutathione S-transferase (8.82, 0.87) and intestinal fatty-acid binding protein (7.62 and 0.78) [66]. While promising, the performance of these biomarkers is suboptimal for routine clinical

Table 1 The modified gastrointestinal failure score (mGIF) to assess intestinal dysfunction in patients with severe acute pancreatitis (adapted from [59])

Modified gastrointestinal failure score			
Item	*Points*		
	0	*1*	*2*
gastrointestinal failure score	0	1–2	≥3
Intra-abdominal pressure (mmHg)	<12	12–20	>20 or ACS
Endotoxin concentration (pg/mL)	<10	10–50	>50
CT scan findings of bowel wall	None	Thickening or dilation	Thickening and dilation

	Gastrointestinal failure score
Points	*Clinical symptomatology*
0	Normal gastrointestinal function
1	Enteral feeding <50% of calculated requirements
2	Food intolerance or intra-abdominal hypertension
3	Food intolerance and intra-abdominal hypertension
4	Abdominal compartment syndrome

This comprises 4 items, one of which is the gastrointestinal failure score. ACS is abdominal compartment syndrome [106]. CT scan findings including thickening of the small bowel wall (oedema) and/or dilation (diameter > 2.5 cm). Food intolerance is when enteral feeding is not applicable because of high gastric aspirate volume, vomiting, bowel distension or severe diarrhoea

Table 2 Tests used to assess gut barrier function [adapted from [65]]

Classification	Subclassification	Test
Assessment of intestinal epithelial barrier integrity	Enterocyte injury	Intestinal fatty acid binding protein
		Citrulline
		Reduced glutathione
	Loss of paracellular barrier integrity	F-actin
Functional assessment of intestinal barrier	Active measurements	Lactose/mannitol ratio
		Lactose/rhamnose ratio
		Polyethylene glycols
		D-xylose
		Serum diamine oxidase
	Passive measurements	Endotoxins
Assessment of bacterial translocation		Endogenous anti-endotoxin antibodies
		DNA/RNA
		D-lactate
		Nitric oxide
		Rectal luminal lactate

use in individual patients, but may well have an important role when combined with other assessment methods.

Both citrulline (a byproduct of glutamine metabolism and synthesized in small bowel enterocyte) and intestinal fatty acid binding protein (iFABP, synthesized in mature enterocytes at the tip of small bowel villi, the region most susceptible to ischaemia) have been investigated as markers of intestinal injury in patients with acute pancreatitis, and they identified patients at high risk of complications [67]. In a large (n = 402) prospective multicenter cohort study higher admission serum iFABP levels were associated with pancreatic necrosis, systemic complications, invasive treatment, intensive care admission and mortality, and prediction was improved when iFABP was combined with venous lactate (AUC 0.8) [68]. This is consistent with the importance of early intestinal dysfunction in acute pancreatitis and it was suggested that this combination might be useful in guiding early fluid resuscitation [68] and predicting abdominal pressure related complications [69]. It has been found that iFABP is released almost too readily with mucosal ischaemia [70], and that a marker of ischaemia in the muscle layer of the intestine might have greater utility. For this serum alpha smooth muscle actin has been proposed as a 'troponin T of the gut' [71], but requires investigation in patients with acute pancreatitis.

Prevention and Treatment of Intestinal Dysfunction and Failure in Acute Pancreatitis

Historically the management of acute pancreatitis, as with other acute and critically diseases, has not given due regard to the role of the intestine. This relative 'intestinal neglect' suggests that some of the intestinal dysfunction associated with AP may be iatrogenic, particularly in the Intensive Care Unit (ICU). Aggressive volume replacement can lead to gut-wall (and generalised) edema [72], which with abdominal third spacing of fluids, ileus, and pancreatic fluid collections can contribute to abdominal compartment syndrome, causing further impairment of intestinal perfusion. Effective, goal-directed fluid resuscitation is required to reduce the risk of intestinal injury and dysfunction. The type of resuscitation fluid matters [73], but level 1 evidence is lacking [74]. The use of narcotics should be minimized, as both endogenous and exogenous opioid narcotics stimulate virulent expression of potential pathogens [43, 75]. Opioid narcotics may be avoided by providing alternative therapy [37] with sedatives, hypnotics, propofol or epidural. The inappropriate use of antibiotics may predispose to loss of intestinal commensal bacteria, reduced biodiversity (dysbiosis), and facilitate emergence of virulent antibiotic-resistent pathogens [37]. The judicious use of antibiotics, such as shortening the duration of therapy or employing de-escalation strategies will help promote refaunation of the gut with commensal organisms [75]. The need for vasopressor therapy, especially when non-selective agents are used, increases splanchnic vasoconstriction with the enhanced risk of intestinal ischaemia and pancreatic necrosis. And reliance on the parenteral route for nutrition therapy may exacerbate inflammation within the intestinal mucosa and retard efforts to restore intestinal barrier defences [37].

Oral and enteral nutritional support helps maintain the intestinal barrier and provide the nutritional requirements in a disease that can be highly catabolic. There is no place for not drinking or eating in order to 'rest the pancreas'. This is an outdated concept and might be replaced by the concept of 'gut rousing' which emphasizes the positive benefits of enteral nutrition in patients with acute pancreatitis [76]. Patients with mild to moderate acute pancreatitis can safely commence a soft normal diet on a voluntary basis, do not need to have a period of prior clear oral fluids, and do need to wait for the absence of pain and the normalization of serum pancreatic enzymes [77, 78]. This approach reduces the length of hospital stay. Processed foods containing emulsifying agents (e.g. carboxymethylcellulose or polysorbate 80) should be avoided as they decrease the mucus layer of the intestinal tract, reduce butyrate production, and promote a low-grade virulence of the microbiota [75].

Enteral nutrition becomes more important with more severe acute pancreatitis, and it is the preferred route for nutritional support because of safety, cost, efficacy, and benefits from this route of feeding [79]. It is important to avoid early aggressive enteral feeding in patients who have persisting splanchnic vasoconstriction (e.g. ongoing volume and/or vasopressor requirements) [80]. A slower advancement to goal over 3–4 days is important to decrease risk of mucosal ischemia in such an under-resuscitated patient, reduce the risk of refeeding syndrome, avoid the potential for overfeeding (where exogenous calories are added to the endogenous glucose produced by the liver), and allow time to guage tolerance to enteral feeding. In moderate acute pancreatitis with mild SIRS an on-demand oral diet is tolerated in 69% of patients and has the same outcome as similar patients placed on early enteral tube feeding within 24–36 h of onset of symptoms. However, in patients with severe acute pancreatitis, where SIRS/MODS requires admission to the ICU (especially if placed on mechanical ventilation), achieving enteral access and early initiation of enteral nutrition is required. While supplemental parenteral nutrition is required in 30–40% of patients with severe and critical acute pancreatitis, it is more expensive (~20×), associated with increased mucosal inflammation, increased proinflammatory cytokine release, loss of intestinal barrier function, upregulation of TLRs [37], and a shift in the microbiome from Firmicutes to the potentially pathogenic Proteobacter [81].

Enteral formulations have been evaluated in the context of acute pancreatitis. In an animal model, provision of a commercial blenderized whole food formula was shown to reduce systemic inflammation (measured by serum Il-6 levels), decrease growth of pathogens, and lead to greater colonic bacterial diversity than a chemically refined formula (unpublished). Elemental formulations and immunonutrition have not been shown to have any benefits over polymeric formulations [82]. Immune-modulating formulas (e.g. containing fish oil with or without arginine) have been tested in three small randomized controlled trials but the meta-analysis failed to show any significant impact on outcome [82]. This strategy probably warrants study in larger trials, as arginine acts as a vasodilator and might counter the splanchnic vasoconstriction with severe AP [20]. Glutamine supplementation appears of confer an advantage with parenteral nutrition but not with enteral nutrition [83]. Also polyamines derived from arginine and ornithine have been shown to be essential for epithelial cell migration, resolving intestinal wounds, and helping regulate epithelial permeability (by increasing expression of E-Cadherin tight junction proteins) [14].

Reducing the severity of intestinal mucosal injury is another potential strategy and there have been a number of promising approaches. In experimental models of severe acute pancreatitis the severity of intestinal mucosal barrier injury/dysfunction can be reduced with treatment by apocynin (NADPH oxidase inhibitor) [84], berberine from plants [85], anthraquinones isolated from rhubarb [86, 87], and continuous blood purification [88].

There are other approaches that target the intestinal lumen and microbiome to reduce intestinal dysfunction but these all require further investigation, These include soluable prebiotic fibre, which has been shown to decrease neutrophil infiltration and mucosal injury due to butyrate [14, 43]. The use of probiotics to promote refaunation with commensal organisms remains controversial. The probiotic arm of the PROPATRIA trial had a worse outcome due to non-occlusive mesenteric ischaemia [89]. Subsequent trials of probiotics have shown a reduced infection and hospital length of stay [90, 91]. Faecal transplantation to restore normal microbiome also has potential [29]. It has been shown that commensal bacterial populations in the context of AP are associated with a reduced level of inflammatory cytokines, systemic infectious complications and disease severity [43]. Other approaches requiring investigation in the context of AP include bovine serum derived immunoglobulin that can bind pathogens in the lumen and improve mucosal health [75]; fish oil derived Specialized Proresolving Molecules to reduce intestinal inflammation [92]; interference with bile salt metabolism by Farnesoid-X receptor antagonists to decrease the Firmicutes:Bacteroidetes ratio and improve insulin sensitivity [93]; the release of phosphate (bound to PEG and released in cecum) to reduce virulence expression by promoting reversion towards commensal pattern [36].

Experimental treatment strategies that improve intestinal motility include melatonin (induced by enteral feeding) [14], rhubarb [94, 95] and other traditional chinese medicines which are anti-inflammatory and prokinetic (producing diarrhoea and gut decontamination) [96]. Systemic experimental anti-inflammatory treatments that might reduce intestinal and systemic inflammation, include anti-TNF-alpha [14], PPAR-alpha agonists [29], and Lactated Ringer's solution for fluid resuscitation [29, 97].

Treatment strategies are being developed to target the effects of toxic mesenteric lymph in acute pancreatitis [47]. Enteral lipophilic supplements that target toxic moieties in mesenteric lymph may reduce SIRS/MODS [98] and prove more effective than external drainage of thoracic duct lymph [99, 100].

Role of Surgery in Treating Intestinal Failure in Acute Pancreatitis

The 'step-up approach' to the treatment of infected local complications of acute pancreatitis has meant that open surgical treatment is now rarely required [101, 102]. This approach entails drainage (endoscopic or percutaneous) which is successful in up to half of the patients for whom open pancreatic necrosectomy would have previously been required. Minimally invasive necrosectomy (MIN, endoscopic or percutaneous debridement) is indicated when this drainage fails, and only if MIN fails would a patient be considered for open pancreatic necrosectomy. The open surgical treatment of infected pancreatic necrosis is associated with an increased risk of enterocutaneous fistulae [102, 103]. Surgery may also be required for the management of enterocutaneous fistulae (see Acute Surgical Intestinal Failure. Sepsis and Enterocutaneous Fistula(s)). These rarely occur spontaneously, and are most often seen following open surgery where there has been inadvertent bowel injury. It also happens as a result of drain erosion into bowel.

Surgery is no longer first-line treatment for the haemorrhagic complications of acute pancreatitis, as selective angiography and embolization are usually successful [104]. Open surgery is now only required for a number of specific indications, and these have some relevance to intestinal dysfunction. The development of abdominal compartment syndrome, which contributes to intestinal and renal dysfunction, might be treatment by temporary laparostomy for decompression [105]. This problem is now less frequent with a less aggressive approach to fluid resuscitation [106, 107]. Urgent abdominal surgery is sometimes required for NOMI, and the extent of intestinal resection will be dictated by the extent of infarction. Early detection of NOMI by CT might circum-

vent surgery by stopping enteral feeding, non-selective vasopressors and close observation [57].

Conclusion

Intestinal dysfunction and failure are important features of acute pancreatitis, that have not been given due regard. For decades, the focus of management in severe AP has centered on reducing inflammation within the gland, forbidding oral intake and 'putting the pancreas to rest'. Current management of acute pancreatitis can result in an iatrogenic intestinal dysfunction and failure. This can occur with aggressive fluid resuscitation, narcotic analgesia, antibiotic treatment and vasopressor support. Intestinal dysfunction occurs early and is a key driver of disease severity, amplifying the systemic inflammation and organ dysfunction, increasing disease severity, increasing the need for intervention and the risk of local and systemic complications, including mortality. There are new developments in the clinical and radiological assessment of intestinal dysfunction, which should allow earlier detection and intervention. The causes and effects of intestinal dysfunction are being elucidated and these give impetus to new treatment approaches that will specifically target aspects of intestinal dysfunction, including intestinal permeability, dysregulated immune responses, dysbiosis, and gut-derived sepsis. Successful treatments will be evidenced by refaunation of commensal bacteria, intact barrier defenses and intestinal homeostasis. And enteral nutrition will continue to have a vital role in the prevention and treatment of intestinal dysfunction, and further advances will include supplements to improve barrier and immune dysfunction. These should in turn reduce the systemic inflammatory response, the risk of end-organ dysfunction and the severity of acute pancreatitis.

Medical, Nutritional and Surgical Management of Chronic Pancreatitis

John S. Leeds

Key Points

1. Alcohol is often overestimated as an aetiological factor. 10% of people who have high alcohol consumption develop exocrine pancreatic disease. Tobacoo smoking has a synergistic effect with alcohol.
2. Other important aetiological factors for chronic pancreatitis include: hypercalcaemia, hypertriglyceridaemia, chronic kidney disease and immunoglobulin G4 related disease (this responds to steroids).
3. Faecal elastase may aid early detection of chronic pancreatitis; however about 85% of the pancreatic parenchyma needs to be lost before steatorrhoea occurs.
4. Measurement of weight, fat soluble vitamins, glycosylated haemoglobin and an assessment of bone mineral density should all be undertaken as a baseline assessment and at follow up assessments (except bone density which may be repeated every 3 years).
5. At diagnosis around 30% of patients with chronic pancreatitis have diabetes mellitus and this prevalence increases with duration of the disease.
6. Symptoms include abdominal pain, weight loss, diarrhoea and any combination of these. Asymptomatic presentations, as an incidental finding, also occurs.
7. The starting dose for pancreatic enzyme replacement therapy (PERT) should be a minimum of 50,000 units of lipase with meals and 25,000 units with snacks. Not more than 150,000 units at a time should be necessary.
8. Complications include pseudocyst formation (with compression of the upper gastrointestinal system), pancreatic strictures and stones, thromboses (splenic and portal veins), reduced bone mineral density, fat soluble vitamin deficiencies, undernutrition and pancreatic cancer.
9. Most treatments are to prevent further parenchymal damage and management of complications. These include pain management, diabetes control, nutritional input, assessment of bone health and vigilance for cancer. Endoscopic and/or surgical treatments may be used to decompress the pancreatic duct in managing pain.

Chronic Pancreatitis

Definition and Epidemiology

Chronic pancreatitis is a progressive, fibro-inflammatory disorder which occurs in individuals with genetic, environmental and/or other risk factors and leads to irreversible damage to pancreatic tissue [1]. In most cases, this is occurs over many years and begins with a subclinical phase that is very difficult to identify. Current understanding is that most cases of chronic pancreatitis develop following serial episodes of acute insults to the pancreas. Older post-mortem studies have shown that the prevalence of chronic pancreatitis between 6–12% [2, 3]. Whilst this seems high compared to clinical practice, a more recent study using digital autopsy techniques appears to confirm these findings showing that 13.5% had pancreatic calcifications and 16% had pancreatic atrophy [4]. The true incidence and prevalence of chronic pancreatitis is not fully known due to subclinical disease but current estimates of global incidence are around 9.6 per 100,000 person years [5]. Prevalence of clinically apparent chronic pancreatitis varies depending upon which population is examined but ranges between 11–50 per 100,000 people [6, 7]. Prevalence is also higher in males and with increasing age [6].

Causes

Unfortunately, chronic pancreatitis has been closely associated with alcohol however most recent surveys have shown that this is over-represented as a cause [8, 9]. Multiple causes have been identified for chronic pancreatitis and, interest-

Table 1 The TIGARO classification of causes of chronic pancreatitis

Group	Aetiological factor	Estimated prevalence in people with chronic pancreatitis
Toxins/metabolic	Alcohol Smoking Hypercalcaemia Hyperlipidaemia Chronic kidney disease	40–70% 60% Unknown 3–13% 2–5%
Idiopathic	True idiopathic Tropical pancreatitis	Approximately 10% Unknown
Genetic	PRSS1 cationic trypsinogen CFTR mutations SPINK1 mutations Other mutations	3–10% Up to 7% 10% 3–5%
Autoimmune	IgG4 disease Other autoimmune disease e.g. Sjorgrens syndrome	1–2%Unknown
Recurrent and severe acute pancreatitis	Any cause of recurrent acute pancreatitis Sentinel attack of severe necrotising pancreatitis	Unknown Unknown
Obstructive	Duct obstruction due to tumours Pancreas divisum	Overall all account for between 2–9%

TIGAR-O: Abbreviation for the aetiology of chronic pancreatitis. Toxic-metabolic, idiopathic, genetic, autoimmune, recurrent and severe acute pancreatitis, or obstructive

ingly, most lead to the same pathological features on imaging. This suggests that whatever the cause, there is a common pathophysiological mechanism leading to pancreatic inflammation and fibrogenesis [10]. The current classification system for the aetiology of chronic pancreatitis is called TIGAR-O (Table 1) [11].

As above, alcohol excess is associated with development of chronic pancreatitis but the exact mechanism and risks are not entirely elucidated. Alcohol is most likely a cofactor in susceptible patients and has certainly been shown to be synergistic with tobacco smoking [12, 13]. Similar to development of alcohol related liver disease, only around 10% of people who have high alcohol consumption develop exocrine pancreatic disease [14]. There is no threshold of alcohol intake that is associated with development of chronic pancreatitis and the correlation with the level of alcohol consumption is weak [15].

Tobacco smoking has been shown to be an independent factor for the development of chronic pancreatitis [12]. Smokers have a significantly higher risk of developing chronic pancreatitis compared to non-smokers [16]. The mechanism is not entirely understood but older studies have shown that smoking reduces pancreatic output particularly of bicarbonate [17].

Other toxic and metabolic causes include hypercalcaemia, hypertriglyceridaemia and chronic kidney disease. Hypercalcaemia has long been known to cause acute pancreatitis, however, conditions such as hyperparathyroidism have been shown to be associated with development of chronic pancreatitis [18]. Development of chronic pancreatitis due to derangement of lipid metabolism has been controversial. The likely mechanism is via episodes of recurrent acute pancreatitis leading eventually to a chronically scarred gland [19]. The finding of pancreatic abnormalities in patients with chronic kidney disease has been previously demonstrated but the underlying mechanisms are again uncertain [20].

The contribution of genetics to the development of chronic pancreatitis is an area of great interest. Several gene polymorphisms have been associated and have also helped to uncover some of the mechanisms for development of chronic pancreatitis. Mutations in the cationic trypsinogen gene (PRSS1) lead to a "gain of function" mutation causing premature activation of trypsin within the pancreas leading to recurrent episodes of pancreatitis [21]. The most common mutations are R122H, R122C or N29I. Other genetic mutations in proteases have also been found.

Mutations in the SPINK1 gene, which encodes for the pancreatic secretory trypsin inhibitor, are also associated with an increased risk of chronic pancreatitis. This gene product helps to "mop up" any excess trypsin and therefore is the natural defence protein against trypsin in the pancreas. The most common mutation is N34S. Other well-known genes include mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene. This gene encodes for a protein that enables secretion of fluid and bicarbonate into the pancreatic duct and loss of this function causes pancreatitis. Most patients are heterozygous for these genes and therefore the interplay between them and other environmental factors may be important [22].

Autoimmune pancreatitis is now known to be a manifestation of the systemic disorder Immunoglobulin G4 related disease (IgG4 RD). This disease may involve multiple organs throughout the body, has characteristic imaging and histological findings. These include an abundance of IgG4-positive plasma cell infiltrate in the involved organs and a predictable response to steroid therapy [23, 24]. There have been several diagnostic criteria culminating in the International Consensus Diagnostic Criteria (ICDC) [25]. These criteria use a combination of radiological, histological and serological findings along with evidence of extra-pancreatic involvement and a rapid (<2 week) response to corticosteroid treatment. This disease can present in several forms, including a mass forming type, often mimicking pancreatic cancer. Biopsy of the "mass" is usually performed by endoscopic ultrasound and confirms a lack of cancer tissue

and an abundance of IgG4 positive chronic inflammatory cells with associated fibrosis and vascular inflammation [26]. This is a particularly important type of chronic pancreatitis to identify as treatment with steroids can salvage both endocrine and exocrine function [27].

As above, recurrent acute pancreatitis from any cause can lead to enough of the gland to be damaged giving changes of chronic pancreatitis. If a cause can be identified then treatment directed at aborting or reducing number and severity of attacks may prevent progression to chronicity. A severe, sentinel attack of necrotising pancreatitis may destroy enough of the pancreas to lead to exocrine and/or endocrine dysfunction [28]. Duct obstruction, mainly seen in pancreatic tumours, can lead to obstructive pancreatopathy with subsequent exocrine and endocrine insufficiency.

In all of these underlying mechanisms, as the disease progresses and more of the pancreatic tissue is destroyed, both the endocrine and exocrine functions of the pancreas begin to become deranged. This leads onto the different clinical presentations of chronic pancreatitis.

Clinical Presentations

There several ways in which patients with chronic pancreatitis present to medical services. These symptoms can present individually or in combination and require assessment and specific treatments.

Pain

The most common symptom described by patients with chronic pancreatitis is abdominal pain. This is usually in the epigastric region and commonly radiates through to the back and left side of the abdomen. The pain is often worse after food and helped by leaning forward, avoiding food and applying heat pads (can result in erythema ab igne). It may last for a week. The pain can be episodic with acute presentations sometimes due to acute flares mainly due to acute pancreatitis superimposed upon a background of chronic pancreatitis. Most patients describe a background of chronic pain. This pain can be severe and patients often require strong analgesia including opiates for relief. There does also appear to be a neurogenic component to the pain and therefore use of neuromodulators such as amitryptylline, gabapentin or pregabalin is also common. The cause of the pain can be multifactorial and includes increased pressure in the pancreatic duct, pancreatic duct strictures, pancreatic duct stones, scarring of the pancreas, pseudocyst formation, and other associated diseases such as coeliac disease, Crohns' disease and gallstones [29].

Exocrine Insufficiency

The pancreas is almost entirely responsible for digestion of fat and when enough of the exocrine component is destroyed fat malabsorption will occur. Previous studies have suggested that loss of more than 85% of the pancreatic parenchyma is needed before steatorrhoea occurs and lipase production is also less than 10% of normal [30, 31]. However, steatorrhoea is a late symptom and many patients describe diarrhoea. Waiting for frank steatorrhea to occur promotes a late diagnosis and complications such as a lack of fat soluble vitamins may not be recognised. Use of tests to identify exocrine insufficiency earlier, such as faecal elastase-1, can allow prompt treatment of this important manifestation and reduce or prevent the clinical sequelae [32]. No test is 100% sensitive in identifying exocrine insufficiency and it is not clear exactly when this occurs in patients with chronic pancreatitis. The prevalence of exocrine insufficiency increases with duration of chronic pancreatitis and therefore, even if not clinically apparent at presentation, should be monitored for during clinical follow up. In patients with overt steatorrhoea and clear evidence of chronic pancreatitis there is little need to perform a test of exocrine function and treatment with pancreatic enzymes replacement therapy (PERT) should be commenced. In the absence of symptoms of exocrine insufficiency, including weight loss, testing exocrine function at presentation should be performed and repeat assessment conducted during follow up. Measurement of weight, fat soluble vitamins and assessment of bone mineral density should all be undertaken at baseline assessment [33, 34].

Dietetic involvement can help patients to titrate PERT dosage, give guidance on diet and has been shown to stop weight loss [35].

Some patients present via colorectal cancer pathways with change in bowel habit due to exocrine insufficiency and weight loss. There is often little pain and the diagnosis is usually made following CT scanning which picks up the abnormal pancreas. The exact proportion of patients with chronic pancreatitis that present this way is unknown.

Diabetes

Diabetes secondary to diseases of the exocrine pancreas have been classified as Type 3c diabetes in the American Diabetes Association classification [36]. Table 2 shows the causes of Type 3c diabetes. The risk of developing diabetes appears to increase with duration of chronic pancreatitis [35]. Some patients present initially as endocrine failure to diabetes services and often have minimal gastrointestinal symptoms that

Cystic fibrosis
Pancreatic trauma

may alert the clinicians to the diagnosis of chronic pancreatitis. Gastrointestinal symptoms are quite common in patients with diabetes [37] and previous studies have examined cohorts of patients with diabetes showing that approximately 10% could be re-classified as type 3c [38].

It has long been known that patients with both type 1 and type 2 diabetes have a high prevalence of abnormal levels of faecal elastase-1 [39]. This high prevalence of abnormal elastase does not seem to translate into large numbers of patients with diabetes being treated with PERT. In fact, only one study exists which showed no change in diabetes markers (namely Hb_{A1c}) or symptoms but did show improvement in number of episodes of hypoglycaemia and that PERT does not destabilise diabetes control [40].

Incidental

There are a group of patients that are identified as "incidentalomas". These patients have usually undergone cross sectional abdominal imaging for other reasons, e.g. renal scanning, and this has identified pancreatic changes consistent with chronic pancreatitis. These patients often have minimal symptoms of either pain or exocrine insufficiency but should be assessed clinically and exocrine and endocrine testing performed along with measurement of fat soluble vitamins and bone mineral density.

Diagnosis

Diagnosis of chronic pancreatitis is sometimes challenging. Obvious cases of late stage disease with clear symptoms, exocrine insufficiency, diabetes and gross changes on imaging are straight forward. However, as mentioned above, the changes in the pancreas usually develop over time and many cases are subclinical. In earlier stages the diagnosis is usually made by using a combination of factors. These include symptoms, exocrine function testing, endocrine function testing, nutritional markers and cross sectional imaging. In cases of IgG4 RD there are specific criteria which also include histological changes [25]. Symptoms have been described above.

Table 3 Testing of exocrine pancreatic function

Direct tests	Indirect tests
USS	Faecal fat
Pancreatic EUS	PABA
CT scanning	MTBT
MRCP	Triolein breath test
Lundh test meal	Pancreolauryl test
SCT/SPT	Faecal chymotrypsin
ERCP	Faecal elastase
Histology	

SCT secretin cerulean test, *SPT* secretin pancreozymin test, *PABA* para-aminobenzoate test, *MTBT* mixed triglyceride breath test

Exocrine Function Testing

There have been many tests of exocrine pancreatic function over the years which are shown in Table 3. Many of these test are now not available routinely in European centres. The gold standard for exocrine testing was the secretin cerulean test (SCT) which involved laying on the right side for 4 h with a naso-duodenal tube in situ. Secretin was then given intravenously and aspirates were taken every 15 min for measurement of enzyme levels and bicarbonate. This was difficult to perform and not favoured by patients. This led onto the 'indirect' tests which used a substrate that was ingested orally and digested by pancreatic enzymes. The products of this digestion were then measured in blood, breath or urine and the amount of product correlated to exocrine function. Many of these tests had limitations or involved several hours with repeated measurements. Assessment of pancreas specific proteins in the stool led to the faecal chymotrypsin test and subsequently this was modified to the faecal elastase test. This is almost exclusively the only test remaining in many centres. Faecal elastase measurement is very good for moderate and severe exocrine insufficiency but has limited sensitivity for early disease. It should also be noted that this is a test for exocrine insufficiency and not chronic pancreatitis and has been used to other disease areas. The test has some limitations including dilution in watery stool but has the advantage of being cheap, outpatient and can be performed in large numbers. Faecal elastase has been compared the previous gold standard tests and appears to have good sensitivity and specificity for severe and moderate disease (both approaching 100%) [41, 42] but is less accurate in mild disease [43, 44]. Additionally, faecal elastase cannot be used to monitor progress or response to therapy.

More recently a new type of mixed triglyceride breath test has been proposed by the group in Santiago De Compostela which appears to have a good sensitivity and specificity [45]. This test has been compared to faecal fat estimation and correlates well with the coefficient of fat absorption. This test can also be used to determine whether a patient is receiving sufficient doses of PERT but has the disadvantage that it

takes around 6 h to complete and requires a special spectrometer to measure carbon-14 [46].

The ideal test for measuring exocrine pancreatic function is still being searched for and would need to be cheap, outpatient based, reproducible in large numbers, highly accurate, acceptable to patients and changes dynamically with enzyme replacement.

Endocrine Function

The main easily measureable endocrine function is glycaemic control. At diagnosis around 30% of patients with chronic pancreatitis have diabetes mellitus and this prevalence increases with duration of the disease [33, 35]. At diagnosis of chronic pancreatitis all patients should have an assessment of glycaemic control and the NICE guidelines recommend measuring HbA1c at least every 6 months. If there is uncertainty around glycaemic control then either glucose tolerance testing or assessment by diabetes services can be performed. It is important to note that patients with type 3c diabetes also have reduced alpha cell mass meaning that their ability to produce glucagon is impaired, meaning that they are at higher risk of developing severe hypoglycaemia and generally they need lower doses of insulin than other types of diabetic. It is important to note that not every patient with chronic pancreatitis that has diabetes has type 3c diabetes. Patients with type 3c diabetes have similar cardiovascular and neuropathic risks to patients with other types of diabetes and should be monitored by diabetes services appropriately. Both type 1 and type 2 diabetes can have occurred prior to the diagnosis of chronic pancreatitis.

Nutritional Markers

Patients with chronic pancreatitis can have a number of nutritional deficiencies mainly as a consequence of fat malabsorption but others occur as alongside fat malabsorption [47]. The most commonly identified micronutrient deficiency in patients with chronic pancreatitis is vitamin D and occurs in 50–60% of patients [48, 49]. Deficiency in vitamins A, E and K have also been reported but only rarely have clinical manifestations [48–51]. Iron deficiency is also seen in patients with chronic pancreatitis and may be due to reduced intake, duodenitis due to lack of bicarbonate production or part of the general malabsorptive condition. Zinc deficiency has been noted [52]. Epidemiological studies have also identified deficiency in magnesium as a marker for underlying exocrine insufficiency although the exact mechanisms are not clear [47].

Current UK guidelines recommend measurement of iron, B_{12}, folic acid, fat-soluble vitamins (although not specified), selenium, zinc, magnesium, copper and clotting status [34]. It should be noted that none of the micronutrient deficiencies are specific enough to chronic pancreatitis or exocrine insufficiency and cannot be used as a screening tool.

Imaging

Structural information about the pancreas is essential in aiding diagnosis. Many studies have been conducted that report the specific characteristics and accuracy of different imaging modalities in making a definitive diagnosis of chronic pancreatitis. Historically, transabdominal ultrasound scanning and ERCP were used to confirm or refute the diagnosis of chronic pancreatitis. With increasing access to and resolution of cross sectional imaging with multi-detector CT scanners and higher Tesla MRI scanners, these modalities are now often the first line investigations for patients with abdominal and suspected pancreatic diseases. Furthermore, endoscopic ultrasound has also progressed from mechanical radial images to high quality, high resolution images and is not affected by bowel gas in the same way that transabdominal ultrasound is (Fig. 1). The main issue with endoscopic ultrasound is the "endoscopy" part requiring an invasive procedure which has a long learning curve and similar issues with operator variability as transabdominal ultrasound. One of the benefits of CT and MRI imaging is the ability for this to be stored, transferred and reviewed in fora such as a multidisciplinary team meeting. A recent meta-analysis of imaging modalities for aiding diagnosis in patients with suspected

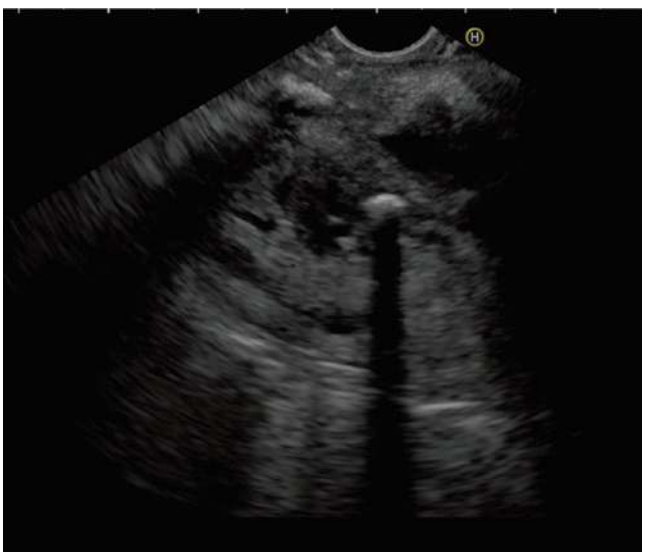

Fig. 1 Endoscopic ultrasound image showing calcific chronic pancreatitis (hyperechoic stone in duct with acoustic shadowing)

Table 4 Sensitivity and specificity of different imaging modalities for suspected chronic pancreatitis

Imaging modality	Sensitivity	Specificity
Transabdominal ultrasound	67% (53–78%)	98% (89–100%)
CT	75% (66–83%)	91% (81–96%)
MRI	78% (69–85%)	96% (90–98%)
ERCP	82% (76–87%)	94% (87–98%)
Endoscopic ultrasound	81% (70–89%)	90% (82–95%)

chronic pancreatitis reported the highest sensitivity with endoscopic ultrasound and ERCP and the lowest was transabdominal ultrasound [53]. Table 4 shows the reported sensitivity and specificity of each of these imaging modalities as reported by Issa and colleagues [53]. Despite these findings, it is recommended that non-invasive testing is conducted first and that the need for endoscopic ultrasound is mainly when there is uncertainty from cross sectional imaging. ERCP should not be used as a diagnostic tool at all due to the high risk of causing acute pancreatitis. Often both CT and MRI are utilised as they provide complimentary information with CT being better for soft tissue findings and MRI giving more detail on ductal anatomy. The addition of secretin during MRI scanning can also give dynamic imaging changes which can increase the diagnostic yield [54]. Similarly, adjunctive technologies at endoscopic ultrasound may also help to increase the yield including elastography which determines tissue "stiffness". This adjunct is easy to perform during the examination but validation is required [55].

Most guidelines recommend the initial imaging modality to be CT scanning or MRI depending upon local availability and expertise.

Complications of Chronic Pancreatitis

Given the progressive and irreversible nature of chronic pancreatitis some patients develop secondary complications which require surveillance and management. Recurrent episodes of acute pancreatitis can lead to local pancreatic complications such as pseudocyst formation which may cause more pain and occasionally lead to compression of the upper intestinal tract. Stricture formation in the pancreatic duct, and often associated stones, can also lead to episodes of pain from obstruction and flares of acute pancreatitis. Vascular complications such as splenic vein thrombosis, portal vein thrombosis and pseudoaneurysm formation are also described and can present with bleeding or ascites. Formation of an inflammatory mass in the pancreas (particularly the head of the gland) can cause gastric outlet obstruction and/or biliary obstruction. Duodenal strictures can also be encountered either from compression from the head of pancreas or potentially recurrent duodenal ulceration due to a lack of bicarbonate production.

Endocrine and exocrine insufficiencies are described above. Abnormalities of bone mineral density are common in patients with chronic pancreatitis and occur in around 40% of patients [56]. There is also an increased risk of developing pancreatic cancer which can be very difficult to identify on cross sectional imaging as well as endoscopic ultrasound particularly in very calcified, diseased glands. The overall risk of developing pancreatic cancer for most types of chronic pancreatitis is increased but this risk is confounded by other variables such as smoking [57]. For patients with genetic causes and those with PRSS1 mutations in particular, the risk is very significantly elevated [58]. Screening for pancreatic cancer is not currently performed for most forms of chronic pancreatitis and familial/hereditary aetiologies are encouraged to enrol in well conducted research registries such as EUROPAC. Otherwise, urgent CT scanning should be performed in patients with chronic pancreatitis and worrisome symptoms such as unexplained weight loss and jaundice.

Management of Chronic Pancreatitis

The majority of management options for patients with chronic pancreatitis are medical. However, some patients may benefit from other interventions including endoscopic and surgical treatments. The mainstay of management is to relieve symptoms, manage complications and prevent/slow the progression of the disease.

Pain

Management of pain can be difficult in chronic pancreatitis and has been discussed previously. Use of the analgesic ladder is recommended with use of adjunctive treatments such as neuromodulatory medications. If pain is due to ductal stones and/or structuring then endoscopic or surgical intervention may be required and this will be discussed later.

Coeliac plexus block has been investigated for this group of patients and has been found wanting. Pain relief is temporary and lasts for up to 3 months only with around 50% of patients describing a response [59].

Pancreatic Enzyme Replacement Therapy

One of the main treatments is pancreatic enzyme replacement therapy (PERT) which is required in the majority of patients with chronic pancreatitis. Historically, PERT has been under prescribed and patients under treated with resultant subtherapeutic outcomes. In patients with clear symptoms of exocrine insufficiency and other supportive evidence of chronic pancreatitis on imaging, testing exocrine function prior to commencing treatment is not required. (UK guidelines) Treatment

with PERT has been shown to ameliorate symptoms of exocrine insufficiency, improve nutritional status, improve survival and has a positive effect on quality of life in patients with chronic pancreatitis [60–62]. One study examined 2 cohorts of patients with chronic pancreatitis who were referred to a specialist centre in Germany. One cohort were patients with a new diagnosis of chronic pancreatitis and the other cohort were patients with an existing diagnosis of chronic pancreatitis who were already on PERT. Assessment of gastrointestinal symptoms and quality of life (measured using the Gastrointestinal Quality of Life Index) was conducted at baseline, 6 months and 1 year. Unsurprisingly, the cohort with a new diagnosis showed significant improvement in all parameters during follow up. Perhaps most interesting was the improvement seen in those patients whom had already been started on PERT at another centre and then referred on [63]. The reasons for this group improving are not easily elucidated from the study but most patients had their PERT titrated up and had other adjunctive input including dietetics. This study reinforces the historical issue of under dosing of PERT and the need for follow up by clinicians with the relevant knowledge for managing exocrine insufficiency.

With this in mind, the starting dose for PERT should be a minimum of 50,000 units of lipase with meals and 25,000 units with snacks [60, 64]. The expectation should be that this is very much the starting dose and that this is likely to increase dependent upon clinical response [34]. PERT is most effective when taken throughout the course of the meal and this has been confirmed in randomised studies [65]. If patient cannot swallow the capsules then either one of the powdered preparations can be used or capsules can be opened and the contents sprinkled over the food. Many formulations are enteric coated, however, inpatients who have undergone previous gastric surgery, non-enteric coated formulations should be used or the capsules opened and sprinkled onto the food.

There is no maximum dose of enzymes that can be provided. Historically, there were reports of a rare complication called fibrosing colonopathy in patients on high dose PERT [66]. This was only seen in paediatric patients with cystic fibrosis and with an enzyme formulation that is no longer available. It is thought that this may have been related to materials in the capsule rather than the enzyme preparation [67]. However, if total lipase dose per meal is higher than 150,000 units without sufficient improvement in symptoms then investigation of other causes should be undertaken.

Lack of response to PERT should lead to a systematic reassessment of the causes for this. The most common reason for lack of response is related to total lipase intake, timing of PERT throughout the meal or denaturing of the enzymes by inappropriate storage [68]. Involvement of a dietitian to provide education around these issues can be of great benefit to the patient [35]. If there is still a lack of response despite addressing these issues and increasing the dose of PERT, adding in a proton pump inhibitor to reduce acidic destruction of enzymes should be considered [69]. If this does not improve symptoms then further investigations should be undertaken to exclude secondary causes [68]. Commonly associated conditions include small bowel bacterial overgrowth, bile acid malabsorption, coeliac disease and inflammatory bowel disease [70–72].

Other considerations for PERT are that all current commercially available products are porcine in nature and patients should be made aware of this prior to prescription. A non-porcine formulation is in development but is yet to be deemed non-inferior to currently available products. As there is no current alternative, most religious groups will accept current products [73, 74].

Special Circumstances

Patients with chronic pancreatitis may require enteral feeding via tubes such as nasojejunal tubes or a gastrostomy (insertion techniques are discussed elsewhere). Provision of PERT in a patient on infusion feeding regimens can be an additional challenge and little data is available to guide practice. Addition of enzymes to the feed or flushing of powdered preparations through the feeding tube every 2 h are suggested [75]. This appears to work most optimally when a peptide feed is used.

Endoscopic Treatment

Interventional endoscopic techniques have rapidly expanded over the last decade and perhaps this is best demonstrated in the area of therapeutic endoscopic ultrasound. Endoscopic interventions for patients with chronic pancreatitis need to be considered carefully and is best done in a multidisciplinary team meeting involving endoscopists, surgeons and radiologists. Most endoscopic interventions are for management of complications of chronic pancreatitis mainly in the form of drainage procedures. Conventionally, interventions in chronic pancreatitis were in the form of surgery but some patients are not suitable for surgical intervention and some procedures are best performed endoscopically.

Pseudocysts are common in patients with chronic pancreatitis and can occur in up to 20% of patients. Intervention is only required in those patients in whom the cyst is causing symptoms which are mainly pain or compression of the gut or biliary tree. If occurring after an acute flare episode many of these will spontaneously resolve and some can be managed expectantly. Those with severe and/or persistent symp-

toms may benefit from cyst drainage which is most commonly performed using endoscopic ultrasound. Endoscopic ultrasound allows for assessment of the cyst, identification of local vascular structures and drainage under real time ultrasound. This can be done in the endoscopy department rather than theatre using conscious sedation, is faster and less costly than surgery and has a high technical and clinical success rate [76]. Pure pseudocysts can be drained using plastic stents rather than lumen apposing metal stents (LAMS) which are cheaper. Cyst with evidence of necrotic material are best drained using LAMS which allows for endoscopic necrosectomy [77].

Pancreatic duct stones and strictures can also be managed using endoscopy ususally in the form of ERCP. Pancreatic duct stones are conceptually different to bile duct stones. Bile duct stones *are* the disease whereas pancreatic duct stones are a *consequence* of the disease and therefore removal does not necessarily improve symptoms for the patient. Pancreatic duct stones should therefore only be treated if they are causing symptoms particularly acute episodes of pain or pancreatitis [78]. Location of the stones is very important as is the presence of stricturing of the duct proximal to the stone. Smaller stones, located in the head in a dilated duct have a higher chance of endoscopic extraction than larger stones found in the body or tail especially if associated with a stricture [79].

Strictures causing symptoms in the absence of stones can also be managed endoscopically using stents. Figure 2 shows the ERCP findings in a 60 year old female patient with a symptomatic stricture in the head of pancreas causing dilatation of the main pancreatic duct with subsequent plastic stent insertion leading to resolution of pain. Newer fully covered metal stents are now available for use in the pancreatic duct for remodelling of strictures in selected cases.

One of the most common indications for ERCP in patients with chronic pancreatitis is for management of biliary strictures. These occur due to fibro-inflammatory tissue encroaching on the distal bile duct causing obstruction and up until the last 10 years were managed surgically. In patients who were not suitable for surgery, insertion of multiple plastic stents to slowly dilate the stricture was employed but this has now been largely superseded by the use of fully covered metal stents [80, 81]. Use of fully covered stents allows for high volume, reliable biliary drainage with dilatation and remodelling of the stricture. The majority of patients have resolution of the stricture with one stent but some do recur mainly due to factors leading to relapse of chronic pancreatitis such as smoking.

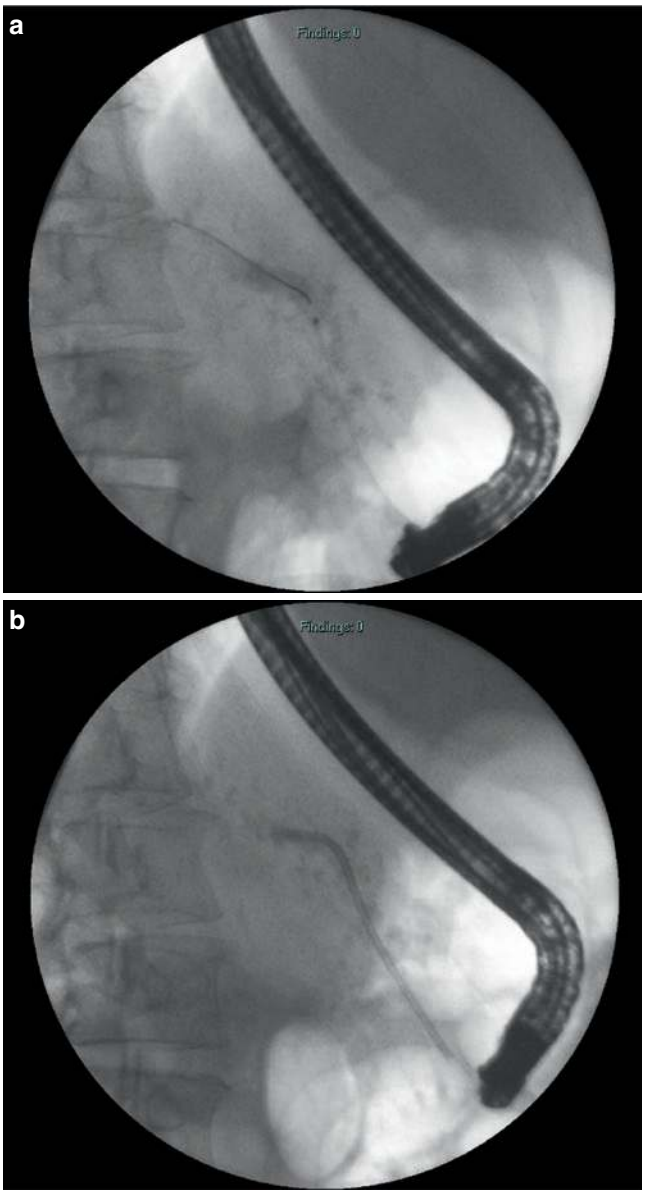

Fig. 2 ERCP findings in patient with chronic pancreatitis and recurring pain. (**a**) Visible calcifications on plain film. Stricturing of the duct in the head. (**b**) Subsequent plastic stent insertion

Surgical Treatment

Surgical treatment of chronic pancreatitis follows the same principles as endoscopic treatment and ideally used for symptom control. Surgery used to be the main treatment modality for management of pseudocysts, pancreatic duct stones, pancreatic duct strictures and biliary strictures but

has largely been replaced with endoscopic intervention as above. There are some areas where surgery should be considered primarily. In patients with pain and a dilated pancreatic duct, one randomised control trial showed superiority of open surgical duct drainage using the Puestow procedure (lateral pancreatico-jejunostomy) compared to endoscopic therapy using ERCP [82]. The primary outcome measure was relief of pain and this was significantly better at all time points in the surgical arm. Long term follow up of this cohort showed that these effects were long lasting [83]. One of the difficulties with this trial were the large number of exclusions meaning that surgical intervention was not an option for some patients. Therefore, whilst surgical intervention has moved to the fore in this group of patients, for those in whom surgery is not suitable or not palatable, endoscopic intervention still carries some value.

Surgical intervention is also beneficial in patients with an inflammatory mass in the head of pancreas. Surgery (usually in the form of a Whipple's procedure) removes the inflammatory tissue and also improves luminal symptoms of delayed gastric emptying. Some surgeons use partial head resection techniques such as the Frey-Beger procedure if there is duct dilatation but no enlargement of the pancreatic head [84, 85].

In very selected cases, total pancreatectomy may be required. For young patients and those with hereditary pancreatitis, the addition of islet cell transplantation to maintain some degree of glycaemic control can be considered [86, 87]. In the UK, there are currently only 3 pancreatic centres that offer this intervention.

Radiological Treatment

In some patients with chronic pancreatitis, endoscopic and/or surgical intervention is not suitable or desirable and therefore radiological approaches can be considered. These are usually via the percutaneous route and are reserved for collections or cysts not reachable by endoscopic means or where previous surgery (such as gastric bypass) prevents an endoscopic treatment [88]. Some centres use radiological interventions more readily due to local availablility and expertise in this area compared to endoscopic or surgical skill mixes. High volume operators have been shown to have improved outcomes for procedure such as percutaneous transhepatic cholangiography [89].
