Table 59.9 Intravenous iron preparations[a]

Compound	Adult dosing	Adult administration
LMW Iron dextran[b]	500–1000 mg	Test dose (25 mg) needed; Remainder of dose over >60 min
Ferric gluconate	125 mg	Diluted infusion over 1 h Undiluted up to 12.5 mg/min
Iron sucrose	100 mg	Injection: 2–5 min (≤200 mg) Infusion: ≤200 mg: 15 min; 300 mg: 1.5 h; 400 mg: 2.5 h; 500 mg: 3.5–4 h
Ferric carboxymaltose	≥50 kg: 750 mg × 2 (≥1 week apart) or 15 mg/kg (max 1 g) × 1 dose <50 kg: 15 mg/kg (once or twice ≥1 week apart)	Injection: 100 mg/min (≤750 mg) or over 15 min (1 g dose); infusion (diluted) over ≥15 min
Ferric derisomaltose	≥ 50 kg: 1 g <50 kg: 2 mg/kg	Infusion: ≥30 min
Ferumoxytol	1020 mg (one dose) or 510 mg (2 doses) ≥ 3 days apart	Infusion: 510 mg: ≥ 15 min; 1020 mg ≥ 30 min

LMW low molecular weight

[a]Dosing and administration recommendations may vary by country and change over time. Review current, local recommendations prior to using

[b]Smaller doses may be used for maintenance therapy, typically in hemodialysis patients

60 or 90 min, were well tolerated [164], as were infusions over 1–4 h) [165]. In children, one study reported administration of doses ranging from 1.5 to 8.8 mg/kg, with the child receiving the highest dose having a significant adverse event [152]. Thus, acute doses of ferric gluconate in patients not receiving HD should not exceed 4 mg/kg (250 mg if >60 kg), which should be given over at least 90 min.

Iron sucrose is generally well-tolerated [166, 167] and effective in correcting iron deficiency in patients with CKD [168–170]. Iron sucrose is available in 50 mg vials. Adult HD patients are usually given 50 or 100 mg over 5 min [166]. Infusions of 100 mg over 10 consecutive dialysis sessions is used for acute dosing to provide a total of 1000 mg. For chronic dosing in adult HD patients, doses of 50 or 100 mg avoids wasting medication and can be given weekly or every other week [166].

In adult PD or predialysis pat over 1.5–2 h, appear to be well tolerated. Doses of iron sucrose as high as 500 mg have been given, but the infusion time must be extended to avoid side effects, and this dose may not be tolerated in smaller adults [169, 171, 172]. In children, a dose of 2 mg/kg (maximum 100 mg) over 3 min or 5 mg/kg (maximum 300 mg) over 90 min is well-tolerated [173]. The 5 mg/kg dose can be repeated the next day [173].

Ferric carboxymaltose is effective in treating iron deficiency and is approved for use in non-dialysis CKD patients [174–178]. When ferric carboxymaltose was directly compared to iron sucrose, there was more hypertension in the ferric carboxymaltose group and more hypotension in the iron sucrose group [177]. There are recommendations for acute dosing in adults: 15 mg/kg (maximum 750 mg) with a second dose at least 1 week later. It is administered over 15 min. There is substantial pediatric experience with ferric carboxymaltose, but limited experience in children with CKD [179–183]. In one study, the usual dose was 15 mg/kg, with a maximum dose of 750 mg [179]. In another study, the usual dose was 20 mg/kg, with a maximum dose of 1000 mg in children >35 kg and 500 mg in children <35 kg [183]. Ferric carboxymaltose is available in 750 mg vials, precluding its use in a chronic dosing strategy (see below) or in small children without wasting medication. Hypophosphatemia is a complication in adults with CKD and children who receive ferric carboxymaltose for other indications [177, 184–187].

Ferumoxytol, approved for CKD patients, is effective when given to adults at a dose of 510 mg, followed by a second dose 3–8 days later, though single doses of 1020 mg also appear safe [188–191]. The infusion rate should not exceed 30 mg of iron/second. The large vial size (510 mg) limits

its utility in small children or for use in a chronic dosing strategy. There is limited pediatric experience, albeit not in children with CKD [192, 193]. In one study, ferumoxytol at a dose of 10 mg/kg (maximum 510 mg) was administered over 60 min and 15 min for the first infusion and subsequent infusions, respectively [193].

Ferric derisomaltose is approved and marketed in more than 30 countries worldwide, including the US, the EU, Canada, and Australia for treating iron deficiency. It has comparative efficacy to iron sucrose in patients without CKD and patients with pre-dialysis CKD. There is no published pediatric experience [194, 195].

Acute Dosing

Acute doses of IV iron are given when the patient has evidence of iron deficiency (see criteria above). The goal of acute IV iron dosing is to normalize the serum ferritin and the TSAT. In some cases, an acute dose may be used as a trial of IV iron in a patient with normal iron studies, but a poor response to an ESA. In these patients, the goal of acute IV iron is a reduction in ESA dose or correction of resistant anemia.

In adult HD patients, studies suggest that a total dose of 1000 mg of iron, divided over multiple consecutive dialysis sessions, is appropriate, since smaller doses are not as effective [162]. A total dose of 1000 mg has been used in older children with good results [136]. A randomized study of children receiving HD compared 2 acute dosing regimens of ferric gluconate (1.5 mg/kg/dose and 3.0 mg/kg/dose; maximum dose, 125 mg/dose) given during 8 consecutive HD sessions. The patients had a TSAT <20% and/or a ferritin less than 100 ng/mL at baseline. Both doses led to an increase in Hb and normalization of iron indices. Since there was no difference in the response, the authors recommended a dose of 1.5 mg/kg/dose (maximum of 125 mg/dose) for 8 consecutive HD sessions [196]. This provides a total dose of 12 mg/kg (maximum dose of 1000 mg). Based on the available evidence, the total dose for acute pediatric dosing should be between 12 and 25 mg/kg (1000 mg maximum) divided over up to 12 HD sessions, depending on the dose and iron preparation (see above discussion of specific preparations).

Chronic Dosing

Acute dosing is effective in correcting iron deficiency, but especially in HD patients there is a risk of ongoing episodes of iron deficiency due to continued blood loss. Transient iron deficiency may lead to decreased red blood cell synthesis. This has led to more frequent chronic IV iron use. Observational studies in adults suggests that maintenance therapy may be associated with better outcomes than an acute dosing strategy [197, 198].

In one pediatric study, 1 mg/kg of ferric gluconate for 12 weeks led to a significant increase in Hb [135]. In another pediatric study, chronic IV iron sucrose (2 mg/kg [max = 200 mg] weekly) produced a reduction in rHuEPO dose [153]. A randomized 16-week study in children receiving HD compared maintenance IV iron dextran (doses of 25, 50 or 100 mg/week based on weight; doses therefore ranged from 1.25–2.5 mg/kg/week) with oral iron (4–6 mg/kg/day). The patients receiving IV iron had a significant increase in ferritin when compared to the oral iron group. There was a trend toward a reduction in rHuEPO dose in the IV iron group when compared to the oral iron group [155].

Another study randomized children receiving HD to intermittent IV iron versus maintenance IV iron. There was a higher rate of iron overload in the children receiving intermittent IV iron [199]. This observation may be secondary to a decreased ability to utilize stored iron in children receiving HD due to an inflammatory block. The low doses of maintenance IV iron are immediately employed for red cell synthesis, avoiding an excessive accumulation of stored iron. This contrasts with intermittent IV iron; the high doses cannot all be utilized immediately, increasing the risk of eventual iron overload.

One pediatric study prospectively followed children who were started on a maintenance dose of 1 mg/kg/week of ferric gluconate and then adjusted the dose of ferric gluconate based on iron studies. The majority of the patients completing the study required a dose of 1.5 mg/kg to maintain adequate iron stores [200].

Maintenance IV iron in children receiving HD should be started at about 1 mg/kg/week, usually given as a once/week dose. The maintenance

dose is titrated to keep the TSAT above 20% and the ferritin above 100 ng/mL; IV iron should be held if the TSAT is greater than 50% or the ferritin is greater than 500 ng/mL.

Complications

There are some complications of IV iron that are specific to the particular preparation. Iron dextran may cause an acute anaphylactic reaction, which is potentially fatal [201]. Iron sucrose [159] and ferric gluconate [162] have a safer side effect profile, although all IV iron preparations have the potential to cause serious adverse reactions. Children and adults who have had anaphylactic reactions to iron dextran have tolerated other iron preparations [152, 202, 203]. High doses of iron dextran may cause patients to develop arthralgias and myalgias [204].

There are reports of laboratory findings and clinical symptoms that may be due to acute iron toxicity during the use of iron sucrose and ferric gluconate. This effect is related to the dose and infusion rate and is presumably secondary to rapid release of free iron. Symptoms with ferric gluconate have included loin pain, hypotension, emesis and paresthesias [205]. Iron sucrose side effects have included rash, flushing, and hypotension, which were rapidly reversible [206]. These side effects limit the maximum single dose of these compounds when compared to iron dextran, which releases free iron at a slower rate.

Use of IV iron may increase generation of reactive oxidative species, which has the potential to impair endothelial cell function, promote atherosclerosis, cause inflammation, and decrease immune function [207–210]. There is evidence of an association between higher iron dose and increased adverse outcomes, recognizing a variety of potential confounders [211]. These adverse events may be less likely with iron preparations that release iron more gradually (e.g. ferric carboxymaltose, ferumoxytol and ferric derisomaltose) than iron sucrose or ferric gluconate. This was seen in a randomized study comparing iron sucrose with ferumoxytol [177]. Yet, there is not yet enough evidence to reach a conclusion on this issue given the limitations with the extant literature [212].

Ferumoxytol is associated with higher rates of adverse events than iron sucrose or ferric gluconate [167]. Adverse reactions include injection site reactions, hypersensitivity reactions and hypotension that can be severe [213]. Patients should be observed for at least 30 min after receiving ferumoxytol. Its use may also transiently affect MRI interpretation since it is also used as a contrast agent for MRIs [213].

Iron overload is a potential complication of IV iron therapy, and may occur in CKD patients receiving IV iron [214–216]. There is concern that current IV iron protocols may lead to more problems with iron overload, which has been seen in children receiving acute or maintenance IV iron [153, 199].

IV iron may cause hypophosphatemia, which appears to be mediated by increased levels of FGF-23 and urinary phosphate wasting [217, 218]. Clinically significant, sustained hypophosphatemia is associated with ferric carboxymaltose [186, 187, 219].

IV iron may increase the risk of infection [220]. A multivariate analysis did not find a relationship between IV iron and infection, although there was a trend toward more infections among those patients who received large amounts of IV iron versus those who received lower doses [221]. Given this potential complication, IV iron should be held in patients with acute infections.

60 Disorders of Bone Mineral Metabolism in Chronic Kidney Disease

Claus Peter Schmitt and Rukshana C. Shroff

Introduction

Disturbances of bone and mineral metabolism almost inevitably develop in the course of chronic kidney disease (CKD). These comprise altered calcium and phosphate homeostasis, abnormal synthesis and secretion of parathyroid hormone (PTH) and vitamin D, and alterations in bone metabolism and function. If not treated appropriately, severe and sometimes disabling complications may occur. Alterations of bone and mineral metabolism originating in childhood contribute not only to degenerative bone disease, but also to vascular morbidity and mortality in young adult life. Hence, adequate control of bone and mineral metabolism is one of the major challenges in the treatment of pediatric patients with chronic renal failure.

With the growing awareness that mineral dysregulation in CKD is closely linked to abnormal bone pathology, and that these in turn lead to extra-skeletal calcification, Kidney Disease Improving Global Outcomes (KDIGO) have proposed a broad and encompassing term chronic kidney disease - mineral and bone disorder (CKD-MBD) to describe this clinical entity [1]. CKD-MBD is defined as a systemic disorder of mineral and bone metabolism that is manifested by either one or a combination of the following:

- Abnormalities of calcium, phosphorus, PTH, or vitamin D metabolism
- Abnormalities in bone turnover, mineralization, linear growth, or strength
- Vascular or other soft tissue calcification

A proposed framework for classifying CKD-MBD divides patients into four types based on the presence or absence of abnormalities in the three primary components used in the definition of the disorder: laboratory abnormalities, bone disease, and calcification of extraskeletal tissue. In this chapter we discuss the pathophysiology, clinical presentation and treatment of CKD-MBD in children.

Epidemiology

Metabolic derangements begin as early as in CKD stage II (glomerular filtration rate [GFR] of 60–90 ml/min/1.73 m^2), plasma levels of active 1,25-dihydroxyvitamin D [1,25$(OH)_2D_3$] decline and parathyroid hormone [PTH] and fibroblast growth factor-23 [FGF23] levels start to increase [2] (Fig. 60.1), with Fibroblast growth factor 23 (FGF-23), a phosphaturic hormone, being the earliest marker of disrupted mineral homeostasis

[3]. Mineralization defects have been demonstrated in 29% of children with CKD stage 2 [4]. When end stage renal disease (ESRD) is reached, most patients have abnormal bone histology. The specific features of bone disease depend on the degree of hyperparathyroidism and the therapeutic measures taken to control the disease, whereas the mode of dialysis therapy, PD or HD, does not appear to play a major role [5]. Adynamic bone disease has a high prevalence, being observed in 40–50% of adult and almost 30% of pediatric ESRD patients (Fig. 60.2) [5–7]. Amongst children, CKD related bone disease can manifest as bone pain and deformities, growth retardation and fractures and have long-term consequences. In a cohort of 249 young Dutch adults with onset of end-stage renal failure before the age of 14 years 61% had severe growth retardation, 37% bone disease (defined by at least one of the following conditions: deforming bone abnormalities, chronic pain related to the skeletal system, disabling bone abnormalities, aseptic bone necrosis and atraumatic fractures and 18% disabilities resulting from bone impairment [8].

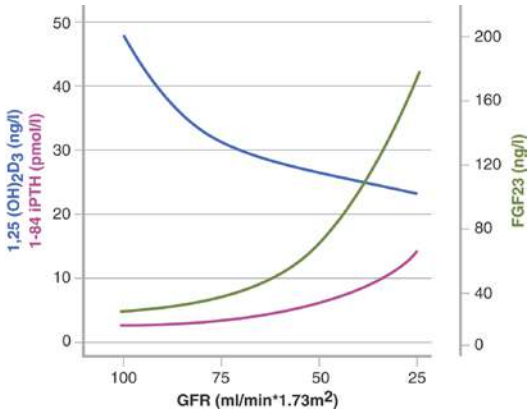

Fig. 60.1 Mean plasma intact PTH, $1,25(OH)_2D_3$ (left y-axis) and FGF23 concentrations (right y-axis) in patients with different degree of CKD. Individual values may vary considerably especially in patients with advanced renal failure

There is a complex interplay between CKD-related bone disease and cardiovascular disease that begins early in the course of CKD, is seen even in children [9], and leads to a significant decrease in life expectancy [10, 11]. Several large national registries have published similar findings for pediatric dialysis recipients. The United States Renal Data Systems (USRDS) has reported that 23% of all deaths in dialysis patients were from cardiovascular causes [12], and 50% of all deaths in young adults who received dialysis as children were from cardiovascular or cerebrovascular causes [10]. Encouragingly, recent reports suggest that there is a substantial decrease in mortality rates over time among US patients [13]. Cardiovascular disease in CKD is discussed in greater detail in Chap. 61.

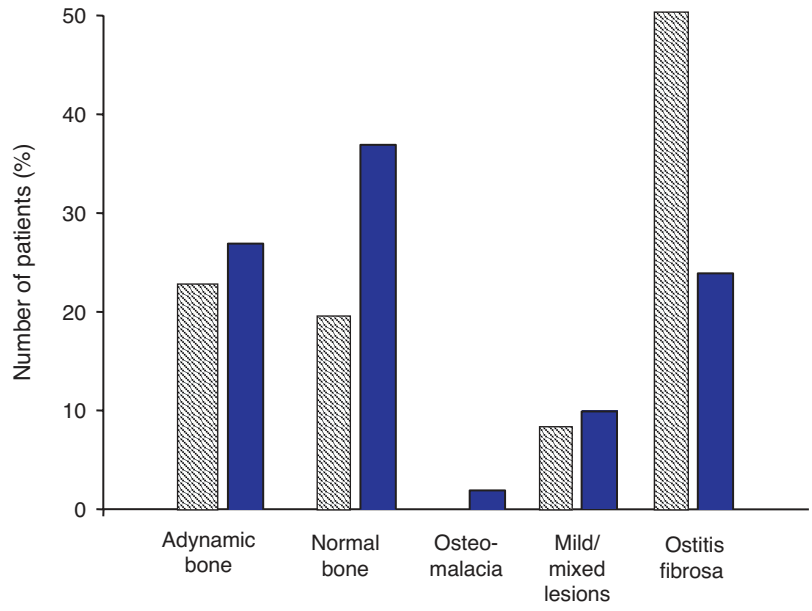

Fig. 60.2 Spectrum of renal osteodystrophy in children with CKD stage 5 diagnosed in the USA in the early 1990s (hatched bars, adapted from [6]) and in Poland in the late 1990s (filled bars, adapted from [5])

Pathogenesis

Bone and mineral homeostasis are regulated in a complex network of local and systemic factors. Patients with CKD develop major disturbances in calcium, $1,25(OH)_2D$ and phosphate homeostasis and subsequently abnormal parathyroid gland function, which ultimately drives the course of the disease (Fig. 60.3). FGF23 has added a new dimension to the Ca-P-PTH axis and advanced our understanding of mineral dysregulation in CKD [3]. FGF23, along with its membrane receptor klotho, acts through an intricate negative feedback system involving PTH and vitamin D to regulate serum calcium and phosphate levels.

Disorders of Calcium Homeostasis

In healthy individuals 99% of total body calcium is stored in the bone, 0.975% in soft tissues and only 0.025% is circulating in blood. Plasma ionized calcium levels are tightly controlled by PTH and $1,25(OH)_2D$. The parathyroid gland senses changes in ionized calcium by a G-protein coupled membrane receptor. Acute hypocalcemia is counteracted by an instantaneous and marked increase in PTH release from storage vesicles, rapidly normalizing plasma calcium levels, and by an increased PTH gene transcription and synthesis rate, an adaptive response which takes several hours to occur. In addition, hypocalcemia stabilizes PTH mRNA by increased binding of a cytosolic adenosine-uridine-rich protein (AUF1) in the 3′ untranslated region of the PTH mRNA [14]. A subsequent increase in $1,25(OH)_2D$ synthesis further stabilizes plasma calcium levels via stimulation of gastrointestinal calcium absorption. A recent study has shown that 76% of children with CKD4-5D had a dietary Ca intake <100% Reference Nutrient Intake, largely because a restriction of dairy foods as part of a P controlled diet limits Ca intake, and additional Ca from medications is required to meet the KDOQI guideline of 100–200% normal recommended Ca intake [15].

In CKD, reduced $1,25(OH)_2D$ synthesis impairs intestinal calcium resorption, resulting in an activation of the regulatory circuits described above and a resetting of ionized calcium at low or low-normal levels. The calcemic response of bone to PTH is reduced and higher PTH levels are required to maintain calcium homeostasis and bone turnover. Uremic toxins, low levels of $1,25(OH)_2D$, accumulation of inactive PTH fragments and osteoprotegerin, and altered PTH receptor expression have been implicated in the skeletal resistance to PTH, providing yet another

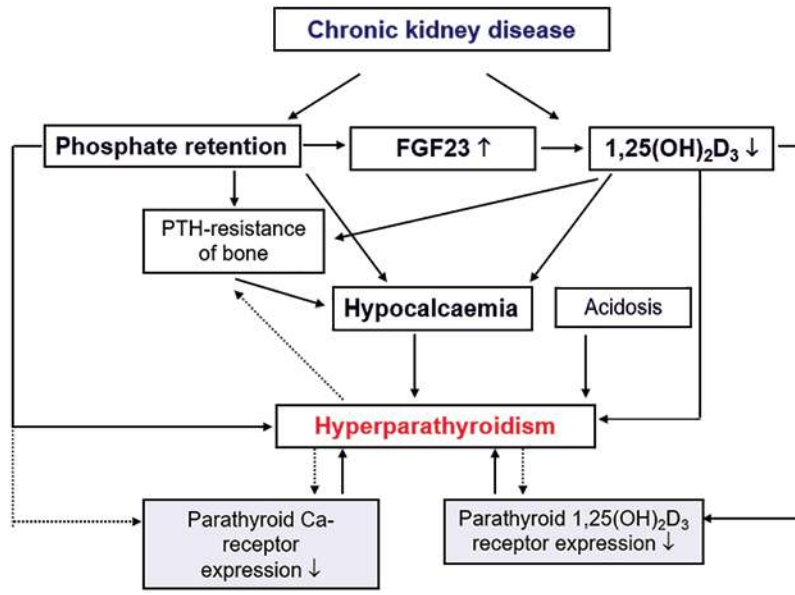

Fig. 60.3 Pathophysiology of secondary hyperparathyroidism

mechanism contributing to the development of hyperparathyroidism (Fig. 60.3) [16].

Plasma ionized calcium is the major regulator of the parathyroids at the level of gene expression, secretion and cell proliferation. Induction of hypocalcemia stimulates PTH release, PTH peptide synthesis via stabilization of PTH mRNA and, if sustained, induces profound parathyroid cell proliferation [17]. Hypocalcemia appears to be a more important regulator of the parathyroid than vitamin D, as suggested by the efficient control of hyperparathyroidism in vitamin D-receptor knock-out mice by a selective increase of dietary calcium content [18]. Moreover, calcimimetic agents suppress PTH by up to 80%, independent of plasma phosphate and $1,25(OH)_2D$ levels.

Abnormalities of $1,25(OH)_2D$ Metabolism in CKD

25(OH)D is converted to the systemically active $1,25(OH)_2D$ by the enzyme 1-alpha hydroxylase. Progressive loss of intact renal parenchyma, low 25(OH)D levels and increased FGF-23 release from the bone result in low circulating $1,25(OH)_2D$ levels. This in turn leads to reduced intestinal calcium absorption and hypocalcemia; it is estimated that the intestinal calcium absorption increases from ~45% to 65% in the presence of adequate vitamin D. Hypocalcaemia triggers PTH release in order to maintain calcium homeostasis and to stimulate 1-alpha hydroxylase.

$1,25(OH)_2D$ controls parathyroid gland function not only via modulating plasma ionized calcium, but also directly by suppressing PTH gene transcription [19] and by upregulating its own receptor in parathyroid cells. Moreover $1,25(OH)_2D$ binds to a response element in the promoter region of the calcium receptor, resulting in increased calcium receptor abundance, thereby increasing the sensitivity of the parathyroid gland to ionized calcium [20]. Hypocalcemia on the other hand compromises vitamin D action by upregulating calreticulin, a repressor of the vitamin response element in the parathyroid glands [21]. In addition, $1,25(OH)_2D$ regulates parathyroid cell proliferation, with low levels promoting parathyroid gland hyperplasia.

FGF23 controls $1,25(OH)_2D$ production through a complex feedback mechanism [22]. FGF23 suppresses the renal 1-alpha-hydroxylase and thereby reduces conversion of 25(OH)D to $1,25(OH)_2D$. In addition, FGF23 increases the activity of 24,25 hydroxylase to degrade $1,25(OH)_2D$.

$1,25(OH)_2D$ has numerous additional important functions outside the bone and parathyroid. The hormone is an important regulator of the immune system and affects the contractility, growth and migration of vascular smooth muscle cells (VSMCs) as well as the evolution of vascular calcifications. Both endothelial and VSMCs express high-affinity Vitamin D3 receptors. $1,25(OH)_2D$ deficiency may contribute to cardiovascular disease by unrepressed production of proteins involved in arterial calcification such as bone morphogenetic protein-2 [23, 24] or by suppressed production of local inhibitors of mineralization, e.g. matrix GLA protein [25]. High doses of $1,25(OH)_2D$ on the other hand promote vascular calcification via an increased calcium phosphate product and transition of vascular smooth muscle cells to an osteoblast like phenotype. Of note in this context, $1,25(OH)_2D$ is not only an endocrine factor exclusively secreted by the kidney. Extrarenal 1-α-hydroxylase expression has been demonstrated in various tissues such as bone, smooth muscle cells and parathyroid glands [26, 27], suggesting an additional paracrine mode of action independent of renal conversion.

25-Hydroxy Vitamin D Deficiency

The widespread deficiency of 25(OH)D is even more pronounced in CKD patients than in the general population, related to multiple potential causes [28]: (1) Patients with CKD may be less active and have less sunlight exposure; (2) The endogenous synthesis of vitamin D in the skin is reduced in CKD; (3) Ingestion of foods that are natural sources of vitamin D may be diminished; (4) Proteinuria may be accompanied by high urinary losses of vitamin D binding protein (VDBP),

leading to increased renal losses of all vitamin D metabolites; (5) 25(OH)D and VDBP may be lost in peritoneal dialysis fluid. There is debate about what levels of vitamin D can be considered adequate. Current clinical practice recommendations for children with CKD suggest a target level of 30–48 ng/ml (75–120 nmol/L) [29].

Low 25(OH)D levels result in muscle weakness [30] and bone pain and aggravate renal bone disease [31, 32]. Bone histomorphological changes are correlated with plasma 25(OH)D levels [31, 33]. *In vitro*, a concentration of 40 ng/ml 25(OH)D is as efficient in suppressing PTH as calcitriol at a maximally PTH suppressive dose. A randomized trial in 47 children with CKD2–4 demonstrated a longer time to development of secondary hyperparathyroidism with vit. D supplementation as compared to those children on placebo [34].

Abnormalities of Phosphate Metabolism and Phosphaturic Hormone FGF23

Phosphate excretion declines early with failing renal function and this is a driving force of CKD-MBD. When the GFR falls to <50 ml/min/1.73 m^2, phosphate accumulates [2]. In early stages, the decline in renal phosphate excretion is counteracted by the phosphaturic hormones Fibroblast Growth Factor 23 (FGF23) and PTH. Clinical studies have identified increased FGF23 levels as the earliest biological marker of deranged calcium - phosphate homeostasis in CKD, even before PTH levels start to rise [3, 35, 36] (Fig. 60.2). FGF23 is mainly secreted by osteocytes and acts on the type IIa and IIc sodium-phosphate co-transporters (NaPi) in the apical membrane of proximal tubular cells to increase urinary phosphate excretion. It suppresses $1,25(OH)_2D$ synthesis by suppressing 1-α hydroxylase (CYP27B1) and increasing $1,25(OH)_2D$ degradation to 24,25(OH)2D by promoting CYP24A1 [37]. Thus, by reducing circulating $1,25(OH)_2D$ levels, FGF23 reduces phosphate absorption from the gut. Also, FGF23 suppresses PTH mRNA and decreases serum PTH [38]. In turn, FGF23 secretion is stimulated by phosphorus, $1,25(OH)_2D$ and PTH. Mutations in the FGF23 gene result in severe hypo- and hyperphosphatemic disorders (see Chap. 34). Recent data suggests that FGF23 may in fact play a key role in calcium homeostasis and increased FGF23 is associated with higher calcium levels [39].

FGF23 signaling requires the presence of the transmembrane protein klotho on its target cells. Klotho is highly expressed in the kidneys where it serves as a high-affinity receptor for FGF23 [40]. When its extracellular domain is shed from the cell surface, it enters the circulation as soluble klotho and functions as a humoral factor that regulates ion channels and transporters (including NaPi and the calcium channel TRPV5 in the gut). Klotho deficiency develops with declining GFR and leads to a state of relative FGF23 resistance. However, FGF23 may be a 'double edged sword': although elevated FGF23 levels increase phosphate excretion in early stages of CKD, they have been associated with increased cardiovascular mortality both in CKD patients [41] and the general population. FGF23 exerts a direct toxic effect on the myocardium and is associated with left ventricular hypertrophy [42, 43].

A decline in circulating P concentrations can be observed in very early CKD when circulating FGF23 levels and bone FGF23 expression are increased. In contrast, in advanced stages of CKD hyperphosphatemia does contribute to increased FGF23 and treatment with active vitamin D analogs further contributes to increasing FGF23 levels. In all CKD stages, non-mineral metabolism factors such as iron status, erythropoietin and inflammation may also contribute to increased FGF23 production. In murine models, both absolute and "functional" iron deficiency increase bone FGF23 expression [44]. Erythropoietin can also stimulate FGF23 production and, conversely, FGF23 may suppress erythropoiesis [45]. FGF23 levels are higher in patients with glomerular diseases when compared to those with congenital anomalies of the kidneys and urinary tract (CAKUT) [46]; inflammation increases bone and circulating FGF23 levels [44].

Hyperphosphatemia has multiple deleterious effects. It contributes to hyperparathyroidism

independently of plasma calcium and $1,25(OH)_2D$ [47, 48] via increasing PTH gene transcription, PTH peptide secretion and parathyroid cell proliferation. Furthermore, hyperphosphatemia reduces renal $1,25(OH)_2D$ synthesis, inhibits the suppressive action of $1,25(OH)_2D$ on the parathyroid glands and promotes resistance of bone to PTH. Another indirect mechanism by which high phosphate drives hyperparathyroidism is via physicochemical precipitation of calcium-phosphate salts, a process aggravating hypocalcemia. High phosphate levels are very difficult to control as phosphate binders are one of the most difficult medications to comply with. The International Pediatric Peritoneal Dialysis Network has shown that 45% of all children have hyperphosphataemia, with the prevalence increasing to >80% amongst adolescents [49].

Secondary Hyperparathyroidism

The multiple effects of $1,25(OH)_2D$ deficiency, hypocalcemia and hyperphosphatemia in CKD lead to the development of secondary hyperparathyroidism, with a progressive demineralisation of the bone. Pre-pro PTH gene transcription rate, mRNA stability, protein synthesis and secretion of the mature protein are increased. Persistent hyperparathyroidism induces distinct changes in parathyroid gland morphology and function. Parathyroid cell proliferation results in diffuse and polyclonal and eventually monoclonal cell growth, associated with the formation of adenoma. Regulatory systems include endothelin, TGF-alpha, epidermal growth factor receptor and the cell cycle inhibitor p21 [50–53]. Monoclonal parathyroid cell growth is the result of an array of possible genetic aberrations such as gene deletions, loss of heterozygosity, clonal rearrangement and /or oncogene overexpression and tumor suppressor gene inactivation. Polymorphisms in the PTH, Vitamin D receptor and calcium receptor genes may also be involved and explain some of the clinical variability of the disease [54]. Reduced expression of the parathyroid calcium sensing receptor and of the vitamin D receptor

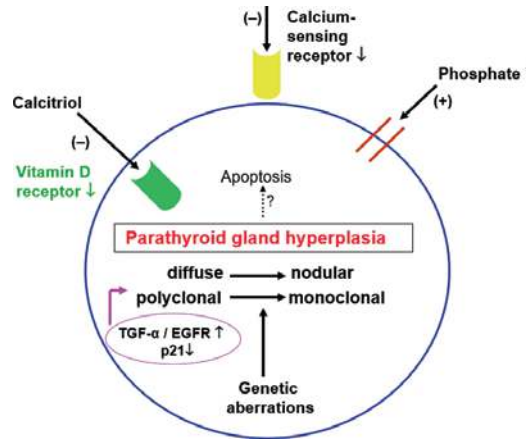

Fig. 60.4 Cellular alterations of parathyroid gland function in CKD

leads to a progressive escape from the two key physiological control mechanisms and ultimately to parathyroid gland autonomy (Fig. 60.4).

Minute to minute analyses of PTH secretion have revealed distinct alterations of the dynamics of oscillatory PTH release in uremic patients, including a markedly reduced secretory capacity to counteract changes in ionized calcium by modulation of the frequency and mass of PTH secretory bursts [55, 56].

Apoptosis is a rare event in normal parathyroid tissue; parathyroid cells can survive for >25 years, so, although uremia is associated with increased apoptosis of parathyroid cells, this mechanism is insufficient to counterbalance enhanced proliferation [57]. Whether an inversion of this imbalance, i.e. regression of parathyroid hyperplasia, occurs in uremic patients, or after correction of uremia, remains controversial [58].

In uremia, *fragments of the intact 1–84 PTH* peptide accumulate in the circulation and exert distinct biological activity, most notable 7–84 PTH fragments that are thought to be biologically inactive are present in the circulation and offset the classic biological actions of PTH [59–61]. 7–84 PTH internalizes the PTH type-1 receptor without prior activation. This may be one explanation for the reduced PTH1R level in uremia, the resistance of bone to PTH and the dissociation of phosphorus and calcium homeo-

stasis in CKD patients. Interindividual variation of 7–84 PTH /1–84 PTH ratios is high. Alternatively, PTH fragments may also signal via receptors distinct from the PTH1R, e.g. through a C-terminal PTH receptor [62] and by this impact on bone. Up to now, there is only limited evidence that the differentiation of PTH fragments is clinically helpful for defining low and high turnover bone disease. The use of PTH assays measuring 7–84 in addition to 1–84, intact-PTH is therefore currently not recommended for routine clinical practice.

Oxidative stress is increased in CKD, and the amino acid methionine at two positions in the PTH peptide is prone to oxidation. A large proportion of circulating PTH measured by standard assay systems is oxidized and may thus not be biologically active. Non-oxidized PTH concentrations are 1.5–2.25 fold higher in patients in renal failure as compared to health controls [63]. Oxidation blunts the biological activity of the peptide. Oxidized PTH (oxPTH) loses its PTH receptor-stimulating properties, whereas non-oxidized PTH is a full agonist of the receptor [63]. Measurements of non-oxidized PTH should reflect the hormone status more precisely, but a recent bone biopsy study in 31 patients with CKD suggests no additional benefit [64]. Non-oxidized PTH measurements are currently not recommended for routine clinical practice.

The Impact of Metabolic Acidosis

Metabolic acidosis, an almost inevitable covariate in patients with failing renal function, has a number of untoward effects on bone. These include physicochemical dissolution of bone with inhibition of osteoblast and activation of osteoclast activity leading to a net calcium efflux from the bone. This is associated with impaired bone mineralization and an increased incidence of osteomalacia, which can be improved by correction of metabolic acidosis [65]. Moreover some evidence suggests that metabolic acidosis increases PTH levels in CKD patients and enhances the peripheral actions of PTH on bone by increasing the expression and ligand affinity of the PTH receptor [66]. The relative quantitative contribution of metabolic acidosis to bone disease in CKD patients remains uncertain.

Further Mediators of CKD Bone Disease

The kidney-bone-vessel interaction is not confined to the homeostasis of calcium-phosphate and $1,25(OH)_2D$ synthesis, but a number of other key molecules are involved.

Bone morphogenetic protein-7 (BMP-7) is produced and secreted in postnatal life mainly by renal collecting tubule cells. CKD is associated with a marked deficiency of circulating BMP-7, most likely due to reduced renal synthesis. In the uremic rat model, adynamic bone disease develops if serum calcium, phosphate, vitamin D and PTH levels are maintained in the normal range. This observation has led to the hypothesis that the variable histopathological appearance of uremic bone may reflect the net balance of hyperparathyroidism inducing a high-turnover and BMP-7 deficiency causing a low-turnover state. At least in the uremic rat, exogenous administration of BMP-7 can reverse both adynamic and high turnover bone disease by improving osteoblast number and bone formation activity [67] . Moreover, BMP-7 reduces vascular calcifications in uremic animals, possibly by increasing the skeletal deposition of phosphorus and calcium [68] . The Diabetes Heart Study showed that single nucleotide polymorphisms in the BMP-7 gene have significant and reciprocal effects on vascular calcification and bone density [69]. Despite these notable discoveries BMP-7 has not entered the clinical arena so far; neither have circulating BMP-7 measurements been established as a biomarker of bone health nor have therapeutic studies progressed beyond the preclinical phase to date.

Osteoprotegerin (OPG) is a soluble protein of the tumor necrosis factor (TNF) receptor superfamily and a decoy receptor for the *receptor activator of nuclear factor kappa B ligand (RANKL).* By binding RANKL, OPG inhibits nuclear kappa

B, which is an essential transcription factor for immune and inflammation related genes, cell survival and differentiation. OPG inhibits the differentiation of osteoclast precursors into mature osteoclasts and regulates the resorptive action. OPG-deficient mice exhibit media calcifications. In humans, circulating OPG levels associate with vascular calcifications and in CKD patients in particular with aortic and coronary calcifications [70, 71]. Low levels of soluble RANKL indicate a higher risk for cardiovascular events [72] and predict CV mortality in patients with CKD [73]. Prospective clinical trials with the OPG analogue, RANKL inhibitor denosumab suggest improved bone mineral density in early stages of CKD [74], the impact on vascular calcifications is yet uncertain.

Sclerostin is a glycoprotein secreted by osteocytes. It binds to a transmembrane complex (consisting of the frizzled receptor and the low-density lipoprotein receptor-related protein 5 or 6 coreceptor) and inhibits the Wingless-type mouse mammary tumor virus integration site (Wnt) pathway. The Wnt pathway stimulates stem cell and pre-osteoblast proliferation, induces osteoblastogenesis, inhibits osteoblast and osteocyte apoptosis and attenuates osteoclastogenesis. Sclerostin is produced by osteocytes and has an anti-anabolic effect on bone. Ageing, mechanical unloading of the skeleton, low PTH levels and progression of CKD have been associated with high circulating sclerostin levels. In HD patients, sclerostin levels correlate negatively with histomorphometric parameters of bone turnover, osteoblast number and function [75]. Sclerostin expression is increased during vascular smooth muscle cell calcification, where it potentially inhibits local arterial Wnt signalling and thus may represent a defense response against calcification. High circulating sclerostin levels have been associated with improved survival in hemodialysis patients [76].

Bone Histology in CKD-MBD

The term "renal osteodystrophy" is reserved for the spectrum of histological changes in CKD-associated bone disease, including changes in bone turn-over, mineralization and volume (TMV). The type of renal osteodystrophy in an individual patient depends on the therapeutic interventions taken to counteract an otherwise progressive disease (Fig. 60.5). Changes in bone turnover develop early in the course of CKD, prior to measurable changes in mineral homeostasis, possibly effected by osteocyte cytokines such as sclerostin [77]. In untreated children with CKD histological signs of fibrosis and demineralization prevail, whereas aggressive long-term treatment with calcium and vitamin D is associated with low bone turn over. At present, an adequate balance with normal or mild alterations in bone morphology is achieved only in a minority of the children [1]. A histological classification of renal osteodystrophy is given in Table 60.1, and respective histopathological illustrations are given in Fig. 60.6.

Children with some forms of rare inherited kidney diseases may have an element of bone disease independent of the degree of kidney failure and CKD-MBD, due to potential functions of the mutated genes in bone homeostasis. Exacerbated skeletal disease is prevalent in patients with cystinosis, primary hyperoxaluria and some primary ciliopathies [78–80]. Understanding the impact

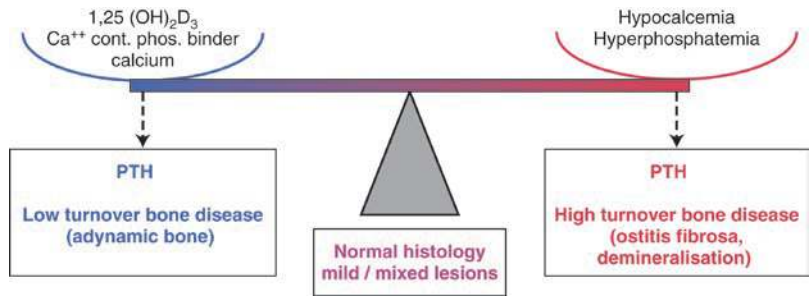

Fig. 60.5 The type of renal bone disease depends on therapeutic interventions

Table 60.1 Histological classification of renal osteodystrophy

Type	Etiology	Description	Comments
High turnover bone disease (Ostitis fibrosa)	Hyperparathyroidism	– Increased bone formation, resorption and osteoid deposition/seams – Disorganized collagen (woven bone), marrow fibrosis	– Frequent in untreated patients – Skeletal deformities, bone pain, epiphysiolysis
Low turnover: I Adynamic bone	– Relatively low PTH – Ca^{++} load, vit. D metabolites – Uremic toxins – Altered cytokines/ growth factors	– Low bone formation and resorption rate – Decreased osteoid deposition	– Most common type – Increased fracture risk (?) – Extraosseus calcifications (?)
II Osteomalacia	– Aluminium – Unknown factors	– Accumulation of osteoid – Inhibition of the mineralization process	– Incidence ↓ with adequate dialysate purification and withdrawal of aluminium cont. Phosphate binders
Mixed disease	– Hyperparathyroidism – Aluminium – Unknown factors	– Increased remodelling, resorption and osteoid, – Areas of low bone formation	

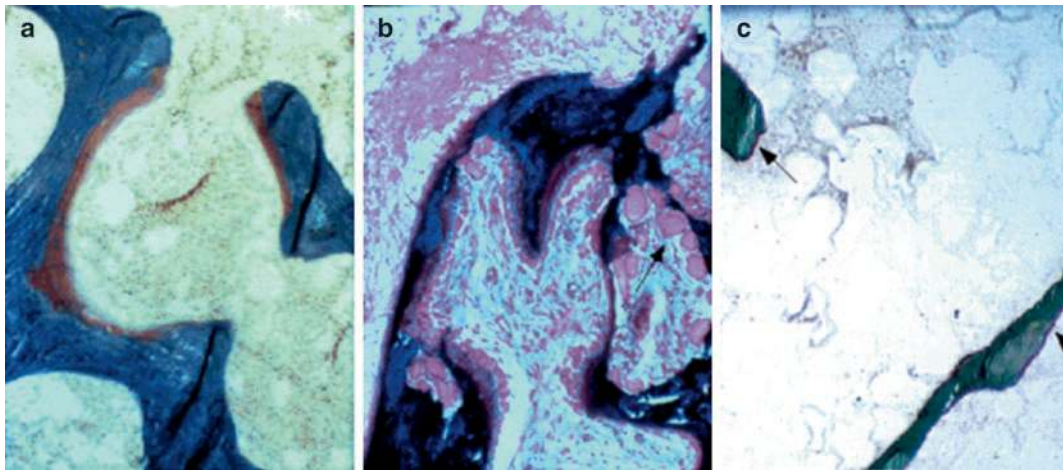

Fig. 60.6 Representative examples of different types of bone histology in patients with CKD (courtesy of LD Quarles, Department of Nephrology and Hypertension, University of Kansas Medical Center, Kansas City, Kansas, USA). (**a**) Histologic appearance of normal bone. Goldner Masson trichrome staining shows mineralized lamellar bone in blue and adjacent nonmineralized osteoid in red-brown. Osteoid comprises less than 25% of bone surfaces. The cellular area between the osseous structures is the marrow space. (**b**) Goldner Masson trichrome staining showing osteitis fibrosa due to secondary hyperparathyroidism with increased number of osteoclasts (arrow) and extensive bone marrow fibrosis (as shown by the light blue staining of the marrow). The increased resorption results in a thin and scalloped appearance of mineralized trabecular bone. Osteoid and bone formation are relatively increased, too. (**c**) Adynamic bone disease, characterized by reduction in bone formation and resorption. The osteoid seams are thin (red lines at the bone surface; arrows), and there is little evidence of cellular activity

of the different genetic defects on the growing skeleton will likely lead to targeted therapeutic strategies.

Bone Mineral Accrual and Peak Bone Mass

Bone mass is mainly genetically determined [81], but exogenous factors also play a major role. Bone mass markedly increases during childhood, reaching a peak at 25–30 years of age [82]. The growing skeleton of children is uniquely vulnerable to factors that can impair bone accrual including poor growth, delayed maturation, muscle deficits, decreased physical activity, abnormal mineral metabolism, and secondary hyperparathyroidism. Skeletal calcium increases from 25 g in newborns to 900 and 1200 g in adult females and males, respectively. Increased $1,25(OH)_2D$ levels coincide with an increased rate of skeletal calcium accumulation during puberty [83]. In healthy adolescents approximately 25% of total skeletal mass is laid down during the 2-year interval of peak height velocity. This gives rise to an increased calcium and phosphate requirement in children, especially during periods of rapid growth, and the enormous buffering capacity of the growing skeleton. Calcium balance studies have shown that in healthy children on a high calcium diet the amount of calcium incorporated into the skeleton increases up to a threshold dietary intake above which no further bone accumulation occurs [84]. Calcium requirements are highest in the first year of life (503 ± 91 mg/day) and during pubertal growth (396 ± 164 mg/day), dropping thereafter to normal adult requirements (114 ± 133 mg/day) [84].

The mineral requirements of the growing skeleton have two important consequences: the normal range for Ca and P varies substantially with age (Fig. 60.10), and secondly, the high Ca and P requirements of the bones can 'buffer' increased dietetic calcium and phosphate loads, preventing extra-skeletal mineralization and ectopic calcification. Normal serum calcium and phosphate levels fall steeply from birth until the age of 1–2 years and then gradually reduce up to the age of 7 years when they reach adult levels. Children with CKD are highly prone to develop mineralization defects. Almost one third of children with CKD stage 2 and more than of 90% of children on dialysis have deficient mineralisation [4], while this is the case in only 3% of adult dialysis patients [85]. Hence, calcium balance studies are urgently required in children with CKD to determine balance at different levels of calcium intake and at different stages of puberty, ideally correlating this data with bone histology.

Osteomalacia in animals with FGF23 deficiency suggests that FGF23 may play a direct role in skeletal mineralization; both overexpression [86] and ablation of FGF23 [87] in mice with normal renal function is associated with abnormal mineralization of osteoid, although by different mechanisms. The phosphaturic effect of increased FGF23 may cause rickets and osteomalacia through an insufficiency of mineral substrate.

Both, bone mass and bone geometry are altered in children with uremic bone disease, depending on the degree of hyperparathyroidism, disturbed vitamin D metabolism and therapeutic counteractions taken to control the disease. In CKD patients DXA (dual energy x-ray absorptiometry) scans are not a reliable measure of bone mineral density (BMD), but peripheral quantitative CT (pQCT) scans provide a useful measure [88]. In children with CKD low calcium and high PTH levels have been associated with a decrease in tibial BMD on pQCT [89]; this study also showed that a 1 SD decrease in BMD was associated with a twofold increase in fracture risk.

Linear Growth

Longitudinal growth is a unique feature of childhood. Growth occurs through the modelling of new bone by skeletal accretion and longitudinal growth in the growth plate. Bone

formation in children occurs by two distinct mechanisms: skeletal remodelling of existing mineralized tissue that is controlled by osteoclasts and osteoblasts and modelling of new bone by skeletal accretion and longitudinal growth from the growth plate, through the action of chondrocytes [4, 90]. The growth plate is an avascular tissue between the epiphyses and metaphyses of long bones. During endochondral bone formation it is progressively replaced by bone. Bone formation in the endochondral growth plate is regulated by growth hormone (GH) and the PTH/PTH-related protein-receptor axis that together promote chondrocyte proliferation, matrix synthesis and chondrocyte differentiation into osteogenic cells [91].

Clinical Manifestations

Symptoms of renal osteodystrophy can develop early, especially in children with CKD from infancy. Initial signs are often vague and nonspecific and may not come to the attention of the caregivers. Especially young infants require meticulous monitoring, since the high growth velocity, the high mineral demand and the enhanced pressure load to joints with increasing mobility can rapidly lead to severe deformations.

Bone Pain

Bone pain is a common manifestation in children with CKD. Initial symptoms may be difficult to distinguish from other causes of pain, but become more specific with progressive disease and localize to the weight bearing joints. Since symptoms vary considerably among individual patients, they do not allow for conclusions regarding the type and severity of the underlying bone disease. Limping, bone deformities and axial displacement require a prompt and thorough diagnostic process, including biochemical and radiographic studies. A recent study reported that significant bone pain hindered the daily activities of 58% of children with advanced (i.e. stages 4–5) CKD [88].

Myopathy

Patients with severe bone disease may also show muscular symptoms such as muscle weakness and wasting, exercise limitation, and waddling gait. The pathogenesis seems to be complex. One major reason is vitamin D deficiency, but inefficient clearance of uremic toxins, insulin resistance, carnitine deficiency, malnutrition and anemia may also contribute [92]. Muscle fat mass is increased in CKD children and negatively correlated with physical performance [93]. Some studies indicate an abnormal oxygen conductance from the muscular microcirculation to the normal functioning mitochondria [94]. Myopathy may further reduce bone strength 96).

Skeletal Deformities

Bone deformities include bowing of the weight bearing bones, with genua valga being most frequent. Genua vara, coxa vara, ulnar deviation and ankle deformations may also be seen, whereas avascular necrosis rarely occurs unless glucocorticoids are given. In infants, skeletal abnormalities often resemble vitamin D deficient rickets. Widening of the metaphyseal regions may develop in all long bones. The degree is dependent on the severity of metabolic bone disease and metaphyseal growth which varies with age. Particular attention has to be paid to deformities in small children when they start to bear weight. Physical examination should always include a detailed bone status and in case of suspicious findings be followed by radiological studies. According to the International Pediatric Peritoneal Dialysis Network clinical symptoms and/or radiological signs of bone disease are seen in about 15% of children on PD including 5% with limb deformities, with the latter possibly necessitating corrective orthopedic procedures [49].

Slipped Epiphyses

Pronounced secondary hyperparathyroidism, hypocalcemia and severe osteitis fibrosa cause disintegration of the growth plate and increase the risk of epiphysiolysis. Fibrotic alterations develop in the region connecting the epiphysis and the metaphysis. The growth cartilage columns are disorganized and partly substituted by fibrous tissue predisposing to local displacement with shear stress. Slipped epiphyses are more common in children with severe hyperparathyroidism, especially when insufficiently controlled for an extended period of time. The most frequently affected site is the proximal femur, followed by distal radius, ulna, distal femur, humerus, tibia and fibula, often depending on the mechanical stress put on the joints. Virtually any epiphysis may be involved (Figs. 60.7 and 60.8). Since epiphyseal slipping is a potentially severe and eventually incapacitating complication resulting in osteonecrosis, severe deformities, and degenerative joint disease, one should always be aware of the characteristic clinical symptoms. These include pain, limping, waddling gait, inability to walk and limited range of motion on examination. In infants the deformities may develop within few weeks. Diagnosis is established by radiography, treatment includes correction of factors involved in the metabolic bone disease, in particular control of secondary hyperparathyroidism, reduced weight bearing and conservative orthopedic measures. If these measures are not successful, surgical intervention for stabilization may be required. Surgery should only be performed after control of secondary hyperparathyroidism has been achieved, if necessary by cinacalcet therapy or even parathyroidectomy. Even though prospective studies are missing, a failure of orthopaedic corrective measures has been documented in patients with uncontrolled high turnover bone disease.

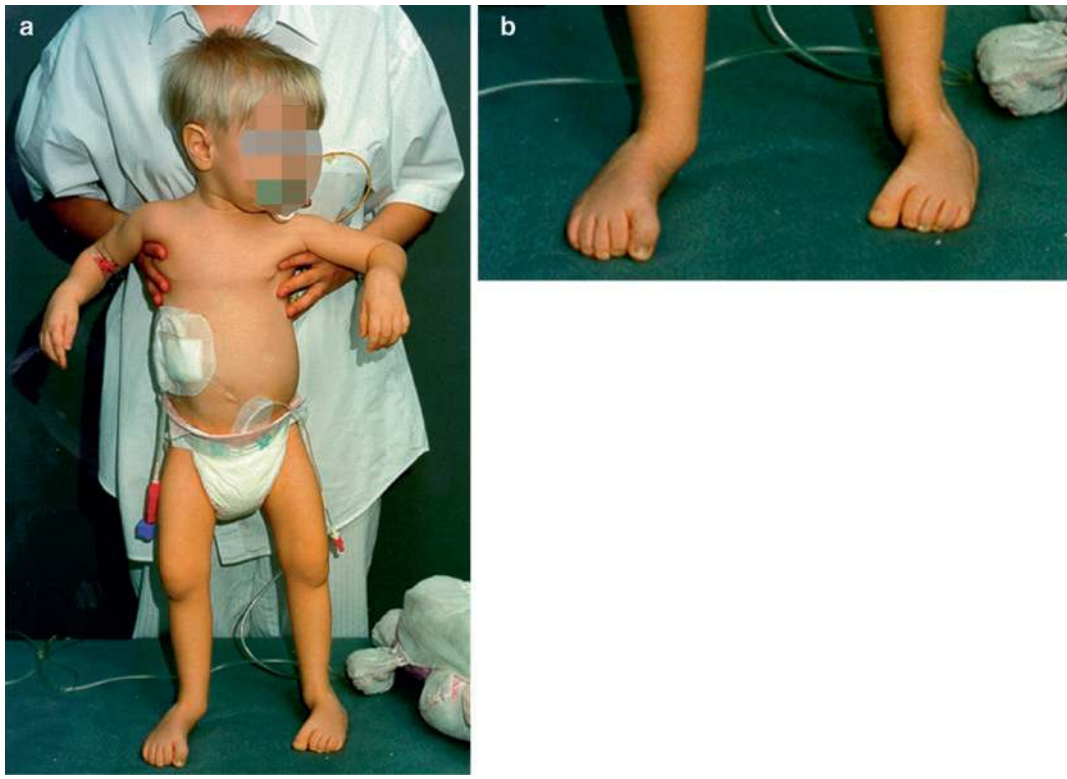

Fig. 60.7 3-year-old boy with ESRD at age 1 year due to prune belly syndrome. He rapidly developed severe renal osteodystrophy with epiphyseal slipping of multiple joints after non-adherence to calcitriol therapy

Fig. 60.8 X- rays of the left knee of the same boy as in Fig. 60.7. (**a**) Prior to therapy. (**b**) After 1 year of treatment with calcitriol and calcium i.v. and i.p. and parathyroidectomy with autotransplantation of parathyroid tissue. The severe deformities have substantially improved, surgical intervention was not required

Fractures

Healthy children have an incidence of 14 fractures per 1000 person years, mainly localized to the limbs [95]. In children with CKD fracture risk is increased [96]. Besides complete fractures, bone deformities, slipped epiphyses and microfractures are common. While microfractures may occur and be rapidly repaired at high bone turnover, subjects with low bone turnover may be at increased risk of macrofractures; however this concept has not been proven consistently [97]. In large prospective studies of children with CKD, including the North-American Chronic Kidney Disease in Childhood (CKiD) cohort, a 2.4- and three-fold higher rate of fractures have been reported in boys and girls, respectively, with predialysis CKD as compared to healthy children [98]. Fracture risk in pediatric CKD is associated with baseline-walking difficulty, Tanner stages 4–5 pubertal development, lower height Z-score, higher parathyroid hormone (PTH) levels, lower Ca and 25-hydroxyvitamin D (25D) levels and team sports participation [98]. Phosphate binder use, and particularly Ca-based phosphate binder use has been associated with decreased fracture risk in children with pre-dialysis CKD, suggesting that improved phosphate control and/or increased calcium intake may exert some protective action [98].

Studies using peripheral quantitative CT scans have demonstrated that children with CKD have significant deficits in cortical volumetric bone mineral density. A reduction in tibial cortical BMD z-score over 1 year follow-up was associated with low serum calcium and high PTH levels [89] as well as uremic myopathy [96]. Growth hormone appears to have a protective effect [96].

Bone biopsies in adults demonstrate that both low and high bone turnover are associated with distinct abnormalities contributing to the diminished mechanical competence of bone in CKD. Low turnover bone is characterized by lower cancellous bone volume and reduced trabecular thickness, high turnover bone by a reduced mineral to matrix ratio and lower stiff-

ness [85]. The fracture risk of adult dialysis patients correlates with plasma iPTH in a U-shaped manner, with the lowest risk observed at average PTH levels around 300 pg/ml [99]. After pediatric kidney transplantation the incidence of fractures is increased five-fold as compared to healthy children, i.e. to 76 fractures per 1000 patient years, two thirds of which affect the vertebrae [95].

Growth Retardation

Growth failure, a regular feature of children with CKD, is mainly due to endogenous growth hormone and IGF1 resistance, malnutrition (especially in infants) and metabolic acidosis. The effects of altered Vitamin D and PTH metabolism on growth are not entirely clear.

In children with CKD a short-term improvement of growth rate has been reported with 1,25-OH_2-D treatment [100]; this however was not confirmed in long-term observations. Excessive vitamin D treatment may even result in adynamic bone disease and growth retardation [91]. *In vitro*, calcitropic and somatotropic hormones interact with the proliferation of growth plate chondrocytes [101]. PTH-rP, which acts via the type I PTH receptor, is an important local inhibitor of growth plate chondrocyte maturation [102]. In rats, intermittent bolus injection of PTH increases growth rate whereas this is not seen with continuous PTH infusion, indicating that fluctuations in the level and not the PTH plasma concentration alone impact on bone [103].

From clinical observation it is not clear which PTH range is optimal for growth. In two studies a positive correlation between mean plasma PTH levels and growth was observed, suggesting that higher PTH levels promote growth [91, 104]. Others reported a normal growth rate in children with CKD stage II-IV with PTH levels in the normal range, as well as in CKD stage V with mean plasma PTH concentrations only 50% above the upper limit of normal. In these children particular attention was paid to adequate nutritional support and a strict control of serum phosphate levels within the normal range [105]. Whether normal bone turnover was maintained in these children is unclear since bone biopsies were not performed [104–106]. In 214 children followed prospectively in the International Pediatric PD Network (IPPN) Registry, the annual change in height SDS tended to be inversely correlated with mean plasma PTH levels. Patients with mean PTH > 500 ng/ml exhibited a significant loss in height SDS [43].

Cardiovascular Calcifications

Cardiovascular mortality is markedly increased in uremic patients. Vascular calcification is one of the main mechanisms underlying this most important long-term complication of renal replacement therapy. In a study published in 2000 36 of 39 young adults with childhood onset of CKD already had significant coronary artery calcifications [10]. Alterations of the morphological and functional properties of arteries have been reported as early as in the second decade of life in children on dialysis [9, 10, 107, 108]. The presence of vascular calcification on CT scan is directly related to hyperphosphatemia, the average calcium x phosphate product over time, intake of calcium containing phosphate binders and plasma PTH levels [9, 10]. In a post mortem analysis of 120 children with CKD, soft tissue and vascular calcification was associated with the use of active vitamin D and calcium containing phosphate binders [109]. Both low and high levels of 1,25(OH)2D have been associated with coronary artery calcification: very low 1,25(OH)2D levels were associated with high turnover bone disease as well as with greater inflammation whereas very high 1,25(OH)2D increase gut calcium absorption and suppress bone calcium and phosphate uptake with adynamic bone disease [110]. Although calcium balance studies have not been performed in children with CKD. Calcium supply should be higher with rapid growth, but it is suspected that the calcium load is often too high in children with advanced CKD treated with active vitamin D, calcium containing phosphate binders and dialysis solutions containing unphysiologically high calcium lev-

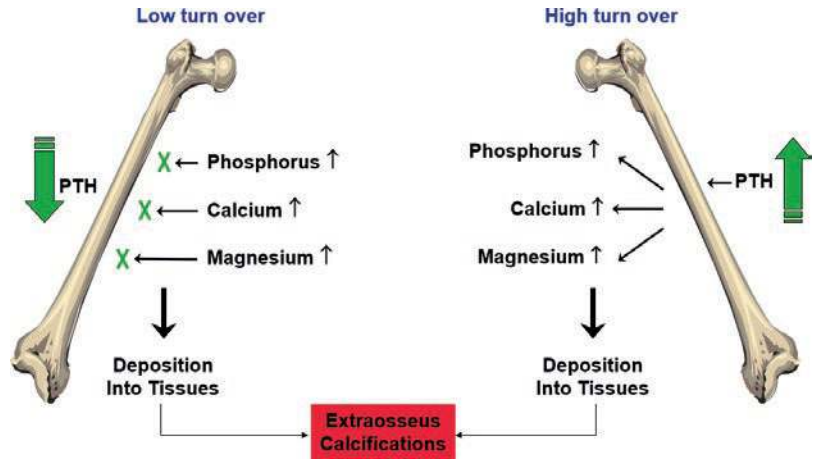

Fig. 60.9 Bone disease and soft tissue calcification. Low PTH levels (low turnover bone disease) prevent mineral deposition into bone, high PTH levels result in mineral release from bone. Excessive minerals precipitate in soft tissues

els. On the other hand, the calcium buffering capacity of bone is reduced in patients with low- and high-turn-over bone disease (Fig. 60.9). Noteworthy, calcifications are not merely a passive process of precipitation but triggered by oxidative stress, advanced glycation endproducts and regulated by locally and systemically acting proteins [71]. The plasma protein fetuin is significantly reduced in CKD patients and correlates with cardiovascular mortality [111] and vascular calcification even in children on dialysis [112].

Calcifications may also occur in other sites than the vascular wall, such as the lung or and in periarticular areas. Calciphylaxis, a severe form of extra-skeletal calcifications, has been described in children with tertiary hyperparathyroidism [113]. It is characterized by painful nodules that become mottled or violaceous, indurated and ultimately ulcerated. Accurate diagnosis and optimal treatment of disturbance in bone and mineral metabolism may be crucial in preventing these life-limiting sequelae in children with CKD. Vascular calcification is discussed in detail in chap. 58.

Post-transplant Bone Disease

Successful renal transplantation should reverse all pathologic conditions that lead to CKD-associated mineral and bone disease. In both adult and pediatric kidney recipients, bone histologic changes associated with secondary hyperparathyroidism resolve within 6 months after kidney transplantation; bone mineral content Z-scores, however, remain significantly reduced, especially in cortical bone [114]. Interestingly, a disconnect is observed between circulating PTH levels and bone turnover post transplantation; some patients have persistently elevated rates of bone turnover while others develop adynamic lesions, despite moderately elevated serum PTH levels [115].

Immunosuppressive treatment, in particular glucocorticoids, and any degree of CKD developing in the post-transplant course interferes with bone metabolism. Persistent hypophosphatemia is a common finding in renal allograft recipients, especially within the first months post-surgery. Tubular dysfunction secondary to any toxicity, persistent HPT and increased plasma FGF23 levels are considered the main causes of exaggerated renal phosphate secretion after transplantation. Of note, plasma phosphate levels can be normal despite reduced total body phosphate content. In these patients increased skeletal phosphate removal due to increased PTH and inappropriately low calcitriol levels may counterbalance the phosphatonin (FGF23)-induced persistent renal phosphate loss [116]. Likewise, magnesium, an integral part of the hydroxyapatite structure of the bone and essential for osteoblast and osteoclast function, is wasted secondary to calcineurin inhibitor use.

According to bone biopsy studies in adults, loss of bone volume and mineralization leading

to low turn-over bone disease is frequent in adults after successful transplantation [117, 118]. The risk of fracture is particularly high the first several months following transplantation. Skeletal lesions may improve subsequently, depending on renal function and pharmacological treatment, but do not resolve completely in the majority of patients [115]. Assessment of BMD by means of DXA shows conflicting results, possibly due to the inadequate standardization and the failure to correct for height and muscular mass. PQCT results demonstrate nearly normal BMD for height and muscle mass, while cortical thickness is reduced [119]. The fracture risk is increased (see above). Avascular necrosis is reported to develop in 4% of children after organ transplantation, most often in the femoral head, but it may also develop in the talus, the humeral neck and other skeletal sites [120]. Avascular necrosis has become less common in recent years, due to steroid sparing with newer immunosuppressive protocols.

Assessment of Renal Bone Disease

Apart from thorough physical examination, the diagnosis of the uremic bone mineral metabolic disorder is mainly based on repeated biochemical analyses (Table 60.2). Even though no single biochemical marker is able to provide a complete assessment of renal osteodystrophy, bone biopsies are rarely performed for the clinical management of patients. In a study of 161 children undergoing chronic PD, high PTH and low serum calcium levels were seen in those with defective mineralization, irrespective of their bone turnover rate [122]. As recommended by KDIGO guidelines, a thorough assessment of CKD-MBD parameters requires serial assessment of phosphate, calcium and PTH levels, considered together, with trends in levels being most useful in guiding clinical decision making [123]. The 2010 Cochrane review on 'Interventions for Bone Disease in Children with CKD' [124] and the 2013 NICE guideline on hyperphosphataemia management in adults and children with CKD and on dialysis [125, 126] emphasize the lack of pediatric information and the need for more research in children with CKD.

Biochemistry

Serum Calcium

Measurement of total calcium is the mostly used method to assess serum calcium levels. Normal serum concentrations depend on age (Fig. 60.10). Of note, normal total serum calcium may not indicate normal serum ionized calcium levels, and should be corrected for serum albumin concentration if this is low. pH corrected ionized calcium levels are the best reflection of free (biologically available) calcium. Importantly, serum calcium levels are not a reflection of the total body calcium stores, since calcium levels are tightly regulated by multiple negative feedback systems as described above.

Serum calcium is usually normal or low in untreated patients with advanced CKD, with the maintenance of calcium homeostasis being exerted mainly by a compensatory increase in PTH. Once treatment with active vitamin D and calcium containing phosphate binders is initiated, serum calcium levels increase and PTH

Table 60.2 Suggested monthly intervals for the frequency of measurements for biochemical markers of renal osteodystrophy [121]. More frequent measurements may be required in young children, in patients treated with severe renal osteodystrophy, non-compliant patients, and after renal transplantation

CKD stage	GFR (ml/min*1.73 m^2)	Calcium/Ca^{++}, phosphate, AP, PTH	Total ALP	PTH	Serum $25(OH)_2D_3$	Bicarbonate
2	60–89	6	12	12	12	6
3	30–59	6	6	6	6–12	6
4	15–29	3	3	3	3–12	3
5	<15, dialysis	1	1–3	1–3	3–12	1

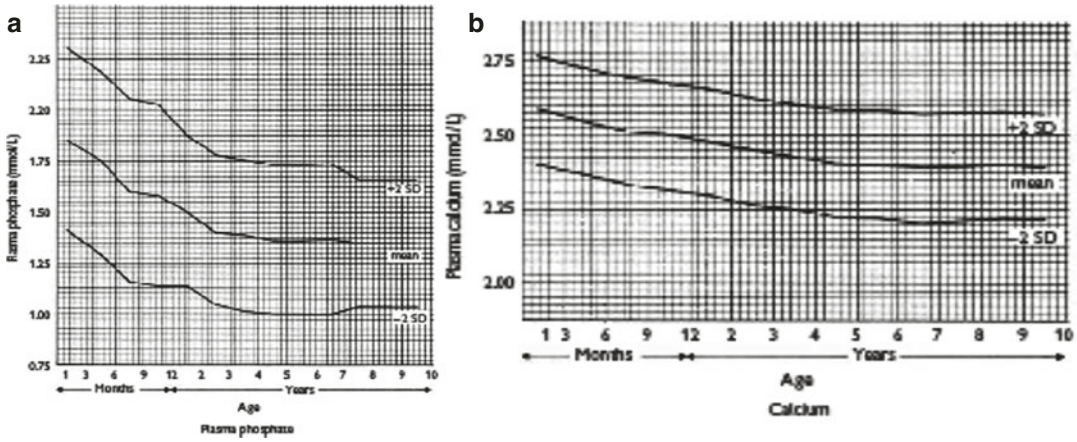

Fig. 60.10 Age-dependent calcium and phosphate percentiles in the plasma of healthy children. (**a**) Calcium, (**b**) Phosphate. *SD* standard deviation. Permission obtained from Blackwell Scientific © Claytob B.E. et al. Pediatric chemical pathology; clinical tests and reference ranges (1980)

declines. Hypercalcemia is still rare in calcitriol treated children with stage IV CKD [104], but seen in about 6% of measurements in children on peritoneal dialysis treated with calcitriol, calcium containing phosphate binders and PD solutions with calcium concentrations of 1.75 mmol/L [127]. Children with low turn-over bone disease and children with tertiary hyperparathyroidism treated with calcitriol are particularly prone to hypercalcemia, because the calcium buffering capacity of bone is reduced. An important differential diagnosis of hypercalcemia in children on dialysis is volume depletion. This condition is usually characterized by a high total but normal ionized calcium concentration. Alternative causes of hypercalcemia to consider include immobilization and, rarely, paraneoplastic release of PTHrP and extrarenal calcitriol production in granulomatous diseases such as tuberculosis and sarcoidosis.

Serum Phosphate

Dietary phosphate intake usually exceeds renal phosphate removal if GFR drops below 40 ml/min/1.73 m^2 but may be noted earlier if phosphate intake is high. The serum concentration of phosphate should be kept in the normal range. Of note, the renal phosphate threshold and serum phosphate concentrations are age-dependent with an upper limit of normal of 2.4 mmol/L in small infants, 2.1 and 1.9 in preschool and school children, and 1.44–1.9 mmol/L in adolescents according to different reference tables [128]; (Fig. 60.10). The physiological range depends on whether a child is growing or postpubertal. In non-fasting adolescents serum phosphate is subject to significant circadian variations following an M-shaped curve with peaks at 4 PM and 3:30 AM and a maximal diurnal amplitude of 1 mmol/L [129]. These fluctuations are not related to food intake and largely disappear with advancing CKD [130].

Parathyroid Hormone

Plasma PTH levels are a key element in the diagnosis and therapeutic monitoring of renal osteodystrophy and should be measured together with calcium, phosphate, alkaline phosphatase and blood bicarbonate at least every 6 months when GFR drops below 60, every 3 months at a GFR below 30 ml/min/1.73 m^2 and every month when end stage renal disease is reached (Table 60.2).

However, the interpretation of PTH measurements is compromised by significant variation between PTH assays and the variable presence of biologically inactive PTH fragments and oxidized

PTH as discussed above. The target range for PTH which allows for normal bone turnover and growth and which is not associated with increased vascular calcifications is not clear. In children with CKD stage 5, values of iPTH below 200 pg/ml have been suggested to indicate adynamic bone disease whereas values above 500 pg/ml are associated with osteitis fibrosa; however, considerable overlap exists [6]. A study of the IPPN registry found a markedly increasing risk of symptomatic bone disease with PTH exceeding 300 pg/ml and impaired longitudinal growth at mean PTH concentrations above 500 pg/ml, whereas the risk of hypercalcemia increased at levels below 100 pg/ml [49]. These findings support a PTH target range of 100–300 pg/ml in the pediatric age group (Table 60.3). In another study, children with PTH levels below twice the upper limit of normal had less vascular calcification compared to those with PTH levels above twice the upper limit of normal [9].

Alkaline Phosphatase

Measurements of serum total alkaline phosphatases, a marker of osteoblast activity, can be helpful in predicting bone turnover in conjunction with PTH [131]. Values are strongly age dependent with higher activity present during periods of rapid growth. Bone specific alkaline phosphatase may further increase predictability of bone turnover and may be advantageous in subgroups of patients, e.g. with hepatic diseases, to exclude measurement of non-skeletal enzyme. The potential benefits have to be weighed against the considerably higher costs.

Table 60.3 Target iPTH range in children with CKD 2–5 (adapted from 133;135). Recommendations for CKD stage 2–4 are opinion based; stage 5 recommendations are evidence based but still debated. Whole-PTH assays provide values which are only 50–60% values obtained with iPTH assays; this however may vary considerably

CKD stage	GFR (ml/min*1.73 m^2)	Target iPTH range (pg/ml)
2	60–89	35–70
3	30–59	35–70
4	15–29	70–110
5	<15, dialysis	100–300

25(OH)D and 1,25(OH)$_2$D

Serum levels of 25(OH)D give an estimate of vitamin D body stores; it's serum half-life is 3 weeks. There is debate about what levels of vitamin D can be considered adequate, but most authorities agree that a level of 20–30 ng/ml is sufficient to maintain normal serum calcium levels and prevent hyperparathyroidism. Recently published ESPN guidelines suggest that serum 25D levels be maintained above 75 nmol/L (30 ng/ml), and below 120 nmol/L (48 ng/ml) [29]. These levels maintain optimal gut Ca absorption and prevent seasonal fluctuations that can predispose even healthy children to nutritional rickets [28]. Serum levels <5 ng/ml have been categorized as severe deficiency, 5–15 ng/ml as mild deficiency and serum levels of 16–30 ng/ml as vitamin D insufficiency. Since 25(OH)D may have numerous physiological functions, vitamin D deficiency must be avoided at all stages of CKD. 25(OH)D serum levels should be measured 6–12 monthly depending on CKD stage in children not on vitamin D treatment. In case vitamin D supplementation is required, levels should be measured again after 3 months [29] (Table 60.2). Oral 1,25(OH)2D is rapidly absorbed and peak plasma levels are reached within 3 h in children with CKD [89]. Due to the short plasma half-life of 1,25(OH)$_2$D (4–6 h), the clinical usefulness of 1,25(OH)$_2$D measurements in plasma is limited. However, plasma 1,25(OH)$_2$D levels have been correlated with the presence of vascular calcification in children on dialysis [110].

Additional Serum Markers of Bone Turn Over

Biomarkers of bone formation, e.g. osteocalcin and procollagen type I carboxyl terminal peptides, and of bone resorption, e.g. type I collagen cross linked telopeptide and pyridinoline, have not been studied widely to date in children with CKD. Most of them are eliminated via the kidney and accumulate with reduced renal function. TRAP-5b and osteoprotegerin may prove as useful indicators of bone metabolism, based on the

central role of RANK ligand/osteoprotegerin in bone metabolism [71]. FGF23 has been correlated with indices of bone mineralization in children [4] and sclerostin, an inhibitor of bone formation, with bone turn-over rates [75]. Further studies correlating the circulating levels of these potential biomarkers to bone histology, growth and established biochemical markers will be required to determine their added value in the monitoring of uremic bone disease.

Aluminum

Aluminum containing phosphate binders are not recommended in children and dialysis water purification has generally improved. Therefore, aluminum related bone disease and encephalopathy should not develop anymore, and plasma aluminum levels do not need to be determined on a regular base. Exposure to aluminum, however, may still occur in some countries.

Imaging

Radiography of the Skeleton

Conventional radiographs of the skeleton are relatively insensitive in detecting renal bone disease, and only grossly evaluate bone structure and mineralization. They should be performed in patients if results are expected to impact on treatment, in case of bone pain and suspicion of fracture and in children with genetic diseases with specific bone involvement [121]. Hand and wrist X-rays can demonstrate severe hyperparathyroidism induced hyperosteoclasia and osteitis fibrosa as subperiostal resorption zones (Fig. 60.11), subperiostal erosions of the phalanges, and acroosteolyses at the end phalanges and at sites of ligament endings. In the skull, hyperparathyroidism results in ground-glass- or granular appearance, focal radiolucencies and sclerotic areas. In children with CKD widened radiolucent areas of the growth zones also indicate accumulation of fibrous tissue, in contrast to nutritional rickets where the radiolucent areas are mainly due to accumulation of unmineralized growth cartilage. Brown tumours also present accumulation of hyperosteoclastic tissue. They can typically be seen at the metaphyses of long bones but also at other skeletal sites such as the jaw. In contrast to hyperosteoclastic patients, there are no specific signs of osteomalacia. Even Looser zones, straight wide radiolucent bands within the cortex, can represent osteomalacia lesions but also fibrous tissue.

Fig. 60.11 Left hand X-ray in 18-year-old boy with signs of severe renal bone disease: subperiostal erosions, especially of the middle phalanges, brown tumor in the second digit, "ricket-like" lesions and vascular calcifications at the forearm (Courtesy of J. Troeger, University Hospital for Pediatric and Adolescent Medicine, Heidelberg, Germany)

Measurements of Bone Mineral Density

Measurements of bone mineral density are not routinely used in the monitoring of CKD-associated bone disease. Prospective interven-

tional studies are lacking and problems in interpreting results are common. Dual-energy X-ray absorptiometry (DXA) is the most widely used method for measuring bone mineral content and bone mineral density (BMD). BMD (g/cm^2) is often falsely taken as a surrogate parameter of bone strength and fracture risk. BMD increases physiologically in childhood with age and, more closely, with measures of body size such as height and weight. As a consequence, measurements should not be normalized to age but to body height, bone size or muscle function [132]. The interpretation of DEXA measurements is further complicated by the lacking distinction between cortical and cancellous bone. The ISCD 2007, the KDIGO 2017 guideline update and the European Pediatric Clinical Practice Points [121] recommend against routine DXA BMD testing in CKD3–5 since BMD does not predict the type of renal osteodystrophy. This is because PTH excess has generally catabolic effects on cortical bone with decrease in cortical volumetric BMD and cortical thickness whereas it exerts anabolic effects on trabecular bone. A recent study showed that combination of routine biomarkers were better predictors of cortical BMD evaluated by pQCT, and BMD measurement by DXA did not correlate with biochemical data or pQCT measures [88]. Thus, these imaging techniques are not recommended for routine screening tools of bone health or fracture risk prediction in pediatric CKD patients [121].

Peripheral Quantitative Computer Tomography (pQCT)

Peripheral Quantitative Computer Tomography (pQCT) is an alternative technology which permits resolution of cancellous and cortical bone. pQCT of the tibia provides a detailed picture of bone health, including volumetric bone density, separate evaluation of cortical and trabecular components, and measurement of bone dimensions, parameters of bone strength and muscle mass. The reported measurement error in children and adolescents is <2%. pQCT has been widely used in children with CKD and is a good predictor of future fracture risk [89]. In children with CKD, pQCT revealed reduced cortical area and a decline in cortical BMD with time, in association with high PTH plasma levels [96]. pQCT also unmasks differences in total bone density between patients with high turnover and adynamic bone disease [118]. Despite these promising findings, routine application of pQCT has not yet been recommended due to a lack of prospective information regarding an impact of pQCT monitoring on treatment outcomes.

Bone Biopsy

Micromorphometric analysis of the bone is the gold standard for characterization and quantification of renal bone disease. The biopsy procedure is safe and well tolerated by most children. It provides information on the current histologic status and, if double tetracycline staining is performed, the dynamics of bone formation and mineralization can be assessed. Bone biopsies are not needed for routine diagnosis and treatment of renal osteodystrophy, but may be considered if the clinical and biochemical findings do not explain underlying bone disease, e.g. severe bone deformity or pain, low-energy fracture, persistent hypercalcemia or hypophosphatemia, despite optimized treatment [121]. Since few bone biopsies have been performed in children with CKD in the last 20 years, cooperation with the few remaining centres with respective experience regarding the technical procedure and histomorphometric analyses is recommended. Bone biopsies may have a role in clinical trials in which the effect of therapeutic interventions require histological verification.

Imaging of the Parathyroid Glands

In children with severe secondary hyperparathyroidism, sonography of the parathyroid glands should be performed. Parathyroid glands usually cannot be detected by ultrasound unless they are enlarged. The indication of advanced imaging procedures in patients with refractory hyperpara-

thyroidism is controversial. MIBI scan and MRI may give additional information in cases where parathyroidectomy is considered, e.g. an ectopic gland, especially prior to re-exploration of unsuccessful parathyroidectomy. Preoperative imaging by ultrasound, and even by MIBI scan or MRI, may fail to detect adenomas. Therefore, a negative result should not prevent thorough surgical exploration if clinically indicated.

Imaging of Vascular Alterations

The intima media thickness (IMT) of the common carotid artery as assessed by high resolution sonography is a sensitive marker of early vascular lesions, and in adults with CKD it is a strong predictor of future cardiovascular events and death [133]. In children with CKD, carotid IMT has been correlated with the time averaged serum Ca x P product, the cumulative dose of calcium-based phosphate binders, and the mean calcitriol dose [9, 107, 108]. In experienced hands, sequential sonographic IMT assessments can be a valuable diagnostic tool of vasculopathy secondary to altered bone and mineral metabolism.

In cases of severely disturbed bone and mineral metabolism, plain x-rays may be performed to screen for vascular and soft tissue calcifications (Fig. 60.11).

Coronary artery calcifications can be assessed quantitatively by electron-beam or ECG-gated computer tomography, and vessel stiffness by applanation tonometry, ultrasound based or newer oscillometric techniques. These are discussed in detail in Chap. 58.

Treatment

CKD-MBD management in children needs to focus on three key areas. First, to maintain normal calcium - phosphate homeostasis so as to obtain acceptable bone quality and cardiovascular status, second to provide optimal growth in order to maximize the final height and third, to correct all metabolic and clinical abnormalities that can worsen bone disease, growth and cardiovascular disease, i.e. metabolic acidosis, anaemia, malnutrition and 25(OH)vitamin D deficiency.

Many of the factors contributing to the development of secondary hyperparathyroidism and renal osteodystrophy are present early in the course of renal disease (Fig. 60.1). Since patients are usually asymptomatic, insufficient attention is often paid to progressive alterations in bone and mineral homeostasis. With advancing renal failure, parathyroid glands become hyperplastic and less sensitive to therapeutic interventions. Therefore, **prevention** should always be the primary objective in children with CKD in order to delay the development and its osseous and cardiovascular sequelae. An overview of key preventative strategies is given in Table 60.6. A scheme summarizing the treatment in patients with established hyperparathyroidism is given in Fig. 60.12.

Optimal control of serum **phosphate** levels is probably the crucial element of preventive management. Hyperphosphatemia is an independent risk factor for secondary hyperparathyroidism, renal osteodystrophy and vascular calcifications. As early as in CKD stage II, regular dietary counseling should be performed and drug therapy may already be considered. On the other hand, hypophosphatemia, as commonly seen in children with associated tubulopathies even in CKD stage II–IV or after renal transplantation, may induce hypophosphatemic osteomalacia and should also be avoided.

Serum **calcium** must be maintained in the normal range, taking care of maintaining a normal serum calcium phosphorus ion product. The upper limit for the serum calcium × phosphorus ion product recommended for adults (55 mg^2/dl^2) is applicable in adolescents, whereas the upper normal limit is higher in children below 12 years of age (65 mg^2/dl^2) and even higher in infants. The calcium × phosphate product is rarely used in clinical practice now since it is not a 'biological' value and does not represent the true physic-chemical coupling in hydroxyapatite crystals (chemical formula $Ca_{10}(PO_4)_6(OH)_2$). Clinicians are advised to follow serum calcium and serum phosphate levels, particularly trends in both of these, rather than the calcium × phosphate product.

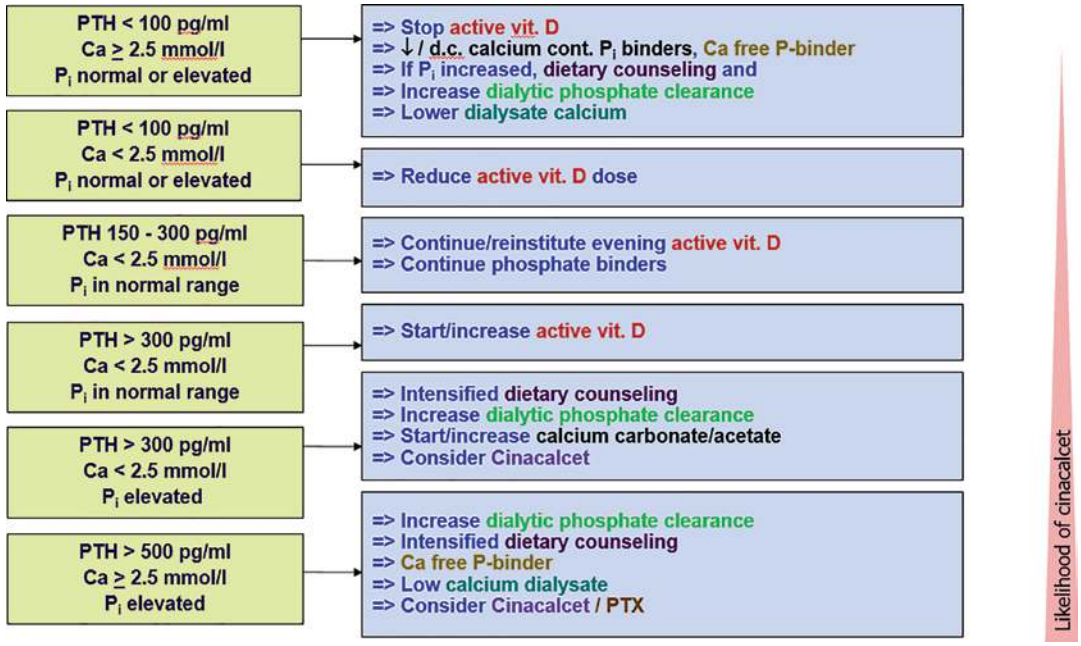

Fig. 60.12 Therapeutic algorithm for treatment of hyperparathyroidism in children with CKD

In CKD stage 5, serum calcium levels in the upper normal range should be avoided [128, 134] and hypercalcemia must be prevented. In case of hypercalcemia, all calcium containing phosphate binders must be withheld, vitamin D therapy be stopped and, if hypercalcemia persists, PD fluid with 1.25 mMol/L calcium be administered. Even lower dialysate calcium concentrations may be used in HD patients. On the other hand, pediatricians must keep in mind that growing infants and children need a positive calcium balance. In growing children hyperparathyroidism may often be triggered insufficient calcium supply. The routine use of dialysate calcium concentrations of 1.25 mmol/L may be inadequate in patients with major UF associated calcium losses. Thus 1.5 and 1.75 mMol/L dialysate calcium concentrations are often needed, depending on the oral calcium load and active vitamin D treatment.

The sensitivity of the skeleton to **PTH** effects decreases with declining renal function. Therefore, an increasing PTH target level has been suggested. These target levels are given in Table 60.3. For CKD stage II–IV target PTH recommendations only reflect expert opinion. For patients with CKD stage V there is some biopsy-derived evidence for the indicated target ranges, which, however, is challenged by recent studies [105, 135]. If plasma PTH levels are below the target range and serum calcium levels are increased vitamin D therapy and calcium containing phosphate binders should be reduced or even discontinued, a reduction in dialysate calcium concentration may be justified. Of note, growth hormone should not be given to patients with uncontrolled hyperparathyroidism, symptomatic high turn-over bone disease or slipped epiphysis.

Diet

Regular dietary counseling is an essential part of CKD-MBD management. Optimal control of serum P concentration is a crucial element of preventative management, starting early in the course of CKD. K/DOQI and the Pediatric Renal Nutrition Taskforce [136] have published guidelines on the dietary management of Ca and P in children with CKD2–5D. They recommend regular dietary counseling from early CKD and limit-

ing dietary P intake to within the age-appropriate normal ranges for children in the mild-moderate stages of CKD and to the lower limit of the normal range in patients with advanced CKD who have persistent hyperphosphatemia or hyperparathyroidism [128, 136, 137]. For detailed dietary recommendations regarding dietary calcium and phosphorus intake, please refer to Chap. 55.

Importantly, processed foods are likely to contain inorganic P additives (such as phosphoric acid and sodium phosphate), which are almost completely absorbed, unlike organic phosphates that have a lower bioavailability. Aggressive dietary P restriction is difficult since it may compromise adequate intake of other nutrients, especially protein and Ca [15]. P intake is directly linked to protein intake, with 10–12 mg of P accompanying each gram of protein; any reduction in P intake should not compromise protein intake. In a recent study 67% of children with CKD stages 4–5 had a dietary Ca intake below the recommended nutrient intake, and additional Ca from medications, mainly in the form of P binders, was required to maintain nutritional Ca requirements [15].

Dialysis

The efficacy of dialysis in removing excess phosphate is modifiable to some extent but overall limited [138]. E.g., an anuric child of 20 kg body weight and a daily protein intake of 1.4 g/kg ingests 430 mg phosphate per day. Concomitant intake of calcitriol and phosphate binders will result in absorption of roughly 50% of phosphate (215 mg/d). This amount of phosphate is the maximum that can be eliminated by conventional dialysis. At a protein intake of 2 g/kg*d, the phosphate balance will be positive by more than 60 mg per day on a conventional PD or hemodialysis schedule. A weekly creatinine clearance of more than 80 L/1.73m^2 would be required to compensate the dietary phosphate load. This efficacy can only be achieved by frequent [139] or long nocturnal hemodialysis [140]. Slow-flow nocturnal hemodialysis performed over 6–9 h per night five to six times per week dramatically improves phosphate clearance and may even require phosphate supplementation p.o. or in the dialysis bath to prevent phosphate depletion and aggravation of bone disease [141, 142]. If such intensified hemodialysis is not available or not feasible, repeated dietary counseling and optimized oral phosphate binder management are essential (see below). In children receiving automated peritoneal dialysis, total PD fluid turnover should be maximized using maximally tolerable fill volumes, maximally acceptable cycler times and additional day time exchanges [138]. In a prospective multi-centre study serum phosphate levels were similar between HD and HDF patients but PTH levels declined in the HDF cohort over 12 months while remaining static in those on HD [143]. A further study has shown that FGF23, a middle molecular weight substance, if cleared more efficiently on HDF, with 30% lower levels than conventional HD [144].

Phosphate Binders

Restriction of dietary phosphorus intake may be sufficient in early stages of CKD. However, even with some dietary restriction of phosphate intake, normophosphatemia may only be maintained at the expense of increased PTH and FGF 23 plasma levels, both of which decrease tubular phosphate reabsorption. As renal function deteriorates, dietary control of phosphate becomes more difficult and overt hyperphosphatemia usually develops. Oral phosphate binding agents should be added. Calcium salts are used as first line phosphate binders. They have limited phosphate binding capacity (Table 60.4). The dose required depends on the oral phosphorus intake, and often reaches several grams per day. While in hypocalcemic and rapidly growing children the additional calcium load still is beneficial, many patients tend to develop hypercalcemia with prolonged administration. Significantly more calcium is absorbed and little phosphorus retained when calcium containing phosphate binders are not given with meals. Calcium acetate contains 25% of elemental calcium, calcium carbonate 40%. Calcium acetate binds more phosphorus per unit of calcium content and thus allows for higher doses and improved phosphate

Table 60.4 Phosphate binding agents

Compound	Calcium content (%)	Calcium absorbed (%)	Phosphate bound per g compound	Phosphate bound per Ca^{++} absorbed	Comment
Calcium Carbonate	40	20–30	39 mg / g	≈ 1 mg/8 mg	High Ca^{++} load, inexpensive, GI side effects
Calcium Acetate	25	22 (between meals 40)	45 mg / g	≈ 1 mg/3 mg	GI side effects, less Ca^{++} load than $CaCO_3$, inexpensive
Mg + Ca carbonate	Variable	20–30% of Ca	NA	≈ 1 mg/2.3 mg	Less Ca^{++} load, GI side effects, long term effects?
Sevelamer HCl/– Carbonate	0	0	Similar to calcium acetate[a]	NA	Ca^{++} and Al^{+++} free, cholesterol ↓, costs ↑, acidosis ↑ (in case of HCl)
Aluminum cont. Binders	0	0	Similar to calcium acetate	NA	Effective but toxic, not recommended

NA not applicable or no data
[a]See Ref. [145]

Table 60.5 Suggested treatment for vitamin D supplementation in children with CKD and on dialysis. With permission from [29]

Age	25(OH) D serum (nmol/L)[a]	Vitamin D supplementation dose (daily)	Monitoring
Intensive replacement phase			
<1 year		600 IU/day[b]	– Serum calcium and urinary calcium levels 1–3 monthly based on CKD stage
>1 year[b]	<12	8000 IU/day	– 25(OH)D levels: after 3 months
	12–50	4000 IU/day	
	50–75	2000 IU/day	
Maintenance phase			
<1 year	>75[d]	400 IU/day	– 25(OH)D levels: after 6–12 monthly
>1 year[c]		1000–2000 IU/day based on CKD stage	

[a]To convert nmol/L to ng/ml divide by 2.5
[b]In infants <1 year, a fixed dose is recommended irrespective of the level of 25(OH)D
[c]Consider adjusting dose by body size (weight or body surface area)
[d]If levels remain <75 nmol/L, then give doses as per the 'intensive replacement' schedule for a further course of intensive replacement and recheck levels

control. If given at similar doses, calcium acetate results in a reduced incidence of hypercalcemia as compared to calcium carbonate (Table 60.4). On the other hand, less gastrointestinal side effects have been reported with calcium carbonate. An individual choice is required to assure optimal patient compliance and control of calcium and phosphate uptake.

Calcium citrate is also effective, but citrate increases aluminum resorption and should therefore be avoided (Table 60.5).

Magnesium Salts

Magnesium salts have a relatively weak intestinal phosphate binding activity and require higher dosing, but avoid calcium exposure. An inverse relationship between serum Mg, hyperparathyroidism and vascular calcification has been demonstrated in adult dialysis patients and thus potential benefits have been attributed to magnesium salts [146]. Interestingly, in addition to the beneficial effects of intestinal phosphate binding of magnesium, experimental studies suggest inhibition of vascular smooth muscle cell transition into an osteoblast like phenotype, and inhibition of nanocrystal formation from calcium and phosphate ions, a key mechanism in the formation of ectopic calcification in CKD [147]. Diarrhea, hyperkalemia and hypermagnesemia are their main side effects. The long-term effects of an increased magnesium load are not clear. At present, magnesium containing phosphate binders may be given as adjuncts to calcium containing binders.

Table 60.6 Measures for prevention of MBD in children with CKD

• Active screening for hyperparathyroidism—measurement of PTH begins when the GFR falls to <90 ml/min/1.73 m^2
• Control of hyperphosphataemia
– Diet
– Phosphate binders:
first line—calcium-based phosphate binders
second line or if hypercalcaemia—calcium-free phosphate binders
(in addition to calcium-based binders or as a substitute)
• Control of hypocalcaemia using lowest possible dose of vitamin D
– native vitamin D in CKD 1–3
– active vitamin D analogues in CKD 4–5 and 5D
• Improve dialysis efficiency for phosphate removal
• Pre-emptive renal transplantation where possible
• Avoid vitamin K antagonists like warfarin to prevent inactivation of calcification antagonist MGP
• Cinacalcet, especially in case of high doses of active vitamin D and high serum calcium concentrations
• Parathyroidectomy—in case of hyperparathyroidism refractory to all therapeutic measures including cinacalcet

Calcium Free Phosphate Binders

Growing evidence for a role of the oral calcium load in the progression of cardiovascular calcifications urged the development of calcium free phosphate binders. They are especially indicated in patients with a calcium intake exceeding twice the recommended daily intake (which increases from 210 mg elemental calcium per day in the first 6 months of life to 1250 mg/d in adolescents), reduced PTH levels (with likely adynamic bone disease), hypercalcemia or even emerging soft tissue calcifications.

Sevelamer hydrochloride is a hydrogel of polyallylamine, which is resistant to digestive degradation and therefore not absorbed. It binds dietary phosphate and releases hydrochloric acid. This may reduce plasma bicarbonate levels [145], a problem which can be circumvented by the use of sevelamer carbonate [148]. Intestinal binding of bile acids significantly lowers LDL cholesterol. The major advantage of sevelamer is that in contrast to calcium containing phosphate binders, sevelamer reduces serum phosphate without increasing serum calcium levels. Hypercalcemia occurs less frequently: in an 8-week cross-over study in children, sevelamer and calcium acetate were equally effective at reducing serum phosphate levels, but significantly less hypercalcaemia occurred in the sevelamer group [145].

Aluminum Containing Phosphate Binders

Aluminum containing phosphate binders are efficient phosphate absorbers but may result in aluminum intoxication. Their administration is not recommended in children. If their use cannot be avoided, e.g. in case of a severely increased calcium phosphate product not manageable otherwise, dosage should be limited to 30 mg/kg*d. Aluminum containing binders should only be given if other calcium free alternatives (see below) are not available. Regular monitoring of aluminum blood levels is needed. In case of persistent hyperparathyroidism cinacalcet and even parathyroidectomy should be considered (see below) to avoid extended exposure to aluminum containing binders.

Lanthanum carbonate binds intestinal phosphate more effectively than calcium carbonate and sevelamer. However, patients on extended treatment show increased lanthanum serum levels. Significant tissue accumulation has been demonstrated in rats. In light of the past experience with aluminum toxicity, lanthanum containing phosphate binders are currently not recommended in children with CKD. Nonetheless, according to the International Pediatric PD Network 1.6% of all children monitored worldwide until 2020 have been receiving lanthanum containing phosphate binders.

Iron-Based Phosphate Binders

Iron-based phosphate binders reduce serum phosphate and FGF 23 concentrations while simultaneously increasing serum iron stores in

patients with CKD and on dialysis [149, 150]. A recent randomized open-label study has shown that sucroferric oxyhydroxyde is as effective as Ca acetate in controlling serum P levels in children with CKD [151]. Similar to other P-binders, adverse events are primarily GI-related.

Newer P-Binders

Intestinal P absorption is regulated by sodium-dependent P co-transporter type 2b (NPT2b). Treatment with niacin (vitamin B3) or its metabolite nicotinamide/niacinamide, both of which modulate NPT2b expression, result in a sustained reduction in serum P concentrations in adult dialysis patients [152]. However, in a randomized trial of adult HD patients, NPT2b inhibition was not effective in reducing serum P concentrations [153]. Targeting salivary P using P-binding chewing gum has also been proposed [154]. These agents have not yet been studied in children.

Long-term Safety of Phosphate Binder Therapy

The long-term cardiovascular safety of phosphate binder therapy is still controversial. A randomized clinical trial in adults with a GFR of 20–45 ml/min/1.73 m^2 demonstrated an increase in arterial calcification with calcium, lanthanum and sevelamer binder therapy, but not in placebo treated patients [155]. Others showed progressive arterial calcification in predialysis patients on low-phosphorus diet alone. Progression was less in calcium carbonate-treated patients, and absent in sevelamer-treated patients [156]. The Independent trial demonstrated improved survival in predialysis patients randomized to sevelamer as compared to those treated with calcium carbonate [157, 158]. A recent meta-analysis comprising 104 studies involving 13,744 adults concluded that sevelamer may lower death (all causes) compared to calcium-based binders in patients on dialysis and incur less treatment-related hypercalcaemia, but demonstrated no clinically important benefits of any phosphate binder on cardiovascular endpoints or fracture risk. Likewise no such beneficial effects could be demonstrated in patients with CKD2–5 [159]. Respective data in children is scant. Still, in view of the key pathophysiological role of phosphate in CKD MBD cardiovascular disease, most children with hyperphosphatemia are treated with phosphate binders, considering the calcium demand of the growing bone and the treatment associated calcium load.

Vitamin D

Oral treatment with ergocalciferol or cholecalciferol is suggested when serum 25(OH)D concentrations are below 30–40 ng/ml in order to prevent muscular weakness, secondary hyperparathyroidism and osteomalacia. At least in early stages of CKD, supplementation of cholecalciferol can prevent or reduce hyperparathyroidism and should be prescribed before calcitriol is considered. In an RCT of 25(OH)D therapy in children with CKD stages 2–4, children on ergocalciferol who achieved 25D levels >75 nMol/L had a significantly longer time to development of secondary hyperparathyroidism compared to those on placebo [34].

No clear consensus exists on the preferable type of native vitamin D supplement (ergo vs cholecalciferol), its dosage, frequency of administration or duration of treatment in healthy children or children with CKD. The KDIGO and ESPN guidelines recommend a loading regimen or intensive replacement period for a variable duration of 4–12 weeks followed by a maintenance regimen [29, 128]. Both guidelines further recommend escalating doses for intensive replacement depending on the baseline 25(OH)D level; cholecalciferol doses range from 2000 to 8000 IU/day for intensive phase replacement and 1000–2000 IU/day for maintenance therapy. The therapeutic window is wide; hypercalcemia, hypercalciuria, and symptomatic toxicity have been reported only when serum 25(OH)D levels exceed 250 nmol/L. Current clinical practice recommendations for children with CKD suggest a target level of 75–120 nmol/L (30–48 ng/ml).

Vitamin D repletion strategies include daily, weekly, monthly and even 3-monthly dosing regimens. Several trials have evaluated the short-term safety, efficacy and tolerability of these protocols. A recent randomized trial compared cholecalciferol dosing regimens for achieving and maintaining 25OHD concentrations ≥30 ng/ml in children with CKD stages 2–4, and showed that cholecalciferol as daily, weekly or monthly administration yielded similar 25OHD concentrations without toxicity [160]. Children with glomerular disease required higher doses of cholecalciferol compared to those with non-glomerular disease.

Active Vitamin D Sterols

Recent ESPN guidelines have addressed treatment with active vitamin D sterols [161]. These are indicated in pediatric CKD patients whose serum PTH levels remain elevated despite normal serum 25D and P levels. Alfacalcidol (1-α hydroxyvitamin D_2) or calcitriol (1,25-dihydroxyvitamin D_3) are most commonly used. The dose of calcitriol depends on initial PTH, Ca and phosphate values. An initial dose of 5–10 ng/kg*d is effective and safe in most children with CKD [128, 161]. Alfacalcidiol is often used in infants and small children since a liquid formula is available, and the dose can be carefully titrated. Higher doses relative to calcitriol may be required due to the requisite hepatic metabolism to 1,25 vitamin D. The frequency of calcium, phosphate and PTH monitoring should be adapted to the dose of vitamin D administered. All vitamin D analogues can get adsorbed to plastic tubing to varying degrees, and therefore should not be administered via feeding tubes.

Calcitriol efficiently controls secondary hyperparathyroidism. With prolonged treatment a substantial number of children, however, develop adynamic bone disease, which has been associated with a reduced growth rate and frequent episodes of hypercalcemia [58, 63].

A second consequence to consider with active vitamin D treatment is the increase not only of intestinal absorption of calcium [162] but also of phosphate. Calcitriol increases intestinal phosphate absorption from around 60% to 90% [163] (Fig. 60.13). Calcitriol use often is limited by aggravated hyperphosphatemia and hypercalcemia. Calcitriol, hypercalcemia and hyperphosphatemia contribute to extraosseus tissue calcifications and decreased survival in children with end stage renal disease [67, 68]. Deterioration of renal function is not accelerated by calcitriol [164], at least if administered at moderate doses not resulting in increased serum calcium and phosphate concentrations.

All activated vitamin D analogs increase FGF23 secretion. Although the consequences of these increased FGF23 levels in dialyzed patients remain to be completely determined, current evidence suggests that excessive circulating FGF23 is associated with increased mortality rates and cardiovascular disease [41]. Two randomized trials have demonstrated that vitamin D analogs do not improve cardiac function for patients with CKD stages 3–5 during one year of treatment [165, 166].

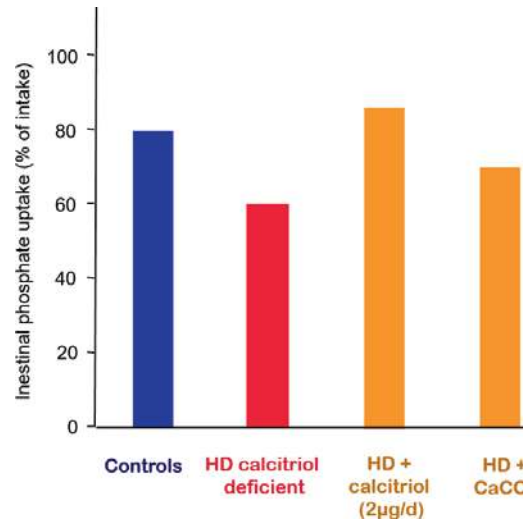

Fig. 60.13 Effect of calcitriol and oral phosphate binder on intestinal phosphate uptake. Calcitriol significantly increases phosphate uptake in hemodialysis patients (HD). $CaCO_3$, given at a dose of 75 mEq prior to a standardized meal, reduces phosphate uptake but increases oral calcium intake by 1.4 g compared to placebo, the intestinal calcium uptake increases to 28% of the ingested amount as compared to 14% with placebo

The Mode of Calcitriol Administration

The mode of calcitriol administration is of minor importance. Some studies including bone biopsies suggested a strong effect of calcitriol on bone metabolism with intermittent oral, intravenous and intraperitoneal administration. These studies, however, were not controlled against a daily administration mode [127]. Prospective randomized studies comparing daily versus intermittent oral calcitriol in healthy children and children with CKD stages 2–4 revealed no differences in PTH suppression, intestinal calcium absorption, the incidence of hypercalcemia and hyperphosphatemia or longitudinal growth rates [167, 168]. Overall, the response to calcitriol depends less on the mode of administration than on the degree of secondary hyperparathyroidism, hyperphosphatemia and the degree of parathyroid gland autonomy.

Synthetic Vitamin D Analogues

Synthetic vitamin D analogues have been developed to reduce intestinal calcium and phosphorus absorption at equipotent PTH suppressive action. Three sterols have been approved, i.e. 22-oxacalcitriol, 19-nor-1,25 dihydroxy vitamin D2 (paricalcitol) and 1α-hydroxyvitamin D2 (doxercalciferol). In adult hemodialysis patients, paricalcitol treatment is associated with a more rapid achievement of PTH control and fewer episodes of sustained hypercalcemia and increased Ca × P product than calcitriol therapy In children with CKD 3–5 and on hemodialysis paricalcitol appears to be efficacious and safe [169, 170]. The still limited evidence for a superior efficacy-safety profile of the synthetic vitamin D analogues must be balanced against their high costs.

There is also observational evidence for a survival benefit associated with the use of vitamin D sterols in general, which awaits confirmation in prospective trials. It may reflect a plethora of beneficial immunological and cardiovascular effects of active vitamin D compounds. In summary, active vitamin D sterols are indispensable therapeutic agents in the management of CKD but should always be used with caution and in awareness of their limited therapeutic window, beyond which major untoward effects to the bone, cardiovascular and potentially other systems may occur.

Calcimimetic Agents

Calcimimetics are a new class of compounds that bind to the parathyroid calcium sensing receptor, increase its sensitivity to ionized calcium by allosteric modification, and dose dependently decrease plasma PTH levels by up to 80%. The effect is largely independent of baseline PTH and phosphate levels and thus allows for control of parathyroid gland function even in patients with otherwise refractory hyperparathyroidism. **Cinacalcet** is the only currently approved calcimimetic agent. Cinacalcet also reduces serum calcium and phosphate levels, possibly via increased mineral deposition into bone. A randomized clinical trial in adult dialysis patients suggested attenuation of vascular and cardiac valve calcification with cinacalcet plus low-dose vitamin D sterols [171]. However, in a large placebo-controlled trial only a non-significant 7% reduction in death or first cardiovascular event was observed. A nominally significant 12% reduction in the risk of death was observed after adjustment for the unevenly distributed baseline characteristics [172].

Observational studies, industry sponsored phase 2 and 3 randomized studies, and one single arm extension study in pediatric dialysis patients demonstrated good efficiency of cinacalcet, i.e. suppression of PTH, and good tolerability [173]. Cinacalcet has therefore been licensed for children on dialysis above 3 years of age. According to a recent position statement of the respective European Working groups, the starting dose of cinacalcet should be about 0.2 mg/kg/day based on dry weight [174]. The dose may be increased at 4-week intervals by about 0.2 mg/kg/day to a maximum daily dose of 2.5 mg/kg (and not exceeding 180 mg), based on serum PTH levels and albumin corrected calcium levels >2.2 mmol/L. The cina-

calcet dose should be decreased in case of PTH levels between 100 and 150 pg/ml, and lower serum calcium, and withheld if PTH levels fall <100 pg/ml and if albumin-corrected serum calcium levels are <2 mmol/L and/or ionized calcium levels <1.0 mmol/L. About 10–20% of the children on cinacalcet developed episodes of hypocalcemia in clinical trials. A fatality reported together with diarrhea-associated hypocalcemia and long QT time demonstrates the need of careful serum monitoring, i.e. within one week after initiation of cinacalcet and up-titration, and monthly with stable cinacalcet dose. Next to hypocalcemia, the main side effects of cinacalcet are nausea and vomiting, which can be attenuated by evening administration. Prior to start of cinacalcet a normal corrected QT (cQT) time should be verified by ECG. Concomitant medications with the potential to increase the QTc or to interfere with cinacalcet metabolism need to be carefully considered [174]. At present, it is recommended to initiate cinacalcet in children in whom SHPT cannot adequately be controlled with standard of care therapy. Whether cinacalcet is useful earlier in the course of treatment, i.e. to prevent high dose active vit. D analogues is yet unknown. The calcium sensing receptor is expressed on epiphyseal chondrocytes and calcimimetics have been shown to reduce serum testosterone levels in HD patients by 30%. Hence, an impact on longitudinal growth and pubertal development cannot be ruled out. Reassuringly, animal studies and the clinical data obtained thus far do not suggest an impact of cinacalcet on pubertal development and longitudinal growth [174, 175].

Etelcalcetide is a novel calcium receptor sensitizing, calcimimetic compound with a prolonged half-life, administered intravenously. It has been licensed for adult patients on hemodialysis and has the potential to improve treatment adherence since it is administered during hemodialysis sessions. A recent phase 1, single dose clinical trial in 11 children on hemodialysis demonstrated similar pharmacokinetics and pharmacodynamics as in adults [176]. A pediatric single arm study over 6 months is currently under way. Whether the different pharmacodynamics with three-times-weekly i.v. dosing as compared to daily oral cinacalcet administration is of clinical relevance is currently unclear.

Parathyroidectomy

Despite intensive vitamin D and phosphate binder treatment, some children with CKD may develop refractory hyperparathyroidism, in particular if renal transplantation cannot be performed for an extended period of time. In young adult CKD patients, the incidence of parathyroidectomy is more than 2 per 100 patient years. In our experience the incidence of parathyroidectomy in children has been at least similar to adults. Indications for parathyroidectomy are persistent and recurrent hypercalcemia and hyperphosphatemia despite optimized dietary efforts and medication including cinacalcet, progressive and debilitating bone disease and progressive extraosseus calcifications. Latest findings in adults indicate a more than 50% reduction in the incidence of unremitting hyperparathyroidism and thus the need of parathyroidectomy, possibly related to the use of cinacalcet [177].

Total parathyroidectomy and autotransplantation of tissue fragments in the abdominal subcutaneous layer is preferred to subtotal parathyroidectomy, since the remaining tissue tends to grow again and the transplant is easier to access for diagnostic and curative purposes. Total parathyroidectomy without autotransplantation may result in difficulties to control calcium homeostasis, in particular after kidney transplantation. Ablation of parathyroid tissue by ethanol injection has been suggested as an alternative to surgery; published pediatric experience is limited to a 15 year boy successfully treated 2 months after renal transplantation [178]. Some centers give active vitamin D 72 h prior to surgery to lessen postoperative hypocalcemia; this, however, is not indicated if calcium and phosphate values are markedly increased.

Postoperatively serum ionized calcium needs to be monitored closely, because most of the children develop “hungry bone” syndrome. Due to

the rapid decline of PTH, skeletal calcium uptake increases markedly. In most of the children calcium infusions are required within few hours after operation, especially in children with high preoperative PTH and alkaline phosphatase levels. Calcium infusion can be started at a rate of 0.05 mmol/kg*h (2 mg/kg*h) of elemental calcium, but must continuously be adapted according to the changes in serum ionized calcium levels. Calcium infusion is often required for several days, subsequent oral calcium administration for many weeks. In addition, patients should be given high doses of calcitriol (up to 2 μg/d) and dialyzed with a high dialysate calcium concentration. Serum phosphate levels also decline; however, phosphorus supplementation may aggravate hypocalcemia and should only be initiated in case of significant hypophosphatemia.

Success rate is high in children. Parathyroid tissue fragments autotransplanted subcutaneously, usually start to secret PTH soon. Symptomatic hypocalcemia may develop in children not adhering to the medication; irreversible recurrent nerve palsy is rare. PTH and calcium x phosphate product remain within in the target range for many years [179].

Treatment After Renal Transplantation

Children receiving a renal allograft are at risk for multifactorial, progressive bone disease. Persistent hyperparathyroidism, hypophosphatemia and glucocorticoid use require close monitoring of bone metabolism, even if transplant function is normal. Serum calcium, phosphate and bicarbonate should be measured weekly within the first 2 months and at least monthly during the following months. Subsequent determinations also have to be adapted to renal function. PTH should be checked initially and 1 month post transplantation. If plasma PTH remains elevated further controls and therapeutic measures are required. If renal function is reduced, the frequency of determinations should be according to the stage of CKD (Table 60.2) and subsequent treatment strategies follow the guidelines for CKD (Table 60.3). Hypophosphatemia should be corrected. Glucocorticoids should be given at the lowest dose possible and may be withdrawn in patients with stable transplant function. Calcium and active vitamin D therapy lessen glucocorticoid induced bone loss in adults and have been recommended, however no pediatric data have been provided to date. Likewise, next to a case report only one observational study on the off-label use of cinacalcet in 20 children after kidney transplantation has been published [180]. It suggests efficient PTH suppression, and acceptable tolerability despite relatively high cinacalcet doses. The effect of cinacalcet on urine calcium excretion and allograft function is uncertain; some adult studies highlighted the potential risk of nephrocalcinosis. In case cinacalcet is used in children after transplantation, e.g. in order to circumvent parathyroidectomy, careful monitoring is required.

Future Therapeutic Perspectives

Bisphosphonates, selectively blocking osteoclasts and thus bone resorption, appear to be safe at all stages of CKD. Dose reduction is probably required in CKD stage 5, at least based on pharmacokinetic studies. These agents have been recommended for high-risk adult transplant patients on glucocorticoid treatment, although according to a recent meta-analysis the evidence for a reduction in fracture risk and bone pain is low [153]. Important concerns regard their long-lasting action and the risk of hypocalcemia associated with overdosing. Likewise, the effects of bisphosphonates on vascular calcifications need further study, because low bone turnover might exacerbate vascular calcifications. Even if bisphosphonates prove safe, their efficacy in CKD is uncertain. More clinical research data are mandatory before their use in growing children with CKD or glucocorticoid-induced osteoporosis can be considered.

BMP-7 has been used successfully in animal models of renal osteodystrophy and vascular calcification. Human data are currently limited to orthopedic interventions, where it has been employed successfully to induce healing of pathologic fractures. **Blockade of** the Wnt pathway inhibitor **sclerostin** is currently investigated in patients with osteoporosis. Whether sclerostin is a simple marker or an active mediator of bone and cardiovascular disease in CKD and whether sclerostin blockade mitigates these essential comorbidities is currently unknown.

Prognosis

Despite an increasing number of therapeutic options, the management of mineral metabolism remains difficult. More than one third of adults with pediatric-onset CKD have clinical symptoms of bone disease and almost one out of five patients is disabled by bone disease [8]. The CKD-associated alterations of bone mineral metabolism disorders and their treatment during childhood years substantially contribute to the development of uremic arteriopathy, and probably to the excessive cardiovascular mortality in early adult life [10]. Barriers to success are limited patient compliance, the limited efficacy of prescribed measures, the prohibitive costs of novel, more efficacious therapies, and the progressive development of parathyroid autonomy.

Still, there is hope that prevention of mineral dysregulation with early and appropriate use of phosphate binders, prevention of 25(OH)D deficiency, new vitamin D analogues and calcimimetics may reduce the prevalence of mineral disorder and prevent bone disease and vasculopathy in children with CKD. Moreover, the attention to the various clinical practice guidelines available now for pediatric patients with CKD, the establishment of patient registries monitoring achievement of targets and prospective, randomized trials evaluating clinical outcome parameters should result in more favorable long-term outcomes of children with CKD.

Cardiovascular Disease in Pediatric Chronic Kidney Disease

61

Anke Doyon and Mark Mitsnefes

Epidemiology

Cardiovascular Mortality: Leading Cause of Death in Children with CKD

In 1998, the National Kidney Foundation Task Force on cardiovascular disease (CVD) declared an epidemic of cardiac disease in end-stage kidney disease (ESKD) patients [1]. This report however provided no information on CVD in children. Over the next two decades, there have been important studies around the world addressing CVD in children with ESKD.

In 2002, as a follow up on a Task Force, Parekh et al. [2], using the United States Renal Data System (USRDS) database, performed the first analysis to evaluate the risk of a cardiac death in children and young adults (age 0–30 years) and to identify factors potentially associated with CVD mortality. A total of 1380 deaths between 1990 and 1996 were analyzed. There were 311 cardiac deaths (23% of the total). These data were in great contrast to the general pediatric population where CVD mortality was low and accounted for less than 3% of all causes of death [3]. The analysis also showed that the rates of cardiac deaths in this age group were approximately 1000 times higher than in the general pediatric population. Subsequent reports from international registries over the next few years have confirmed that CVD is the leading cause of death in children with ESKD and in adults with childhood onset of CKD. The Australia and New Zealand Dialysis and Transplant (ANZDATA) [4], Dutch national cohort study (LERIC) [5] and a large German study [6] report that 40–50% of all deaths are from cardiovascular or cerebrovascular causes. Cross-sectional studies of young adults with childhood-onset ESKD have found a cardiac death rate of 35% in U.S. children transplanted at age 0–19 years [7]; 23% in 150 German patients transplanted as children between 1970 and 1993 (almost ten times higher than the occurrence of malignancies [8]), and 32% in another series of dialyzed or transplanted young adults from Germany [9].

Foster et al. analyzed the long-term survival of 18,911 patients who received a first kidney transplant during childhood (at <21 years old, 1983–2006) and confirmed that the majority of deaths

were from cardiovascular causes especially after graft failure (45%) versus those with a functioning graft (25%) [10]. The hazard ratios (HR) for cardiovascular mortality associated with dialysis after graft failure was 7.8 as compared to those with functioning graft. As other studies, this study also observed an improvement in cardiovascular mortality in transplant recipients. However, even in these patients, the mortality rates were still significantly higher (approximately 10 times) than in the general pediatric population. Mitsnefes et al. [11] analyzed data from more than 20,000 pediatric ESKD patients followed over two decades, with follow-up to 2010. The authors demonstrated that mortality rates for children and adolescents being treated with dialysis have improved dramatically between 1990 and 2010.

While most published studies analyzing mortality in young adults have focused on patients who developed ESKD during childhood, there have been very few studies examining cardiovascular morbidity and mortality specifically in patients who developed ESKD during young adulthood (21–29 years). Using USRDS data collected in 2003–2013, Modi et al. [12] showed that the risk for cardiovascular mortality in these young adults was 143–500 times higher compared to age-matched young adults in the general population. During the study follow-up period, 16.2% of the cohort died, and CVD accounted for 38% of all deaths. The risk of death among those with onset of disease during young adulthood was similar to that of young adults with childhood-onset ESKD (1–11 years or 12–21 years). Presence of diabetes, coronary artery disease, and heart failure were notable risk factors for cardiovascular-related mortality.

Modi et al. also compared the risk of cardiovascular-related hospitalizations. Not surprisingly, the rates of cardiovascular hospitalization during the five-year follow-up period were highest for those 22–29 years and lowest for those 1–11 years, with risk remaining stable in children but increasing over time in the adolescent group until reaching the hospitalization rate of young adults. As expected, patients receiving hemodialysis and peritoneal dialysis were at higher risk for cardiovascular-related hospitalizations compared to patients receiving preemptive transplantation.

Ku et al. [13] compared trends over time in mortality from CVD-related causes of death among more than 80,000 children and young adults <30 years of age starting dialysis in 1995–2015. Overall, 40% of deaths were cardiovascular-related causes. The risk of cardiovascular-related death was stable initially, began improving after the early 2000s, and became significantly lower after 2006 in those starting dialysis as either children or young adults (Fig. 61.1).

Taken together, these data show that despite significant improvement in patient survival, mostly due to decrease in cardiovascular (especially in those after kidney transplantation) and infectious disease mortality, CVD remains the world-wide biggest obstacle to long-term survival of children and adolescents with ESKD, especially those on maintenance dialysis [14] (Fig. 61.2). Not surprisingly, the American Heart Association guidelines for cardiovascular risk reduction in high-risk pediatric patients continue to stratify pediatric CKD patients in the “highest risk” category for the development of CVD [15, 16].

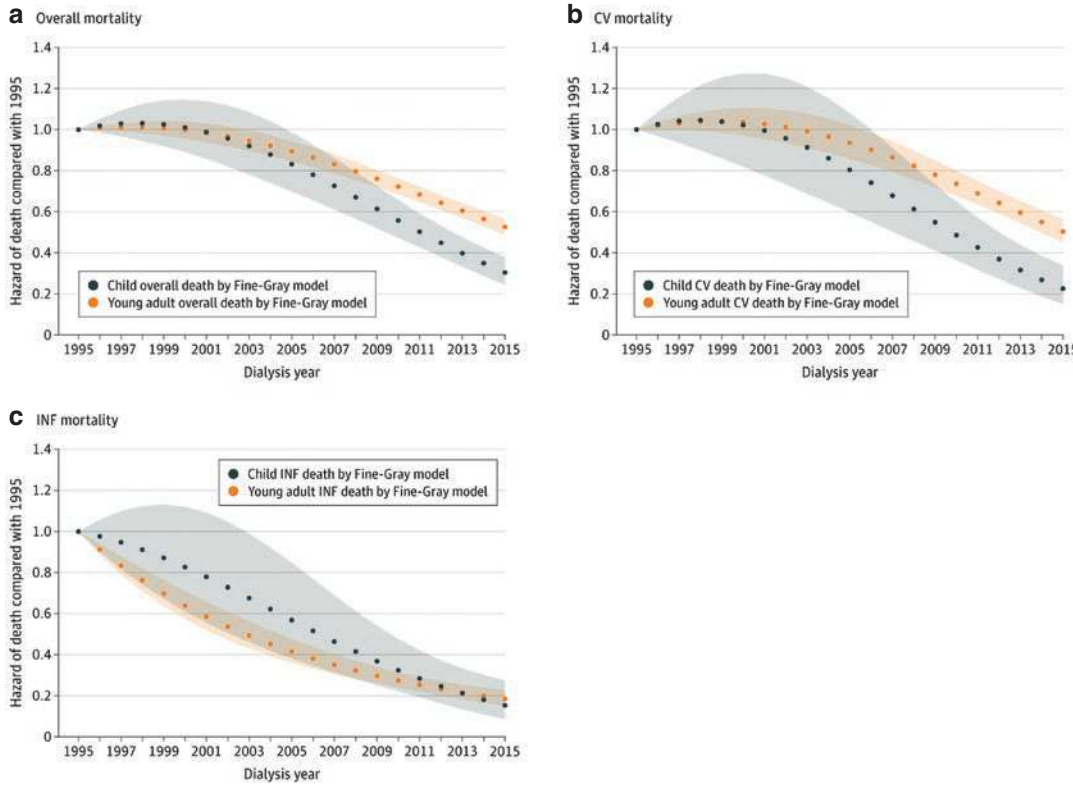

Fig. 61.1 Trend in cause-specific deaths among children and young adults by calendar year of dialysis initiation using fine-Gray models. Shaded areas represent 95%CIs for the point estimates in young adults and children. *CV* indicates cardiovascular, *INF* infection. From Ku et al. [13]

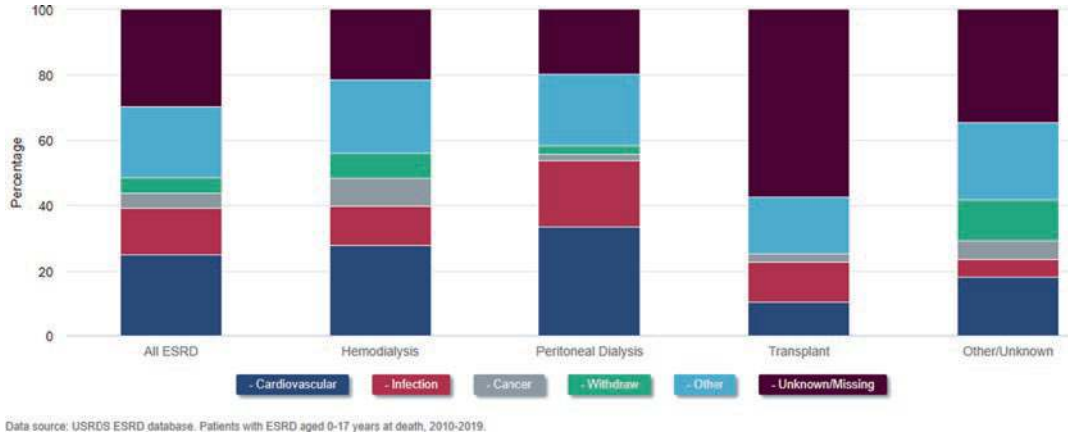

Fig. 61.2 Cause of death in children with ESKD, by treatment modality, 2010–2019. The most common cause of death in children with ESRD was a cardiovascular cause, followed by an infectious cause, but the causes of death differed by treatment modality. For example, children receiving PD died more commonly of infections than children receiving HD. A large proportion of the causes of death in children were of unknown cause (30%), and the cause was particularly likely to be unknown for children with a kidney transplant. *US Renal Data System: USRDS 2020 Annual Data Report: ESRD among Children and Adolescents.* https://adr.usrds.org/2020/end-stage-renal-disease/7-%20esrd-among-children-and-adolescents

Specific Causes of Cardiac Death

The term "cardiac death" may include several diagnostic categories, such as cardiac arrest, arrhythmia, myocardial infarction, valvular heart disease, cardiomyopathy, etc. (Table 61.1).

Although it is common to group these diagnoses together, this may obscure the issue; the diagnosis of arrhythmia could be due to hyperkalemia (possibly due to noncompliance, dietary mistakes, acidosis, insufficient dialysis, etc.) or due to coronary artery disease or other causes. Therefore, diagnostic categories do not necessarily permit conclusions regarding the pathogenesis of CVD events.

In the initial USRDS study almost 20 years ago of Parekh et al., cardiac arrest was the most common cause in each of the age groups, followed by arrhythmia and cardiomyopathy [2]. The incidence of cardiac arrest in the youngest age group (0–4 years) was 5–10 times higher than in other age groups, perhaps, as noted by the authors, a reflection of the difficulty of ascertaining the true cause of death in young children. Some of these young children might have died from other co-morbid conditions such as congenital disorders which are not included in the USRDS database.

Table 61.1 Most common cardiovascular risks, abnormalities and cardiac causes of death

Cardiovascular risks and abnormalities[a]	Cardiac causes of death
CV Risks	*Dialysis*
Hypertension	Cardiac arrest/ arrhythmias
Dyslipidemia	Cerebrovascular disease
Hyperphosphatemia	Congestive heart failure/pulmonary edema
Increased Ca × P product	Cardiomyopathy
Anemia	Acute myocardial infarction
Early CV abnormalities	Pericarditis
Left Ventricular hypertrophy	*Transplant*
LV Systolic and diastolic dysfunction	Cardiac arrhythmias
Increased cIMT	Cerebrovascular disease
Increased PWV	Acute myocardial infarction
Coronary artery calcification	Cardiomyopathy

[a]The frequency of cardiovascular risks and abnormalities increases with advancing of CKD with the greatest prevalence during maintenance dialysis. Despite some improvement, many of these factors persist after transplantation

The most recent study by Ku et al. [13] also using the USRDS indicated that while sudden cardiac death remained the leading cause of death, its risk has improved steadily but to a greater degree in children versus young adults comparing 2015 versus 1995. In contrast, trends differed for heart failure-related mortality: while the risk of dying from heart failure did not change over time in children, it began to decline in those starting dialysis as young adults after 2008. The risk of dying from a myocardial infarction was significantly lower after 2005 compared to 1995 in young adults, but was not different during most of the follow-up time in children although the event rate was very low. The risk of dying of a stroke began to improve after 2009–2010 in both those starting dialysis as children and young adults.

The high rate of sudden cardiac death in children, especially in infants with ESKD, is poorly understood and warrants further investigation. In adults, sudden cardiac death is often a result of fatal arrhythmias due to acute ischemia of preexisting atherosclerotic disease. It is believed that arrhythmias are also the likely cause of most cases of sudden cardiac death in children. However, the origin of acquired malignant arrhythmias in children is unlikely to be an atherosclerotic lesion. Instead, dilated, especially hypertrophic cardiomyopathies are a leading cause of sudden cardiac death in children [17]. The macroscopic and microscopic structural abnormalities in cardiomyopathies involve fibrosis and cellular hypertrophy that predispose to an electrical instability with resultant arrhythmias. Ischemia of small coronary vessels secondary to medial hypertrophy might result in dispersion of repolarization properties and arrhythmia from reentrant or autonomic mechanisms. As we discuss in more detail below in this chapter, many children with CKD develop left ventricular hypertro-

phy (LVH), which is frequently severe, especially in children on prolonged dialysis therapy [18, 19]. It is currently unknown if LVH in young patients with CKD is characterized by structural abnormalities similar to familial or idiopathic hypertrophic cardiomyopathies associated with sudden cardiac death. To what extent LVH can contribute to an increased risk for sudden cardiac death in children with CKD is also not known. Deadly arrhythmias in children with ESKD could also be evoked by acute changes in the cardiac extra- or intracellular ionic milieu, especially involving abnormalities of sodium- and potassium-based repolarization currents.

Symptomatic ischemic heart disease and myocardial infarction are typical complications of CVD in older patients with CKD and account for more than 50% of death in these patients [20]. In contrast, young patients as a rule have no symptoms of ischemic heart disease such as angina pectoris and no myocardial infarction but remain asymptomatic. Could this imply that ischemic heart disease is silent and therefore underdiagnosed? Silent myocardial ischemia is frequently found in patients with CKD, especially during dialysis [21]. Myocardial infarction may also be disguised, as has been noted in younger women who may have significantly different symptoms at initial presentation [22]. There is a paucity of studies regarding EKG monitoring in children with CKD, but circadian rhythms of blood pressure (BP) and heart rate are altered in children with CKD [23]. There are no systematic autopsy studies in young patients with CKD focusing on vascular and coronary pathology. Therefore, the lack of symptomatic ischemic heart disease in young patients and paucity of cardiac deaths due to confirmed myocardial infarction remains an important observation; however, it is presently unknown whether absence of symptoms truly implies absence of advanced vascular and cardiac disease.

Risk Factors

In the general population, CVD in most patients is the result of atherosclerosis. Atherosclerosis is a multifactorial disease affecting the heart and large and medium-sized arteries, with a focal distribution, and with the characteristic appearance of lipid-rich plaques in the intima of the arterial wall. Clinical manifestations include coronary heart disease, cerebrovascular disease, aortic aneurysm, and peripheral arterial occlusive disease. This disease is slowly progressive over several decades. Atherosclerosis has a multifactorial pathogenesis, but the occurrence of the disease is associated with typical risk factors: dyslipidemia, hypertension, smoking, male gender, diabetes, abdominal obesity, lack of physical activity. In the INTERHEART study, a case-control study of acute myocardial infarction performed in 52 countries more than 15 years ago, these traditional risk factors (in combination with psychosocial factors, consumption of fruits, vegetables, and alcohol) accounted for 90% of the attributable risk in men and 94% in women, indicating their worldwide predictive value irrespective of gender, race, or region [24].

CKD has been appropriately described as a "vasculopathic state" because of the extraordinary risk indicated by the accumulation of numerous risk factors [25]. The occurrence and prevalence of these risk factors have been exhaustively described [26–28]. Traditional risk factors (for atherosclerosis), non-traditional (uremic) risk factors and cardiomyopathy (a risk factor in itself) most likely act synergistically, resulting in altered vascular and cardiac structure and function in CKD [29].

What makes children with CKD so highly predisposed to the development of accelerated atherosclerosis/arteriosclerosis and premature CVD during young adulthood is likely a unique combination of extremely highly prevalent traditional and CKD-related risk factors (Table 61.1).

Traditional Risk Factors

The high prevalence of traditional cardiovascular risk factors is already evident in children with early stages of CKD. Many publications from the Chronic Kidney Disease in Children (CKiD) study, an observational cohort study of more than one thousand children (aged 1–16 years) with CKD stages 2–4 initiated in the early 2000s, provided contemporary data on the prevalence of

cardiovascular risk factors over the last decade. An initial cross-sectional study showed that 54% of participants had **hypertension**; among children receiving antihypertensive medication, 48% still had elevated blood pressures [30]. Ambulatory blood pressure monitoring (ABPM) demonstrated a high frequency of masked hypertension (38%) [31]. During a 4-year follow up, only 46% of hypertensive patients achieved controlled clinic BP [32]. In a study comparing ambulatory BP control over two time periods (2005–2008 and 2010–2013), there was a significantly higher prevalence of masked hypertension and a lower prevalence of normotension in the more recent period [33]. Recent data indicate that unrecognized and untreated hypertension is more prevalent and persistent in younger children [34]. Thus, despite publication of the initial CKiD hypertension data in 2008–2010, plus published recommendations and guidelines for stricter BP control in patients with CKD, hypertension has remained under-recognized and under-treated in children with CKD.

Dyslipidemia was initially found in 43% of the CKiD cohort: 32% had triglycerides levels >130 mg/dL; 21% had HDL-cholesterol levels <40 mg/dL and 21% had total cholesterol >200 mg/dL [35]. Dyslipidemia persisted (51%) 6.5 years later in the CKiD participants [36]. Likewise, the prevalence of dyslipidemia was 61.5% in children with CKD enrolled in KNOW-PedCKD, the KoreaN cohort study for Outcomes in patients With Pediatric Chronic Kidney Disease [37].

Among the CKiD participants, about 30% were either **overweight or obese** [38]. Although diabetes is very rare in children with CKD, hyperinsulinemia and insulin resistance was present in 9% and 19% respectively of the CKiD cohort [38]. Importantly, almost one half of the CKiD cohort had a combination of traditional cardiovascular risk factors [38]. Even lean patients had a high prevalence of multiple traditional cardiovascular risks, with nearly one-quarter having two or three cardiovascular risk factors. Overweight or obese study participants had a very high prevalence of multiple risk factors, similar to rates in severely obese (BMI > 40 kg/m^2) children without kidney disease. This pattern differentiates the population of children with CKD from healthy children, in whom the coexistence of multiple cardiovascular risk factors is extremely infrequent, and restricted to those who are obese (metabolic syndrome). However, classical **metabolic syndrome** is also very frequent in the CKiD cohort with a prevalence of 40% in overweight patients and 60% in the obese children [39]. In this study, those with persistent metabolic syndrome had approximately twice the odds of kidney function decline (>10% per year) compared to those without multiple cardiometabolic risk factors and normal BMI.

The frequency of traditional risk factors is highest in children on maintenance dialysis (Table 61.1). Successful kidney transplantation leads to elimination of many uremia-related risk factors for atherosclerotic CVD. However, transplant recipients are not free from multiple complications and transplantation frequently amplifies many of the traditional risk factors (Table 61.1). One multicenter study determined that 38% of kidney transplant recipients had a coexistence of at least three traditional cardiovascular risk factors [40].

CKD-Related Risk Factors

While the high prevalence of traditional risk factors might explain a higher prevalence of accelerated CAD and premature cardiac death in young adults, it cannot explain the high rates of cardiac death in 0–19 year olds on maintenance dialysis or after transplant. To understand the risk of cardiac disease in these children, the focus has been on evaluation of uremia-related risk factors. As in adults, abnormal mineral metabolism is frequent in children with CKD. The role of mineral and bone disorder (MBD) in development of vascular disease in CKD will be discussed extensively later in this chapter. As with traditional risks, the rates of abnormalities are higher in dialysis patients versus those with pre-ESKD (Table 61.1).

Despite widely spread use of erythropoietin and iron therapy, **anemia** is still frequently poorly controlled, especially in children with advanced CKD [41] or on maintenance dialysis [42]. Data

from the CKiD study indicate that 26% of children with non-glomerular and 43% of children with glomerular CKD had hemoglobin levels less than the fifth percentile using age- and sex-specific norms [43]. Data from the Korean cohort (KNOW-PedCKD) demonstrated 40% prevalence of anemia [44].

One of the largest studies to date from the international Pediatric Peritoneal Dialysis Network (IPPN) (1394 pediatric patients aged 1 month to 20 years from 81 pediatric dialysis centers in 30 countries) showed that 25% of patients had a hemoglobin level < 10 g/dL despite more than 95% of participants received erythropoietin therapy [45]. In an early USRDS study, severe anemia has been linked to overall mortality in these children but not to cardiac death [46]. Similarly, in the IPPN study overall death occurred more frequently in those with hemoglobin <11 g/dL (4.2%) versus those with hemoglobin >11 g/dL (2.6%) [45].

Inflammation is also mainly evident in chronically dialyzed children. However, there have been no studies examining the role of inflammation in cardiac death of children with ESKD. Even though there have been no studies of a direct link between specific traditional and uremia-related risks and CVD mortality, epidemiological data presented above showing remarkable decrease in mortality post-transplant versus dialysis, clearly point out to dialysis vintage as a major cause of cardiac death in children and young adults with childhood onset of ESKD.

In summary, children and adolescents with CKD harbor a multitude of risk factors for CVD that at this age seems without parallel [47]. The overall effect of these risk factors and their relative contribution to morbidity and mortality in young patients is yet unknown. While studies in adult CKD patients predominantly focus on symptomatic cardiovascular events and all-cause mortality to identify risk factors, these end-points fortunately are rare in the pediatric setting. Studies in this age group therefore have to rely on surrogate endpoints such as the identification and progression rate of subtle cardiovascular changes (Table 61.1). The scarce knowledge about the extent of the progression of cardiovascular alterations and promoting factors is often a result of relative small patient numbers in individual pediatric nephrology centers. For this reason, multicenter studies are a logic and reasonable consequence to advance cardiovascular research in children with CKD. In this regard, two large consortiums in Europe and the United States have formed more than a decade ago to monitor and evaluate the children with CKD with a special emphasis on the cardiovascular status. In addition to the CKiD study that was introduced earlier in the chapter [48], the European consortium has initiated the Cardiovascular Comorbidity in Children with Chronic Kidney Disease Study (4C Study) which prospectively follows more than 700 children with more advanced CKD all over Europe [49]. In both studies, yearly exams evaluate the cardiovascular status in these patients by vascular ultrasound, BP measurement, other traditional and CKD related CVD risk factors, echocardiography and assessment of arterial stiffness. It has provided important insight about who is or will be at a particularly high risk to suffer from cardiovascular complications. In this chapter, we describe the current findings from the above multicenter observational studies.

Vascular Disease in Pediatric CKD

Non-invasive Studies of Vascular Abnormalities

Coronary Artery Calcification

CT scans were the earliest imaging modalities to detect vascular abnormalities such as coronary artery calcifications (CAC) in young adults with ESKD. Braun et al. [50] were the first to describe increased calcium scores in young dialysis patients when compared with non-dialysis patients with known or suspected coronary artery disease and a number of studies confirmed this finding for young patients with ESKD starting in childhood or adolescents [6, 51–58]. Also, coronary calcium scores increased significantly in dialysis patients even over short time periods [52, 57]. Two studies reported the occurrence of CAC only starting at the age of 20 or 31 years in their

patient cohorts respectively [53, 57] whereas others detected them already during adolescence [51, 58]. The percentage of patients with proven CAC was highly variable between studies and ranged between 10% and 92%, possibly reflecting the wide age range, differences in cumulative time on dialysis or after transplantation, and variation in medical treatment policies. Recent studies of CAC in children with ESKD have been performed by Srivaths et al. [54–56]. In their initial study, 5 of 16 patients (31%) had CAC. In a follow up study, the CT was repeated 1 year after the initial evaluation. Three patients with initial CAC progressed based on increased Agaston score; one patient developed new and none of the patients resolved CAC.

Although heterogeneous in age, duration and mode of renal replacement therapy, several risk factors for the presence and severity of CAC were consistently identified in the majority of studies. Among them are the patients' age, cumulative time on dialysis, CRP, PTH, FGF23, mean serum phosphorus and calcium-phosphorus product levels, and cumulative exposure to active vitamin D.

Carotid Intima-Media Thickness

In adults, carotid intima-media thickness consensus (cIMT) measurement is considered a valid and reliable assessment of atherosclerotic burden [59–62] that can predict coronary atherosclerosis and its clinical sequelae, such as myocardial infarction and stroke [60, 62]. Measurement of cIMT is recommended by the American Heart Association for risk stratification in adults whose CV risk is not clear or is intermediate [61] and as a standard non-invasive assessment of subclinical atherosclerosis in children and adolescents [61].

Briefly, cIMT is measured at the far wall of an ultrasound image recorded with a high-frequency probe. Normal values were first developed for children between 10 and 20 years based on measurements in 241 healthy children [63] and later on for children between 6 and 18 years in a cohort of 1155 healthy non-obese and non-hypertensive children [64]. The study demonstrated low inter- and intraobserver variation, confirming the suitability of cIMT measurements as a surrogate marker of the vascular health status in multicenter trials.

Ultrasound studies in pediatric predialysis, dialysis and transplanted patients revealed significant alterations of the vessel wall compared to healthy controls, which start well before attainment of ESKD. This was first shown in smaller studies [65, 66] and confirmed in the large observational multicenter studies of CKiD and 4C.

CKD patients of the CKiD study showed increased cIMT which was correlated with hypertension and dyslipidemia [67]. The baseline evaluation of the 4C Study cohort revealed elevated cIMT in 42% of patients (Fig. 61.3) [68]. cIMT was higher in girls and associated with higher systolic blood pressure SDS, BMI SDS, physical activity and serum phosphorus [68].

Oxidative stress has been suspected as a potential factor involved in the pathogenesis of large vessel arteriopathy, but so far, few associations to the clinical vascular status have been reported in pediatric CKD. In 134 predialysis and dialysis patients aged 2–16 years, reduced glutathione levels but not other oxidative stress markers such as malondialdehyde, nitric oxide and homocysteine were found to be associated with cIMT [69].

In children with ESKD receiving **dialysis**, cIMT is more markedly increased than in the predialytic CKD population [58, 65, 69]. In these children cIMT is consistently linked to abnormal mineral metabolism and associated medications, as indicated by associations with serum phosphorus, calcium-phosphorus product, iPTH levels, and calcium based phosphate binder therapy. In addition, a strong association between active vitamin D dosage and cIMT was noted in the largest study of cIMT to date in pediatric dialysis patients [58]. Notably, not only an excess of active vitamin D but also 1.25 Vitamin D deficiency is a risk factor for increased cIMT in dialyzed children, constituting a U-shaped relationship of serum 1.25-vitamin D levels and cIMT [70].

Increased cIMT in pediatric **kidney transplant recipients** has consistently been demon-

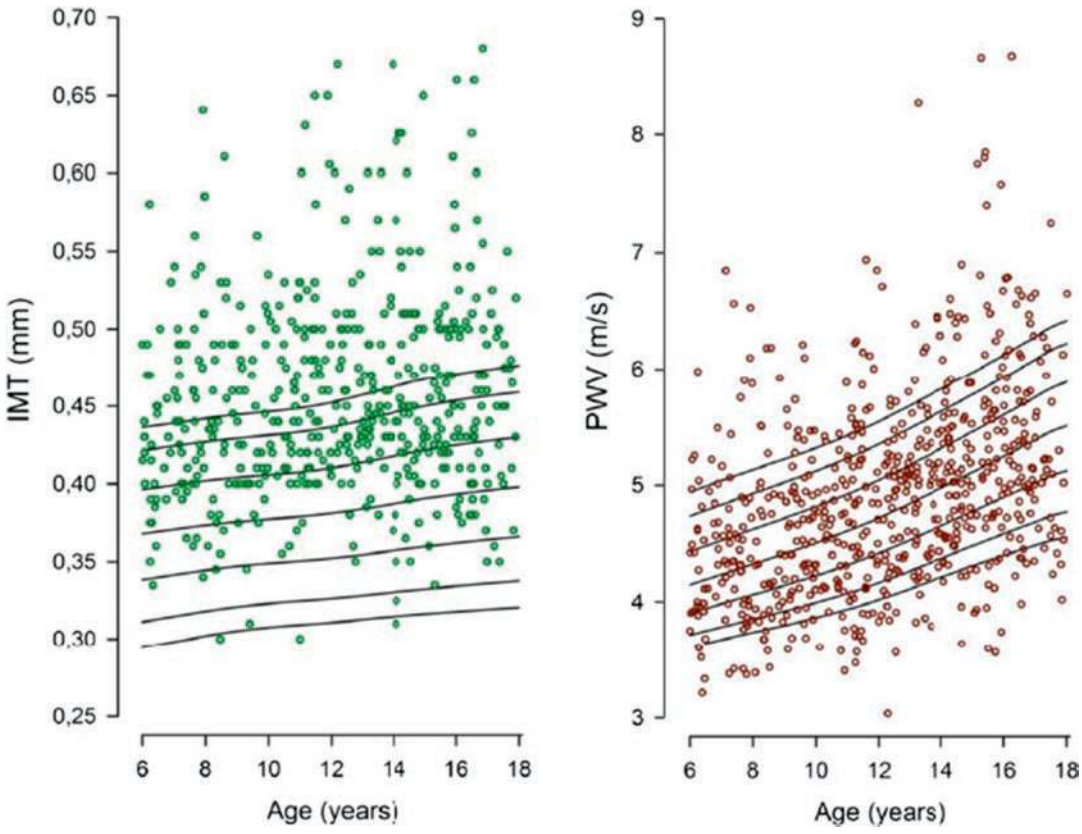

Fig. 61.3 Surrogate marker measurements. Distribution of carotid intima-media thickness (IMT; left panel) and pulse wave velocity (PWV; right panel). Curves represent 5th, 10th, 25th, 50th, 75th, 90th, and 95th reference percentiles. From Schaefer et al. [69]

strated. A meta-analysis of 2016 estimated that cIMT was about 0.05 mm higher in these patients than in healthy controls [71]. It included 9 studies and a total of 259 mostly kidney and few liver transplant patients. In a study of 109 children in three German centers, cIMT was elevated in 43% of patients with a kidney transplant [72].

There is scarce information about the progression of cIMT over time in children with CKD. Time on dialysis is associated with higher cIMT levels, as reported by Chavarria et al. in 60 dialyzed children [73] and by Oh et al. in 39 young adults with childhood-onset ESKD [6]. In a prospective study following 24 children with CKD stage 3–5 and 32 patients on dialysis, cIMT values increased both in the predialysis and the dialysis patients. By contrast, among patients who were transplanted during the observation period, those with elevated cIMT at baseline showed significant regression after transplantation [74]. In children of the 4C cohort who underwent pre-emptive kidney transplantation when reaching ESKD, cIMT did not regress but increased significantly less than in children who started dialysis [75].

Importantly, clinical morphologic measures appear to reflect structural changes even on the molecular level. In patients of the 4C Study, cIMT measured by ultrasound was correlated with arterial calcium content in arterial biopsies and corresponding transcriptional alterations regarding pro-calcifying factors, calcification inhibitors and extracellular matrix components were demonstrated [75].

Pulse Wave Velocity

In recent years, research has focused not only on morphological but also on functional measures of the vascular status. A variety of technologies to non-invasively assess arterial properties *in vivo* have been introduced. Among different techniques, pulse wave velocity (PWV) is one of the most studied in children with CKD. PWV is a measure of arterial stiffness derived from the propagation of the pulse wave along the vessel wall between two defined points of the arterial tree. Similarly to normal values of blood pressure, PWV is strongly age- and height-dependent and considerably lower in children and young adolescents than in adults. Therefore, age- or height normalized values should be used for the interpretation of PWV. The European Heart Association rates PWV as "gold-standard" to assess arterial stiffness and recommends its measurement for the evaluation of cardiovascular risk. In adults, a relationship to mortality independent of blood pressure and other confounding factors was demonstrated in 241 patients with ESKD and 439 patients with CKD stage 2–5 [76, 77]. Savant et al. reported PWV comparable to healthy children in a group of patients from the CKiD study with more than 50% of patients in CKD stage 1 or 2 [78]. The baseline assessment of children with **pre-dialytic CKD** of the 4C study (CKD stage 3–5) showed elevated PWV in 20% of patients (Fig. 61.3) [68]. PWV in these patients was associated with higher systolic blood pressure, albuminuria and iPTH and with lower vitamin D levels [68]. While slightly different methods were used in both studies (applanation tonometry vs. oscillometric recording) a turning point towards increasing arterial stiffness at CKD stage 3 might be implied.

Considerably increased PWV has been reported in several smaller studies in pediatric **dialysis** patients [58, 77, 79]. The 3H study found higher PWV in patients on conventional hemodialysis than in patients receiving hemodiafiltration [80]. PWV decreased over time in both groups.

Increased PWV has also been detected in a cross-sectional analysis of pediatric **transplant recipients** [81]. In a longitudinal analysis of 4C Study patients who started renal replacement therapy, PWV decreased after pre-emptive kidney transplantation but increased after the start of dialysis treatment [75]. The 4C study recently analyzed changes in PWV in children with ESKD who underwent kidney transplantation [82]. In their analysis, PWV significantly increased after transplantation and was significantly higher in girls compared to boys. PWV was positively associated with time on dialysis and diastolic blood pressure in both sexes. Authors concluded that girls with CKD are more susceptible to develop arterial stiffness compared to boys and that this difference persist after transplantation and might contribute to higher mortality rates seen in girls with kidney failure.

Blood pressure has been identified as the most important predictor for PWV in all CKD stages. In addition, associations to markers of CKD-MBD and uremic toxins have been described in pediatric cohorts [83–86]. There is also evidence that the NO pathway is altered in CKD which associates with measurements of arterial structure and function. Shroff et al. showed that HDL derived from pediatric CKD patients inhibited NO production in vitro, which was correlated inversely to measures of PWV and cIMT in these subjects [87].

ABPM and Ambulatory Arterial Stiffness Index (AASI)

Ambulatory Blood Pressure Monitoring (ABPM) does not only characterize BP status, rhythm and daily variability but can also provide information about vascular stiffness. The Ambulatory Arterial Stiffness Index (AASI) is computed as 1 minus the diastolic-on-systolic blood pressure slope of the linear regression line between 24-h ambulatory diastolic and systolic blood pressure readings. It was found highly correlated with PWV and the central and peripheral augmentation index. In children with hypertension, AASI is increased and associated with the duration and origin of hypertension [88]. In a study of 51 kidney transplant recipients, AASI was increased in hypertensive subjects and the main determinants were dipping time, volume overload and time on dialysis, while PWV was increased also in normotensive patients and predicted by a dialysis vintage of more than 1 year. This observation led to the interpretation that PWV might represent

structural long-term changes of the vessels, while AASI rather demonstrates the volume- and pressure-associated arterial stiffness [89]. While further evaluation of AASI as a cardiovascular marker is desirable, it could be a useful tool to monitor volume status and to adjust diuretic therapy [90].

Flow-Mediated Dilation, Postischemic Reactive Hyperemia

Endothelial-dependent flow-mediated dilation (FMD) measures the dilation of an artery after a short occlusion of the subjacent arteries. It depends on the potential of the vessel endothelium to produce nitric oxide (NO) or prostanoids to trigger vasodilatation and thereby characterizes endothelial reactivity and function [91]. Practically, the dilation of the brachial artery is measured by ultrasound at baseline and after the release of a BP cuff which has been placed on the upper arm or the forearm and has been inflated to approximately 50 mmHg above the systolic BP for several minutes. Despite a high interobserver and within-subject variability [92], a multitude of studies in adults have used FMD as surrogate marker for endothelial dysfunction. Several recent studies in adult CKD patients have demonstrated a reduction of FMD in both predialysis and dialysis patients [93]. Moreover, reduced FMD was predictive of fatal and non-fatal cardiovascular events in a prospective study of 304 adult predialysis patients [94]. The applicability of FMD in children is compromised by the limited tolerance to a BP cuff inflated over several minutes, and the unpleasant phase of hyperemia often prevents repeated measurements. Nevertheless a few small studies have been performed in children with CKD, two of which found decreased FMD in 23% and 71% of children with CKD stage 2–4 and 4, respectively [95, 96]. In another study which included predialysis, dialysis and transplanted patients, 60% had impaired FMD, which was significantly associated with cIMT [97]. A study of 44 pediatric patients after kidney transplantation found that treatment including everolimus resulted in reduced FMD compared to standard calcineurin inhibitor treatment [98]. While this study was cross-sectional only, it indicated that implications of different treatment regimens may become apparent by comparing surrogate endpoints, making them a feasible option also for prospective clinical trials.

Mechanisms of Vascular Calcification in CKD

Patients with CKD develop different types of vascular pathology. The predominant alteration consists of progressive calcification of the tunica media (Fig. 61.4). Additionally, calcification of

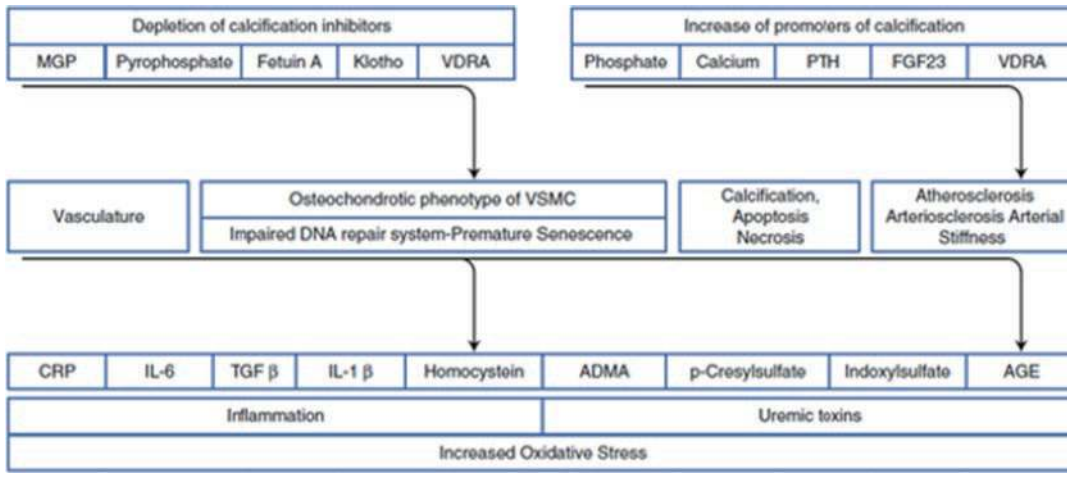

Fig. 61.4 Pathophysiologic mechanisms of vascular calcification. *MGP* Matrix Gla protein, *VDRA* vitamin D receptor agonist, *AGE* advanced glycosylation products, *ADMA* asymmetric dimethylarginin

the intima can occur and further deteriorate the vascular phenotype. Vascular smooth muscle cells (VSMC) play a key role in medial calcification. They are actively involved in calcification processes and undergo alterations including premature senescence and apoptosis, loss of calcification inhibitory capacities, osteogenic transformation and deposition of hydroxyapatite [99]. As a dysregulated mineral metabolism in CKD plays a key role in this process KDIGO explicitly includes "vascular or other soft-tissue calcification" in the definition of CKD-MBD [100]. The so-called kidney-vascular-bone axis reflects the direct and deleterious consequences of an unbalanced mineral metabolism on the vascular system.

The Kidney-Vascular-Bone Axis

In addition to hypertension and dyslipidemia, mineral metabolism plays a crucial role for vascular alterations in CKD. Among the directly or indirectly involved factors are serum levels of calcium, phosphate, vitamin D, PTH, FGF23 and Klotho.

Although serum calcium levels are usually low in untreated CKD patients, medications such as calcitriol and calcium-based phosphate binders can significantly increase serum calcium, especially in the presence of low-bone turnover disease. High calcium uptake by VSMC can induce matrix vesicle calcification similar to processes in the bone [101] and promote apoptosis of the cells leading to release of calcium in the extracellular matrix and formation of calcification "nidus" [102]. High phosphate levels are frequent in advanced CKD and might even occur at milder stages depending on phosphate intake. Phosphate is a key mediator of medial calcification. In vitro experiments have demonstrated that phosphate can induce an osteochondrogenic state in VSMC [103].

Given the outlined consequences of an altered mineral metabolism, a linear association of arterial deterioration and calcification with failing kidney function would seem logical. However, vessels of dialysis patients seem to be substantially more prone to calcification from hypercalcemia and hyperphosphatemia than vessels of healthy individuals, as demonstrated in both in vitro and in vivo models of human vessels. In a model of intact human vessels, Shroff et al. showed that calcium accumulation already started during pre-dialysis CKD while the number of VSMC and vessel architecture was normal. In dialysis vessels however, calcification was significantly accelerated and vessels showed deranged architecture, increased VSMC death and deposition of hydroxyapatite laden vesicles. In addition to high serum calcium levels, it is likely that reduced concentration or activity of calcification inhibitors such as Fetuin-A and MGP contribute to the calcification process [104, 105].

Calcium and phosphate levels are subject to tight regulatory circles. An important mechanism of phosphate homeostasis includes FGF23 and Klotho. FGF23 is induced by high phosphate levels, it increases urinary phosphate excretion and inhibits 1.25 vitamin D synthesis [106]. Klotho is a coreceptor for FGF23 and is involved in the regulation of phosphaturia and 1.25 vitamin D production [107]. There is a free soluble form, but it is also expressed in arteries and VSMC [108]. FGF23 is upregulated and vascular Klotho downregulated early in the course of CKD [109] and several studies have linked increased calcification to reduced vascular Klotho expression in CKD [108, 109]. Reversal of Klotho insufficiency by transgenic overexpression in mice with CKD ameliorated phosphate extretion, preserved renal function and decreased calcification, potentially identifying a new therapeutic option [110]. Increases in FGF23 have been linked to increased mortality independently of phosphate levels [111]. *In vitro*, FGF23 enhances phosphate-induced calcification [112] and *in vivo*, the severity of calcification in patients with a nonzero Agatston score is associated with FGF23 in CKD patients [113]. In children on dialysis with coronary artery calcification, Srivath et al. found significantly increased FGF23 levels compared to those without calcification [55]. In adults however, there are conflicting results about the role of FGF23 for vascular calcification, endothelial dysfunction and arterial elasticity [114, 115].

Regarding phosphate binders, there seem to be different effects on aortic calcification depend-

ing on the type of phosphate binder [116]. As there are no data about the effect of phosphate binders on arterial calcification and Klotho or FGF23 in children, future studies are recommendable to improve therapeutic approaches.

Calcium levels are controlled by vitamin D levels, which themselves play a role in vascular calcification. Besides increasing calcium levels, vitamin D receptor agonists themselves can induce calcification by induction of an osteoblast phenotype of VSMC [117]. They also increase the secretion of alkaline phosphatase, which can worsen the calcification inhibitory capacity of VSMC by degrading pyrophosphate, a potent calcification inhibitor [118]. However, there is also evidence from a mouse model that vitamin D receptor agonists induce Klotho and lower FGF23, thereby exerting a beneficial effect on medial calcification [119]. These contradictory observations may help to explain the bimodal relation between vitamin D levels and calcification in clinical studies [70].

Calcification Inhibitors

Evidently, additional or permissive factors contribute to the disposition of a vessel for calcification particularly in dialysis. In fact, healthy individuals benefit from strong inhibitors of calcification such as pyrophosphate, Fetuin A and MGP. These inhibitors are loaded in vesicles of VSMCs and are released in the presence of increased serum calcium scores. Under normal conditions these vesicles can prevent calcification, but if the inhibitory contents are compromised or if their capacity is overrun by extreme dysbalance of mineral homeostasis, hydroxyapatite crystals can form from these calcium-rich vesicles. Uptake of hydroxyapatite crystals in turn can lead to apoptosis and necrosis of VSMCs, further diminishing the calcification inhibitory capacity of the vessel [99]. This is the initiation of a vicious cycle as a consequence of the disturbed mineral metabolism in CKD and aggravated by abnormalities of mechanisms protective of calcification. Inhibitors of calcification have been studied extensively in adults and to a lesser extent in children with CKD.

The active form of **MGP** is y-carboxylated and antagonizes BMP signaling, which is involved in endothelial dysfunction, formation of vascular lesions calcification and neoangiogenesis [120]. Vitamin K deficiency, as it occurs e.g. with warfarin treatment or in CKD, therefore leads to reduced levels of active MGP and a disposition to increased calcification. But serum levels of MGP alone have no protective effect on calcification, instead MGP therefore has to be expressed in VSMC [121]. Accordingly, no associations of serum levels of undercarboxylated or y-carboxylated MGP to vascular measures have been identified in two studies with dialyzed and transplanted children [85, 122]. Nevertheless, histologically, pediatric dialysis patients showed deposition of undercarboxylated MGP in calcified vessels [104].

Fetuin A is a circulating calcification inhibitor and also a content of VSMC vesicles. In the presence of fetuin A, calcium and phosphate form soluble calciprotein particles instead of hydroxyapatite crystals and thereby prevent ectopic calcification [123]. In children, there are conflicting results of fetuin A levels in dialysis patients. One study found reduced fetuin levels in pediatric dialysis patients compared to healthy controls and children with mild CKD or after transplantation [124]. They were positively correlated with 25OHD dosage and calcium, but not with 25OHD serum levels. Another study found higher fetuin A serum levels in dialysis patients and an inverse correlation with time on dialysis. Vascular calcification was associated with lower fetuin A levels and vascular measures were inversely correlated to aoPWV and augmentation index [85]. Histologically, increased fetuin-A staining was demonstrated in calcified vessels of dialysis patients [105].

Promoters of Calcification and Premature Aging in CKD

There is evidence that the balance of vascular homeostasis shifts towards calcification not only by the loss of inhibitors but also by promoting factors. Uremic toxins induce oxidative stress which in turn hampers the ability of VSMC to

regenerate. Instead, a disabled DNA damage repair system leads to senescence of the cells. An important marker in this process is prelaminin A. Nuclear laminas are of essential significance for the nuclear integrity of cells, and prelamin A normally is converted to laminin A over several steps including farnesylation and subsequental cleavage by the metalloproteinase FACE1/Zmpste24. Oxidative stress induces a down-regulation of FACE1/Zmpste24 and thereby inhibits the completion of functional laminin A [125]. Other than being a biomarker for premature cell senescence, farnesylated prelamin A is possibly actively involved in cell damage, specifically to the nuclear structure. In vessels of pediatric dialysis patients, there was a high prelamin A deposition in calcified arteries which provoked a osteogenic differentiation of VSMC and a senescence-associated secretory phenotype with increased expression of bone morphogenetic protein 2, osteoprotegerin and interleukin 6 [126]. These factors in turn can induce osteogenic differentiation in endothelial and mesenchymal progenitor cells, hereby involving also the vessel endothelium and initiating yet another vicious cycle in the calcification process [127].

Uremic Toxins and Endothelial Dysfunction

Another important pathway of vascular damage is endothelial dysfunction, triggered by the uremic milieu and accumulating toxins. Uremic toxins can be either water-soluble or protein-bound, accumulating either by reduced excretion or alterations of metabolic pathways in uremia. Besides well-studied factors such as homocystein, recently discovered toxins include *p*-cresylsulfate, indoxylsulfate, aysmmetric dimethylarginin (ADMA), advanced glycation endproducts and many more.

Hyperhomocysteinemia is a well-known risk factor for ischemic heart disease and stroke [128]. Homocysteine impairs endothelial function and inhibits endothelium-dependent vasodilatation. It also inhibits angiogenesis and endothelial repair [129]. Plenty of studies have linked homocysteine levels to increased mortality in adults. The highest homocysteine levels in this regard are found in patients with mutations in enzymes or cofactors of the homocysteine metabolism. Also in dialysis patients, homocystein is significantly increased compared to the normal population and high values are associated with an elevated risk for vascular complications [130]. According to a meta-analysis of Wald et al. [131] the risk for ischaemic heart disease, pulmonary embolism and stroke increases with homocysteine levels as identified by comparing individuals with genetically caused higher homocysteine levels to controls without the mutation. However, several controlled clinical trials including trials with CKD patients have failed to show a beneficial outcome when homocystein levels were reduced by substituting folic acid together with either vitamin B6, vitamin B12 or both [132–134]. Several explanations have been proposed to explain this, for example the fact that most studies treated patients with only mildly elevated homocysteine, which might not lead to a measurable effect. Also, homocysteine might be not the real culprit but only a measurable effect of yet another toxic agent. Finally, folic acid, the treatment for hyperhomocysteinemia, increases levels of S-adenosylmethionin, which in turn can increase ADMA levels by providing a methyl donor group to N-methyltransferases. By increasing another uremic toxin, this might partly explain the failure of folic acid to prevent cardiovascular disease by reducing homocysteine [135]. Data about homocysteine and the vascular status in children with CKD is scarce; one small study showed no associations of homocysteine to the cardiovascular status as assessed by flow-mediated dilation of the brachial artery and cIMT [97].

ADMA is a methylated L-arginine derivative which accumulates in chronic kidney disease [136]. It is protein-bound and therefore poorly dialzed. *In vitro* ADMA production is increased by activation of the NADPH oxidase and *in vivo* by angiotensin II infusion [137]. ADMA inhibits NO production, which leads to an increase of systemic vascular resistance, blood pressure and sodium retention [138]. Furthermore, it promotes an inflammatory phenotype and premature senescence of endothelial cells [129]. In children with

CKD stage 1 to 4, increased systolic BP and non-dipping nocturnal BP in 24 h BP measurements were found associated with increased ADMA relative to arginine and symmetric dimethylarginine levels in the urine [139].

***p*-cresylsulfate** and **indoxylsulfate** are produced by intestinal bacterial from *p*-cresol and tryptophan respectively. The EUTox working group analyzed *p*-cresylsulfate and indoxylsulfate in 139 adult patients and both were inversely correlated with renal function and mortality [140, 141]. *p*-Cresyl sulfate was also positively correlated with vascular calcification and mortality [140]. Indoxyl sulfate was associated with vascular calcification and pulse wave velocity [141]. In 609 children with CKD from the 4C Study cohort, serum levels of indoxyl sulfate and *p*-cresylsulfate at the baseline visit were inversely correlated with eGFR. Serum indoxyl sulfate levels were associated with higher cIMT and progression of PWV within 12 months of follow-up [86]. Indoxyl sulfate, but not *p*-cresyl sulfate levels were also independently associated with the prospective loss of kidney function in the same study cohort [142].

The Heart in Pediatric CKD

Cardiac Remodeling

Cardiac remodeling is a chronic and progressive process resulting in genome expression, molecular, cellular, and interstitial transformations that manifest as changes in the size, shape, and function of the heart after cardiac injury [143]. The triggers that initiate cardiac injury are diverse. In case of CKD, mechanical or hemodynamic overload is the initial stimulus, although hormones and cytokines may play an important role in its maintenance. The first response to imposed pressure or volume overload is the hypertrophy of cardiomyocytes (Fig. 61.5). The patterns of sarcomere formation induced by pressure or volume overload are distinct. Pressure-induced hypertrophy, concentric LVH, is characterized by a parallel addition of sarcomeres resulting in the increase of cross-sectional area and diameter of the myocytes. Concentric LVH is closely associated with systolic or pulse pressure. From a physiological view, increased systolic BP and pulse pressure due to increased peripheral resistance and arterial stiffness are the principal factors opposing LV ejection and leading to increased LV workload. With volume-induced hypertrophy, eccentric LVH, addition of sarcomeres occurs in series resulting in longitudinal cell growth with secondary addition of new sarcomeres in parallel. Both myocyte diameter and length are proportionally increased, resulting in a balanced increase in overall wall thickness and LV volume. In the transition to maladaptive LVH, LV dilatation becomes disproportional to wall thickness with myocytes elongated without an increase in diameter.

In patients with CKD, the principal features of volume-induced LV enlargement include volume and sodium retention, anemia, and arteriovenous shunt.

Experimental models of cardiac hypertrophy developed over the last two decades support the theory that mechanical stress due to either pressure or volume overload is a trigger for activation of multiple other mechanisms leading to myocardial remodeling [144, 145]. These factors include metabolic defects in fuel utilization and efficiency, inflammatory responses, lipotoxicity, pathological growth of myocytes and loss of cytoprotective signaling [145]. In patients with CKD, these mechanisms might be activated independently of hemodynamic overload since uremia *per se* is associated with alteration in multiple factors [146–148].

Studies over the last decade have identified fibroblast growth factor 23 (**FGF23**), a bone-derived circulating peptide, as a novel CKD-related risk factor in the development of LVH. Plasma concentrations of FGF23 increase early and progressively in both children [149] and adults [150] with advancing CKD. High FGF23 is associated with premature death [111, 151], cardiovascular events [152], and LVH [153, 154], with experimental data favoring a direct pathophysiologic role of FGF23 in promoting LVH via an FGF receptor 4-dependent pathway [155, 156]. The CKiD study determined that among children and adolescents with GFR

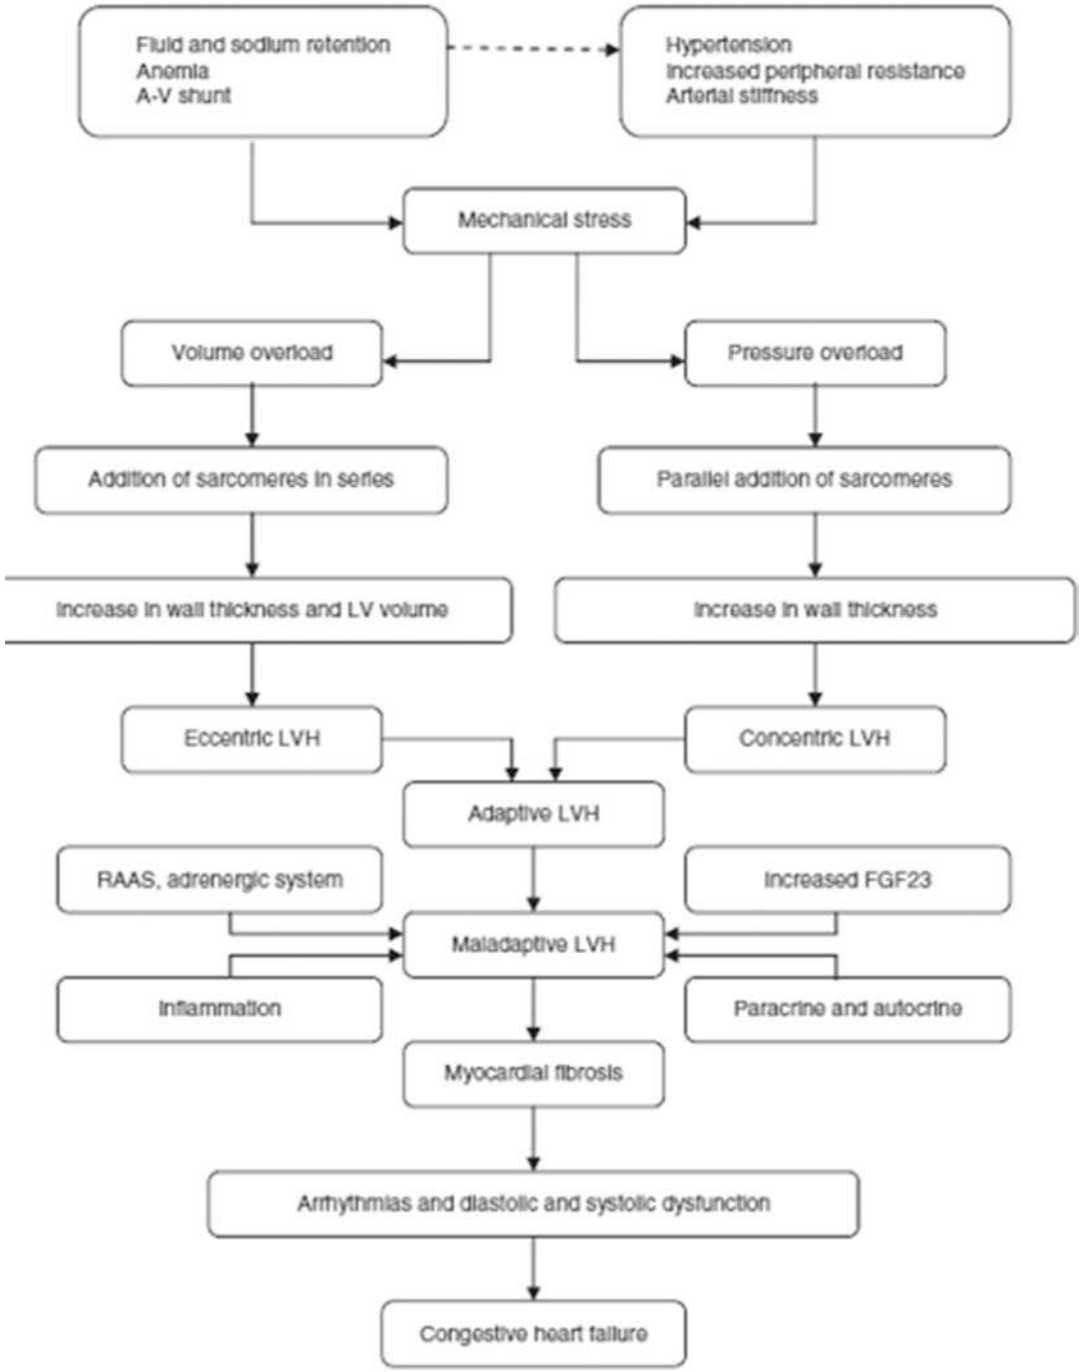

Fig. 61.5 Pathophysiologic mechanisms of LVH. Myocyte hypertrophy is likely an adaptive mechanism designed to improve pump function by expanding the number of contractile units in the myocardium while simultaneously reducing wall stress by increasing wall thickness. The transduction of mechanical stress occurs through the integrin proteins, transmembrane receptors that couple extra cellular matrix components directly to the intracellular cytoskeleton and nucleus. A signal for hypertrophy is mediated by a complex cascade of signaling systems within cardiomyocytes resulting in gene reprogramming. Activated hypertrophy-related genes induce the synthesis of new contractile proteins that are organized into new sarcomeres

≥45 mL/min per 1.73 m^2, higher plasma FGF23 concentrations were independently associated with a higher prevalence of LVH [157]. This association was strongest in participants with FGF23 levels ≥170 RU/mL in whom the odds of LVH was three times higher than in those with FGF23 levels <100 RU/mL.

One of the possible mechanisms of LVH and LV dysfunction is abnormal sphingolipid metabolism leading to **cardiac lipotoxicity**. This condition leading to dilated cardiomyopathy has been described in congenitally obese Zucker diabetic fatty (ZDF) rats [158] and in adults with obesity and diabetes [159]. This is especially relevant to CKD patients, a population with a high prevalence of obesity, metabolic syndrome, and diabetes. In adult incident hemodialysis patients, Mitsnefes et al. [160] demonstrated that high plasma glucosylceramides were consistently and independently associated with CVD outcomes including uncontrolled hypertension, LVH, and decreased ejection fraction. The authors also reported that higher levels of glucosylceramide, C16GC, were associated with increased risk of CVD and all-cause mortality independent of diabetes, comorbidity index, and lipid levels.

A recent study demonstrated that mice with CKD had **T cells** infiltrating the heart and T cell depletion significantly improved both diastolic function and myocardial strain [161]. In the same study, children with CKD had increasing frequency of T cells bearing activation markers PD-1 and/or CD57 that was associated with worsening diastolic function on echocardiogram.

The association of different biomarkers with abnormal cardiac structure and function was examined in the Chronic Renal Insufficiency Cohort (CRIC) Study [162]. The researchers found that the novel biomarker growth differentiation factor 15 (**GDF-15**), a marker of inflammation and tissue injury, and clinical biomarkers N-terminal pro-B-type natriuretic peptide (**NT-proBNP**) and high-sensitivity troponin T (**hsTnT**), were associated with increased LVM and systolic dysfunction.

Initially, LVH is beneficial. It optimizes ejection performance by normalizing systolic wall stress and reducing tension among greater number of sarcomeres. Maladaptive cardiac hypertrophy which develops secondary to prolonged and proportionally increased pressure and volume overload (see above) with declined renal function is a proposed mechanism of congestive heart failure. This in turn results in excessive cardiac myocyte work relative to the supply of oxygen. As a consequence, myocyte death and fibrosis develops, with chamber dilatation and systolic dysfunction. However, the specific mechanisms of *cardiac myocyte death* are not well-determined. Unlike in direct cardiac injury (e.g. acute ischemia) where both necrosis and apoptosis produce cell death, chronic remodeling and transition to overt heart failure have been associated primarily with an elevated degree of apoptosis. However, it is not clear whether apoptosis is a cause or consequence of heart failure. With time, capillary density, coronary reserve and subendocardial perfusion decrease resulting in myocardial fibrosis [163]. *Intermyocardiocyte fibrosis* is a unique feature of uremic heart disease. Experimental uremic models showed selective increase in cardiac interstitial cells and nuclear volume but not in endothelial cell volume [164]. During this phase, patients present with arrhythmias and diastolic and systolic dysfunction, ultimately transitioning to overt heart failure.

Early Markers of Cardiomyopathy

Since symptomatic CVD is very rare in children, the focus of research has been on identifying in children with CKD early markers or intermediate CV outcomes. Over the last two decades, echocardiographically detected abnormalities of the LV such as LVH and LV dysfunction have been accepted as early markers of cardiomyopathy. In adults, the CRIC study demonstrated that the prevalence of LVH was 32%, 48%, 57%, and 75% for eGFR categories ≥60, 45–59, 30–44, and <30 mL/min per 1.73 m^2, respectively [165]. These abnormalities historically have been considered as strong independent predictors of coronary artery disease, heart failure and cardiac mortality both in the general population and in adults with hypertension and CKD. As early as in 1989, Silberberg et al. [166] showed that adult

patients on maintenance dialysis who were diagnosed with LVH had a 52% higher 5-year mortality rate than patients without LVH. A few years later, Foley et al. [167] determined that LV dilatation and systolic dysfunction at start of dialysis were independently associated with mortality. The results of these studies triggered an investigation of cardiac structure and function in pediatric patients with CKD. Studies over last two decades have proven that abnormalities of LV are also present in children with CKD.

Evaluation of LVM in Children

M mode echocardiographic measurement is currently the most commonly clinically used imaging modality to assess LVM. The LVM is calculated according to recommendations from the American Society of Echocardiography [168]. This method applies measurements of LV end-diastolic diameter (LVED) and septal (IVS) and posterior wall (PW) thicknesses and accurately predicts LVM through the equation: $0.8[1.04\{[LVED + PW + IVS]^3 - LVED^3\}.] + 0.6$. Adjusting the calculated LVM to account for differences in age, height and weight is the next step to establish uniform reference values and criteria for LVH. Unfortunately, there is no uniform definition of LVH in children. The most ideal *indexing* parameter is lean body mass (LBM), but this is difficult to measure. Indexing LVM by patient height raised to approximately cubic exponential power has been shown to produce the greatest reduction in LVM variability in normal subjects, most correctly to detect differences between normal and obese subjects [169], and, importantly, correlates most closely to indexing by lean body mass [170]. However, in children, dispersion of residual variation of LVM/height$^{2.7}$ increases with either increasing height or age suggesting that other variables effect ventricular growth in children. Though further investigation is needed to determine the most ideal indexing parameter, dividing LVM by height$^{2.7}$ (g/m$^{2.7}$) seems to work well for older children and adolescents [171]. For children older than 9 years, the value of LVM index 95th percentile is relatively stable and is 38–42 g/m$^{2.7}$. The most recent American Academy of Pediatrics Clinical Practice Guidelines (CPG) published in 2017 for screening and management of high BP in children and adolescents formally recommend LVM index value of 51 g/m$^{2.7}$ as a conservative cut point to define LVH in children >8 years of age [172]. This value is above 99th percentile for children and adolescents and associated with up to a fourfold increase in cardiovascular morbidity in adults with hypertension [171]. The use of this value to define LVH in young children is problematic since the normative values for LVM index (g/m$^{2.7}$) are significantly higher than in older children as can be seen in study by Khoury et who published pediatric reference values for LVM index (g/m$^{2.7}$) based on the analysis of 2273 non-obese, healthy children and adolescents (0–18 years) [173] (Table 61.2. The data indicate that indexing of LVM to a power of height$^{2.7}$ is age and gender specific. For example, the 95th percentile for LVM index varies from 40 to 45 g/m$^{2.7}$ in adolescent girls and boys to about 70 g/m$^{2.7}$ in one-year old children; boys have a slightly larger LVM for a given height throughout childhood and adolescence (Fig. 61.6).

One of the potential pitfalls in using age-dependent LVM indexing in children with CKD is related to short stature. Foster et al. [174] demonstrated that LVMI (g/m$^{2.7}$) varies not only according to age but also according to absolute height with higher values in children with shorter height, especially in those with height < 110 cm. Given that the CKD patients have significantly reduced height relative to age, poor growth may result in some miss-classification of diagnosis of LVH in very young children. To account for short stature, Borzych et al. [175] suggested substituting chronological age by height age (*i.e.*, the age of a child of the same height growing at the 50th height percentile) using Khoury et al. [173] references. Chinali et al. studied 400 healthy children and proposed to use a single value of 45 g/m$^{2.16}$ across the whole pediatric age range to diagnose LVH, arguing that the allometric exponent 2.16 fully normalizes the LVMI in children of all ages and both sexes and removes the need to calculate specific percentiles for height and sex (Fig. 61.7) [176]. This alternative method of indexing LVM is promising and potentially, if validated in larger

Table 61.2 LVM (g) and LVMI (g/m$^{2.7}$) percentile values

LVM left ventricular mass, *LVMI* left ventricular mass index (with permission of Elsevier from Khoury et al. [173])

studies, could replace currently utilized normative data.

Cardiac MRI is considered to be the most accurate imaging modality to measure LVM. While the normative pediatric percentile values have been developed [177], this modality has limited availability and still remains too expansive to recommend it for routine use. In addition to measurement of LVM, M mode echocardiography can be used to define *LV geometric pattern* (Fig. 61.8).

LV geometry is evaluated based on the 95th percentiles for LVM index and relative wall thickness. Relative wall thickness (RWT) is calculated from measurements made at end diastole as the ratio of the PW thickness plus IVS thickness over the LVED. Normal geometry is defined as LVM index and RWT below the 95th percentile. Concentric remodeling is defined as LVM index below the 95th percentile with RWT greater than the 95th percentile. Eccentric LVH is defined as LVM index greater than the 95th percentile and RWT below the 95th percentile. Concentric LVH is defined as both LVM index and RWT greater than the 95th percentile. As in case of LVM index, the 95th percentile values for RWT are not uniform and vary from 0.375 to 0.41. Thus, the frequencies of different geometric patterns may differ depending on the cut off points used in the study.

Studies of LVH in Children with CKD

As in adults, LVH develops when **CKD** is mild or moderate in children and progresses as kidney function deteriorates. The baseline data on LVH from the CKiD cohort indicated a prevalence of 17% [31]. In this study, in addition to confirmed hypertension (elevated casual and ambulatory BP) and lower hemoglobin, masked hypertension (normal casual BP and elevated ambulatory BP) and female gender were independently associated with LVH. The likelihood of having LVH was four times higher in children having masked hypertension compared to children with normal clinic and ambulatory BP. The follow up study determined that over 4 years, the prevalence of LVH diminished from 16% to 11% [178]. Decrease in BP corresponded to regression of LVH in these children. As in the cross-sectional baseline analysis, the likelihood of developing of LVH was four times higher in females. The 4C study reported an increase in the prevalence of LVH from 10.6% in CKD stage 3a to 48% in CKD stage 5 [68].

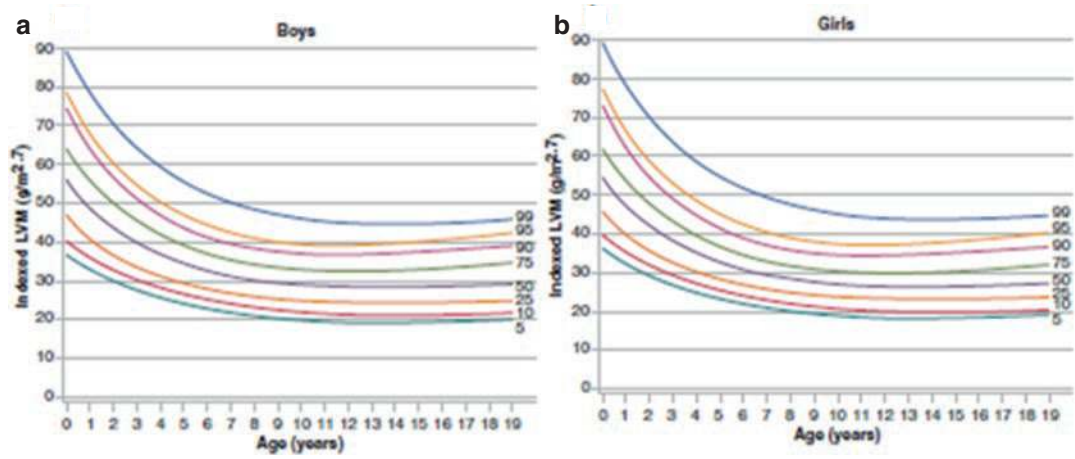

Fig. 61.6 The estimates of the 5th, 10th, 25th, 50th, 75th, 90th, and 95th quantiles of LVM indexed to height$^{2.7}$ for ages 0 through 18 years. Values displayed separately for boys (**a**) and girls (**b**) (used with permission of Elsevier from Khoury et al [173])

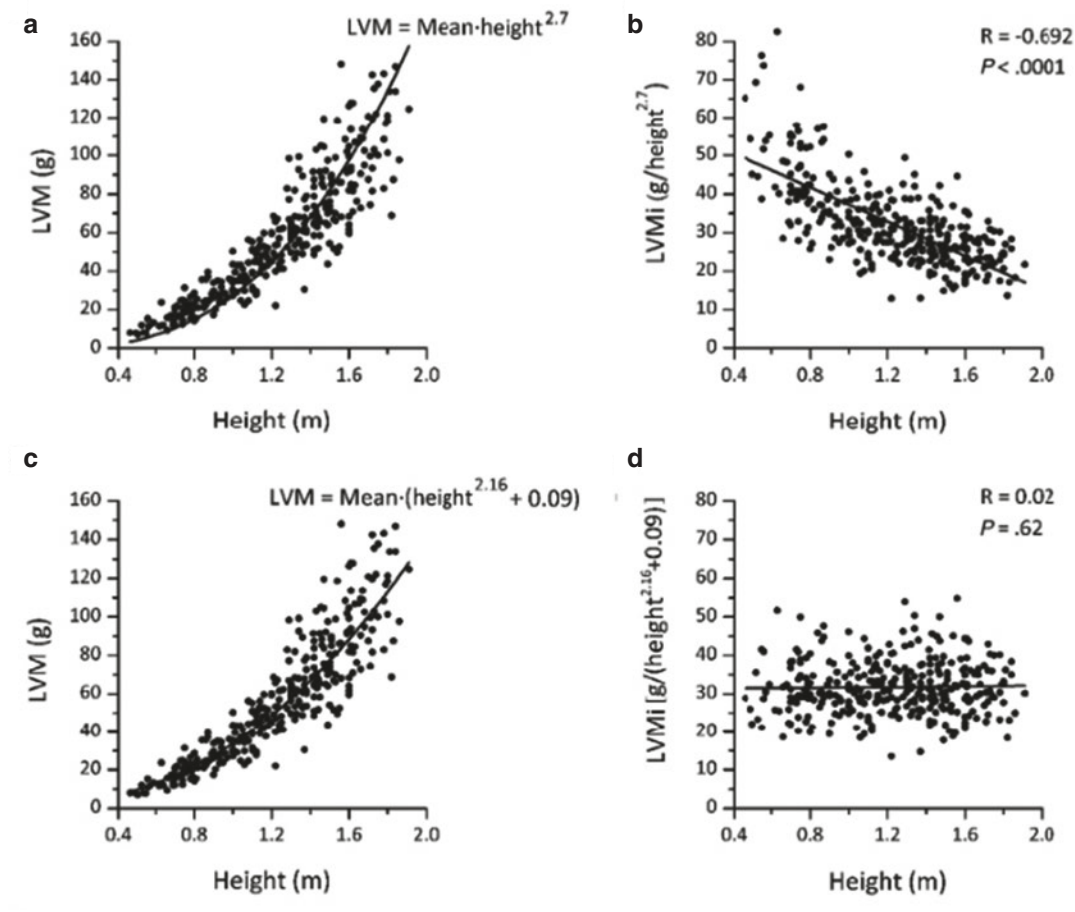

Fig. 61.7 (**a**) Regression of LVM with height 2.7; (**b**) distribution of residuals for height 2.7; (**c**) regression of LVM with height2.16; (**d**) distribution of residuals for height2.16; and. *LVMi* LVM index (adapted and used with permission of Elsevier from Chinali et al [176])

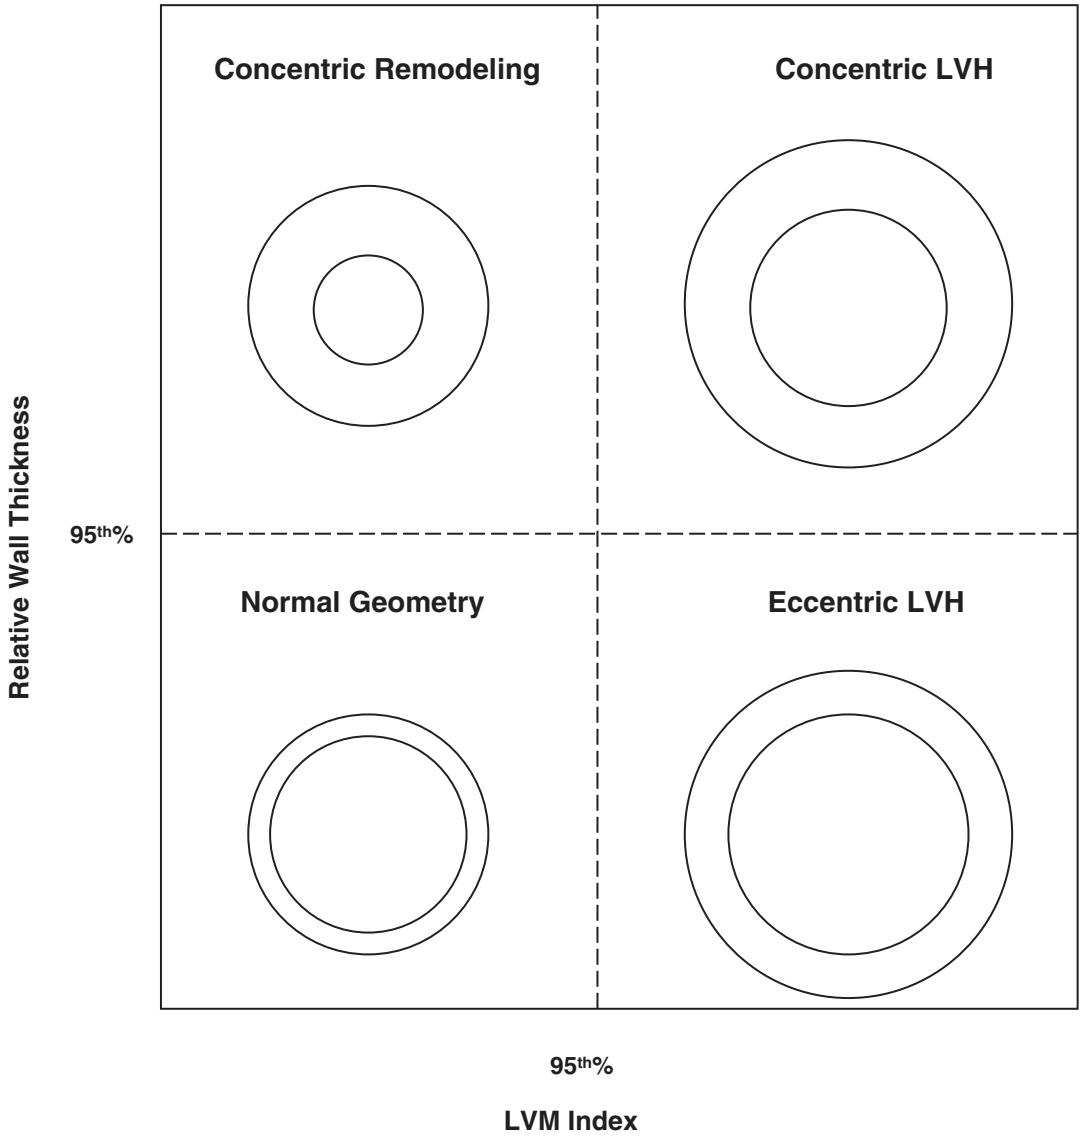

Fig. 61.8 LV geometry

Since the early 2000s there have been many studies around the world evaluating LVH in patients on maintenance **dialysis** and all indicated a much higher prevalence of LVH (40–80%) [18, 179–185] than in children prior to dialysis or after kidney transplantation. Small retrospective studies also suggest that with a better BP and volume control LVH regression might be achieved in young patients on dialysis [179, 180, 186]. The largest retrospective analysis from the International Pediatric Peritoneal Dialysis Network (IPPN), using height-age adjusted normative values for LVMI [175], demonstrated an overall LVH prevalence of 48.1% [187]. In the prospective analysis, the incidence of LVH developing *de novo* in patients with normal baseline LVM was 29%, and the incidence of regression from LVH to normal LVM 40% per year on PD. Transformation to and regression from concentric LV geometry occurred in 36% and 28% of the patients, respectively. Hypertension, high body mass index, use of continuous ambulatory peritoneal dialysis, renal disease other than hypo/dyspla-

sia, and hyperparathyroidism were identified as independent predictors of LVH.

As in children prior to transplantation, most single-center pediatric studies indicate that LVH remains common (30–50%) **post-transplant** and relates to not adequately controlled blood pressure [181, 188–193]. A study from the Midwest Pediatric Nephrology Consortium (MWPNC) showed that LVH was significantly more common in those with metabolic syndrome (55%) than in those without (32%) [40]. In contrast to the above studies, some studies showed a significantly lower frequency of LVH. Englund et al. [194] reported the results of a longitudinal analysis of children who received renal transplants 10–20 years ago. Of 53 children who received a renal transplant between 1981 and 1991, 47 survived and were observed for 10 to 20 years. Before primary transplant, 51% of the 53 children were prescribed antihypertensive treatment. At the 10-year follow-up, echocardiography showed minor LVH in only two children with hypertension. No child without hypertension at 10 years showed LVH. Progressive aortic insufficiency was discovered in two children, one of whom had a supravalvular aortic aneurysm requiring surgical repair 10 years after transplant. Low prevalence of LVH post-transplant (4.5%) attributed to well-controlled ambulatory blood pressure was observed in a study by Balzano et al. [195].

There are have been few small studies assessing LVH status in children with CKD using cardiac MRI. In a study by Schaefer et al. [196], LVH has been demonstrated in 12 of 15 (80%) patients with CKD, while the prevalence of LVH was seven of 18 (39%) in the transplant patient group. Avendt et al. [197] found only 3 of 20 patients on maintenance dialysis and 1 of 18 patients post kidney transplant to have LVH. In the largest study to date (n = 120) utilizing cardiac MRI, Cheang et al. [198] demonstrated increased LV mass to volume ratio (MVR) in children with severe CKD suggesting LV concentric remodeling.

Left Ventricular Function and Pediatric CKD

In contrast to adults, in whom *systolic dysfunction* is frequently associated with early cardiac failure and decreased survival, in children with CKD systolic LV function is usually preserved [181, 199, 200]. The majority of pediatric studies have examined LV systolic performance using indices of performance which are dependent on loading conditions. This presents a major problem in patients with CKD or on dialysis because they may have substantial alteration of preload and afterload. A load independent index of contractility can be determined based on the relation between heart rate-corrected velocity of circumferential fiber shortening (VCF) and end-systolic wall stress (WS) by calculation of the difference between measured and predicted VCF for the calculated WS [201]. Using this index, Mitsnefes et al. [202] showed that children with CKD or on maintenance dialysis had increased LV contractility at rest. However, patients on dialysis had decreased contractile reserve during exercise, which might herald the development of a maladaptive stage of LVH. The mechanism of increased contractility in pediatric patients with CKD is not clear. The combination of increased heart rate, cardiac output and hypertension in these patients is consistent with a hyperdynamic circulation and suggests the possible role of sympathetic overactivity. Similar results were demonstrated in a more recent study by Gu et al. [203].

A study from the ESCAPE trial argues that subclinical systolic dysfunction is already present in predialysis children [204]. The authors analyzed LV shortening at the midwall level (midwall shortening [mS]), which more accurately reflects the contractile force independent of pathologic changes in LV geometry [205, 206]. Using this index, the study determined that the prevalence of subclinical systolic dysfunction as defined by impaired mS was more than five-fold higher in patients with CKD compared with control subjects (24.6 *versus* 4.5%; $P < 0.001$). Systolic dysfunction was most common (48%) in

patients with concentric hypertrophy and associated with lower hemoglobin levels. The authors concluded that the combination of concentric LV geometry with midwall dysfunction might represent a cardiac phenotype designating an increased risk for development of overt CVD.

Additional, more novel and sensitive, assessments of cardiac systolic function, including strain and strain rate, have been shown to detect differences in function prior to ejection or shortening fraction in a variety of populations, such as Duchenne muscular dystrophy [207], sickle cell disease [208] and survivors of childhood acute leukemia [209]. An analysis of the 4C study showed a high prevalence of subclinical systolic dysfunction in children with CKD characterized by lower radial and circumferential LV strain paired with a mild cardiac systolic dyssynchrony [210].

Relatively few studies have assessed *LV diastolic function* in pediatric patients with CKD [181, 200, 211–214]. Doppler measurement of mitral inflow velocity has been the most widely used method to assess LV diastolic function. Unfortunately, the transmitral Doppler velocities and, therefore the E/A ratio, are affected by several factors, including left atrial pressure and preload. This is particularly important for patients with advanced CKD, since many of them are hypervolemic. Tissue Doppler Imaging (TDI) is a more reliable method to assess diastolic function in CKD patients since it is less load dependent and provides a more accurate measure of diastolic function. Studies employing TDI determined that children with CKD have abnormal diastolic function [211, 212]. In these studies, children on maintenance dialysis had significantly worse diastolic function than children with mild-to-moderate CKD or post-transplant. Poor diastolic function in patients on dialysis was associated with anemia, hyperphosphatemia, increased calcium-phosphorus ion product and LVH. Data from the 4C study demonstrated an independent association of worse E/e', a marker of LV compliance, with higher systolic BP and a better E/e' z-score with RAS inhibition [214]. Recent data from the CKID study showed that 15% of participants had abnormally high E/e' ratio [215]. In adjusted analysis, a higher E/e′ ratio was independently associated with ambulatory (sustained) hypertension, higher LVM index *Z* score, increased BMI *Z* score, lower hemoglobin, higher phosphorus level, and younger age. Casual blood pressure was not significantly associated with higher E/e′. These data indicated that ambulatory blood pressure might better identify children with CKD at risk for subclinical cardiac dysfunction than clinic blood pressure alone. Long-term significance of diastolic dysfunction in pediatric patients with CKD is not known. Longitudinal studies are necessary to determine if abnormal diastolic function predicts the development of systolic dysfunction and congestive heart failure in these patients.

Hothi et al. [216]. measured myocardial stunning as a marker of cardiac function in children on maintanence hemodialysis. Eleven of 12 patients developed myocardial stunning with varying degrees of compensatory hyperkinesis in unaffected segments, maintaining left ventricular ejection fraction throughout treatment. Recently, these authors evaluated regional LV function and mechanical synchronicity echographically by two-dimensional segmental longitudinal, circumferential and radial myocardial strain [217]. All patients were assessed pre-dialysis and at the end of dialysis. Radial strain was lower in uremic patients and increased during HD. Circumferential strain was preserved in uremic patients and fell during HD. Intrasegmental deformation synchronicity was progressively worse pre-dialysis and end of dialysis compared with controls. Some observations suggest that cardiac MRI and MR Spectroscopy could play a potentially useful role in the early detection and monitoring of cardiac dysfunction in children with CKD. Malatesta-Munter et al. [218] studied the biomarkers of cardiac function that included peak LV myocardial circumferential strain (Ecc) to assess regional LV function, T2 relaxation time to quantify myo-

cardial structural composition, and phosphocreatinine/ATP (PCr/ATP) ratio from phosphorus-31 Magnetic Resonance Spectroscopy (^{31}P MRS) to assess muscle energy metabolism. This report demonstrated decreased Ecc (45%), decreased energy metabolism and abnormal myocardial micro-composition. These abnormalities were detected despite uniformly normal ejection fractions.

Clinical Approach to CVD in Children with CKD

The primary goal to prevent and minimize development of CVD in children with CKD is avoidance of long-term dialysis and preemptive transplantation if feasible. For those children who must have long-term dialysis, the strategy is directly linked to achievement of adequate dialysis outcomes, including aggressive monitoring and management of hypertension, dyslipidemia, mineral metabolism, anemia, nutrition, inflammation, and other dialysis complications. Unfortunately, achieving recommended Kt/V urea does not necessarily lead to control of the above problems. Epidemiologic data on cardiac death in both peritoneal dialysis and hemodialysis clearly indicate that current dialysis adequacy recommendations based on Kt/V are not adequate to decrease CVD morbidity in children with ESKD. Unlike in adults, there have been no randomized pediatric studies examining the role of more frequent or nocturnal hemodialysis in cardiac outcomes. However, small single-center studies of frequent or nocturnal dialysis indicate clinically important improvement in children' health including growth, hypertension, cardiac hypertrophy and function [219–222]. Hemodiafiltration (HDF) is also advocated as a preferred dialysis modality that might improve cardiovascular health in children with ESKD. Results from the HDF, Heart and Height (3H) study, a nonrandomized observational study comparing outcomes on conventional hemodialysis (HD) versus postdilution online HDF in children showed that HDF was associated with a lack of progression in vascular measures versus progression with HD, as well as an increase in height not seen in the HD cohort [223]. The study also indicated improved patient-related outcomes among children on HDF correlating with improved BP control and clearances. Taking the potential for a longer and possibly more productive life, the benefits of HDF, more frequent and longer dialysis treatment might be more far reaching in children than in older adults [224].

Otherwise, management strategies should be specific to the stage of CKD (predialysis, dialysis, or transplant) as each has a unique subset of common risk factors. KDOQI and/or KDIGO recommendations for the management of most common individual CV risk factors are relatively recent but overall these guidelines are not based on strong evidence, especially when applied to children. For these reasons, the recommendations should always be tailored to the specific patient. Typically, separate recommendations are provided for advanced and end-stage kidney disease.

As in the general pediatric population, traditional risk factors like hypertension, dyslipidemia, and obesity should be a primary focus in CV risk reduction in children with CKD. In addition, evaluation and treatment of mineral metabolism abnormalities should be a prioritized focus of management.

Hypertension

The most recent 2012 KDIGO recommendations on BP control are restricted to non-dialysis (CKD and transplant) patients only [225]. These guidelines do not focus on methodological or diagnostic issues or lifestyle modification options to treat hypertension and are restricted to pharmacological treatment only. The recommendations are based on renal outcomes; however, because of the association of hypertension with LVH and increased cIMT, they can be reasonably applied to prevent and minimize CV outcomes. The BP targets refer to manual auscultatory BP. However, some of the recommendations are based on the results of studies

utilizing ambulatory blood pressure monitoring. Since the publication of the 2012 KDIGO recommendations, there have been updated guidelines on management of BP in children from USA, Europe and Canada. While these updated guidelines are generally consistent with KDIGO recommendations, they are not identical. There are three main recommendations. First, KDIGO recommends initiation of BP lowering treatment when BP is consistently above the 90th percentile for age, sex, and height (1C level of evidence). This recommendation is consistent with the Canadian guidelines [226] but not with that of the 2017 AAP [172] or 2016 European Society of Hypertension (ESH) guidelines [227], which recommend starting BP medications if BP is consistently above the 95th percentile in the general pediatric population. The AAP 2017 also recommends using adult guidelines for initiating treatment (BP is >130/80 mmHg) for children aged 13 years and older. However, some of these patients might have small stature and may require a lower BP threshold to initiate treatment.

The second recommendation is to lower manually obtained clinic BP below 50th percentile for age, sex, and height, particularly for those children who have proteinuria (2D level of evidence). However, this recommendation is based on the results of the ESCAPE study even though the ESCAPE trial used mean arterial pressure from ABPM to classify BP [228]. A 2017 KDIGO controversy conference report on BP in kidney disease advised to revise this recommendation accordingly [229]. However, because ABPM is not widely available, the conference also recommended using oscillometric devices as an alternative.

The third recommendation is the use of ACEI or ARB irrespective of the level of proteinuria. Despite only 2D level of evidence, this recommendation is relatively well accepted by the pediatric nephrology community. The KDIGO guidelines are slightly different from the 2016 ESH guidelines [227]. Based largely on the ESCAPE trial results, ESH guidelines recommend that in children with CKD, BP targets should be below the 50th percentile in the presence of proteinuria (the same as KDIGO) and below the 75th percentile (versus 90th percentile KDIGO) in the absence of proteinuria.

In the child on dialysis the presence of hypertension is mostly related to fluid overload, and attainment of dry weight will result in lowering of BP in the majority of patients. Dry weight and dialysis prescription need to be frequently adapted to avoid fluid overload induced hypertension. Thus, more frequent or prolonged dialysis sessions are the primary intervention to control hypertension. In addition, supportive measures aiming for a low extracellular volume as dietary salt restriction, low dialysate sodium content and restriction of fluid intake are important to complement an adequate dialysis prescription. The BP targets for dialysis patients are not as strict as for non-dialysis patients. The KDOQI guidelines recommend the BP target to be below the 95th percentile for age, sex, and height [230]. The KDIGO 2019 Controversy Conference on BP and volume management in dialysis addresses four major topics including BP measurement and targets, pharmacologic management, dialysis prescriptions as they relate to BP and volume and extracellular volume assessment and management with a focus on technology-based solutions; and volume-related patient symptoms and experiences [231].

Dyslipidemia

The latest guidelines for lipid screening and treatment in children with CKD by KDIGO published in 2013 recommend evaluation with a lipid profile (total cholesterol, LDL cholesterol, HDL cholesterol, triglycerides) in newly diagnosed CKD (including those treated with chronic dialysis or kidney transplantation) [232]. Management of dyslipidemia should include therapeutic lifestyle changes including dietary modification, weight reduction, increased physical activity, reducing alcohol intake, and treatment of hyperglycemia (if present), especially in overweight/obese children. In case of significant hypertriglyceridemia, dietary changes include a very

low-fat diet (15% total calories), medium-chain triglycerides, and fish oils to replace some long-chain triglycerides. The initiation of statin therapy is based on a risk assessment and LDL-cholesterol level. Because children with CKD belong to a high level risk factor group, the statins are recommended at LDL-cholesterol level > 160 mg/dL. However, if there are additional moderate risks (e.g., hypertension, obesity, nephrotic syndrome as a cause of CKD), statins should be started at LDL-cholesterol >130 mg/dL. Given the lack of evidence for the benefit and safety of combination therapy with bile acid resins, colestipol and ezetimibe in pediatric CKD populations, the KDIGO Work Group does not recommend the use of such multi-drug regimens even in children with severely elevated LDL-C. Pharmacological treatment of hypertriglyceridemia with fibrates is not recommended in children with CKD because of concerns of developing pancreatitis.

Obesity and Physical Inactivity

Evidence from adult maintenance dialysis populations suggests a survival advantage conferred by higher BMI [233]; however, this appears to be limited to those with low body fat and high muscle mass [234]. Per KDOQI, "the safety and efficacy of weight loss in the overweight dialysis patient is unknown. Therefore, weight loss in the dialysis patients should be approached with close monitoring by a registered dietician and physician" [230]. However, increased levels of physical activity are encouraged to improve exercise capacity [235]. It is unknown whether obesity in children with ESKD confers survival benefits while on maintenance dialysis. For children with CKD prior to dialysis or post-transplant, treatment of obesity and maintenance of normal body habitus (BMI between fifth and 85th percentile for age, sex) is advisable. This recommendation is based on the evidence that obesity is associated with worse long-term outcomes. For example, it has been long known that severe childhood obesity is a significant risk factor for CKD in children and adults [237–239]. After pediatric renal transplantation obesity is associated with higher rates of graft dysfunction and graft loss [239, 240]. Recommendations on management of obesity in CKD children should be individualized according to their age, physical tolerance, CKD stage, dialysis and co-morbidities and, as in the general pediatric population, include dietary modification, behavior modification and physical activity. Older adolescents with CKD, extreme obesity (BMI $\geq$ 40) and other comorbidities associated with long-term risks who failed to respond to dietary or behavior modifications may consider weight loss surgery.

Left Ventricular Hypertrophy

Overall, based on data that LVH is more frequent in children diagnosed with hypertension, it seems appropriate to perform echocardiography in children with CKD and in renal transplant recipients who have elevated casual BP and/or masked hypertension on ABPM. Echocardiography also should be considered in children with severe anemia. If LVH is diagnosed, periodic follow-up echocardiographic monitoring is suggested. Although not perfect, we suggest using the 2017 AAP CPG recommendations to diagnose LVH. Specifically, one can use the references of Khoury et al. [173] for children $\leq$8 years of age and a single cut off point of 51 g/m$^{2.7}$ for older children. If the child has a short stature, height age adjustment is warranted as described by Borzych et al. [175]. As we mentioned above in this chapter, alternative approach using a single cut off point of 45 g/m$^{2.16}$ to define LVH has recently been introduced and used in Europe [176].

Mineral and Bone Disorder

In clinical practice, the focus should be on maintaining serum phosphorus and calcium levels at age-appropriate normal range and on prevention of significant hyperparathyroidism and low vitamin D levels. The most recent KDIGO Clinical Practice Guideline Update for the Diagnosis,

Evaluation, Prevention, and Treatment of Chronic Kidney Disease–Mineral and Bone Disorder (CKD-MBD) [241] provides specific recommendations on timing of assessment and treatment options if abnormal markers of MBD are found (discussed in details in chap. 58). The dietary management of calcium and phosphate in children with CKD stages 2–5 and on dialysis is updated by recommendations from the Pediatric Renal Nutrition Taskforce [242].

Future

Since the first description of increased cardiovascular risk in children with CKD more than two decades ago, significant improvements have been achieved and guidelines have been developed to address individual cardiovascular risk factors. However, many recommendations are still based on opinion rather than on clear clinical evidence. Current and future longitudinal multicenter studies have the potential not only to monitor the implementation of treatment goals, but also to analyze the success in improving cardiovascular outcome in pediatric patients with CKD. Insights from these studies will also pose new questions which have to be brought from bedside to bench and vice versa, ultimately helping to continuously improve recommendations for each individual patient.

Acknowledgments We thank Dr. Uwe Querfeld for his contribution to this chapter in the first edition of the textbook.

Ethical Issues in End Stage Kidney Disease

62

Aaron Wightman and Michael Freeman

Introduction

Since the development of pediatric nephrology as a discipline in the twentieth century, we have experienced a progressive expansion of our capabilities in caring for children with significant kidney disease. As treatments improved, patients and their families have been asked to choose from a wider array of treatments, and decisions to pursue or forgo those interventions have acquired greater ethical weight. Moreover, as care of children with kidney disease is provided within the context of health care systems and policies on a regional, national, and international level, the ethics of medical care must be considered with a broader lens than simply doing "what is best" for our individual patients. In this chapter we will review both the structures of contemporary bioethics as it applies to decisions made by patients and their families, as well as some of the current areas of ethical concern within pediatric nephrology.

Contemporary Bioethics and the Limits of Parental Decision-Making

When providing care to a competent adult, there is a strong presumption that the decisions made by the patient should direct care. While it is true that factors such as the clinician's assessment of what might be beneficial or harmful to the patient, as well as broader system issues regarding resource availability may also play a role, the wishes of the patient are generally paramount. This framework of medical decision-making is derived from an understanding that individual adults have both a right to dictate the care that they receive based on a fundamental respect for bodily integrity and are in the best position to assess how a given treatment course will support their own goals and values [1]. In contrast, by nature of the fact that they are continuing to grow and develop, children are assumed to lack a long-standing system of values or the appropriate understanding of the implications of a given treatment decision. As such, there is a long-standing tradition of deference to parental decisions in pediatric care.

Although parents are generally considered the primary decision-makers in the pediatric setting, their authority is not absolute. Both the child, as well as society more broadly, have an interest in the child's well-being. This is reflected across laws in numerous countries that place limits on

parental activities such as corporal punishment, and mandate that parents provide for children's basic needs, including nutrition, education, and health care [2, 3]. While the details of these laws are shaped by local custom and other social aspects, they reflect an acknowledgement that the community has an obligation to provide for children given their vulnerable state. Within the context of healthcare, this raises the possibility of significant conflict when a decision made by a patient and their family is incompatible with what the clinician thinks would be most beneficial to the patient.

Historically, when these conflicts have arisen, they have been resolved by an assessment of what would broadly be considered in the child's best interest [4]. Within bioethics, the best interest standard requires a decision-maker to consider the child's present and future self-regarding interests alone and select the treatment that maximizes benefit and minimizes harms [4]. While the best interests standard is well suited to conflicts when the risks and benefits of each treatment course are clearly disproportionate (such as a decision to forgo antibiotic therapy for bacterial pyelonephritis), there are other instances in which the determination of what is "best" is dependent on highly personalized assessment of the relative value of different factors. In a more complicated case, such as dialysis for a preterm infant, it is entirely possible that parents and clinicians may consider the same risks and benefits of treatment and reach different conclusions on what is "best." Additionally, children have a variety of physical, intellectual, social and emotional interests and a precise determining what actions "best" support these interests may not be possible. Finally, the best interest standard fails to acknowledge that we do not typically require that parents do what is absolutely "best" for children in all circumstances. Given the varied obligations that parents have to themselves, their children, and their community this would be impossible.

Instead of seeking to overrule parental authority for decisions that are not in the best interests of the child, Diekema argues such actions should be reserved for parental choices, generally refusals, that place a child at clear risk of significant harm [5]. The harm principle allows for the differing values that parents may place on benefits and burdens of treatment options when compared to the opinions of medical professionals, but does not allow for parents to refuse a treatment in which serious, imminent harm is expected to occur and where there is a reasonable intervention that could avoid that harm [5]. The best interest standard and harm principle were further operationalized through the concept of the zone of parental discretion, which sought to highlight the range of choices parents may make so long as they do not exceed a harm threshold [6]. Although the concept of "best-interest" is frequently referenced in the clinical setting, there is broad consensus within the field of pediatric ethics that in complex medical decision-making, such as the care of children with chronic kidney disease (CKD), the best interests standard is better considered aspirational to guide decision-making and the harm principle is better reserved for situations where clinicians must consider overruling parental authority [7].

Ethical Issues in Dialysis and ESRD

Withholding, Withdrawal, and Forgoing Dialysis Treatment

There is no universally accepted criterion for forgoing life-sustaining treatments such as dialysis. Decisions concerning withholding or withdrawing dialysis remain a source of controversy and distress for children, their families, and nephrologists. Withdrawal of dialysis is common among adults on dialysis, accounting for approximately one quarter of deaths among dialysis patients in the United States. Withdrawal of life-sustaining treatments is also a leading cause of death in neonatal and pediatric intensive care units [8, 9]. Less is known about withholding or withdrawal of dialysis treatment for children, although one analysis of French-speaking pediatric nephrology centers from 1995–2001 found 50 cases where dialysis was withheld or withdrawn among

440 children with end-stage kidney disease (11.5%) [10]. The most common reasons for withdrawal included concerns of subsequent quality of life, severe neurological handicap, and consequences of the disease on the family [10].

Decisions made to forgo dialysis should be individualized, shared, and consistent with the interests of the child and the benefits and burdens resulting from renal replacement therapy or compassionate conservative treatment [11]. Choices should reflect the patient and family's goals of care that are achievable and be centered upon the patient's quality of life [11–13]. Four concepts that may influence decisions to forgo dialysis treatment include: perception of moral difference between withholding and withdrawing treatment, the technological imperative, futility, and time-limited trials of therapy.

Withholding, Withdrawal, Equivalence

Withholding dialysis is defined as foregoing dialysis in a patient for whom dialysis has yet to be initiated (i.e. never starting). Withdrawal of dialysis means the discontinuation and forgoing of ongoing dialysis therapy (i.e. stopping after dialysis has been started or attempted). Both situations are similar in that life-sustaining treatments are possible but are not provided.

A series of surveys of pediatric specialists, intensivists, neonatologists, general practitioners, intensivists, and palliative care specialists have shown that many clinicians do not feel that decisions to withhold and withdraw life-sustaining treatments are morally the same [14–18]. Clinicians may sense that withdrawing dialysis or other life sustaining-treatments feels more distressing than never starting. This may reflect a perception of greater moral agency, responsibility, and culpability on the part of the healthcare provider for a patient's death associated with withdrawal of treatment (commission) vs. never initiating treatment (omission). There is a tendency to describe a situation in which treatment has begun as "the train has left the station" and cannot be stopped [19]. Other clinicians may sense it is more problematic to withhold rather than to withdraw a life-sustaining treatment like dialysis. For example, Ladin and colleagues found that many adult nephrologists do not routinely discuss withholding dialysis treatment with elderly patients for fear of missing out on potentially beneficial therapy, being perceived as abandoning the patient or not providing care, and concern that withholding dialysis did not represent an "active" option [20]. Others have argued that withholding a life-sustaining treatment like dialysis precludes the possibility of an unexpected recovery and denies an opportunity to learn more about the benefits and burdens of therapy and the patient's prognosis. If dialysis is initiated and later withdrawn, the treatment is forgone only after its lack of utility has been confirmed [21].

Nephrologists' perceptions of a moral difference between withholding and withdrawing dialysis may result in negative consequences for patients. Implicit belief that withholding is preferable to withdrawing can create an "up front barrier" to appropriate treatment which may result in both inappropriate under treatment (reticence to begin therapy due to concerns of being trapped by biomedical technology that once begun cannot be stopped) and overtreatment (failure to withdraw harmful treatment once started) [22, 23]. Overtreatment may result in waste of limited medical and financial resources by insisting on a therapy that is no longer beneficial or desirable for the patient [22–24]. Others who feel withholding dialysis is more problematic than withdrawal may require all patients to undergo dialysis treatment, as withholding precludes a dying patient of a chance, even if extremely limited, of benefitting from dialysis treatment. While this approach offers the opportunity for unlikely patients to benefit, it would result in suffering for the majority who will not benefit and significant waste of resources by providing treatment unlikely to be beneficial [21, 25, 26].

It is generally accepted that there is no ethical distinction between withholding and withdraw-

ing life-sustaining treatments, even if there may be an emotional distinction for patient, family and the medical team [1, 11, 19, 23]. The equivalence thesis is an important concept in understanding these difficult cases. The equivalence thesis holds that all other things being equal, if it is permissible to withhold a medical treatment for a patient, it is also permissible to withdraw the same treatment and vice versa [27, 28]. Both not initiating and stopping life-sustaining therapy can be justified, depending upon the circumstances. Both can be instances of allowing to die, and both can be instances of killing [27, 28]. In situations where the physician has a clear duty to treat, omission of treatment by withholding or withdrawing violates that duty. Conversely, if there is no a clear duty to treat, then both withholding and withdrawing could be considered to be permissible [27, 29]. Given the consequences that arise from implicit beliefs of moral differences between withholding and withdrawing, nephrologists would be better served to combine the concepts into a single term, foregoing.

Technological Imperative

The technological imperative may influence pediatric nephrologists reluctance to forgo dialysis treatment [30]. The technological imperative has been suggested as something which is imprinted on physicians early in training: the drive to use the best, most modern and most high-tech interventions because they are available [31]. It may be best understood at its core as "That which is possible to do must be done" [32]. Pediatric nephrologists are well trained in the technical aspects of dialysis, but are less well trained in holding back, declining to offer therapy when the burdens outweigh the benefits or when a patient or family does not want the treatment. Recognizing that the technological imperative that is a natural part of pediatric nephrology may help clinicians when faced with a patient or family who desire to forgo medically available treatment. The technological imperative should not be allowed to stand in the way of shared decision-making, as it sometimes is just as powerful to leave a tool unused.

Futility

When considering life-sustaining treatments such as dialysis, nephrologists may be tempted to claim that treatment should not be provide because it is futile. Futility is a tool used by clinicians to make a unilateral decision to forgo a treatment because the treatment cannot produce the benefit that the patient or family seek [33]. In this sense a claim of futility is extremely powerful because if a treatment is futile not only is there no duty for clinicians to perform it, but there may also be a duty not to perform it. In spite of this, futility has important limitations that generally preclude its use in pediatric nephrology. The greatest limitation of futility is that it has many different meanings to clinicians, families, patients, and society [33]. Generally, three definitions of futility are most often utilized [34]. First, physiologic futility is a claim that the treatment cannot produce the benefit sought. A classic example is treating a viral infection with antibiotics. Antibiotics cannot accomplish the goal of treating viral infection. In contrast the goal of dialysis treatment is to improve fluid and metabolic balance. If access can be obtained and BP is sufficient, dialysis will almost always improve fluid and metabolic balance. Therefore, dialysis is unlikely to be physiologically futile. Second, quantitative futility is a claim that, while it is possible the treatment may produce the benefit sought, it is so unlikely as to not be worth it. In proposing this definition, Schneiderman and colleagues ask clinicians to reflect on the last 100 similar patients or the published literature [35]. If chance of failure is >99%, then the treatment is futile. For dialysis, if access can be obtained and blood pressure managed this threshold is very rarely achieved. Third, qualitative futility is a judgement that while a treatment has a reasonable prospect of producing the benefit sought it isn't worthwhile all things considered. This judgement does not reflect clinical expertise or medical judgement and instead is a cost/benefit analysis informed by the goals of care which are typically determined by the patient or their parents with the input of clinicians rather by clinicians alone.

The purpose of this discussion is not to claim that in every instance dialysis should be pursued; rather, that futility is an inappropriate reason not to do so. The assessment of benefit in such cases goes beyond whether dialysis will provide metabolic clearance and ultrafiltration to more global questions focused on quality of life for the patient. These considerations are inherently value-based and should be determined by the child's informed parents except when there is reason to believe that the parents are not acting as appropriate decision makers for the child [12, 33, 36].

Time-Limited Trial of Therapy

In the setting of uncertainty or discordance between a treating team or between treating team and family, a time-limited trial is sometimes considered as a third option in addition to initiating or forgoing life-sustaining treatments like dialysis [24, 37, 38]. A time-limited trial is an agreement between care providers and surrogate decision-makers to provide a medical therapy over a defined period of time to determine if the patient improves or deteriorates according to agreed-upon objective clinical outcomes [37]. Time-limited trials offer potential benefits of alleviating the burden of decision-making in the setting of uncertainty, avoiding interprofessional conflict, and providing support for patients, their families, and clinicians. A trial of dialysis therapy may allow for further information to be gathered about the benefits and burdens of dialysis without committing the child to a lifetime of renal replacement therapy [11, 38, 39]. Yet, when considering life-sustaining treatments such as dialysis unlikely to meet a physiologic definition of futility, time-limited trials have important limitations. These include the arbitrary duration of a trial, use of value-laden considerations as "objective" outcomes, and concern that parents may have a different understanding of a "trial" than clinicians. With the exception of some neonates, most children with chronic kidney failure will require some form of renal replacement therapy for the remainder of their lives. As the treatment is life-long, any time duration of a trial is arbitrary. Seemingly objective outcome often considered in a time-limited trial of dialysis include factors such as dialysis catheter failure, peritonitis, extubation, or neural imaging findings. Catheter failure and peritonitis are relatively common and treatable complications of dialysis treatment and thus do not seem to describe failure of dialysis treatment. Rather than being objective, outcomes such as extubation or neuroimaging findings instead reflect implicit assessments of the quality of a life on chronic mechanical ventilation or with a neurodevelopmental disability. This is an example of a technical criteria fallacy in which inherently value based decisions are medicalized without engagement in the key ethical arguments that would justify their use [40]. Finally, parents may have a different conception of a trial of a life-sustaining treatment like dialysis. Parents have described a "trial" of therapy as treatment until a complication arose where it was clear that the burdens of continued treatment (generally pain) outweighed the benefits of continued treatment; otherwise, treatment continues indefinitely [24, 41]. This is a reasonable assessment, but is a description of initiating treatment, not a trial. Treating teams and families should continually reassess whether the benefits of any treatment outweigh its burdens and whether the treatment continues to support the patient's goals of care. For an efficacious life-sustaining treatment like dialysis, nephrologists are better suited to avoid discussion of time-limited trials and instead focus on initiation or forgoing treatment with the understanding that such a decision should be continually revisited in light of the benefits and burdens experienced by the child [10, 24].

Palliative Care

Discussion about initiation or forgoing life-sustaining treatments like dialysis and transplant can feel dichotomous in nature. It is important to recognize that relationships between patients, families, and clinicians are not. This means duties to care and support patients, families, and colleagues persist regardless of any decision made

about life-sustaining treatments and intensification of palliative treatments should occur in conjunction with any decision to forgo life-sustaining treatments [42]. This highlights the importance of continued care including palliative care.

Pediatric palliative care strives to (1) relieve physical, psychological, social, practical, and existential suffering, (2) improve quality of life, (3) facilitate decision-making, and (4) assist with care coordination for children with life-threatening or life-shortening conditions [43–47]. Even in resource-limited health system settings, the Worldwide Palliative Care Alliance identifies early integration of palliative care as a human right for children [48]. While initially limited to patients with terminal illnesses such as children with kidney failure where renal replacement treatments were forgone, pediatric societies increasingly recommend PPC for all children with a "life-threatening" condition [43, 44, 45, 47, 49] This encompasses children with life-limiting conditions, where cure is not possible, and children with life-threatening conditions, where cure is possible and disease-directed treatments are ongoing [43–45, 47, 49] Importantly, most, if not all, children with advanced CKD fall into one of those two groups [47, 50].

CKD is an incurable, life-long and life-shortening condition which imposes significant burdens on children and their families. Children with kidney failure receiving dialysis treatment or who received a kidney transplant experience poorer health-related quality of life (HRQoL) compared to healthy peers and peers with other chronic illnesses [51–57]. CKD negatively affects mental health and well-being including high rates of depression and anxiety [58–60]. Further, pain needs of children with CKD may go under recognized. For example a multicenter study utilizing the Patient Reported Outcomes Measurement Information System (PROMIS) demonstrated that about half of children with CKD, regardless of stage or transplant history, experienced pain within the last week interfering with daily activities [61]. Children with CKD also experience impaired sleep, with studies showing high rates of sleep disturbances in children with non-dialysis dependent (37%) and dialysis dependent CKD (86%) [62, 63]. The importance of recognizing and developing strategies to address these burdens was highlighted by a recent qualitative study in which adolescents with CKD shared their desire that outcomes such as fatigue, lifestyle restrictions, and physical activity be prioritized [64].

To date, utilization of pediatric palliative care for children with CKD and their families has been limited [27, 65, 66]. This calls for future clinical and research efforts to integrate palliative care into the care of children with CKD similar to the evolution in practice in adult nephrology and other pediatric chronic diseases [47, 67, 68–70].

Ethical Issues in Kidney Transplantation

Consideration of Quality of Life in Transplant Decisions

Some have argued that transplant listing decisions should consider degree of improvement in quality of life that can be expected from transplant rather than expected graft and patient survival [71]. The net effect would be to prioritize children without intellectual disabilities as transplant candidates. Indeed, survey data suggests many pediatric kidney transplant programs do consider cognition as criterion for kidney transplant and may utilize different considerations for potential candidates with intellectual disabilities [72, 73]. These approaches appear to lack empiric support. Graft and recipient survival following kidney transplant do not appear to be notably different between recipients with and without intellectual disability [74]. Further, a successful kidney transplant improves the quality of life for children with kidney failure regardless of level of cognition [75, 76]. Rather than focusing on relative degree of improvement in quality of life that can be expected from a transplant, nephrologists are better suited to reflect on whether of whether the potential recipient would benefit sufficiently relative to the burdens that transplantation would pose.

Assessment of Adherence

Transplant organs remain an inherently scarce resource. As such, within the transplant system there is a strong emphasis on avoiding circumstances expected to result in premature graft loss. Assessment of a potential recipient's adherence to treatment recommendations is part of that process and referral to transplantation may be delayed or denied due to concerns of non-adherence [77]. There is evidence that non-adherence is common in the pediatric kidney disease population, particularly among adolescents [78–80]. Potentially as a result of this phenomenon, older adolescents and young adults demonstrate a markedly increased rate of graft failure as compared to both younger children and older adults [81].

While adherence is a critical for a transplant recipient to be successful, there are important limitations in applying concerns about non-adherence to clinical practice. Physicians' ability to predict the future adherence of their patients are quite limited [82, 83]. Further, patients who are members of minority population are more likely to be judged to be non-adherent [84, 85]. This is of particular significance, as many of the studies that have sought to describe factors that might predict non-adherence rely, at least in part, on healthcare provider's assessment of non-adherence [80, 86]. These same studies have frequently identified psychosocial risk factors as predictive of non-adherence, including gender, ethnic background, being a member of a single parent household, and socio-economic status [86, 87]. Given the subjectivity of many assessments of non-adherence, particularly in disease states where more 'objective' markers of adherence such as drug levels are not routinely followed, it becomes readily apparent how this can represent a vicious cycle. Patients who are socially disadvantaged by these psycho-social criteria may be more likely to experience delays or denial in transplant due to concerns regarding adherence or be judged to be non-adherent following transplant. This in turn has the potential to reinforce existing biases and disparities in care.

Acknowledgement of these concerns is not meant to be an argument against the inclusion of assessments of adherence and social support within the transplant process. Instead, nephrologists should be aware of the limitations of their ability to assess these factors and incorporate this uncertainty into the relative weight placed on these factors in decisions.

Assessments of Alcohol and Other Substance Use

A recent study of pediatric transplant programs suggest that substance use by potential pediatric transplant recipients remains a concern for clinicians and in some cases sobriety or cessation therapy is a requirement for listing a patient for organ transplantation [88]. Unfortunately, substance use is very common among adolescents with chronic illness. In a recent study of youth in the US with a variety of chronic illnesses, 36.5% of high school students reported alcohol use and 20% reported marijuana use [89]. Similar to studies of the broader adolescent population in the US [90]. Population level studies in a variety of other countries demonstrate prevalent adolescent substance use as well [91, 92].

In pediatric populations, studies suggest a correlation between substance use behaviors and non-adherence to medical regiments [89, 93]. Studies assessing the influence of alcohol and other substance use on post-transplant outcomes among adults have been mixed, but are broadly indicative of worse outcomes, at least among heavy substance users [94–98]. As such, consideration of substance use among potential pediatric transplant recipients is a valid concern in considering post-transplant outcomes. Unfortunately, many pediatric transplant programs lack clear policies regarding substance use in transplant referral and listing decisions [88]. In a recent study of transplant center practices, the majority of programs did not routinely or universally use urine or blood toxicology screening to assess for substance use, instead utilizing this testing only in circumstances of clinician suspi-

cion of substance use or in the setting of patient self-report [88]. This approach is not reliable due to the limitations of self-report of substance use by adolescents in the clinical setting [99, 100] and pediatric clinician's limited ability to assess substance use by clinical impression alone [100].

From an ethical standpoint, the use of screening approaches that are neither standardized nor universal increases the risk of clinician bias influencing the selection of patients that require more intensive screening. While research suggests that substance use in pediatrics may increase the risk of a poor transplant outcome as compared to a control population, it is important to acknowledge that many transplant candidates may be at greater risk of poorer transplant outcome than their peers due to a variety of factors such as their underlying disease [101], concurrent illnesses [81], and age at transplantation [81]. Undue emphasis on "risk" arising from substance use (as opposed to other categories) may perpetuate existing racial, ethnic and psychosocial biases in transplant care.

Justice and Broader Social Concerns in Pediatric Kidney Care

Caregiver Burden

Pediatric CKD affects not only the child, but their family and community. Caregiver burden is a multidimensional construct reflecting an individual's perception of overload during the caregiving process in one or more of four perspectives: physical, psychological, social, and financial [102]. While caregiver burdens may be greatest for younger children and those with more advanced kidney disease, they are experienced caring for all children at all levels of CKD [64, 103–108, 109]. At its most significant, caregivers (particularly mothers) experience extraordinary burdens which, in some circumstances exceed their available physical, financial, or psychological resources so they are unable to meet their duties to themselves or to others for whom they are responsible [64, 103–105, 110, 111]. This experience has been reported by caregivers throughout the world and is influenced by the available social resources within each country [105]. Patients also express concern over caregiver burden. In a recent study, adolescents and young adults with kidney disease expressed guilt over the stress and burdens that their treatment imposed upon their families [64].

In light of the severity of the burdens experienced by at least some caregivers and the concern for caregiving demands voiced by adolescents and young adults, it seems cruel and unjust for nephrologists not to discuss expected burdens with parents. This raises challenging ethical questions, including how clinicians and parents could or should incorporate considerations of caregiver burden into medical decision-making for a child with kidney disease. Where caregiving burden is significant, it is possible a treatment choice may be in the best interest of a child, but not in the best interest of other children in the family, the family as a whole, or the community. Yet, the dominant frameworks of pediatric medical decision-making utilize the best interest standard, which focuses exclusively on the self-regarding interests of the child when weighing treatment options. Such frameworks seek to highlight the primacy of the needs of the child, protect the child from exploitation by those more powerful, and hold that a child's basic needs must always be met [5, 112, 113]. While intuitively appealing, such a stance overlooks that parents, siblings, and other caregivers are also moral agents with finite resources and pragmatically that even in the wealthiest countries public resources may be insufficient to meet the needs of children with kidney disease and their families [105]. Yet it seems unfair for societal failures to support children and families to fall exclusively on the vulnerable child with kidney disease. The ethical tension between the needs of the child, other members of the family, and community in a setting of constrained resources does not offer a ready solution. It highlights a gap in the current ethical framework of pediatric medical decision-making. Recognition of caregiver burden calls for advocacy from the pediatric nephrology community to appeal for greater supports for children and their families, but also for nephrologists to recognize the situation their patient and their patient's families find themselves.

Racism, Disparities and Structural Injustices

Social determinants play a dramatic role in shaping health outcomes for children with CKD and their families [114]. Healthy People 2020 organizes social determinants of health around 5 key domains: (1) economic stability, (2) education, (3) neighborhood and built environment, (4) social and community context, and (5) health and healthcare [115]. These are influenced by societal problems of structural racism, sexism, ableism, classism and the biases associated with them which are experienced differently by particular individuals and groups within populations [116–120]. In addition, adverse environmental conditions and differences in access to healthcare, housing, clean water, healthy food, and opportunities for exercise experienced by particular groups can influence both the emergence and the progression of kidney disease [116, 119]. This insight supports the need for critical reflection in nephrology clinical practice and research. For example, the use of race as a prognostic factor or association with an outcome of interest may overlook the impact of racism rather than race in influencing clinical outcomes [121–124]. The intersection between kidney disease and racial, ethnic, gender, and socioeconomic disparities further highlights how particular groups are disadvantaged [125, 126]. One notable example is the intersection between race, socioeconomic deprivation and access to kidney transplant [127–130]. Nephrologists should seek to become aware of the impact of social determinants of health, systemic inequities, and implicit biases and work to dismantle structural causes of inequity that impact the health and well-being of patients, families, and colleagues [118, 119, 131]. Additionally, nephrologists should seek to engage with the communities they serve to promote partnerships and build trust and be trustworthy to the underserved populations that historically have been victimized by acts of injustice [119, 131–133].

Further, it is incumbent upon nephrologists to recognize how historic injustices, including colonialism and racism, contribute to the inequities resulting in high rates of acquired kidney disease in children in low- and middle-income countries. These impacts include high prevalence of bacterial, viral, and parasitic infections, limited access to reproductive care, low birth weight, malnutrition, food insecurity, poor sanitation, unsafe water supply, and pollution, all of which contribute to the development of kidney disease [116, 134–137]. These injustices highlight the need for increased and sustained efforts to support children with kidney disease and those caring for them throughout the world as an integral part of pediatric nephrologists' roles as advocates and global citizens.

Ethical Care in the Setting of Resource Limitations

It is important to acknowledge that all health care environments have limited resources. In the setting of national or other public health systems, these limitations may be dictated by realities of budgeting and health care prioritization. In the setting of private insurance, these limitations may be enacted by the policies of individual insurance programs. Institutions may vary in their ability to provide ancillary support services to the populations they serve, and families may be limited in the financial or psychosocial burdens that they can assume when caring for a child with kidney disease.

Given this reality, it is evident that there are inequities in the healthcare provided and received in different clinical settings. This is a challenge to the notion of fairness, which suggests that differential treatment of individuals is only justified if there is a morally significant difference between them [1]. Considerations such as wealth are not thought to be morally significant. Yet, resource limitations in a given practice environment may force nephrologists to deviate from what they consider optimal kidney care [138–140]. This in turn induces moral distress, a term that describes the distress that occurs not because of uncertainty regarding the most ethical course of action, but because the most appropriate ethical course is known but cannot be pursued [138, 139, 141].

Resource constraints and the lack of equity in resources for pediatric kidney care are likely beyond the efforts of individual clinicians to address. Given these constraints, however, one can consider three general guidelines in the provision of care that is limited by resource availability:

1. *In the face of resource limitations, ethically optimal care is contextual*: Different practice environments may have different prevailing standards of nephrologic care. While it is incumbent upon healthcare providers to provide the optimal care their treatment environment allows, they cannot be considered ethically required to provide care for which there is insufficient resource support. If better care could be provided in another practically accessible care setting (for example, transfer to another institution with increased resource availability or placement of the child in a different home environment to allow the provision of outpatient dialysis services), these interventions should be considered. However, it is important to recognize that these transitions may themselves be restricted due to a lack of resources and may be associated with other significant burdens that make this approach untenable.
2. *In the face of resource limitations, ethically optimal care is holistic*: It is important to recognize that a given treatment course may result in benefits and burdens beyond simple medical efficacy. The impact of treatment recommendations on patients and their family should be assessed with this in mind. For example, if the medial costs associated with the "standard of care" in a given setting might be financially ruinous to a family, deviation from this standard of care may be ethically permissible or even necessary. If the harm experienced by the child and their family from a treatment course exceeds the value of the health benefits gained, an alternative treatment course should be considered.

   It is important to note that this concept may be applied more broadly on a systems level. As an example, while the overall benefits of the use of phosphate binders as a whole are at times called into question [142], meta-analyses have suggested that the use of sevelamer results in a reduction in all-cause mortality as compared to calcium containing phosphate binders [143]. However, sevelamer based phosphate binders are substantially more expensive than calcium-containing phosphate binders and as such wholesale transition away from calcium containing binders may place a substantially increased burden on patients, dialysis units and healthcare systems [144–146]. The relative utility of making changes of this type depend on the resources available and the alternative use to which those resources might be applied.
3. *In the face of resource limitations, ethically optimal care requires advocacy*: While it is true that resource constraints may be beyond the ability for individual medical practitioners to control, our obligations to our patients require us to serve as an advocate to ensure that their health care needs can be addressed appropriately. At its core, advocacy involves attempting to address the factors that constrain healthcare providers from providing the highest quality care possible. On an individual patient level, advocacy often takes the form of seeking to secure resources that have, in the view of the healthcare provider, been misallocated or circumstances in which the patient may experience a disproportionate benefit from receiving those resources. This may be as simple as obtaining additional financial support for patients facing significant transportation barriers, or as complex as petitioning private or national formularies to consider an exception to provide a therapy that is typically not available. More expansively, advocacy on the local, regional, national and international level seeks to alleviate those resource limitations that adversely and unjustly affect the populations that we care for and about.

Psychosocial Issues in Children with Chronic Kidney Disease

63

Amy J. Kogon and Stephen R. Hooper

Introduction

The psychosocial functioning of children and adolescents with chronic kidney disease (CKD) typically receives little attention in the busy pediatric nephrology clinic, but there is a growing literature to suggest that it should play a critical role in the overall care of this population. It is important for the quality of care received by the child and their family, the impact that psychiatric difficulties can exert on that quality of care, the interaction of such problems with other neurodevelopmental functions such as cognitive functioning and social development, and the economics of care as related to poor adherence to and the risk of adverse events. Psychosocial issues have been shown to have an adverse impact on disease progression and health care costs [1–4].

This chapter provides a comprehensive overview of what is known about the broad area of psychosocial issues in children with CKD going back approximately three decades. Couched within the context of the epidemiology of childhood psychiatric disorders, this chapter discusses many of the available studies addressing (1) psychiatric disorders and symptoms, (2) social functioning, (3) quality of life, and (4) long-term functional outcomes. Additionally, guidance for measuring psychosocial issues in the clinical setting and associated management strategies will be reviewed. The chapter concludes with a brief discussion of gaps in the literature and future clinical research suggestions for the future.

Psychiatric and Psychosocial Challenges

In general, the psychiatric and psychosocial challenges faced by all children and adolescents is staggering. Based on data from the National Survey of Children's Health [5], approximately 7.7 million children and adolescents in the United States have at least one mental health disorder. These disorders included depression, anxiety, attention deficit-hyperactivity disorder, and a variety of other conditions. With rates of identification ranging from 7.6% to over 27%, this equates to about 1 in 7 children and teenagers (14.3%) who have a condition that could be treated; however, nearly half of these individuals do not receive treatment to address their mental health needs. Left untreated, these conditions can impact neurodevelopment, general health, and wellbeing. These rates coincide with rates of psychiatric disorders

from large epidemiological studies in the United States (e.g., The Smokey Mountain Study = 13.3% [6]), although some have been alarmingly higher (e.g., National Comorbidity Survey = 40.3%) [7], and with rates across the globe (13.4%) [8]. These rates are lower than those for children with various disabilities, such as cerebral palsy, with rates as high as 57% [9]. Additionally, these rates do not include those children and adolescents who may be experiencing significant psychological stress/distress or those who may have subthreshold psychiatric symptoms.

Further, studies of children with pediatric chronic illnesses have clearly demonstrated the consequences of co-morbid psychiatric disease on the primary medical disease, with higher health care utilization and costs [10], worse medical adherence [11], and worse control of the underlying medical condition [10, 11]. These outcomes are less rigorously studied in children and adolescents with CKD, but a study of pediatric hemodialysis (HD) patients and a study that included renal transplant patients identified a relationship between adherence and depressive and/or anxiety symptoms [12, 13]. Accordingly, a complete understanding of the psychiatric and psychosocial challenges of CKD is critically important to optimal clinical management and care across the lifespan.

Psychiatric Disorders and Symptoms

Life with CKD is difficult, and as a child the multiple adversities related to living with such a complex disease can predispose to psychiatric complications (see Fig. 63.1). Children with CKD experience higher rates of psychiatric illness when compared to their healthy peers. Although there are many reports on the prevalence of psychiatric disease, estimates vary depending on the specific population evaluated and the tools used for diagnosis. The difficulties surrounding psychiatric complications in pediatric CKD exist universally, with studies documenting the morbidity of psychiatric complications extending from North and South America to Asia (see Table 63.1).

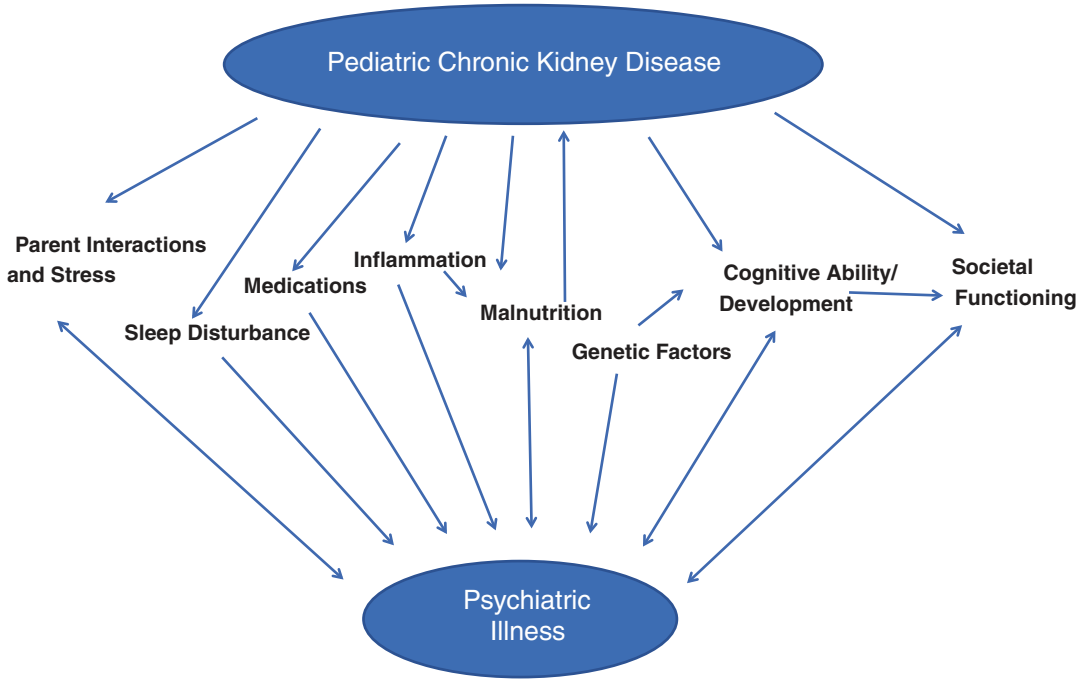

Fig. 63.1 The multiple factors that contribute to psychiatric illness and symptoms in pediatric patients with chronic kidney disease

Table 63.1 Studies examining the psychiatric and social functioning and quality of life functioning in pediatric chronic kidney disease

Study	Sample	Measures	Findings
Psychiatric disorders and symptoms			
Garralda et al. 1988 [14]	22 children on dialysis, 22 children with CKD not on dialysis; 31 controls matched to age and sex with dialysis patients; 2–18 years	Patients: Full psychiatric interview with a doctor, The Birleson Depression inventory, Lipsitt self-concept scale for self-esteem, General health questionnaire if they left school, Denver developmental screening test Teachers: Rutter Child Scale Parents: Modified psychiatric interview with parents, Rutter parental screening, Behavior check list, Highlands Dependency questionnaire or Vinelands Social Maturity scale, Modified social stress and supports interview, General health Questionnaire to assess mental distress in parents	Excess psychiatric adjustment noted in ill children with marked disturbance more common in dialysis group. By composite report, a definite psychiatric disorder noted in 32% dialysis, 23% CKD and 21% of controls. Marked worrying/ anxiety identified in 30% of dialysis, 40% of CKD and 14% of control participants
Eisenhauer et al. 1988 [23]	15 children with CKD: 8 ESKD and 7 mild CKD 8–16 years old	DICA	Depression was most common psychiatric disorder diagnosed in those with ESKD at 63% and anxiety the most common disorder diagnosed in those with mild disease at 57%
Reynolds et al. 1991 [32]	29 functioning renal transplant recipients, 22 on HD, 22 CKD and 31 healthy controls 1–18 years of age	Rutter A and B, Birleson and Lipsitt questionnaires	92% of parents reported improvements in their child's health after transplant and none of parents felt that their child had serious behavioral or emotional difficulty as compared to 1/3 of those with CKD and dialysis. Parents also described their child as happier and less irritable than before transplant. Behavioral problems in the Rutter A questionnaire were more than twice as common in the group who had transplants than in the HD or healthy group. Behavior at school of transplanted patients as assessed by Rutter B did not differ from controls but showed worse scores than HD
Brownbridge et al. 1991 [33]	73 ESKD, 32 HD, 28 CAPD, 13 transplant recipients; 2–21 years of age	Study specific questionnaires completed by patients and parents for measures of health status; Structured family interviews; CDI STAIC Rutter A scale Leeds scale for the self-assessment of anxiety and depression	Transplant recipients had less functional impairment and less social impairment, but groups did not differ on levels of anxiety, depression or behavioral disturbance. Patients on CAPD had less social impairment, lower depression scores, and less behavioral disturbance than HD patients. Parents of children on CAPD had less depression and anxiety then the parents with children on HD

(continued)

Table 63.1 (continued)

Study	Sample	Measures	Findings
Fukunishi et al. 1993 [27]	23 children on CAPD, 23 healthy controls; 4–18 years if age	DICA obtained monthly for 3 months followed by 9 months psychiatric interview	69.6% of dialysis patients had an anxiety disorder vs 8.7% of controls. 65.2% of dialysis patients experienced separation anxiety
Fukunishi et al. 1995 [28]	26 patients on CAPD, 27 transplant recipients, 27 controls; 6–15 years old	DICA –administered at least 3 times over 3 months Interviewed parents regarding school maladjustment	65% of dialysis patients had separation anxiety which associated with the family psychological environment. After receiving a transplant, school maladjustment remained and adjustment disorder was in 27% which was related to poor relationship with peers. For those on CAPD, 68% had separation anxiety, along with 18.5% of transplant recipients and 3.7% of controls
Brownbridge et al. 1999 [90]	60 dialysis patients 2–21 years of age	Structured family interview	Low adherence associated with self-ratings of anxiety and depression
Fielding et al. 1999 [90]	60 patients on dialysis; 2–21 years of age	Patient: CDI, STAIC Parents: Rutter A scale, Leeds Scale for the self-assessment of anxiety and depression	Poorer socioeconomic status associated with more behavioral disturbances in children and increased depression and anxiety in parents. Children who suffered greater functional impairment as a result of illness were more likely to be depressed, anxious, and show behavioral disturbance. Children's scores on social impairment scale correlated with parents' depression and anxiety scores
Soliday et al. 2000	41 parents of children with kidney disease:15 with SSNS, 12 with CKD, 14 transplant recipients compared to 34 controls; 1–18 years	CBCL PSI-SF FES	Mean scores on CBCL and parenting stress scores were within normal limits. 28.6% of transplant patients had clinically significant levels of internalizing symptoms and 20% of children with SSNS had clinically significant externalizing symptoms
Penkower et al. 2003 [91]	22 renal transplant recipients; 13–18 years	Face to face interviews BDI state anxiety, state-trait anxiety and state anger subscales of Spielberger	36.4% demonstrated symptoms of depression, 36.4% anxiety and 18.2% excessive state anger. Adolescents with excessive anger were at greatest risk for missing medications
Wallace et al. 2004 [30]	64 renal transplants recipients; 6–21 years old	FEATS CDI Davidson Trauma Scale	36% had results consistent with depression and/or PTSD; FEATS identified a subset of patients who were not identified using the self-report measures. Davidson scores correlated with hospital days and FEATS correlated with height Z score and donor type. Depression wad identified by CDI in 19% and PTSD by Davidson scores in 42%

Table 63.1 (continued)

Study	Sample	Measures	Findings
Bakr et al. 2007 [16]	9–15 years, 19 children on HD, 19 children CKD	Semi-structured clinical interview for children and adolescents on structured observation and self-report	Prevalence of psychiatric disorders 52.6%: 68.4% HD, 36.8% CKD. Adjustment disorder 18.4%, Depression 10.3%, NC 7.7%, Anxiety 5.1%
Berney-Martinet et al. 2009 [29]	Matched 20 CKD, 40 transplant recipients and 40 controls; 12–18 years	K-SADS-PL CBCL	Lifetime depressive disorder in of 35% transplant recipients, 35% CKD, and 15.2% of controls. Anxiety disorders seen in 22.5% of transplant recipients, 35% of CKD, and 5% of controls. Behavioral disorder seen in 30% transplant recipients, 15% of CKD, 20% of controls
Amr et al. 2009 [34]	19 patients on HD, 19 CKD and19 controls	CBCL SCICA	Mean internalizing score was significantly higher in dialysis than in CKD and controls. No difference in externalizing scales. Mean scores of SCICA observed problems and total self-reports higher in the control group than CKD groups. Positive correlation between SCICA self-report and CBCL
Dobbels et al. 2010 [26]	23 kidney transplant recipients; 10–18 years old	BDI KIDSCREEN-27	Depressive symptoms occurred in 17.4% and 75% of those with depressive symptoms were non-adherent to medications. Parents rated their adolescents to be significantly lower on psychological well-being, autonomy, and school functioning
Hernandez et al. 2011 [36]	67 patients on dialysis: 43 PD, 24 HD; 4–18 years old	Birleson Scale	10% with high occurrence of depressive symptoms and 42% without any symptoms-all of those with high depressive symptoms were female and none had a friend to confide in. For those on PD, depressive symptoms associated with lower Kt/v
Kogon et al. 2013 [25]	44 children: 20 pre-ESKD, 15 dialysis, 9 transplant recipients; 9–18 years	CDI-II	30% of cohort had depression: 25% of those pre-ESKD, 13% of those on dialysis, 67% of the transplant recipients
Selewski et al. 2014 [92]	233 children with CKD III-V including ESKD; 8–17 years old	PROMIS	Recent hospitalizations and edema predicted worse depression and anxiety scores. Those with 2 or more co-existing medical conditions had worse score in depression, anxiety, social-peer relationships
Moreira et al. 2015 [93]	28 pre-ESKD CKD, 28 controls; 9–18 years old	CDI self-report for childhood anxiety related disorder scales	Higher clinically significant depressive symptoms and higher scores for separation anxiety in those with CKD. Less resilience in those with depression

(continued)

Table 63.1 (continued)

Study	Sample	Measures	Findings
Yousefichaijan et al. 2016 [31]	80 children stage 1–3 CKD and 80 controls; 7–17 years old	Obsessive compulsive inventory-child	Mean scores for doubting/checking, ordering, and total scores significantly higher in CKD
Kogon et al. 2016 [38]	420 children CKD; Median age 11.45 years	BASC	Genomic disorders associated with more internalizing problems
Kogon et al. 2016 [24]	344 CKD subjects; 6–17 years	CDI	7% diagnosed with depression. Higher scores associated with less maternal education and lower HRQOL
Kogon et al. 2019 [37]	71 CKD stage II & higher (including ESKD) and 64 controls; 8–25 years old	CDI-II or BDI	Depression in 17% of those with CKD and 12.5% controls. Obesity associated with depression
Cueller et al. 2019 [40]	47 patients with ESKD: 12 PD, 17 HD, 18 renal transplant recipients; 7–18 years old	CDI	64% with symptoms of depression: 61% of transplant recipients, 65% of HD patients, and 66% of those on PD. More depression associated with shorter duration of ESKD and older age. Less depression in transplant recipients from a living donor
Dinc et al. 2019 [15]	66 CKD subjects: 21 transplant recipients, 27 dialysis, 18 CKD and 37 controls	Parent: Parental Attitude Scale, Symptom Checklist-90 by mothers Self: CDI, STAIC, K-SADS	Higher median CDI score for CKD group but no difference in STAIC scores. 41% of children in CKD group diagnosed with current psychiatric disorder vs 16% in control group: 43% of those with transplant, 33% of those on dialysis,50% of those with CKD. A past psychiatric disorder was identified in 52% of those CKD vs 22% of controls: 71% of those with renal transplant, 30% of those on dialysis, 61% of controls. Major depression identified in 9% of CKD overall vs 0% controls: 9.5% of those with a transplant, 15% of those on dialysis, 0% of those with pre-ESKD CKD. No differences found within CKD modalities. No difference in STAIC scores versus controls
Kang et al. 2019 [21]	166 participants with CKD stage 1–4; <18 years old	Korea-CBCL	20.5% had significant mental health problems, 22.3% had psychosocial adjustment problems. 12.7% had clinically significant internalizing problem and 9% had clinically significant externalizing problem. Those with short stature and with multiple comorbidities were more likely to score within the clinical range
Johnson et al. 2020 [20]	845 CKD patients	BASC	On depression scale, higher income and IQ associated with fewer symptoms. Time in study associated with lower depression scores

Table 63.1 (continued)

Study	Sample	Measures	Findings
Social functioning			
Fukunishi et al. 1995 [41]	30 CAPD, 35 transplant recipients, 33 controls; 6–15 years old		No difference between CAPD and transplant patients for school maladjustment with academic problems. CAPD endorsed significantly worse school absenteeism than controls and CAPD and transplant patients had worse and relationships with peers than controls
Qvist et al. 2004 [39]	32 children with renal transplant; under the age of 5	CBCL, CBCL-TRF, HRQOL	Total scores on CBCL did not differ from normative sample. Somatic complains and social problems more frequent in boys. Patients with low scores had more comorbidity and were more likely to attend a special school. Girls had less externalizing problems as rated by teacher than reference. Scores on attention scales were higher in boys and girls as rated by parents and teachers. HRQOL scores differed significantly
Gerson et al. 2004 [94]	13 pediatric renal transplant patients 2–21 years old	BASC Children's Health Questionnaire Young Adolescent Body Image Scale PSI-SF FES	More attention problems associated with worse adherence and better child behavior associated with better medication adherence
Berney-Martinet et al. 2009 [29]	Matched 20 CKD, 40 transplant recipients, 40 controls; 12–18 years old	CBCL	Transplant scored lower than CKD in social competence score; no difference between groups in activities score. Social issues related to psychiatric problems
Hooper et al. 2009 [19]	26 children with CKD: 13 on dialysis, 13 CKD and 33 controls 7–19 years old	BASC	More internalizing problems and behavior symptoms index score in CKD group, although scores fell within the average range. No group differences on adaptive skills or externalizing problems. On parent ratings, CKD participants scored worse on anxiety and depression
Hooper et al. 2016 [22]	124 preschool children mild to moderate CKD	BASC-2, ABAS-II	Parent rating of social-behavioral functioning were in the average range. No problems noted for internalizing, externalizing, or overall behavioral symptoms. On ABAS-II, scores were in the low average to average range in particular for the Practical Composite Score-reflecting capabilities in age-appropriate social functioning. 32–51% of preschoolers were at risk for not developing age-appropriate activities of daily living. No CKD related variables were risk factors

(continued)

Table 63.1 (continued)

Study	Sample	Measures	Findings
Xiao et al. 2019 [35]	318 patients and reference population, CKD stage II or higher including ESKD 13–19 years old	National Youth Risk Behavior Survey	Children with CKD reported significantly lower prevalence of risk behaviors
Johnson et al. 2020 (repeated from above) [20]	845 CKD patients	BASC-2 Parent Rating Scale	Average BASC scores for the group, with ratings improving over time. Male was risk factor for poorer scores. Persistent hypertension was associated with worse scores on the Behavioral Symptoms Index
Quality of life			
Fadrowski et al. 2006 [58]	78 adolescents with CKD, including ESKD; 11–18 years old	CHQ	Increasing height associated with positive change in physical and psychosocial summary score. Increasing age associated with decreasing psychosocial score
Sundaram et al. 2007 [52]	51 liver transplant and 26 kidney transplant recipients; 11–18 years old	CHQ-PF and CF	Caregivers reported lower physical functioning and general health than the normative population, but similar psychological health. All caregivers shared a negative emotional impact on them and their families. Parent-youth concordance was highest for physical functioning, pain, behavior problems, and self-esteem, but lowest for mental health and family cohesion
Falger et al. 2008 [44]	37 children renal transplant recipients; 5–17 years old	Child Quality of Life Questionnaire & CBCL completed by parents and youth.	Parents and youth reported impaired emotional functioning, which was correlated with adverse family relationships and maternal distress. No differences between parent and child quality of life ratings, but ratings were correlated with maternal distress
Gerson et al. 2010 [61]	402 children with mild to moderate CKD 2–16 years old	PedsQL completed by parents and youth	Patients had significantly lower physical, school, emotional and social domain scores than healthy youth. Longer disease duration and older age were associated with higher quality of life. Short stature associated with lower physical functioning scores
Diseth et al. 2011 [53]	28 transplant recipients and 40 cancer survivors and 42 controls; 12–19 years old	Strengths & Difficulties Questionnaire & PedsQL completed by parents and youth; General Health Questionnaire & Quality of Life Scales for parents	PedsQL emotional functioning of the transplant group was lower than the health controls, but similar to that of the cancer group. Parents from both transplant and cancer groups reported similar levels of negative impact of their child's illness on their functioning and on family functioning

Table 63.1 (continued)

Study	Sample	Measures	Findings
Heath et al. 2011 [50]	225 patients with CKD stages 3–5: 47 dialysis, 128 transplant recipients, 49 pre-ESKD; 6–18 years old	Generic Children's Quality of Life Measure Questionnaire completed by child	No significant differences between scores when compared to normative group, and no differences seen across various treatment modalities
Marciano et al. 2011 [48]	136 CKD patients: 39 dialysis, 29 transplant recipients 75 ore-ESKD	Strengths & Difficulties Questionnaire; PedsQL rated by parents & youth	Parents of CKD patients reported the rate of emotional & disruptive disorders to be about 50% higher than in normative group. In contrast, about 1/3 of children reported emotional problems. There was a large negative correlation between the presence of behavior and emotional disorders and the PedsQL total score
Park et al. 2012 [51]	92 children with ESKD: 11 HD, 44 PD = 44, 37 transplant recipients; 2–18 years old	PedsQL ESKD Module	Children with kidney transplant or on dialysis did not differ on perceptions of family and peer interactions, worry, physical appearance, or communication. Parents reported communication problems were worse for children on dialysis than transplant recipients
Neul et al. 2013 [55]	53 dialysis patients and their parents	PedsQL & PedsQL ESKD Module administered at 6-month intervals over a 2-yr. period completed by both patients and parents.	Parent Global PedsQL ratings did not change over time, but ratings were lower in girls and in those with longer dialysis vintage. Emotional and school domains decreased over time. Patient reported scores were higher compared to the parent ratings
Al-Uzri et al. 2013 [57]	483 children with mild to moderate CKD; 2–17 years old	PedsQL completed by parents and youth over two visits.	Significant association between catch-up growth and growth hormone use on parent reports of child physical and social functioning domains. Older children had higher ratings than their parents on all PedsQL scales.
Haavisto et al. 2013 [45]	77 transplant patients: 16 heart, 44 kidney, 14 liver; 6–16 years old	HRQOL & CBCL completed by parents, patients, & teachers.	No differences in HRQOL scores between transplant recipients, but younger participants had lower scores compared to norms. When compared to normative data, the adolescent transplant group reported less distress and more vitality, but more problems attending school and being with friends. Parents and teachers reported more internalizing problems than the normative group, but scores were in the average range. Parents reported more problems with health and physical functioning than patients

(continued)

Table 63.1 (continued)

Study	Sample	Measures	Findings
Killis-Pstrusinska et al. 2013 [46]	203 children with CKD: 25 HD, 41 PD and 137 pre-ESKD and 388 parent proxies; 2–18 years old	PedsQL Inventory completed by patients & parents	Lower HRQOL scores in all CKD groups compared to norms, and HD patients had the lowest scores. There was significant discordance between parents and patients on emotional functioning in the PD group, but not in the HD or conservative treatment groups
Baek HS et al. 2017 [54]	376 parents and 305 children; <18 years of age	PedsQL	Lower HRQOL identified in female patients and those with more co-morbidities and by parent report in those with lower kidney function and anemia. Growth and bone mineral density were positively correlated with QOL. There was no relationship between HRQOL and age or duration of disease
Splinter et al. 2018 [47]	192 ESKD patients 8–18 years in Europe	PedsQL	Patients reported significantly lower scores compared to the healthy norms and other chronic health conditions. Those who had undergone a preemptive transplant reported better physical health scores that were similar to other chronic conditions
Francis A et al. 2018 [49]	375 children 6–18 years with CKD stages I-5 including dialysis and transplant recipients	Health Utilities Index (HUI)	The lowest scores were for those on dialysis, followed by transplant recipients, then CKD stages 3–5 with the highest scores seen in those with CKD stages 1–2
Pardede SO et al. 2019 [56]	112 children including hemodialysis; 2–18 years of age	PedsQL	The lowest scores were seen in the school and emotional domains. HRQOL was lowest in those with CKD diagnosis >60 months, female and in middle school.
Carlson et al. 2020 [60]	733 children and adolescents with mild to moderate CKD; Median age 11 years	PedsQL completed by parents and children over multiple visits.	Presence of anemia was associated with significantly lower overall HRQOL and physical functioning as per child ratings. On parent ratings, anemia was associated with lower emotional functioning scores. Caregivers did not observe declines in their children's other PedsQL subscales in the presence of anemia
Díaz-González de Ferris ME et all 2021 [59]	734 children median age of 11 years	PedsQL	Average HRQOL scores were higher in younger children, but were more highly related to number of medications, with lower HRQOL associated with the number of unique medications
Long-term functional outcomes			
Roscoe et al. 1991 [95]	118 adolescents treated between 1966 and 1986	Functional status obtained by structured telephone interview	80% survival after 15 years for transplanted patients. 29% were living on their own or with a spouse, the rest mostly living with a family member.14% were neither enrolled in an educational program nor employed

Table 63.1 (continued)

Study	Sample	Measures	Findings
Mellerio et al. 2014 [96]	374 adult aged patients transplanted as children; Median age 27 and 12.3 years since first transplant	Questionnaire with data compared to French general population using indirect standardization matched for gender, age, period	Compared to the general population 31% versus 52.2% lived with partner, 36% v 21% lived with parents and 19% v 10% were unemployment. Factors predictive of poor outcome were primary disease severity, presence of comorbidities or disabilities, being on dialysis, and female gender
Lewis et al. 2014 [64]	236 young adults with ESKD presenting as children compared to those presenting as adults.	Questionnaires	30% of those with a pediatric and 20% of those with an adult presentation were labeled disabled. There was lower educational attainment in pediatric presentation and those with pediatric presentation less likely to have full or part-time paid work (57% v 76%) and less likely to be living with a partner
Murray et al. 2014 [65]	57 young adults:5 CKD, 8 dialysis, 45 TX; 27 were pediatric presentation	Semi-structured interview	Median age leaving school was 16 year: 17.5% still studying, 75% completed education, 60% employed, and 33% unemployed. For those with pediatric presentation: 7% were in special ed. and 26% earned a general certificate of secondary education. 75% felt that their employment or work was negatively affected by ESKD. 33% unemployed and not in school vs 22% in general population. 8.5% were receiving welfare vs 4% in general population
Enden et al. 2018 [97]	29 young adult men who underwent renal transplantation in childhood and 56 matched survivors of childhood acute lymphoblastic leukemia and 52 controls with other childhood illness	RAND-36 BDI	Compared to leukemia survivors and controls transplant recipients had higher BDI scores and reported more bodily pain and worse general health which associated with older age, longer duration of dialysis, multiple transplantations and lower graft function. Transplant recipients were less likely to be in permanent relationship (40% v 8-% controls and 50% leukemia survivors). Transplant recipients reported lower HRQOL. 10% of transplant recipients had at least one child compared to 21% of leukemia survivors, and 43% of controls. 4% transplant recipients graduated from university compared to 14% of leukemia survivors and 18% of controls. 67% of transplant recipients were employed compared to 90% leukemia survivors and 100% of controls

(continued)

Table 63.1 (continued)

Study	Sample	Measures	Findings
Groothoff et al. 2018 [42]	144 patients with onset of ESKD before 14 years of age born before 1979		67.4% of ESKD patients were employed with 19.1% involuntarily unemployed vs 6.4% of general population. 53% had low skill occupation and 10% had high skilled-significantly different than general population. Being on dialysis, motor disabilities and chronic fatigue most important predictors of unemployment. Average income was significantly lower than general population. 21% felt that disease has significant negative influence on professional achievement and career. 34% lived with their parents but 10 years later 67.4% were married or lived with a partner. 31.5% had offspring compared to 74.4%, and 65% of ESKD children scored lower in all domains of developmental milestones than healthy peers
Hamilton et al. 2019 [43]	417 transplant recipients and 173 dialysis patients; 16–30 year old	Study developed survey	Compared to the general population those with ESKD were less likely to live with partner or have children, more likely to live with parents, had poorer quality of life and were twice the likely to have a psychological problem. They were also less likely to have drunk alcohol, 1.6 years older at first alcohol consumption, less likely to have tried cannabis or street drugs, spent money gambling or been in trouble with the law, and twice as likely to have never had sex
Kerklaan et al. 2020 [98]	30 patients diagnosed with non-ESKD CKD during childhood; 18–35 years old	Semi-structured interview	Struggled with daily restrictions, felt defeated hopeless and lagging behind studies and life goals. 20% worked full time, 23% part-time, and 13% unemployed. 43% were students, 26% married or living together, 60% single, 63% living with parents/families, 23% living with partner, and 7% had 1 child

CKD chronic kidney disease, *ESKD* end stage kidney disease, *DICA* diagnostic interview for children and adolescents, *CAPD* continuous ambulatory peritoneal dialysis, *CDI* children's depression inventory, *STAIC* state-trait anxiety inventory for children, *CBCL* child behavior checklist, *PSI-SF* parenting stress index-short form, *FES* family environment scale, *SSNS* steroid-sensitive nephrotic syndrome, *BDI* beck depression index, *FEATS* formal elements of art therapy scale, *PTSD* post-traumatic stress disorder, *K-SADS-PL* Kiddie Schedule for Affective Disorders and Schizophrenia Present and Lifetime Version, *SCICA* semi-structured clinical interview for children and adolescents, *HRQOL* health related quality of life, *PROMIS* The Patient-Reported Outcomes Measurement Information System, *BASC* Behavior Assessment System for Children, *ABAS* Adaptive Behavior Assessment System, *CHQ-PF/CF* Child health questionnaire-Parent form/child form

With respect to general rates of psychiatric disorders in pediatric CKD, Garralda et al. completed modified psychiatric interviews with parents and determined that psychiatric disorders were more common in dialysis patients and CKD patients than in healthy controls [14]. More recently, a study from Turkey also found a high prevalence of psychiatric disorders in children with CKD, including those with a transplant and on dialysis, when compared to the control group. Specifically, they found that 41% of children with CKD were diagnosed with a current psychiatric disorder, compared to 16% in the control group, and that 52% of those with CKD reported a prior psychiatric diagnosis as compared to 7% in the control group [15]. A study from Egypt of children on dialysis and with pre-dialysis CKD evaluated for the presence of a psychiatric disorder using a semi-structured clinical interview. The overall prevalence of psychiatric disorders was 53%, including 68% of patients on HD and 37% of CKD patients without end-stage kidney disease (ESKD) [16].

Emotional-behavioral functioning more broadly has often been assessed through the use of the omnibus ratings scales, such as the Child Behavioral Checklist (CBCL)[17] and Behavior Assessment System for Children (BASC) [18]. A study compared ESKD, CKD, and controls and found that behavior ratings on the BASC by parents and children fell within the average range. Parent ratings showed increased number of internalizing symptoms, but otherwise did not show concerns for social-behavior functioning [19]. Likewise, the Chronic Kidney Disease in Children (CKiD) cohort study investigated emotional-behavioral functioning in children using the BASC-2 completed by parents and found that, on average, children with CKD scored in the typical range, although more children than expected scored >1 standard deviation towards a score of impairment [20]. This was also shown in a study of children with CKD stage I–IV in Korea, which found that based on the parent-proxy CBCL 20.5% and 22.3% of children had scores consistent with clinically significant mental health and psychosocial adjustment problems, respectively [21]. Similar to the findings in older children, this pattern has been demonstrated in preschool children with CKD. The median parent scores on the BASC-2 were consistently within the average range, although 37% of children scored >1 standard deviation above the mean on adaptive behavior problems [22].

In addition to the general prevalence rates of psychiatric disorders and emotional-behavioral functioning in pediatric CKD, there also have been studies that have focused on the prevalence of depression and anxiety. The prevalence of depression or elevated depressive symptoms identified in studies of children with CKD ranges from 7% to 67% (see Fig. 63.2) [23]. The most commonly used instrument to document these findings is the Children's Depression Inventory (CDI). In CKiD, one of the largest studies to date to evaluate depressive symptoms, 7% of 344 children with CKD had a diagnosis of depression or elevated depressive symptoms [24]. This study, which is part of a multi-year, prospective, observational cohort design, identified a lower prevalence than described in other studies, which have primarily been single-center studies. This may be due to selection bias since participants in the CKiD study may be self-selected and have a lower likelihood of psychiatric comorbidity. A single-center study that used the CDI to evaluate for depression in children and adolescents with CKD found that 30% of the participants scored within the clinical range. The most likely to be depressed were the transplant patients (67%) followed by the pre-ESKD patients (25%) and the dialysis patients (13%). This pattern persisted even after adjustment for age and gender [25]. Similarly, Berney-Martinet et al. evaluated CKD patients, healthy controls and transplant recipients for the lifetime prevalence of depression with the Kiddie Schedule for Affective Disorders and Schizophrenia (K-SADS). They found that 35% of transplant recipients and 35% of pre-ESKD recipients have been depressed, compared to 15% of controls. Another study of adolescent transplant patients identified that 17.4% were depressed based on the Beck Depression Inventory [26].

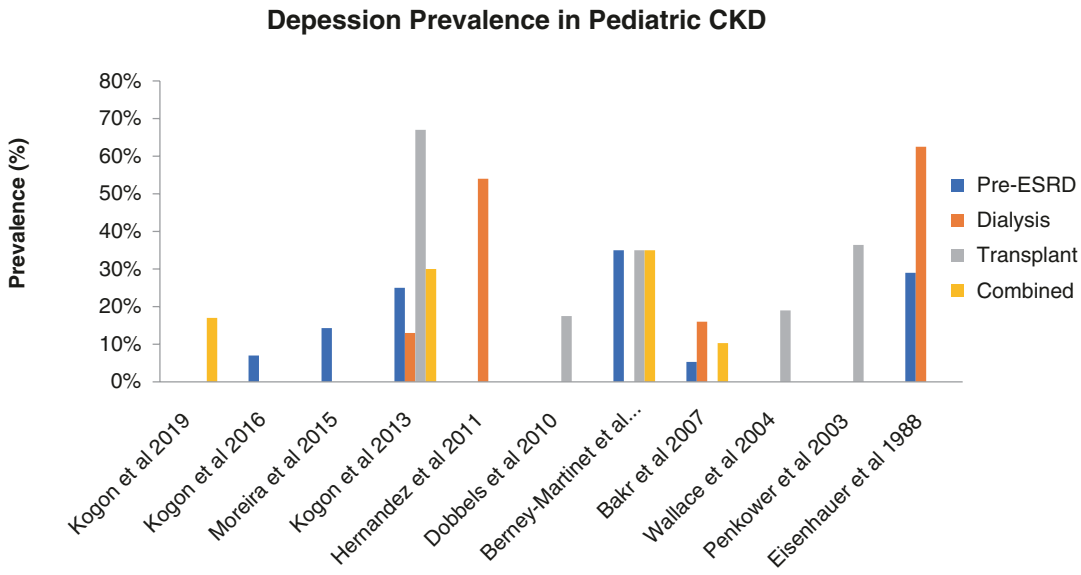

Fig. 63.2 Studies depicting depression prevalence in pediatric chronic kidney disease: prior to end-stage kidney disease (pre-ESRD), dialysis, and transplant

Although less studied than depression, anxiety disorders are also common in children with CKD compared to controls. A study in Japan from 1993 found that 69.6% of children on peritoneal dialysis (PD) experienced an anxiety disorder as compared to only 8.7% of controls, with separation anxiety disorder being the most common in both groups [27]. A subsequent study by the same group also found anxiety to be more common in renal transplant recipients, though not as common as in dialysis patients, than in controls [28]. In another study, the prevalence of an anxiety disorder was 22.5% kidney transplant recipients, 35% in those with pre-ESKD CKD and only 5% in healthy controls [29]. Post-traumatic stress is also of concern, particularly for those with more morbid disease. In a study of renal transplant recipients, 6–21 years of age, 42% of participants had Davidson Trauma Scale scores consistent with post-traumatic stress disorder (PTSD), and the scores correlated with the number of hospital days in the previous year [30] One study from Iran evaluated 80 children with CKD stages 1–3 and 80 healthy children for the presence of obsessive compulsive disorder (OCD) using the Obsessive Compulsive Inventory-Child Version. The mean total scores of children with CKD were significantly higher than for the healthy children, with higher scores being noted particularly in the symptom of doubting/checking and ordering [31].

Renal transplantation remains the optimal therapy for ESKD and is highly advocated for patients on dialysis. Despite receiving a renal transplant, the challenges of living with CKD remain, and as noted above, renal transplant recipients may still suffer from psychiatric and emotional distress. Many studies have compared the burden of psychosocial disease of living with a transplant to pre-ESKD and dialysis. One study clearly demonstrated that families report considerable improvements in a child's physical health. Yet, behavioral problems were twice as common in children who had received a transplant than in the healthy and pre-ESKD groups. Additionally school behavior in the transplant group, as rated by teachers, was similar to the healthy group and overall families reported an improvement in their children's behavior and quality of life [32]. Berney-Martinet et al. likewise did not find that transplantation associated with a lower prevalence of depression when compared to those who were pre-ESKD [29]. Another study also showed similar scores on the CDI and the State-trait anxiety inventory for children (STAIC) between the

transplant and dialysis groups [33]. Other studies even document that the prevalence of psychiatric disorders in renal transplant recipients exceeds those with pre-ESKD CKD [25].

Studies have attempted to identify the risk factors for psychiatric morbidity in children with CKD. Although limited by sample size, most studies have not found disease-related variables to be significantly associated with psychiatric functioning [14, 24, 25, 34, 35], although one study reported higher parent-rated internalizing problems scores in children with non-glomerular disease than glomerular disease [20]. When comparing psychiatric morbidity by dialysis modalities, children undergoing PD appear to fare better than those undergoing in-center HD [33]. A study in Peru showed that 10% of children and adolescents with CKD reported high depressive symptomatology based on the Birleson Scale, and for children on PD the presence of depressive symptoms was significantly associated with Kt/V [36]. Additionally, as in the general population, obesity may play a role in increasing the risk for symptoms of depression [24, 37]. There is also evidence of a genetic role for depression. A CKiD study found that children with CKD who also had a pathogenic genomic copy number variation were more likely to endorse increased internalizing symptoms [38]. An increase in comorbidities, including preterm birth and developmental delay, also likely predisposes an individual with CKD to worse psychiatric functioning [21, 39].

Overall, psychiatric disorders and symptoms appear to be more common in pediatric CKD than in the general pediatric population, and the complications do not fully resolve with transplant. However, longitudinal studies of psychiatric functioning have found that instead of worsening with progression or duration of disease, there are fewer psychiatric complications in those with longer duration of disease and over time [40]. This can be seen in a CKiD study of parent-completed BASC-2 scores that identified improved scores over time [20]. These findings suggest that some children with CKD adapt to their circumstances; however, the examination for the presence of psychiatric disorders and emotional distress remain a critical area.

Social Functioning

The research on social functioning of children and adolescents with CKD is more limited than that of psychiatric functioning (see Table 63.1). Unlike other illnesses, such as childhood cancer, there are no studies directly comparing the classroom and extracurricular behaviors of children with CKD to healthy peers. Much of the available literature is embedded within studies that investigate psychosocial functioning more broadly. For example, the opportunities to make friends is likely impacted by CKD, but there are few studies examining this important social function. One study found that only 30% of children on dialysis, 55% of children with CKD not on dialysis and 83% of control participants reported having a special friend [14]. Similarly, the children with CKD also reported more loneliness than the control participants. Interestingly, in this study, those with CKD not on dialysis reported double the prevalence of being lonely (10%) than those on dialysis. In Japan, a study used the Diagnostic Interviews for Children and Adolescents monthly for 3 months in order to assess school adjustment of children with a renal transplant, children on PD, and control participants [41]. They found the children on dialysis had the most indicators of school maladjustment and that even children in the transplant group indicated significantly more school maladjustment than the control participants.

Evidence for the impact of social functioning and psychosocial development in CKD is also found in studies that compare risky behaviors in adolescents with CKD to control participants. In a multicenter study of North American adolescents with CKD stage II or higher, including ESKD, completed the National Youth Risk Behavior Survey [35]. Compared to a reference group, adolescents with CKD reported significantly fewer high-risk behaviors, including smoking, sexual activity, and unsafe driving, than the reference group. Although it is reassuring that adolescents with CKD appear to be participating in less high-risk behavior than their peers, there is concern that this indicates a delay in developmental milestones since engaging in risky behavior is part of normal adolescent behavior.

Additionally, children with CKD report a delay in the ages of first sexual intercourse and first alcoholic beverage [42, 43]. These delays may indicate a break with typical development that could negatively impact adult outcomes.

Quality of Life

As seen in Table 63.1, quality of life is heavily studied in pediatric CKD. The bulk of these studies have been cross-sectional, with only a few longitudinal studies. Most of the literature has focused on quality of life in patients receiving renal replacement therapies, while other studies have focused on group comparisons across different chronic health conditions and specific CKD groupings. The measure of quality of life usually includes multiple domains (i.e. physical, school, emotional and social) that reveal particular aspects of health related quality of life (HRQOL) that may be affected more than other aspects in particular settings.

There have been a number of studies examining quality of life in kidney transplant recipients. Falger et al. looked at the psychosocial adjustment post-transplant using the Netherlands-based Quality of Life Questionnaire and the CBCL [44]. They found that the dimension measuring emotional functioning was rated as impaired according to both parent and youth report. There were no statistical differences between parent and child ratings with regard to quality of life. Maternal distress showed a negative correlation with most dimensions of the quality of life scale. In Belgium, Dobbels et al. conducted a cross-sectional study with adolescent kidney transplant patients [26]. They assessed HRQOL using the short form of the KIDSCREEN and depression using the BDI. Adolescent transplant patients perceived their physical and psychological functioning about the same as healthy controls. However, parent's ratings of their adolescent's psychological well-being, level of perceived autonomy, and school functioning were significantly lower when compared to healthy controls. Finally, Haavisto et al. examined the quality of life in kidney transplant patients [45]. Data were collected from patients, caregivers and teachers. Using a Finnish HRQOL Questionnaire and U.S. normative date, the adolescent transplant group had significantly less self-reported feelings of distress and experienced more vitality than the controls; but, they described more problems attending school and being with friends. Additionally, parents described the transplant group as experiencing more problems in health and physical functioning than the transplant patients themselves. Taken together, while a transplant clearly contributes to improved health for children and adolescents with CKD, quality of life ratings remain significantly lower.

With respect to renal replacement therapies, a number of studies also have compared quality of life findings across different treatment modalities. Killis-Pstrusinska et al. administered the PedsQL (Pediatric Quality of Life Inventory) to Polish children with CKD and to their parents [46]. The sample included children on HD and PD and pre-ESKD patients. Children on PD reported significantly better quality of life compared to those on HD, and there was significant disagreement between parents and children, with parents reporting worse quality of life. Another study from Europe also demonstrated significantly lower HRQOL across all domains of ESKD (dialysis and transplant) when compared to healthy norms and other chronic conditions, with those who had received a preemptive transplant reporting higher scores on physical health [47]. They also identified that comorbidities was the most important determinant associated with lower HRQOL. Marciano et al. investigated the prevalence of behavior disorders (measured using the Strengths and Difficulties Questionnaire) and the relationship to HRQOL (measured using the PedsQL Global score) in children from Brazil with CKD, including pre-ESKD and dialysis patients and kidney transplant recipients [48]. Parents reported a negative correlation between the presence of behavior and emotional disorders and the HRQOL score. A large study from Australia and New Zealand used the Health Utilities Index (HUI) to show that children on dialysis had the lowest HRQOL, followed by transplant recipients, children with CKD stages 3–5 and children with CKD stages 1–2 [49].

In contrast, several studies have not demonstrated significant concerns for quality of life in children and adolescents with CKD receiving renal replacement therapies. Specifically, Heath et al. evaluated dialysis and kidney transplant patients in the United Kingdom using the Generic Children's Quality of Life Measure (GCQ) and compared their results with normative data [50]. The GCQ questionnaire assesses how the child views his or her life and how they would like it to be. Quality of life is measured as the discrepancy between the two viewpoints. No significant differences between the mean GCQ scores of the participants in various treatment modalities or from the mean of the normative group were observed. Similarly, Park et al. examined the quality of life in Korean children on HD or PD and transplant recipients using the PedsQL End-Stage Renal Disease Module [51]. There were no significant group differences on perceptions regarding family and peer interactions and communication. However, parent reports suggested that communication problems were worse in children on dialysis than in transplant recipients.

A few studies have compared quality of life in children with CKD and other medical conditions. Sundaram et al. evaluated a cohort of liver and kidney transplant patients using the Child Health Questionnaire (CHQ) completed by both parent and child [52]. Caregivers reported lower physical functioning and general health, but similar psychological health to the normative population. Caregivers expressed a negative emotional impact of their child's health on themselves and the family. Diseth et al. evaluated the mental health and quality of life of 28 transplanted youth and compared them to healthy controls and children who had survived acute lymphoblastic leukemia in Norway [53]. In addition to the Strength and Difficulties Questionnaire, the PedsQL was administered to youth and their parents. Similar to previous reports, emotional functioning of the transplant group was poorer than the healthy group, but similar to the cancer group. With regard to maternal mental health and maternal quality of life, parents of the transplant and the cancer groups reported similar degrees of impact of the child's illness on their functioning and on family functioning.

One of the challenges with examining the CKD population is that most studies enroll small numbers, with heterogeneity of age and CKD severity. These challenges likely explain some of the inconsistencies between reports. However, there are several consistent risk factors for lower HRQOL. Repeatedly, females have reported lower HRQOL than males [54–56] and those with short stature suffer lower HRQOL, particularly in the physical functioning domains [54, 57, 58]. Expectedly, maternal distress and adverse family relationships has also repeatedly been identified as associating with poorer HRQOL [44]. Similarly, emotional and behavioral disorders also associate with poorer HRQOL [48]. Other factors identified as associating with HRQOL include number of medications prescribed and the presence of anemia [59, 60]. The relationships between duration of disease and age with HRQOL are more mixed [54, 56, 59, 61].

Lastly, there are only a few longitudinal studies examining quality of life in CKD Neul et al. used a longitudinal case control method to track changes in physical, emotional, social, and educational functioning in dialysis patients and parents over 2 years [55]. The PedsQL and the End-Stage Module of the PedsQL were administered at approximately 6-month intervals. Parent-reported Global PedsQL scores did not change over time; however, global scores assessed by parents were significantly lower in females than males. After adjusting for a number of variables (e.g. dialysis), parents rating of school functioning declined significantly over the 2 years. Further, patients on dialysis had significantly lower emotional functioning. In contrast, patients reported more positive functioning compared to their parent's perceptions. Fadrowski et al. conducted a longitudinal study of physical and psychosocial functioning [58]. In this multicenter study, adolescents and their parents completed the CHQ over 4 years. After adjusting for targeted covariates, the Physical Summary score declined as glomerular filtration rate declined. Additionally, annualized height gains were associated with a improvements in Physical and Psychosocial summary scores, as seen in other studies [49, 57]. Finally, the effect of anemia on

HRQOL using the PedsQL was investigated in 773 children with mild to moderate CKD, with approximately 30% having anemia at the index visit [60]. The presence of anemia was associated with significantly lower overall HRQOL and physical functioning as reported by the children. For the parent ratings, the development of anemia was associated with lower emotional functioning and decreased physical functioning over time compared to those who remained anemia-free. No other findings on the PedsQL were noted.

Long-Term Functional Outcomes

As can be seen in Table 63.1, there is a paucity of scientific exploration into the long-term functional outcomes of childhood CKD. In a study from the United Kingdom that compared 976 young adults with ESKD to the general population, ESKD patients were more likely to live at home with parents and to be unemployed. Further, those who were employed were more likely to participate in low-skill occupations and have significantly lower incomes [43, 62]. Similar findings have been reported in young adults with ESKD in France, the United Kingdom and the United States [63–66].

Fortunately, there is some evidence that socio-professional outcomes are improving for young adults with ESKD. A study from the Netherlands compared the socio-professional achievements of adults with ESKD in 2010 and 2000. In 2010, they were more likely to live with a partner and to have completed a high level educational degree [67]. Clearly, this is an area of interest from a psychosocial perspective, and there is a need for more evidence-based interventions.

Identification and Measurement of Psychosocial Issues in the Clinical Setting

The identification of psychosocial issues may be straight forward. A patient may present with somatic complaints that are not compatible with their medical condition; they may appear withdrawn, with blunted affect; or demonstrate concerning grooming or social habits. A family member or member of the treatment team may raise concern. There are several methods for making a formal diagnosis, including standardized inventories, clinical or structured interviews or direct observation. Interpretation of data gathered from these methods requires consideration of the type of measurement being employed (e.g., is it a rating scale, a clinical interview, an observation?), its psychometric properties (i.e., is it reliable and valid?), who is providing the information (i.e., parents, teachers, the child or adolescent?) including their honesty, forthrightness and insightfulness, and the clinical utility of the obtained information (i.e., how will the information be used and what resources are available to address the chronicity and/or severity of the concerns?).

Clinical interview is a long-held approach to obtaining patient information [68]. When systematic and structured, this approach can provide substantial information about the psychosocial functioning of a child or adolescent. Children can be interviewed alone or with their parent or caregiver. Adolescents typically are interviewed alone. The challenge with clinical interviews is that they tend not to be systematic and there is no assurance that all diagnostic questions will be asked of each patient. This can be addressed by using a structure interview that addresses all necessary questions based on the clinical situation. Examples of structured interviews include the Diagnostic Interview of Children and Adolescents (DICA) [69], the Kiddie Schedule for Affective Disorders and Schizophrenia (K-SADS) [70], the Child and Adolescent Psychiatric Assessment (CAPA) [71], and the Preschool Age Psychiatric Assessment (PAPA) [72], for preschoolers and early elementary age children. The primary advantages of a structured interview is that it increases the probability that necessary questions will be asked, particularly with respect to diagnostic criteria; however, it can be time consuming, limiting its application in a rapid-paced clinical setting. Nonetheless, structured interviews are usually considered the gold standard in clinical research for psychiatric conditions, and

several studies have employed these scales with pediatric CKD.

Another approach to psychosocial assessment is behavioral rating scales. These scales are standardized, normed across a wide age range, typically have strong psychometric properties, and are cost and time efficient, with many now being computer administered and scored. They require some level of literacy on the part of the respondent, but can be completed by a child, adolescent, parent, teacher, or other caregiver. Further, rating scales have been developed to assess a wide variety of psychosocial issues as well as to assess specific concerns. For example, omnibus rating scales that utilize a multi-rater, multi-setting, multi-instrument assessment design include the Child Behavior Checklist (CBCL) [17], Behavior Assessment Scale for Children (BASC) [18], and the Conners' Rating Scale-3 (Conners) [73]. These scales provide a vast amount of information, as informed by the rater, and can assist in identifying psychosocial difficulties as well as screening for psychiatric diagnoses. All of these measures have been used in the assessment of psychosocial functioning in pediatric CKD.

Similarly, rating scales have been developed to identify symptoms and behaviors associated with specific disorders. For example, the Child Depression Inventory-2 (CDI-2) [74] assess for depression or depression symptoms and has been commonly used to identify depression in pediatric CKD. There are also specific rating scales for anxiety (e.g., Multidimensional Anxiety Scale for Children-2 [75]), anger [76], attention deficit hyperactivity disorder (Vanderbilt ADHD Diagnostic Rating Scale [77]), self-esteem (Multidimensional Self-Concept Scale [78]), OCD (Yale-Brown Obsessive-Compulsive Survey [79]), quality of life (PedsQL [80]) and other conditions [81]

While most assessments of psychosocial functioning typically use some combination of clinical interviews and rating scales, the applicability and utility of any of these approaches are determined by the nature of the clinic and the type of services that can be offered. Additionally, the use of multi-rater, multi-setting, multi-instrument assessment models, while providing a wide array of data on the social and emotional functioning of the patient, can present discrepancies in the data across different instruments and different raters. In fact, discrepancies between child and parent perceptions regarding the presence and the severity of psychosocial issues should be expected as they are consistently observed in nearly all of the studies cited in this chapter. For this reason, obtaining information from multiple informants is advisable [82]. Additionally, it is important to note that perceptual discordance is particularly pronounced during adolescence [57] and it is important to consider this discordance in the interpretation of psychosocial measures. Working with a pediatric psychologist or other mental health professional (e.g., social worker, counselor, child psychiatrist) can assist in the interpretation of these assessments.

Management of Psychosocial Issues in the Clinical Setting

Addressing the psychosocial needs of children and adolescents with CKD is important but can present challenges. Nephrology providers manage the medical complexity of CKD and may have limited time to address psychosocial issues, especially given limited knowledge in this area. In addition, families may be reluctant to raise yet another problem that may need to be addressed by adding more providers, appointments, or medications to their already complicated regimens. Moreover, there are no data specific to treating psychosocial issues in the context of pediatric CKD.

To address the psychiatric challenges, a medical social worker is often already part of the team in many pediatric nephrology programs and can be a good resource for families. The social worker can address any background stressors and can provide coping strategies to the patients. Community mental health provides also may be an option, although in the United States access can be limited by insurance constraints and community providers may feel more comfortable partnering with the medical team given the complexity of CKD. Referral to pediatric psycholo-

gists can be helpful for administration of evidence-based therapies, such as cognitive-behavioral therapy, to address psychiatric issues. In the United States, access to pediatric psychologists can also be a barrier. For adolescents, referral to an adolescent medicine specialist can be helpful for strategies to manage living with a chronic condition. Lastly, pharmacotherapy for treatment of anxiety, depression, ADHD, and other psychiatric conditions can be useful. Although not specifically studied in children and adolescents with CKD, the selective serotonin uptake inhibitors have been studied in adults with CKD and ESKD and therefore should be considered first-line agents for managing depression and anxiety. Fluoxetine and citalopram do not require dosage adjustments in CKD, while the maximum dosage of sertraline may need to be reduced [83].

There are additional options to support the social and behavioral health of children and adolescents with CKD. Families can be supported by connecting them with other families of children with CKD, which can include connections through social media or kidney camps. Attending kidney camps has been shown to be beneficial for both patients and their families [84–86]. Pediatric psychologists and medical social workers can provide parenting tools and stress management techniques. In addition, child life providers can help manage the anxiety and psychological trauma that may come from repeated invasive medical procedures and encounters. To reduce stress in the school setting, medical social workers can advocate for a patient's needs and accommodations.

While a discussion of school-related functions is beyond the scope of this chapter, there is a longstanding recognition of the negative impact of physical illness on educational and eventual occupational functioning as these disruptions can affect psychosocial functioning. Educational and occupational problems appear to be major areas of concern for children and their parents; chronic school absenteeism is alarmingly common in children with CKD [87]. Not only do school absences have a direct impact on gaining fundamental academic proficiencies, but missed school also interferes with children acquiring essential social competencies and developing social support networks. Even with the relatively reassuring educational and occupational assessments of children with CKD [88], continued efforts need to be made to allow for school-based accommodations as well as work-based accommodations for absences due to medical appointments and sporadic exacerbations of kidney disease.

Finally, the type of mental health treatment and/or social supports for children and adolescents with CKD may vary by developmental level. For example, adolescents with CKD may face barriers during their transition to early adulthood, particularly with respect to their healthcare. The transition to adulthood is an important period in human development that requires an individual to increase autonomy, find gainful employment, and build social relationships. Pediatric CKD and the medical complications that can be associated with CKD can prevent many adolescents from making this transition and facing these developmental challenges successfully. To date, intervention research geared toward the medical and psychosocial barriers that impede transition to adulthood is emergent and several possibilities exist that might prove instrumental in smoothing the transition for adolescents with CKD. The issue of transition is critical to the psychosocial health of this population, particularly given the medical needs that will continue into adulthood and the concomitant psychosocial burden that many of these youth will experience as they move into the adult world [89].

Gaps in the Literature and Future Directions

It is clear that children and adolescents with CKD experience psychosocial challenges and that these challenges should be addressed. More research is needed to provide evidence-based literature to define appropriate interventions. In addition, more interdisciplinary support, such as therapists, psychologists and psychiatrists, would enable better care for pediatric CKD patients. Research that clearly establishes the relationships

between psychosocial distress and outcomes, such as healthcare costs and utilization and educational and professional attainment, and demonstrates improvement in outcomes with appropriate interventions would be helpful to justify increased psychosocial support.

Conclusions

Children with CKD have many challenges, including short stature, chronic school absenteeism and reduced social opportunities. Consequently, children and adolescents with CKD at all stages of disease may experience mental health and adjustment problems that extend into adulthood and affect quality of life. Although renal transplant is the optimal therapy for ESKD, it is not curative, and children and adolescent renal transplant recipients have psychosocial issues, and some may even be exacerbated. Disease related variables have not consistently been shown to associate with psychiatric functioning, but obesity, genetics, comorbidities and preterm birth may predispose a child with CKD to impaired psychosocial health. There are many tools to measure psychosocial performance to aid in identification of impairment. Although medical social workers, community mental health providers and adolescent medicine doctors may offer support and strategies to struggling patients, more research is needed to define the interventions that will improve the psychosocial health, and ultimately improve the long-term outcomes of children with CKD.

Part XIII

Kidney Replacement Therapy

64 Initiation of Kidney Replacement Therapy: Strategic Choices and Preparation

Jérôme Harambat and Iona Madden

Introduction

During the past three decades, the management of children with chronic kidney disease (CKD) and end-stage kidney disease (ESKD) has improved dramatically. In high-income regions, though the financial cost is important, provision of kidney replacement therapy (KRT) by dialysis or pre-emptive transplantation is considered standard care for the great majority of children for whom this therapy is indicated. However, in lower income countries, the economic, human, and technical resources required for the treatment of childhood ESKD make it a major health challenge.

Children with CKD and their families/caregivers experience a complex decision on KRT initiation and treatment modality choice for a lifelong condition. The timing and circumstances of KRT initiation, and the choice of KRT modality can significantly impact clinical outcomes as well as the child's and caregivers' mental health and social life. The chosen KRT modality for children should ensure the lowest risk of mortality and morbidity and provide the best quality of life. In this regard, (living donor) pre-emptive kidney transplantation, when feasible, is considered the best choice of KRT in children. However, the majority of pediatric patients with ESKD will require dialysis. Chronic peritoneal dialysis (PD) can offer several advantages over hemodialysis (HD) for children.

This chapter outlines the current distribution of KRT modalities among incident and prevalent pediatric patients worldwide, the main outcomes according to KRT modality, the optimal timing of KRT initiation (dialysis initiation, preemptive kidney transplantation), the dialysis preparation and transplant workup. In addition, the chapter explores the pros and cons of each KRT modality taking into consideration the widely variable access to KRT around the world, and the lifetime perspectives of the choice to be made. Topic reviews that include more comprehensive management, complications and outcomes of the different modalities of KRT are discussed in separate chapters.

Current Distribution of Initial KRT Modalities Among Pediatric Patients Worldwide

The incidence, prevalence, and treatment modalities of pediatric ESKD worldwide are only partially known because of differences in pediatric patient definitions, disease classification, and lack of national registries and health information systems, especially in low- and middle-income

countries [1, 2]. Most of the epidemiological data on pediatric ESKD requiring KRT (dialysis or kidney transplantation) is derived from high-income countries due to the availability of robust national or international registries mainly in Europe, Australia and New Zealand, and the United States [1].

The incidence of ESKD in children varies widely across different countries but ranges from 5–15 per million children per year among patients under 20 years. The number of children starting KRT has decreased in the United States where the incidence rate was the highest worldwide, remained stable in other high-income countries [3, 4], and may have increased in some lower income countries. The prevalence of ESKD in children varies between 40–60 per million children in Western Europe and Australia, with the prevalence being higher in the US (around 100 per million children) and lower in South America and Eastern Europe. Globally the prevalence of children undergoing KRT (functioning transplant or maintenance dialysis) may be increasing, yet there is considerable variation in access to and practices of initiating KRT worldwide. Several factors may have contributed to the increase: improved survival of ESKD children, broadening pediatric KRT acceptance criteria, and better access to pediatric KRT (especially dialysis) in low- and middle-income countries.

However, major disparities currently exist in access to kidney care services for children, particularly in low- and middle-income countries so that most pediatric patients with ESKD in these countries have no or limited options for KRT and the vast majority of children receiving KRT worldwide reside in high-income countries [1, 5, 6]. A wide variation in the initial KRT modalities exists across the world.

Kidney transplantation is the preferred KRT option in children and adults with CKD, conferring significant survival advantage, improved quality of life, and health system cost savings. According to the Global kidney Health Atlas, kidney transplantation is not available in more than 20% of countries worldwide (>60% of African countries) and the proportion of countries that cannot provide pediatric kidney transplantation is expected to be much higher [7]. In Europe and the United States, approximately 20% of children start KRT with pre-emptive kidney transplantation [3, 4]. The access to pediatric kidney transplantation is influenced by ethnic, economic and geographic disparities [8–10]. For example, across 32 countries in Europe, a strong association was found between country income based on the GDP per capita and the country-specific rate of pediatric kidney transplantation [11]. In some countries, kidney transplantation is not available as an option for initial KRT in children.

Children who do not receive pre-emptive kidney transplantation may receive PD or HD, but the prevalence of the use of each of these modalities varies substantially depending on the center, country, reimbursement system for ESKD care, and public policies [5, 12]. In Europe and the UK, there is an almost equal distribution between HD and PD as initial modality. HD is the most common initial dialysis modality in the US and Brazil, while PD is more frequently chosen as first modality in Australia/New Zealand and Japan (Fig. 64.1). There seems to be trend towards a decrease in PD use versus HD as first KRT modality, particularly in the UK and the US [3, 13]. PD may be the preferred chronic dialysis modality in low-resource settings although HD in adult dialysis facilities is often the only option because of the cost and logistical challenges associated with PD in children [14, 15]. Globally, PD, most commonly provided with an automated cycling device (CCPD), is usually the first dialysis modality for infants and young children, while HD predominates among children above 10 years and adolescents. Home hemodialysis (HHD) is offered to a small number of selected children by a few centers [16].

Main Outcomes According to KRT Modality

It has been established that (pre-emptive) kidney transplantation offers better patient survival than dialysis [17–19]. In the US, children treated with HD or PD have a five and two times higher 1-year mortality rate after initiation of KRT than those receiving a preemptive transplantation [3]. In Europe, starting KRT with dialysis is associated with a two-fold higher hazard of death as compared to preemptive kidney transplantation [20]. Children and adolescents <21 years of age initiating KRT with preemptive transplantation have a higher 5-year survival of 96–97% in the US and Europe as compared to ~86% (US) and ~ 90–92% (Europe) with dialysis [3, 21]. Mortality on dialysis is particularly high in infants and children younger than 5 years of age. In the very long-term, both European and US data suggest that children treated with dialysis would have a deficit in their expected remaining lifetime of 40–50 years vs. 12–20 years for transplanted patients [3, 22]. Nonetheless, about 80% of pediatric patients are either started on dialysis to bridge the preparation time needed for transplantation or will require dialysis after graft loss [3, 4].

Survival comparisons by dialysis modality in a randomized clinical trial setting proved extremely difficult [23]. Consequently, survival comparisons rely on registry data [24, 25]. In the pediatric dialysis population, there seems to be a consistent trend showing survival advantage in patients on PD with a 20–30% reduced mortality risk as compared to those who start KRT on HD [24–26] (Fig. 64.2). In the USA, this better survival on PD was only present in children <5 years, whereas in Europe, the effect size was smaller in children <5 years and no difference was observed in infants <12 months [26]. Furthermore, European data show that this PD treatment effect was stronger during the first year of dialysis, in older children, and in children late referred to pediatric nephrology care [25]. However, despite adjusted or stratified analyses, the risk of indica-

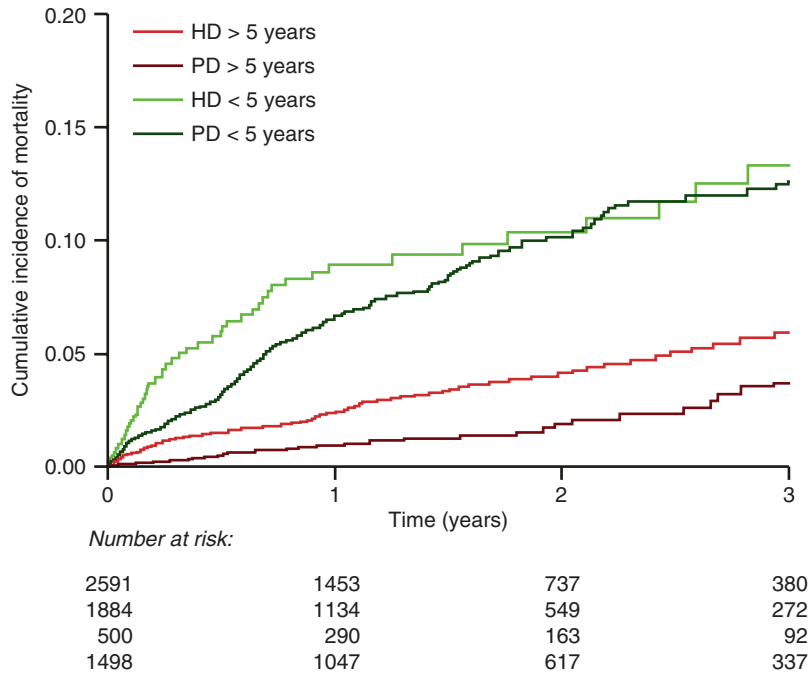

Fig. 64.2 Cumulative incidence of mortality in European children on hemodialysis and peritoneal dialysis at start of kidney replacement therapy (used with permission from [25])

HD hemodialysis, *PD* peritoneal dialysis

tion bias inherent to observational studies remains, as sicker patients are more likely to be started with HD. Dialysis in neonates is challenging but technically feasible. Data on 264 patients from 4 international registries who commenced chronic dialysis in the first month of life showed a 3- and 5-year survival rates of 80 and 76%, respectively [27].

Children and adolescents undergoing dialysis report severely decreased health-related quality of life (QoL) compared to those with a functioning transplant but, surprisingly, most studies did not find significant differences between patients on HD and those on PD [28, 29]. However, PD has been associated with more dietary and fluid freedom, and less disruption in children's schooling and social life compared with HD [30].

Moreover, preemptive kidney transplantation has been associated with improved post-transplant outcomes such as significantly reduced risk of graft loss [19, 31, 32], reduced risk of acute rejection [33], and better health-related QoL in the domain of physical health [34].

Optimal Timing of KRT Initiation

Current Recommendations and Guidelines

In 2020, a position statement from an expert group recommended dialysis initiation when the eGFR drops below 10 mL/min/1.73 m^2 or when the child has uremic symptoms refractory to medication or dietary management [35]. All other recommendations come from adult guidelines. The Kidney Disease Outcomes Quality Initiative (KDOQI) suggested in 2006 that dialysis should be considered when eGFR is <14 mL/min/1.73 m^2 and recommended when eGFR falls to <8 mL/min/1.73 m^2 [36]. The updated 2015 KDOQI (for HD) stated that symptoms and signs associated with CKD complications, rather than a specific eGFR, should guide the decision to initiate dialysis [37]. The KDIGO conference report in 2018 confirmed that there is no specific eGFR threshold for dialysis initiation in the absence of symptoms, and that current data do not support pre-emptive dialysis initiation [38].

Regarding transplantation as an initial KRT modality, the European Renal Best Practice (ERBP) recommended to develop programs for preemptive living donor kidney transplantation [39]. There is no guidance for the timing of preemptive transplantation but a statement that the optimal timing should be to avoid dialysis in a patient who otherwise would need to start it according to current guidelines i.e., shortly or a few months before the need to initiate dialysis [39]. Indeed, in adults, neither patient nor graft survival was influenced by the level of pretransplant eGFR [40]. A recent KDIGO clinical practice guideline also recommended that patients should be referred for evaluation 6–12 months before anticipated dialysis to facilitate preemptive kidney transplantation [41]. The KDIGO guideline specifically recommends preemptive kidney transplantation (living or deceased donor) in children when the eGFR is <15 mL/min/1.73 m^2 or earlier with symptoms [41].

Pre-ESKD Care and Referral for KRT Initiation

Optimal CKD care should include timely referral and frequent visits with a multidisciplinary team of physicians, nurses, dieticians, social workers and pharmacists. This integrated model of CKD care has been associated with improvement in measurable outcomes [42, 43]. Recommendations for "timely referral" to a pediatric nephrologist should allow access to multidisciplinary care for CKD, patient and family education and support, and considering a preemptive kidney transplantation.

Delayed referral, lack of patient preparedness and urgent-start of dialysis have been associated with higher morbidity on dialysis, lower access to kidney transplantation, and worse kidney graft survival [44–46]. Late referral has been defined as starting dialysis between 1 and 3 months after the first appointment with a pediatric nephrologist. Late referral in adults has been associated with limited choice of dialysis modality and worse clinical outcomes, including more hospitalizations and deaths [47]. Similar findings have been reported in children. In the UK, 25% of children with ESKD were referred late (defined as having <3 months between first visit with a pediatric nephrologist and commencement of KRT). These patients were less likely to receive a kidney transplant after 1 year of dialysis (21% vs. 61% for early referral) without difference in mortality [45]. In a study from Poland, children with a late referral had more metabolic and clinical complications, more admissions to ICU, and a lower chance to receive a kidney transplant within 3 years [48]. Of 1527 children in the ESPN/ERA-EDTA registry whose first appointment with a pediatric nephrologist was known, late starters (45%, defined as eGFR <8 mL/min/1.73 m^2 at start of KRT) were significantly more likely to be late referrals [49]. However, the access to kidney transplantation at 1, 2, and 5 years was similar regardless of the timing of referral [49].

Urgent Versus Non-urgent and Planned Versus Unplanned Start of KRT

In 2018, a KDIGO Consensus Conference defined urgent-start dialysis by the need to initiate dialysis imminently or in less than 48 h after presentation in order to correct life-threatening manifestations [38]. An unplanned start is defined as dialysis initiation when access is not ready for use or when dialysis is initiated with a modality that is not the patient and family's choice. HD and PD are possible in both planned or unplanned and urgent or non-urgent start of dialysis. However, children requiring KRT in the setting of hyperkalemia, volume overload or critical illness may not be good candidates for urgent start with PD. The risk factors for urgent and unplanned start of dialysis include late referral, lower socio-economic background, lower health literacy, acute illness, rapid (and often unpredictable) loss of kidney function, and severe symptoms [50–52]. When urgent or unplanned start dialysis limit the initial modality choice, patients and families need to subsequently be provided with education and support to allow them choos-

ing their preferred modality when feasible. Conversely, a planned initiation of dialysis is performed when the modality has been chosen prior to the need for dialysis and the access is ready for use. A preemptive kidney transplantation is by definition a planned modality of KRT.

Outcome According to the Timing of KRT Initiation

There is a large variation around the world in the threshold of eGFR for the initiation of dialysis in children. There is variation in approach both between and within countries. The median eGFR at dialysis initiation in pediatric patients in Europe and the USA is around 8 mL/min/1.73 m^2 but the range is wide, from less than 5 to over 10 mL/min/1.73 m^2 [49, 53, 54]. In the Japanese registry, the median eGFR at KRT initiation (including kidney transplant) was 12 mL/min/1.73 m^2 [55]. There is a trend towards earlier start of dialysis: a USRDS registry study including more than 15,000 children found that the proportion of children starting dialysis with an eGFR >10 mL/min/1.73 m^2 increased from 16% in 1995 to 40% in 2015 [54]. In Canada, there has been a change over the past 20 years with dialysis currently being initiated at an eGFR ≥10.5 mL/min/1.73 m^2 in one-third of children, a higher rate than previously reported [56]. The reasons for this trend are unclear. Possible reasons could be the adoption of changing trends in the clinical practice guidelines, starting from KDOQI 2006 in which the recommendations were to consider dialysis if eGFR was below 14 and start when eGFR was below 8 mL/min/1.73 m^2 [36]. However, updates from KDOQI 2015 and KDIGO 2019 recommend commencement of dialysis when the patient becomes symptomatic [37, 38].

A specific eGFR value for initiating dialysis in the absence of symptomatic kidney failure has not been established in adults. The IDEAL trial could not demonstrate a benefit of commencing dialysis at higher levels of eGFR [57]. Recently, there have been three large pediatric registry studies from USRDS and ESPN/ERA-EDTA examining the association between eGFR at initiation of chronic dialysis and clinical outcomes [49, 53, 54]. Of nearly 10,000 incident dialysis patients aged 1–17 years in the USRDS registry (1995–2016), higher eGFR at dialysis start was associated with a higher mortality risk. Specifically, compared with eGFR of 7 to <9 mL/min/1.73 m^2, eGFR <5 and ≥12 mL/min/1.73 m^2 were associated with lower and higher mortality, with adjusted HR of 0.57 and 1.31, respectively [53]. In stratified analyses, mortality risk was associated with higher eGFR in children ≥6 years, whereas the association was attenuated among those younger than 6 years. Although this study suggests that initiating dialysis at eGFR >12 mL/min/1.73 m^2 is associated with increased mortality, there seems to be a similar outcome across the range of 5–12 mL/min/1.73 m^2 in which the majority of ESKD patients will start KRT [53]. Another study from the USRDS assessed the association between eGFR at dialysis initiation and hazard of death in a total of 15,000 children aged 1–18 years in the period 1995–2015 [54]. Mortality risk was 36% higher among those with higher (> 10 mL/min/1.73 m^2) versus lower (≤ 10 mL/min/1.73 m^2) eGFR at dialysis initiation. The mortality associated with higher eGFR risk was more pronounced among children receiving HD (HR 1.56) while the association with eGFR was no longer significant among those treated by PD [54]. In Europe, a retrospective ESPN/ERA-EDTA Registry study of ~3000 children aged <18 years from 21 countries found no difference in mortality risk and access to transplantation between children who started dialysis at eGFR ≥8 mL/min/1.73 m^2 vs. < 8 mL/min/1.73 m^2 [49] (Fig. 64.3).

Notably, the ESPN/ERA-EDTA Registry study found no significant difference in other outcomes such as anemia, hyperphosphatemia, growth, and access to transplantation between late starters at eGFR <8 mL/min/1.73 m^2 (median 6) and early starters at eGFR ≥8 mL/min/1.73 m^2 (median 10.5) [49]. However, the prevalence of hypertension was higher in late starters (61%) than in early starters (54%) [49]. In a Turkish study of 245 children, patients with early-start dialysis at eGFR >10 mL/min/1.73 m^2 (mean 13.5) and late-starters at eGFR <7 mL/

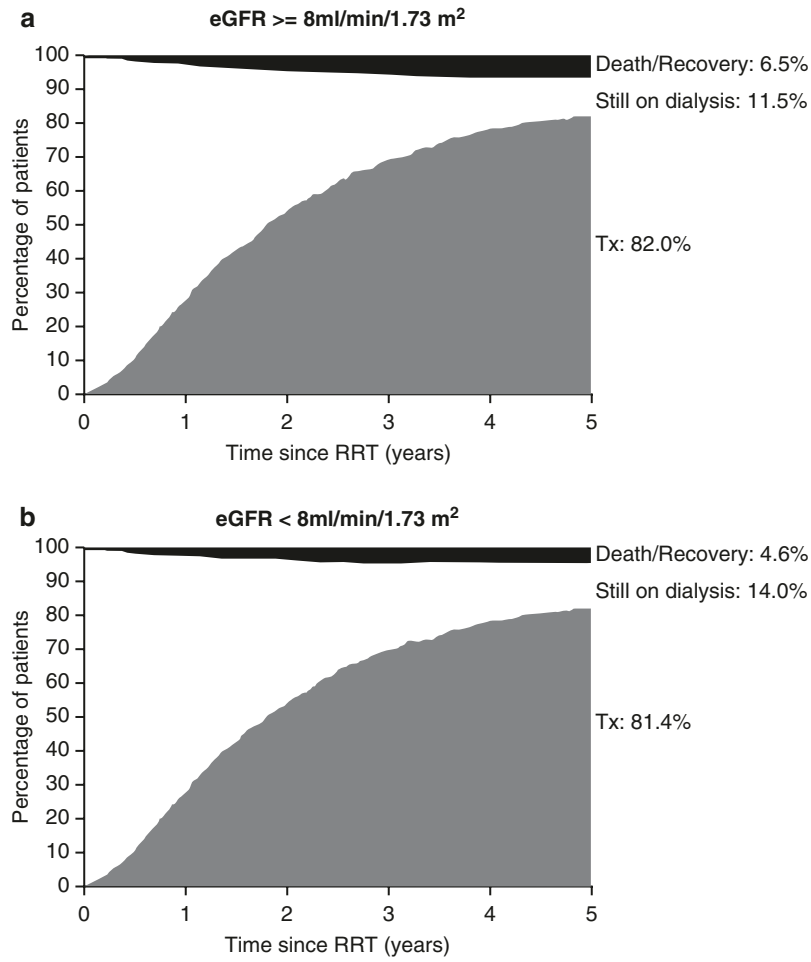

Fig. 64.3 Cumulative incidence of death and kidney transplantation within 5 years of dialysis initiation for European children starting dialysis early (eGFR ≥8 mL/min/1.73 m^2) (A) and children starting dialysis late (eGFR <8 mL/min/1.73 m^2) (B). Used with permission from [49]

Tx kidney transplantation, *eGFR* estimated glomerular filtration rate, *RRT* renal replacement therapy

min/1.73 m^2 (mean 5.5) did not significantly differ in left ventricular mass index (LVMI) and left ventricular hypertrophy (LVH) [58].

Regarding nutrition and growth, the ESPN/ERA-EDTA study showed that height SDS was not different at start of dialysis with an eGFR above or below 8 mL/min/1.73 m^2 (−1.79 vs. −1.76), and the drop in height SDS after 1 year of dialysis was similar in both groups (−0.22 vs. −0.24) [49]. The distribution of BMI was also comparable between the two groups. However, in a cohort study of the International Pediatric Peritoneal Dialysis Network (IPDN) (1000 PD children from 35 countries), an underweight status was twice more common in children starting PD at eGFR <6 mL/min/1.73 m^2 (11%) compared to those starting PD at eGFR 9–12 mL/min/1.73 m^2 (5%) [59].

There is no pediatric data to suggest that patient or graft survival could be influenced by the level of eGFR at time of preemptive kidney transplantation.

KRT Initiation

The timing of KRT initiation is a complex decision that needs to take into account the eGFR and the rate of its loss, the treatment modalities available, and symptoms or signs attributable to kidney failure. Initiation of KRT is usually considered in case of inability to control volume status or blood pressure, deterioration in nutritional status or growth failure, severe biochemical abnormalities such as hyperkalemia, hyperphosphatemia or metabolic acidosis, and

patient reported outcome measures such as fatigue, nausea and loss of appetite, declining cognitive performance, or poor QoL [30, 35].

While the optimal timing for starting KRT is unknown and the reasons for initiating dialysis are highly variable, risk equations may be potentially helpful to predict the time when KRT will be necessary although validation studies are limited in children [60, 61]. This may be combined with, and not replace, clinical judgement. The decision to start KRT should ideally always be reached by discussions between the child when appropriate, caregivers, and the CKD multidisciplinary care team.

Once maintenance dialysis has been initiated in pediatric patients there is a recovery rate of 2% within 2 years after the start of dialysis [62]. There is a particularly high chance of recovery (>10%) in children starting dialysis for vasculitis, ischemic kidney failure, and hemolytic uremic syndrome, which should be considered when planning expedited kidney transplantation [62].

Dialysis Availability and Choice of Modality

Dialysis modalities include in-center and, rarely, home HD, as well as continuous ambulatory and automated PD. Prescription patterns can be categorized as conventional, intensive (short daily or nocturnal), or exceptionally palliative in children [63, 64]. Availability of modalities and prescription patterns usually depends more on local resources and infrastructures, reimbursement policies, center practices and expertise, than patient and family preferences. In most high-income countries, in-center hemodialysis is the predominant modality whereas PD is the first option in some areas. In high-income countries, PD may be more cost effective than HD, yet the opposite might be true in low- and middle-income countries where KRT is offered to children but manufacturing or importing PD fluids could be more expensive [38].

The selection of dialysis modality is based on the patient's age and comorbidity, family support and psychosocial conditions, local resources, modality contraindications, healthcare team expertise, and child and family choice (Table 64.1). The only absolute contraindication for maintenance HD is the absence of possible vascular access or prohibitive cardiovascular instability (Table 64.2). PD is contraindicated if the peritoneal membrane is not functional or PD catheter is not possible (Table 64.2). All other conditions are relative contraindications.

Table 64.1 Issues to be considered in the selection of kidney replacement therapy modality in children

Factors to be considered
Patient and family preference
Patient age and size
Medical/surgical comorbidities, contraindications
Geographic location, distance to the center
Local nephrology/surgical expertise
Family burden
Psychosocial support
School attendance
Growth
Lifelong morbidity and mortality
Healthcare system, out-of-pocket costs

There is no study to suggest that either PD or HD is superior in children with ESKD. PD is often preferred and widely used in infants and small children for whom the creation and maintenance of a suitable vascular access can be challenging. Home dialysis modalities such as automated PD using a cycling device (CAPD) and rarely home HD (HHD) can improve patient autonomy, flexibility and QoL, and facilitate regular school attendance [35, 63]. PD is also preferred over HD in children with cardiovascular instability, and some reports have suggested benefits of HHD in children with cardiac failure [65]. Preserving residual kidney function is important in the choice of KRT modality and should be a goal for pediatric nephrologists. Although PD may be associated with a slower decline in residual kidney function than HD, the evidence regarding the effect of initial dialysis modality and therapeutic strategy is limited in children [66, 67].

In addition to medical factors, the proximity to a pediatric HD center and the heavy burden of home dialysis care for families should be considered when choosing a dialysis modality. In some countries, it has been reported that children with

Table 64.2 Contraindications to the different kidney replacement therapy modalities in children

	Preemptive kidney transplantation	Peritoneal dialysis	Hemodialysis
Absolute contraindications	• Active infection • Severe irreversible multisystem organ failure • Severe pulmonary or cardiac dysfunction in a child not suitable for multiorgan transplant • Life-threatening extrarenal disorder not correctable by kidney transplant • Uncontrolled malignancy	• Abdominal wall defects • Diaphragmatic hernia • Bladder exstrophy • Obliterated peritoneal cavity • Peritoneal membrane failure	• No vascular access • Severe cardiovascular instability • Unavailability of facilities
Relative contraindications	• Active systemic disease (lupus, vasculitis, anti-glomerular basement membrane disease) • Unstable psychiatric disorder • Ongoing, health-compromising nonadherent behavior	• Ileo/colostomies • Recent major abdominal surgery • Infant with organomegaly • Inadequate living situation for home dialysis, lack of caregiver support	• Difficult vascular access • Coagulopathy • Unstable psychiatric disorder

social disadvantage tend to receive more commonly HD than PD compared to those from wealthier families and have less access to preemptive kidney transplantation [46, 68]. This suggests delayed referral as well as concerns by healthcare providers and/or caregivers themselves about their ability to safely provide dialysis at home. Further investigation is needed to clarify whether social inequities exist in the provision of KRT in children. Although the published data is limited in pediatric nephrology, there has been growing recognition of the importance of patient and caregiver involvement in planning CKD care and shared decision-making regarding KRT modality [68–70]. The modality selection should therefore reflect informed child and family choice adapted to their health and social conditions and appropriate to the healthcare system and local resources.

Dialysis Preparation and Transplant Workup

Dialysis Preparation

Many children, for various reasons, require a variable period of dialysis before transplantation is possible. Dialysis is considered a bridge to kidney transplantation and should be as short as possible to improve outcomes [19, 31]. Adequate dialysis preparation enables better understanding of the dialysis process, reduces fear and anxiety regarding long-term dialysis, thus ensuring improved therapy adherence and better overall outcomes.

Before starting dialysis, patients and their caregivers should meet the following criteria: (i) they need to have a good understanding of the different treatment options available, (ii) they should have a functioning permanent access for the dialysis modality of their choice, and (iii) they should not require hospitalization for untreated complications of acute or chronic uremia [30, 35, 38, 71].

1. Education

   Patient education and decision support are essential in helping patients and families to better understand ESKD and available KRT options, improve literacy and possibly outcomes. In adults, early education has been associated with better survival after dialysis initiation [72]. Effective education programs should be offered to the child if appropriate, and the family or caregivers when the eGFR is <30 mL/min/1.73 m^2 (CKD stage 4). Comprehensive education material should

provide information related to all forms of dialysis. In addition, a thorough psychological, social and economic evaluation of the family or caregivers is required to determine their ability to cope with the burden of care associated with the provision of home KRT (PD or HHD) [63]. The multidisciplinary care team can therefore individualize the training plan to meet the needs of the parents or caregiver.

2. Dialysis access

PD access should be prepared whenever possible at least 2 weeks before starting KRT. For late-referred patients, this might imply switching to HD temporarily or definitively. However, urgent-start PD has been proven safe in adults, and early catheter use feasible in children. Gastrostomy tube feeding in children already receiving PD is not contraindicated but a gastrostomy tube should be ideally inserted prior to the placement of a PD catheter [73]. There are guidelines regarding optimal timing and placement technique for PD catheters, access type, PD training, and prevention of complications in the pediatric population [74–76]. Constipation has been associated with increased risk of post placement PD catheter migration and should be addressed preoperatively. The use of a double-cuff Tenckhoff catheter has been recommended [75], and omentectomy to prevent PD catheter occlusion should be considered at the time of catheter insertion.

Among children receiving HD, central venous catheter (CVC) is the predominant vascular access choice. The International Pediatric HD Network reported the use of an arteriovenous fistula (AVF) in 26% of children initiating HD; this rate was higher in an ESPN/ERA-EDTA study (45%), and much lower (< 15%) in a recent USRDS report [3, 77, 78]. A vascular access with an AVF has been associated with better dialysis efficacy, fewer medical complications, less vascular access procedures, lower costs, and higher deceased donor transplantation rate than an access with a CVC [77, 78]. It is therefore recommended that children start HD with a functioning AVF which should be created at least 3 months before anticipated use [79]. However, in some circumstances such as in infants and young children depending on size and surgical expertise, those requiring unplanned HD, those with an anticipated short period of dialysis before (living donor) kidney transplantation, or patient choice, a cuffed CVC is preferred [79]. The choice for access thus requires individualization for each patient and a dedicated vascular access clinic may optimize the timing and quality of vascular access in this setting [79–81].

Kidney Transplant Workup

1. General principles

The pre-transplant evaluation (Table 64.3) is an essential part of the kidney transplant process and aims to reduce complications and increase graft and patient survival [41, 82]. The transplant workup should be started 6 to 12 months before the patient is likely to require KRT in known CKD patients, but should start as soon as possible in patients with a late referral. It includes a medical and psychosocial evaluation, and patient/caregiver education. The initial phase is to rule out any contraindications (Table 64.2). The medical evaluation also includes the detection of anti-Human Leukocyte Antigen (HLA) antibodies to the donor, the detection and treatment of any infection prior to transplantation, the completion of immunizations, screening for coagulation and thrombosis abnormalities, and the correction of any significant urinary tract abnormality. In certain cases, the indication for native nephrectomy should be discussed. Patients and their families or caregivers should be provided with sufficient information regarding patient survival, transplant complications and immunosuppressive drugs used and their side effects.

2. Blood group

The majority of kidney transplantations are ABO compatible and most allocation schemes allocate donor kidneys on the basis of blood

Table 64.3 Proposed pre-transplant assessment check list

	Relevant workup		Date/frequency
Planned transplant type	Living or deceased donor		
Chronic kidney disease evaluation	Diagnosis (± genetic testing when relevant)		
	Dialysis history		
	Previous transplants (living donor – deceased donor)		
	Creatinine		
	eGFR		
	PTH, calcium and phosphorus levels		
Immunology	Blood group		
	Tissue typing		
	Cross match		
	HLA antibodies		/3 months
Infectious disease workup	Serologies/PCR	CMV	/3 months if negative
		EBV	/3 months if negative
		Hepatitis B	
		Hepatitis C	
		Hepatitis A	
		Varicella	
		Measles/mumps/rubella	
		Toxoplasmosis	
		HIV	
		Syphilis (VDRL/TPHA)	
	Immunization history

BCG Bacille Calmette-Guerin, *CMV* cytomegalovirus, *CYP3A5* cytochrome P450 3A5, *EBV* Epstein-Barr virus, *eGFR* estimated glomerular filtration rate, *G6PD* glucose-6-phosphate dehydrogenase; *HIV* human immunodeficiency virus, *HLA* human leukocyte antigen, *PCR* polymerase chain reaction, *PTH* Parathormone, *TB* tuberculosis, *TPMT* Thiopurine methyltransferase

group identity. However, given donor shortages, an increasing number of centers provide living donor blood group incompatible transplantation. Recipient anti-B or anti-A titers are measured and depending on the level, the decision is made regarding the kidney transplantation feasibility and the treatment required to prevent a reaction (rituximab, plasmapheresis, immunoadsorption) [83].

3. Histocompatibility and immunogenetics

HLA typing is performed for all patients undergoing kidney transplantation and refers to the characterization of the individual's HLA genes and the identification of the HLA molecules expressed on the surface of their cells. DNA technology has led to the identification of many more alleles and is the gold standard for HLA typing. Sensitization is the development of antibodies to HLA antigens and their presence is likely to result in antibody mediated rejection and early graft loss. Sensitization can happen in the following main situations: previous transplant, blood, platelet or fresh frozen plasma transfusions, and pregnancy. It can also happen spontaneously through cross-sensitization from infection and pro-inflammatory events [84]. Several different assays are available to determine the sensitivity of a potential transplant recipient to donor HLA antigens. Microbead array and ELISA techniques have been proven to be more sensitive than cytotoxicity. Pre-transplant cross-matching is mandatory and aims to confirm the absence of donor-directed HLA antibodies. A positive cross-match is a potential contraindication for kidney transplantation.

Assays for Cross-match Testing

- The complement-dependent **cytotoxic crossmatch** is the most common test where donor lymphocytes are incubated with recipient serum in the presence of complement. If donor specific antibodies are present, cell lysis is observed, and the crossmatch is deemed positive.
- The **flow cytometry cross-match** is a more sensitive cross-match. Recipient serum is added to the donor lymphocytes, followed by the addition of a secondary fluorochrome-conjugated antibody that detects human IgG. Samples with the patient's serum incubated with the donor cells are compared with a negative control containing pooled sera

from normal, healthy, unsensitized individuals. It is particularly useful in sensitized patients and can be performed with peripheral blood cells.

– **Virtual cross-matching** involves reviewing the donor HLA profile against the patient's HLA antibody profile to determine whether the patient has donor-directed antibodies that would cause a positive cross-match test result. This technique can be performed in a certain number of patients with a low immunological risk and reduces the cold ischemia time. A further cross-match test must be performed retrospectively to confirm the negative virtual cross-match.

4. Infectious Disease Issues

Infections are an important cause of morbidity and mortality post-transplant. As such, pre-transplant infectious screening is an essential step in preparing for kidney transplantation [85]. The urinary tract, skin, teeth, and sinuses should be carefully examined for signs of infection or site of chronic infection. Lack of prior exposure to certain pre-transplant viruses may affect transplantation outcomes. Post-transplant viral disease may be more severe (CMV, influenza), increase the risk of chronic allograft dysfunction (CMV, BK virus) and can increase the risk of post-transplant lymphoproliferative disease (EBV) [86].

Routine childhood immunizations should be completed prior to kidney transplantation according to age-appropriate guidelines and should be updated using expedited regimens where necessary [86, 87]. Live vaccines, such as varicella, tuberculosis and measles, should be administered at least two months prior to transplantation. Live vaccines are contraindicated after transplantation [87].

5. Coagulation and thrombosis screening

The patient's history of bleeding and/or clotting is an important aspect. All patients should have a pre-transplant coagulation and thrombophilia screen to avoid bleeding/clotting complications.

6. Urinary tract abnormalities

The lower urinary tract should be evaluated using a voiding cystourethrogram to detect any abnormality that should be corrected prior to transplantation in patients with history of congenital abnormalities of the urinary tract or infection. Bladder and urethra abnormalities may be responsible for ureterohydronephrosis of the transplant, thereby increasing the risk of graft loss. These and other abnormalities may increase the risk of urinary tract infection. Patients with lower urinary tract obstruction are at the highest risk of post-transplant bladder dysfunction. These patients should be assessed carefully with urodynamic studies. It may be necessary to create an appendicovesicostomy in patients that require clean intermittent catheterization and/or to enlarge the bladder with an intestinal segment in patients with a small pathologic bladder [85, 86].

7. Native nephrectomy

The need for native nephrectomy is controversial. The benefits of retaining native kidneys may include preservation of residual urine output, production of native erythropoietin and better vitamin D/calcium homeostasis. However, in certain cases, native nephrectomy may be beneficial, although data are limited and no guidelines exist. Native nephrectomy prior to transplant may be considered in patients with glomerular disease with significant proteinuria (to reduce risk of thrombosis due to low albumin), autosomal dominant polycystic kidney disease (to avoid symptoms secondary to extremely large polycystic kidneys such as pain, hematuria and pressure effects causing gastrointestinal or respiratory symptoms), high-grade vesicoureteral reflux (to reduce post-transplant infection/bladder dysfunction), severe uncontrollable hypertension, and malignancy or malignant predisposition (WT1 gene variants) [88–90]. These indications are center-dependent and no clear guidelines detailing for example proteinuria/polyuria cut-offs or the degree of hypertension exist.

8. Donor options

Access to kidney transplantation is highly variable globally and even regionally, with a limited number of low-middle and low-income countries offering pediatric kidney transplantation [3, 5–8, 11]. While well-established national policies and organizations for organ procurement and allocation account for higher deceased donor (DD) transplantation rates in high-income countries, most low-middle and low-income countries initiate pediatric kidney transplantation through a living related donor (LD) program [3, 7, 11]. The transplanted kidney has a limited survival and most children with ESKD will require two, three or even more kidney transplants in their lifetime. In this regard, a LD transplant provides a better long-term graft survival and is a better option for children [86]. Even in LD kidney transplant recipients, there is a benefit in graft survival for preemptive transplantation (vs. non preemptive) [19, 31]. When there is no LD identified or available, the choice of accepting or declining a DD kidney is a difficult decision-making process involving recipient's age and size, current morbidity, time spent on dialysis and sensitization, as well as donor history, age and size, kidney risk profile, HLA matching and expected cold ischemia time [91].

An important dilemma for pediatric nephrologists is, if there is only one possible living donor, should the first kidney transplant be from a LD or a DD. The pros for receiving a DD kidney first are that children have access to good-quality donors in a relatively short period of time. Therefore, the LD could be saved for a later time after first transplant failure when the waiting time may become longer. An argument against this would be that later, the potential donor will be older and may have health issues preventing re-transplantation with a LD [91]. This question has been addressed in the US by data from the Scientific Registry of Transplant Recipients (SRTR) showing in almost 15,000 pediatric kidney transplant recipients that the cumulative graft life was similar with both strategies, i.e. living first-deceased second and deceased first-living second [92]. The same authors examined this question of optimal timing regarding the order of DD and LD kidney transplantation using a Markov decision process model to compare the relative survival benefit of each strategy over a time horizon of 20 years [93]. It was shown that for the most highly sensitized patients (PRA > 80%), a DD-first strategy was associated with a survival advantage, but for all other patients (with PRA < 80%), a LD-first strategy conferred a better patient survival [93].

Although the choice of donor should be made on an individual basis, we, and others, feel that the best treatment should be proposed for children with ESKD and recommend that a preemptive living donor kidney transplantation should always be considered as the first option.

Summary: Lifetime Perspectives

The initiation of KRT and subsequent changes of modality are intrinsic processes in the life of a child with ESKD and should be planned and reflect patients' life goals and preferences when possible. There are pros and cons of each KRT modality (CAPD/CCPD, in-center HD, home HD, preemptive/post-dialysis transplantation, living/deceased donor) to be considered in order to provide personalized care for a child with ESKD (Table 64.4). Both the short- and long-term benefits and risks of each KRT modality across the entire patient's lifespan should be carefully evaluated, considering the widely variable practice patterns and access to KRT around the world. From a lifetime perspective, it is essential for pediatric nephrologists not only to provide the best initial KRT modality available but also to keep in mind the subsequent best treatment modality and access for an individual patient.

We suggest that an integrated life plan approach for pediatric KRT should take into account the long-term consequences of the decisions and choices to be made such as dialysis

Table 64.4 Advantages and disadvantages of different kidney replacement therapy modalities in children

Modality		Advantages	Disadvantages
Kidney transplantation (KT)	KT (compared to dialysis)	Avoids dialysis morbidity and mortality	Variable access to transplantation
		Better patient survival	Not suitable for smaller children (< 10 kg)
		Better psychosocial outcome	Surgical complications
		Better quality of life	Infections
		Fewer restrictions (dietary, time, medications)	Malignancy
		Better growth	Burden of graft failure/repeated KRT modalities
		More cost-effective	
	Preemptive (compared to non-preemptive) KT	Better graft survival	Psychosocial difficulties
	Non-preemptive KT		Increased risk of graft failure
	Living donor (compared to deceased donor) KT	Better long-term graft survival	Kidney health risk for the donor
		Shorter waiting time	Psychological and socioeconomic issues for the donor
		Better graft quality	Possibility of poorer HLA matching
		Reduced delayed graft function	
		Reduced hospital costs	
	Deceased donor (compared to living donor) KT	Priority in allocation schemes	Increased risk of graft failure
Peritoneal dialysis (PD)		Increased patient freedom	Dependent on parental/caregiver participation
		Longer preservation of residual kidney function	Caregiver burden
		Avoidance of vascular access	Medicalization of the home
		Improved school attendance	Infections
		Fewer dietary restrictions	Risk of peritoneal membrane failure if on PD for years
		Technically more feasible in smaller children	
		Possible for patients who live far away from HD centre	
		Lower cost compared to HD	
Hemodialysis (HD)	In-centre HD (ICHD)	Long-term technique survival	Limited by availability of vascular access
		Suitable if patients/parents/caregivers unable to perform dialysis at home	Availability dependent on local resources
		Decreased treatment duration	Increased cost when compared to other modalities
	Home hemodialysis (HHD)	Increased flexibility with dialysis times	Dependent on parental/caregiver participation
		Improved school attendance compared to ICHD	Caregiver burden
		Reduced intradialytic symptoms and hypotensive episodes	More rapid loss of residual kidney function
		Improved cardiovascular outcomes compared to ICHD	Medicalization of the home
		More cost-effective compared to ICHD	Increased AVF complications
		Improved nutrition and growth compared to ICHD	Increased home utility bills (water, electricity)

access sustainability, cardiovascular morbidity and mortality associated with prolonged dialysis, cumulative functioning graft survival according to the order of donor type, long-term morbidity of cumulative immunosuppressive load post-transplant, family/caregiver burden, interference of modalities with social life and relationships, growth and cognitive outcomes, QoL, and patient-centered outcomes (Fig. 64.4).

The (very) long-term outcome studies clearly favor early (living donor) kidney transplantation in children with ESKD, which appears to have a beneficial effect on overall mortality, morbidity, and psychosocial maturation. The cumulative duration of dialysis in relation to years with a functioning kidney graft has been strongly associated with many adverse outcomes, especially with cardiovascular mortality, but also short stature, impaired cognitive performance, locomotor disorders, social dependence and depression [94–99]. The impact of dialysis on physical condition is also reflected by the sharp difference in physical health perception of dialysis and transplanted patients. On the other hand, some registry data (ANZDATA, ERA-EDTA) suggested that a short period of dialysis (up to 1 year) did not affect overall mortality [17, 100]. A longer period of dialysis has been associated with a higher risk of death regardless of donor source [19]. Although PD patients may have short-term survival advantage compared to HD, no studies showed significant differences in long-term outcome of PD and HD. However, PD may certainly be favorable over HD to achieve the longest and most feasible dialysis access life plan for the individual patient.

Although dialysis is the most unfavorable mode of KRT, kidney transplantation is associated with considerable late morbidity. Disabling co-morbidity was reported by 40% of all kidney transplant recipients in the Dutch late outcomes study (LERIC) [98]. Apart from clinical bone disease, the most frequently reported disabling problems were daily headaches, tremors and severe itching, most of them appearing in transplanted patients. Malignancies, infection, cumulative cardiovascular burden (hypertension-related LVH and arterial wall stiffening) are the most life-threatening problems after kidney transplan-

tation [99, 101]. Although current data shows a much lower mortality in pediatric kidney transplant recipients than in those remaining on dialysis, the need for many decades of kidney graft function will expose more patients to risk of life-threatening infections and malignancies at relatively young adult age.

The approaches to optimize long-term outcomes and QoL in pediatric patients with ESKD include timely referral for multidisciplinary CKD care, education and support for patients and caregivers, promotion of pre-emptive and living-related transplantation, reduction of KRT time on dialysis to the minimum, favor home dialysis therapies, consider intensive dialysis, individualization of the subsequent KRT modality and dialysis access plan in a lifespan perspective. There is general consensus that providing personalized care which incorporates patient goals and preferences has become a priority.

Management of Peritoneal Dialysis in Children

65

Alicia M. Neu, Bradley A. Warady, and Franz Schaefer

Introduction

Peritoneal dialysis (PD) is the most frequently prescribed maintenance dialysis therapy for children with kidney failure worldwide, particularly in infants and very young children [1–3]. Technical advances and increasing efforts to minimize risk for infection and cardiovascular disease, the leading causes of morbidity and mortality, have contributed to improvements in technique and patient survival among children on maintenance PD [4–7]. However, mortality for children on dialysis remains unacceptably high and notably higher than for children who receive a kidney transplant [2, 3, 7]. Ongoing efforts to further improve outcomes in children on maintenance PD must include prescribing, monitoring and adjusting the dialysis treatment to meet the unique needs of the child [8, 9]. This chapter focuses on the principles involved in developing and monitoring the PD prescription, establishing a functioning access to perform the dialysis procedure and the infectious and non-infectious complications seen in children on maintenance PD. Kidney failure is an incredibly complex condition and therefore comprehensive care of the child on maintenance peritoneal dialysis must not only include tailoring the PD prescription to provide optimal solute and fluid removal, but also maximizing growth and neurocognitive development, managing anemia, minimizing bone and mineral metabolism disorder and cardiovascular disease, and addressing the psychosocial well-being of the child and their family [8, 9]. Each of these important topics is therefore covered in a separate chapter of this book.

The Peritoneal Dialysis Prescription

The directly modifiable components of the PD prescription include the composition and volume of the dialysis fluid and the schedule by which that fluid is instilled and removed from the peritoneal cavity. Although empiric recommendations for prescribing maintenance PD in children are often used when initiating dialysis, optimal care requires that the PD prescription be modified to meet the unique needs of the individual child or adolescent with kidney failure [8–10]. This requires a basic knowledge of the physiology of dialysis which, in turn, relies on an under-

standing of the peritoneal membrane as the primary barrier to solute and fluid transport. This chapter therefore begins with a brief overview of the structure of the peritoneal membrane, followed by a discussion of the physiology of dialysis, that is, the driving forces for the exchange of solute and fluid across the peritoneal membrane. The application of these principles to guide selection of the modifiable components of the PD prescription is then presented.

The Peritoneal Membrane

The peritoneal membrane is a thin structure lining the inner surface of the abdominal wall and the majority of visceral organs. It is lined by the mesothelium, a continuous layer of flattened epithelial cells covered with numerous microvilli, and includes a dense network of capillaries distributed within a thin interstitium [11–13]. The pathway for the solute and water exchange between the plasma in the peritoneal capillaries and the dialysate in the peritoneal cavity of the child on PD includes the continuous capillary endothelium, the peritoneal interstitial space, and the mesothelium [14]. Of these, the capillary endothelium appears to be the primary determinant of resistance to transport, and microvascular density is therefore a major determinant of transport characteristics [11, 15–18]. The permeability of the endothelium lining the peritoneal capillaries has been functionally described by the three-pore model proposed by Rippe and colleagues [19]. In this model, the major route for small-solute and water movement is represented by the spaces between the endothelial cells, the so-called small pores, which have a radius of 40–50 Å, slightly larger than albumin (36 Å) [12, 19]. Ultrasmall pores, with a radius of approximately 2.5 Å, are the most abundant type of pores and are involved in sodium-free water transport [12, 19]. Several lines of evidence have demonstrated that the water channel aquaporin-1 corresponds to the ultrasmall pore [20, 21]. The third group of pores is the transendothelial 'large pore' pathways, which have a radius of approximately 250 Å, and which account for only 0.01% of the total population of capillary pores and through which macromolecules are transported [19].

The Physiology of Dialysis

The driving forces for exchange of solute across the peritoneal membrane include diffusion and convective mass transfer through the small pores in the capillary endothelium. The rate of solute movement by diffusion is determined by the concentration gradient of the solute between the dialysate in the peritoneal cavity and the plasma in peritoneal capillaries, the effective surface area of the peritoneal membrane in contact with the dialysate, the so called "wetted membrane," and the permeability of the peritoneal membrane to that solute, which, in turn, is influenced by the molecular weight of the solute [13, 22]. Convective mass transfer occurs as water moves through small pores from capillaries to dialysate, "dragging along" dissolved solutes. The amount of solute removed by convective mass transfer is, therefore, determined by the amount of water removed and by the membrane permeability, or sieving coefficient for that solute. While small molecular weight solutes, like urea, move by both diffusion and convective mass transfer, the movement of larger molecular weight compounds, including the uremic "middle molecules," is driven primarily by convective mass transfer [23].

The bulk movement of water, or ultrafiltration, is driven by Starling forces, i.e. osmotic and hydrostatic pressure [12, 23]. Figure 65.1 depicts the Starling forces (P, hydrostatic pressure; Π, oncotic or osmotic pressure) that operate across each of the pore types in the three-pore model [12]. Movement of water through the ultrasmall pores is driven by the osmotic gradient between the plasma in peritoneal membrane capillaries and the interstitium and, ultimately, the dialysis fluid in the peritoneal cavity. The osmotic pressure in the plasma is generated primarily by albumin, whereas osmotic pressure in the dialysate is typically generated by crystalloid, i.e. glucose, or the glucose polymer icodextrin. This "water only" movement through the ultrasmall pores explains the transient decrease in dialysate sodium concentration during the early phase of a dialysis dwell, which is referred to as sodium

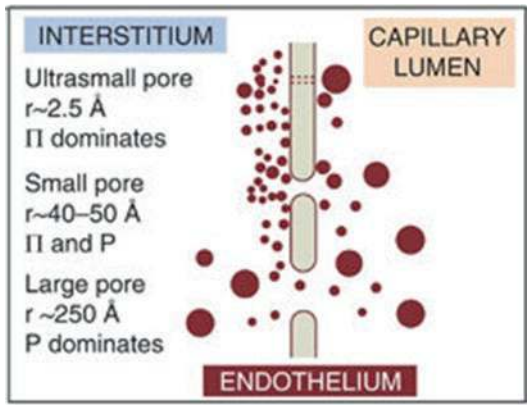

Fig. 65.1 The Starling forces (P, hydrostatic pressure; Π, oncotic pressure) operating across each type of pore in the three-pore model of peritoneal membrane capillary permeability. *Å* angström, *r* functional radius. (From [12], with permission)

sieving. Movement of water through small pores is influenced by both hydrostatic and osmotic forces (Fig. 65.1) [12]. In simplest terms, hydrostatic forces in plasma and osmotic forces in the dialysate promote ultrafiltration, while osmotic forces in plasma and hydrostatic pressures in the peritoneal cavity oppose it [24]. Several factors contribute to the generation of these forces; however, the critical component for ultrafiltration during PD is the difference in osmotic pressure between the dialysate and the plasma, which, in turn, is largely dependent on the osmotic agent present in the dialysate [24]. The amount of water removed from the person on PD, or net ultrafiltration, is also influenced by water movement from the peritoneal cavity back to the capillaries in the late stages of a dwell, when the osmotic gradient generated by dialysate glucose may have dissipated, and by uptake of water from the peritoneal cavity into tissue and lymphatics [25, 26]. The contribution of water movement through the relatively rare large pores to net ultrafiltration is felt to be minimal [12].

These principles of solute and fluid movement during PD should be used to guide selection of the various components of the dialysis prescription, including dialysate composition, fill volume and the schedule by which dialysis is instilled and removed from the peritoneal cavity (PD modality/dwell time), to optimize solute and fluid removal.

Determination of Fill Volume

As discussed above, the movement of solutes and water during PD is intrinsically dependent on the amount of peritoneal membrane surface area available for exchange, or the "wetted membrane" [13]. Although the peritoneal membrane has an estimated surface area of 1 m^2 in adults, computed tomography studies in people on maintenance PD have demonstrated that only 30–60% of this anatomic area is in contact with dialysate [27]. The peritoneal membrane contact area can be influenced by position, increasing in the supine position, and by increasing the volume of the infused dialysate, or fill volume [28]. In children, where body size varies considerably, the concept of scaling the fill volume to body size is intuitive. Fill volume should be based on body surface area (BSA), rather than weight, as the relationship between peritoneal membrane surface area and BSA is constant and age-independent [29]. Body surface area can be calculated from anthropometric data, i.e. height and weight. The most commonly used equation is that of Gehan and George [30]:

$$\text{BSA } (m^2) = 0.0235 \times (\text{height, cm})^{0.42246} \times (\text{weight, kg})^{0.51456}$$

As stated above, increasing the fill volume will promote solute and fluid removal by maximizing peritoneal membrane contact area [31]. In addition, increasing fill volume will facilitate movement by diffusion. The impact of fill volume on diffusion rests on the principle of geometry of diffusion, that is, the larger the dialysate volume, the longer the transperitoneal concentration gradient will persist to drive diffusion [32]. However, increasing fill volume also increases intraperitoneal pressure (IPP) which may lead to patient discomfort and other complications including hernia formation, hydrothorax and gastroesophageal reflux (See Non-Infectious Complications) [10, 26, 28, 33]. In addition, elevated IPP may increase lymphatic uptake of fluid, thereby reducing net ultrafiltration [10, 33]. Studies in children on PD revealed that the peritoneal membrane vascular surface area available for exchange increased by a mean of 21% as fill

volumes were increased from 800 to 1400 ml/m^2, with no further improvement as fill volumes increased to 2000 ml/m^2 [28, 34]. These data support current recommendations that, if required for solute clearance and fluid removal, the fill volume should be gradually increased to an upper limit of 1200–1400 ml/m^2 in children over age 2 years [10]. Infants may not tolerate such large fill volumes, and an upper limit volume of 800 ml/m^2 is currently recommended in this age group [10]. The maximal volume for individual children on PD should also be influenced by the child's comfort level and when indicated, an objective measure of IPP [35]. Measurement of IPP can be done at the bedside, using a manometer attached to the PD catheter. The mean IPP is calculated from the pressure measured during inspiration and expiration. Normal ranges of mean IPP for children over age 2 years have been reported to be 7–14 cmH_2O, with an upper tolerated limit of 18 cmH_2O [35, 36].

Choice of PD Fluid

Conventional PD Solutions

PD solutions typically contain an osmotic agent, a buffer and sodium, chloride, calcium and magnesium in varying concentrations, in an effort to provide not only removal of fluid and waste products, but also electrolyte homeostasis, and acid-base and calcium balance. The composition of the most widely used commercially available dialysis solutions attempt to mimic normal plasma, while allowing mass production and storage stability [37]. These constraints led to the selection of glucose in supraphysiologic concentrations as the osmotic agent and lactate alone as the buffer, with a resultant low pH of the dialysis fluid. This allows heat sterilization without caramelization of the glucose, and minimizes precipitation of calcium and magnesium from the solution, which may occur when bicarbonate is used as the buffer [37]. From the description of the Starling forces involved in water movement during PD, it follows that increasing the concentration of glucose in the dialysis fluid increases the osmotic gradient driving ultrafiltration. From a functional standpoint, because glucose is a diffusible solute, it is absorbed from the dialysate to plasma via the small pores, resulting in a time-dependent loss of the crystalloid osmotic gradient. Thus, glucose is unable to provide sustained ultrafiltration during extended exchange dwell times. In addition, absorption of glucose can contribute to anorexia and lead to elevated serum glucose and hyperinsulinemia, even in non-diabetic patients [38]. This increased carbohydrate load can predispose to abnormalities of lipid metabolism and insulin resistance (See Non-Infectious Complications) [37, 39]. In addition to the negative effects associated with glucose absorption, the heat sterilization process used with conventional PD solutions produces high levels of glucose-degradation products (GDP), which are directly toxic to the peritoneal mesothelium and are systemically absorbed [40]. GDPs also enhance production of advanced glycation end products, which along with high concentration of glucose have been implicated in the development of structural changes in the peritoneal membrane including vascular proliferation and progressive fibrosis, both of which contribute to peritoneal membrane failure [31, 37, 41, 42].

Alternate Osmotic Agents

In light of these findings, minimizing the exposure of the peritoneal membrane to hypertonic glucose is a therapeutic aim [43]. Currently, there are two commercially available PD solutions that contain osmotic agents other than glucose; one contains icodextrin and the other amino acids. Icodextrin is a glucose polymer with a molecular weight of approximately 16,000 Daltons, which exerts its osmotic effect through the small pores in the capillary endothelium. Thus, there is little to no salt-free water movement through the ultrasmall pores (sodium sieving) and sodium removal is typically higher than with glucose-based solutions [44]. Because icodextrin does not diffuse through the peritoneal membrane, the osmotic gradient, and therefore ultrafiltration, is typically sustained, and icodextrin solutions are therefore used during dialysis exchanges with a prolonged dwell time [45, 46]. The net ultrafiltration seen in individual people on PD can be variable, probably owing to variability in the peritoneal residual volume, i.e. the amount of

non-icodextrin containing fluid remaining in the peritoneal cavity from the previous exchange, which modifies the concentration of icodextrin and, therefore, the osmotic pressure difference between the peritoneal cavity and plasma [47, 48]. Another factor influencing net ultrafiltration is lymphatic absorption of icodextrin, which has been reported to be as much as 45% within 12–14 h in children on PD. [49] Reabsorption may be particularly high in infants on PD, limiting the ultrafiltration achieved with icodextrin in this age group [50]. Finally, a minimum daytime fill volume of 550 ml/m^2 has been suggested to optimize ultrafiltration with icodextrin in children [51]. Icodextrin is metabolized to maltose and a number of oligosaccharides which reach systemic steady state levels within 2 weeks of initiating treatment, and concerns about higher levels of these non-degradable compounds limits the use of icodextrin containing solutions to a single daily exchange [43, 45]. Hypersensitivity reactions have also been reported with icodextrin-containing solutions [45].

Amino acids, in a 1.1% solution, are also used as an osmotic agent in a commercially available, non-glucose PD solution. This solution is as efficient an osmotic agent as a 1.36% glucose-based solution. Amino acid-based solutions initially appeared particularly appealing for children on PD because of the potential nutritional benefit; however, studies revealed conflicting impact on nutrition, as well as increases in blood urea nitrogen and metabolic acidosis [52]. Given these findings, it is not recommended that amino acid solutions be used as a nutritional source in children on PD. [43] The benefits and potential drawbacks of each of the three solutions described here are summarized in Table 65.1 [37].

Table 65.1 Characteristics of currently available single-chamber peritoneal dialysis solutions, based on osmotic agent. Modified from [37], with permission

Buffer	Potential drawbacks	Potential benefits
Glucose	Low pH High GDP Poor peritoneal membrane biocompatibility Infusion pain Local and systemic glucose exposure	Ease of manufacture Low cost
Icodextrin	Hypersensitivity Low pH Systemic accumulation of oligosaccharides Lactate containing	Sustained ultrafiltration Preservation of RKF Hypertonic glucose replacement Reduced hyperglycemia Desirable effects on metabolic profile and body composition
Amino acid	Low pH Exacerbation of uremic symptoms and acidosis	No GDP Avoid systemic and peritoneal glucose exposure Peritoneal membrane protection Enhanced nutrition in adults

Biocompatible Solutions

The supraphysiologic concentrations of glucose and the presence of GDPs are not the only contributors to the bio-incompatibility of standard dialysis solutions. Low pH is associated with infusion pain and directly induces neoangiogenesis and mesothelial cell damage [53, 54]. Even at a neutral pH, lactate-based peritoneal dialysis solutions have been associated with impaired mesothelial cell viability and function [55, 56]. The effort to provide truly biocompatible solutions therefore includes not only the use of alternative osmotic agents, but also a solution composition that results in a more neutral pH and reduced exposure to lactate. The development of multi-chamber dialysis solutions has allowed these issues to be addressed at the commercial level. These bags isolate the buffer during storage, thus allowing glucose to be stored at low pH, ensuring stability, and avoiding the creation of GDP during heat sterilization. This also avoids bicarbonate-induced precipitation of calcium and magnesium in the solution [37]. A summary of the benefits and potential drawbacks of the currently available multi-chamber PD solutions is shown in Table 65.2 [37]. All of these solutions provide lower GDP levels than standard glucose-containing solutions. Although numerous in vitro studies have supported the biocompatibility of

Buffer	Potential drawbacks	Potential benefits
Lactate alone	More physiologic, but not neutral, pH Local and systemic glucose exposure	Lower GDP levels More physiological pH Improved peritoneal membrane biocompatibility Preserved membrane defense
Lactate/ bicarbonate	Local and systemic glucose exposure Does not eliminate peritoneal lactate exposure	Lower GDP levels More physiologic pH Improved peritoneal membrane biocompatibility Preserved membrane defense Reduced infusion pain
Bicarbonate alone	Local and systemic glucose exposure	Lower GDP levels More physiologic pH Improved peritoneal membrane biocompatibility Preserved membrane defense Improved correction of acidosis

GDP glucose degradation product

these solutions, a study of peritoneal biopsies in children at the time of PD catheter insertion and then after receiving maintenance PD with neutral pH, low GDP fluids revealed a doubling of peritoneal microvascularization and exchange area within a few months of initiating PD, calling into question the ability of these fluids to preserve membrane function and structure [41]. A subsequent analysis found that the duration of dialysis and dialytic glucose exposure were the primary determinants of the alterations to the peritoneal membrane [57]. Although biocompatible fluids may, in turn, not eliminate the structural changes to the peritoneal membrane, there may be some benefit of using bicarbonate, rather than lactate, as the dialysis solution buffer. A multicenter randomized controlled trial in 37 children on PD compared two multi-chamber, neutral pH, low GDP PD solutions that differed only with regard to the buffer, lactate versus bicarbonate. This study found equivalent correction of metabolic acidosis with the two solutions, but bicarbonate-based solutions were associated with better long-term preservation of peritoneal membrane function as measured by ultrafiltration capacity [58]. In addition, data from the International Pediatric Peritoneal Dialysis Network (IPPN) revealed that young infants exposed to neutral-pH, low-GDP PD solutions exhibited significant catch-up growth, whereas patients using conventional PD fluids showed no improvement in height standard deviation scores over the same time period. These findings led investigators to speculate that reduction of the inflammatory processes associated with conventional solutions might improve growth in children undergoing maintenance PD [59]. Finally, a Cochrane Review revealed that use of a neutral pH, low GDP PD solution is associated with improved preservation of residual kidney function and urine volume in adults on PD [60]. Given these findings, use of the more biocompatible solutions is encouraged, while recognizing that cost and availability of these solutions may limit widespread use [43]. In fact, data from IPPN reveals significant regional variability in the prescription of neutral pH PD solutions among children on PD enrolled in that registry [61]. When excluding children from the United States, where neutral pH PD solutions are not approved, 8% of children from low-income countries are prescribed these solutions, compared to 68% of children in high-income countries [8, 61].

Determination of PD Modality/ Dwell Time

CAPD vs. APD

There are two major PD modalities utilized for maintenance PD, continuous ambulatory peritoneal dialysis (CAPD), in which 3 or 4 exchanges

are performed manually during the day with an exchange with a long dwell time conducted overnight, and automated peritoneal dialysis (APD), in which multiple exchanges are provided, typically overnight, by a cycler. The most commonly prescribed APD schedules are continuous cycling PD (CCPD) and nightly or nocturnal intermittent PD (NIPD). Both provide multiple exchanges overnight, but in CCPD, 50–100% of the nightly fill volume is instilled at the end of the APD session for a daytime exchange. For NIPD, no daytime exchange is used, and the person on PD is said to have a dry day with no dialysate being present in the peritoneal cavity. Other modifications can include the addition of a mid-day manual exchange, sometimes referred to as semi-automated PD, and tidal PD, where only a portion of the initially instilled fill volume is drained and replaced with each exchange overnight, with the full volume drained only at the completion of the APD session. Tidal therapy has been found to be particularly beneficial in patients who experience "drain pain."

The selection of PD modality should be individualized for each child based on a number of factors, including age, residual kidney function, nutritional status, tolerance/comfort and the preference of the child and their caregivers [8, 9]. The physiology of PD should be considered so that the modality selected meets the child's solute and fluid removal requirements. Because APD allows more exchanges to be conducted during a 24-h period than CAPD, the peritoneal membrane is exposed to a larger total volume of dialysate in this time period which may enhance clearance of small solutes. In addition, during APD the majority of exchanges occur at night, when the child is in the supine position, which optimizes peritoneal membrane contact area and minimizes increases in IPP [28]. Conversely, CAPD allows increased clearance of middle molecules, which is dependent on the duration of contact between dialysate and the peritoneal membrane [62]. The requirement for fluid removal will also impact modality selection. In CAPD, daytime dwell times are typically 4–6 h long, as more frequent exchanges may be too cumbersome for the child/caregivers to perform. These long dwell times may result in reduced ultrafiltration, due to the loss of glucose-generated osmotic gradient, and necessitate higher glucose-containing solutions to maintain that gradient. Recall that in the early part of an exchange, sodium-free water movement occurs via the ultrasmall pores. Thus, frequent exchanges with short dwell times characteristic of APD may result in a relatively higher contribution of free water transport to total fluid removal, that is, more water than sodium is removed. Conversely, an exchange with a longer dwell time, as occurs with CAPD, allows more time for convective losses of sodium, but also allows back-diffusion and back-filtration, and may result in net fluid and sodium retention [26].

From a practical standpoint, because a cycler is not required for CAPD, the training and equipment required are less than for APD. However, because APD, is performed at night, this therapy minimizes the restriction on daytime activities, such as school attendance for children and work for adult caregivers, which is a significant benefit associated with the use of this modality [63].

Empiric Dialysis Prescriptions

A typical empiric APD prescription includes 5–10 exchanges over 9–12 h overnight, with an identical fill volume and duration for each exchange. A daytime exchange is usually prescribed, particularly in children who are anuric. More recently the concept of adapted PD, with initial cycles using a relatively small fill volume and short dwell times to maximize ultrafiltration, followed by a larger fill volume with longer dwell times to promote solute clearance, has been suggested as a means of improving dialysis efficiency, and in particular sodium and fluid removal [26, 64]. Not all commercially available PD cyclers are able to provide adapted PD and further prospective crossover studies in children on PD are required for validation. As stated previously, the typical CAPD prescription includes 3–4 exchanges during the day and a long overnight exchange.

Measures of Peritoneal Membrane Function

Because peritoneal membrane transport characteristics may vary considerably between people on PD, and even in a single person over time, it is important to evaluate these characteristics to optimize the PD prescription. Pediatric guidelines recommend evaluating peritoneal membrane function within the first month of initiating PD and then

after any event that may impact peritoneal membrane transport capacity, such as peritonitis [65]. The most commonly used test to characterize peritoneal membrane transport capacity is the peritoneal equilibration test or PET, developed by Twardowski [66]. The PET measures the rate at which solutes, specifically urea, creatinine and glucose, equilibrate between the blood and the dialysate. In the PET, dialysate is infused into the peritoneal cavity using a standardized fill volume and glucose concentration. Because the fluid used in the exchange immediately preceding the PET may influence results, the solution used for the PET should also be used for the dialysis session the night prior [67, 68]. Once the dialysis solution is instilled, the concentrations of creatinine and urea in the dialysate and in plasma are measured after 2 and 4 h of dwell time to derive dialysate to plasma ratios (D/P). The concentration of glucose in the dialysate at 2 and 4 h after instillation is compared to the concentration of glucose in the dialysate at the time of instillation (D/D_0). The D/P and D/D_0 ratios are then compared to standard curves to characterize the child as having high, high average, low average or low peritoneal membrane solute transport capacity [66]. People on PD with low or low average transport capacity may benefit from exchanges with longer dwell times, which will allow maximal diffusion of solutes. Conversely, rapid diffusion of glucose in patients with high peritoneal membrane transport capacity necessitates the use of exchanges with short dwell times to achieve ultrafiltration. The crossing point of the urea and glucose equilibration curves obtained from the standardized PET, referred to as the Accelerated Peritoneal Examination (APEX) time, has been proposed as a means to identify the dwell time to be used to optimize ultrafiltration [69]. The characteristics seen with the various peritoneal membrane transport types, and the percent of children enrolled in the IPPN with each are shown in Fig. 65.2.

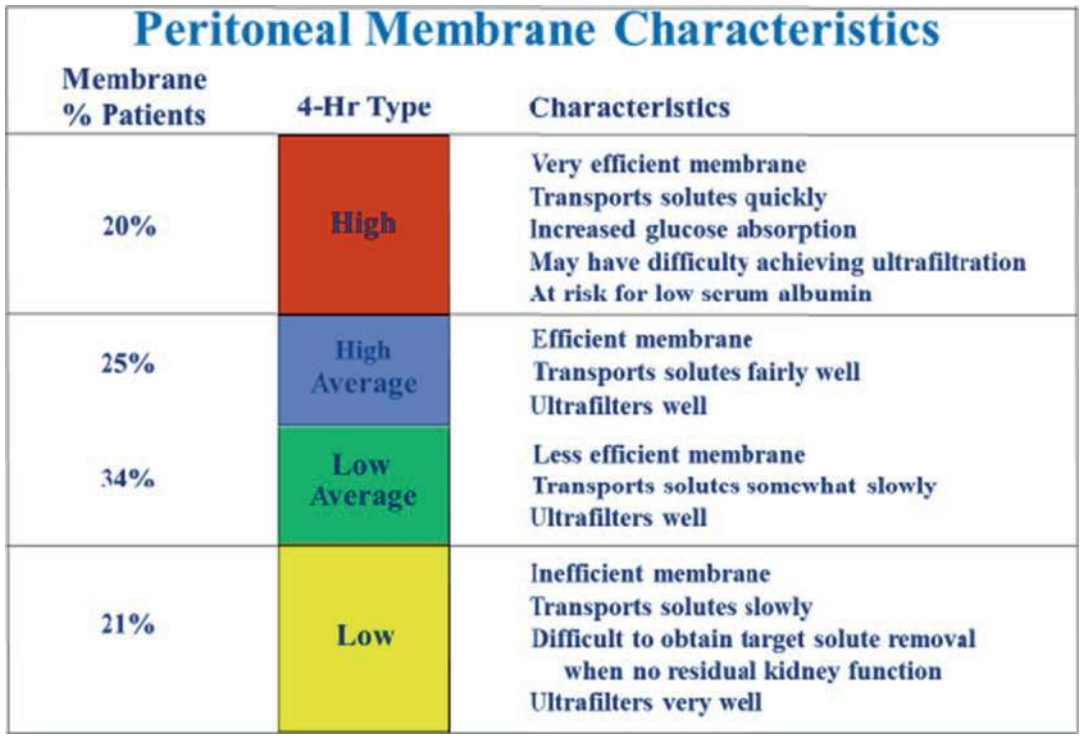

Fig. 65.2 Characteristics of the various peritoneal membrane transport types (high, high average, low average and low) and the percentage of children with each of the types enrolled in the registry of the International Pediatric Peritoneal Dialysis Network (personal communication, B Warady)

The PET has been validated in children on PD, using 2.5% dextrose, or 2.3% glucose PD solution and a fill volume of 1100 ml/m^2 [70, 71]. In infants, the fill volume used for the PET is usually the clinically prescribed fill volume [23]. Figures 65.3 and 65.4 show the standardized D/P creatinine and D/D$_0$ glucose curves, respectively, from which a child's peritoneal membrane transport capacity can be characterized [70]. In a study of 20 children on maintenance PD, nearly identical characterization of peritoneal membrane function was found with the D/P creatinine or D/D$_0$ glucose at 2 and 4 h, and it has therefore been suggested that a 2 h or short-PET may be reasonable in children on PD [72]. The sequential PET, in which the standard PET is followed by a "mini-PET," has been proposed as a method for providing more complete characterization of both solute and fluid transport [73]. The mini-PET is a modification of the

(From [70], with permission)

standard PET which uses a 3.86% glucose solution instilled for 1 h. Dialysate sodium concentration is measured just prior to infusion and after 60 min, providing more accurate information about the ultrafiltration capacity and assessment of sodium sieving [74].

Data obtained from the PET can also be used to calculate the mass area transfer coefficient (MTAC) [70, 75, 76]. The MTAC has been variably defined as the area available for solute transport divided by the sum of resistances to peritoneal diffusion. The MTAC represents the maximal clearance of a solute theoretically achievable at a constantly maximal gradient for diffusion, i.e. when the dialysate concentration of the solute remains at zero. Unlike the D/P ratio, MTAC is essentially independent of dialysate glucose or fill volume. Calculation of MTAC requires rigorously performed PD exchanges and complex mathematical equations. However, with the assistance of computer programs, data from a carefully performed PET can be used to derive MTAC. These programs, which have been validated in children on PD, can also be used to predict solute and fluid removal for individualized dialysis prescriptions [77, 78]. It must be recognized that the results predicted by these programs assume optimized conditions and therefore the actual amount of dialysis delivered by any prescription needs to be measured (See Goal-directed Approach to Prescribing PD).

Goal-Directed Approach to Prescribing PD

Solute Clearance

Historically, modification of the empiric PD prescription has been driven by the concept of achieving "dialysis adequacy," i.e. the dose of dialysis delivered is measured and adjustments are made to exceed a minimum dose below which patient outcomes are unacceptable. For decades, adequacy targets focused on the delivered dialysis dose in terms of small solute clearance. Peritoneal dialysis adequacy guidelines recommended the use of urea removal, scaled for the urea volume of distribution, Kt/V_{urea}, to monitor solute clearance and guidelines published in 2006 in the United States and internationally suggested a minimum target of a total weekly (residual kidney and dialysate) Kt/V_{urea} of 1.8 or 1.7 for adults on PD, respectively [65, 79]. These targets were largely based on studies in adults on PD which suggested improved survival with increasing small solute clearance [80, 81]. However, a reanalysis of data from a large prospective study in Canada and the United States (CANUSA) found the association between small solute clearance and mortality to be completely explained by the clearance contributed by residual kidney function, with no association between increasing dialysate small solute clearance and survival [82]. Similarly, two large prospective randomized trials did not demonstrate an association between increasing small solute clearance and mortality in adults on PD [83, 84]. A retrospective analysis of administrative data in the United States did reveal an increased risk for mortality with a $Kt/V_{urea} < 1.7$ in anuric adults on PD [85].

Although a prospective study of 171 children on PD demonstrated a positive correlation between dialytic creatinine clearance and change in height standard deviation score, and cross-sectional and retrospective studies have suggested improved growth and cardiac function with increasing small solute clearance, there are no large-scale, prospective, randomized studies of the influence of small solute clearance on outcomes in children on PD to more definitely define adequacy targets [86–88]. In light of this, the 2006 guidelines recommended that the total weekly Kt/V_{urea} in children should meet or exceed the adult standard [65].

Measurement of total weekly Kt/V_{urea} should incorporate both dialysate and residual kidney clearance [65]. This is accomplished by collecting the volume of urine from a 24-h period, as well as the peritoneal dialysis effluent from the PD exchanges during those 24 h. The volume is recorded and urea measured on each sample. Blood urea nitrogen concentration is also measured.

The total dialysate Kt/V_{urea} is then calculated by:

(24 h Dialysate/Plasma urea×24 h drained volume × 7) / Volume of distribution of urea

The residual kidney urea clearance is calculated by:

(Volume of 24 h urine in mL×urine urea nitrogen concentration)/(1440 min/day × blood urea nitrogen concentration)

From this, the residual kidney Kt/V_{urea} can be calculated as:

(Kidney urea clearance (ml/min) × 1440 min/day × 7 days)/1000 mL × Volume of distribution of urea.

The total weekly Kt/V_{urea} is the sum of the weekly dialysis and residual kidney Kt/V_{urea} [65].

The volume of distribution of urea, V, is assumed to be equal to total body water. Therefore, accurate estimates of total body water are important to accurately determine Kt/V_{urea}. The gold standard method for determining total body water, the heavy water dilution technique, is rarely applied in the clinical setting. Equations using anthropometric information (height and weight) are more commonly used to estimate total body water, and sex-specific nomograms developed in children on PD are available [89].

Guidelines for children on PD recommend that total weekly Kt/V_{urea} be measured within the first month after initiating dialysis and then at least twice yearly, and following any change in the child's clinical status that could influence solute clearance or ultrafiltration capacity [10, 90]. Given these recommendations, measurement of small solute clearance is standardly performed, and achievement of the minimal target for Kt/V_{urea} in adults and children on PD is used as a measure of the quality of care by dialysis organizations around the globe and regulatory and payment agencies in the United States. However, the data linking small solute clearance to outcomes in people on PD remains relatively weak, with no prospective intervention trials since publication of the 2006 KDOQI guidelines, and prospective cohort and retrospective studies in adults on PD only confirming that patient outcomes are more closely linked with residual kidney function than clearance of solute by dialysis [91–98]. In addition, it has been increasingly acknowledged that optimal care requires that all aspects of management, including the PD prescription, be driven by the unique needs of the person with kidney failure, and not solely by small solute clearance [8, 91]. In 2018, a Kidney Disease: Improving Global Outcomes (KDIGO) Controversies Conference focused on dialysis proposed a change in terminology from "adequate" to "goal-directed" dialysis, where shared decision-making between the person on PD and the care team is utilized to establish realistic care goals that allow the person on PD to meet their life goals and allow the care team to provide individualized, high quality dialysis care [99]. In this framework, solute removal targets are interpreted and implemented in the context of the overall goals and clinical status of the person on PD [99]. In alignment with this statement, the International Society for Peritoneal Dialysis (ISPD) published new practice points for prescribing high-quality, goal-directed PD in 2020, including specific practice points for children on PD [8, 9, 91]. These documents suggest that modifications to the PD prescription should be based on regular assessment of clinical well-being, volume status (see below) and other laboratory parameters, in addition to Kt/V_{urea}, with a minimum target total weekly Kt/V_{urea} of 1.7 [9]. The guidance document specifically states that children on PD with $Kt/V_{urea} < 1.7$ should not have their PD prescription modified for the sole purpose of achieving the target, if close and repeated assessment of clinical and laboratory parameters suggest that the child is otherwise doing well [9].

The 2020 ISPD guidance document for children on PD also suggests that the PD prescription be adjusted with the goal of achieving a normal serum phosphate level [9]. Because phosphate clearance is related to contact time between dialysate and the peritoneal membrane, optimizing the long daytime exchange is suggested to enhance phosphate removal [100]. It is recognized, however, that phosphate control cannot be achieved with dialytic clearance alone and dietary restriction and phosphate binders are required in most children on peritoneal dialysis [9].

Fluid Removal

Cardiovascular disease, as manifested by hypertension and left ventricular hypertrophy, is unfortunately quite common in children on dialysis, and fluid overload is a major contributor to both [4, 5, 61, 87, 101–104]. PD guidelines have therefore consistently emphasized the importance of adjusting the dialysis prescription to provide adequate salt and water removal [9, 79, 105].

Routine assessments of fluid status should be included in the care of children on PD. Casual blood pressure should be monitored, both in the clinic and at home, and ambulatory blood pressure monitoring may be performed to more accurately assess blood pressure and detect masked hypertension [106]. Central to the evaluation of fluid status is assessing the "dry" body weight of the child on PD, which should be performed routinely. However, determination of fluid overload may be inaccurate when based on clinical assessment alone and is further complicated by the expected weight gain in the growing child. Bioimpedance, if available, may be used as a component of the assessment of fluid status, and a recent study demonstrated that multifrequency whole-body bioimpedance spectroscopy successfully quantified total body water and acute changes of extracellular and intracellular water in children with chronic kidney failure, including those on dialysis [9, 107–109]. Data from the IPPN found that anemia tended to be associated with characteristics of the patient with fluid overload, including low urine output, high ultrafiltration requirements, high transport status on PET, hypertension, and left ventricular hypertrophy [101]. In addition, serum albumin and hemoglobin levels were closely associated, suggesting that fluid overload could result in dilution of both markers [101]. These findings led the authors to speculate that ESA-resistant anemia and hypoalbuminemia may be indicators of "occult" fluid overload in children on PD.

Adjustment to the dialysis prescription should, in turn, be made to achieve "dry weight" and blood pressure control. Efforts to optimize ultrafiltration while avoiding exposure to high glucose containing solutions include the use of icodextrin-containing dialysate for an extended daytime exchange, modifying dwell time using the APEX time, and potentially the use of adapted PD, as discussed previously [9, 26, 69, 110].

The amount of sodium removal required will depend on salt intake. Infants have very low sodium intake from formula or breast milk, and may have significant urinary losses of sodium associated with underlying congenital anomalies of the kidney and urinary tract. As a result, additional sodium losses from dialysis may result in hyponatremia, hypovolemia and hypotension. Therefore, infants on PD often require sodium supplementation [111]. On the other hand, older children and adolescents on PD are typically salt overloaded. In these children, the sodium gap, defined as the difference between the calculated theoretical sodium removal (plasma sodium concentration multiplied by ultrafiltration volume) and the amount actually removed (dialysate sodium concentration multiplied by ultrafiltration volume), is positive, reflecting inadequate sodium removal [112]. Most commercially available PD solutions have a sodium concentration of 132–134 mmol/L, just slightly lower than the concentration in normal serum. Studies of PD solutions containing 115–126 mmol/L sodium in adults on PD have shown increased sodium removal and a lower sodium gap, with associated improvements in blood pressure and fluid status [112–114]. However, very low sodium solutions require slightly higher glucose concentrations to maintain osmolarity and therefore may increase overall glucose exposure [112]. There are currently no studies of the impact of lower sodium-containing dialysis solutions on sodium and fluid balance in children or adolescents on PD.

Peritoneal Dialysis Access

Catheter Configuration

Successful PD requires a catheter that provides reliable, rapid dialysate flow rates without leaks or infections. The first description of placement of an indwelling catheter for maintenance PDs was in 1968 by Tenckhoff, and the Tenckhoff catheter continues to be the most commonly used

PD access in children [3, 115, 116]. Despite significant improvements in catheter design, however, the catheter has continued to be a significant barrier to successful PD because of catheter-related complications. A recent analysis of 824 incident PD catheters in the IPPN revealed that more than 20% required revision and 83% of those revisions occurred in the first year after placement [116]. Need for access revision increased the risk of peritoneal dialysis technique failure or death [116]. This section will review the currently available catheter configurations and placement techniques. Associations between the various configurations and risk for catheter-associated infectious and non-infectious complications, including catheter malfunction, are discussed later in this chapter.

The most commonly used catheters for maintenance PD are constructed of soft material, such as silicone rubber or polyurethane. There are a wide variety of catheter configurations available, which differ in their intraperitoneal configurations (curled or straight), the number of Dacron cuffs (one or two) and the subcutaneous tunnel configuration (straight or "swan-neck"). Figure 65.5 shows the most common combinations of these configurations [117]. Table 65.3 reveals the percentage of catheters with the various configurations in children on PD from large national and international collaborative projects: IPPN, the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS), and the Standardizing Care to Improve Outcomes in Pediatric End stage kidney disease (SCOPE) collaborative [3, 115, 116]. These data demonstrate that a curled intraperitoneal configuration is most commonly used in children on PD [3, 115, 116].

The next catheter characteristic to consider is the number of Dacron cuffs on the catheter. If a single cuff catheter is used, it is generally recommended that the cuff be positioned between the rectus sheaths in the rectus muscle, and not be located in a superficial position. The addition of a second cuff was prompted by the potential to better secure the catheter and reduce migration of bacteria into the peritoneal cavity. Early data in children on PD demonstrated a lower incidence of infection with catheters having two cuffs, rather than one [3]. Based on these data, current guidelines recommend use of a 2-cuff PD catheter in children, except possibly in the very small infant in whom it may not be technically feasible [118]. Accordingly, the percentage of children on PD with 2-cuff catheters has increased, from roughly half of children in the NAPRTCS report from 2011, to more than 70% and 80% in recent reports from SCOPE and IPPN, respectively (Table 65.3) [3, 115, 116]. If two cuffs are used, the second cuff should be located at least 2.0 cm from the exit site to reduce the risk for cuff extrusion [117, 119]. If cuff extrusion occurs, prompt

shaving of the cuff off the catheter has been advocated to reduce infection risk [120, 121].

The shape of the extraperitoneal portion, or tunnel, of the catheter can be straight or have a preformed angle ("swan neck"), in which there is an inverted U-shape arc (170–180°) between the deep and the superficial cuffs (Fig. 65.5). The purpose of the catheter arc is to allow the catheter to exit the skin in a downward pointing direction, which may be associated with a decreased likelihood for the accumulation of dirt and debris within the catheter tunnel which, in turn, may reduce the development of a tunnel infection/peritonitis (see Infectious Complications) [3, 122]. In addition, the swan neck configuration allows the distal end of the catheter to enter the peritoneal cavity in an unstressed condition (i.e. without too much torque because of the synthetic material's memory), thereby decreasing the chance for its migration out of the pelvis, and the associated risk for impaired drainage [123, 124]. Since its introduction, the use of swan neck catheters has been increasing in children on PD and is now placed in the majority (Table 65.3) [3, 115, 116].

A modification of the swan neck catheter is the swan neck presternal catheter, which has a very long subcutaneous portion (Fig. 65.5). This catheter has been utilized when it is necessary to make the exit-site remote from the abdomen, such as in infants and children with incontinence, intestinal stomas, and suprapubic catheters, and the catheter exit-site is typically located in the anterior chest wall [125–127]. However, infants with complex congenital anomalies often have minimal subcutaneous tissue over the chest, which makes cuff erosion more likely in that location. One suggested approach to this problem is to place the two cuffs below the costal margin and then have the catheter exit high on the chest wall [126]. Conversely, a single cuff catheter may be used.

Preoperative Evaluation and Preparation

Careful preoperative evaluation is required for all children and adolescents prior to PD catheter placement. The preoperative evaluation should include screening and treatment of constipation, which is common in children with kidney failure and has consistently been associated with an increased risk for post placement PD catheter migration and malfunction [128]. The preoperative physical examination should include evaluation for the presence of hernias. The incidence of hernias is inversely proportional to age, with an

overall frequency of 8.0–57.0% [129–132]. The highest frequency of inguinal hernias occurs in the first year of life; they are often bilateral and all require surgical correction. Umbilical hernias can worsen in a child on PD as a result of the increase in intra-abdominal pressure generated by instillation of dialysis solution (see Non-infectious complications). As a result, some have advocated peritoneography or laparoscopic inspection for hernias at the time of catheter placement [130]. If detected, the hernias can then be fixed at the same time the PD catheter is inserted [133, 134].

A critical portion of the pre-catheter assessment is deciding upon the most appropriate location of the exit-site. In infants, the exit-site of the catheter needs to be outside of the diaper area to help prevent contamination. In older children, it should be either above or below the beltline. The presence of a vesicostomy, ureterostomy, colostomy or gastrostomy will also influence the preferred exit-site location. The exit-site must be planned so that it is either on the opposite side of the abdomen from any stoma site or, as stated previously, the exit-site may be placed on the chest to increase the distance from any stoma.

Catheter Placement Technique

Since Moncrief and Popovich first reported on the use of CAPD, there have been a number of modifications of the technique for the implantation of the PD catheter [135]. The two most common PD catheter insertion techniques are open and laparoscopic. Although there are no randomized trials in children comparing outcomes in PD catheters placed using these two approaches, several case series report excellent outcomes with the laparoscopic approach, including excellent revision free survival and a lower incidence of catheter flow problems [117, 136–138]. SCOPE data reveals that more than 65% of catheters in the collaborative were placed using a laparoscopic procedure, with no statistically significant difference in placement technique (open versus laparoscopic) between children with and without peritonitis in the first 60 day after catheter placement [115].

Infectious Complications

PD-associated infections include PD catheter-related infections, i.e. infection at the catheter exit-site and/or the subcutaneous tunnel, and peritonitis. Infectious complications remain the most significant cause of morbidity and PD technique failure in children on maintenance PD [2, 3, 139–141]. In addition, infection is a leading cause of death in children on PD [2, 3, 141]. Analyses of data from large pediatric dialysis registries have revealed associations between many factors and the risk for PD-related infections in children on PD. Recognition of these risk factors is important, as they may prompt modification of care practices, which, in turn, may lower infection rates as well as the rates of patient morbidity and mortality.

Risk Factors and Prevention

Patient Age

Data from collaborative registries have consistently identified young age at dialysis initiation, and specifically age less than 2 years, as a risk factor for peritonitis [3, 122, 142–144]. It seems intuitive that the relatively close proximity of the PD catheter to the diaper region or urinary or gastrointestinal ostomy sites in a small infant would increase the risk for bacterial contamination and subsequent infection. As stated previously, efforts to maximize the distance between the catheter exit-site and the diaper area and stomas are important to decrease the risk for infection [125, 145].

PD Catheter Design, Insertion and Post-operative Exit-Site Care

As discussed previously, early studies of data from children on PD suggested a higher incidence of infection and a higher risk for relapsing peritonitis with a one cuff rather than a two cuff catheter, and current guidelines recommend a catheter with two cuffs in children on maintenance PD [3, 118, 146]. However, more recently the SCOPE collaborative has failed to show any relationship between the number of catheter cuffs

and the development of either exit-site/tunnel infections or peritonitis [122, 147]. Data in adults on PD suggest that benefit of a second cuff for infection prevention may have been reduced by widespread adoption of application of antibiotics at the catheter exit-site [117, 148].

While some studies in adults have found the use of the swan neck catheter to be associated with less frequent exit-site/tunnel infections, other studies have been unable to confirm these results [149–151]. As stated previously, one advantage of the swan neck catheter is that it allows a downward, rather than upward, pointing exit-site. Data from NAPRTCS has consistently identified an upward facing exit-site as a risk factor for peritonitis, a finding confirmed by a recent analysis of SCOPE data [3, 122]. Accordingly, current guidelines for children on PD recommend that the exit-site orientation be in the downward or lateral position [118].

Efforts to minimize the risk for peritonitis at the time of catheter placement include the provision of antibiotics prior to surgical incision [118, 152, 153]. Although vancomycin may be slightly more effective than a first-generation cephalosporin in the prevention of post-operative peritonitis, use of the latter is recommended because of concern for the generation of vancomycin resistance [118, 153–155]. The ultimate choice of antibiotic for perioperative prophylaxis should be influenced by the PD unit's antibiotic susceptibility patterns [118, 154]. Current guidelines also recommend that while securing the newly inserted catheter and minimizing movement at the exit site is important, sutures should not be placed at the catheter exit-site at the time of surgical placement, as they may increase risk of bacterial colonization and subsequent infection [118].

In the immediate post-operative period, PD catheter and exit-site care are aimed at optimizing healing and minimizing bacterial colonization [156]. Current guidelines suggest that the sterile dressing placed in the operating room following PD catheter placement remain in place for at least 7 days, and subsequent dressing changes should be performed by trained staff, using aseptic technique, no more frequently than weekly until the exit-site is healed [118, 157]. More frequent dressing changes should be performed only if the dressing becomes loose, damp, or soiled [118]. The catheter should be immobilized to optimize healing and minimize trauma [118, 158]. It is generally recommended that initiation of dialysis be delayed for at least 2 weeks following catheter placement to minimize the risk of leak at the peritoneal insertion site, although exit-site healing may take as long as 6 weeks [156–158]. In support of this, an analysis of SCOPE data demonstrated an association between use of the PD catheter for dialysis within 14 days of placement and an increased risk for early peritonitis, defined as peritonitis occurring within the first 60 days following catheter insertion [115].

Training

Because PD is a home dialysis therapy, appropriate training of the child with kidney failure and caregivers is essential to minimize the risk for infection. Unfortunately, there are no randomized controlled trials to evaluate the relationship between various training elements or the training process itself and outcomes [159–161]. Several observational studies have shown associations between shorter training time (<15 h), training in the 10 days after catheter insertion and small center size with an increased risk for peritonitis [159–164]. Current guidelines for children on PD suggest that training should include the use of a formalized teaching program that has clear objectives and criteria, with incorporation of adult learning principles [118, 159]. The training should be performed by an experienced PD nurse with pediatric training and should include core topics, including those related to infection prevention such as hand hygiene, aseptic technique, exit-site care and appropriate treatment for contamination [118, 159]. It is suggested that PD training should include no more than one child/family simultaneously [118, 159]. A syllabus for teaching PD to patients and caregivers has been published by the ISPD, and includes a checklist for PD assessment and another for PD training [165]. It remains to be determined if widespread use of this syllabus and the associated tools leads to a decrease in infection rates.

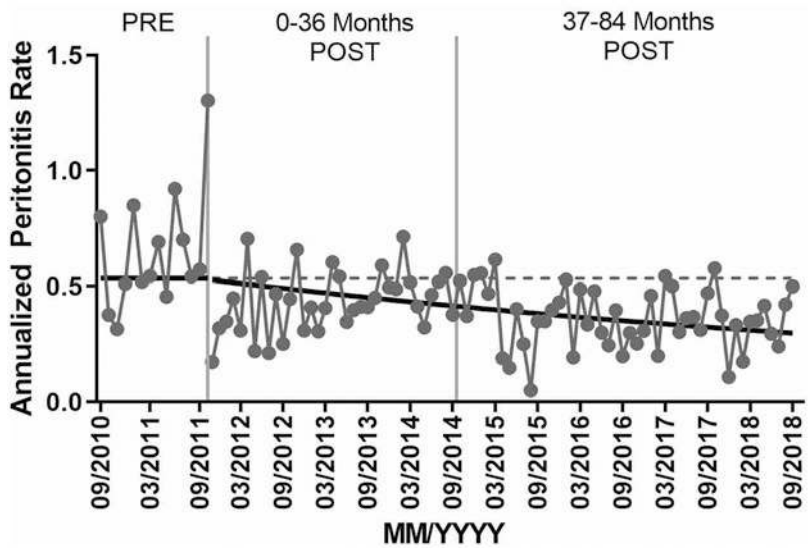

Fig. 65.6 Average monthly peritonitis rates, expressed as annualized rates, among 19 pediatric dialysis centers in the United States participating in the Standardizing Care to Improve Outcomes in Pediatric End Stage Kidney Disease (SCOPE) Collaborative from collaborative launch on October 1, 2011 through September 30, 2018. Differences between peritonitis rates in the 13 months prior to launch (pre-launch period) and the post-launch period were modeled using Generalized Linear Mixed Models techniques and revealed that the decrease in infection rate observed in the first 36 months persisted and there was a significant reduction in the average monthly peritonitis rates from 0.53 (95% CI 0.37, 0.70,) pre-launch to 0.30 infections per patient year (95% CI 0.23, 0.43) at 84 months post launch, $p < 0.001$). From [170], with permission)

Current guidelines suggest periodic retraining of the persons performing PD in the home, particularly after a peritonitis episode [118, 159]. The Trial on Education and Clinical outcomes for Home PD patients (TEACH), compared PD-related infections in adults on PD randomized to receive home visits for retraining every 1–3 months over a 24-month period compared to no re-training [166]. The study failed to demonstrate a significant difference in peritonitis rates between the two groups, although a sub-analysis demonstrated a significantly lower risk for first peritonitis episodes in patients >60 years of age who received frequent home visits [166]. The SCOPE collaborative includes a "follow up" care bundle, which requires a review of key aspects of hand hygiene, exit-site care, and aseptic technique at each monthly follow up visit in the clinic, redemonstration of competency with these procedures every 6 months, regular scoring of the PD catheter exit-site and treatment of touch contaminations according to ISPD guidelines [118, 167, 168]. SCOPE centers demonstrated a significant increase in compliance with this care bundle over the first 3 years of the collaborative, accompanied by a significant reduction in peritonitis rates [169]. A more recent analysis demonstrated that centers participating in the collaborative for 7 years were able to achieve and then maintain high level compliance with the follow up bundle and had continued reduction in center peritonitis rates over the collaborative's entire post-launch period (Fig. 65.6) [170]. An analysis of SCOPE data at the patient level also demonstrated that compliance with the follow up care bundle was significantly associated with a lower rate of peritonitis [122]. These data suggest that in addition to comprehensive training at the initiation of dialysis, ongoing review with regular testing of competency of PD catheter care and the dialysis procedure may minimize the risk for peritonitis.

Chronic Exit-Site Care

Once the catheter exit-site has healed, regular exit-site care is vital to minimize the risk for PD catheter-related infection. Current guidelines rec-

ommend regular cleansing of the exit-site with a sterile antiseptic solution and sterile gauze [118, 171]. Several cleansing agents are available and none has been shown to be superior in the prevention of catheter-related infection [118, 171]. In addition, there is no clear guidance for the optimal frequency of exit-site care, e.g. daily, every other day, or weekly [118, 171]. Not surprisingly, data from the International Pediatric Peritonitis Registry (IPPR) revealed significant variability in exit-site practices around the globe, including the frequency of exit-site care as well as the type of antiseptic agent used [172]. IPPR data also revealed that peritonitis due to *Pseudomonas* species was significantly more common at centers where exit-site care was performed more than twice weekly and where non-sterile cleansing agents (e.g. saline, soap) were used [172]. Among SCOPE participants, compliance with the specific recommendation to review exit-site care at each visit was associated with lower exit-site infection rates [147].

In addition to regular exit-site cleaning, current guidelines suggest application of a topical antibiotic during routine care, in an effort to minimize colonization of the exit-site with *Pseudomonas aeruginosa* (*P. aeruginosa)* and *Staphylococcus aureus (S. aureus),* both of which are widely accepted as risk factors for exit-site infection and subsequent peritonitis [118, 171, 173–176]. A number of observational studies, randomized controlled trials and meta-analyses have demonstrated that mupirocin applied to the skin around the exit-site reduces the risk for exit-site infections [118, 153, 171, 177–181]. However, there is concern that routine use of mupirocin may be associated with an increased risk for gram-negative infections and the emergence of mupirocin resistant *Staphylococcus* species [172, 182, 183]. Topical gentamicin is an alternative therapy, and a randomized trial in adults showed that daily application of gentamicin cream to the exit-site was not only effective in reducing exit-site infections caused by *Pseudomonas* species, but it was as effective as topical mupirocin in reducing *S. aureus* infections [180]. There are concerns, however, about the possible development of gentamicin-resistant organisms and an increased risk of fungal infections with this therapy.

Touch Contamination

Accidental contamination of the sterile portions of the PD catheter transfer set or dialysis tubing, or touch contamination, is a leading cause of peritonitis [122, 184, 185]. Current guidelines recommend that contamination prior to the infusion of dialysis fluid into the peritoneal cavity be treated with a sterile transfer set change alone, without antibiotics [118]. If the contaminating event occurs after dialysate has been infused into the peritoneal cavity, both a sterile transfer set change and antibiotic prophylaxis is recommended [118, 163]. Intraperitoneal administration of a first-generation cephalosporin for 1–3 days is typically recommended, unless the patient has a history of methicillin-resistant *S. aureus* (MRSA), in which case a glycopeptide (vancomycin or teicoplanin) should be used [118, 163]. Gram-negative coverage may be appropriate if the contamination may have included enteric organisms, e.g. from stool in a diapered infant [118]. An effluent sample should be obtained for cell count, differential and culture prior to delivery of antibiotics, if possible, and culture results and susceptibility testing used to guide any subsequent antibiotic usage [118].

Ostomies

As stated previously, ostomy sites, including gastrostomy, ureterostomy, nephrostomy and colostomy, may increase the risk of bacterial contamination of an adjacent PD catheter. In fact, data from the IPPN demonstrated an increased risk for peritonitis in the presence of any ostomy [186]. Data in children on PD have not revealed a consistent association between presence of a gastrostomy tube (GT) and risk for infection, including fungal infection; however, among infants on PD enrolled in SCOPE, placement of a GT after PD catheter placement was associated with increased risk for bacterial peritonitis [122, 144, 185, 187–190]. Although data on the subject is limited, current guidelines suggest that an open procedure should be used to place a GT in patients who are already receiving PD, while either open or laparoscopic placement may be used if the gastrostomy is placed prior to initiating PD. [118, 191]. Prophylactic

antibiotics, typically a first-generation cephalosporin, and antifungal therapy should be provided during gastrostomy tube placement in a patient with a PD catheter [118].

While an analysis of SCOPE data did not find an association between the presence of a colostomy and the risk for peritonitis in multivariable analysis, a recent study from IPPN revealed a significantly higher rate of peritonitis among patients with a colostomy [122, 192]. The number of children on PD with colostomies in these analyses was relatively small at 14 and 20, respectively [122, 192].

Antibiotic and Antifungal Prophylaxis

Although fungal peritonitis is relatively uncommon in children on PD, it is associated with an increased risk for significant morbidity and mortality [190, 193–195]. Observational data suggests that risk factors for fungal peritonitis include prior treatment with antibiotics, recurrent peritonitis, and immunosuppression [189, 190, 195–199]. Antifungal prophylaxis with either oral nystatin or fluconazole is currently recommended whenever antibiotics are administered to children on PD, although data from SCOPE reveal that this practice is not uniformly implemented, particularly when antibiotics are prescribed for infections other than bacterial peritonitis [118, 190, 200–204].

Prophylactic antibiotic and antifungal therapy should also be provided when children on PD undergo certain procedures, including gastrostomy tube placement, as previously discussed, as well as invasive dental, gastrointestinal or genitourinary procedures [118, 205, 206].

Other Factors

The risk factors listed in this section were largely derived from data collected by observational registries and quality improvement collaboratives that identified associations between various factors and risk for infection among a cohort of children on PD. There are clearly many other factors that may impact the risk for infection in individual children. The dialysis unit should perform a formal review, or apparent cause analysis, of each infection in search of causation [118, 162, 163]. This review should include nurses and physicians at a minimum. Inclusion of the child on PD and their caregivers/family, social worker, infection preventionist and infectious disease specialist is encouraged. Identification of causation will allow appropriate intervention for the individual, and potentially other children on PD in the unit.

Catheter-Related Infections

Infections of the PD catheter include exit-site and tunnel infections. PD catheter-related infections are associated with an increased risk for peritonitis. However, even without subsequent peritonitis, exit-site and tunnel infections require exposure to antibiotics with the subsequent risk for fungal infection and drug resistant organisms, both of which may require catheter removal [147, 207–209]. Catheter-related infections also carry a high risk of recurrence. In a Japanese multicenter study, 15% of all infections and 40% of MRSA infections relapsed [210].

Routine use of an objective scoring system is recommended to monitor the status of the catheter exit site and to optimize the diagnostic accuracy of exit-site infections. The pediatric Exit Site Score (ESS) considers pericatheter swelling, crust, redness, tenderness and secretion with a score range from 0 to 10 (Table 65.4) [118, 168]. An exit site infection is diagnosed by an ESS >1 in the presence of a pathogenic organism, or >3 irrespective of culture results. A tunnel infection is defined by an ESS >5 [118]. Sonographic examination may help to evaluate the extent of infection along the catheter [211, 212]. Data from SCOPE, which requires scoring of the exit-site at every monthly visit, revealed that an ESS of anything more than

Table 65.4 Catheter exit-site scoring system. From [118], with permission [168]

	0 Points	1 Point	2 Points
Swelling	No	Exit only (<0.5 cm)	Including part of or entire tunnel
Crust	No	<0.5 cm	>0.5 cm
Redness	No	<0.5 cm	>0.5 cm
Pain on pressure	No	Slight	Severe
Secretion	No	Serous	Purulent

zero is associated with an increased risk for an exit-site infection in the following month [147]. However, significant variability in exit-site scoring using this tool has been noted at SCOPE centers, and the collaborative is currently modifying the tool in an effort to promote more consistent scoring and, therefore, greater uniformity in the diagnosis of exit-site infections.

Uncomplicated catheter exit-site infections can be treated with oral antibiotics according to culture results and susceptibilities [118]. Empiric therapy for tunnel infections may be via the oral route; however, intraperitoneal or intravenous antibiotics are often indicated, particularly if signs of severe infection and/or a history of *S. aureus* or *P. aeruginosa* are present. Infections with gram-positive bacteria should be treated with a first-generation cephalosporin or a penicillinase-resistant penicillin. Intraperitoneal or intravenous glycopeptide therapy should be reserved for cases with proven MRSA infection [118]. The use of oral ciprofloxacin for infections due to *P. aeruginosa* had previously been recommended, with the addition of a second antibiotic such as cefepime, piperacillin, or a carbapenem, if resolution of the infection is slow, or there is recurrence [118]. However, recent reports from observational studies have suggested an increased risk for aortic aneurysm or dissection associated with fluoroquinolone use, particularly in the setting of other risk factors such as hypertension, which led the United States' Food and Drug Administration to issue a safety announcement (https://www.fda.gov/Drugs/DrugSafety/ucm628753.htm) [213–216].

Adjunctive therapy for exit-site/tunnel infections should include daily or twice daily dressing changes, and cautious removal of exuberant granulomatous tissue ("proud flesh") with silver nitrate.

Antibiotic treatment should be administered for a minimum of 2 weeks and for at least 7 days beyond complete resolution of the infection. Treatment for at least 3 weeks is recommended for infections caused by *S. aureus* or *P. aeruginosa*. Extension of antibiotic therapy beyond 4 weeks should be avoided. In case of persistence of symptoms or recurrence after discontinuation of antibiotic treatment, the catheter should be removed and replaced [118]. Surgical shaving of the external cuff may be an alternative to catheter removal for treatment of a persistent exit-site infection if the inner cuff is not involved [121, 217].

Peritonitis

The diagnosis of peritonitis should be considered in any child on PD with abdominal pain and/or cloudy PD effluent, with an effluent white blood cell count of greater than 100/mm^3 and at least 50% polymorphonuclear neutrophils (PMN) confirming the diagnosis [118]. For children on automated PD, the effluent white blood cell count should be obtained from an exchange with the dialysis solution instilled for at least 1–2 h [118]. In this setting, the presence of 50% or more PMN is highly suggestive of peritonitis when the clinical features of peritonitis are present, even if the total white blood cell count is below 100/mm^3. Bacterial growth in the effluent confirms the diagnosis, whereas a negative culture does not rule out a bacterial etiology. The efficiency of microbiological diagnostics can be maximized by incubating the effluent in 3–4 blood culture bottles, and by centrifuging large effluent volumes. A culture-negative rate of less than 10% should be aimed for according to consensus guidelines [218]. However, international surveys have shown that this target is far from being achieved by pediatric PD centers around the globe [172]. Data from the SCOPE collaborative revealed an overall culture negative rate of 26.6% and significant variability in the culture negative rate and culture techniques among centers, although no associations between practices and culture negative rate could be elucidated [219]. In response to these data, the SCOPE collaborative has implemented a standardized PD effluent culture bundle and has already demonstrated a decrease in the both the culture negative rate and the percentage of cultures that are negative per month (unpublished finding). Among culture-positive cases, IPPN discovered wide regional variability in causative organisms, but in general gram-positive organisms predominate, with coagulase-negative *Staphylococci* and *S. aureus* most frequently cultured [122, 172].

Empiric intraperitoneal antibiotic treatment should be initiated as soon as the diagnosis of peritonitis is considered, and include coverage for both gram-positive and gram-negative organisms

[118]. Monotherapy with cefepime may be considered for empiric therapy, while a first-generation cephalosporin or a glycopeptide combined with ceftazidime or an aminoglycoside may be used if cefepime is not available [118]. However, global peritonitis data from children on PD reveals not only significant variability in the causative organisms, but also associated antibiotic susceptibilities, prompting the additional recommendation that empiric coverage be guided by the center-specific antibiotic susceptibility pattern [172]. Specifically, the empiric use of glycopeptides should be restricted to centers where the rate of MRSA exceeds 10%. Antibiotic therapy should be modified based on culture and antibiotic susceptibility results. Dosing recommendations are given in Table 65.5 [118]. If cultures remain sterile and signs and symptoms of peritonitis are

Table 65.5 Dosing recommendations for anti-infective agents in children with peritoneal dialysis catheter-related peritonitis. Administration should be via intraperitoneal route unless specified otherwise. Intermittent doses should be applied once daily unless specified otherwise. From [118] with permission

Imipenem/Cilastin	250 mg/L	50 mg/L	—
Oral			
Linezolid	<5 years.: 30 mg/kg/day divided TID; 5–11 years: 20 mg/kg/day divided BID; ≥12 years 600 mg/dose BID		
Metronidazole	30 mg/kg/day divided TID (max daily dose 1.2 g)		
Rifampin	10–20 mg/kg/day divided BID (max daily dose 600 mg)		
Antifungals			
Fluconazole	6–12 mg/kg IP, IV or PO q 24–48 h (max daily dose 400 mg)		
Caspofungin	IV only: initial dose 70 mg/m^2 on day 1 (max daily dose 70 mg); Subsequent dosing 50 mg/m^2 daily (max daily dose 50 mg)		

[a] For continuous therapy, the exchange with the loading dose of antibiotics should dwell for 3–6 h, followed by the use of the maintenance dose for all subsequent exchanges

[b] Aminoglycosides and penicillins should not be mixed in dialysis fluid because of the potential for inactivation

[c] Accelerated glycopeptide elimination may occur in patients with residual renal function. If intermittent therapy is used in this setting, the second dose of antibiotic should be time-based on a blood level obtained 2–4 days after the initial dose. Redosing should occur when the blood level is <15 mg/L for vancomycin, or 8 mg/L for teicoplanin. Intermittent therapy is not recommended for patients with residual renal function unless serum drug levels can be monitored in a timely manner

improved, empiric antibiotic therapy should be continued for 2 weeks with the exception of aminoglycosides, which should be discontinued after 72 h in culture-negative peritonitis [118].

General adjunctive measures include the reduction of the peritoneal fill volume during the initial 24–48 h of therapy in children with significant abdominal discomfort, and intraperitoneal administration of 500–1000 IU/L heparin until complete resolution of dialysate cloudiness [118].

Most children with PD-associated peritonitis achieve clinical improvement within two to three days following the initiation of antibiotic treatment [168, 185]. The initial treatment response is predictive of the functional recovery of PD and the risk of peritonitis relapse [142, 146]. Prolonged attempts to treat refractory peritonitis and to "save the catheter" should be avoided to minimize permanent injury to the peritoneal membrane [220]. In children who fail to respond clinically within 72 h of initiation of appropriate antibiotic therapy, repeat effluent cell count, differential and culture should be performed and potential sources of persistent infection should be sought. Treatment failure in peritonitis with *S. aureus* or *P. aeruginosa* points to a concomitant tunnel infection and requires catheter removal [118]. Treatment-resistant peritonitis with anaerobic bacteria or multiple gram-negative organisms is suspicious of intraperitoneal pathology (*e.g.,* ruptured appendix). Catheter removal is also recommended for any bacterial or culture-negative peritonitis that fails to resolve within 5 days of appropriate antibiotic treatment [118, 221, 222].

Ten to twenty percent of peritonitis episodes recur within 4 weeks of completion of antibiotic treatment with the same bacterial strain as indicated by identical antibiotic susceptibilities ('relapsing peritonitis') [146, 168, 185]. Repeated bouts of peritonitis are a risk factor for incomplete functional recovery and PD technique failure [146]. In relapsing peritonitis, empiric therapy should be reinitiated using an antibiotic combination covering the susceptibilities of the previous causative organism. Slime-forming bacteria can survive antibiotic therapy in a biofilm matrix or fibrinous adhesions on catheter surfaces. Accordingly, intraluminal fibrinolytic therapy may expose sequestered bacteria and render them susceptible to antibiotic activity. Local instillation of fibrinolytic agents (urokinase or recombinant tissue plasminogen activator), followed by instillation of high-dose antibiotics, has been shown to be efficacious in preventing further peritonitis relapses [223–225]. Hence, intraluminal fibrinolytic therapy should be considered in patients with a first peritonitis relapse which is not explained by extraluminal pathology such as a tunnel infection or an intraabdominal abscess. If a second relapse occurs, the catheter should be removed as soon as peritonitis is controlled by antibiotic therapy [118].

Fungal peritonitis is an infrequent but potentially serious complication of PD fraught with a high risk of PD technique failure and sometimes life-threatening, systemic infection [189, 190, 195]. Fungal infections represent 1–4% of all peritonitis episodes, although roughly 8% of peritonitis episodes reported to the SCOPE collaborative have been due to fungi [122, 185, 189, 190]. Treatment of fungal peritonitis consists of prompt catheter removal and appropriate antimycotic therapy [193, 226]. Fungi avidly grow on PD catheter surfaces, and resolution of infection is usually not possible as long as the catheter is in place. Fluconazole is the treatment of choice for most *Candida* species due to its excellent bioavailability and peritoneal penetration [227]. Alternative agents are echinocandins (e.g. caspofungin) for non-responding, non-albicans candida, and posaconazole or voriconazole for filamentous fungi such as Aspergillus [227]. Following catheter removal, effective antimycotic therapy should be administered for at least 2 weeks beyond complete resolution of clinical symptoms [118]. Reinitiation of PD following the treatment of fungal peritonitis in children has been successful [189].

Non-Infectious Complications

Non-infectious complications can result in significant morbidity, including the need to terminate PD [116, 228]. Non-infectious PD complications can be divided into catheter-related complications, and complications related to the dialysis procedure itself (Table 65.6) [229–231].

Table 65.6 Non-infectious complications of peritoneal dialysis [229–231]

Catheter related complications
Obstruction/reduced inflow or outflow
Migration of catheter out of pelvis
Catheter kinking
Catheter blockage
Fibrin
Blood clot
Omentum
Catheter compression
Stool/Constipation
Tumor or other intraabdominal mass
Peri-Catheter leak
Catheter cuff extrusion
Complications associated with the dialysis procedure
Related to increased intraperitoneal pressure
Subcutaneous leak
Gastroesophageal reflux and delayed gastric emptying
Abdominal and back pain
Hernia
Hydrothorax
Related to transfer of solutes during dialysis (electrolyte and metabolic derangements)
Hypokalemia
Hypo/hypermagnesemia
Hyperglycemia
Hyperinsulinemia
Hypertriglyceridemia
Related to exposure of peritoneal membrane to dialysis fluid
Membrane failure
Pancreatitis
Encapsulating peritoneal sclerosis

Catheter-Related Complications

Catheter-related complications include catheter malfunction, i.e. poor inflow and/or outflow, and leaks at the catheter exit-site. A recent analysis of data from the IPPN revealed a catheter revision rate of 1 per 83.2 patient-months, and the leading indication for revision was catheter malfunction, particularly in the first year after placement (Fig. 65.7) [116]. In that study, the need for access revision increased the risk of PD technique failure or death, and access dysfunction due to mechanical causes doubled the risk of technique failure compared with infectious causes [116]. The risk of access revision was associated with younger age, diagnosis of congenital anomalies of the kidney and urinary tract, coexisting ostomies, presence of a swan neck tunnel with curled intraperitoneal portion, and a high gross national income [116].

Catheter malfunction may be caused by obstruction from the omentum, kinking or migration of the catheter out of the pelvis, or blockage by fibrin or clots. Omentectomy at the time of catheter placement may reduce the risk of obstruction, and is practiced in most centers [133, 232, 233]. In practical terms, the omentectomy does not have to be complete. The remnant amount needs to be such that it cannot reach the distal catheter once it is positioned in the pelvis. However, one group of investigators, despite reporting a 20% decrease in the incidence of catheter blockage with omentectomy, calculated that eleven omentectomies would be required to prevent two omental PD catheter blockages. Therefore, the authors felt that nine patients would undergo an unnecessary omentectomy. In their hands, a secondary omentectomy was not difficult, resulting in their conclusion that omentectomies should only be carried out after a blockage occurs [232].

Migration of the catheter out of the pelvis can lead to poor dialysate inflow or outflow, as well as increased pain with dialysis. As mentioned previously, constipation is a risk factor for migration and should be monitored for and treated aggressively. Once migration has occurred, interventional radiology (IR) techniques may be used to reposition the catheter, with laparoscopic repositioning if IR repositioning fails [234]. For catheters that are occluded by fibrin or blood clot, installation of fibrinolytic agents can be very effective in restoring catheter flow [235–237].

Leaking of fluid from the peritoneal cavity through the PD catheter tunnel is a significant risk for the development of peritonitis. As previously discussed, delaying use of the PD catheter for routine dialysis for at least 14 days is advised to minimize the risk for leaks, and subsequent infection [115, 118]. The use of fibrin glue in the PD catheter tunnel has been reported to be both effective in treating established leaks and, when used at the time of catheter implantation, may help prevent the development of peritoneal leaks around catheters that are used soon after being placed [238, 239].

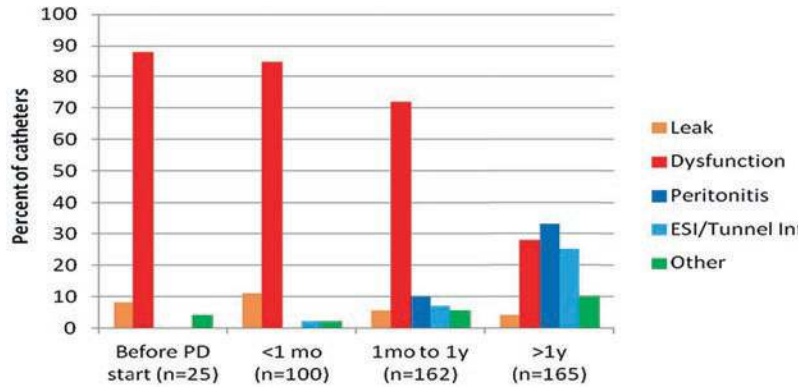

Fig. 65.7 Characterization of 452 access revisions by indication and time on peritoneal dialysis (PD) among children enrolled in the International Pediatric Peritoneal Dialysis Network (IPPN) Registry. ESI, exit site infection; tunnel inf, tunnel infection. (From [116], with permission)

Hemoperitoneum, or blood in the dialysate effluent, is common immediately after PD catheter placement and typically clears with dialysis exchanges. Heparin may be added to the dialysate to reduce the risk of clotting within the PD catheter. Strictly speaking, most cases of hemoperitoneum beyond the post-implantation period are not a complication of PD *per se*, but rather diagnosed because of the ability to visualize peritoneal fluid during the dialysis procedure. A common benign cause of hemoperitoneum in female adolescents and young adult women is menstruation. Blood may appear a few days prior to menstruation and arise from shedding of intraperitoneal endometrial tissue if endometriosis is present, or from the uterus in a retrograde fashion through the fallopian tubes [230, 231]. Hemoperitoneum can also be seen at the time of ovulation. Other causes of hemoperitoneum include trauma, bleeding disorders, anticoagulation therapy, and rupture of a hepatic, ovarian or renal cyst. Finally, bleeding into the peritoneal cavity may be associated with intraperitoneal calcifications, which may occur as a consequence of chronic kidney disease bone and mineral metabolism disorder, or in the setting of encapsulating sclerosing peritonitis (see below) [231].

Complications Related to the Dialysis Procedure

Complications related to the dialysis procedure can be divided into those due to the increased intraperitoneal pressure that arises with instillation of dialysis fluid into the peritoneal cavity, those occurring as a consequence of the transfer of solute between plasma and dialysate during the dialysis exchange (i.e. metabolic or electrolyte derangements), and those that are either directly related to or exacerbated by exposure of the peritoneum and other intra-abdominal organs to dialysis fluid (Table 65.6) [230, 231].

Complications Related to Increased Intraperitoneal Pressure

Since the efficacy of the dialysis procedure is dependent on the area of the peritoneal membrane in contact with the dialysis fluid, increasing this contact area by increasing the fill volume is a therapeutic aim. However, an increase in the fill volume is associated with an increase in the intraperitoneal pressure (IPP) [35]. Elevated IPP can lead not only to patient discomfort and intolerance of the dialysis procedure, but may also increase the risk of dialysis leaks, gastroesophageal reflux, hernia formation and hydrothorax [10, 33, 34]. While leaks at the catheter exit-site occur most frequently around the time of catheter placement, more subtle leaks may occur well after the catheter exit-site has healed [240]. These leaks typically present with accumulation of fluid in the subcutaneous tissue, weight gain, and peripheral and/or genital edema, and often resolve with reduction in fill volume, avoiding a daytime fill, or temporary cessation of PD. Complaints of back or abdominal pain and gastroesophageal reflux may be eased by efforts to lower the IPP, including a reduction of the fill volume, particularly during the day.

As stated previously, hernias are common in children and their frequency is inversely related to age. Ideally, hernias are identified and repaired at the time of PD catheter placement [133, 134, 241]. Hernias may develop after PD is initiated at the sites of surgical incisions or areas of anatomic weakness such as the umbilicus or the linea alba. Small hernias may be followed with careful monitoring for incarceration, with efforts to reduce IPP as described above. However, many hernias in children ultimately require surgical repair.

Hydrothorax in the patient on PD occurs when an elevated IPP causes fluid to enter the pleural space by way of a pleuroperitoneal leak, presumably at the site of a diaphragmatic defect [242]. This defect is almost always on the right side; the presence of the heart and pericardium may limit leak of fluid across the left hemidiaphragm. Hydrothorax usually presents with shortness of breath and chest discomfort and must be differentiated from congestive heart failure. In addition, other causes of transudative pleural effusion, including volume overload, should be ruled out. Diagnosis is typically made by measuring glucose in the fluid obtained by way of thoracocentesis, with an elevated pleural fluid glucose relative to serum glucose verifying the peritoneal dialysate origin of the fluid [231, 242]. Confirmatory tests can include CT peritoneography or a technetium scan, followed by serial imaging [243]. First line treatment of hydrothorax is transient cessation of PD, which may allow closure of the diaphragmatic defect [244]. If conservative therapy fails, chemical pleurodesis with tetracycline, talc or autologous blood may be successful [244, 245]. Other therapeutic options include thoracoscopic pleurodesis, and thoracoscopic or open diaphragmatic repair [231, 244].

Complications Related to Transfer of Solutes During the Dialysis Procedure

The bidirectional transfer of solutes between the plasma in peritoneal capillaries and the dialysate in the peritoneal cavity is the therapeutic goal of the PD procedure. However, the transfer of solutes cannot be precisely controlled and so certain electrolyte and metabolic derangements should be anticipated. The most common of these is hypokalemia, the result of potassium losses into the potassium-free dialysis solution. Liberalization of dietary intake will typically restore normal potassium, but enteral supplementation may be required, particularly in infants or young children on low potassium formulas. The possible association between hypokalemia and the risk for peritonitis should prompt attention to and correction of this issue.

Hypermagnesemia is relatively common in children with kidney failure secondary to reduced kidney clearance of magnesium. Magnesium concentrations in commercially available dialysis solutions range from 0.25–0.75 mmol/L. Elevated serum magnesium levels are typically seen with use of solutions containing 0.75 mmol/L magnesium and high magnesium levels may contribute to adynamic bone disease [246–248]. On the other hand, use of solutions containing both 0.5 mmol/L and 0.25 mmol/L magnesium has been associated with hypomagnesemia in adults on PD [246]. Given the lack of data available on magnesium homeostasis in children on PD, current recommendations suggest choosing a solution that allows maintenance of a high normal serum magnesium, i.e. 0.9–1.0 mmol/L, in this population [43].

Hyperglycemia, hyperinsulinemia and dyslipidemia are present even in the early stages of kidney failure in children [249, 250]. These conditions persist or worsen on dialysis [251–253]. The pathophysiologic mechanisms contributing to disturbances in glucose and lipid metabolism seen in children with kidney failure are quite complex, and beyond the scope of this chapter. It is important to recognize, however, that in people on PD, exposure to glucose-containing dialysis solutions provides a substantial glucose load, which induces insulin resistance and an atherogenic lipid profile [38, 229, 254]. Thus, PD may contribute to the development of disturbances of glucose and lipid metabolism, or exacerbate them if already present. These findings reinforce recommendations to minimize exposure to glucose by using the lowest dialysate glucose concentration possible, with the addition of icodextrin if required to maintain euvolemia [9, 43]. The pri-

mary therapeutic approach for dyslipidemia is lifestyle modifications, including nutrition and dietary counseling to address obesity if present. Although several pharmacologic therapies for dyslipidemia are available, given the lack of data on safety and efficacy of these agents in children, KDIGO guidelines suggest that statins or statin/ezetimibe combinations not be initiated in children less than 18 years of age with kidney failure, including those on maintenance dialysis [255].

Complications Related to Exposure of Peritoneal Membrane to Dialysis Fluid

Peritoneal membrane failure, or the inability of the membrane to provide adequate removal of fluid and/or solutes, is an important complication of PD as it typically necessitates conversion to hemodialysis. International and national registry data suggest that 4.2–8% of the children on PD in these large cohorts required transfer to HD due to membrane failure, and the percentage is as high as 27% in smaller series [3, 116, 256]. Severe, persistent or recurrent peritonitis is a significant contributor to membrane failure, but as previously discussed, an increasing body of experimental evidence suggests that exposure of the peritoneal membrane to PD solutions, and high concentrations of glucose in particular, is a predominant contributor to progressive fibrosis [41, 57, 257].

Pancreatitis in people on PD may be caused by the same precipitating factors as in people who are not on PD, such as infection, medications, hypercalcemia and hyperlipidemia. However, irritation from the peritoneal dialysis fluid and/or PD catheter has also been reported as a cause of pancreatitis in people on PD [258]. The presenting symptoms of abdominal pain, emesis and cloudy dialysis effluent may mimic peritonitis, and thus the diagnosis can be missed. The diagnosis should be considered in people on PD with sterile peritonitis, particularly if their symptoms do not improve. Most episodes may be treated conservatively, although recurrence with reintroduction of dialysate into the abdomen may prompt at least the temporary cessation of PD [231].

Encapsulating peritoneal sclerosis (EPS) is a rare, but extremely serious complication of PD defined by the ISPD as ‘a clinical syndrome continuously, intermittently or repeatedly presenting with symptoms of intestinal obstruction due to adhesions of a diffusely thickened peritoneum’ [259]. EPS has been reported in 0.7–3.3% of adult cohorts, with a mortality rate of 35–69% [259–262]. A 10-year survey of 1472 children on PD revealed a similar prevalence of EPS at 1.5% or 8.7 cases per 1000 patient-years on PD, but a lower mortality rate with 3 deaths among 22 cases after a median follow-up of 4.8 years [263]. Non-PD related risk factors for the development of EPS include previous intra-abdominal surgery, beta-blockers, and cirrhosis with ascites [259]. Among people on PD, the cause of EPS is likely multifactorial, but recurrent infection and long term exposure to dialysate are thought to be the major contributors [259, 261, 264]. As in adults, data from children on PD reveal that increasing time on PD is associated with an increased risk for EPS [263, 265, 266]. Efforts to prevent EPS, therefore, have included pre-emptive transfer to hemodialysis in people who remain on PD for more than 8 years. Ongoing treatment with PD beyond this time period can be considered if the person on PD has a stable dialysate/plasma creatinine (D/P Cr) ratio based on PET, no evidence of high peritoneal transport capacity, no requirement for frequent use of hypertonic dialysis solution, normal or only intermittently elevated serum C-reactive protein level, absence of recurrent peritonitis and clinical stability defined as “good appetite and no signs of fluid overload.” [265, 267].

People on PD with EPS typical present with symptoms of bowel obstruction, including abdominal pain, emesis, anorexia, abdominal mass, weight loss, ascites and hemoperitoneum, and EPS is almost universally associated with progressive loss of ultrafiltration [259]. The diagnosis is usually confirmed radiographically, with either ultrasound or CT demonstrating loculated/septated ascites, adherent bowel loops, peritoneal thickening, and peritoneal calcification. Treatment typically consists of transfer to HD and bowel rest with provision of parenteral nutri-

tion [261, 264]. Treatment with several immunosuppressive agents, including prednisolone, sirolimus, mycophenolate mofetil, and tamoxifen, has been reported with variable success [259, 260, 268–271]. EPS can develop in patients on immunosuppression following kidney transplantation, calling into question the role of immunosuppression in this condition [264]. In adults with EPS, surgical intervention at specialized centers has shown improvement in symptoms and survival [272, 273]. Ongoing prospective efforts to monitor peritoneal membrane function and ultrastructural changes in people on PD should provide valuable information about the risk factors for developing EPS and ultimately strategies to minimize the risk for its development [71, 274].

Introduction

Hemodialysis (HD) was introduced as a treatment for uremia at the end of World War II [1]. A decade later, Mateer et al. reported the first experience using HD to treat five uremic adolescents using 15 meter cellophane tubing and a 32 liter dialysis bath. Each dialysis procedure was 13 h, and although the metabolic and fluid status of their patients improved, there were challenges related to anticoagulation of the circuit and achieving normal plasma calcium and potassium concentrations [2]. Maintenance HD was not practical because vascular access required cannulae placed in the radial artery and saphenous vein prior to each session. This problem was overcome by the development of silastic arteriovenous cannula by Scribner et al [3] which were inserted in the forearm vessels and could be used for repeated blood access. What followed was the report by Fine et al [4] describing the use of HD for maintenance treatment of end-stage kidney disease (ESKD) in five adolescents who were dialyzed three times weekly for 7–8 h per session using a concentrated dialysis solution mixed with tap water. A urea clearance of 45 ml/min resulted in a urea reduction rate (URR) of 48% during each 7–8 h treatment. While maintenance HD was now a realistic option for children with ESKD, technical difficulties persisted in small children and the need for 20 h of treatment per week required long periods of time in the hospital.

In 1971, Kjellstrand et al. reported their experience treating 10 children <15 kg [5]. Applying data from adults receiving dialysis, the authors recommended a urea clearance in children based on body weight, with a goal urea clearance of 2–3 ml/kg/min during each dialysis session. This clearance, multiplied by the number of hours of dialysis, allowed an accurate prediction of the expected fall in urea during a single HD session. This reduced the risk of disequilibrium syndrome from excessive reductions in urea and established a standard formula for dialysis urea clearance in children that is still used today.

Despite the initial success of the Scribner shunt, clotting and infection of the vascular access remained common. Arteriovenous fistulae reduced this problem and remain the gold standard for dialysis access. However, creation of fistulae in small children is technically challenging and requires surgical expertise and a critical mass of patients to maintain skills, which are not available in many pediatric centers [6]. These technical challenges, combined with the desire to avoid repeated needle punctures in small children, led Mahan et al. to use a Hickman central venous catheter for prolonged HD vascular access in children [7]. Central venous catheters have since become the most widely used HD access [8]. While allowing children to obtain puncture-free HD, catheters have a high rate of clotting, infection, and decreased blood flow and therefore should only be used for long-term access when creation of a suitable fistula or access to expert fistula teams is not possible.

Technological improvements over the last 50–60 years have made HD widely available for children with ESKD. While overall and cause-specific mortality have decreased for children initiating maintenance dialysis over the last several decades, children with ESKD continue to experience unacceptably high rates of morbidity and mortality compared to the healthy pediatric population [9]. Improvements in dialysis equipment, medications, and consensus treatment guidelines are likely responsible for better patient outcomes (Fig. 66.1) [9]. Today, children often receive less than half the weekly HD treatment time compared to when the therapy first became widely available, as described above [4]. To dramatically improve outcomes further may require a fundamental change to the "standard" thrice weekly HD prescription. Initial pediatric experiences using short daily or nocturnal HD dialysis and hemodiafiltration (HDF) have been very positive, although widespread application remains futuristic due to logistic and funding barriers in some countries.

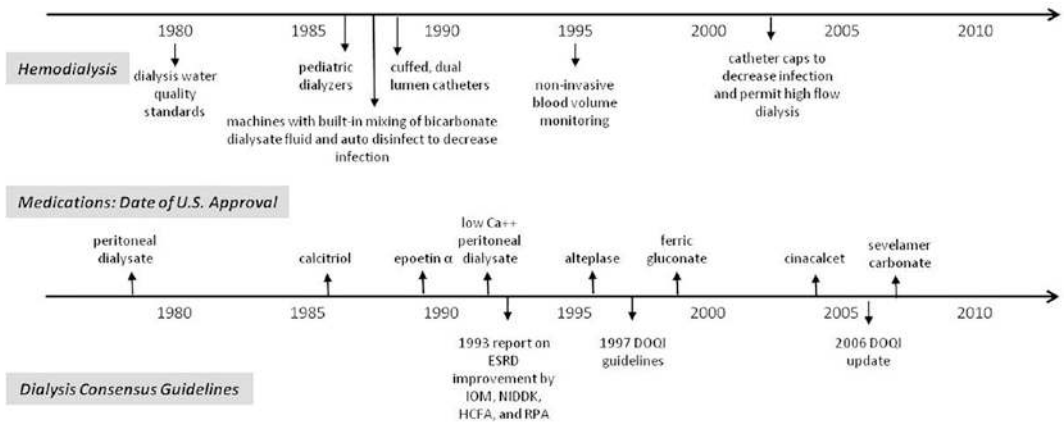

Fig. 66.1 Improvements in hemodialysis from 1980–2010

Prescribing Hemodialysis

Most of the HD literature reports on adults, with less data available in pediatric patients. In theory, the principles learned from adults are universal and applicable to children, but adjustments are required to accommodate the spectrum of age, weight, growth, and physiological development that are specific to children. Ideally, children should receive ESKD treatment at specialized pediatric centers with the necessary technical expertise, staffing, and multidisciplinary resources (physicians, nurses, psychologists, dieticians, social workers, teachers, and child-life specialists) to provide optimal care [10]. The two primary objectives of HD are to clear metabolic waste products and to UF excess fluid. To achieve these goals, the prescriber must calculate adequate clearance and estimate the patient's dry weight. To complete the HD prescription, one must then choose the blood flow rate, dialyzer, extracorporeal tubing, dialysate electrolyte composition and temperature, and anticoagulation.

Adequacy

The publication of the National Cooperative Dialysis Study (NCDS) in 1981 [11, 12] addressed how dialysis might best reduce patient morbidity and mortality by comparing four groups of patients with high or low timed-average-concentration of urea (TAC-urea) and with either long (4.5–5 h) or short (2.5–3.5 h) dialysis sessions. The results showed that the TAC-urea was the most important determinant of patient morbidity and hospitalization. In a subsequent analysis of the NCDS using a single-pool urea kinetic model, Gotch and Sargent argued for the use of Kt/Vurea to measure the adequacy of dialysis [13]. This unitless measure is an estimate of the clearance of urea from the blood during a dialysis session, standardized by total body water (which reflects the urea distribution volume). Kt/Vurea has become the standard measure of the delivered dialysis dose and the adequacy of dialysis.

Various methods for calculating Kt/V have been proposed. The single pool (spKt/V) method assumes urea is removed from a single pool and so a delayed postdialysis sample is not required. However, this method overestimates urea clearance because it ignores urea rebound postdialysis from access recirculation, cardiopulmonary recirculation, and tissue redistribution**.** Access recirculation becomes insignificant within 15–20 s of the blood flow being reduced to <50–80 ml/min. Cardiopulmonary recirculation only occurs with arteriovenous access and not with central lines. Cardiopulmonary recirculation is a

result of blood returning to the dialyzer after circuiting the heart and lungs without passing through the other tissues and ceases 1–2 min after slowing blood flow. Conversely, urea tissue rebound continues over a longer time because there is diminished blood flow to muscle, which has high urea content, during dialysis [14]. Urea rebound is minimized by using either of the following two methods proposed by National Kidney Foundation Dialysis Outcomes Quality Initiative (KDOQI) guidelines [15]. With the slow blood flow method, the dialysate is turned off and the UF is minimized at the end of dialysis. The blood flow is then decreased to <100 ml/min for 15 s and then the urea sample is obtained. Using the stop dialysate method, the same protocol is used, except the blood flow is maintained at a normal rate for 3 min prior to drawing the postdialysis urea sample. Standardization is important, especially because different results for Kt/V have been shown in children depending on which day of the week laboratory studies are performed [16].

The double pool Kt/V recognizes that postdialysis rebound of plasma urea may be substantial. Therefore, a urea sample drawn 60 min postdialysis is required to avoid the overestimation of urea removal. This method is probably the most accurate estimate of Kt/V, but the need for a delayed postdialysis blood sample and lack of validation studies have limited its use.

Calculating Kt/V with urea kinetic modeling requires sophisticated computer algorithms which may not be available in many pediatric dialysis units. However, websites including Hypertension Dialysis and Clinical Nephrology (www.hdcn.com) and www.Kt-v.net provide programs for calculation of single and double pool Kt/V measurements, some of which have been used in pediatric studies [17]. The major advantage of kinetically modeled methods to estimate Kt/V is that they also provide an estimate of the urea generation rate from which the normalized protein catabolic rate (nPCR), an estimate of dietary protein intake, can be calculated. Nevertheless, several potential inaccuracies are intrinsic to the measurement of kinetically derived Kt/V. Urea clearance (K) for individual dialyzers is derived from the manufacturer's specifications, which do not account for recirculation or reductions in dialyzer efficacy due to clotting of dialysis fibers or interruptions in treatment from kinked lines. Also, determining the urea distribution volume (V) may be imprecise, particularly in children [18].

To overcome these limitations, more simplified equations for calculating Kt/Vurea have been proposed [19]. One such formula [Kt/V = – Log n (R – 0.008 t) + (4–3.5 R) UF/BW] estimates the spKt/V where R is the ratio of the predialysis to postdialysis urea, t is the time of dialysis in hours, UF is the UF volume in liters, and BW is body weight in kg. This formula varies by only 6% from formal urea kinetic modeling in children [17]. To correct for postdialysis urea rebound, additional equations have been developed to calculate the equilibrated Kt/V (eKt/V) in patients with arteriovenous [eKt/V = spKt/V – (0.6 × spKt/V/T) + 0.03] or venovenous [eKt/V = spKt/V – (0.47 × spKt/V/T) + 0.02] access. Standardized (stdKt/V) formulas are available to estimate the Kt/V over a week, which are useful in patients regularly receiving more frequent or intensified dialysis regimens, or for those requiring occasional extra sessions for UF [18, 20].

Finally, the URR measures the percentage decrease in blood urea during a dialysis session. The URR as a marker of dialysis adequacy was evaluated retrospectively in 13,473 patients, and the mortality rate increased by 28% when URR values of <60% were obtained [21]. Despite its validation as a measure of morbidity, URR is not recommended as the primary measure of dialysis adequacy because significant variations of Kt/Vurea may be obtained with each URR value, particularly when URR is greater than 65%. Also, with increasing UF, URR underestimates urea removal. Nonetheless, targeting a URR of <50% for the first several treatments in a patient initiating chronic dialysis is a useful means of preventing dialysis disequilibrium. As no upper limit of Kt/Vurea has been established, care must be taken with aggressive treatment. Even

in patients who have been on dialysis for a long time as excessive urea removal can lead to symptoms of dialysis disequilibrium.

KDOQI guidelines published in 2000 recommended that the delivered dose of HD in both adults and children should be measured using formal urea kinetic modeling with a spKt/V urea of at least 1.2. In 2002, the HEMO Study randomized 1846 patients on conventional thrice weekly HD to either a standard or high-dose of dialysis as well as to a low-flux or high-flux dialyzer. In high-dose patients, the URR was 75% and spKt/V 1.71, compared with standard-dose patients whose Kt/V was 1.32 with a URR of 66%. Neither dialysis dose nor dialyser flux affected the relative risk of death. The authors concluded that there was no major benefit from a higher dialysis dose than recommended by KDOQI or from the use of high-flux dialysis membranes [22].

However, dialysis dose may be associated with mortality in association with body mass index (BMI). In patients with lower BMI, a URR of >75% was associated with a lower risk of death compared to patients with a URR of 70–75% [23]. Daugirdas et al. found that by normalizing Kt/V to body surface area (BSA), most children less than 10 years of age would receive less dialysis compared to older patients, despite acceptable eKt/V and stdKt/V values [18]. Theoretically, it is tempting to postulate that there may be a survival advantage in increasing the HD dose in women and patients with a low BMI, such as children.

The Dialysis Outcomes and Practice Patterns Study (DOPPS) review of 22,000 adult HD patients from seven countries found that a higher dialysis dose, as reflected by a higher Kt/V, was important and an independent predictor of lower mortality. Survival was greatest when combining a higher Kt/V with a longer treatment time. For every 30 min longer on HD, the relative risk of mortality was reduced by 7% [24]. Reports from the Australian and New Zealand Dialysis and Transplant Registry and the United States support that longer treatment times, notably those >4–4.5 h, are associated with a lower risk of death, independent of adequate clearance [25, 26]. Such research establishes the basis for intensified dialysis programs (see below), namely a move away from conventional 3–4 h, three-times-per-week dialysis to more frequent and/or more prolonged dialysis sessions.

The KDOQI guidelines for HD adequacy were revised in 2005 to recommend a minimum spKt/V urea of 1.2 per session, with a target spKt/V of 1.4 and URR of 70%. These recommendations were consistent with the minimal Kt/V reported in the HEMO Study and also the European Guidelines for Hemodialysis, which endorsed a spKt/V of 1.4–1.5 [27]. However, no large scale studies have assessed HD adequacy in children. Buur and colleagues compared two urea kinetic models with direct quantification of urea removal and found that although each method produced different results, correlation between the methods was very high [28]. The authors commented that for practical purposes, and to limit blood sampling, one of the direct single-pool methods of urea kinetic modeling should be used. A study of 8 children <18 years of age compared an online urea monitor (UM 1000™, Baxter Healthcare) with single and double-pool formulas and separately with single-needle dialysis [29]. The study reported considerable differences in Kt/V urea between single and double pool formulae and concluded that online urea monitoring was inaccurate during single-needle dialysis.

Despite the limited data in children, expert working groups have developed guidelines for HD in children both in Europe and North America [10] together with European adult guidelines [27]. These are summarized in Table 66.1. We recommend maintaining a spKt/Vurea between 1.4–1.8 in children dialysed for 3–4 h per session. It is imperative that the prescribed dialysis dose for an individual child should be based on more than just an estimate of urea removal. Achieving optimal dialysis must also include a careful clinical assessment including growth, nutrition, cardiovascular health (especially blood pressure (BP)), anemia treatment, and the bone and mineral health of a developing child [30].

Table 66.1 Published guidelines for hemodialysis adequacy

Source	Urea Clearance	Other
KDOQI, adults	Minimum spKt/V ≈ 1.2target spKt/V ≈ 1.4	URR ≈ 65%URR ≈ 70%
European, adults	eKt/V > 1.2spKt/V ≈ 1.4	Double-pool urea kinetics preferred
KDOQI, children	spKt/V > 1.4	Assess nutrition (nPCR)optimize ultrafiltration
European, children	eKt/V ≥ 1.2–1.4	Assess nutrition (nPCR)monitor growth and cardiac function

Estimation of Dry Weight

UF is targeted to an estimated 'dry weight.' Dry weight is most commonly defined as the post-HD weight at which the patient is close to euvolemia without experiencing symptoms. Overestimation of the dry weight places patients at risk of developing volume-dependent hypertension, left ventricular hypertrophy (LVH), and congestive heart failure. An underestimation of the dry weight increases the risk of symptoms from intradialytic volume depletion. In children, growth and changes in lean body mass and body habitus necessitate regular and frequent re-evaluation of the dry weight to detect subtle differences in the ratio of total body water to body mass. This is especially important in infants and young children receiving HD for ESKD as they are growing rapidly, Therefore, tests for evaluating dry weight have to be easily accessible, reproducible, and ideally non-invasive.

The clinical examination is the most widely used test, but at best it only provides a crude assessment of volume status. In children with ESKD, even the most sensitive signs are rendered imprecise. For example, as dialysis patients have fluid removed there are a number of factors that can result in hypotension (cardiac dysfunction, low vascular tone, hypoalbuminemia, medications) and thus changes in orthostatic vital signs are not diagnostic of true hypovolemia. Jugular venous distension, though infrequently assessed in children, is a useful sign in the assessment of central venous pressure, provided heart failure is absent [31].

Biochemical markers including plasma atrial natriuretic peptide and brain natriuretic peptide correlate with increased plasma volume in ESKD [32], but levels can also remain elevated in volume contracted individuals and hence they lack the ability to detect volume depletion. Brain natriuretic peptide appears superior to atrial natriuretic peptide in predicting LVH and dysfunction. However, in the context of defining dry weight, results have been variable [33].

Ultrasound guided supine inferior vena cava (IVC) diameter measurement and its decrease on deep inspiration, better known as the collapse index (CI = end expiratory IVC diameter minus end inspiratory IVC diameter)/end expiratory IVC diameter), have been shown to correlate with right atrial pressure and circulating blood volume [34]. Results are influenced by wide interpatient variability, lack of validated normal values for children, the timing of the measurement in relation to dialysis, and the presence of heart failure or tricuspid regurgitation. As a result of these limitations, although it is a non-invasive test which could conceivably become available at most centers, it cannot reliably predict dry weight in children.

Bioelectrical impedance technology can directly assess extracellular volume (ECV), intracellular volume (ICV) and total body water (TBW) by detecting differences in the degree of resistance (impedance) as electric currents pass through each fluid compartment. At low frequencies, current cannot cross cell membranes and only flows through ECV; at higher frequencies it flows through both the ICV and ECV. Three methods for assessing dry weight using bioimpedance are available: (1) The normovolemia/hypervolemia slope method uses whole body multi-frequency bioimpedance spectroscopy to measure the ECV (Fig. 66.2) [35]; (2) The resistance-reactance graph method uses whole body single-frequency bioimpedance analysis to estimate TBW, but is unable to separate ECV from ICV, and therefore only useful when trying to

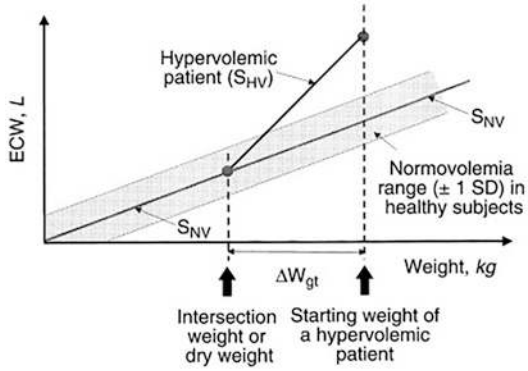

Fig. 66.2 Bioelectrical impedance to estimate dry weight using the normovolemia/hypervolemia slope method with whole body multi-frequency bioimpedance spectroscopy

differentiate between excessive body water and true weight gain [36]; (3) The continuous intradialytic calf bioimpedance method records changes in extracellular resistance in real-time, generating a curve whose slope flattens as excess ECV is removed, dry weight defined as flattening of the curve over a period of 20 minutes [37]. Premature flattening of the curve may occur in the presence of venous thrombosis or lymphatic edema. The value of bioimpedance techniques to estimate dry weight in pediatrics is unknown and limited by incomplete data in children and from patients with ESKD, and the inherent underestimation of TBW with multi-frequency bioimpedance methods. Importantly, changes in electrolyte, red cell, and protein concentrations and patient temperature are all known to influence bioimpedance. Bioimpedance may be used more frequently as increasing evidence from clinical studies validate its assessment of fluid status [38, 39].

Finally, on-line non-invasive blood volume monitoring (NIVM) is commonly used in clinical practice. NIVM provides information on intradialytic blood volume changes and vascular refilling rates. The magnitude of blood volume changes differs between patients and dialysis sessions, but if combined with post-dialytic vascular compartment refilling rates, dry weight can be assessed. Vascular refilling typically occurs in the first 10 min after stopping UF and is characterized by an increase in the relative blood volume (RBV), which can continue for up to 60 min. Steuer et al. achieved a twofold reduction in intradialytic symptoms using NIVM in 6 hypotension prone adults, without reducing the UF volume or increasing treatment times [40]. Others have shown an increase in the UF potential, lowering of the dry weight, improved patient well-being and reduced hospitalization due to fluid overload.

NIVM is based on the principle of mass conservation: the concentration of measured blood constituents (hemoglobin/haematocrit/plasma protein) confined to the vascular space is proportional to changes in the vascular volume. Individual NIVM devices differ by their intrinsic sensing technique. Optical devices measure the absorbance of monochromatic light via an optoprobe in the arterial line to estimate the hematocrit because the optical density of whole blood is a measure of red blood cell concentration. The Crit-line™ (Fresenius) is a stand alone device, while the Hemoscan™ (Hospal-Dasco, Medolla, Italy) is a component of the dialysis machine. Blood density monitors are dependent on the total protein concentration (plasma protein concentration + mean cellular hemoglobin concentration). The Blood Volume Monitor™ (BVM, Fresenius AG, Bad Homburg, Germany) measures the velocity of sound through blood, as a reflection of blood density, by means of a cell inserted in the pre-pump segment of the arterial line. Schneditz et al. demonstrated a 2% difference in RBV changes between the Crit-line and BVM which developed 1 h into dialysis and persisted thereafter [41].

NIVM is used to divide patients into 4 groups. Group 1: Absence of postdialysis refilling with no symptoms suggestive of intradialytic hypovolemia or post-dialytic fatigue: the patient is likely to be at their dry weight. Group 2: Postdialysis refill, lack of a substantial change in blood volume during HD, and no intradialytic or post dialytic symptoms: indicative of extracellular fluid expansion and the need to lower the patient's dry weight. Group 3: Absence of postdialysis refill, intradialytic and/or post dialytic symptoms: indicative of hypovolemia and the need to increase the dry weight. Group 4: Postdialysis refill but intradialytic symptoms of hypovolaemia: indicative of slow vascular refilling rates, but ECV expansion at the end of dialysis. This suggests that the dry

weight needs to be reduced incrementally and slowly following changes to the dialysis prescription to increase the UF potential. Extended duration of dialysis sessions may be necessary.

Information on blood volume status can be particularly helpful in the pediatric HD setting as the prevalence of intra- and interdialytic morbidity may be underestimated because children often do not verbalize early warning symptoms. Jain et al. show reduced dialysis associated morbidity with NIVM, with the greatest impact on children weighing less than 35 kg [42]. Michael observed improved targeting of the dry weight in children, which reduced the requirement for antihypertensive medication [43]. Using a constant dialysate sodium concentration of 140 mmol/L, Jain also defined a safe UF rate as an RBV change of <8% per hour in the first 90 mins and then <4% thereafter, with no more than a 12% net RBV change per dialysis session [42]. Hothi et al. reported in 11 pediatric HD patients that the gradient of the RBV curve in the first hour, as well as changes in heart rate, were the strongest predictors of treatment-related complications [44].

In summary, evaluating a patient's dry weight can be a challenge. The limitations and benefits of the available tests to estimate dry weight are summarized in Table 66.2. As of yet no gold standard has been defined and for the majority, applicability in pediatrics has not been validated. We recommend the use of NIVM combined with clinical assessment. NIVM also offers the advantage of accurate assessment of the patient's hemoglobin, allowing for tracking of responses to changes in erythropoietin stimulating agent and iron administration. This is especially important in young children in whom frequent blood draws for lab testing can exacerbate anemia secondary to ESKD and blood loss from HD.

Blood Flow Rate

The blood flow rate is a major determinant of solute clearance on dialysis. With increased blood flow, more solute is delivered to the dialyzer, resulting in higher dialyser "flow limited clearance." However, clearance is also determined by the membrane's permeability to the solute, which is known as "membrane limited clearance." With poorly permeable solutes, increasing the blood flow will only produce a mild increase in clearance (Fig. 66.3). The dialyser flow clearance is limited and starts leveling off at blood flows of 250–300 ml/min, and therefore some adult dialy-

Table 66.2 Summary of Methods for Assessing Dry Weight [246]

Modality	Pros	Cons
Biochemical markers	-ease of use -noninvasive	-wide variability -poor correlation with volume depletion -not available at most laboratories -inaccurate in patients with congestive heart failure
Inferior vena cava diameter	-correlated with right heart pressure and intravascular volume -noninvasive	-no normative values for children -technician dependent -cost -limited availability -unclear which time after HD to measure
Bioimpedance	-measures ECFV and ICFV, estimating fluid shifts from various compartments -strong correlation with ultrafiltration volume	-limited normative values for children -unclear which time after HD to measure -cost -underestimates volume shifts from trunk
Non-invasive blood volume monitoring	-ease of use -ease of interpretation -decreases risk of intradialytic hypotension -validated use in children	-no standardization across devices -requires active intervention by providers -only measures fluid shifts from intravascular space and refilling rates Cost

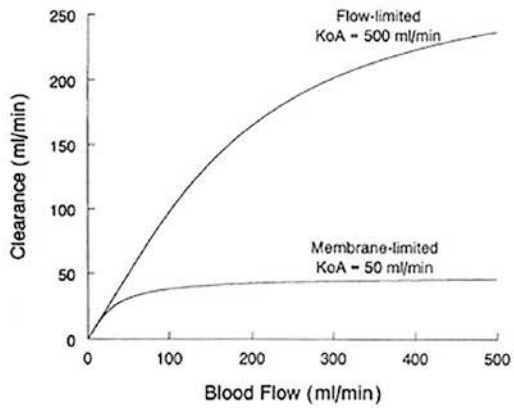

Fig. 66.3 Blood flow-limited and membrane-limited clearance

sis units have set this as their maximum blood flow rate.

The effective blood flow rate is largely determined by the vascular access, especially in pediatrics. For chronic HD we recommend a blood flow rate that is equivalent to 4–6 ml/kg/min urea clearance obtained from dialyser urea clearance estimates provided by the manufacturer. In infants, a minimum blood flow of 20–30 ml/min avoids the risk of clotting the circuit. Effective blood flows are often lower than those prescribed due to partially occlusive pumps, malposition of the vascular access needle, access failure, tubing diameter changes, and shear effects. The efficacy of dialysis is also reduced by recirculation effects, which are more pronounced with higher dialyzer blood flows, vascular access inflows lower than dialyzer blood flow, stenosis at the access outflow, single lumen access particularly with small stroke volumes, increased length of blood lines, and small needle and tubing diameter [45]. This places infants with blood flows determined by small, high resistance double-lumen central venous catheters or single lumen catheters with high recirculation rates at the highest risk of inadequate dialysis with conventional dialysis regimens. This can be improved by increasing the dialysis time, which in our experience is best tolerated by increasing the frequency and not the duration of treatment.

Choice of Dialyser

When selecting a dialyser for maintenance HD, several membrane characteristics need to be taken into consideration [10]. To improve efficacy, dialysers are designed to maximize the surface area available for diffusion. Two designs have predominated, namely hollow fibre and parallel plate dialysers. In the latter, parallel layers of membranes are separated by flat supporting structures. Their greatest disadvantage is their high compliance and thus large filling and priming volumes. Therefore, in children, they have largely been replaced by hollow fibre dialysers, which consist of a bundle of capillaries potted at both ends into a plastic tubular housing unit with sealing material. Hollow fibre dialysers have virtually no compliance and lower priming volumes, but the sealing materials are at risk of releasing solvents or ethylene oxide after gas sterilization, and thus producing anaphylactic reactions. As a general rule, the dialyser membrane surface area (which is readily available on the label of most dialysers) should be approximately equal to the patient's BSA. It is important to regularly assess the choice/size of the dialyser in growing children and those who are receiving inadequate dialysis.

Because the dialysis membrane is in direct contact with the patient's blood, it can initiate leucocyte and complement activation. The extent of the inflammatory response reflects the biocompatibility of the material that makes the dialyser. Three types of membranes are presently available, those made from unmodified cellulose, modified/regenerated cellulose, and synthetic membranes. Unmodified cellulose membranes, such as cuprophan, are relatively inexpensive but also the most bioincompatible. The modified cellulose membranes such as the cellulose acetate or hemophan® have some or all of the hydroxyl groups esterified to make them more biocompatible. However, such modifications may result in increased activation of the coagulation cascade and thus increase the anticoagulation requirement of the HD circuit. Synthetic membranes are made from polysulfone, polycarbonate, polyamide or polyacryl-polyam-

ide acrylate. These membranes are relatively biocompatible, except for the negatively charged AN69 polyacrylonitrile membranes, which are known to cause hypotension, inflammatory hyperemia, oedema and pain secondary to a bradykinin mediated reactions. Dialysis patients most at risk are infants requiring blood to prime their HD circuit [46] and children that are concurrently taking angiotensin converting enzyme (ACE) inhibitors[47] or angiotensin II receptor antagonists (ARB) [48]. Synthetic membranes are generally more hydrophobic than cellulose membranes and therefore have higher adsorption properties [49]. Their increased ability to bind proteins may be partly responsible for their improved biocompatibility, and also makes them the membrane of choice for therapies such as albumin dialysis or in the treatment of acute toxicities where the undesired toxin is highly protein bound.

Membrane solute permeability refers to the clearance of middle molecular weight molecules, and is assessed by measuring the rate of β2-microglobulin clearance. Solute permeability is determined by the number of pores, the size of the pores, and the membrane wall thickness. A highly permeable membrane is one that is thin, with a high pore density and large diameter pores. Efficiency, represented as the KoA or mass transfer coefficient of urea, is a measure of urea clearance, a surrogate marker of small molecule clearance. Traditionally, membranes have been characterized as low-flux or high-flux according to their solute permeability. High-flux membranes are highly permeable membranes that can permit convective solute clearance of molecules weighing between 5000–25,000 Daltons, but urea clearance rates vary. Highly efficient membranes have high urea clearance rates but differ in their hydraulic permeability, and thus may be limited in their ability to clear middle molecules (Table 66.3).

A useful measure of the hydraulic permeability of a membrane is the K_{UF}, the UF coefficient, defined as the volume of UF produced per hour per mmHg transmembranous pressure, which is determined at a blood flow of 200 ml/min. K_{UF} is most directly influenced by the membrane's mean pore size. In turn, the mean pore size influences the solute sieving coefficient and molecular weight cut-off for a membrane. High-flux dialysers with larger mean pore sizes have a higher molecular weight cut-off and are most efficient in clearing larger uremic compounds. The UF rate and the dialyzer membrane's sieving coefficient are the most important determinants of convective solute removal [50]. Therefore, in consideration of predominantly convective therapies such as hemofiltration or HDF, high-flux dialysers are required.

Analyzing the United States Renal Data System (USRDS) database, Bloembergen et al. demonstrated a 20% decrease in the relative risk of death for modified cellulose and synthetic membranes compared with cellulose membranes [51]. In a retrospective analysis of 715 patients, Woods et al [52] compared mortality in a group treated exclusively with low-flux polysulfone dialysers with another treated for at least 3 months with high-flux polysulfone dialysers. The high-flux group had a significant 65% reduction in the risk of death compared with the low-flux group. A Kaplan-Meier analysis suggested a higher 5-year survival in the high-flux group, but a statistically significant difference was only seen after 4 years of dialysis.

In conclusion, epidemiological studies suggest improved morbidity and mortality in dialysis patients treated with modified cellulose or synthetic membranes but few have been able to demonstrate whether the effects were due to differences in flux, biocompatibility or middle

Table 66.3 Dialyser classification [247]

Class	Surface area	K_{UF} (ml/h/mmHg)	Urea clearance	β2 microglobulin clearance
Conventional	< 1.5 m^2	< 12	Moderate	Negligible
High efficiency	> 1.5 m^2	> 12	High (KoA > 600 ml/min)	Negligible
Mid-flux	Variable	12–30	Variable	Moderate
High-flux	Variable	> 30	Variable	High (>20 ml/min)

molecule clearance. Few, if any, paediatric centers practice dialyzer reuse. Reuse is associated with a reduction in the incidence of "first use" reactions, but may be associated with allergic reactions to residual sterilizing agents, such as formaldehyde. Inadequate sterilization of dialyzers may cause pyrogen reactions or frank infection, manifest by fever, chills and rigors [53].

Extracoporeal Circuit

Multiple dialysis machines are on the market, each with different sizes, weights, capabilities for home therapy, and interfaces with providers (reviewed in [54]). Regarding the extracorporeal circuit, during pediatric dialysis, if the total blood volume of the circuit is greater than 10% of the estimated total blood volume (TBV) a circuit prime with 5% albumin or blood is recommended. Even though traditionally blood has been preferred, these recommendations come from an era when severe anaemia was the rule for children with ESKD. However, minimizing exposure to blood products may decrease the risk of human leukocyte antigen sensitization in young children awaiting transplantation. The TBV is approximately equal to 100 ml/kg body weight in neonates and 80 ml/kg for infants and children. As a general rule, we use blood primes if the patient is anaemic. To avoid the risk of clotting the circuit, priming can be achieved with packed red blood cells diluted with normal saline or 5% albumin to achieve a final haemtocrit of 30–35%. Alternatively, the circuit can be primed with undiluted packed red blood cells from the blood bank when manipulation of the product is not permitted. The potassium load to the patient can be minimized by using fresh blood, and once priming is completed, recirculating the blood through the dialyser for 10 min, without connecting to the patient. At the end of dialysis, we do not recommend retransfusing the blood back into the infant, and if a blood transfusion is required, to give this during the dialysis session infused through a peripheral line or via a Y-connection at the venous return site to reduce the possibility of clotting the circuit.

Dialysate Water

Dialysate contaminants can be both chemical and biological, and can cause significant morbidity. It is therefore imperative that each dialysis unit ensures that disinfection practices are in place to achieve these standards, combined with regular surveillance to ensure that they are sustained. Dialysate quality is known to be an important component of the biocompatibility of the HD procedure and therefore also contributes to the chronic inflammation of dialysis [55]. In vitro studies have shown that bacterial products can cross both high-flux and low-flux dialysis membranes and stimulate synthesis of inflammatory mediators such as cytokines within the blood compartment [56]. The degree of cytokine stimulation is related to the concentration of endotoxin and other 'cytokine-inducing substances' in the dialysate compartment [57, 58] and the permeability of the dialysis membranes to these substances. In general, polysulfone and polyamide based membranes are effective barriers to endotoxins because of their high adsorptive properties [59] whereas high-flux membranes and low-flux cellulose based membranes are less protective [60, 61]. With an increasing use of high-flux membranes, especially with HDF therapy, a very high degree of water purity is essential (see section on 'backfiltration' below).

Water Purification Systems

A standard water treatment device consists of a water softener, an activated carbon filter, a sediment filter, and a reverse osmosis system [62]. Water softeners contain a resin that exchanges sodium cations for calcium, magnesium, and other polyvalent cations. Water softening not only prevents hard water, but also protects the reverse osmosis membrane used in the final step of water treatment from the build-up of scale and subsequent failure. The resin is regenerated periodically with concentrated sodium chloride solution, which also reduces bacterial growth in the resin bed. Activated carbon filters remove chloramines and organic solvents, but

tend to release carbon particles and therefore require a sediment filter placed downstream. The final purification step is performed by reverse osmosis where the water is forced through a semipermeable polyamide or polysulfone membrane at 14–28 bar. This step removes 90–99% of inorganic and organic substances, pyrogens, bacteria, and particulate matter. The purified water is pumped from the reverse osmosis module to the individual treatment stations in a recirculating ring loop which delivers the water produced in excess back to the reverse osmosis module, avoiding wastage of high-quality water. The ring loops themselves require regular disinfection, and this is performed either by heat or chemical disinfection.

Testing Water Quality

The International Organization for Standardization (ISO) has published a series of standards addressing fluids for extracorporeal therapies. Specifically, ISO 11663:2009, Quality of dialysis fluid for hemodialysis and related therapies, requires that replacement fluid used for HDF be sterile and pyrogen-free; the currently accepted norms for ultrapure dialysate are defined as containing <0.1 colony-forming unit/ml and <0.03 endotoxin unit/ml. In addition, the chemical composition of water must be tested at least once per year [63].

Dialysate Composition

The composition of the dialysate fluid will influence the exchange of electrolytes during the dialysis treatment and thus ultimately creates an opportunity to modify adverse events during dialysis and the net transfer of electrolytes to or from the patient.

Sodium

Following a sodium load, even in the presence of renal failure, the mechanisms responsible for preserving plasma tonicity will maintain plasma sodium within narrow limits by changing the plasma volume. During HD, dialysate sodium generates a crystalloid osmotic pressure and thus influences fluid shift between the different body compartments, but it also permeates the dialysis membrane and thus has the potential for becoming a sodium load.

Diffusive sodium transport is proportional to the difference in sodium activity between blood and dialysate compartments. Dialysate sodium activity is approximately 97% of the measured sodium concentration, but varies with changes in dialysate temperature, pH, and the presence of additional ions. The proportion of plasma water free sodium ions that are unbound to protein and other anions can be measured by direct ionemetry. Plasma sodium activity is influenced by the Donnan effect: negatively charged proteins (mainly albumin) produce a small electrical potential difference across the membrane (negative on the plasma side) that prevents movement of the positively charged sodium ions. In the absence of UF, the concentration of dialysate sodium needed to achieve isotonic dialysis can be approximated by correcting the blood sodium measured by direct ionometry for a Donnan factor of 0.967.

Hyponatremic dialysis causes osmotic fluid shift from the extracellular to intracellular compartment, contributing to dialysis disequilibrium and intradialytic hypotension. Hypernatremic dialysis transfers sodium to the patient, causing interstitial edema, interdialytic thirst, increased interdialytic weight gain and worsening hypertension. A therapeutic advantage can be gained by manipulating the dialysate sodium concentration throughout dialysis, known as sodium profiling, and typically utilizes a sodium concentration that falls in a step, linear, or exponential fashion (Fig. 66.4). The higher dialysate sodium at the start allows a diffusive sodium influx to counterbalance the rapid decline in plasma osmolarity due to clearance of urea and other small molecular weight solutes. Low dialysate sodium at the end aids diffusive clearance of the sodium load and minimizes hypertonicity. Compared with a constant dialysate sodium bath, profiling has been shown to increase stability of intradialytic blood volume and reduce both intradialytic cramps and interdialytic fatigue in children and adults [64,

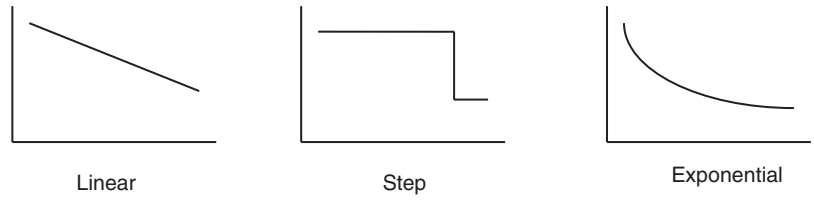

Fig. 66.4 Sodium profiling options

65]. Compared with exponential profiles, step profiles are most effective at attenuating postdialytic hypotension and early intradialytic hypotension, while linear profiles best reduce cramps and late intradialytic hypotension. Sodium profiling is also indicated in the prevention of dialysis dysequilibrium.

The difficulty with sodium profiling is finding the concentration gradient that offers the benefits of cardiovascular stability without exposing the patient to a small but repeated sodium load. A net sodium gain of 1 mmol/L will result in a 1.3% expansion of the extracellular space. Based on concerns of inducing hypervolemia, neutral sodium balance profiles may be preferred. Protocols of isonatremic dialysate are similar, with time averaged dialysate sodium 2–3 mmol/L lower (Donnan effect) than the predialysis sodium [66]. Results indicate benefits similar to those described with sodium profiling, but with a significant decrease in the interdialytic weight gain and thirst score [67, 68]. The difference is likely to be due to an improvement in sodium balance, but as neutral balance is unlikely even with the 'isonatraemic' protocols we recommend monitoring for changes in interdialytic weight gain and BP.

Potassium

One of the key objectives of HD is to maintain the plasma potassium levels within a narrow normal range, both during the intradialytic and interdialytic periods. The risk of arrhythmia, QT dispersion [69] and ventricular ectopic beats is increased with hypokalemia and also if the rate of decline is rapid early in dialysis, even if the actual plasma potassium levels are normal. This is one of the postulated mechanisms for the phenomenon of sudden cardiac death in HD patients. Conversely, failure to normalize serum potassium levels is also arrhythmogenic [70].

The challenge is that HD can only remove potassium from the extracellular compartment and that comprises 2% of total body potassium. In addition net potassium removed is influenced by a number of dialysis related factors. During HD, approximately 85% of potassium is removed by diffusion and this is influenced by the serum:dialysate potassium gradient. The rate of potassium removal is highest in the first hour of dialysis and then declines as the serum:dialysate potassium gradient falls. Therefore the greatest fall in plasma potassium levels are in the first hour, with a more gradual reduction in the subsequent 2 h, and almost no change in the plasma potassium level in the fourth and fifth hours as the serum:dialysate concentrations reach equilibrium. Postdialysis the plasma potassium rebounds and again the serum:dialysate gradient appears to influence the magnitude of this rebound, with a rapid postdialysis rebound of potassium levels with higher gradients compared with smaller gradients [71]. Convective clearance of potassium by UF accounts for approximately 6% of the total potassium mass removed. The glucose content of dialysate solutions is important with high glucose–containing dialysate solutions resulting in higher potassium removal as a result of osmotic shifts of intracellular potassium to the extracellular space [72]. The other major factor is the dialysate bicarbonate. Higher dialysate bicarbonate concentrations result in a rise in serum bicarbonate levels during HD, enhancing Na^+/K^+-ATPase activity with a larger shift of potassium into the intracellular space and a lowering of serum potassium levels, but total body potassium removal is not improved [73].

Optimizing the management of potassium removal in patients on HD involves reducing large intradialytic potassium shifts as well as providing adequate potassium removal to minimize hyperkalemia. However, there is no consensus on how best to achieve this. As a general rule, we would recommend dialyzing children against a potassium bath of 2 mmol/L. If patients are hyperkalemic and asymptomatic, use a 1 mmol/L potassium bath for the first 1–2 h of dialysis, and then switch to 2 mmol/L for the second half of dialysis. We discourage the use of zero potassium dialysate solutions unless the patient is severely hyperkalemic and symptomatic. If predialysis serum potassium levels are low or low normal, a potassium bath of 3–4 mmol/L may be required.

Bicarbonate

Acetate was originally used as the buffer in dialysate as it was inexpensive, offered equimolar conversion to bicarbonate, and was bacteriostatic. However, 10% of patients, especially women, are poor metabolizers of acetate. The high plasma acetate levels led to impaired lipid and ketone bodies metabolism, vasodilatation, depressed left ventricular function, intradialytic hypotension, and hypoxaemia, particularly in the first hour [74]. Consequently, most centers switched to sodium bicarbonate.

The preparation of bicarbonate based dialysate requires a second proportioning pump that mixes solution or dry powder bicarbonate to water, and an 'acid' compartment containing a small amount of acetate or lactate, sodium, potassium, calcium, magnesium, chloride and glucose. During the mixing procedure, the acid in the acid concentrate reacts with an equimolar amount of bicarbonate to generate carbonic acid and carbon dioxide. The generation of carbon dioxide causes the final solution pH to fall to approximately 7–7.4. It is this lower pH, combined with the lower concentrations of calcium and magnesium that prevents precipitation from occurring in the final solution. Cartridge systems containing pure, dry sodium bicarbonate powder are often preferred as they are less conducive to bacterial growth, and liquid bicarbonate has to be used within 8 h of opening the container to avoid significant bicarbonate loss.

Dialysis aims to correct the metabolic acidosis of ESKD by the removal of organic anions and restoration of the bicarbonate deficit. Plasma bicarbonate levels rise by 4–5 mmol/L and then fall to predialysis levels by 48 h. The adjusted survival of HD patients decreases with predialysis serum bicarbonate levels <18 mmol/L and >24 mmol/L [11], suggesting a "U" shaped correlation with mortality. The severity of metabolic acidosis also correlates with bone disease [75], muscle wasting [76], and ß2-microglobulin levels [77]. With standard dialysate bicarbonate concentrations of 35 mmol/L, the HEMO study showed that 25% of patients had predialysis levels below 19 mmol/L. [78] Increasing the dialysate bicarbonate concentration to 39–40 mmol/L will improve the predialysis bicarbonate levels but in some will result in a transient alkalosis. This has a hypothetical risk of facilitating calcific uremic arteriolopathy, reducing phosphate removal because of shift of phosphate into cells, and intradialytic vascular instability by causing a sudden drop in the plasma potassium and calcium levels.

Alkalosis has been shown to rapidly reduce dangerously high serum potassium levels, albeit with a potentially increased postdialysis rebound effect [79]. Finally on a more experimental level, the use of citric acid in place of acetic acid in the dialysate acid concentrate was shown to improve both acidosis and delivered dose of dialysis [80]. The role for citrate is expanding in the dialysis community; however, caution is advised as it increases aluminum absorption and therefore plasma aluminum levels must be monitored.

Calcium

Owing to fear of inducing extra-skeletal calcium deposition, KDOQI guidelines suggest maintaining plasma calcium levels in the low normal

range. Using a dialysate calcium concentration of 1.25 mmol/L permits higher doses of vitamin D and calcium based phosphate binders in the management of hyperparathyroidism. In a proportion of patients this can lead to hypocalcaemia and worsening hyperparathyroidism [81]. Hypocalcaemia also depresses myocardial contractility and reduced vascular reactivity [82] and thus increases the risk of intradialytic hypotension. This forms the basis for the short-term use of a higher calcium bath. In our experience, the only situation requiring routine use of 1.5 mmol/L calcium baths are in patients receiving nocturnal HD, who have a reduced need for calcium containing phosphate binders and increased calcium clearance [83].

Phosphate

Phosphate is the major anion in the intracellular compartment and the steep gradient between the intracellular and extracellular compartments is maintained by active transport systems. The factors that limit the removal of excessive phosphate are dialysis clearance and the kinetics of phosphate distribution within the body. During dialysis, plasma phosphate levels initially fall, but thereafter plateau or increase, with a postdialysis rebound effect persisting for up to 4 h [84]. The implication is slow mobilization of phosphate from the intracellular stores and bone and phosphate generation from reserves triggered by falling extracellular [85] or intracellular levels [86]. The point at which phosphate generation is initiated appears to correlate with predialysis phosphate levels. There is also evidence for a "switching on" effect to protect against critically low intracellular phosphate levels.

Phosphate supplementation to dialysate may occasionally be required in severely hypophosphatemic patients with tubulopathies, severely malnourished children who develop hypophosphataemia secondary to refeeding syndrome, and those receiving more frequent, daily, or nocturnal HD.

Magnesium

Typically the concentration of magnesium in dialysate is 0.5–1 mmol/L. If magnesium containing phosphate binders are used, a lower concentration may be required to avoid hypermagnesemia. Conversely low magnesium levels can result in cramping and arrhythmias and therefore higher magnesium baths may help to improve cardiovascular stability and reduce intradialytic symptoms.

Glucose

Glucose concentration of dialysate usually approximates 100–200 mg/dL (6–11 mmol/L). This level of glucose should ensure patients remain normoglycemic unless hyperglycemic or hypoglycemic at the start. If hyperglycemic, a dialysate glucose in the recommended range will remove glucose, and if hypoglycemic the dialysate will provide supplemental glucose. There is a theoretical risk of inducing hypertriglyceridemia by addition of glucose to dialysate but this should not be significant with dialysate values of 100–200 mg/dL. If the patient is hyperkalemic, less potassium might be removed when dialysate glucose is elevated, causing hyperinsulinemia, which pushes potassium into cells. However, this should not be a problem with the dialysate glucose levels recommended above.

Dialysis Flow Rate

Typically, dialysate flow rates of 300–500 ml/min are employed. During infant dialysis, the practice within our unit is to start with a dialysate flow rate of 300 ml/min. If clearance is inadequate, increasing the dialysate flow rate can produce improvements, but eventually plateaus. The HEMO Study provided in vivo confirmation of increased hemodialyzer mass transfer-area coefficients for urea at high dialysate flow rates [87]. A subsequent study showed that the relative gains in spKt/V for increasing the dialysate flow rate

from 300 to 500 ml/min and 500 to 800 ml/min were 11.7% ± 8.7% and 9.9% ± 5.1%, respectively [88].

Dialysate Temperature

By modifying skin blood flow, we can control heat exchange between the body and the environment. This is mediated by two sympathetic nervous system effects, an adrenergic vasoconstrictor and a lesser understood sympathetic vasodilator. During times of increased body core temperature, tonic sympathetic vasoconstriction is relaxed and active vasodilatation is initiated [89] and the skin blood flow rate can increase from a baseline of 5–10% of the total body cardiac output to approximately 60% [90, 91].

Traditionally, dialysate temperatures have been set at ≥37 °C, based to match physiological normal values and to compensate for losses of heat in the extracorporeal circuit. Both of these assumptions have in fact been found to be untrue. In a study of adult HD patients, 62.5% of 128 patients had predialysis body temp below 36.5, with marked inter- and intra-individual differences [92]. There is growing evidence in both adults and children of a net gain rather than loss of heat during dialysis. This is the result of higher resting energy expenditure in HD patients compared to the normal population, especially in those with residual renal function [93]. Secondly, UF activates sympathetic vasoconstriction, reducing skin blood flow and therefore heat exchange, with a direct correlation between UF volume and net heat gain [94]. If the accumulation of heat causes an increase in the body core temperature, UF induced vasoconstriction is overridden by active vasodilatation. Blood is redistributed to the skin [95], and the peripheral vascular resistance falls, resulting in decreased cardiac refilling and hypotension [51]. Fine and Penner [92] showed that dialysis patients with subnormal body temperature (below 36 °C) dialyzed against a 37 °C dialysate had a 15.9% incidence of symptomatic hypotensive episodes, which fell to 3.4% with 35 °C dialysate.

The hemodynamic advantage of "cool" HD has been documented, but may be uncomfortable for patients and reduce urea clearance as a result of compartmental dysequilibrium. Application of thermoneutral (no gain or removal of thermal energy from the extracorporeal circuit) and isothermic (patient temperature is kept constant) dialysis is technically possible, but the dialysis circuit has to be adapted to accommodate a feedback control circuit. A more practical option is to individualize the dialysate temperature based on the patient's predialysis temperature. Even then, efforts may be hampered by the current standards of the Association for the Advancement of Medical Instrumentation (AAMI) that requires the dialysate temperature at the dialyser to be maintained within ±1.5 °C of its set point.

Infants have an increased susceptibility to hypothermia. As a result, infants have traditionally been dialysed against higher dialysate temperatures of 37.5 °C to 38 °C. Alternatively, one may consider more physiological dialysate temperatures with the use of external warming methods to maintain normothermia. The impact of either strategy on thermal balance and cardiovascular stability has not been studied.

Anticoagulation

Anticoagulation of the extracorporeal circuit is usual but not mandatory and should be determined by estimating the risk of bleeding against that of clotting the circuit, which results in blood loss and reduced dialysis efficacy. In children, unfractionated heparin (UFH) remains the agent of choice for systemic anticoagulation, but low molecular weight heparin (LMWH) and citrate have been used.

UFH is a mixture of polyanionic branched glycosaminoglycans that bind with high affinity to antithrombin causing a structural change, converting it from a slow to a very rapidly (1000 times) acting inhibitor of thrombin. It interacts with other components of the coagulation cascade, producing a combined effect of inhibiting fibrin formation and thrombin-induced platelet activation and increasing vessel wall

permeability. The polyanionic nature of heparin allows non-selective binding to other proteins and cell membranes. This mediates the adverse effects associated with UFH use such as activation of lipoprotein lipase causing increased generation of free fatty acids, which can induce platelet aggregation, and loss of bone mass resulting in osteoporosis [96, 97].

UFH has to be administered intravenously as intestinal absorption from oral therapy is poor. Following a bolus injection, the non-specific interactions reduce bioavailability to approximately 30%. Consequently, an initial bolus is usually recommended to saturate these non-specific binding sites as the dose-response relationship becomes almost linear thereafter. UFH is metabolized by the liver, and the kidney clears desulfated fragments. Owing to a marked inter-individual sensitivity to heparin and the possibility of heparin inactivation in the extracorporeal circuit, it is essential to individualize heparin requirements during dialysis and review dosing needs with time (Fig. 66.5).

The consensus on the desired degree of anticoagulation varies amongst different dialysis units, ranging between 25 to 300% above baseline. In our experience, for the majority of patients, adequate anticoagulation is achieved with activated clotting time 50% above the baseline. Standard regimens consist of a bolus dose of 15–20 units/kg of heparin at the start of dialysis followed by a continuous infusion of 15–20 units/kg/h, stopping the heparin infusion over the last 30 min of dialysis. In children weighing less than 10 kg, the likelihood of clotting is increased. Nonetheless, safe, effective anticoagulation with lower activated clotting time target ranges is possible with tight heparin regimens [98].

In high-risk groups, there is a 10–30% risk of bleeding with unfractionated heparin. Alternative options include regional anticoagulation with citrate, use of prostacyclin infusion, high flow rate HD, calcium free dialysate with calcium infusion back to the patient in a closely monitored setting, or modification of the standard heparin regimen. Low dose heparin or

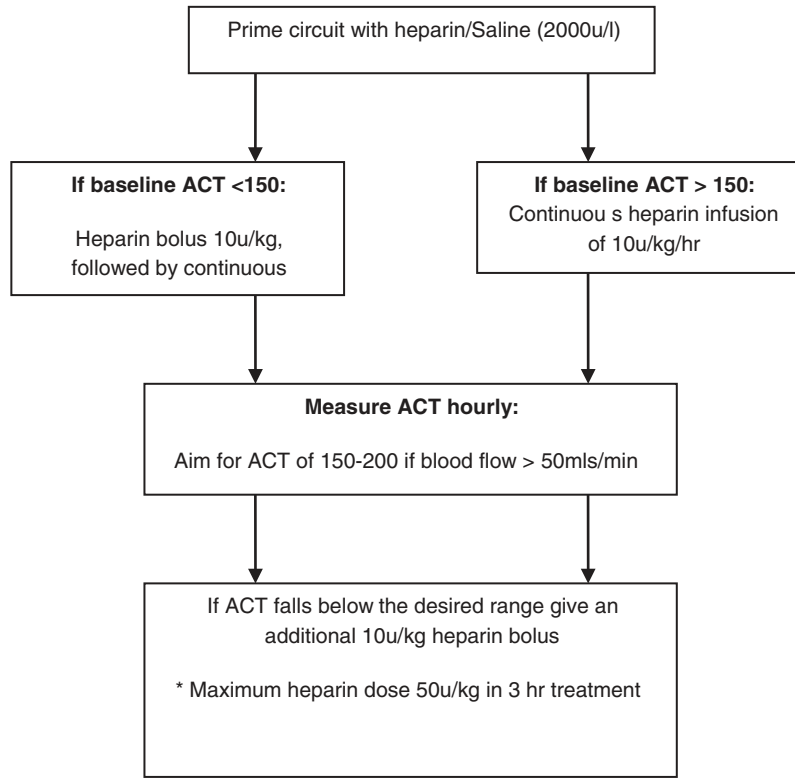

Fig. 66.5 Tight heparin regimen

heparin free dialysis combined with regular intermittent saline flushes is possible without compromising dialysis dose or causing unwanted bleeding complications in children at increased of bleeding [98].

LMWH is composed of smaller molecules prepared from UFH through enzymatic or chemical depolymerization. They act predominantly by inhibiting factor Xa, but also cause a variable degree of thrombin inactivation. Following a single subcutaneous injection, bioavailability reaches 100%, but with differences in inter-individual sensitivity, fixed dosing is inappropriate. LMWHs are principally cleared by the kidney, and therefore in ESKD the drug's pharmacokinetics are unpredictable.

Due to the prolonged half-life in kidney failure and lack of a commercially available antidote, there has been a reluctance to use LMWH. However, several adult trials show that sustained intradialytic anticoagulation can be achieved following a single bolus dose at the start of dialysis, making it a very convenient option. The negative charge of the LMWH complexes makes them impermeable across dialysis membranes and therefore, in spite of their low molecular weight, there is no relevant elimination either through HD or hemofiltration [99, 100]. One meta-analysis comparing the safety and efficacy of LMWH compared with UFH showed no difference in preventing extracorporeal thrombosis and demonstrated comparable bleeding risks [101].

The use of LMHH was first described in children on HD by Bianchetti et al. who successfully hemodialyzed 7 children for an average time of 4 h, using enoxaparin 24–36 mg/M^2 [102]. More recently, Davenport has reviewed the issue of anticoagulation for children on HD and has proposed doses for LMWH in children receiving HD [103].

It has become our routine practice to use LMWH in our home HD population in London. All patients are commenced on 50 units/kg of dalteparin as a single intravenous dose at the start of dialysis. The dose is then adjusted in 20% increments according to percentage of visible clot formation in the dialyser at the end of dialysis, predialysis anti-Xa levels and, in those with fistulae, the presence of prolonged bleeding times after removing fistulae needles. All patients with fistulae are also placed on low dose aspirin. No patient has lost a circuit from excessive clotting. The final dose of dalteparin ranges from 21 to 58 units/kg, with a trend for infants and young children to be on higher doses of dalteparin (52–58 units/kg) compared with teenagers (21–41 units/kg). Those switching from an evening dialysis schedule to nocturnal schedule require on average a 50% increase in their dalteparin dose. The anti-Xa level 1 h after dosing ranged from 0.13–0.6 and predialysis anti-Xa levels suggests no bioaccumulation of dalteparin.

Citrate is a small molecule and is dialyzable, with an extraction coefficient similar to that of urea, and any citrate that escapes into the systemic circulation is rapidly cleared by the tricarboxylic acid pathway, primarily in the liver and skeletal muscle. Citrate exerts its anticoagulant effect by chelating ionized calcium ions, preventing activation of calcium-dependent procoagulants. Regional anticoagulation of the extra-corporeal circuit without systemic effects is achieved by infusing citrate solution through the arterial limb of the circuit, removal of citrate through dialysis and then neutralizing its anticoagulant effect by infusion of calcium into the venous limb of the circuit, making it a very attractive option for patients with a bleeding risk despite a lack of supportive data in children on maintenance dialysis.

Each method of anticoagulation is associated with specific side-effects. Heparin-induced thrombocytopenia is mediated by heparin-dependent IgG antibodies that bind to platelets, causing platelet activation and subsequent risk of thromboembolic events, characterized by markedly increased thrombin levels. Several alternatives to heparin are commercially available, but only danaparoid sodium use has been documented in pediatric HD, reporting stabilization of both thrombocytopenia and thromboembolic risk [104]. However, it has 30% cross-reactivity with platelet-heparin antibodies [105]. The direct thrombin inhibitor, hirudin, is efficacious but its half-life is prolonged in renal failure and it is

associated with anaphylactic reactions [106, 107]. Argatroban, a synthetic direct thrombin inhibitor shows the greatest promise owing to its rapid onset of action, a half-life ranging from 39–51 min, hepatic metabolism, and the fact that it can be used in dialysis patients with no dose adjustment as only a 20% systemic clearance is seen even with high-flux dialyzers. Complications reported with citrate dialysis include hypocalcemia resulting in arrhythmias and paresthesias, hypernatremia, volume expansion, and metabolic alkalosis (one molecule of trisodium citrate is metabolized to 3 molecules of bicarbonate). Citrate toxicity with metabolic acidosis can occur from citrate accumulation due to ineffective dialysis clearance or poor metabolism secondary to impaired synthetic liver function. It is diagnosed biochemically by an increased anion gap acidosis and high total plasma calcium combined with low or normal plasma ionized calcium (so-called citrate lock).

Additionally, evidence suggests a role of citrate in attenuating the chronic inflammatory response to HD, which is linked to atherosclerosis, arteriosclerosis and malnutrition [108]. The use of citrate in pediatrics is growing through its application in plasmapharesis and continuous renal replacement therapy and because its actions are easily neutralized with calcium. These factors make it an attractive option, but until protocols are simplified and validated in children, it cannot presently be recommended as an alternative to heparin for routine dialysis therapy.

Commonly Encountered Hemodialysis Complications

Dialysis Disequilibrium Syndrome (DDS)

Dialysis disequilibrium occurs as a result of changes in osmolarity inducing water shifts from the extracellular to the intracellular compartment across the highly permeable blood brain membrane. It manifests during or immediately after HD as a self-limiting entity, but recovery can take several days. Symptoms typically include nausea, vomiting, headache, blurred vision, muscular twitching, disorientation, hypertension, tremors, seizures and coma, but others such as muscular cramps, anorexia, restlessness, and dizziness have been reported. The diagnosis is often one of exclusion.

The exact pathophysiology of disequilibrium remains unknown, although two mechanisms have been proposed. Both mechanisms support that rapid changes in brain volume disrupt the blood brain barrier and cerebral autoregulation. The reverse urea effect postulates that urea is cleared from plasma more rapidly than from brain tissue, resulting in a transient osmotic gradient and cerebral oedema. The second theory is based on the observation of a paradoxical acidaemia of the cerebral spinal fluid and cerebral cortical grey matter in patients and animals treated with rapid HD. This is accompanied by increased brain osmole activity due to displacement of sodium and potassium ions and enhanced organic acid production. The increased intracellular osmolarity induces fluid shifts with subsequent cytotoxic oedema.

The dialysis prescription can be adjusted to reduce the rate of plasma urea clearance by using a smaller dialyser, decreasing the blood or dialysate flow rate, or switching to more frequent, shorter, treatments. Intradialytic osmotic shifts can be minimized with the use of sodium profiles or higher dialysate sodium concentrations, the substitution of bicarbonate for acetate in the dialysate, or if the patient is grossly fluid overloaded, sequential HD in which an initial period of UF alone is followed by conventional dialysis. Mannitol is an osmotically active solute that artificially increases plasma osmolarity at the time of rapid urea clearance. It rapidly lowers intracranial pressure within minutes of administration and has a peak effect at 20–40 min. A maximal intradialytic dose of 1 g/kg is recommended once a week in high risk patients. If more frequent dosing is required, a smaller dose of 0.5 g/kg is advised, as mannitol accumulates in renal failure (half-life: 36 h) and can cause a rebound rise in the intracranial pressure, especially in the face of acidosis. Other adverse effects include nausea, vomiting, lower limb oedema, thrombophlebitis, headache and chest pain. An alternative to man-

nitol is infusion of 3–5% sodium chloride or the use of higher dialysate sodium baths. Concurrent antiepileptic therapy is required with both therapies if the patient is seizing.

Intradialytic Hypotension

The major barrier to achieving optimal UF is the development of hemodynamic instability, manifesting as intradialytic hypotension. Hypotension occurs in about 20–30% of treatments, can result in underdialysis because of treatment interruptions, and may leave the patient volume overloaded. Frequent hypotensive episodes may accelerate a decline in residual renal function and potentially lead to serious vascular complications such as cerebral, cardiac, and mesenteric ischaemia. In children, the UF goal is often higher because of nutritional supplements or poor adherence to fluid restrictions.

As fluid is removed, plasma refilling, passive venoconstriction and active increases in heart rate, heart contractility and arterial tone are working simultaneously to preserve the effective plasma volume. As a result, even with a UF volume equal to the entire plasma volume, the measured blood volume only changes by 10–20%. Impaired compensatory responses cause hypotension in the face of total body water expansion. Most of the plasma volume resides in the veins, with a marked difference in the venous capacitance between organs. During fluid removal, the ability to mobilize blood from the splanchnic venous pool is vital for preserving the central blood volume. Venous tone is affected by vasoactive hormones, the sympathetic nervous system, and upstream filling pressures. The De-Jager Krogh phenomenon refers to the transmission of upstream arterial pressure through the capillaries to the veins causing venous distension and altered venous capacitance. During arteriolar constriction the distending pressure to the vein is reduced and blood is extruded centrally towards the heart to maintain cardiac refilling. Conversely, factors that cause arterial dilatation, such as antihypertensive medications, increase venous capacitance, reduce cardiac filling pressures and, through transmission of increased hydrostatic pressure to the capillary bed, inhibit vascular refilling. Adenosine is thought to augment splanchnic blood pooling through an inhibitory effect on norepinephrine release and by causing regional vasodilatation. It is hypothesized that during a sudden, but not gradual intradialytic hypotensive episode, ischaemia leads to increased metabolism of adenosine triphosphate and generation of adenosine [109].

The sympathetic nervous system is the principal control mechanism of arteriolar tone and therefore of central BP. Patients with ESKD show increased basal level of peripheral sympathetic activity [110]. In HD patients prone to hypotension, a paradoxical decrease in sympathetic activity is seen at the time of a hypotensive episode [110], which results in a rapid decline in the peripheral vascular resistance and increased vascular bed capacitance. Problems with sympathetic end-organ responsiveness and the efferent parasympathetic baroreceptor pathway have also been reported, but the underlying mechanism remains unexplained. Some believe this may be a heightened manifestation of the Bezold-Jarisch reflex, a cardiodepressor reflex resulting in a sudden loss of sympathetic tone causing abrupt severe hypotension accompanied by bradycardia. It is postulated that conditions associated with reduced cardiac refilling pressures such as LVH, diastolic dysfunction, or structural heart defects stimulate cardiac stretch receptors and thus is a maladaptive variant of the Bezold-Jarisch reflex resulting in hypotension.

The final and interconnecting component relating to intradialytic hypotension is plasma refilling, the movement of fluid from the extravascular to the vascular compartment under the influences of hydraulic, osmotic, and oncotic pressure gradients at the capillary wall. If UF rates exceed refilling rates the intravascular volume will fall. Arterial vasoconstriction decreases hydrostatic pressures in the capillary bed, facilitating vascular refilling. The oncotic pressure, which is effectively the plasma protein concentration, promotes refilling. Plasma sodium and glucose mobilizes fluid from the intracellular space as a result of increased plasma tonicity

[111]. Finally, refilling is facilitated by greater tissue hydration and occurs at a faster rate when the interstitial space is overloaded. Hypovolaemia within the uremic milieu can augment ineffective venoconstriction, inadequate cardiac refilling, reduced plasma refilling and activation of the Bezold-Jarish reflex leading to sudden hypotension.

Haemodynamic stability during dialysis is improved by withholding antihypertensive medications on dialysis days, avoiding food during dialysis, cooling dialysate, using bicarbonate buffers, high sodium dialysate, and treating intradialytic hypocalcaemia. In some patients, the intradialytic BP can be artificially maintained by pharmacological measures. One study demonstrated that prophylactic caffeine administration, an adenosine antagonist, reduced the occurrence of sudden intradialytic hypotensive episodes [112]. A more widely used alternative is midodrine, a prodrug of a specific α-1 adrenergic receptor agonist, desglymidodrine. It maintains intradialytic BP by mediating constriction of both arterial and venous capacitance vessels and preventing venous pooling while increasing the central BP. Administered orally route, it achieves peak levels at 1 h, and has a half-life of 3 h. We have used it in children successfully, starting with doses of 2.5 mg, incrementally increased to 10 mg. A systematic review of 9 trials, using midodrine doses of 2.5–10 mg given 15–30 min before dialysis, reported a benefit in 6 trials with attenuation of the drop in BP during dialysis, and a decrease in number of hypovolaemia related symptoms. No serious adverse events were described, but minor reactions such as scalp paraesthesia, heartburn, flushing, headache, weakness and neck soreness were reported [113].

Modifying the UF rate throughout dialysis to allow adequate vascular refilling may optimize fluid removal. This is the rationale behind UF profiles. The plasma refilling capacity increases proportionately with interstitial volume expansion. Decreasing stepwise or linear profiles start with high UF rates at the time of maximal tissue hydration, progressively reducing the rate in line with decreasing interstitial hydration in the hope of maintaining the crucial balance between fluid removal and vascular refilling. Intermittent profiles aim to provide periods of active mobilization of interstitial fluid into the vascular space when UF rates are low, making it amenable to removal during periods of high UF rates (Fig. 66.6).

Donauer et al. reported less symptomatic hypotension with the decreasing profiles, but the intermittent profile was associated with an increased incidence of symptomatic hypotension and postdialysis fatigue [114]. The incidence of intradialytic hypotension was highest with UF rates greater than 1.5 times the average. Ronco et al. observed hypotension at a rate of 6.7/100 treatments when the UF rate was 0.3 ml/min/kg, increasing to 15.8 at an UF rate of 0.4 ml/min/kg, 25.6 at a rate of 0.5 ml/min/kg, and 67.4 at a rate of 0.6 ml/min/kg [115]. In children, application of these figures would suggest that hypotension

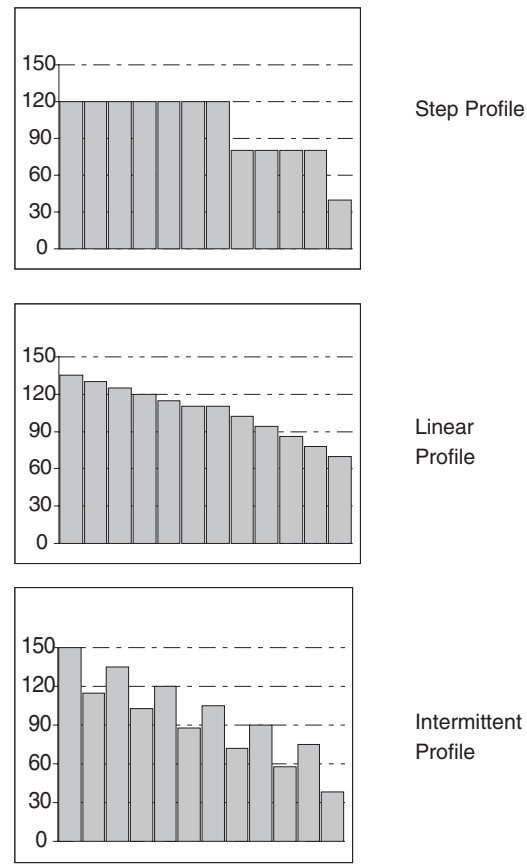

Fig. 66.6 Ultrafiltration profiles

may occur in 25.6 of 100 treatments if a UF rate of 30 ml/kg/h (300 ml/h in a 10 kg child) is exceeded. This data has not been validated in children, but in our experience increasing the UF rate increases the likelihood of intradialytic morbidity. UF profiles will inevitably result in higher UF rate for part of the treatment; the maximal UF rate has to be factored in when considering the most appropriate profile for a patient.

Combining UF profiles with sodium profiles can induce plasma hypertonicity through utilization of a high UF rate during a high-sodium period, and thus provide a greater driving force for plasma refilling. It has been shown to be superior to either sodium or UF profiles alone in attenuating intradialytic symptoms and cardiovascular instability. Finally, the supportive measures for managing hemodynamic instability in high risk patients have a ceiling effect and in resistant cases patients may need to be switched to alternative dialysis programs. HDF, short daily HD, and home nocturnal HD can all potentially be of benefit in these situations.

Myocardial Stunning

Acutely, intradialytic hypotension requires immediate action to stop or reduce the severity of symptoms that may precede or follow the drop in BP. These include a temporary suspension of UF, a 5 ml/kg fluid bolus, and in resistant cases, premature discontinuation of the dialysis treatment. Such measures, although necessary, have an adverse impact on dialysis outcomes by reducing UF goals and adequacy of solute removal. Of greater concern, however, is the evidence linking repeated episodes of intradialytic hypotension with a more severe effect on morbidity and mortality. Several observational studies in adult patients with essential hypertension have described a "J" shaped curve between BP and mortality [116]. The same trend has been described in adult dialysis patients, with a suggestion that hypertension is associated with morbidity, but mortality is more closely associated with hypotension [117]. Zager et al. reported a fourfold increase in the relative risk of cardiac-related death in adults patients with predialysis systolic BP less than 110 mmHg compared with a systolic BP between 140 to 149 mmHg, and a 2.8-fold increase in relative risk for a cardiac-related death with postdialysis systolic BP less than 110 mm Hg compared with systolic BP 140 to 149 mmHg [118].

Frequent intradialytic hypotensive episodes have been implicated in accelerating the decline in residual renal function and precipitating serious vascular complications. There is growing evidence from isotopic, electrocardiographic, biochemical and echocardiographic studies implicating HD as a source of recurrent ischemic injury. Silent intradialytic ST depression [119, 120] associated with acute changes in serum cardiac troponin levels both in adults [121, 122] and children [123] have been demonstrated. Using single photon emission computed tomography, McIntyre et al. demonstrated an acute reduction in global and segmental myocardial blood flow in adults during dialysis with matched reductions in segmental contractile function, even in patients without angiographically proven epicardial coronary artery disease [124]. A direct correlation was seen between the degree of myocardial dysfunction and intradialytic BP changes and UF volume [125]. Such transient myocardial ischemia with resultant reversible regional left ventricular dysfunction is known as myocardial stunning [126]. In the model of coronary heart disease, repeated stunning is progressive and leads to myocardial hibernation, defined as ischaemic, and non-infarcted myocardium that exists in a state of contractile dysfunction [127]. In dialysis patients, myocardial stunning also appears to be progressive. In a 12 month follow-up of adult HD patients, the presence of acute HD induced regional myocardial dysfunction negatively influenced survival, increased the likelihood of cardiac arrhythmias [128], and resulted in regional fixed systolic dysfunction and a reduction in global systolic function [125, 129] with resultant congestive heart failure. Records from the USRDS have shown that HD associated de novo and recurrent congestive heart failure is highly relevant as it is associated with a 2-year mortality as high as 51% [130]. The left atrial volume is commonly driven

by intravascular volume overload and progressive diastolic dysfunction. In a single observational study, the strongest predictor of left atrial volume indexed to height (LAVI) was the presence of stunning. LAVI was a better predictor of mortality than left ventricular (LV) mass index, but both factors became statistically insignificant during a multi-confounder analysis with the addition of myocardial stunning [131].

Of greater concern, perhaps, has been the demonstration of dialysis induced acute regional myocardial dysfunction in 15 children aged 2–17 years. This was associated with varying degrees of compensatory hyperkinesis in unaffected segments and thus the global LV function was maintained throughout HD. In children, intradialytic systolic BP reduction was significantly associated with segmental left ventricular dysfunction, but no correlation was seen with actual intradialytic systolic BP or dialysis vintage [132, 133]. Interestingly, patients on peritoneal dialysis do not appear to have an increased risk of myocardial stunning, despite changes in systemic hemodynamics [134].

We know HD poses a significant hemodynamic challenge. It is conceivable that other vulnerable vascular beds with defective vasoregulation may also be susceptible to significant episodic dialysis-related ischemia. The gut for example is also a high-flow vascular bed. Translocation of endotoxin across the gut wall causes endotoxinaemia and becomes a profoundly pro-inflammatory stimulus. In both children and adults with chronic kidney disease (CKD), circulating endotoxin levels were 1000 times greater than in patients without CKD and almost quadrupled from predialysis levels after initiating HD [135]. Serum endotoxin levels correlated with intradialytic instability, systemic inflammation and dialysis-induced myocardial stunning [135]. One group have even postulated that postdialysis fatigue is a clinical manifestation of cardiac ischemia and cardiac fatigue [136]. The acute cardiac injury that occurs as a direct effect of the HD procedure may be attenuated by altering the dialysis prescription. Cooling, biofeedback and frequent dialysis have all been demonstrated in adults to lower the risk of myocardial stunning [137–139].

Intradialytic or Paradoxical Hypertension

Hypertension is endemic in HD patients and is most often due to salt and volume overload, which responds to UF. The prevalence of hypertension in children receiving HD is reported at 65–69% in studies conducted in Europe and the United States [140, 141]. Intradialytic or paradoxical hypertension is less well-characterized but nonetheless important. Estimates of its frequency are hampered by the lack of a standardized definition. Suggested definitions include an increase in mean arterial pressure of more than 15 mmHg during or immediately after dialysis or an increase in BP that is resistant to fluid removal. Estimates of the incidence in adults range from 5–15%, with no pediatric data available [142].

The pathogenesis of intradialytic hypertension is complex and poorly understood. There may be an iatrogenic aetiology with mobilization of extracellular fluid or in response to osmotic agents such as sodium, mannitol, or concentrated albumin solutions or dialysis induced hypokalemia. Dolson et al. demonstrated significant rebound hypertension at 1 h postdialysis in patients dialyzed against lower potassium baths [143]. In these instances, the hypertension is frequently transient and improves with UF.

Sustained hypertension is commonly due to failure to achieve an appropriate dry weight [144]. However, some patients manifest refractory intradialytic hypertension despite appropriate UF. It is speculated that overzealous UF activates the renin-angiotensin system with resultant vasoconstriction. In support of this theory is the lower incidence of hypertension in anephric HD patients.

Sympathetic nervous system overactivity is well documented in CKD secondary to a number of mediators, including angiotensin II, afferent renal nerve stimulation, impaired brain nitric oxide synthesis and increased production of catecholamines [145–149]. Studies have shown enhanced endothelin I production during dialysis in hypertensive patients, especially those exhibiting paradoxical hypertension [150–152]. This raises the possibility that paradoxical hyperten-

sion is secondary to an imbalance of nitric oxide and endothelin I production [153]. Pearl et al. suggested a role for a new pressor protein a 30-kD extra-renal enzyme related to the coagulation factor β-FXIIa that exhibits cardiotonic and pressor activity in rats. The serum of three anephric children produced characteristic pressor responses, suggesting in vivo activation of this protein as a contributory factor in their hypertension [154].

Finally, a number of antihypertensive drugs are removed by dialysis and this conceivably may result in paradoxical hypertension. As a general rule, the beta blockers (atenolol, nadolol, metoprolol), angiotensin converting enzyme (ACE) inhibitors (captopril, enalapril, lisinopril, ramipril) and vasodilators such as minoxidil, nitroprusside and diazoxide are removed, by a variable degree, during dialysis. Calcium channel blockers such as amlodipine and angiotensin receptor blockers (ARBs), such as losartan, are generally not cleared during HD. No data exists for α-blockers such as doxazosin. The management of intradialytic hypertension should start with an assessment of the dry weight and salt and fluid intake. Treatment options include further salt and water restrictions, and where feasible, augmentation of urine output with loop diuretics. The dialysate composition should be examined for the sodium, potassium and calcium content to ensure that the dialysis procedure does not result in acute hypokalemia or a net transfer of sodium and calcium load. Consideration should be given to replacing conventional HD prescriptions with intensive HD or HDF. If hypertension persists despite appropriate salt and water control, blockade of the renin-angiotensin system with ACE inhibitors or ARBs have been shown to improve BP control and reduce sympathetic tone in HD patients. If this produces insufficient BP control, the addition of α-blockers, β-blockers or centrally acting antihypertensive such as methyldopa is physiologically logical. Attention should be paid to the timing of BP medications to ensure they do not contribute to intradialytic hypotension. Similarly, if drug removal by HD is contributing to suboptimal BP control, consideration should be given to switching to an agent that is not significantly removed by dialysis such as calcium channel blockers. Finally, the incidence of hypertension in dialysis patients appears to have increased in the post-erythropoiesis stimulating agent (ESA) era. This may relate to increased viscosity, increased peripheral vascular resistance or a direct effect of ESAs on the vascular endothelium. While there are no published studies showing a direct relationship between hemoglobin and hypertension, effort should be made to avoid excessive hemoglobin values in patients with intradialytic hypertension.

Left Ventricular Hypertrophy

LVH is common in dialysis patients. At the initiation of dialysis, 69–82% of children show evidence of LVH [155] and during maintenance dialysis 40–75% of children have LVH [156]. Several factors increase the risk of developing cardiac hypertrophy, including chronic hypervolemia, a hyperdynamic circulation secondary to arteriovenous fistulae or anemia, increasing arterial stiffness and elevated parathyroid hormone (PTH) levels [157]. There is emerging evidence from established animal models of CKD implicating a klotho-independent, causal role for FGF23 in the pathogenesis of LVH. This raises the possibility of FGF23 being directly involved in the high rates of LVH and mortality in HD patients [158]. Somewhat surprisingly, both adult data and now pediatric data from the ESCAPE trial have failed to demonstrate any relationship between office BP or ambulatory BP and left ventricular mass [159].

Cardiac hypertrophy in combination with continued mechanical stress triggers pathways that result in myocardial remodeling characterized by decreased capillary density and reduced coronary flow reserve predisposing the heart and other organs to ischemic injury. Fortunately, cardiac hypertrophy in HD patients is amenable to treatment, with evidence of resolution in patients on intensified dialysis programmes and HDF.

Endothelial Dysfunction

Endothelial dysfunction is thought to be the initiating step in atherosclerosis and arteriosclerosis. It starts early in renal failure, progressing in dial-

ysis as a number of pathophysiological pathways contribute. HD is pro-inflammatory as a consequence of an immune mediated response to bio-incompatible membranes, blood contact with non-sterile dialysate solution and "back-leaking" of dialysate across the membrane. UF changes endothelial cell dynamics through its effects on blood viscosity and laminar shear stress [160]. Intradialytic hypotension and resultant ischemia causes apoptosis of the vascular endothelium. Finally, reduced clearance of asymmetric dimethylarginine, decreased bioavailability of endothelial nitric oxide, activation of angiotensin II, hyperhomocystinemia and hyperlipidemia are postulated mechanisms for endothelial dysfunction. Compounding these effects, uremia is also associated with reduced hematopoiesis and capacity for repair. In adults, endothelial progenitor cells are reduced, with pronounced functional impairment [161, 162], and HD depletes this source further. In contrast, the pool of smooth muscle cell progenitor cells are preserved and with it the potential for adverse remodeling [163]. Little is known about circulating endothelial progenitor cells in children, but there is clinical evidence of endothelial dysfunction with loss of flow-mediated dilatation and increased aortic pulse wave velocity in children on dialysis [164, 165]. Encouragingly, the degree of endothelial injury is attenuated by switching adults HD patients to either HDF or home nocturnal HD [166, 167].

Sudden Cardiac Death

Sudden cardiac death is a common phenomenon in dialysis patients that appears to be temporally related to the HD procedure. In adults, the risk of sudden death is 1.7 times higher in the 12 h period starting with the dialysis procedure and 3 times higher in the 12 h before HD at the end of the weekend interval [168]. Cardiac arrests are 50% higher for HD patients 3 months after dialysis initiation. The risk remains higher in HD compared with peritoneal dialysis for up to 2 years on maintenance dialysis, but then the trend reverses at 3 years of maintenance dialysis. The most vulnerable patients are infants aged 0–4 years, with a five- to ten-fold increase risk of cardiac arrest compared to other age groups [169].

The precise aetiology of sudden cardiac death remains elusive but a number of dialysis specific and uremic factors have been implicated. Myocardial interstitial fibrosis, LVH, endothelial dysfunction, cardiac and vascular calcification, microvascular disease with decreased perfusion reserve and diminished ischemia tolerance are all prevalent in dialysis patients and increase the vulnerability of the heart. This, in combination with dialysis related acute fluid shifts, acid-base disturbances, rapid electrolyte shifts and autonomic imbalance with abnormal sympathetic activity, places patients at risk of sudden cardiac death.

Clinically the only modifiable risk factor for fatal cardiac events is manipulation of the dialysate potassium. Patients who suffered a cardiac arrest at the time of dialysis were twice as likely to be dialyzed against a 0 or 1.0 mEq/L potassium dialysate compared to controls, despite no difference in predialysis potassium levels [170]. Kovesdy et al. found that serum potassium between 4.6 and 5.3 mEq/L was associated with the best survival, but levels below 4.0 mEq/L or higher than 5.6 mEq/L were associated with increased mortality [171]. As a result, there is a growing consensus of nephrologists advising against zero potassium dialysate baths.

Atherosclerosis, Arteriosclerosis, and Calcification

Calcification of the cardiovascular system is accelerated in dialysis patients. Studies of young adults who developed ESKD during childhood found a high prevalence of abnormal carotid intima-media thickness (cIMT), diminished arterial wall compliance and coronary artery calcification [172, 173]. Such vascular and cardiac aberrations were also demonstrated in children on dialysis [174]. The vascular abnormalities positively correlated with serum phosphorus levels, while cIMT and cardiac calcification scores also correlated with intact PTH levels and dosage of vitamin D. Patients with mean intact PTH levels greater than twice the upper limit of normal

demonstrated stiffer vessels and increased cIMT and cardiac calcification scores. In contrast, 1,25-dihydroxy vitamin D levels showed a U-shaped distribution, with a significantly greater cIMT and calcification score in patients with low and high 1,25-dihydroxy vitamin D levels compared with patients with normal levels. Calcification was most frequently observed in patients with the lowest 1,25-dihydroxy vitamin D and the highest high-sensitivity C-reactive protein (CRP) [175]. Litwin et al. reported vascular abnormalities in children with CKD, but again found the most marked changes in the dialysis patients. The degree of arteriopathy correlated with conventional cardiovascular disease risk factors such as hypertension and dyslipidemia in predialysis CKD and with hyperphosphatemia, hyperparathyroidism and treatment with calcium-containing phosphate binders in dialysis patients [176]. In contrast, in a study examining the effects of dialysate calcium concentrations on changes in arterial stiffness, increased pulse wave velocity was seen even in the group dialysing using the lowest dialysate calcium [177]. Therefore, it is highly probably that factors other than simple net calcium influx and efflux during dialysis are involved in the pathogenesis of accelerated vascular calcification in HD patients.

Inflammation

Inflammation predicts mortality in dialysis patients and may contribute to cardiovascular risk. CRP, an acute phase protein, is a recognized marker of inflammation, but is also reported to be predictive of mortality, structural heart changes such as LVH, and higher coronary calcification scores. Data has also implicated CRP in the pathogenesis of vascular inflammation and atherosclerosis [178]. Plasma CRP levels increase with declining kidney function and then continue to rise after initiation of HD, with levels correlating with the length of the dialysis session [179]. It has been postulated that an interaction of circulating monocytes with bio-incompatible membranes, blood contact with non-sterile dialysate solution and "back-leaking" of dialysate across the membrane results in a chronic inflammatory state. However because there is a high incidence of pre-dialytic inflammation [180], the dialysis procedure is unlikely to be the only factor associated with inflammation [181]. Changes in CRP may also represent an acute inflammatory stimulus [182]. Additionally, vitamin D deficiency has been correlated with inflammatory cytokine levels (IL-10 and SIL-2R) in children receiving HD [183].

The dialysis prescription can be modified to become less inflammatory by using ultrapure dialysate and synthetic biocompatible membranes. Both ACE inhibitors and statins, more commonly recognized for their respective roles in treating hypertension and hypercholesterolemia, have been reported to have anti-inflammatory actions [184, 185]. Finally, lifestyle and dietary changes may be associated with decreasing inflammation and uremic toxins (p-cresyl sulfate and indoxyl sulfate), although data is limited in children [186].

Malnutrition

Protein malnutrition and growth delay commonly occurs in underdialyzed patients and may be associated with mortality in children [187, 188]. Measurement of the nPCR has become an indirect measure of daily protein intake in stable dialysis patients. Measurement of nPCR has traditionally relied on the availability of formal urea kinetic modeling and is included with the web-based programs (www.hdcn.com, and www.Kt-v.net) alluded to above. Goldstein, however, has demonstrated strong agreement between nPCR calculated from urea kinetic modeling and the formula [nPCR = 5.43 × G/V + 0.17] [187]. This calculation requires a blood urea nitrogen (BUN) level 30 s after a mid-week dialysis session, documentation of the time until the next dialysis session, and a BUN value prior to the second dialysis session. In this formula the urea generation rate (G) is calculated as G (mg/min) = (predialysis BUN2 × predialysis V) – (postdialysis BUN1 × postdialysis V)/T, where V is total body water estimated from 0.58 × body weight, and T

is time in minutes from the end of the mid-week dialysis treatment to the beginning of the next dialysis treatment. Validation of this formula has eliminated the need for complicated computer modeling in order to measure nPCR and estimate daily protein intake. A subsequent report, which compared the values of nPCR calculated as above with a simplified formula using only pre- and postdialysis BUN specimens from the same mid-week session has found there is a significant and variable difference between the two methods and invalidates the simplified formula [189].

Although nPCR values are a useful guide to protein intake, because nPCR values may be influenced by factors other than nutrient intake, these values should be interpreted in combination with a review of weight gain and the dietary history. Goldstein et al [190] demonstrated a substantial increase in nPCR associated with improvement in nutritional status of three adolescents treated with intradialytic total parenteral nutrition. However, Van Hoek et al. in a comparison of protein intake from dietary records kept by children, with an estimate of nPCR calculated using an on-line urea monitor, showed significant variation, and PCR significantly underestimated the prescribed and recorded protein intake [33]. These authors concluded that use of their online urea kinetic monitor is therefore not recommended for estimation of nPCR. Also, as reported by Grupe et al. [191], nPCR may be significantly affected by factors other than nutrient intake in as many as 25% of patients.

The safety of enteral intake during dialysis should be assessed on a patient-by-patient basis as blood is diverted to the splanchnic circulation, potentially increasing the risk of intradialytic hypotension. In patients able to tolerate enteral intake during dialysis, it offers an opportunity to provide nutritional supplements. Intradialytic parenteral nutrition is an alternative method of providing calories and protein to undernourished patients during HD. While this increases the amount of fluid needed to remove, utilizing a constant UF to parallel the infusion can minimize excessive UF rates. Use of recombinant growth hormone is another important means of maximizing growth in children on HD, assuming their nutritional status has first been optimized [192].

Dialysis-Related Carnitine Disorder

Levocarnitine (L-carnitine) facilitates the transport of fatty acids across the inner mitochondrial membrane and is thus a critical co-factor for normal energy production in cardiac and skeletal muscle. There is evidence of reduced plasma free carnitine levels in HD patients, with an inverse relationship between muscle carnitine and duration on dialysis [193]. Within a single dialysis session, clearance is 30 times greater than would be expected in a healthy individual [194] and HD results in an abnormal acylcarnitine:free carnitine ratio (normal <0.25).

Low carnitine may be associated with anaemia that is hyporesponsive to ESAs, intradialytic hypotension, cardiac dysfunction, fatigue, muscle cramping, and reduced exercise tolerance [195]. The National Kidney Foundation Interdisciplinary Consensus Panel recommends L-carnitine [196] supplementation for those patients with these clinical findings even in the absence of a low plasma carnitine levels. As measuring skeletal muscle L-carnitine concentrations is not feasible, some advocate a trial of therapy with discontinuation at 9–12 months if no benefits are observed [196]. Repeated doses of 20 mg/kg given intravenously at the end of dialysis appear to be the most beneficial, as oral carnitine is not recommended in ESKD due to the toxicity of metabolites which accumulate in kidney failure.

Hyperhomocysteinaemia

Homocysteine is a non-protein forming amino acid that results from methionine metabolism. Only 1–2% of total homocysteine circulates freely in the blood in a reduced form, 70–90% is protein bound, and the rest exists in oxidized forms. Studies have shown that plasma homocysteine concentrations start rising in CKD and are inversely related to glomerular filtration rate.

ESKD results in hyperhomocysteinaemia from altered metabolism and impaired clearance. There is conflicting evidence on the impact of hyperhomocysteinemia on outcomes. A meta-analysis reported a positive association between hyperhomocysteinemia and atherosclerosis, ischemic heart disease, stroke, and thrombosis [197]. Conversely, others have found no significant or even an inverse association between plasma homocysteine levels, cardiovascular events, and mortality in ESKD patients [198]. In addition to being a potential marker of inflammation, homocysteine, like β2-microglobulin, can also be a marker of middle molecule clearance in patients receiving more frequent, longer duration, or convective treatment modalities (detailed below).

Treatment options for hyperhomocystinaemia have included folate and vitamin B12 supplementation to achieve supranormal plasma levels and intravenous N-acetylcysteine [199]. An alternative therapeutic strategy involves using high-flux dialysers to achieve greater clearance, but this has not impacted predialysis plasma concentrations [200]. With these therapeutic options, plasma homocysteine levels improve, but normalization is uncommon.

Future Directions

Hemodiafiltration

Conventional HD is based on diffusive transport of solutes across a semipermeable membrane and is effective in removing small uremic retention solutes, such as urea, and correcting electrolyte and fluid imbalances. However, as clearance is inversely proportional to the molecular weight of the toxin (and also depends on its protein binding and tissue distribution), conventional HD does not clear large or protein-bound toxins effectively, and fails to adequately correct the uremic milieu [201, 202]. In HDF, solute clearance involves a combination of diffusion and convection. HDF optimizes the removal of middle (up to 300–500 Dalton (Da) molecular weight) and larger molecules (greater than 15–50 kilo Da).

Definition of HDF Therapy

The European Dialysis Working Group (EUDIAL) has defined HDF as a blood purification therapy that combines diffusive and convective solute removal by UF of 20% or more of the blood volume processed through a high-flux dialyzer and maintenance of fluid balance by sterile replacement fluid infused directly into the patient's blood [202, 203]. Sterile replacement fluid is obtained in large amounts by on-line filtration of standard dialysate through a series of bacteria- and endotoxin-retaining filters [203]. A high-flux membrane is defined as one that has an UF coefficient greater than 20 mL/h/mmHg transmembrane pressure/m^2 and a sieving coefficient for β2-microglobulin of greater than 0.612.

Importance of Convective Volume

A high convective volume is a fundamental requirement for HDF [202, 204]. The convective volume is the sum of the net UF volume (i.e., the amount of fluid removed during a dialysis session based on the interdialytic weight gain) and the amount of substitution fluid (i.e., the sterile replacement fluid given as replenishment for the removal of extra fluid during HDF).

The effectiveness of a membrane to UF fluid is described by the UF coefficient (KUF):

$$KUF = QUF/\Delta P$$

(volume of UF per unit time, divided by the pressure gradient across the membrane, also called the transmembrane pressure gradient [TMP])

Theoretically, the convective volume should be prescribed as a proportion of plasma water volume processed rather than blood volume processed, but blood volume processed is displayed on the machine control panel, and hence this term is commonly used. An UF volume equivalent to 20% of the total blood volume processed for the treatment was chosen by the EUDIAL group because randomized controlled trials in adults [205–207] and a pooled individual participant data analysis [208] suggest that any improved

survival associated with HDF occurs when the convective volume exceeds 20 L/session.

Depending on where the replacement volume is infused in the dialysis circuit, there are different modalities of HDF: pre-, post-, mid- or mixed-dilution HDF. Post-dilution, where the replacement fluid is infused downstream of the dialyser, usually into the venous bubble-trap, is the most commonly performed.

The phenomenon of 'backfiltration,' which commonly occurs during high-flux HD [209] (but not in low-flux HD), can achieve some convective clearance, but this is low and unreliable, and called the 'poor man's HDF'! Backfiltration occurs because the hydrostatic pressure of both blood and dialysis fluid decrease as they pass through the dialysis filter. Since blood and dialysis fluid pass through the filter in counter-current directions, the resulting TMP may become negative at the venous side, especially when the venous blood pressure is low. In adults it has been shown that the convective volume achieved by back-filtration is no more than 1–10 L per session depending on the dialyser type, and can vary throughout the dialysis session depending on TMP. Importantly, given the phenomenon of backfiltration, it has been suggested that dialysis fluid used for high-flux HD should also be sterile and pyrogen-free.

Essential Requirements for Performing HDF

High Flux Membranes

Only highly permeable membranes, defined as membranes characterized by an UF coefficient (KUF) greater than 20 mL/h/mmHg transmembrane pressure/m^2 and a sieving coefficient (S) for β2-microglobulin of greater than 0.6 [202, 203, 210], are suitable for HDF. A high-flux membrane allows a larger and pre-defined convective flow as required for HDF. In practice, the KUF should be high enough to allow 50 mL/m/m^2 BSA (equivalent to 2 mL/min/kg body weight) convective flow in post-dilution HDF. The albumin loss through a high-flux membrane should be <0.5 g in a 4-h HD session [210–212].

As with conventional HD, the dialyser surface area must be equal to (or slightly higher) than the BSA for maintenance dialysis, so that the internal volume of the dialyser and blood lines is less than the safe extracorporeal blood volume permissible (i.e. less than 10 ml/kg body weight). For HDF a biocompatible dialyzer must be selected; biocompatibility is assessed by complement activation, thrombogenicity, contact activation and cytokine generation [63, 211]. European recommendations state that ultrapure dialysate must be used with synthetic high-flux membranes [63].

Ultrapure Water for HDF

Sterile, non-pyrogenic fluid that is used to maintain fluid balance is called replacement fluid or substitution fluid. This can be provided as a sterilized, packaged solution (like intravenous fluid) or as an on-line prepared solution. In all modern HDF machines, the replacement fluid is generated on-line by filtering dialysis fluid through bacteria- and endotoxin-retentive filters to prepare a sterile and pyrogen-free solution that is immediately infused into the patient. Strict safety standards and regulatory oversight are required as large volumes of fluid are removed from, and added to, blood during on-line therapies. Water purification systems are discussed separately in this chapter. Bacteria- and endotoxin-retentive filters installed on the inlet dialysis fluid circuit are the key components of the on-line HDF safety system. Those filters are disinfected after each dialysis treatment according to manufacturer's recommendations and replaced periodically to ensure proper operation of the cold sterilization process.

Dialysis Machines with Accurate Ultrafiltration Control

Today almost all new dialysis machines allow for both HD and HDF. These machines are suit-

able for children from 10–17 kg body weight, and require a pediatric circuit with low extracorporeal volumes. These systems can be used in a pressure-control mode (fixed TMP and variable substitution flow rate) or a volume-control mode (the target substitution volume or the substitution flow rate are set). Some machines offer an automatic substitution mode, in which the substitution rate is automatically regulated in response to variations in patient- and treatment-related parameters throughout the session.

Writing a HDF Prescription

The following points need to be considered when writing an HDF prescription:

1. A high-flux membrane with surface area equal to the child's BSA is used.
2. Double needle circuits—HDF is rarely ever performed with single-needle circuits given the high convective volume goals.
3. The total extracorporeal circuit should be less than 10 ml/kg body weight. Pediatric blood lines (36–105 ml volume) with or without the possibility to do on-line HDF and to monitor blood volume variation are available.
4. Blood flow: HDF requires an optimal arterial blood flow of 5–8 mL/min/kg body weight or 150 to 250 mL/m^2 BSA per minute. An optimal blood flow can be achieved through either a fistula or a central venous line, although in most cases a fistula allows a higher blood flow rate. Both the diffusive clearance of molecules with a high K0A and the substitution volume in post-dilution HDF depend on the blood flow rate.
5. Dialysate flow of twice the blood flow is sufficient to optimize the diffusive blood purification process using highly permeable membranes for HDF.
6. Replacement fluid that is generated on-line from the dialysate must be ultrapure (<0.1 CFU/ml and <0.03 endotoxin unit/ml, as per European guideline Dialysate purity 2002, European Pharmacopoeia 2009) [63] as discussed earlier. The microbiologic purity (bacterial count and endotoxin level) should be determined at intervals of 1–3 months.
7. Convective flow is equal to total UF flow, that is, the sum of the desired UF volume and the replacement fluid. The convective flow needs to be maximal, but is limited by the risk of the filter clotting. Modern dialysis machines automatically adjust the convective volume throughout the session in order to optimize this convective flow without increasing the coagulation risk. In pre-dilution HDF, the convective flow is set at 100% of blood flow. The actual substitution volume obtained per session has to be monitored regularly in order to ensure that the goal of 23 L/1.73 m^2 per session in post-dilution and 75–100% of blood volume treated in pre-dilution is achieved.
8. The dialysate and substitution fluid are produced 'on-line' by the dialysis machine by dilution of acid concentrate and bicarbonate powder with dialysis water produced by the water treatment system. Dialysate composition is similar to that used in HD, but careful attention to dialysate sodium concentration is important in order to maintain sodium balance and for hemodynamic tolerance of the session [63]. To avoid the risk of positive sodium balance, the dialysate sodium concentration required is lower than in conventional HD, particularly when high convective volumes are infused, as with pre-dilution HDF. Sodium is predominantly drained in ultrafiltered water by convection [213]. A low dialysate sodium enables additional sodium removal by diffusion, but it may be associated with a risk of intradialytic hypotension and disequilibrium syndrome. Conversely, a high dialysate sodium increases hemodynamic tolerance, but causes sodium and water overload that leads to hypertension and increased thirst post-session.
9. Anticoagulation to prevent filter clotting can be achieved with a single dose of LMWH that is effective for a 4-h session. Alternatively, a continuous heparin infusion may be used.

To attain a high convective volume, one needs a high blood flow rate because filtration fraction depends on blood flow and cannot be higher than 35%; optimization of substitution volume by automated programs in new dialysis machines; and careful monitoring of the dialysis prescription and blood results to ensure that all dialysis related parameters are achieved [214–216]. In the HDF, Hearts and Height (3H) study (described in detail below), median convection volumes of 13.4 L/m^2 were achieved in children [217], which is comparable to the 23 L per 1.73 m^2 per session that proved beneficial in the pooled adult studies [208]. Importantly, the convection volume was independent of patient related factors such as age, gender, access type or dialyser used, but strongly correlated with the blood flow rate [217], implying that convection volume is a modifiable factor that can be manipulated and optimized by the dialysis team.

Potential Advantages of HDF Over Conventional HD

HDF is thought to be superior to conventional HD in the following key areas:

1. Clearance of toxins across a wide molecular weight range: HDF has been shown to clear 70–80% of β2-microglobulin compared to HD [218], and increase removal of inflammatory cytokines, with reduction in inflammation and oxidative stress [219].
2. Improved hemodynamic stability: HDF increases UF and improves intradialytic hemodynamic stability [220], leading to less intradialytic hypotension [221], reduced incidence of strokes [221] and faster recovery time postdialysis, even in children [222].
3. Biocompatibility and reduced inflammation: The use of ultrapure dialysate and increased removal of inflammatory cytokines reduces inflammation and oxidative stress [219].

Clinical Studies

A Cochrane review suggests that there is no clear benefit of HDF over HD, but these meta-analyses combine outcomes of both hemofiltration as well as HDF studies as 'convective therapies' and do not interpret outcomes based on convective volumes [223]. The Estudio de Supervivencia de Hemodiafiltración On-line (ESHOL) randomized controlled trial (RCT) comparing HDF vs. high-flux HD in adults, and achieving convective volumes of 23 L/session, has shown that patients on high volume HDF have a survival benefit compared to those on high-flux HD [206]. Pooled data [208] from the three RCTs (including the Turkish [207] and CONTRAST [205] studies) has indicated a critical dose-response relationship between the magnitude of the convective volume and survival, with a goal of at least 23 L per session.

In children, Fischbach et al. showed improved growth, with children achieving a normal height at or above their target mid-parental height [224, 225], reduced inflammation [225], regression of LVH [226, 227], improved anaemia control [214] and reduced postdialysis recovery time [222, 224] in a small number of children undergoing daily HDF. However, this study utilised 6 days per week HDF in the pre-dilution mode, making it difficult to ascertain the benefits of HDF vs. longer dialysis therapy times. A small single-centre study also suggests that switching children from nocturnal in-centre HD to nocturnal in-centre HDF may significantly improve BP, phosphate and PTH control [228]. Further single-centre studies have shown improvements in left ventricular function within a short period of HDF therapy [229]. Studies have shown that when HD patients are switched to HDF, keeping all other dialysis related parameters constant, a significant improvement in inflammation, antioxidant capacity and endothelial risk profile is achieved within 3 months [219], suggesting that even in children who have a short anticipated time on dialysis, HDF is superior to conventional HD. A report from the Italian Registry suggests that HDF use in Italy has been limited to approxi-

mately a quarter of patients on extracorporeal dialysis, in particular to those with high dialysis vintage, younger age or a long expected waiting time to renal transplantation [230].

The International Paediatric Hemodialysis Network (IPHN) has performed a multicenter observational study to test the hypothesis that HDF improves the cardiovascular risk profile, growth, nutritional status and health-related quality of life in children compared to conventional HD—the HDF, Hearts and Height (3H) study [217, 222]. The 3H study suggests that HDF halts the progression of increasing carotid intima-media thickness, is associated with an increase in height standard deviation score and improves patient-related outcomes compared to HD [222]. Children on HDF had improved blood pressure and hemodynamic stability, reduced inflammatory markers and lower β2-microglobulin compared to children on HD [222]. The annualised change in vascular measures correlated with improved BP control and clearances on HDF. In a post-hoc analysis of the 3H data, it was shown that children on HD had a significant and sustained increase in BP over 1 year compared to a stable BP in those on HDF, despite an equivalent dialysis dose.Improved fluid removal as well as clearance of middle molecular weight uraemic toxins by HDF were strongly correlated with improved vascular outcomes in HDF [231]. Although mechanisms of improved growth in HDF are not clear, the 3H study showed an inverse correlation between height SDS increase and serum β2-microglobulin, suggesting that clearance of middle-molecular weight compounds may partly alleviate growth hormone resistance in dialysis patients. In the HDF cohort, patient related outcome measures that are primarily associated with fluid status, such as the postdialysis recovery time, headaches, dizziness and cramps, were less frequent and severe compared to HD patients, leading to an improvement in school attendance as well as physical activity [222]. Importantly, HDF is a safe treatment, with no reduction in serum albumin levels, and no difference in the rate of change of residual renal function [222] compared to conventional HD.

Intensified Hemodialysis Options

Our current standard of three times weekly hemodialysis evolved during the 1960s from one 24 h treatment per week, to twice weekly treatments of 16–24 h each, and finally three weekly sessions of 8–10 h performed at home. By the time United States Medicare program adopted its ESKD program in 1973, the three times per weekly schedule offered the optimal balance between patient outcome, quality of life, and cost. Remarkably, the first patient treated with these prolonged sessions lived for more than a decade. More than 50 years later, similar outcomes have become difficult to achieve [232].

To improve the health of patients receiving three times weekly in-center hemodialysis, researchers have trialed alternative, intensified dialysis regimens. These methods include short daily hemodialysis, nocturnal home hemodialysis, and in-center nocturnal hemodialysis. In 2010, the Frequent Hemodialysis Network, sponsored by the National Institutes of Health, published their findings in 245 adults randomized to three times versus six times per week in-center hemodialysis. After 1 year of treatment, those in the more frequent group averaged about 5 sessions per week and demonstrated improvements in mortality, LVH, reported physical health, hypertension, and hyperphosphatemia. However, they were also more likely to receive vascular access interventions compared to the three times per week treatment group [11]. A treatment benefit was not observed among adults randomized to 6 times per week home nocturnal hemodialysis [233].

Smaller, uncontrolled studies in children have also supported the potential benefits of intensified dialysis regimens. As mentioned above, Fischbach et al. reported their experience treating 12 children (median age 7 years) in France with 5–6 times per week in center HDF. After a median follow-up of 11 months, dietary restrictions could be lifted and BP and phosphate control improved [234]. Observations by the same group have also noted decreased LVH and postdialysis fatigue with six times per week treatments [225]. In children, weekly treatment times of 15–18 h have

been associated with improved growth [224, 227, 235, 236].

The success noted by the investigators in France has prompted others to trial alternative dialysis regimens in children. Four children treated at The Hospital for Sick Children had improved dietary intake, BP control, and school attendance with home nocturnal hemodialysis [237]. Calcium and phosphate metabolism improved, even requiring dialysate phosphate supplementation during therapy [83]. These experiences have been expanded to a larger group of children in Europe, resulting in no postdialysis recovery time and improved energy and quality of life. Patient selection criteria for home therapy have included weight >20 kg, adequate family support and supervision, and the necessary technology to operate the dialysis equipment [237, 238]. While the therapy may represent a 30% cost savings compared with in-center treatment, the requirements for staffing and family resources are high [237]. Future technology may allow home HD to be performed in infants.

In the United States, a published report of four children treated with 6 times per week, in-center or home hemodialysis used the NxStage™, which provides sterile dialysis fluid without the requirement for home modifications for a reverse osmosis water treatment system [239, 240]. After a 16 week pilot study, these children no longer needed antihypertensive therapy and had improved BP control as measured by 24 h ambulatory monitoring, without reporting treatment-related complications [240].In London, we have dialysed 15 children aged from 3 to 17 years on the NxStage™ system. We are currently using 3 circuits: the standard CAR172 circuit, CAR124 for those developing intradialytic thrombocytopenia and CAR125 for children weighing less than 18 kg. Routinely children start on 5 h of dialysis 4 evenings/week (except infants) [241]. From 2 months onwards, we discuss the possibility of switching to nocturnal HD where appropriate. All children report reduced or no postdialysis recovery times, greater energy and improved quality of life scores and vastly improved school attendance, social and family lives. All the children on 20 h or more of dialysis/week are free of diet and fluid restrictions; appetites have improved with better growth. Cardiac echocardiograms were normal at baseline in 6/11, in the 5 remaining signs of LVH and/or fluid overload had regressed within 6 months. PTH levels were successfully maintained within twice upper limit of normal in all except 2 teenagers who became calcium deficient on 1.5 mmol/l calcium dialysate baths [241]. In our experience, one advantage that intensified home HD holds over all other dialysis treatment is in the management of patients with ESKD and cardiac failure, where intensified dialysis prescriptions have resulted in the complete resolution of the cardiac failure [242].

Combining the benefits of more frequent treatments, the quality of life advantages offered by nocturnal therapy, and the safety and convenience of monitoring available in the clinic, investigators in Germany have reported their experience in 16 children and adolescents treated with in-center, nocturnal hemodialysis. Children were prospectively enrolled over an almost 5 year period and there were over 2000 treatments provided. Participants were treated 8 h per session for 3 days per week and each treatment was monitored by a pediatric nephrologist and 2 dialysis nurses. During the study, quality of life improved and children missed fewer days of school. Nutrition indices improved, phosphate levels decreased, and the number of antihypertensive medications decreased compared to matched control patients [243].

While pediatric studies have been mostly uncontrolled and have included a small number of subjects, most demonstrate that intensified hemodialysis is associated with improved quality of life, biochemical markers (especially phosphate clearance), growth, nutrition, and BP control [244]. Nevertheless, significant barriers exist, precluding the more wide-spread adoption of these potentially beneficial options for children with ESKD. These include financial hurdles related to treatment costs, transportation, missed work for parents, and equipment and supplies for those choosing home therapy [244]. Missed time from school and other social activities is a concern for children treated with non-nocturnal,

more frequent in-center hemodialysis. We must also be mindful of patient, caregiver, and provider burnout in a patient population already struggling with the management of a very significant chronic disease [237, 239, 241, 243].

It is clear that change is needed to improve the health and survival of children with ESKD. Health-related quality of life remains poor in children with CKD, especially in those receiving HD, in whom daily life activities are greatly limited [245]. While the data suggest that the current treatment is not optimal and more intensified treatment may offer benefit, we must also not minimize the subjective input of our patients. To this end, a 16 year old female, after being switched to three times per week long nocturnal hemodialysis, noted, "regular dialysis was hell and I never want to go back to it again." [243]

Immunosuppression in Pediatric Kidney Transplantation

67

Burkhard Tönshoff, Anette Melk, and Britta Höcker

Introduction

Ideally, a recipient (host) would accept a kidney transplant without induction of an antigen-specific response. However, it is not currently possible to induce specific immunologic tolerance, and transplantation requires immunosuppressive therapies. The goal is to use immunosuppressive agents that are not only potent and selective, but allow reversibility of their action, can be reliably delivered and display long-term safety. Most therapies alter immune response mechanisms but are not immunologically specific, and a careful balance is required to find the dose that prevents rejection of the graft, while minimizing the risks of over-immunosuppression leading to infection and cancer.

Current immunosuppressive agents reduce acute rejection, but do not induce tolerance. A few patients with organ transplants can successfully withdraw their immunosuppressive therapy without rejecting their grafts for long periods of time. However, these are rare exceptions, and such patients may eventually reject, even after years as this operational state of prope tolerance is unstable and poorly understood. The hunt for biomarkers to harness this "operational" tolerance state has remained elusive [1]. Even though antigen-specific T cells with reactivity to the foreign antigen persist in the host indefinitely, some graft and host adaptation must occur, since the level of immunosuppression required long-term is very low compared to the levels required within the first weeks post-transplant. This adaptation makes long-term immunosuppression possible; however, the long-term risk of cancer in the immunosuppressed patient remains increased. Thus, the distinction between immunosuppression and tolerance induction is partly artificial: any immunosuppression involves some apparent antigen-specific adaptation, i.e. down-regulation of the host response to the graft; and many tolerance protocols involve some non-specific immunosuppressive therapies.

The goal of immunosuppressive therapy is to prevent acute rejection while minimizing drug side effects. In children who undergo renal transplantation, immunosuppression is divided into 3 categories: (i) Induction therapy, i.e. intense immunosuppression administered during the perioperative period to prevent acute rejection, (ii) maintenance therapy, i.e. immunosuppressive treatment to prevent acute rejection after the peri-

operative period, and (iii) immunosuppressive therapy to treat graft rejection. In general, immunosuppression should be most intense during the first 3 months after transplantation when the risk of acute rejection and allograft loss is greatest. Immunosuppression is tapered slowly to a maintenance level by 6–12 months post-transplant. The goal remains to find the best combination of immunosuppressive agents that optimizes allograft survival by preventing rejection episodes while limiting drug toxicities. Although data from adult renal transplantation trials are used to help guide management decisions in pediatric patients, immunosuppression must often be modified because of the unique clinical effects of some of these agents in children, including their impact on longitudinal growth and development.

Allograft survival rates vary among the various immunosuppressive agents due to patient-specific clinical characteristics, such as age, ethnicity, obesity, hyperlipidemia, hypertension, proteinuria, delayed allograft function and some donor-related factors such as living-related versus deceased kidney donation. Immunosuppressive agents should therefore be chosen in part based on patient characteristics. Other issues to be considered are related to the immunologic history of the patient, such as ABO compatibility and the degree of HLA matching, pre-sensitization, re-transplantation, history of acute rejection episodes and the risk of recurrent disease.

The common immunosuppressive agents used in pediatric renal transplantation include glucocorticoids (steroids), azathioprine (AZA), mycophenolate mofetil (MMF), the calcineurin inhibitors tacrolimus (TAC) and ciclosporin (CSA), the mammalian target of rapamycin (mTOR) inhibitors sirolimus (SRL) and everolimus (EVR), antibodies to cell surface antigens on lymphocytes, including anti-thymocyte globulin (ATG), anti-CD25 antibodies (anti-interleukin-2 [IL-2] receptor antibodies), alemtuzumab (a humanized anti-CD52 pan-lymphocytic monoclonal antibody) and belatacept, a co-stimulation blocker of T cells. The structures of some immunosuppressives are shown in Fig. 67.1 [2]. Our discussion will focus on these agents and how they inhibit the immune response.

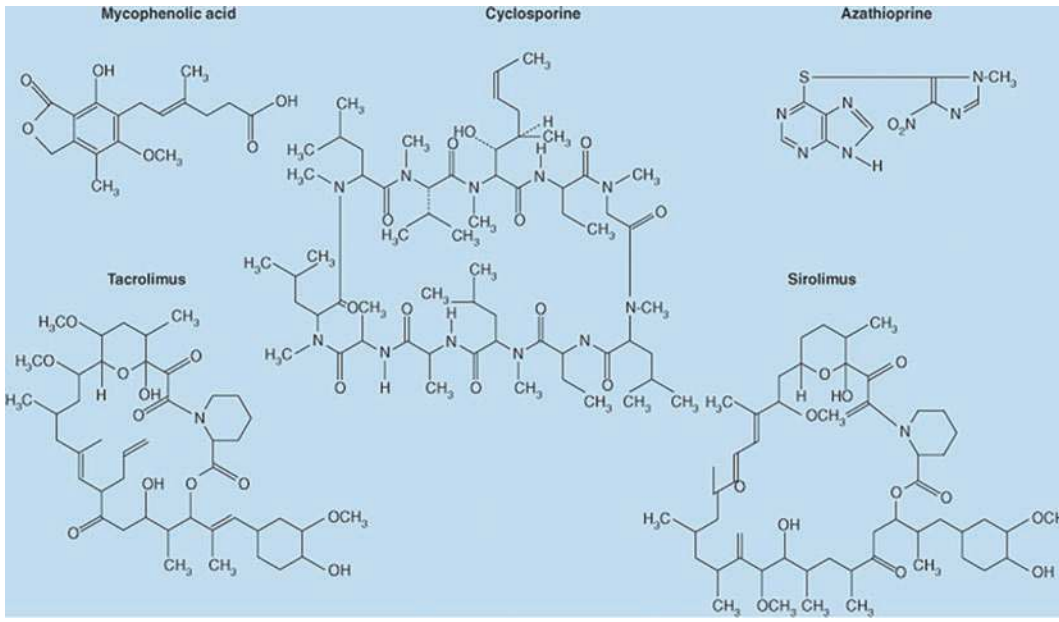

Fig. 67.1 Structure of mycophenolic acid, ciclosporin, azathioprine, tacrolimus, and sirolimus. These are all small molecules with molecular weights of 320, 1203, 277, 804, and 914, respectively. The Immune Response

By the time transplant surgery is completed, the graft has undergone acute injury leading to an increased expression of major histocompatibility complex (MHC) molecules by cells within the graft that are either constitutively expressed (class I, HLA-A and HLA-B) or inducible (class II, HLA-DR) antigens. Injury recruits lymphocytes and antigen-presenting cells (APCs), typically monocytes, macrophages, and dendritic cells from the host. These injury-related events may influence the probability of rejection and thereby contribute to the superior outcome in transplants from live donors (with less injury) vs. those from deceased donors.

Allorecognition of donor MHC molecules may occur either by the direct route (host T cells recognize donor MHC on donor cells) or indirectly (host T cells recognize donor MHC as peptides in the MHC groove of host APCs). T cell receptors (TCR) engaging MHC–peptide complexes provide signal 1. Co-stimulatory signals from the APC engaging receptors on the T cells provide signal 2 (Fig. 67.2) [3]. The major co-stimulatory molecules of the APC are B7–1/B7–2, which bind

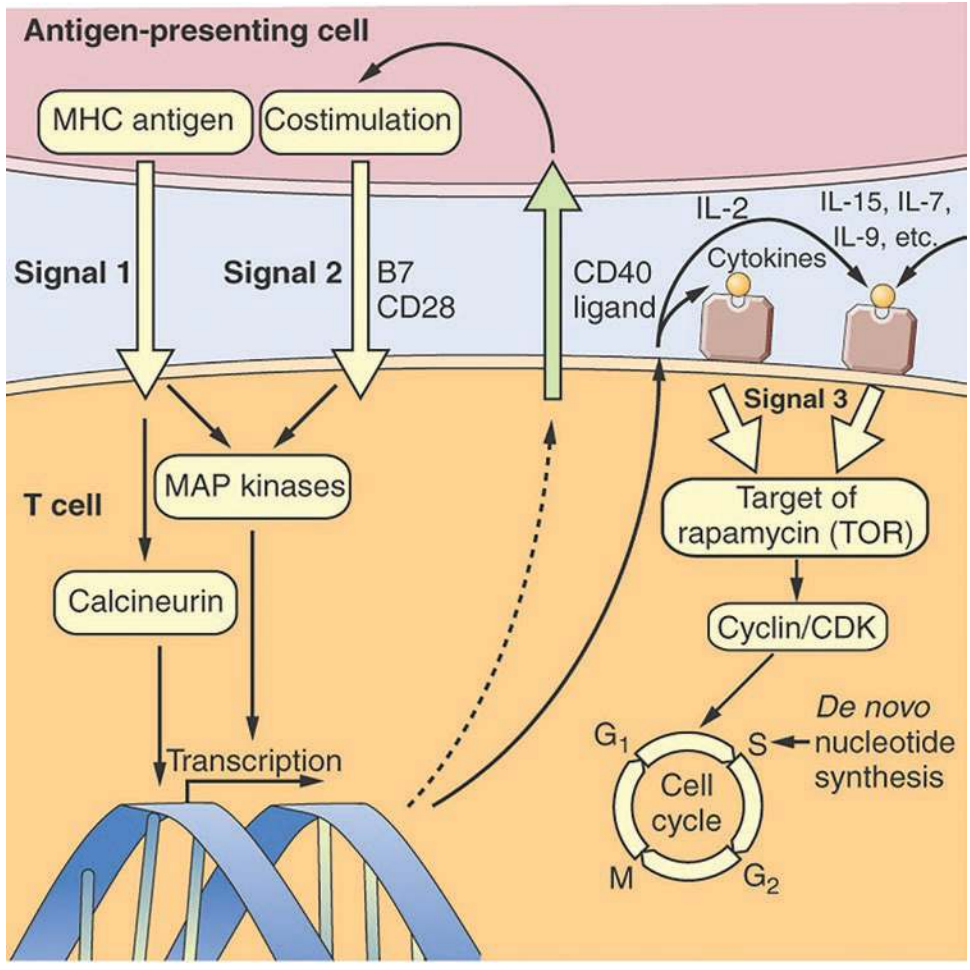

Fig. 67.2 The 3 events in T cell activation. Engagement of the T cell receptor with the antigenic peptide in the context of self–MHC class II molecule leads to the activation of the calcineurin pathway and results in the induction of cytokine genes (e.g., IL–2) (signal 1). Signal 2, the co-stimulatory signal, involves the engagement of CD28 with members of the B7 family. This synergizes with signal 1 to induce cytokine production. Interaction between cytokine production and its corresponding receptor leads to induction of cell division, probably through the target of rapamycin (TOR) pathway. This constitutes signal 3. (Used with permission from Feehally J, Floege J, Johnson RJ (eds.): Comprehensive Clinical Nephrology, 3rd ed. Philadelphia: Mosby, 2007) [3]

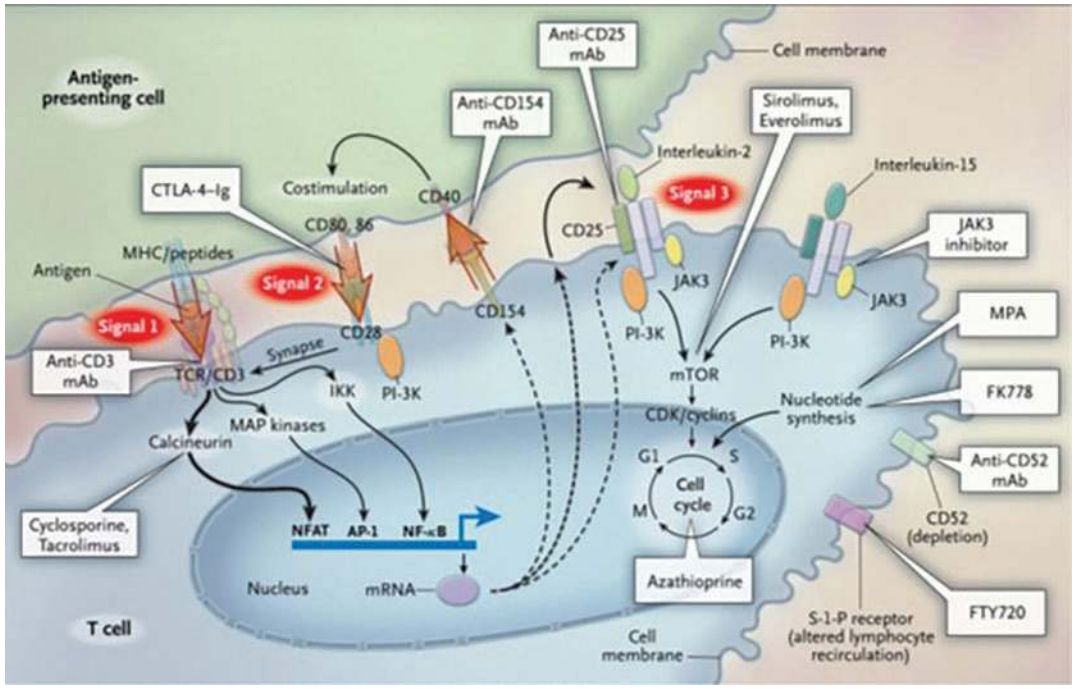

Fig. 67.3 Individual immunosuppressive drugs and sites of action in the 3-signal model. Anti-CD154 antibody has been withdrawn from clinical trials but remains of interest. FTY720 engagement of sphingosine-1-phosphate (S-1-P) receptors triggers and internalizes the receptors and alters lymphocyte recirculation, causing lymphopenia. Antagonists of chemokine receptors (not shown) are also being developed in preclinical models. MPA denotes mycophenolic acid. (Reproduced with permission from [4])

CD28 on the T cells. Activated T cells express CD40L that can activate the APC by engaging CD40 on the APC, and Fas ligand (FasL), which binds Fas on other lymphocytes or other cells to induce apoptosis in the Fas-bearing cell. Activation of signals 1 and 2 is followed by T cell activation with production of many cytokines. Cytokines, such as IL–2, engage specific receptors on the T cells to provide signal 3, the signal for cell division and clonal expansion. The engagement of CD40 by CD40L and the cytokines and growth factors from T cells regulate the T cell response, recruit and activate inflammatory cells, and alter adhesion molecules to cause mononuclear cells to accumulate in the graft. Depending on the type and degree of signaling, full activation of the T cell may occur, or T cells may undergo partial activation, apoptosis, anergy, or neglect (ignoring the antigen). T cells also bind *via* CD40L to CD40 on B cells, thereby directing the switch from IgM to IgG production by B cells and promoting the maturation of IgG-producing B cells.

Chemotactic factors (chemokines) and expression of adhesion proteins and foreign (MHC) antigens mediate localization (homing) of CD4 and CD8 T cells to the graft endothelium. Lymphocyte recirculation depends on the ability to enter and leave lymphoid tissue. CD8 T cells that recognize peptide in the groove of class I MHC become cytotoxic T cells (CTL). Graft rejection is associated with infiltration by cytotoxic CD8 lymphocytes. Delayed type hypersensitivity may also be involved in T cell-mediated damage. Antibody-mediated injury may also occur and causes damage to endothelium. A summary of the effects of immunosuppressive drugs is presented in Fig. 67.3 [3].

Classification of Immunosuppressive Agents

Immunosuppressive and immunomodulatory drugs can be pharmacologically categorized on the basis of their mechanism of action. The 3-signal

model of T cell activation and proliferation is helpful in understanding the molecular mechanisms and site of action of various immunosuppressive drugs. Figure 67.3 depicts a schematic representation of the 3-signal model along with the site of action of common immunosuppressive drugs [4]. Signal 1 features APCs (macrophages and dendritic cells) presenting the foreign antigen to the T lymphocyte, activating the TCR, which further relays the signal through the transduction apparatus known as the CD3 complex. Signal 2 is a non-antigen-specific co-stimulatory signal which occurs as a result of binding of the B7 molecule on the APC to CD28 on the T cell. Both signal 1 and signal 2 activate signal transduction pathways: the calcium–calcineurin pathway, mitogen-activated protein (MAP) pathway, and the nuclear factor-κB (NF-κB) pathway. This in turn leads to increased expression of IL-2, which through its receptor (IL-2R) activates the cell cycle (signal 3). Signal 3 activation requires the enzyme mTOR for translation of mRNA and cell proliferation. Thus, various drugs act on different cellular signals and achieve immunosuppression by a number of mechanisms: depleting lymphocytes, diverting lymphocyte traffic, or blocking lymphocyte response pathways.

Induction Immunosuppressive Therapy

Induction refers to the administration of an intensive immunosuppressive regimen during the perioperative period. The rationale behind this approach is that the risk of acute rejection is greatest in the first weeks and months after transplantation. Induction therapies often involve the use of polyclonal or monoclonal antibodies to achieve rapid and profound early immunosuppression. Polyclonal antibodies used for this purpose include those against thymocytes (e.g., commercially available rabbit or equine preparations); monoclonal antibodies include basiliximab (a chimeric human–murine anti-CD25 or anti–IL-2R antibody) and alemtuzumab (an anti-CD52 antibody targeting both B and T cells), which is not always readily available.

A number of trials have been and are being conducted in adult and pediatric renal transplant recipients to look into the effects of prophylactic antibody induction therapies. Evaluation of any induction protocol requires consideration of the following factors: (i) Incidence and severity of delayed allograft function or primary non-function, including post-transplant dialysis requirements; (ii) incidence of acute rejection; (iii) incidence, type, and severity of associated infections; (iv) long-term allograft survival and function; (v) mortality and morbidity, including length of hospitalization, (vi) cost, and (vii) incidence and type of malignancy during long-term follow-up. Several studies from single centers and registries, as well as meta-analyses, have found that induction with antibodies may be superior to non-antibody-based regimens, especially in high-risk groups [5]. Unfortunately, most if not all published studies have addressed only some of the above issues. As a result, although each protocol may have specific advantages and disadvantages in a particular patient population, none is yet proven to be superior when all the above factors are considered. The optimal prophylactic induction immunosuppressive therapy to prevent renal transplant rejection remains therefore controversial. Figure 67.4 presents the induction antibody use from 2007–2018, as reported in the Scientific Registry of Renal Transplant Recipients (SRTR) 2018 annual report, indicating that administration of ATG has increased while that of anti-IL-2R and no induction have decreased over time. This is in contrast to reports from the Cooperative European Paediatric Renal Transplant Initiative (CERTAIN) Registry showing that 60% of pediatric kidney transplant recipients in Europe do not receive any induction therapy, 35% receive basiliximab and 5% ATG [6]. Hence, the frequency and type of the chosen immunosuppressive anti-lymphocyte regimens for induction therapy vary markedly between North America and Europe and probably reflect differences in patient characteristics and estimated immunological risk, but is unfortunately not based on comprehensive clinical trials.

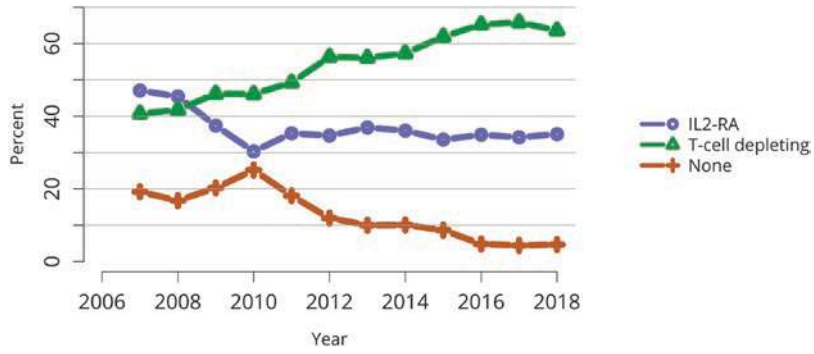

Fig. 67.4 Induction agent use in pediatric kidney transplant recipients in the United States of America. Immunosuppression at transplant reported to the Organ Procurement and Transplantation Network (OPTN) (https://pubmed.ncbi.nlm.nih.gov/31898417). IL2-RA, interleukin-2 receptor antagonist

In fact, induction therapy produces the greatest benefits in groups at high risk of allograft rejection. These high-risk groups include African-Americans, recipients of kidneys with prolonged cold ischemia time, and those at high immunologic risk, particularly individuals who are presensitized. The sequential induction regimen of thymoglobulin followed by a combination of TAC and MMF with or without steroids is recommended in these high-risk groups.

Lymphocyte Depleting Antibodies

Polyclonal Antibodies

Because of the redundancy of the immune system, polyclonal antibodies, which have a broad specificity, should theoretically be more effective in induction therapy than monoclonal anti-lymphocyte agents. Anti-thymocyte globulin (ATGAM) is a purified gamma globulin solution obtained by immunization of horses with human thymocytes. It contains antibodies to a wide variety of human T cell surface antigens, including the major MHC antigens. Thymoglobulin is a rabbit-derived polyclonal antibody preparation approved for the treatment of rejection and induction therapy by the US Federal Drug Administration (FDA). As for ATGAM, thymoglobulin contains antibodies to a wide variety of T cell antigens and MHC antigens.

Polyclonal antibodies act in 3 ways: by activating or altering the function of lymphocytes, by lysing lymphoid cells, and by altering the traffic of lymphoid cells and sequestering them. These antibodies are potently immunosuppressive, but often produce side effects. By triggering T cells, they generate significant first-dose effects, with the release of tumor necrosis factor alpha (TNFα), interferon γ (IFN-γ), and other cytokines, causing a first-dose reaction (flu-like syndrome, fever, and chills).

Dosage of Thymoglobulin

Thymoglobulin induction is usually dosed from 1 to 6 mg/kg per dose, and the duration may range from 1 to 10 days, although a more typical regimen is 1.5 mg/kg per dose for 3–5 days [7–10]. In animal models, higher initial doses of shorter duration approximating a human-equivalent dose of 6 mg/kg were associated with more peripheral and central lymphocyte depletion and better allograft survival [11]. Based on these models, the optimal induction dose is felt to total 6 mg/kg [9, 12]. Total doses of 5.7 mg/kg, on average given as 1.5 mg/kg per day, have been shown to produce similar outcomes as higher doses in high-risk recipients who received an average of 10.3 mg/kg [10]. Higher

doses and prolonged duration of induction agents are thought to be associated with an increased risk of infection and the potential development of lymphoma, whereas cumulative doses of less than 3 mg/kg may not effectively prevent acute rejection [13].

Efficacy and Safety

Few studies have compared the relative efficacy of thymoglobulin and ATGAM for induction therapy. In one study in adult renal transplant recipients, 72 patients were randomly assigned in a double-blind 2:1 fashion to receive intravenous doses of thymoglobulin at 1.5 mg/kg or ATGAM at 15 mg/kg intra-operatively, then daily for at least 6 days [14]. The delayed graft function rate was only 1 percent for both groups. At 1 year, the thymoglobulin group had a significantly lower acute rejection rate (4% vs. 25%, respectively) and higher allograft survival (98% vs. 83%). The lower rejection rate was thought to be due in part to a more sustained lymphopenia with thymoglobulin, while the exceptionally low delayed graft function rate seen in both groups may have been due to the intra-operative use of the ATGs. Both antibodies have the ability to block a number of adhesion molecules, cytokines, chemokines, and their receptors, which may contribute to ischemia reperfusion injury and delayed graft function. At 5 years, allograft survival was significantly better in the thymoglobulin arm (77% vs. 57%, respectively) [15]. Two cases of post-transplant lymphoproliferative disorder (PTLD) developed with ATGAM, while none were observed with thymoglobulin. The mean 5-year serum creatinine concentration was similar in both groups.

In pediatric renal transplant recipients, a historical cohort study compared the rates of survival, rejection, and infection in patients who received induction therapy with ATGAM (n = 127) or thymoglobulin (n = 71) [16]. Maintenance immunosuppression included CSA, AZA or MMF, and prednisone. Mean follow-up was 90 ± 25 months for ATGAM recipients and 32 ± 15 months for thymoglobulin recipients. Overall, the incidence of acute rejection was lower in thymoglobulin recipients vs. ATGAM recipients (33% vs. 50%, P = 0.02). Epstein-Barr virus (EBV) infection was higher in thymoglobulin recipients versus ATGAM recipients (8% vs. 3%, P = 0.002). But the two groups did not significantly differ in patient and graft survival rates, incidence of chronic rejection, EBV lymphoma, or other infections. The authors concluded that thymoglobulin induction was associated with a reduced incidence of acute rejection and an increased incidence of EBV infection in pediatric renal transplant recipients.

IL-2 Receptor Antibodies

Full T cell activation leads to the calcineurin-mediated stimulation of the transcription, translation, and secretion of IL-2, a key autocrine growth factor that induces T cell proliferation. Thus, an attractive therapeutic option is abrogation of IL-2 activity via the administration of anti-IL-2R antibodies. Currently, only basiliximab, a chimeric monoclonal antibody, is commercially available and has been approved by the FDA for use in renal transplantation in adults and pediatric patients (Fig. 67.5). The IL-2R consists of 3 transmembrane protein chains: CD25, CD122, and CD132. CD25 is present on nearly all activated T cells, but not on resting T cells. IL-2 induces clonal expansion of activated T cells. Although CD25 does not transduce the signal, it is responsible for the association of IL-2 with the β- and γ-chains, which triggers the activated T cell to undergo rapid proliferation. This antibody binds to activated T cells and render them resistant to IL-2 by blocking, shedding or internalizing the receptor; it may also deplete and sequester some activated T cells. However, IL-2R functions are partially redundant because other cytokine receptors have overlapping functions, e.g., IL-15R. Therefore, saturating IL-2R produces stable, but relatively mild immunosuppression, and is only effective in combination with other immunosuppressants.

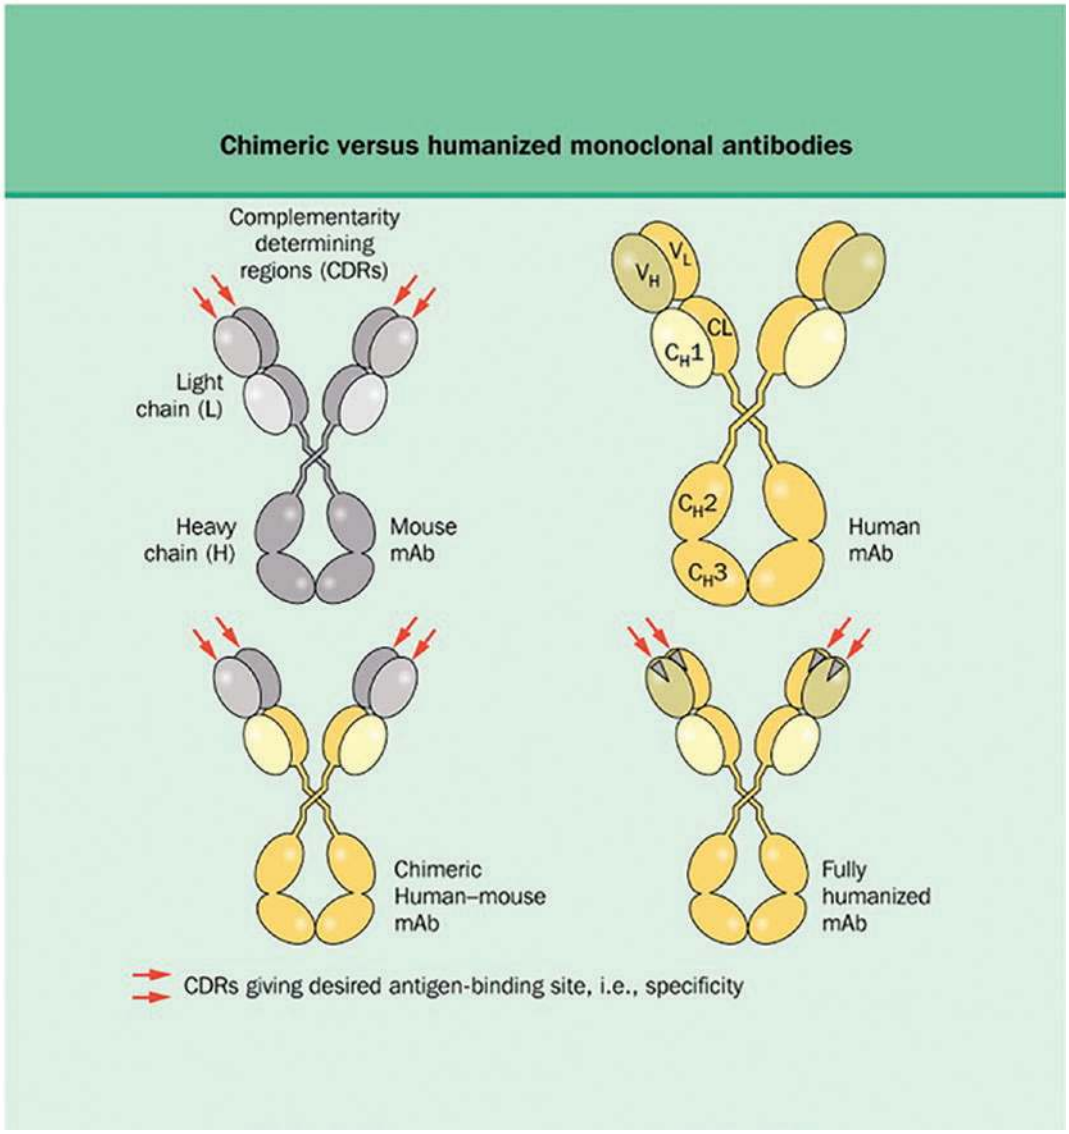

Fig. 67.5 Chimeric vs. humanized monoclonal antibodies. (Used with permission from Feehally J, Floege J, Johnson RJ (eds.): Comprehensive Clinical Nephrology, 3rd ed. Philadelphia: Mosby, 2007) [3]

Dosage of Basiliximab

The dosing schedule for basiliximab is the following: intravenous administration of two 10 mg doses to children <35 kg in weight and two 20 mg doses to children ≥35 kg in weight, with the first dose given within 2 h prior to surgery, and the second on post-transplant day 4. In the 14 patients who were evaluated for the pharmacokinetics and pharmacodynamics of basiliximab and received concomitant immunosuppression with CSA and AZA, the mean duration of IL-2R saturation was 42 ± 16 days [17]. In a larger study of 82 patients who received basiliximab in combination with MMF, MMF reduced basiliximab clearance and thereby prolonged CD25 saturation from 5 to 10 weeks [18].

Efficacy and Safety

The effectiveness of IL-2R antibody therapy was best reported in a meta-analysis involving 38 tri-

als that enrolled nearly 5000 patients that assessed the impact of therapy on allograft loss and rejection [19]. Data were derived from published trials and abstracts of completed and ongoing trials. From these 38 trials, 14 trials enrolling 2410 patients compared IL-2R antagonists with placebo for at least one outcome. Compared with placebo, IL-2R antagonists reduced acute rejection rates at 6 months (relative risk [RR 0.66], CI 0.59–0.74) and 1 year (RR 0.67, CI 0.60–0.75), but the incidence of graft loss was the same.

In pediatric renal transplant recipients, two large prospective randomized controlled trials showed that induction therapy with basiliximab in patients with low to medium immunological risk on maintenance therapy (TAC in conjunction with AZA, or CSA in conjunction with MMF) did not lead to a statistically significant reduction in the incidence of acute rejection episodes [20, 21]. As a result, there is presently no consensus amongst pediatric renal transplantation centers regarding the use of and regimen for immunosuppressive induction therapy. Considerations in choosing the appropriate agent include the efficacy in the patient population (e.g., recipients with high or low risk of graft loss), the side effect profile, and the concomitant immunosuppressive therapy (steroid avoidance, early steroid withdrawal, or conventional steroid therapy).

Comparison of Basiliximab with Thymoglobulin

Few studies have compared the use of different induction immunosuppressive regimens. In adult patients at increased risk of acute rejection, thymoglobulin is more effective than basiliximab in preventing rejection [22–25]. A multicenter, international, randomized, prospective study of 278 first deceased-donor kidney transplant recipients compared the safety and efficacy of a 5-day course of thymoglobulin (n = 141) or 2 doses of basiliximab (n = 137) [26]. Recipients and donors were chosen based upon characteristics that would predict an increased risk of rejection or delayed graft function. Patients in both arms were administered CSA, MMF, and prednisone for maintenance immunosuppression, and received antiviral prophylaxis with ganciclovir. The primary endpoint was a composite of acute rejection, delayed allograft function, transplant loss, and death. At 1 year, there was no difference between thymoglobulin and basiliximab in the incidence of the composite endpoint. However, thymoglobulin was associated with a significantly lower acute rejection rate (16% vs. 26%), and incidence of acute rejection that required antibody treatment (1.4% vs. 8%). Although overall adverse event and serious adverse event rates were similar, thymoglobulin was associated with a higher incidence of infection (86% vs. 75%), but lower incidence of cytomegalovirus (CMV) disease (8% vs. 18%).

At 5-year follow-up, the incidence of acute rejection and need for antibody treatment of acute rejection remained lower among those treated with thymoglobulin, compared with basiliximab (16% vs. 30% and 3% vs. 12%, respectively) [22]. Patients treated with thymoglobulin also had a significantly lower composite endpoint of acute rejection, graft loss, and death at 5 years (39% vs. 52%) and incidence of treated CMV infection (7% vs. 17%); however, the incidence of malignancy did not differ. Hence, the relative benefits of thymoglobulin were sustained over a 5-year period.

Alemtuzumab

Alemtuzumab (Campath-1H, MabCampath) is a humanized IgG1 monoclonal antibody directed against CD52, a glycoprotein expressed on mononuclear cells, including T and B lymphocytes, monocytes, and natural killer cells [23]. Its efficacy for induction and maintenance immunosuppression with low-dose calcineurin inhibitors (CNIs) was first introduced by Calne et al. [24] and later supported by the Pittsburgh group [25] in adults and children. Alemtuzumab induction has been associated with lower rates of acute rejection than basiliximab and daclizumab in low immunological risk patients and was associated with similar efficacy as compared with rabbit anti-thymocyte globulin in high-risk patients [26]. Although most of these studies have involved adult kidney transplant recipients, there is also pediatric experience that supports this efficacy claim, especially in highly sensitized, high-risk children [27, 28]. A significant

reduction of white blood cell and absolute lymphocyte counts, up to 1 year post-transplant, has been observed in children receiving alemtuzumab treatment [29].There is no currently recommended dose for children, but 0.3 mg/kg per dose has been most frequently used in pediatric studies [30]. The most common number of doses administered was 2 doses, with a range from 1 to 4 doses during the first week post-transplant. Due to infusion-related reactions, pre-medication with methylprednisolone, acetaminophen, and diphenhydramine is recommended in addition to administration of anti-emetics to avoid nausea and vomiting. The major side effect that limits the use of alemtuzumab is profound lymphopenia, which may contribute to significant adverse events, including infections, autoimmune complications, and malignancies [30]. The Cooperative Clinical Trials in Pediatric Transplantation program of the National Institute of Allergy and Infectious Disease has completed a multicenter pilot trial of alemtuzumab induction in pediatric kidney transplant recipients with initial maintenance immunosuppression of TAC and MMF, but the results have yet to be published.

Recommendations

There is currently no consensus for immunosuppressive induction therapy following kidney transplantation in children. At the present time, no consistent evidence exists that induction therapy is beneficial or cost-effective in low-risk patients on triple therapy with CNIs in conventional doses, MMF and steroids. According to 2 prospective, randomized, controlled trials, induction therapy with basiliximab in pediatric patients with low or normal immunological risk on maintenance therapy with either TAC in conjunction with AZA or CSA in combination with MMF did not lead to a statistically significant reduction in the incidence of acute rejection episodes [20, 21]. In contrast, the Kidney Disease: Improving Global Outcomes clinical practice guidelines recommend induction therapy for all adult patients, with an IL-2R blocker as first line for those not at high immunological risk [31]. There is some evidence favoring the use of IL-2R blockers over no induction in adult renal transplantation [32]. However, it has been pointed out in the more recent literature that these studies mainly used outdated maintenance regimens [33]. No large randomized trial has examined the effect of IL-2R antibodies or rabbit ATG induction vs. no induction in patients receiving TAC, mycophenolic acid (MPA) and steroids. With this triple maintenance therapy, the addition of induction may achieve an absolute risk reduction for acute rejection of only 1–4% in standard-risk patients without improving renal allograft or patient survival. In contrast, rabbit ATG induction lowers the relative risk of acute rejection by almost 50% vs. IL-2R antibodies in patients with high immunological risk. These recent data raise questions about the need for IL-2R antibodies in kidney transplantation, as it may no longer be beneficial in standard-risk transplantation. Although augmentation of immunosuppression by IL-2R antibody induction may allow steroid minimization, it may be inferior to rabbit ATG in high-risk situations. Updated evidence-based guidelines are necessary to support clinicians deciding whether and what induction therapy is required for their transplant patients today [33]. Studies in the US and Europe have investigated the potential of IL-2R antibodies or thymoglobulin in replacement of steroids with promising results (see section in this chapter on “Steroid Withdrawal or Avoidance”). Another potential application is delayed graft function when the use of CNIs should be avoided.

Maintenance Immunosuppressive Therapy

Maintenance immunosuppressive therapy is administered to kidney transplant recipients for prevention of acute rejection. Although an adequate level of immunosuppression is required to dampen the immune response to the allograft, the level of chronic immunosuppression is slowly decreased over time to help lower the overall risk of infection and malignancy. The type of immunosuppression may also be modified to decrease the risk of developing chronic antibody-mediated rejection, the most common underlying long-term cause of allograft loss.

Conventional maintenance regimens consist of a combination of immunosuppressive agents that differ in their mechanism of action. This strategy minimizes morbidity and mortality associated with each class of agent while maximizing overall effectiveness. Such regimens vary by transplant center and geographic area. There are a number of important issues to consider when deciding upon the immunosuppressive protocol to administer in a particular patient. First, the risk of acute rejection and allograft loss is highest in the first 3 months post-transplant. As a result, immunosuppression should be at its highest during this period (see section in this chapter on "Induction Immunosuppressive Therapy"). Second, the occurrence of the most serious side effects of immunosuppressive therapy, infections and malignancy, correlate with the total amount of immunosuppression. It is therefore essential that immunosuppression is gradually tapered to a maintenance level by 6–12 months post-transplant.

Allograft survival rates vary among the various immunosuppressive agents due to patient-specific clinical characteristics and co-morbidities, such as age, ethnicity, obesity, hyperlipidemia, hypertension, proteinuria, and/or delayed allograft function. The choice of immunosuppression should consider these factors, but also take into account the "immunologic" history of the patient. Transplant physicians must reflect the following questions: Is the patient sensitized? Is this the first kidney transplant or a re-transplant? How many acute rejection episodes has the patient had? What is the degree of HLA matching?

The optimal maintenance immunosuppressive therapy in pediatric kidney transplantation is not established. The major immunosuppressive agents currently used in various combination regimens are TAC, CSA (in standard form or microemulsion), MMF, EVR, SRL, AZA and steroids (primarily oral prednisone or methylprednisolone). We and most transplant centers currently utilize a maintenance regimen consisting of triple immunosuppression therapy with a CNI (TAC or CSA), an anti-metabolite (MMF or AZA), and methylprednisolone. EVR or SRL are also used by some transplant centers in triple therapy regimens, often in place of the CNI or the antimetabolite. Within the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) registry, marked changes in the type of maintenance immunosuppression and dosing strategies have been observed over time [34]. These are substantially caused by the introduction of newer drugs such as MMF and TAC. In the transplant era 2008–2017, the most popular immunosuppressive regimen at post-transplant day 30, utilized in 48.9% of patients, was triple therapy with TAC, MMF and prednisone (Table 67.1).

Glucocorticoids

Glucocorticoids, developed in the early 1950s, represent one of the principal agents used for both maintenance immunosuppression and treatment of acute rejection.

Mechanism of Action

Steroids have both anti-inflammatory and immunosuppressive actions [35]. Lymphopenia and monocytopenia occur with the inhibition of lymphocyte proliferation, survival, activation, homing, and effector functions. Steroids suppress production of MHC molecules and numerous cytokines and vasoactive substances, including IL-1, TNFα, IL-2, chemokines, prostaglandins (*via* inhibition of phospholipase A2), and proteases. Steroids also cause neutrophilia (often with a left shift), but neutrophil chemotaxis and adhesion are inhibited. They also affect non-hematopoietic cells.

Steroids exert their effect by binding to glucocorticoid receptors (GR), which belong to a family of ligand-regulated transcription factors called nuclear receptors. GR are normally present in the cytoplasm in an inactive complex with heat shock proteins (hsp90, hsp70, and hsp56). The binding of steroids to the GR dissociates hsp from the GR and forms the active steroid–GR complex, which migrates to the nucleus and dimerizes on palindromic DNA sequences, called the glucocorticoid response element (GRE), in many genes. The binding of GR in the promoter region of the target genes can lead to either induction or suppression of gene transcription (e.g., of cytokines). GR also exert effects by interacting directly with other transcription factors independent of DNA binding. One principal effect of steroids on immune and inflammatory responses may be attributable to their ability to affect gene transcription by regulating key transcription factors involved in immune regulation: activator protein-1 (AP-1) and NF-κB. The regulation of NF-κB by steroids may be via induction of IkB, the inhibitor of NF-κB. Other effects of steroids are mediated through the release of a regulatory protein, lipocortin, which inhibits phospholipase A2, thereby inhibiting the production of leukotrienes and prostaglandins. The total immunosuppressive effect of steroids is complex, reflecting effects on cytokines, adhesion molecules, apoptosis, and activation of inflammatory cells.

Pharmacokinetics and Drug Interactions

The major steroids used are prednisone or prednisolone (given orally with comparable efficacy) and methylprednisolone (given orally or intravenously with 25% more potency). These agents are rapidly absorbed and have short plasma half-lives (60–180 min), but long biological half-lives (18–36 h). The effect of prednisone (dose per body weight) is greater in the setting of renal failure or hypalbuminemia, in women, and in the elderly, but less prednisone effect is observed in children. Certain drugs can decrease steroid efficacy by increasing metabolism: rifampicin, phenytoin, phenobarbital, and carbamazepine. In contrast, increased steroid effects may be observed in patients receiving oral contraceptives, estrogens, ketoconazole, and erythromycin.

Administration

In many transplant centers, the initial dose of steroids is usually administered during surgery as intravenous methylprednisolone, at doses between 2 and 10 mg/kg body weight. The oral dose of steroids used for maintenance therapy varies between 15 and 60 mg/m^2 per day (0.5–2 mg/kg body weight per day), which is gradually tapered over time to approximately 3–5 mg prednisone per m^2 body surface area, usually taken as a single morning dose. Alternate-day dosing is often administered 6–12 months post-transplant to minimize the effect of steroids on growth.

Side Effects

Steroids have multiple side effects in children, including growth impairment, susceptibility to infections, cushingoid appearance, body disfigurement, acne, cardiovascular complications, hypertension, hyperglycemia, aseptic bone necrosis, osteopenia, cataracts, poor wound healing, and psychological effects (Table 67.2). negative impact that steroids have on appearance may play a role for poor adherence, especially in the body image conscious adolescent. The risk for infection is excessive if high-dose pulse therapy is prolonged (typically >3 g per 1.73 m^2). Steroids dosage should therefore be decreased gradually during rejection treatment even if serum creatinine fails to improve. Interestingly, steroids are not associated with an increased risk of malignancy. One of the most important reasons for stopping steroids or switching to alternate-day therapy is statural growth impairment, which is frequently observed in those on continuous treatment.

Steroid Withdrawal or Avoidance

Because of the multiple adverse effects of maintenance steroid therapy, attempts have been made to withdraw or minimize steroid therapy in children with a renal allograft [36–40]. There are two major strategies in steroid minimization in pediatric kidney transplantation: (i) *Late steroid withdrawal* (>1 year post-transplantation) and (ii) either *complete steroid avoidance* or *early steroid withdrawal* (<7 days post-transplantation). In the *late steroid withdrawal* approach, the patients suitable for minimization are identified by a stable post-transplant clinical course and renal function. In *late steroid withdrawal*, there is no need for an antibody induction in the perioperative period [41]. In *early withdrawal or complete avoidance* protocols, the criteria of suitability are predefined before transplantation (e.g., low immunological risk), and antibody induction is used in all patients [42–47]. There is also an *intermediate* approach, combining elements from *early and late withdrawal* protocols, in which antibody induction is used; however, the decision of *steroid withdrawal* is delayed until 6–9 months post-transplant, when stable renal graft function (sometimes combined with a normal protocol biopsy) allows identification of suitable candidates (as in the late withdrawal approach) [48]. *Steroid withdrawal* has the advantage over *steroid avoidance* that immunologically high-risk patients and those with unstable graft function

can easily be identified beforehand and be excluded from steroid-free immunosuppression.

Late steroid withdrawal without induction therapy was investigated in a trial of 42 patients with low immunologic risk who were maintained on CSA, MMF, and steroids. At 1 year post-transplant, patients were randomly assigned to either steroid continuation or withdrawal over a 3-month period [40]. At 1 year follow-up, the steroid withdrawal group had increased catch-up growth, lower arterial blood pressure, and a better carbohydrate and lipid profile than those on continuous steroid therapy. In a subsequent follow-up report, longitudinal growth in the steroid withdrawal group continued to be superior to controls; catch-up growth was especially pronounced in pre-pubertal patients off steroids (Fig. 67.6) [41]. Although the relative height gain after steroid withdrawal was less pronounced in pubertal patients, they still benefited from cessation of steroid treatment. Also, the prevalence of the metabolic syndrome declined in the withdrawal group from 39% at baseline to 6% 2 years after discontinuing steroid therapy [41]. Allograft function remained stable in the withdrawal group compared with controls, and the incidence of acute rejections was similar in the steroid withdrawal and control groups (4% vs. 11%, respectively). An earlier retrospective case–control study had reported a beneficial effect of *late ste-*

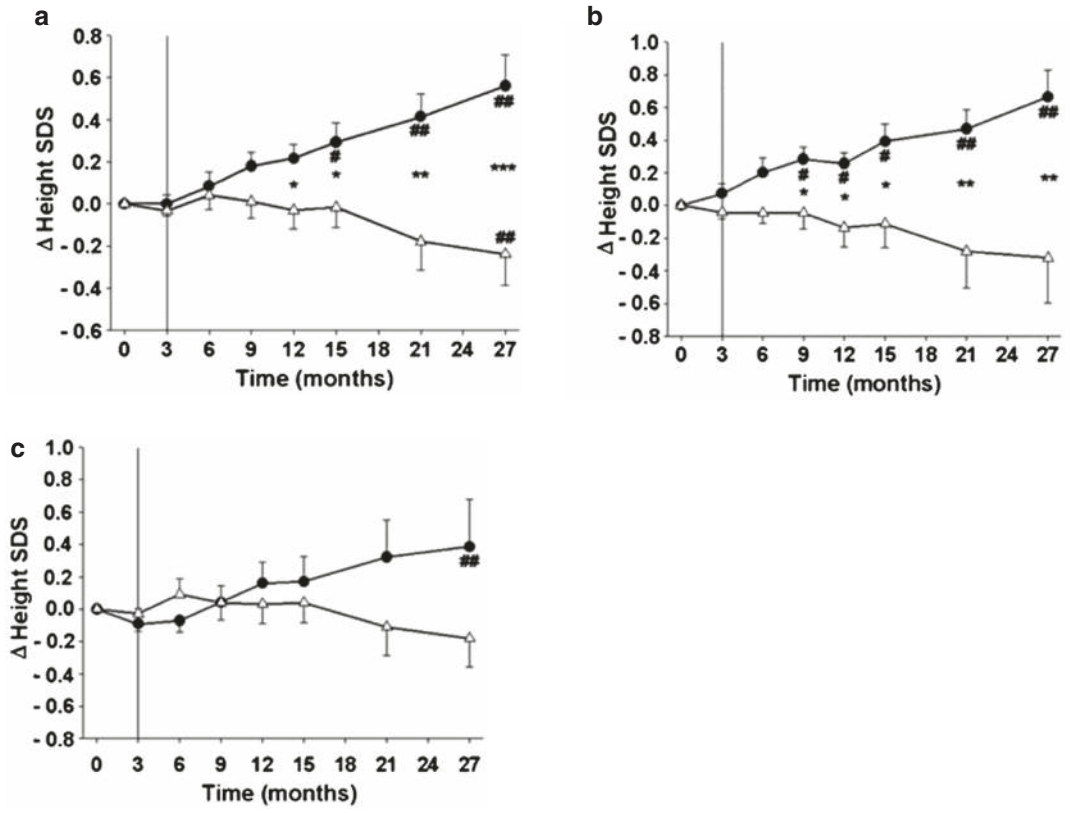

Fig. 67.6 Randomized controlled trial on late steroid withdrawal: Change of height SDS (mean ± SEM) in the steroid withdrawal group (filled circles) and the control group (open triangles) during the 27-month study period. Panel A, all patients; panel B, pre-pubertal patients; panel C, pubertal patients. ∗P < 0.05 vs. control; ∗∗P < 0.01 vs. control; ∗∗∗P < 0.001 vs. control; #P < 0.05 vs. baseline; ##P < 0.01 vs. baseline. Improved growth and cardiovascular risk after late steroid withdrawal: 2-year results of a prospective, randomized trial in paediatric renal transplantation. Nephrol Dial Transplant 2010; 25:617–624) [41]

roid withdrawal (mean time 1.5 ± 1.3 years post-transplant) on growth in similarly treated (pre-pubertal) children. The patients in this study who had steroids withdrawn also had better blood pressure control with a lower requirement for antihypertensive therapy [49].

More recently, a single-center study has reported on efficacy and safety of a different regimen combining the *intermediate withdrawal of steroids* (>6 months and <1 year) with minimization of exposure to CSA. The protocol initially included a 2-dose basiliximab induction, standard exposure to CSA (C_0 150–200 μg/L) and prednisolone. This was followed by adding EVR at 2 weeks (C_0 4–6 μg/L), reducing CSA exposure by half (C_0 75–100 μg/L), and then steroid withdrawal at 9 months in patients with a normal protocol biopsy. Results of the open-label uncontrolled trial have been promising, without acute rejection and a 100% 3-year graft survival [48, 50–52], while another study on *intermediate steroid withdrawal* (2 doses of basiliximab and sequential replacement of tapered steroids with MMF at 6 months post-transplant under protocol biopsy) reported an acute rejection rate of 13% [53]. Another *intermediate steroid withdrawal* protocol was used in a US multicenter trial, during which patients received 2 doses of basiliximab, combined with SRL, TAC or CSA, and steroids. After 6 months and a protocol biopsy without signs of rejection, patients were randomized to withdraw or maintain steroids [37]. It should be noted that during the first phase of the trial (prior to randomization) 6.9% of the patients developed PTLD. This was mainly seen in young EBV-naïve children, receiving an EBV-seropositive renal allograft; however, this complication should not be regarded as directly related to steroid minimization but rather to initial over-immunosuppression [53].

Early steroid withdrawal or s*teroid avoidance* may eventually be found to provide the best overall risk-to-benefit ratio with maintenance immunosuppressive therapy in renal transplantation. *Early steroid withdrawal* or *steroid avoidance* protocols have been used successfully and have undergone extensive evaluation both in the US and in Europe. However, many of these protocols have chosen low-risk individuals and utilized intensive induction therapy with extended daclizumab induction therapy or thymoglobulin, TAC, and MMF [42]. A randomized, controlled study in 196 pediatric kidney transplant recipients investigated the efficacy and safety of *early steroid withdrawal*. Two doses of daclizumab in patients treated with a regimen of TAC and MMF allowed *early steroid withdrawal* on day 5 post-transplant [45]. There was a comparable rate of biopsy-proven acute rejection after 6 months in patients off steroids compared with controls (10.2% vs. 7.1%). In addition, pre-pubertal patients with *early steroid withdrawal* showed better growth and lipid and glucose metabolism profiles compared to controls, without increases in graft loss. These favorable effects were confirmed in a follow-up study over a 2-year observation period [54]. The *steroid avoidance* strategy was examined in a North American, randomized, controlled, multicenter study [55]. One hundred thirty children receiving primary kidney transplants were randomized to steroid-free or steroid-based immunosuppression, with concomitant TAC, MMF and standard dose daclizumab (steroid-based group) or extended dose daclizumab (steroid-free group). Follow-up was 3 years post-transplant. Recipients under 5 years of age showed improved linear growth under a steroid-free regimen compared to controls on steroids. No differences in the rates of biopsy-proven acute rejection were observed at 3 years post-transplant (16.7% in steroid-free vs.17.1% in steroid-based; P = 0.94). Patient survival was 100% in both arms; graft survival was 95% in the steroid-free and 90% in the steroid-based arms (P = 0.30) at 3 years follow-up. Over the 3-year follow-up period, the steroid-free group had lower systolic blood pressure (P = 0.017) and cholesterol levels (P = 0.034) (Fig. 67.7). The authors concluded that *complete steroid avoidance* is safe and effective in unsensitized children receiving primary kidney transplants [55].

Despite these encouraging results, *steroid withdrawal* or *avoidance* following kidney transplantation remains a controversial issue. Although the benefits of using steroid-free protocols in pediatric patients are obvious, they may increase

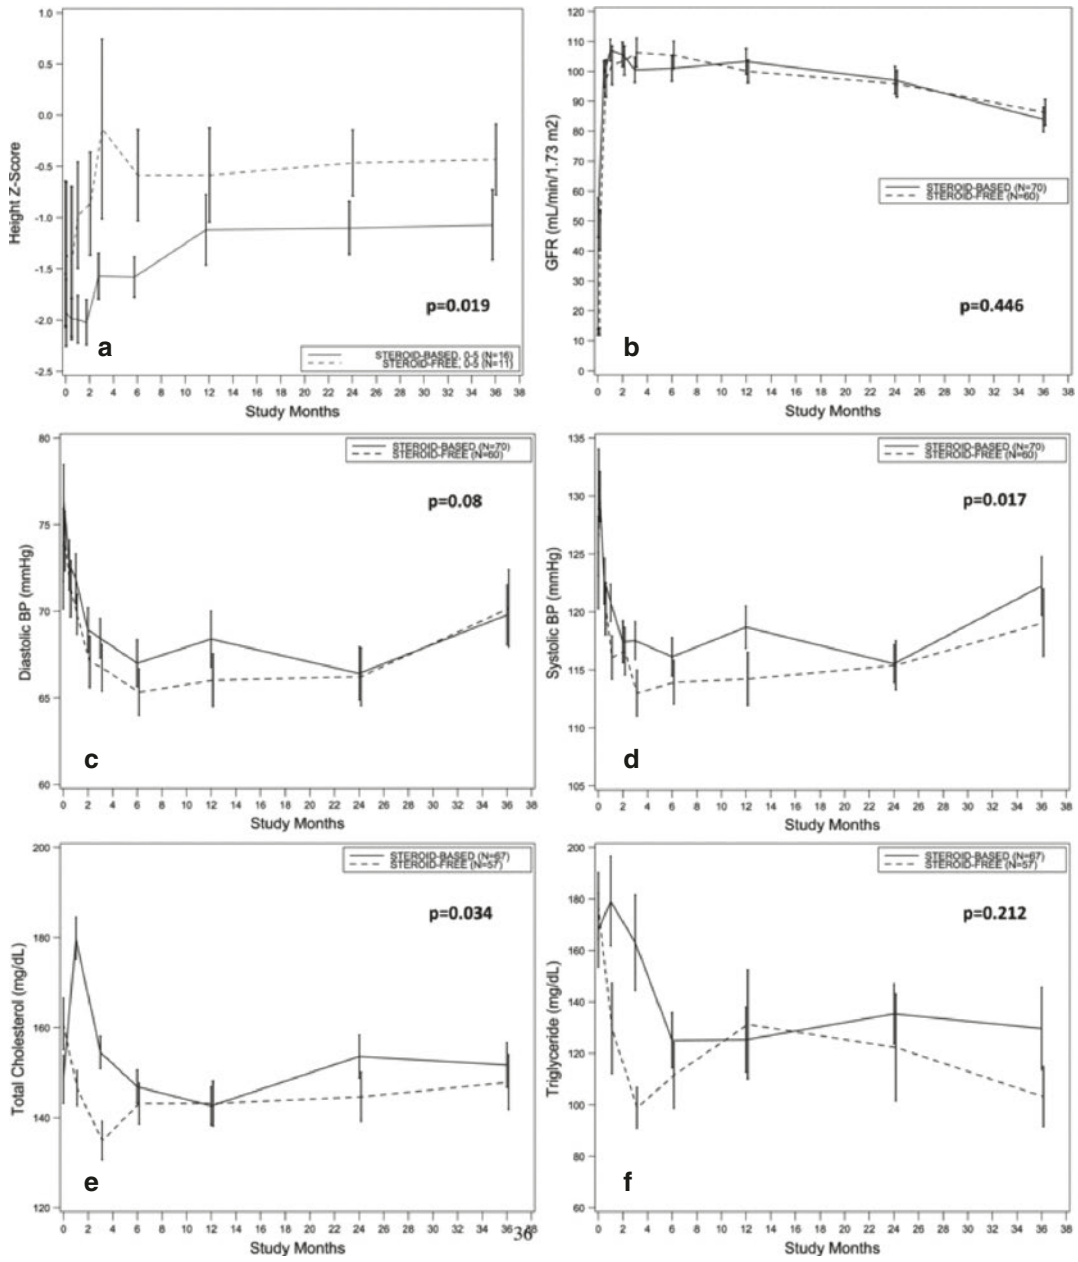

Fig. 67.7 North American randomized controlled multicenter study on steroid avoidance: Estimated group mean standardized change in growth (Z-score) among infants and young children (**a**), mean eGFR level (by Schwartz method) (**b**), mean diastolic (**c**) and systolic (**d**) blood pressure levels and serum cholesterol (**e**) and triglyceride (**f**) levels from transplantation up to 3 years. Complete corticosteroid avoidance is effective and safe in children with renal transplants: a multicentre randomized trial with three years follow-up. Am J Transpl 2012; 12: 2719–29) [55]

risk in patients with certain immunological constellations. Further studies need to identify new monitoring tools to assess the immunologic safety to allow successful and safe conversion of patients to steroid-free immunosuppression at later times after transplantation, even after having

initially started on a steroid-based maintenance immunosuppression protocol.

Recurrent Kidney Disease

Because recurrent disease is the fourth most common cause of graft loss in children undergoing kidney transplantation, there have been concerns that steroid withdrawal may be associated with an increased risk of graft loss. Although information is limited, a study demonstrated no difference in graft survival due to recurrent disease in children (4–18 years of age) treated with a rapid prednisone discontinuation protocol compared with historical controls who received steroid therapy [56]. However, more data are needed to ensure there is not an untoward increased risk of recurrent disease, for example lupus erythematosus-associated nephritis, following steroid withdrawal.

Calcineurin Inhibitors

CSA, a lipophilic cyclic peptide of 11 amino acid residues, and TAC, a macrolide antibiotic, are drugs with similar mechanisms of action that have become major maintenance immunosuppressive agents used in transplantation.

Mechanism of Action

CSA and TAC act by inhibiting the calcium-dependent serine phosphatase calcineurin, which normally is rate-limiting in T cell activation (Fig. 67.8). Calcineurin is activated by the engagement of the T cell receptor, followed by activation of tyrosine kinases and phospholipase C-γ1, release of inositol triphosphate, release of calcium stored in the endoplasmic reticulum, and opening of membrane calcium channels. Calcineurin provides an essential step for transducing signal 1 to permit cytokine and CD40L

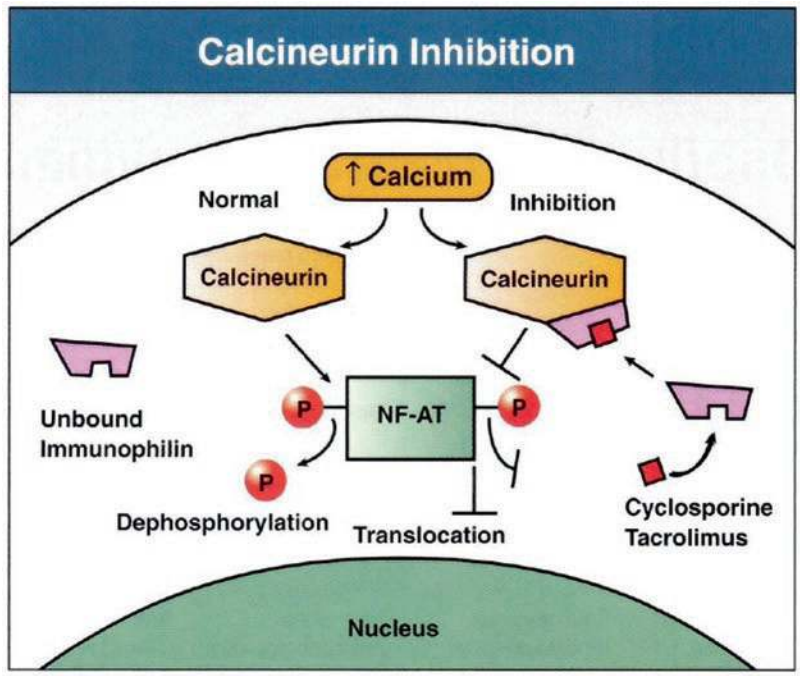

Fig. 67.8 Calcineurin inhibition. During normal T cell activation, calcium release activates calcineurin's phosphatase activity, causing dephosphorylation of the transcription factor nuclear factor of activated T cells (NF-AT) and subsequent translocation to the nucleus. Ciclosporin and tacrolimus form a complex with immunophilins (cyclophilin or FK-binding protein 12, respectively), which bind calcineurin and sterically inhibit the phosphatase activity, preventing dephosphorylation and nuclear translocation of NF-AT. (Used with permission from Floege J, Johnson RJ, Feehally J, (eds.): Comprehensive Clinical Nephrology, 4th ed. St. Louis: Elsevier, 2010)

transcription. A high cytoplasmic calcium concentration activates calcineurin, which then dephosphorylates regulatory sites in key transcription factors, the 'nuclear factors of activated T lymphocytes' ($NFAT_p$ and $NFAT_c$). This causes the NFAT proteins to translocate (with calcineurin) into the nucleus and bind to their DNA target sequences in the promoters of cytokine genes. Calcineurin has been implicated in the dephosphorylation of transcription factor Elk-1, and indirectly in the activation of Jun/AP-1 and NF-κB.

CSA and TAC cross cell membranes freely and bind to immunophilins (cyclophilin and FK-binding protein 12 [FKBP12], respectively), which are ubiquitous and abundant intracellular proteins with isomerase activity. The active complex then binds to a site on calcineurin and blocks its interactions with key substrates. The inactivation of calcineurin bound to CSA–cyclophilin or TAC–FKBP12 is the key to the immunosuppressive effect and some of the toxic effects of these drugs. While inhibition of calcineurin has many effects on the T cell, the best studied is the blocking of the translocation of the NFAT proteins from the cytoplasm into the nucleus.

CSA and TAC partially inhibit the calcineurin pathway at therapeutic blood levels (e.g., trough levels of 200 µg/L CSA or 5–20 µg/L TAC) [57]. However, even partial inhibition of calcineurin reduces the transcription of many genes associated with T cell activation (e.g., IL-2, IFN-γ, granulocyte–macrophage colony-stimulating factor (GM-CSF), TNF-α, IL-4, CD40L). Therefore, the functional consequence of partial calcineurin inhibition is probably a quantitative limitation in cytokine production, CD40L expression, and lymphocyte proliferation. The effect of CSA and TAC on calcineurin *in vivo* is rapidly reversible, emphasizing the importance of patient compliance, drug monitoring, and reliable formulations for delivery. The effects on non-T cells could also be clinically significant.

Pharmacokinetics and Drug Interactions

CSA and TAC are both variably absorbed and are metabolized extensively by the liver via the cytochrome P450 system. CSA is excreted primarily by the biliary system. The absorption of some CSA preparations may be bile-dependent, and therefore may be reduced in the presence of cholestatic liver disease. The absorption of the microemulsion formulations of CSA or TAC is bile-independent. Neither CSA nor TAC pharmacokinetics are affected by alterations in renal function. Both CSA and TAC bind to cells and to plasma components (primarily lipoproteins for CSA and albumin for TAC) in the blood; consequently, they must be assayed in whole-blood. Many drugs and agents can affect CSA and TAC levels through effects on their absorption or metabolism (see Table 67.3).

Since the absorption of CSA is decreased and its metabolism increased in children compared to adults, relatively higher dosages are required in pediatric patients. CSA is usually administered initially as 8–15 mg/kg daily in divided doses (or intravenously using one third the oral dose over a 24-h period) during the induction phase, with target trough blood levels of 150–300 µg/L for the first 3–6 months post-transplant. Doses are reduced after 3–6 months (typically 4–6 mg/kg daily); long-term target trough blood levels of 75–125 µg/L appear to provide comparable patient and graft survival as higher blood levels, but with less risk of malignancy [58]. A microemulsion form of CSA (Neoral™, Novartis, East Hanover, NJ) gives more reliable and slightly higher absorption, and may allow a slightly lower dose. Generic forms of CSA are available, but oral formulations of CSA may not be equivalent and readily interchangeable. Knowledge of the characteristics of the oral formulations is necessary before switching between them.

TAC is 20- to 30-fold more potent than CSA, and is therefore administered at a 20-fold lower dose. Initial dosing is usually 0.2–0.3 mg/kg daily in two divided doses orally (or 0.05–0.1 mg/kg daily intravenously over 24 h), and target trough levels are 5–15 µg/L. Since TAC is more water-soluble than CSA, it is not as dependent upon bile salts for absorption. However, food intake can reduce the absorption of TAC by up to 40 percent; thus, it is recommended that this agent be taken on an empty

Table 67.3 Examples of common drug interactions of immunosuppressants used in solid-organ transplantation: ciclosporin, tacrolimus, sirolimus, and everolimus

Common types of drug interactions	Examples of interacting drugs
Co-administration of drugs that inhibit CYP3A metabolism and/or P-gp efflux can increase immunosuppressant whole blood concentrations, leading to significant toxicities	Amiodarone ART-boosting agents (e.g., ritonavir, cobicistat) Azole antifungals (e.g., fluconazole, posaconazole, voriconazole) HIV protease inhibitors (e.g., atazanavir, nelfinavir, saquinavir) Macrolide antibiotics (except azithromycin) Non-dihydropyridine calcium-channel blockers Ombitasvir-paritaprevir-ritonavir with or without dasabuvir (an HCV, direct-acting antiviral regimen) Grapefruit juice
Co-administration of drugs that induce CYP3A metabolism and/or P-gp efflux pumping can decrease immunosuppressant whole blood concentrations, increasing the risk of organ rejection	CYP3A-inducing anti-seizure drugs (e.g., carbamazepine, fosphenytoin, oxcarbazepine, phenobarbital, phenytoin, primidone) Enzalutamide Nafcillin Rifamycins (e.g., rifabutin, rifampin, rifapentine) St. John's wort
Co-administration of nephrotoxic drugs with cyclosporine or tacrolimus can cause additive or synergistic kidney injury	Aminoglycosides Amphotericin B Colchicine Nonsteroidal anti-inflammatory drugs (NSAIDs)
Co-administration of drugs that increase serum potassium with cyclosporine or tacrolimus may cause severe hyperkalemia	ACE inhibitors/ARBs Amiloride Spironolactone Triamterene Trimethoprim, trimethoprim-sulfamethoxazole (cotrimoxazole)
Co-administration of statin drugs with cyclosporine can increase statin levels and risk of myotoxicity	Atorvastatin Lovastatin Pitavastatin Rosuvastatin Simvastatin

CYP cytochrome P450 metabolism, *P-gp* P-glycoprotein drug efflux pump, *ART* HIV antiretroviral therapy, *HIV* human immunodeficiency virus, *HCV* hepatitis C virus, *ACE* angiotensin-converting enzyme, *ARB* angiotensin II receptor blocker

stomach [59]. In addition, TAC is best absorbed in the morning. There is also an extended release formulation of TAC available that is designed to be given once per day with similar efficacy and safety.

Genetic polymorphisms in genes encoding TAC-metabolizing enzymes partly explain the inter-patient variability in TAC pharmacokinetics [60]. The key enzymes involved in the metabolism of TAC are CYP3A4 and CYP3A5 [61]. Individuals are considered expressers of CYP3A5 if they carry at least one CYP3A5*1 allele, whereas individuals homozygous for the CYP3A5*3 allele are classified as CYP3A5 non-expressers. In addition to CYP3A5*3, the CYP3A5*6 and CYP3A5*7 variant alleles can also lead to non-functional CYP3A5 protein [62]. There are ethnic distribution differences of CYP3A5 variant alleles, with expressers (carriers of the CYP3A5*1 variant allele) being more frequently found among non-Caucasian populations. Approximately 10–40% of Caucasians are CYP3A5 expressers, 33% of Asians and 55% of African-Americans [63]. CYP3A5 expressers require a TAC dose that is approximately 1.5–2-fold higher than non-expressers to reach the same exposure [64, 65]. This implies that, following a standard, bodyweight-based TAC dose,

CYP3A5 expressers are prone to have sub-therapeutic TAC concentrations whereas non-expressers are expected to have supra-therapeutic TAC concentrations [66].

Efficacy: Comparison of Ciclosporin and Tacrolimus

To help assess the relative efficacy of TAC and CSA, a 2005 meta-analysis and meta-regression was performed based upon 30 trials consisting of 4102 adult patients [67]. Despite a certain variability between studies, the overall conclusion from data in adults is that TAC-based immunosuppression is associated with decreased acute rejection rates, superior long-term renal function and more favorable cardiovascular risk profile than CSA-based immunosuppression, which translates into improved long-term renal allograft survival. This statement is supported by the results of the SYMPHONY trial, which compared standard immunosuppression vs. 3 regimens with low-dose or no CNI in *de novo* single-organ renal transplant patients over 1 year [68]. In this prospective, randomized, open-label study with 4 parallel arms, 1645 adult patients in 15 countries were randomized to standard immunosuppression with normal-dose CSA (target trough level 150-300 µg/L for 3 months, 100-200 µg/L thereafter), MMF (1 g bid) and steroids, or to one of three regimens consisting of daclizumab induction, MMF (1 g bid) and steroids potentiated by a low-dose of either CSA (50–100 µg/L), TAC (3-7 µg/L) or SRL (4-8 µg/L). The low-dose TAC group was significantly superior to all other groups with respect to glomerular filtration rate (GFR) and biopsy-proven acute rejection ($p < 0.01$) and to normal-dose CSA and low-dose SRL for graft survival (pair-wise $p < 0.05$). The authors concluded that immunosuppression consisting of daclizumab induction, MMF, low-dose TAC and corticosteroids provides the most optimal balance between efficacy (control of acute rejection) and toxicity (preserving graft function and graft survival) [68].

In pediatric patients, the efficacy and safety of TAC and CSA were compared in one multicenter trial in 196 patients, who were randomly assigned to receive either TAC or CSA microemulsion administered concomitantly with AZA and steroids [69]. TAC therapy resulted in a significantly lower incidence of acute rejection (36.9% vs. 5.91% with CSA therapy (59.1%); P = 0.003) and of steroid-resistant rejection (7.8% vs. 25.8%, P = 0.001) compared with the CSA group. The difference was also significant for biopsy-confirmed acute rejection (16.5% vs. 39.8%, P < 0.001). At 1 year post-transplant, patient survival was similar (96.1% vs. 96.6%); ten grafts were lost in the TAC group compared with 17 in the CSA group (P = 0.06). The TAC group had a significantly better eGFR. A follow-up study at 4 years showed that patient survival was similar (94% vs. 92%, P = 0.86), but graft survival significantly favored TAC (86% vs. 69%; P = 0.025) [70]. The mean eGFR was superior in TAC-treated patients vs. those on CSA (Fig. 67.9). Cholesterol remained significantly higher with CSA throughout follow-up. Three patients in each arm developed PTLD. Incidence of insulin-dependent diabetes mellitus did not differ. From these studies, the authors concluded that TAC was significantly more effective than CSA in preventing acute rejection and preserving renal function in pediatric renal recipients.

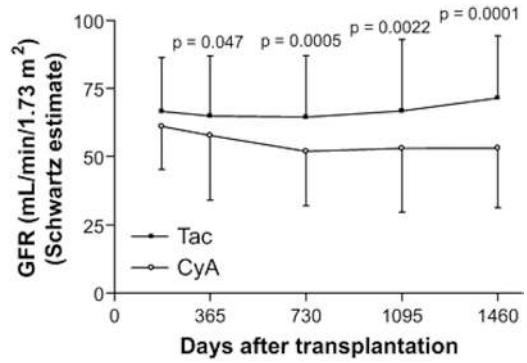

Fig. 67.9 Mean glomerular filtration rate (±1 SD) over 4 years post-transplant. Multicenter trial in 196 pediatric patients, who were randomly assigned to receive either tacrolimus or ciclosporin administered concomitantly with azathioprine and corticosteroids. (Used with permission of John Wiley and Sons from Filler G, Webb NJ, Milford DV, Watson AR, Gellermann J, Tyden G, et al. Four-year data after pediatric renal transplantation: a randomized trial of tacrolimus vs. cyclosporin microemulsion. Pediatr Transplant. 2005; 9:498–503) [70]

A retrospective study of the NAPRTCS database of 986 pediatric renal transplant recipients who were treated either with CSA, MMF and steroids (n = 766) or TAC, MMF and steroids (n = 220) revealed that TAC and CSA, in combination with MMF and steroids, produce similar rejection rates and graft survival in pediatric renal transplant recipients [71]. However, TAC was associated with improved graft function at 1 and 2 years post-transplant (Fig. 67.10). There was no difference in time to first rejection, as well as in risk of rejection or graft failure at 1 or 2 years post-transplant. TAC-treated patients were significantly less likely to require antihypertensive medication at 1 and 2 years post-transplant. TAC-treated patients had a higher mean eGFR at both 1 year (99 vs. 78 mL/min/1.73 m^2, P = 0.0003) and 2 years post-transplant (97 vs. 73 mL/min/1.73 m^2, P < 0.0001). Hence, there is evidence that TAC is superior to CSA (conventional or microemulsion form) in preventing acute rejection after kidney transplantation in adult and pediatric populations. It also seems more effective in improving long-term graft survival in adults.

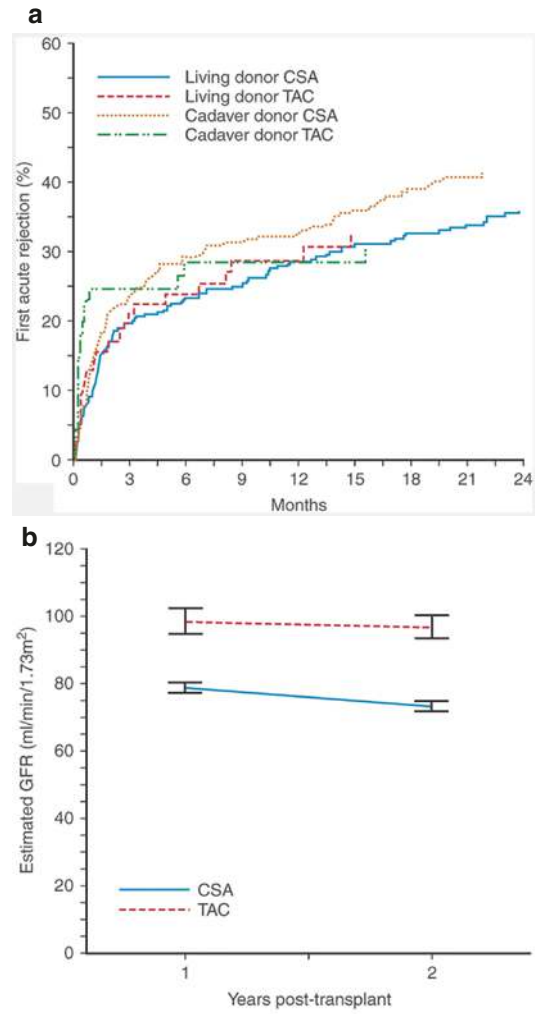

Fig. 67.10 (**a**) Kaplan–Meier estimates of the percentage of patients experiencing a first acute rejection in the first 2 years post-transplant, by treatment group: tacrolimus (TAC), mycophenolate mofetil (MMF) and steroids vs. ciclosporin (CSA), MMF and steroids and donor source. Patients were included in this analysis if they were transplanted between 1997 and 1999 and had a 2-year follow-up in the database. (**b**) Mean eGFR as calculated by the Schwartz formula at 1 and 2 year post-transplant in patients treated with TAC, MMF and steroids or CSA, MMF and prednisone. (Used with permission of John Wiley and Sons from Neu AM, Ho PL, Fine RN, Furth SL, Fivush BA. Tacrolimus vs. cyclosporine A as primary immunosuppression in pediatric renal transplantation: a NAPRTCS Study. Pediatr Transplant. 2003; 7:217–22) [71]

Side Effects

CSA and TAC have similarities and differences in their toxicity profiles (Table 67.2). Both can cause nephrotoxicity, hyperkalemia, hyperuricemia with occasional gouty attacks, hypomagnesemia secondary to urinary loss, hypertension, diabetes mellitus, and neurotoxicity, especially tremor. In the European pediatric study, the incidence of hypomagnesaemia was significantly higher in the TAC-treated group (34%) compared with the CSA-treated group (12.9%) [69]. Similarly, diarrhea was more frequent in TAC-treated patients (13.6% vs. 3.2%). Hypertrichosis, gum hyperplasia and flu syndrome were reported only in CSA-treated patients, and tremor was reported only in TAC-treated patients [69]. These results are similar to that found in adults, where tremor is consistently more common with TAC, and hirsutism and gum disease more common with CSA [72]. Also, hypertension and hyperlipidemia are more commonly observed with CSA. Interestingly, higher CSA doses are more likely to induce higher blood pressure in older girls compared to boys [73]. In the NAPRTCS study, during which CNIs were used in combination with MMF and steroids, TAC-treated patients

were significantly less likely to require antihypertensive medications at 1 and 2 years post-transplant [71]. This is similar to adults, where a lower systemic blood pressure was reported in TAC-treated patients in several studies [72]. In the European pediatric study, the mean total cholesterol levels were reported to decline in the TAC group and increase in the CSA group at the end of 6 months [69]. In the multicenter analysis from the European CERTAIN Registry, the prevalence of dyslipidemia was 95% before transplantation, and 88% at 1 year post-transplant [74]; the use of TAC and MMF was associated with significantly lower concentrations of all lipid parameters compared to regimens containing CSA and mTOR inhibitors. Regimens consisting of CSA, MPA, and corticosteroids as well as of CSA, mTOR inhibitors, and steroids were associated with a 3- and 25-fold increased risk of having more than one pathologic lipid parameter as compared to the use of TAC, MMF, and steroids [74]. Similarly, several studies in adults have shown remarkably lower lipid levels in TAC-treated patients than in those receiving CSA [72]. The improved lipid profiles on TAC may contribute to a better long-term outcome with less cardiovascular morbidity in adult patients.

On the other hand, tremor and glucose intolerance are more common with TAC. In the pediatric multicenter European study, there was no difference in the incidence of new onset insulin-dependent diabetes mellitus between TAC- (3%) and CSA-treated patients (2.2%) [69, 70]. Although in early clinical trials of TAC, a significantly higher incidence of diabetes mellitus was reported in TAC-treated adult patients than in recipients on CSA, the incidence of diabetes mellitus under TAC immunosuppression has become less frequent in recent randomized trials comparing these two CNIs [75]. Post-transplant diabetes regresses after dose reduction in some but not all patients. Both the reduction of steroid dosage and low target trough TAC concentrations contribute to this marked reduction of the incidence of diabetes mellitus under TAC immunosuppression in both adults and children [69, 72]. CSA may also be associated with coarsening of facial features, especially in children. Bone pain that is responsive to calcium-channel blockers may also occur with CSA use and sometimes may require changing to TAC.

The most common serious problem with CNIs is nephrotoxicity, with both a reversible vasomotor component and an irreversible component. Both CSA and TAC can cause acute elevations in serum creatinine that reverse with reduction of the dose, apparently caused by renal vasoconstriction, which may be mediated by calcineurin inhibition. Chronically, CSA and TAC can induce interstitial fibrosis and tubular atrophy with characteristic hyalinosis of the afferent arteriole [76]. This lesion appears to result from long-standing renal vasoconstriction, perhaps mediated in part by an increase in local vasoconstrictor tone (increased angiotensin II, endothelin-1, thromboxane, and sympathetic nerve transmitters) and an inadequate vasodilatory response (impaired nitric oxide formation). The importance of this lesion is apparent from studies in cardiac and liver transplant recipients, in whom CSA or TAC use is associated with chronic kidney disease progressing to end-stage kidney disease (ESKD) in a significant fraction of patients [77]. This problem was more relevant at a time when higher doses of CSA were administered for longer periods. Fortunately, currently, CSA and TAC toxicity is associated with only mild to moderate declines in renal function. However, as the number of patients with long-standing non-renal transplants rises, there is increasing concern about future ESKD in this population. In these cases, it is important to establish the diagnosis of CNI toxicity by renal biopsy and reduce or stop calcineurin inhibition whenever possible [75, 78, 79]. Experimentally, CSA nephropathy is exacerbated in the presence of salt restriction/volume depletion and is lessened by treatment with angiotensin-converting enzyme (ACE) inhibitors, calcium-channel blockers, vasodilators (hydralazine), and steroids.

CSA and TAC treatment can cause hemolytic uremic syndrome, probably through endothelial dysfunction. This complication, which is usually associated with elevated drug levels, may respond to temporary withdrawal of CSA or TAC, plasma

exchange, switching to another CNI, or conversion to another immunosuppressive drug class.

There is no difference in the incidence of PTLD between TAC- and CSA-treated recipients when used in combination with AZA/steroids [1% (1/103) vs. 2.1% (2/93)] [69] or when given in conjunction with MMF/steroids (1.4% vs. 2%) [71]. This is similar to adults, in whom recent large, randomized studies showed no differences in the incidence of malignancy between patients treated with TAC or CSA [72].

Therapeutic Drug Monitoring

CSA is a drug with a narrow therapeutic index and broad intra-individual and inter-individual pharmacokinetic variability. Serious clinical consequences may occur because of underdosing or overdosing. Hence, individualization of CSA dosage by therapeutic drug monitoring is required. The traditional monitoring strategy for CSA is based on pre-dose trough level measurements (C_0). However, C_0 shows a relatively poor correlation with CSA exposure (area under the concentration-time curve [AUC]) and with clinical outcome [80]. Studies on the pharmacokinetic and pharmacodynamic relationship of CSA have shown that CSA induces a partial inhibition of calcineurin activity, the rate-limiting step in the activation of primary human T lymphocytes and the target of the CSA/cyclophilin complex [81]. The greatest calcineurin inhibition and the maximum inhibition of IL-2 production occur in the first 1–2 h after dosing. Calcineurin is only partially inhibited in patients, which can result in rejection even when CSA blood concentrations are in the putative therapeutic range. From these observations, it was hypothesized that the CSA $AUC_{0–4}$(absorption profile) or the C_2concentration (sample 2 h after oral intake) may be a better predictor of immunosuppressive efficacy than the CSA $AUC_{0–12}$. However, a prospective, randomized study in adult renal transplant recipients did not show any advantage of C_2 monitoring strategy in the early post-transplant period compared to a C_0 monitoring strategy, but led to significantly higher CSA doses and blood levels than C_0 monitoring [82]. In a large study in pediatric renal transplant recipients, CSA absorption profiles predicted the risk of acute rejection, while the single pharmacokinetic parameters C_0 or C_2 did not [83]. A disadvantage of C_2 monitoring is the fact that it requires a timed blood sample within a narrow time window (±15 min) that necessitates further organizational requirements for physicians and nursing staff, which may be judged differently between transplant centers. In our center, we routinely monitor CSA therapy by 12-h pre-dose trough concentrations. We aim for the following trough levels in combination with MMF therapy and prednisone: 120–200 μg/L during months 0–3 post-transplant and 80–160 μg/L thereafter. We feel that a monitoring strategy based on CSA C_2 concentrations in the stable period post-transplant is an additional tool in preventing chronic CSA-induced nephrotoxicity. In patients with low or normal immunological risk, who are on additional maintenance therapy with MMF, we aim for CSA C_2 concentrations between 300–600 μg/L beyond the first year post-transplant; C_2 concentrations are monitored every 3–6 months.

When TAC is utilized, a monitoring strategy based on trough levels is in general sufficient because trough levels are good indicators of systemic exposure. In most transplant centers, doses are adjusted to attain target whole-blood trough concentrations of 8–12 μg/L during the first 3 months post-transplant, between 5 and 10 μg/L during months 4–12, and 4–8 μg/L thereafter [84]. It must be emphasized that these target ranges are dependent on the concomitant immunosuppressive therapy. In the SYMPHONY trial, for example, low tacrolimus exposure (trough levels between 3 and 7 μg/L) in the first year post-transplant, in conjunction with MMF, prednisone and daclizumab induction, was associated with excellent efficacy and little TAC-associated toxicity [68]. However, although TAC trough level goals in the low-dose TAC group of the Symphony study were protocol specified at 3–7 μg/L, the achieved levels were 6.4 and 6.5 μg/L at 12 and 36 months post-transplant, respectively. Hence, a more appropriate interpretation of the SYMPHONY trial is that, in combination with MMF, TAC trough level goals of 5–8 μg/L

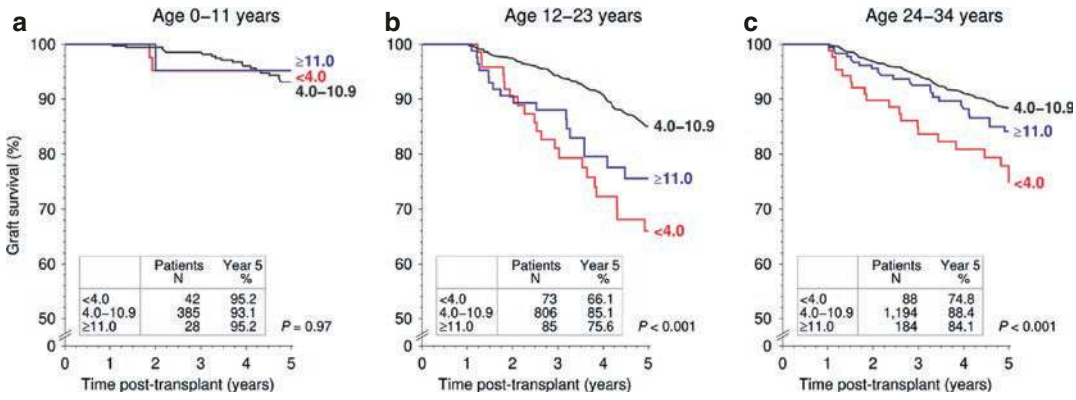

Fig. 67.11 Association of 1-year tacrolimus trough level (ng/mL) with graft survival during post-transplant years 2–5 for the age groups (**a**) 0–11, (**b**) 12–23, and (**c**) 24–34 years at the time of transplantation. Log rank P values of Kaplan–Meier analysis are shown. (Reproduced from [86], with permission)

should be considered as standard of care in adult patients. In addition, recent studies in adult kidney allograft recipients lend support to maintain TAC trough levels above 5 µg/L in order to reduce the risk of *de novo* donor-specific antibodies [85].

Recent registry data indicate that that a more consistent and less variable exposure to the main immunosuppressant TAC later than 1 year post-transplant is associated with a better 5-year graft survival, especially in adolescents and young adults (Fig. 67.11) [86]. In adolescent and young adult patients, the risk of premature graft loss associated with a low 1-year TAC trough level <4.0 ng/mL was 2.38-fold higher compared to a trough level of 4.0–10.9 ng/mL, whereas the risk was not significantly increased in recipients aged 0–11 years. In 24–34-year-old adult patients, the risk of premature graft loss due to a low 1-year TAC trough level <4.0 ng/mL was 1.94-fold increased, but still lower than in adolescent and young adult patients. Importantly, trough levels in the range of 4.0–10.9 ng/mL resulted in a good 5-year graft survival of 85% in the group of 12–23-year-old recipients, comparable to the 88% survival rate observed in 24–34-year-old adult patients (Fig. 67.11). Hence, it appears that optimal TAC exposure can at least partially counteract the enhanced immunoreactivity in this high-risk age group.

Antimetabolic Agents: Azathioprine

AZA, developed by Nobel Prize laureates Elion and Hitchings in the1950s, has been widely used in renal transplantation for 4 decades. AZA is a purine analog derived from 6-mercaptopurine (6-MP).

Mechanism of Action

AZA is metabolized in the liver to 6-MP and further converted to the active metabolite thioinosinic acid (TIMP) by the enzyme hypoxanthine–guanine phosphoribosyltransferase. Some but not all of the immunosuppressive activity of AZA is attributable to 6-MP. AZA acts mainly as an antiproliferative agent by interfering with normal purine pathways, by inhibiting DNA synthesis, and by being incorporated into DNA, thereby affecting the synthesis of DNA and RNA [64]. By inhibiting the synthesis of DNA and RNA, AZA suppresses the proliferation of activated B and T lymphocytes. In addition, AZA has been shown to reduce the number of circulating monocytes by arresting the cell cycle of promyelocytes in the bone marrow. The anti-proliferative action of AZA probably explains much of its observed effects on the immune system and its toxicity. AZA shows some selectivity in its effects with certain cell types and different kinds of immune reactions [87]. For instance, it has been shown that primary immune responses are more susceptible to AZA

than secondary responses despite the fact that there is a more rapid proliferation of lymphocytes during a secondary response.

Pharmacokinetics and Drug Interactions

AZA is administered orally at 1.5 mg/kg per day in conjunction with CNIs and 2.5 mg/kg per day when used without CNIs. Higher initial doses (5 mg/kg per day) combined with monitoring of 6-thioguanine nucleotide levels in red blood cells are associated with an approximately 20 percent reduction in the acute rejection rate as compared to lower doses [88]. It is metabolized in the liver to 6-MP and further converted to the active metabolite TIMP. Because 6-MP is degraded by xanthine oxidase, allopurinol, a xanthine oxidase inhibitor, will increase the levels of TIMP. Severe leukopenia can occur if allopurinol, used for the treatment of hyperuricemia and gout, is given with AZA. Thus, allopurinol should generally be avoided in patients treated with AZA. If, however, the patient has severe gout and allopurinol must be used, AZA doses must be reduced by about two-thirds, and the white blood cell count must be carefully monitored. AZA eventually has to be discontinued in many such patients. A possible alternative is switching from AZA to MMF, which does not interact with allopurinol.

Side Effects

The major side effect of AZA is bone marrow suppression. All 3 hematopoietic cell lines can be affected, leading to leukopenia, thrombocytopenia, and anemia. The hematologic side effects are dose-related and can occur late in the course of therapy. They are usually reversible upon dose reduction or temporary discontinuation of the drug. AZA should be temporarily withheld if the white cell count falls below 3000/mm^3 or if the count drops by 50 percent between blood draws. Recovery usually occurs within 1–2 weeks. The drug can then be restarted at a lower dose and increased gradually to the usual maintenance dose while monitoring the white cell count. Occasionally, AZA has to be discontinued because of recurrent or persistent leukopenia. The mean cell volume is commonly increased in patients on full-dose AZA, and red cell aplasia can eventually result. Interactions between AZA and ACE inhibitors have been reported, causing anemia and leukopenia.

Another potentially serious side effect of AZA, which requires decreasing the dose or even stopping the drug, is hepatotoxicity. This complication is manifested by abnormal liver function tests, usually showing a cholestatic picture. The diagnosis of AZA-induced liver disease is one of exclusion, and the patient should be evaluated for other more serious causes of hepatic dysfunction. AZA has also been linked to the development of skin cancer, the most common malignancy in renal transplant patients. As a result, patients taking AZA for a prolonged period should be instructed to avoid direct exposure to sunlight or to use heavy sun screens when exposed. Other side effects include increased susceptibility to infection and hair loss.

Antimetabolic Agents: Mycophenolate Mofetil

MMF impairs lymphocyte function by blocking purine biosynthesis via inhibition of the enzyme inosine monophosphate dehydrogenase (IMPDH). MMF was developed as a replacement for AZA for maintenance immunosuppression. It is not nephrotoxic and has less bone marrow toxicity than AZA. However, gastrointestinal toxicity can occur, usually manifested by gastritis and diarrhea. MMF is currently available in intravenous, capsule, and liquid formulations.

Mechanism of Action

MPA, the active ingredient of the prodrug MMF, acts by blocking *de novo* purine synthesis in lymphocytes. Purines can be generated either by *de novo* synthesis or by recycling (salvage pathway). Lymphocytes preferentially use *de novo* purine synthesis, whereas other tissues such as brain use the salvage pathway. MPA uncompetitively inhibits IMPDH, which is the rate-limiting enzyme in the *de novo* synthesis of guanosine monophosphate (GMP) (Fig. 67.12). Inhibition of IMPDH creates a relative deficiency of GMP and a relative excess of adenosine monophosphate (AMP). GMP and AMP levels act as a con-

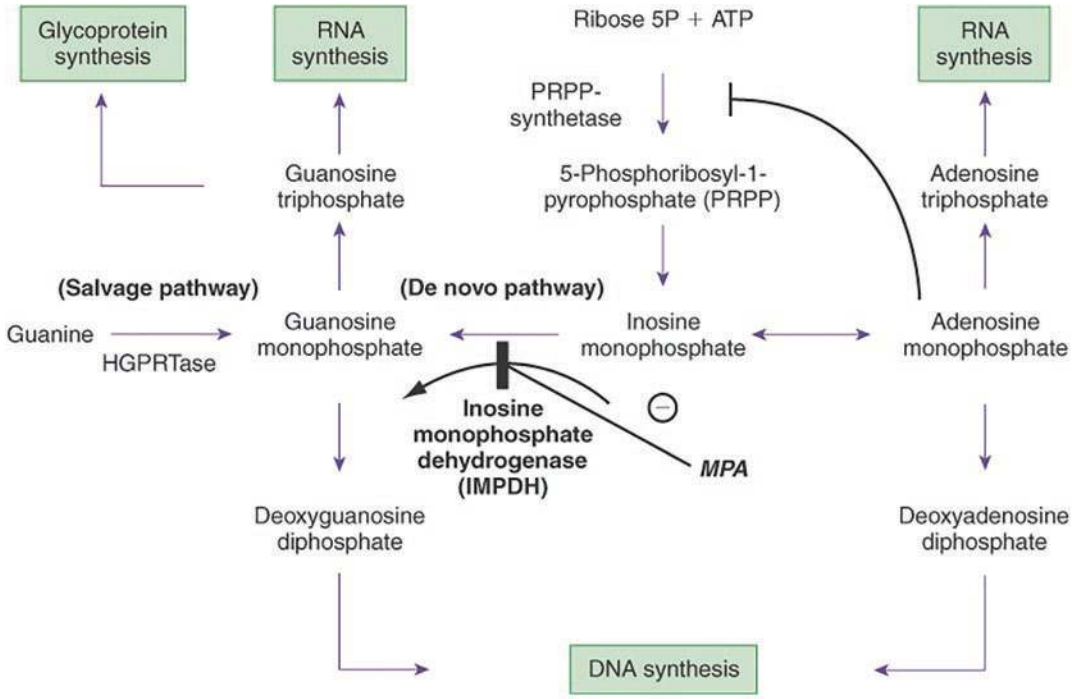

Fig. 67.12 Immunosuppressive mechanism of mycophenolic acid. By inhibiting inosine monophosphate dehydrogenase (IMPDH), mycophenolic acid (MPA) antagonizes the *de novo* pathway of purine synthesis on which lymphocytes particularly depend. Accumulation of adenosine monophosphate inhibits 5-phosphoribosyl-1-pyrophosphate (PRPP) activity thereby diminishing the substrate of IMPDH. Depletion of guanosine phosphates inhibits DNA and RNA synthesis. Lymphocytes lack the salvage pathway of purine synthesis, which depends on the activity of the enzyme hypoxanthine guanosine phosphoribosyl transferase (HGPRTase)

trol on *de novo* purine biosynthesis, which is essential for T and B lymphocyte proliferation, but not for division in other cells. Therefore, MMF, by blocking IMPDH, creates a block in *de novo* purine synthesis that selectively interferes with proliferative responses of T and B lymphocytes, inhibiting clonal expansion, and thus inhibiting antibody production, the generation of cytotoxic T cells, and the development of delayed type hypersensitivity. Furthermore, MPA impairs the ability of dendritic cells to present antigen, suppresses the recruitment of monocyte lineage cells, suppresses the glycosylation of adhesion molecules, inhibits vascular smooth muscle proliferation, improves endothelial function, and inhibits mononuclear cell recruitment into allografts and nephritic kidneys [89]. MPA also decreases cytokine-induced nitric oxide synthesis and prevents the formation of reactive species such as peroxynitrite. Furthermore, MPA exhibits antioxidant effects in experimental nephropathies. These properties of MPA likely augment its immunosuppressive properties by limiting fibrosis and vascular sclerosis after immunological injury [90].

Dosage and Pharmacokinetics

MMF, a semi-synthetic ethyl ester of MPA, is rapidly and completely absorbed and hydrolyzed by esterases to yield the active drug MPA. The recommended dose in pediatric patients in conjunction with CSA is 1200 mg/m^2 per day in two divided doses, the recommended MMF dose in conjunction with TAC is 800 mg/m^2 per day in two divided doses. However, recent data from a large, prospective, randomized study in both pediatric and adult renal transplant recipients on fixed dose MMF vs. a concentration-controlled

regimen, the FDCC study, indicate that a higher initial MMF dose, for example 1800 mg MMF/m^2 per day in conjunction with CSA and 1200 mg MMF/m^2 per day in conjunction with TAC for the first 2–4 weeks post-transplant, is required to achieve adequate MPA exposure in the majority of patients [91, 92]. The MMF dose should be reduced with active CMV infection. When MMF is associated with diarrhea (a side effect of MMF, see below), dividing the daily dosing to 3–4 doses per day may be effective in controlling the diarrhea.

The difference in MMF dosing depending on the concomitant CNI is explained by a pharmacokinetic interaction of CSA with the main MPA metabolite 7-O-MPA glucuronide (7-O-MPAG). CSA inhibits the multidrug resistance protein 2-mediated transport of 7-O-MPAG into the bile. MPAG is subject to enzymatic and non-enzymatic hydrolysis in bile and more importantly in the intestine, thereby liberating the unconjugated drug MPA, which is then reabsorbed into the systemic circulation. This enterohepatic circulation is responsible for a secondary MPA peak occurring 6–12 h after administration. The impact of the enterohepatic cycle on the MPA plasma concentration varies within and between individuals due to factors such as meal times or co-medication of drugs that interrupt the enterohepatic circulation (e.g., bile acid sequestrants, antibiotics). These factors should be considered when evaluating MPA concentrations (particularly pre-dose concentrations) in clinical practice. Furthermore, genetic differences and disease can affect enterohepatic cycling and thus the bioavailability of MPA [93]. If CSA doses are tapered, the pre-dose concentrations of MPA significantly increase, and after complete discontinuation of CSA they can reach about twice the values seen in patients still on CSA co-therapy. When using MMF in combination with TAC or SRL, lower MMF doses can be used to achieve comparable MPA exposure, guided by therapeutic drug monitoring, to that seen with CSA [93]. However, an uncritical approach used by some centers to reduce the MMF dose generally by 50% when co-administered with TAC or SRL is not advisable.

Table 67.4 Drug-Drug-Interactions between mycophenolate mofetil and frequently used co-medications

Drug	Effect	Site of interaction
Antacids	MPA AUC ↓	Absorption
Cholestyramine	MPA AUC ↓ MPAG AUC ↓	Absorption
Corticosteroids	MPA trough ↓ MPA AUC ↓ MPAG ↑	Glucuronidation
Ciclosporin	MPA trough ↓ MPA AUC ↓	Enterohepatic cycling
Metronidazole	MPA AUC ↓ MPAG AUC ↓	Enterohepatic cycling, suppression of anaerobic bacterial glucuronidase
Norfloxacin	MPA AUC ↓ MPAG AUC ↓	Enterohepatic cycling, suppression of anaerobic bacterial glucuronidase
Phosphate binder	MPA AUC ↓ Cmax ↓	Absorption

AUC area under the concentration time-curve, *Cmax* maximal (peak) plasma concentration, *MPA* mycophenolic acid, *MPAG* mycophenolic acid-glucuronide

The metabolism of MPA due to glucuronidation can also be affected by drug induction. Steroids are known inducers of UDP-glucuronosyltransferases *in vitro*, and there is evidence that this may hold true *in vivo*. In one study, for example, the effect of steroid withdrawal on MPA bioavailability was studied in 26 kidney transplant recipients [94]. When steroids were completely withdrawn 12 months post-transplant, a 33% increase in the mean dose-normalized MPA pre-dose concentrations and MPA-AUCs was observed compared with concentrations at 6 months, when the patients were still receiving maintenance doses of steroids. The relevant drug-drug interactions are summarized in Table 67.4.

An important pharmacokinetic property of MPA is its extensive and tight protein binding particularly to serum albumin. The free MPA fraction in individuals with conserved renal function ranges from 1% to 3%. Based on *in vitro* studies, the free MPA fraction is responsible for the pharmacological activity of the drug. Furthermore, it is an important determinant of the

MPA clearance. Of the factors evaluated for their effect on MPA protein binding, serum albumin was the most important. In patients with delayed graft function or renal impairment, there are many factors which can affect MPA protein binding. These may lead to substantially elevated free MPA concentrations despite total MPA levels similar to those found in patients with relatively preserved renal function [95, 96].

Efficacy

Following the success of the early MMF studies in adults, MMF was investigated in pediatric renal transplant recipients in open-label studies with historical controls, since randomized, controlled trials were quite difficult to carry out due to the relatively small numbers of pediatric kidney transplants performed each year. Since studies in adult renal transplant recipients had previously established the superiority of MMF over AZA or placebo in reducing the risk of acute rejection, it was important for the pediatric transplant community to have prompt access to open-label studies. Data from 3 large multicenter studies [97–101] and one smaller study [102] provided support for the safety and efficacy of MMF in the pediatric renal transplant population when used with CSA and prednisone. Induction therapy was optional in one study [97] and not used in the other two studies [99, 102]. The incidence of acute rejection within the first 6 months to 1 year for patients receiving MMF in these studies ranged from 28% to 37% [97, 99, 101]. Those studies comparing MMF patient groups to historical controls reported significant reductions in the incidence of acute rejection with MMF vs. AZA [99, 101]. There was also a significant improvement in the incidence of acute rejection between patients receiving MMF and those receiving AZA at 3 years in a follow-up report to one study [100]. In one large study [97], no differences in the incidence of acute rejection were observed when results were stratified by age. Long-term (3-year) graft and patient survival were excellent, with a 30% incidence of acute rejection [98]. MMF has a role in the prevention and/or treatment of chronic rejection. Among children with chronic rejection, some evidence suggests that substituting MMF for AZA may improve renal function [103, 104].

Side Effects

The major toxicity of MMF is gastrointestinal, mainly diarrhea, possibly as a result of the high concentrations of acyl-MPAG in the gut. MMF is devoid of intrinsic renal, cardiovascular or metabolic toxicities, but can increase the risk for CMV infections, leukopenia, and perhaps, mild anemia (Table 67.2). MPA has been associated with protection from *Pneumocystis jirovecii* pneumonia (PJP) and may actually have some anti-PJP activity because *Pneumocystis jirovecii* has IMPDH activity. MMF should not be used in pregnant transplant patients since its safety in pregnancy has not yet been established.

In the MMF suspension trial in pediatric renal transplant recipients, MMF safety was evaluated based on the occurrence of adverse events, including the development of opportunistic infections and malignancies. The most frequently noted adverse events were hematological problems such as leukopenia and gastrointestinal disorders like diarrhea, which occurred in 25% and 16% of all patients, respectively, and were observed more often in the youngest age group. In general, the risk of developing side effects declined with increasing age.

Therapeutic Drug Monitoring

Patients on standard-dose MMF therapy show considerable between-patient variability in pharmacokinetic parameters. This variability is attributable to factors that influence exposure to MMF, such as renal function, serum albumin levels, concomitant medications such as CSA that inhibit enterohepatic recirculation of the active metabolite of MMF, MPA, (Table 67.4) and genetic polymorphisms of MPA-metabolizing enzymes. This variability is clinically relevant, as higher plasma concentrations of MPA are correlated with reduced risk of acute rejection after kidney transplantation [96, 105]. These findings have suggested that individualizing the dose regimen of MMF may further improve clinical outcomes compared with a standard-dose regimen.

There has been considerable debate regarding the utility of measuring MPA levels. Advocation for MPA monitoring is based on the premise that monitoring will result in avoiding both underdosing, which prevents rejection, and overdosing, which increases the risk of adverse reactions [105]. One study in adults, for example, showed significantly fewer treatment failures and acute rejection episodes in the monitoring arm compared with the fixed dose arm with no significant difference in side effects [106]. Within this study, MPA exposure and MMF dosing were higher in the monitoring arm based on 3 levels measured over the first 3 h post-dose. Awareness of the potential for a more personalized dosing has led to development of methods to estimate MPA AUC based on the measurement of drug concentrations in only a few samples. This approach is feasible clinically, and has proven successful in terms of correlation with outcome [107]. An MPA-AUC > 40 mg x L/12 h has been recommended for sufficient MPA exposure for the prevention of acute rejection episodes [92]. In general, monitoring of MPA exposure by MPA pre-dose plasma levels is more popular in clinical practice than monitoring of the MPA-AUC by a limited sampling strategy, but less precise. Therefore, some transplant centers monitor MPA pre-dose and target levels between 1.5 and 4 mg/L. In addition, they use levels as a measure of adherence.

Target of Rapamycin (TOR) Inhibitors

SRL (sirolimus, rapamycin) is a macrocyclic triene antibiotic that is produced by the actinomycete *Streptomyces hygroscopicus*. SRL was approved in September 1999 by the US FDA and in December 2000 by the European Medicines Agency for use in adult renal transplant recipients. EVR is an analog of SRL that has similar effectiveness and side effect profile.

Mechanism of Action

SRL displays a novel mechanism of immunosuppressive action. Interaction with at least two intracellular proteins is required to elicit its antiproliferative activity. SRL first binds to the cytosolic immunophilin FK-binding protein 12 (FKBP12). In contrast to the TAC-FKBP12 complex, the complex of SRL with FKBP12 does not inhibit calcineurin activity. Instead, this complex binds to and inhibits the activation of mTOR, a key regulatory kinase. This inhibition suppresses cytokine-mediated T-cell proliferation, inhibiting the progression from the G1 to the S-phase of the cell cycle. Thus, SRL acts at a later stage in the cell cycle than do the CNIs CSA and TAC. SRL can, therefore, be used in combination with the CNIs to produce a synergistic effect [108].

Dosage and Pharmacokinetics

EVR is available as tablets and dispersible tablets for administration in water. The current evidence from pediatric renal transplantation suggests that EVR should be administered at an initial dose of 0.8 mg/m^2 body surface area twice daily when given in combination with CSA therapy, adjusted to target a trough concentration of 3–8 μg/L [109, 110]. There is a well-documented drug-drug interaction between mTOR inhibitors and CSA [111], arising from a shared metabolic pathway via the cytochrome P450 CYP3A4 isoenzyme system, and the fact that both are substrates for the drug transporter P-glycoprotein. EVR exposure is increased by up to three-fold in patients receiving concomitant CSA [112, 113], while TAC exerts only a minimal effect [113, 114]. In patients receiving EVR with concomitant TAC, a dose of 2 mg/m^2 body surface area twice daily is therefore appropriate [112]. Similarly, SRL bioavailability is higher in the presence of CSA than TAC [115, 116].

SRL is available as tablets form and an oral solution. Data on target doses and blood concentrations for SRL in pediatric transplant recipients are more limited than for EVR. The half-life of SRL increases with age in children [117]. Twice-daily dosing and daily dosing is therefore recommended in young children and older recipients, respectively. However, there is no clear guidance regarding the age or body weight when the switch should be considered. One trial used 13 years of age as a cutoff point [118]. In a pharmacokinetic study of 13 children receiving SRL in a CNI-free regimen, with a median age of 15.5 years, the

authors concluded that twice-daily dosing was required in this setting due to more rapid metabolism of SRL in the absence of concomitant CNI therapy [119]. High SRL trough concentrations (>10 μg/L) either with or without concomitant CNI appear inadvisable in children in view of the high risk of toxicity and discontinuation. One small prospective study (n = 19) converted pediatric kidney transplant patients to a CNI-free regimen of SRL with MMF using a single SRL loading dose of 5–7 mg/m^2 body surface area, then a daily dose of 2–4 mg/m^2 body surface area adjusted to target a SRL trough concentration of 5–10 μg/L, and achieved a low rate of rejection with a good renal response [118].

EVR and SRL are both macrolide derivatives and share many pharmacokinetic features, including a close correlation between total exposure and trough concentration, low absorption that varies between and within patients, and differences in absorption between adults and children [111, 120]. However, EVR is the 40-O-(2-hydroxyethyl) derivative of SRL, a modification that results in some important pharmacokinetic differences between the two drugs. EVR is more hydrophilic than SRL and is absorbed more rapidly from the gut with more systemic clearance than SRL [121]. As a result, the elimination half-life of EVR is shorter than for SRL (mean 28 h vs. 62 h) [122, 123]. The clinical effect is that no loading dose is required for EVR whereas a loading dose of 3 times the maintenance dose has been recommended for starting SRL in adults to accelerate achievement of steady-state concentration [124]. EVR is administered twice a day in pediatric and adult patients whereas once daily dosing is appropriate for SRL in older children and adult patients (see above for considerations regarding SRL dosing in younger children).

Efficacy

The most frequent reason to include an mTOR inhibitor in the immunosuppressive regimen is to facilitate a reduction in CNI exposure, or to eliminate CNI therapy entirely. The current evidence suggests that *de novo* administration of EVR with low-exposure CNI therapy in children undergoing renal transplantation is efficacious and safe. The recently published 36-month, multicenter, open-label randomized study investigated EVR with reduced-dose TAC and steroid elimination from month 5 post-transplant compared with a standard-dose TAC regimen with MMF and steroids (control) [125]. The incidence of composite efficacy failure (biopsy-proven acute rejection [BPAR], renal allograft loss, or death) at month 36 was 9.8% vs. 9.6% for EVR with reduced-dose TAC and MMF with standard-dose TAC, respectively, which was driven by BPARs. Kidney allograft loss was low (2.1% vs. 3.8%) with no deaths. Mean eGFR rate at 3 years post-transplant was comparable between groups. Growth in pre-pubertal patients on EVR with reduced-dose TAC without steroids was better (P = 0.05) vs. MMF with standard-dose TAC and steroids. The overall incidence of adverse events and serious adverse events was comparable between groups. Rejection was the leading adverse event for study drug discontinuation in the EVR with reduced-dose TAC group. The authors concluded that, although adverse events-related study drug discontinuation was higher, an EVR with reduced-dose TAC regimen represents an alternative treatment option that enables steroid withdrawal as well as CNI reduction in pediatric kidney transplant recipients [125].

Use of *de novo* EVR with complete CNI avoidance has not been explored in large trials in pediatric transplant recipients, but is unlikely to be preferable to concomitant reduced-exposure CNI. Primarily mTOR-based, CNI-free immunosuppression is associated with a significantly increased risk of the development of DSA [126]. Switching maintenance patients to an mTOR inhibitor to facilitate CNI minimization can improve renal allograft function or avoid further functional deterioration, particularly when undertaken before irreversible damage has developed. Late switch below an eGFR of 40 mL/min/1.73 m^2, however, may be associated with an increase in pre-existing proteinuria, favoring early conversion. It remains unresolved whether CNI therapy should be reduced or, indeed, eliminated in maintenance patients regardless of whether renal dysfunction is believed to be due to CNI-related nephrotoxicity. Currently, many

transplant centers use mTOR inhibitors as part of a maintenance immunosuppressive regimen only in the following patient subsets in which this drug class may have particular utility: (i) Patients, who have histologically proven CNI nephrotoxicity despite low levels and doses of the CNI; (ii) patients with malignancy (e.g., skin cancers and Kaposi sarcoma), either in remission or being actively treated; (iii) patients after treatment of B cell PTLD; (iv) patients with recurrent CMV viremia, because EVR has anti-CMV activity *in vitro* and is associated with less CMV replication and disease *in vivo* compared to MMF [127, 128]. Notably, the incidence of EBV or BK polyomavirus infection is not lower in EVR- compared to MMF-treated patients [125].

Side Effects

Clinically relevant adverse effects of SRL and EVR that require a specific therapeutic response or can potentially influence short- and long-term patient morbidity and mortality as well as graft survival include hypercholesterolemia, hypertriglyceridemia, infectious and non-infectious pneumonia, anemia, lymphocele formation and impaired wound healing (Table 67.2). These drug-related adverse effects are important determinants in the choice of a tailor-made immunosuppressive drug regimen that matches the individual patient risk profile. Equally important in the latter decision is the lack of severe intrinsic nephrotoxicity associated with SRL and EVR and its advantageous effects on hypertension, post-transplantation diabetes mellitus and esthetic changes induced by CNIs. Mild and transient thrombocytopenia, leukopenia, gastrointestinal adverse effects and mucosal ulcerations are all minor complications of SRL and EVR therapy that have less impact on the decision for choosing this drug as the basis for tailor-made immunosuppressive therapy.

An additional side effect in the setting of CNI withdrawal and mTOR inhibitor introduction is aggravation of proteinuria in patients with pre-existing proteinuria by a still incompletely defined mechanism. Available data are consistent with the hypothesis that the increase of proteinuria is causally related to CNI withdrawal and not because of initiation of an mTOR inhibitor [129]. On the other hand, it cannot be excluded that SRL and EVR might also affect glomerular permeability in some patients. The potential complication of increased proteinuria, which is an independent risk factor for decreased long-term kidney allograft function, should therefore be considered when converting from a CNI-based to an mTOR-containing maintenance therapy. Preliminary results show that mTOR inhibitor treatment may impair gonadal function after kidney transplantation, but the clinical significance of these effects is unknown [129, 130].

Generic Immunosuppressive Drugs

The number of immunosuppressive drugs prescribed to prevent rejection is relatively small. Not more than 10 different compounds have been used over a period of 50 years. For most of these drugs, the patents have expired (AZA, CSA, TAC, MMF, SRL), or will expire within the next few years (EVR, mycophenolate sodium) [131]. Policy makers consider generic drugs an attractive option to enable savings on medication cost, allowing the savings to be used for funding high-cost medicines. Generic immunosuppressive drugs are available in Europe, Canada, and the US. Between countries, there are large differences in the market penetration of generic drugs in general, and for immunosuppressive drugs in particular. To allow for safe substitution, a number of criteria need to be fulfilled. Generic substitution should not be taken out of the hands of the treating physicians. Generic substitution can only be done safely if initiated by the prescriber, and in well-informed and prepared patients. Payers should refrain from forcing pharmacists to dispense generic drugs in patients on maintenance treatment with brand drugs. Instead, together with transplant societies, they should design guidelines on how to implement generic immunosuppressive drugs into clinical practice. Substitutions must be followed by control visits to check if the patient is taking the medication correctly and if drug exposure remains stable. Inadvertent, uncontrolled

substitutions from one generic to another, initiated outside the scope of the prescriber, must be avoided as they are unsafe. Repetitive subsequent generic substitutions result in minimal additional cost savings and have an inherent risk of medication errors [131].

Adherence to Immunosuppressive Medication

Adherence to medications is defined as the process by which patients take their medication as prescribed. Adherence is of critical importance and it is often lacking, especially in teenagers. Adolescent age at transplant is an independent and significant risk factor for worse long-term renal allograft survival in all major pediatric solid organ transplant types [132]. Adolescents have also been identified to have a multitude of psychiatric and socioeconomic risk factors that deserve greater attention and customized care delivery programs [133]. Immunosuppression obviously only works if it is taken reliably, and there is ample evidence in the literature that this reliability is lacking far too often, leading to adverse outcomes. Moreover, immunosuppressive regimens may need to be adjusted to support adherence, e.g. by combination products to reduce the pill burden and/or by once daily dosing. The latter is realized by a prolonged-release TAC formulation available for older children and adolescents (Advagraf™ in Europe, Astagraf™ in the US). Comparative pharmacokinetic studies have shown that stable pediatric transplant recipients can be converted from immediate-release to prolonged-release TAC at the same total daily dose, using the same therapeutic drug monitoring method [134, 135].

Conclusions

Transplantation in children carries unique challenges. While issues such as controlling rejection and minimizing side effects are similar between adults and children, maintenance immunosuppressant regimens that affect developmental processes have a disproportionate impact on children. This is particularly true for steroids, which have many side effects, including some that can be quite devastating in pediatric patients. Steroid avoidance has been very successful when MMF is combined with TAC and either basiliximab or anti-thymocyte globulin for induction therapy is added; long-term follow-up on these patients with regards to improvements in kidney allograft survival and transplant function will be very informative, as steroid-free patients also have reduction of co-morbidities that drive chronic allograft dysfunction. With the goal of eliminating steroids, the combination of MMF and TAC may strike the correct balance between adequate and excessive immunosuppression. Recently, the use of EVR has been advocated for minimizing CNI exposure after kidney transplantation, but its use is limited by mTOR-related side effects. There is at present no consensus for immunosuppressive therapy following renal transplantation in children.

Newer drugs such as belatacept have not been systematically studied in the pediatric transplant patient population. Since the approval of belatacept in 2011 for use in *de novo* adult renal transplantation, this CD80/86-CD28 co-stimulation blocker has been shown to be a valuable treatment option for maintenance immunosuppression [136]. Belatacept in adults has been associated with a superior GFR as compared to CNI-based treatments because of the absence of nephrotoxicity. Additionally, belatacept avoids cardiovascular side effects (e.g. hypertension and dyslipidemia) caused by a CNI-based-regimen [136]. However, its use is limited to EBV-seropositive patients, since EBV-naïve patients on belatacept have an increased PTLD risk. Nevertheless, there is great interest in belatacept as possible “depot” immunosuppression in adolescent pediatric recipients. The latter population has the highest rates of kidney allograft loss due to immunosuppression non-adherence and will most likely have prior exposure to EBV. Belatacept has been shown to be safe in adolescents, but not yet approved for children or EBV-naïve patients given the additional risk for developing PTLD [137]. Studies are underway to explore safe pro-

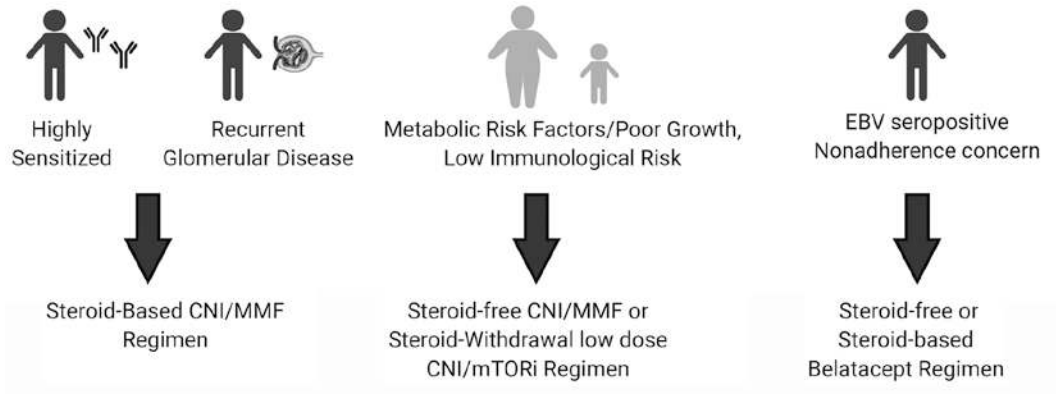

Fig. 67.13 Modern era immunosuppressive strategies in children. The role of a low-dose CNI regimen is illustrated within the context of other maintenance therapies. *CNI* calcineurin inhibitor, *EBV* Epstein-Barr virus, *MMF* mycophenolate mofetil, *mTORi* mammalian target of rapamycin inhibitors. tocols for the use of belatacept in adolescent children.

Currently, there is a paucity of novel maintenance immunosuppressive drugs in the pipeline. Iscalimab, a non-B cell depleting anti-CD40 monoclonal antibody, has been investigated in a phase 2 trial in *de novo* adult kidney allograft recipients with a CNI-free regimen, and other agents targeting co-stimulation blockade are in pre-clinical development [85].

Clearly, much additional work is needed to define optimal immunosuppressive regimens in pediatric renal transplant patients, particularly with respect to newer and evolving regimens. The safety and efficacy of these protocols, with special emphasis on long-term renal allograft survival, PTLD and other malignancies, but also co-morbidities need to be established. The "one size fits all" strategy needs to evolve into tailored strategies based upon a child's medical history and circumstance (Fig. 67.13) [138].

68 Non-Infectious Post-Transplant Complications: Disease Recurrence and Rejection

Lyndsay A. Harshman, Sharon M. Bartosh, and Stephen D. Marks

Introduction

With improved screening for immunological sensitization and newer immunosuppressants, the early renal allograft survival rates have increased considerably over the past three decades. However, the risk of renal allograft loss due to non-infectious complications—such as rejection or recurrence of primary disease—remains a worrisome and stark reality for some pediatric kidney transplant recipients (pKTR). This chapter will discuss the causes of allograft dysfunction, including recurrence of primary kidney disease, rejection, and acute post-operative complications. The investigations and management of these conditions will be considered with particular emphasis on the diagnosis and treatment of graft dysfunction.

Recurrence of Primary Kidney Disease in the Allograft

Overall, recurrence of disease accounts for 7–8% of graft losses in pKTR and is the fourth most common cause of allograft loss after chronic rejection, acute rejection, and death with a functioning graft [1]. Recurrent diseases leading to allograft loss are most commonly glomerulonephritis (70–80%) and inherited metabolic diseases (Table 68.1) [1].

Disease recurrence may render the graft unsalvageable and lead to years of patient and graft life lost [2]. General features of disease recurrence may include renal allograft dysfunction with elevated serum creatinine, hypertension, oligoanuria, hematuria, and/or proteinuria. Recurrence may occur at variable time points post-transplant, with some diseases, such as C3 glomerulopathy (C3G) and focal and segmental glomerulosclerosis (FSGS), having the potential to recur within hours to days after transplant.

In a competing risk analysis of 1955 European children transplanted before age 20 years, the highest rates of allograft failure were seen in

Table 68.1 Estimated rates of disease recurrence following transplantation. (Reproduced with permission from Cochat et al., [1])

Primary disease	Recurrence rate	Graft loss to recurrence
FSGS	14–50%	40–60%
Atypical HUS	20–80%	10–83%
Typical HUS	0–1%	0–1%
MPGN type 1	30–77%	17–50%
MPGN type 2	66–100%	25–61%
SLE nephritis	0–30%	0–5%
IgA nephritis (Berger disease)	35–60%	7–10%
Henoch–Schönlein nephritis	31–100%	8–22%
Primary hyperoxaluria type 1	90–100%	80–100%

those children with immune-mediated kidney disease compared to children with end-stage kidney disease (ESKD) secondary to congenital anomalies of the kidney and urinary tract (CAKUT) [3]. Statistically significant differences in 5-year allograft losses were seen for children with FSGS (25.7%) and membranoproliferative glomerulonephritis (MPGN) (32.4%) compared to transplant recipients with CAKUT (14.4%) as the cause of their ESKD [3].

Focal and Segmental Glomerulosclerosis

Nature and Frequency of Primary Disease

FSGS is the third most common primary diagnosis in children and adolescents, accounting for 10–13.2% of cases in children older than 12 years of age, with nearly 50% of affected patients progressing to ESKD [4]. The percentage of children listed as having either FSGS or other glomerular disease as the cause of their ESKD has been decreasing over the past decade, perhaps related to improved therapeutics and success in treating glomerulonephritis in children. Despite improvements in treatment, glomerulonephritis (non FSGS) is the identified cause of ESKD in 6.5% of children undergoing kidney transplantation in the USA [5].

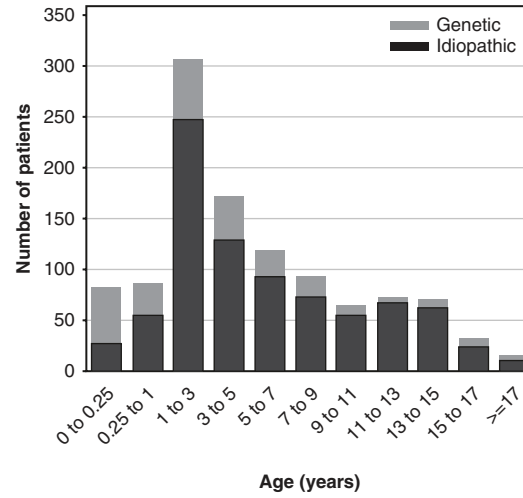

Fig. 68.1 Age at first disease manifestation in children with and without an identified genetic cause of steroid-resistant nephrotic syndrome [13]

Although most cases of FSGS are sporadic (idiopathic), familial forms have been linked to mutations in genes encoding slit diaphragm in addition to other proteins, including nephrin, podocin, WT1, alph-actin-4, CD2AP and TRPC6 [6–12]. The percentage of children having an identified gene mutation is variable depending on the age of the child [13]. In children presenting with NS in the first 3 months of life, 85% have pathogenic mutations. The percentage of children with identifiable mutations decreases with age (for example, 50% in those 4–12 months and approximately 10% in teenagers; Fig. 68.1).

Investigations into podocyte biology and circulating permeability factors have shed light on the pathogenesis of FSGS. A candidate circulating factor, soluble urokinase-type plasminogen activator receptor (suPAR) has been identified to potentially explain the pathophysiology of FSGS at least in some cases of primary, non-familial FSGS [14–16]. The prognostic value of suPAR in the prediction of disease recurrence post-transplant, however, remains unclear [2, 17–20].

Considerations for Transplant Planning: Predicting Risk for Recurrence

In children with ESKD secondary to FSGS, considerations for transplant planning and donor selection are related to the risk of disease recurrence [13]. Much of the early literature relating to recurrence risk did not differentiate between idiopathic cases of FSGS and genetic causes of FSGS. Since genetic FSGS is presumably due to structural alterations in podocyte proteins of the native kidneys, one would not predict recurrence of disease for these patients. Screening for genetic mutations has become a routine part of pre-transplantation evaluation in patients who develop ESKD due to FSGS to allow for appropriate counseling of families and to anticipate the risk of recurrence [6, 21, 22]. Unfortunately, the genotype-phenotype relationship for recurrence risk is not always clear, especially when identified variants are of unknown pathogenic significance.

The clinical course of FSGS prior to ESKD can provide important insight to risk for recurrence. For example, initial steroid responsiveness that evolves to secondary steroid resistance appears to have a higher risk of recurrent disease. In contrast, patients with initial steroid resistance were more likely to have a genetic cause of FSGS and a significantly lower likelihood of developing recurrence post-transplant [23]. Additional clinical risk factors for recurrence include: an aggressive clinical course of primary FSGS with rapid progression to ESKD within 3 years of diagnosis and younger age at onset of nephrotic syndrome [24–26]. The role of race in predicting recurrence of FSGS has been evaluated by several groups. Although African American children tend to have a more aggressive course of initial disease, they do not appear to be at higher risk of recurrence and may be at a lower risk compared to white children [27–29].

Donor type, induction immunosuppression regimen, and timing of corticosteroid withdrawal have all been evaluated using large international registry studies to describe risk for FSGS recurrence after kidney transplant. The TANGO (post-transplant glomerular disease) study evaluated a cohort of 176 patients who presented with nephrotic syndrome and had biopsy proven idiopathic FSGS [30, 31]. FSGS recurrence rate was 32%, with a median time to recurrence of 1.5 months. Among those who had FSGS recurrence, 39% lost their allograft over a median of 5 years. There was a higher risk of recurrence with older age at primary FSGS onset, white race, lower BMI at transplant, and native nephrectomies. No differences were seen for donor type (living or deceased), human leucocyte antigen (HLA) mismatch, induction immunosuppression regimen, pre-transplantation plasmapheresis (PE), or time to ESKD from disease occurrence.

The impact of FSGS on renal allograft survival in children is greatest in transplants after living donation, resulting in loss of the expected living donor allograft survival advantage [28, 32–34]. This effect is particularly evident in adolescents [32]. For this reason, the rationale for use of living donors in children with ESKD secondary to FSGS should be based on factors other than better outcomes typically associated with living donor transplantation [21]. Since the risk of recurrence of FSGS in a second allograft has, in some series, been reported to be as high as 100% [35], further attempts to transplant after allograft loss due to recurrence should be carefully considered [1].

While practices regarding pre-transplant native nephrectomies vary and some experts have supported bilateral native nephrectomy prior to transplantation [36, 37], others have not confirmed this recommendation [38, 39]. While there may be reasons to perform native nephrectomy

prior to kidney transplantation, such as persistence of nephrosis and abnormal coagulation increasing the risk of thrombosis, there is not convincing evidence that native nephrectomies affect FSGS recurrence risk in the pediatric population.

There are no clear data to support a single induction immunosuppression regimen to minimize risk for post-transplant FSGS recurrence. Raafat et al., [40] evaluated retrospective data for 35 pKTR between 1968–1997 at a single center. They found a potentially higher risk of FSGS recurrence associated with use of anti-lymphocyte globulin, with seven of eight patients receiving anti-thymocyte globulin (ATG) experiencing a recurrence. Hubsch et al. [41] compared the incidence of recurrence following induction with ATG and the IL-2 receptor blocker daclizumab. In contrast to data from Rafaat et al., Hubsch found a significantly higher risk of recurrence with daclizumab as induction therapy. More recent multicenter, retrospective data from the North American Pediatric Renal Trials Collaborative Study (NAPRTCS) evaluated patients transplanted between 2002 and 2016, comparing patients with FSGS to other glomerular diseases [34]. Among the cohort of 2010 patients, there was no association between induction agent(s) and allograft survival. Lastly, there are no data supporting use of rituximab as a primary transplant induction agent for prevention of recurrence of FSGS.

As with the data for induction immunosuppression, published literature is mixed as to the impact of corticosteroid avoidance and early corticosteroid withdrawal on potential for FSGS recurrence. Clinical practice regarding use of corticosteroids following transplant is variable. A descriptive survey was performed by the European Society for Pediatric Nephrology to evaluate current practices for recurrence of FSGS after pediatric kidney transplantation [42]. Within this professional cohort, corticosteroids were prescribed for different durations following transplant: (a) life-long (37%); (b) for 3–12 months (17%); (c) 1–2 years (15%); and (4) other or unknown (31%).

Kukla et al., [43] studied the effect of rapid corticosteroid discontinuation on disease recurrence among adult transplant recipients with a history of glomerulonephritis, including recipients with FSGS. They found that corticosteroid avoidance was associated with a higher rate of recurrent glomerulonephritis, but no apparent increase in risk of allograft loss. The 1-, 5-, and 7-year recurrence rate in the glomerulonephritis group completing a rapid corticosteroid discontinuation protocol was 6.7%, 13.7%, and 19.2% and in historic glomerulonephritis recipients maintained on corticosteroids it was 2.4%, 3.8%, and 5.3%, respectively ($P < 0.0001$). Within this sample, rapid corticosteroid discontinuation was also associated with a higher adjusted risk of recurrent disease for all glomerulonephritis types (hazard ratio 4.86; 95% confidence interval 2.34–10.07; $P < 0.0001$). The results of early corticosteroid withdrawal in adult FSGS recipients compared to a historic control group of FSGS patients who received a kidney transplant in parallel with corticosteroid-based immunosuppression was reported by Boardman et al., [44]. There was no significant difference in recurrent FSGS, time to recurrence, or allograft loss.

Given the mixed and limited results across available literature, the use of long-term corticosteroids should be weighed in the context of duration and risk-benefit ratio considering the increased risk for development of new onset diabetes mellitus after transplantation, hyperlipidemia and poor growth.

Treatment of FSGS Recurrence

When FSGS is the cause of ESKD, recurrence is one of the major risk factors for premature allograft loss and has been reported to occur in 14–60% of first transplants and up to 80% of subsequent transplants [1, 25, 27–29, 35, 45–47]. In the NAPRTCS report, 6.6% of index graft failures were due to recurrent disease, with 48% secondary to recurrence of FSGS [48]. There are many approaches for the treatment of recurrent FSGS, and conclusions are limited by small sample sizes and heterogeneity in treatment. The CERTAIN study group recommended initial treatment with early PE or immunoadsorption—

possibly combined with intravenous rituximab—and an angiotensin-converting enzyme inhibitor or angiotensin receptor blocker [21]. If there is inadequate response or patients are dependent on apheresis modalities, then the use of high dose cyclosporin, rituximab, or LDL apheresis should be considered.

Rarely, recurrence may occur intraoperatively at the time of transplant, and approximately 30% of patients with FSGS recurrence have histological evidence of recurrence within the first few days after transplant, with allograft loss in half of these cases [49, 50]. Recurrent disease should be suspected if there is significant proteinuria, which is often accompanied by hypoalbuminemia and other features of nephrotic syndrome. The diagnosis is confirmed histologically with the demonstration of podocyte foot process effacement and without the classical segmental sclerosis of glomeruli [51].

Optimal management of recurrent FSGS remains controversial due to the paucity of well-designed randomized trials and lack of control groups and is often approached in a multimodal manner using various combinations of high dose cyclosporin, cyclophosphamide, intravenous rituximab, PE, immunoadsorption (IA) and LDL-apheresis. To date, no controlled clinical trials comparing different treatment strategies have been performed, and current management recommendations have been adapted from anecdotal reports and small case series.

High dose cyclosporin, with doses of 13–35 mg/kg/day or intravenously at 3 mg/kg/day for up to 3 weeks, has been used for treatment of post-transplant recurrence of FSGS and has been found in retrospective series to achieve remission in approximately 75% of pKTR [52–54]. The reported studies are confounded by the inclusion of patients who had also received plasma exchange in addition to high dose cyclosporin, although the best outcomes were observed when combination therapy was utilized [55]. The CERTAIN study group recommended initial treatment with early PE or immunoadsorption—possibly combined with intravenous rituximab—and an angiotensin-converting enzyme inhibitor or angiotensin receptor blocker [21]. If there is inadequate response or patients are dependent on apheresis modalities, then the use of high dose cyclosporin, rituximab, or LDL apheresis should be considered.

Pre-emptive rituximab monotherapy has not been shown to prevent recurrence of nephrotic syndrome post-transplantation [56]. The addition of rituximab to PE may be considered, with 44–50% of patients treated with rituximab achieving complete remission and 20–25% achieving partial remission, and the reported number of doses given varying from 1 to 6 [57–61]. The optimal timing of rituximab administration and the required number of doses remain unclear. Likewise, a correlation between CD19/CD20 B-cell depletion and clinical efficacy has not been demonstrated. Side effects of rituximab include hypogammaglobulinemia and increased risk for infection.

Due to the successful treatment of children with steroid-dependent or frequently relapsing nephrotic syndrome with oral cyclophosphamide, this treatment has also been used to treat FSGS recurrence. Experience with oral cyclophosphamide in this setting is quite limited but has been reported to be well tolerated and to lead to long-term remission in some patients [35, 45, 62]. In one series of pediatric subjects, a cumulative dosage of 115–121 mg/kg of cyclophosphamide was used over a 3-month period to induce remission following disease recurrence [63].

Clinical and experimental evidence supports the existence of a circulating factor responsible for FSGS, with several candidate factors proposed including galactose, cardiotrophin-like cytokine-1 and soluble urokinase receptor (suPAR) [64]. Due to the possibility of a circulating permeability factor causing progressive podocyte injury leading to FSGS (primary or recurrent), the use of extracorporeal systems aimed at removal of this factor such as PE, IA, and low-density lipoprotein-apheresis (LDL-A) have been introduced. Several groups have reported the favorable effects of PE on remission of recurrent FSGS and on overall allograft survival although these retrospective case series differed in numbers of patients treated, underlying immunosuppression regimens, definition of

recurrence, and ethnicity of the patients [1, 25, 50, 54, 65–68]. Different PE protocols have been reported, with colloid replacement including 4.5–5% albumin, intravenous gamma globulin and fresh frozen plasma. In most reports, PE was started early, within 7 days of developing proteinuria. The outcome of PE in recurrent FSGS may be linked to the number of sessions performed, typically ranging from 5 to 13 treatments. After initiation of PE, the time to remission is also highly variable, ranging from 5 to 27 days in the reported literature. Immediately post-transplant, the exclusive use of 5% albumin should be avoided due to the increased risk of post-operative bleeding. Some centers recommend prophylactic use of PE even before nephrotic syndrome develops [67], although others have not found that preemptive therapy is effective [65, 69]. It is important to note that in reported cases, PE is almost universally used in conjunction with immunosuppressive therapy, including corticosteroids, cyclophosphamide and calcineurin inhibitors (CNIs).

Another therapy for recurrent FSGS which could potentially remove inciting circulating factors is IA [66, 70, 71]. A comprehensive review of the extracorporeal therapies, particularly with respect to the technical aspects, has recently been published [72]. Case series data suggests that IA seems to have comparable efficacy to PE although there are no head-to-head comparisons; thus, the exact mechanism of IA remains unclear. In a multicenter French study of recurrent FSGS in children, 10 of 12 treated with IA responded (eight with complete remission and two with partial remission) [68]. A decrease in proteinuria occurred within the first 10 sessions. Within 3 months of IA, eight pKTR were IA dependent, with two patients able to maintain remission without IA.

Apoproteins play a role in lipid transport and possibly in maintaining the integrity of the glomerular filtration barrier. Loss of these factors may play a role in the pathogenesis of recurrent FSGS [73]. There are many proposed mechanisms through which hyperlipidemia, hypercholesterolemia, and abnormal lipoproteins ultimately lead to progressive renal disease involving oxidative stress, vasoactive substances, and inflammatory factors [74]. LDL-A is a primary selective extracorporeal system that has been studied in FSGS [72]. In addition to inducing remission, LDL-A is purported to improve response rate to corticosteroid and immunosuppressive therapy. Currently, LDL-A is commonly performed using the Liposorber LA-15 system, which was approved by the FDA in the USA for a Humanitarian Device Exemption in 2013 for use in the treatment of pediatric patients with drug-refractory FSGS as well as post-transplant FSGS.

Lastly, renin-angiotensin-aldosterone blockade may be considered in post-transplant recurrence of FSGS, particularly to help diminish protein excretion and to address the suggested role of angiotensin in the role in the pathogenesis of recurrent FSGS [24, 75].

Atypical Hemolytic Uremic Syndrome

Nature and Frequency of Primary Disease

The prevalence of atypical hemolytic uremic syndrome (aHUS) in patients less than 20 years of age is estimated at 2.21–9.4 per million people [76] with the highest disease prevalence occurring in children between 0–4 years of age [77]. Uncontrolled overactivation of the alternative complement pathway (ACP) at the level of the endothelium is a primary immunological feature of aHUS [78]. There are known genetic abnormalities within the ACP which predispose to aHUS, including complement factor H (CFH), complement factor I (CFI), complement component C (C3), complement factor B (CFB), and membrane cofactor protein (MCP). In addition, some patients have aHUS secondary to autoantibodies to CFH. The clinical hallmark of aHUS is a thrombotic microangiopathy (TMA) with a microangiopathic hemolytic anemia, thrombocytopenia and renal dysfunction. Direct kidney injury is largely driven by damage to the glomerular endothelium from the complement-

associated membrane attack complex (MAC) composed of complement components (C) C5b-9 [79]. Kidney damage results in acute kidney injury, difficult to control hypertension, microscopic hematuria, and proteinuria.

Considerations for Transplant Planning

Kidney transplantation should be delayed at least 6 months after starting rescue therapy with eculizumab (a recombinant, humanized monoclonal antibody against the complement protein C5 [80]) as there may be limited recovery of kidney function that occurs within the first several months of eculizumab initiation [81–83]. Furthermore, aHUS-associated hematological features and extra-renal manifestations should be resolved prior to transplantation [81].

The risk for aHUS recurrence post-transplant is strongly linked with several pathogenic complement-based mutations. CFH, CFI, and C3 mutations have the highest risk for aHUS recurrence (68–90%, 70–80%, and 40–50%, respectively) [84]. It is important to note that approximately 30–50% of patients with aHUS have no identifiable genetic mutation or CFH autoantibody using currently available testing platforms [85, 86]. Pediatric patients and families should meet with a genetic counselor having expertise in complement-mediated genetic abnormalities. When counseling families of children and young people affected with aHUS without identification of a genetic mutation or autoantibody, it should be emphasized that there still may be an underlying genetic contribution to aHUS that could confer recurrence risk post-kidney transplant.

The diagnosis of aHUS has implications for evaluation of potential living donors. For example, kidney donation from a living-related donor has historically not been advised given the potential for the related donor to have the same genetic susceptibility factor(s) as the recipient [87]. As noted, if there is no identifiable complement genetic mutation in the patient, then living-related donation is contraindicated given the risk for an unidentified, underlying genetic mutation which could adversely impact the donor [88]. Conversely, if a pathogenic gene variant is identified in the recipient and not present in a potential living-related donor (and the donor has no other evidence of abnormal complement activation), then living-related donation may be feasible [87]. Living donation may, in fact, confer a decreased risk for complement activation secondary to ischemia-reperfusion injury typically encountered with deceased donation [89].

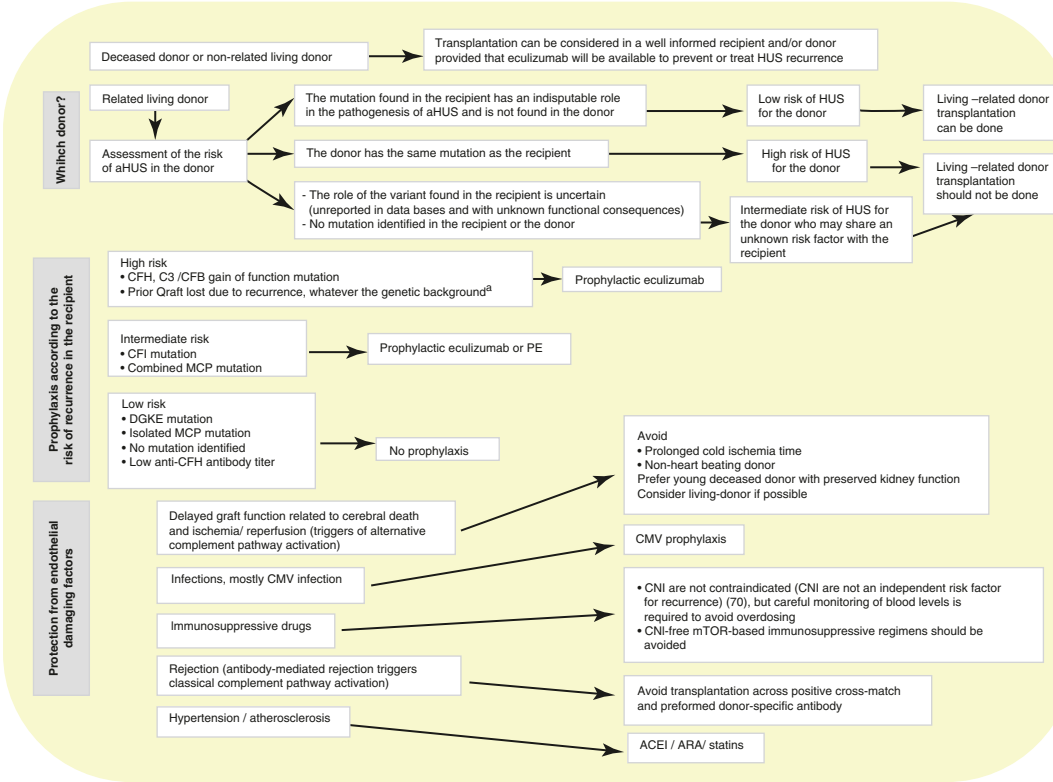
Risk Factors for Recurrence and Treatment of Recurrence

Most aHUS recurrences occur within the first year following kidney transplant. The strongest risk factor for aHUS recurrence is the presence of genetic complement abnormalities [86, 87, 90]. Feitz et al. [84] provide an excellent review of the estimated risk for aHUS recurrence based on complement gene mutation. The development and availability of eculizumab has drastically changed how transplant nephrologists approach prevention of aHUS recurrence. For patients with a known genetic mutation conferring risk for recurrence, intravenous eculizumab should be initiated within 24 h prior to transplantation, with an additional dose on the first post-operative day [87].

Current guidelines from the Kidney Disease Improving Global Outcomes (KDIGO) consensus report provide expert opinion regarding prophylaxis strategies against aHUS recurrence post-transplant based on a risk-assessment strategy (Table 68.2). For example, patients with persistently negative factor H autoantibody and/or isolated MCP mutations can potentially be transplanted without prophylactic eculizumab [81, 91]. In this situation, the child should be followed closely post-transplant for disease recurrence, with a low threshold to initiate intravenous eculizumab therapy. Markers of disease recurrence might include dropping C3, anemia, thrombocytopenia, low haptoglobin, elevated lactate dehydrogenase, new onset hypertension, microscopic hematuria, and/or proteinuria.

There are no data to support that nephrectomy prior to or coincident with transplant decreases

Table 68.2 Expert opinion regarding prophylaxis strategies against aHUS recurrence post-transplant based on a risk-assessment strategy. (Reproduced with permission from Loirat et al., [91])



risk for recurrence. Available, limited data suggest that targeted transplant protocols attempting to minimize endothelial damage may decrease risk for aHUS recurrence in patients not receiving prophylactic eculizumab. For example, induction therapy with basiliximab (interleukin-2 receptor blocker) may be preferable to use of lymphocyte depleting agents [92] in addition to decreasing the target trough CNI levels [93]. A case series [94] demonstrated excellent patient and allograft outcomes using an induction regimen with intravenous basiliximab, reduced-dose tacrolimus, and high-dose mycophenolate mofetil (MMF) in conjunction with early, strict blood pressure control, statin therapy, and angiotensin-converting enzyme inhibition to diminish the risk for endothelial injury that might up-regulate complement activation within the allograft. Acute rejection is an additional risk factor for aHUS recurrence; thus, intensified monitoring for aHUS recurrence may be required during rejection episodes [95].

Risk of Disease Recurrence in the Era of Eculizumab

Prior to the widespread use of eculizumab, kidney transplantation was not a viable option for many aHUS patients given the substantial morbidity and mortality associated with disease recurrence. Without eculizumab, the risk of recurrent disease after kidney transplantation was estimated to be 50–80%, with an overall 5-year graft survival of 36 ± 7% in patients with a recurrence compared with 70 ± 8% in patients without a recurrence [96, 97]. In the absence of effective anti-complement treatment, nearly 30% of the pediatric patients and half of adult patients with aHUS who survived in the acute phase of disease recurrence required long-term dialysis [85, 96]. The 2016 KDIGO consensus report on aHUS suggests that withdrawal of eculizumab should not be considered in patients treated for post-transplant recurrence until there are data demon-

strating the safety of this approach [91]. Limited case-series data suggest that cessation of eculizumab after the first year post-transplant may be a viable, safe option [98]; however, there is currently limited consensus to support this approach.

Additional Post-Transplant Considerations

Due to the risk for sepsis from encapsulated organisms, recipients receiving eculizumab should receive meningococcal and pneumococcal vaccinations prior to transplantation with additional booster vaccinations as necessary following transplantation [99]. The recipient additionally requires prophylactic antimicrobial coverage with ciprofloxacin or penicillin-V for the duration of eculizumab use [99]. The use of eculizumab, MMF, and CNI constitutes triple immunosuppression; thus, terminal CNI levels can potentially be targeted at the lowest end of the clinician's goal range to avoid overimmunosuppression and infectious complications. For example, this may correlate with targeting tacrolimus levels to 3–5 ng/mL after the first 12 months post transplantation in the absence of rejection (expert opinion).

C3 Glomerulopathy

Nature and Frequency of C3G

C3 glomerulopathy (C3G) is an umbrella term that encompasses both C3 glomerulonephritis (C3GN) and dense deposit disease (DDD). C3G is caused by overactivation of the alternative complement pathway. Abnormal complement activation typically may result from loss of function of one of the complement regulatory proteins (factor H or factor I) or from gain-of-function mutations in C3 that lead to resistance to regulation by factor H [100] (see Fig. 68.2). Overactivation of the complement pathway can

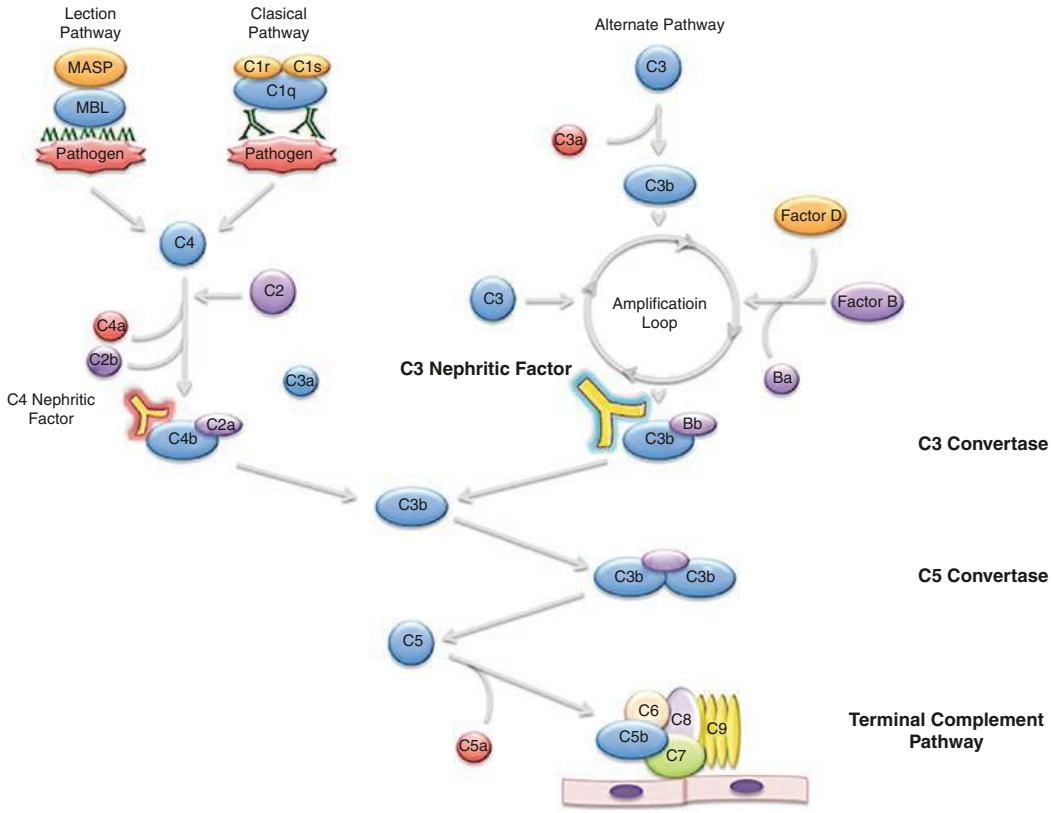


Fig. 68.2 Complement Inhibition in C3G. (Figure used with permission from Nester et al., [100])

also be secondary to generation of a C3 convertase-stabilizing autoantibody, C3 nephritic factor (C3NeF), or production of an autoantibody to factor H. Ultimately, these abnormalities result in overactivity of the C3 convertase and consumption of complement. Thus, low C3 level is a feature of C3G in approximately 75% of cases [78, 101].

C3GN and DDD have an overlapping spectrum of pathological and clinical features. Clinical features are consistent with active glomerulonephritis: nephrotic range proteinuria, microscopic hematuria, hypertension, and renal dysfunction with elevated serum creatinine. The diagnosis of C3G requires a percutaneous renal biopsy demonstrating significant C3 deposition within the kidney, specifically the glomerulus. C3 deposition occurs in the *absence* of immunoglobulin deposition on pathological examination (e.g., negative/near absent immunoglobulin G, immunoglobulin A, and immunoglobulin M) [102, 103]. Electron microscopy findings of electron-dense, "sausage-shaped" deposits within the glomerular basement membrane are pathognomonic of DDD whereas in C3G the deposits are less dense and primarily located within the mesangium.

C3G is an ultra-rare disease with an incidence of around 0.2–1 per 1,000,000 [104, 105]. C3G i has a 10-year kidney survival of 50%, leading to eventual need for kidney replacement therapy [78].

Considerations for Transplant Planning

As with aHUS, planning for transplant in the setting of C3G should include an evaluation with a team experienced in the genetics of complement-mediated kidney disease. This evaluation should include genetic testing of complement genes, measurement/assessment of complement function, and screening for complement autoantibodies. Mutation screening of complement regulatory genes (e.g., CFH, CFI), activation protein genes (C3, CFB), autoantibodies (C3NeF and antibodies to CFH), and assessment of copy number variation across the CFH-CFH-related (CFHR) locus should be done on a case-by-case basis given the need for expert interpretation and clinical validation [81, 102]. Genetic and functional studies may provide insight regarding utility and efficacy of targeted anti-complement therapy (e.g., eculizumab or novel anti-complement therapies in development) should C3G recur following transplant.

Living-related donor kidney transplantation should be approached with caution for both the presumed healthy donor and recipient with C3G. Current international recommendations are that all potential *recipients* of a living-related kidney be screened for genetic abnormalities within the complement system [81]. If a genetic abnormality is found, the donor should subsequently be tested. The presence of an identical genetic abnormality may not constitute an absolute contraindication to donation; however, the individual case be evaluated in conjunction with expert teams in complement genetics and C3G. Furthermore, for donors with identified complement genetic abnormalities, the donor team must disclose the theoretical risks that donation may trigger new disease onset.

There are no published data supporting a specific induction agent; thus, selection is based on center preference. There are no data to support pre- or peri-transplant nephrectomy to prevent disease recurrence. The presence of active disease, specifically heavy proteinuria, is a relative contraindication to transplantation; transplantation should be delayed until there is resolution of nephrotic-range proteinuria, which may require nephrectomies in some patients [81].

Risk Factors for Recurrence and Treatment of C3G Recurrence

C3G recurs at a high rate, with allograft loss due to C3G in approximately 50% of those patients [81]. Patients and families should be counseled on the high risk for disease recurrence. The reported recurrence rate of C3GN is estimated as greater than 50% [106, 107]. The recurrence rate of DDD is much higher and approaches 80–100% [108, 109].

Pediatric patients have lower long-term graft survival. It has been hypothesized that this may be due to more significant complement disruption and aggressive disease in children compared to adults. In one case series, 10-year graft survival was 11% and 21% in pediatric and adult allograft recipients, respectively [110].

Pre-transplantation C3 levels may also predict allograft outcomes. In one small case series, low C3 levels were present pre-transplantation in more than 50% of patients with recurrence; C3 levels were normal pre-transplantation in all patients without recurrence [111]. Other factors associated with an increased risk of C3G recurrence include high levels of circulating autoantibodies (C3NeF and FH autoantibody), rapid progression to ESKD in the native kidneys (crescentic disease) and living-related kidney transplantation [112].

Diagnosis of C3G recurrence requires pathological features of the disease and should be supported by clinical history. Following transplant, patients with history of C3G should be closely followed for signs of recurrence, including proteinuria, hematuria, reducing complement C3 levels and elevated serum creatinine. Up to 90% of C3G allograft recipients will show histological C3 deposition [109, 113]. Data support that protocol biopsies from C3G transplant recipients can show deposition of C3 as early as the first month post-transplant in the absence of clinical disease [113, 114]. Furthermore, glomerular C3 deposition in the absence of other clinicopathological findings is independently associated with a higher risk of allograft failure [114].

Unfortunately, even when recurrence is diagnosed early therapeutic options in the setting of recurrence are very limited. The decision to utilize any therapy for C3G recurrence should be done in parallel with clinical and pathological data as well as comprehensive complement biomarker assessment. There are insufficient data to recommend routine use of plasma exchange for C3G recurrence unless there is an identified complement factor deficiency, such as CFH [81, 102]. Insufficient data exist to support routine use of eculizumab for C3G recurrence [81, 102]. One study [115, 116] suggests that the lowest incidence of allograft loss (33%) among patients with recurrent C3G are those treated with eculizumab. Among those who received no treatment for C3G due to stable allograft function, there is a high incidence of allograft loss of 32% in C3GN and 53% in DDD [115]. Consideration to plasma exchange and/or eculizumab should incorporate assessment of patient complement biomarkers [115]. For example, soluble membrane attack complex levels may help to select good responders to eculizumab.

Due to the mechanistic complexity of C3G, there may not be a single therapeutic option, such as eculizumab for aHUS, that provides comprehensive treatment of C3G recurrence. More promising, perhaps, is the development of complement inhibitors (e.g., inhibition of C3 or complement factor B) which could provide targeted therapy for recurrence of C3G following transplant. Early clinical trial (phase II) data for the novel complement factor B agent, LNP023, demonstrate resolution of proteinuria and stability of kidney function in native kidneys [117]. Data from allograft recipients with C3G recurrence have not been published. With the current lack of treatment options for C3G recurrence post-transplant, loss of a prior allograft due to recurrent C3G indicates a high risk of recurrence upon subsequent transplantation and this should be a major consideration in determining candidacy for re-transplant [112].

IgA-Mediated Kidney Disease

IgA vasculitis (IgAV; previously Henoch-Schönlein purpura) and IgA nephropathy (IgAN) are thought to be related diseases with nearly identical pathology. IgA dominant mesangial deposits are characteristic of both IgAV and IgAN. IgAV is classically described in children, whereas, IgAN occurs more often in early adulthood. IgAV, unlike IgAN, has extra-renal manifestations, including a purpuric lower extremity rash. IgA vasculitis and IgAN are comparatively rare causes of ESKD in pediatric patients.

IgA Vasculitis

Based on limited data, the recurrence rate of IgAV) after transplantation is similar to that of IgAN. A matched retrospective cohort study patients with IgAV in the Organ Procurement and Transplantation Network/United Network for Organ Sharing (OPTN/UNOS) database reported allograft failure from recurrent disease in 13.6%, but no difference in 10-year allograft survival compared to the matched cohort [118].

In a study from six European transplant centers [119], overall allograft survival rates were 84%, 66%, and 56% at 5, 10 and 15 years, respectively. Histologic recurrence occurred in 33% on for-cause biopsies. Clinical recurrence occurred in five patients at a median time of 96 months post-transplant. Allograft loss occurred in three patients resulting in an actuarial risk of allograft loss from recurrence in a first graft of 7.5% at 10 years post-transplant. Severity of disease at presentation and type of immunosuppression post-transplant did not affect recurrence. Although not reaching significance, 60% of those with clinically significant recurrence had living donors compared to 16% of living donors in the cohort who did not experience.

IgA Nephropathy

Nature and Frequency of IgA Nephropathy

IgAN is characterized by a highly variable course ranging from a benign condition to rapidly progressive renal failure and affecting 10–20% of all persons undergoing kidney biopsy, rendering IgAN the most prevalent primary chronic glomerular disease worldwide [120]. Prevalence of IgAN differs among populations of different ancestries, being most frequent among persons of Asian descent, rare in those of African descent, and with an intermediate prevalence among those with European descent.

IgAN is thought to occur due to a primary, inherited defect leading to preferential production of IgA with galactose-deficient O-glycans in the hinge-region. IgA deficient in galactose elicits the production of anti-glycan autoantibodies that lead to the formation and subsequent glomerular deposition of immune complexes. IgA-based activation of alternative complement pathway plays a critical role in the pathogenesis of IgAN. For example, C3 is frequently involved in the formation of circulating immune deposits inducing mesangial stress, podocyte damage and progressive deterioration of kidney function. On this basis, IgAN can be classified as an autoimmune glomerular disease. While the pathogenesis of the disease resulting in IgA1 subclass deficient in galactose is not completely clarified, genome-wide association studies have identified multiple susceptibility loci for IgAN implicating independent defects in adaptive and innate immunity, and alternative complement pathways that potentially influence the different pathogenetic steps towards development of disease [121].

IgAN generally has an indolent course, with a 10-year native kidney survival rate of 90% in adults and children with normal renal function at diagnosis; however, 71% of patients will demonstrate worsened hematuria and/or proteinuria in upwards of 20 years follow-up [122]. Clinical risk factors for progression to ESKD include heavy proteinuria, decreased estimated glomerular filtration rate (eGFR) at diagnosis and uncontrolled hypertension, although the ability to accurately predict individual patient-level risk remains limited [123].

Risk Factors for Recurrence

The reported frequency of histologic or clinically significant recurrence of IgAN post-transplantation varies in the literature. An excellent review of recurrence rates cis available [124]. The recurrence rate in a study from the Australia and New Zealand Dialysis and Transplantation Registry (ANZDATA) was 5.4% and 10.8% at 5 and 10 years, respectively, with a median time to recurrence of 4.6 years [125]. Analysis of data from the ANZDATA showed no increased risk of recurrence in a second allograft after loss of a first allograft to recurrence despite prior reports of increased risk.

Recurrence of IgAN can be "histologic only" when diagnosed on protocol biopsies in asymptomatic patients or "clinical" when associated with urinary abnormalities and/or graft dysfunction. Histologic recurrence in protocol biopsies in adults, with or without evidence of clinical disease, is common, with IgA mesangial deposition being found in up to 32–58% of grafts [126, 127]. In children with IgAN, the recurrence of IgA deposits in the allograft following transplantation is very common, but clinically relevant recurrent disease has been reported to be infrequent [128]. Hematuria, the hallmark of IgAN in the native kidney, is not a reliable manifestation of recurrence, being absent in 52% of cases diagnosed by protocol biopsy [126]. Given the lack of a prospective study involving allograft protocol biopsies in pKTR, the true risk of significant allograft dysfunction and allograft loss from recurrent disease in the pediatric population remains unclear.

No single parameter, including age, gender, race, donor source, HLA typing, pre-transplantation course or biochemical characteristics of serum IgA, has been shown to reliably predict recurrence. Risk factors for recurrence in IgAN have been suggested to be younger age at transplant, male gender, and rapidly progressive course of original disease, but there is not consensus. Furthermore, one study of native kidney biopsies in adults with IgAN showed that younger age at onset of IgAN and greater burden of crescents predicted recurrence after transplant [129]. Longer time following transplantation may also be a risk factor for disease recurrence and supports the suggestion that recurrence may be a time-dependent event [127]. The relationship between donor type and recurrence of disease is discussed below.

Considerations for Transplant Planning

The relationship between the risk of recurrence and the donor type remains controversial, with conflicting reports in the literature [130–135]. There have been no large, prospective studies defining the risk of recurrence in patients with IgAN who receive either living donor or deceased donor renal allograft although there are large registry reports. An analysis of ANZDATA found recurrence was significantly more frequent in the zero HLA-mismatched living donors at 17% vs 7% in the cohort overall. In this report, allograft survival was the same for recipients of zero HLA-mismatched donors and those with one or more HLA mismatches (and no recurrence), suggesting loss of the survival advantage expected with zero HLA-mismatched transplants [136]. The authors concluded that despite increased recurrence risk, since allograft survivals were similar, there is no reason to avoid living donor-recipient pairs with zero HLA-mismatches in IgAN. In the same study, there were no differences seen in recurrence rates in those with HLA B12, B35 or DR4. A more recent report from the same registry, showed a 10-year recurrence rate of 16.7% in living donors, 7.1% in living-unrelated donors and 9.2% with deceased donors, with a significant HR of 1.7 for living-related vs deceased donors [137].

Genome wide association studies have identified abnormalities in the cCFH and CFHR genes in patients with IgAN [121, 138, 139]. Although it is unclear whether these variants increase the risk of recurrence following transplant, familial IgAN should be rigorously excluded in potential living-related donors since familial IgAN is associated with a high risk of ESKD [140].

The effect of immunosuppression regimen on IgA recurrence risk is unclear. Despite initial enthusiasm, newer immunosuppressants seem ineffective in preventing recurrence [141]. Retrospective data suggest that induction with ATG or anti-lymphocyte globulin is associated with a lower risk of recurrence compared to interleukin receptor-2 blockade [142–144].

Corticosteroid avoidance has become a major goal in pediatric kidney transplantation and has been successful in select transplant recipients [145, 146]. There are conflicting reports on the effect of rapid corticosteroid withdrawal or corticosteroid avoidance on IgAN recurrence risk and allograft survival. In a retrospective analysis of adults in the OPTN/UNOS database with IgAN receiving a first kidney transplant, early corticosteroid withdrawal was associated with increased risk of recurrence

compared to patients in the corticosteroid continuation group. Patient survival and death-censored allograft survival were not different [147]. Similarly, in an analysis of the ANZDATA of adult recipients of a primary transplant for IgAN, corticosteroid use was strongly associated with a reduced risk of recurrence, after adjusting for age, sex, HLA mismatch, dialysis duration and transplant era [148]. In this report, 12.6% of graft loss was attributed to recurrence. Conversely, a study of pediatric patients within the OPTN database reported that receiving a corticosteroid avoidance regimen in patients with a pre-transplantation diagnosis of glomerular kidney disease was not associated with an increased risk of allograft failure, although this study was unable to examine recurrence rates [149].

Treatment of IgAN Recurrence

Just as with native kidney IgAN, no therapy for recurrent IgAN has been shown to be effective. In the setting of disease recurrence, KDIGO guidelines recommend treatment strategies to reduce proteinuria, optimize blood pressure, and reduce inflammation [150].

Use of corticosteroids as well as intravenous rituximab to treat recurrence in small numbers of patients has been described [151–153]. Data from Japan have reported favorable outcomes after tonsillectomy in patients with recurrent IgAN, but these results have not been confirmed in other populations [154–156]. The effect of fish oil on recurrent IgAN has not been systematically examined for risk reduction or treatment of IgAN. One study reported a reduction in proteinuria and stabilization of kidney function after budesonide administration in native kidney IgAN patients, possibly by targeting the intestinal mucosa directly, suggesting a possible role in patients with recurrence post-transplant [157].

Impact of IgAN on Graft Function and Survival

Recurrent disease was thought to have little impact on allograft outcomes; however, recent studies with longer duration of follow-up suggest that recurrent disease may contribute substantially to allograft injury. The rate of allograft loss due to recurrence of IgAN varies based on time from transplant, with less early allograft loss attributed to IgAN and significantly more at 10 years post-transplant [52, 54]. True estimates of allograft loss purely attributable to disease recurrence are difficult given the interplay with acute or chronic rejection and calcineurin toxicity, particularly if histology close to the time of graft loss is not available [127, 158, 159].

Lupus Nephritis

Nature and Frequency of Disease

Systemic lupus erythematosus (SLE) is an autoimmune inflammatory disease that is characterized by antibodies directed against self-antigens, resulting in multiorgan damage. SLE in children is more severe than in adults, and there is a higher incidence of lupus nephritis (LN) [160, 161]. Risk factors for development of ESKD due to LN include International Society of Nephrology and the Renal Pathology Society class IV LN, male gender, black race, hypertension, nephrotic syndrome, anti-phospholipid antibodies, high glomerular staining for monocyte chemoattractant protein-1, chronicity on biopsy, poor response to induction therapy, and occurrence of nephritic kidney flare [162, 163]. Lupus nephritis is responsible for approximately 3% of ESKD leading to transplantation in North America [48].

Risk for Disease Recurrence

The reported risk for recurrent lupus nephritis (RLN) after renal transplantation has been quite variable, ranging from <5% [112] to between 30–50% [164] in studies implementing protocol biopsies to evaluate serially for recurrence. The variability in reported recurrence rates has been attributed to varying indications for renal allograft biopsy across transplant centers; single-center versus registry-based study design; follow-up duration; and varying races and ethnicities in study samples [165].

Large-scale data derived from UNOS between 1987 and 2006 estimated period prevalence as well as predictors of RLN and assessed the effects of RLN on both allograft failure and recipient survival [166]. The period prevalence of RLN within the cohort was 2.44%. Non-Hispanic black race, female gender, and age < 33 years were independent risk factors for RLN. In another study, pre-transplantation antiphospholipid autoantibodies confer a higher risk for RLN [167].

Considerations for Transplant Planning

Data are mixed regarding the impact of donor type on RLN. Data from over 30 years ago suggest that grafts from deceased donors are a better option for patients with lupus nephritis than grafts from living-related donors based on lower 1-year graft survival, presumably due to possible familial inheritance through the HLA system [168, 169]. In contrast, more recent data show no difference in allograft loss between the two types of donors [170].

Pre-transplantation clinical condition and immunosuppressive history are important considerations in transplant planning. KDIGO guidelines recommend that lupus should be clinically quiescent and that the patient is receiving minimal (no) immunosuppression prior to transplantation [112]. Delay of transplantation may be necessary for those patients who have received high levels of pre-transplantation immunosuppression or long-term glucocorticoid therapy to minimize the cumulative risk of prior therapy on top of the need for potent induction immunosuppression at the time of transplant [171]. As noted previously, the presence of antiphospholipid autoantibodies should be carefully considered in transplant planning due to the risk of vascular thrombosis and early allograft failure [172, 173]. Anticoagulation in the peri- and post-transplant period should be considered in patients with antiphospholipid autoantibodies to reduce the risk of vascular thrombosis [112, 174]; however, this risk should be balanced by the potential for bleeding in the immediate post-transplant period [173].

The post-transplant immunosuppression for LN patients does not differ from that normally used. The OPTN/UNOS database was utilized to compare rates of allograft loss due to disease recurrence between transplant patients receiving cyclosporin plus azathioprine (CSA + AZA) compared to those receiving cyclosporin plus MMF (CSA + MMF) [175]. There was no difference in the rates of allograft loss due to RLN among recipients receiving either CSA + AZA or CSA + MMF maintenance immunosuppressive therapy at 10-year follow-up. In patients with LN recurrence, an intensification of immunosuppression should be reserved for the exceptional cases showing a severe (life threatening) lupus flare due to the potential risks of serious or lethal infection post-transplant [165].

Impact of RLN on Graft Function and Survival

Retrospective multicenter data from the North American Pediatric Renal Transplant Cooperative Study (NAPRTCS) database demonstrated that kidney transplant outcomes in young patients with LN were comparable to those seen in an age-, ancestry-, and gender-matched control group, in spite of an unexplained increase in recurrent rejections in the living donor LN patients [176].

In an analysis of UNOS data, allograft failure occurred in 93% of those with RLN, 86% of those with rejection, and 19% of control subjects without rejection [166]. Although recipients with RLN had a fourfold greater risk for allograft failure compared with control subjects without rejection, only 7% of allograft failure episodes were attributable to RLN compared with 43% due to rejection. Mortality was similar (11–18%) between those with RLN, rejection, and controls.

Acute Graft Dysfunction in the Early Post-Operative Period

Graft Thrombosis

One cause of acute graft dysfunction in the early post-operative period is graft thrombosis. Around

2–3% of all renal grafts in the pediatric population thrombose and not surprisingly this is seen more frequently in the early post-transplant period [177, 178]. Thrombosis is encountered more commonly in younger children, particularly those less than 2 years of age at the time of transplant and in those receiving a deceased donor graft [177–180]. The size of the native vessels is undoubtedly a contributing factor, and the frequent discrepancy between donor and recipient vessels increases the surgical difficulty of the anastomosis. Previously, high rates of thrombosis were seen when very young donors were used and this is one of the reasons why children under the age of 5–6 years are now usually excluded from being donors [35, 181]. Thrombosis is now the third most common cause of graft loss, accounting for 9.8% of losses overall and for 7% of index graft losses since January 2000 [182].

Thrombosis is reported to occur more commonly in grafts from deceased donors, in those with prolonged cold ischemic time beyond 24 h and in retransplants [177, 180, 181]. Furthermore, there are data to suggest that pr—transplantation peritoneal dialysis increases the risk of thrombosis [181, 183]. Interestingly, the most recent NAPRTCS data suggest that the previously reported risk factors may not be significant and that the use of IL-2 receptor blockers more than halves the risk of graft thrombosis [178]. Further studies are required to establish the true risk factors for this often devastating complication.

There is an apparent higher incidence of thrombophilic risk factors in the ESKD population. In one study of pediatric pre-transplantation patients, 27% were found to have an increased risk of thrombophilia, whereas another group found that almost 90% of children screened pre-transplantation had at least one thrombotic risk factor [182]. There was a higher risk in the "non-anatomical" etiological group of patients where lupus anticoagulant was commonly detected [48]. The routine use of prophylactic anticoagulation remains controversial and the evidence for its use is limited. Currently, there are many different protocols, ranging from no anticoagulation, tailored anticoagulation according to risk and the use of one or more anticoagulants routinely. One study has compared the use of routine unfractionated heparin with historical controls given no anticoagulation and found no reduction in the rate of allograft thrombosis [177]. Others have reported reduced thrombosis rates with the use of low-molecular-weight heparin [184, 185]. Several units where patients are routinely screened for thrombophilic risk factors have shown good outcomes using anticoagulation protocols stratified for risk, but the numbers of patients included have been small and it is difficult to extrapolate the data to the general pediatric ESKD population [150, 185]. Until there is a large, randomized, controlled trial, the benefit of anticoagulation remains undetermined.

Obstruction

Obstruction to the flow of urine from the allograft can occur at any time but is most common in the early post-operative period. Complete obstruction will result in no urine output, but partial obstruction may only be detected on ultrasound. The scan may show dilatation of the renal pelvis with or without urine in the bladder depending on the level of the obstruction. The major concerns with obstruction are the increased pressure on the ureteric anastomosis with the risk of rupture and the long-term effects of increased pressure on the renal parenchyma. There are many reasons for the early increased risk of obstruction, including intravesical clots, stenosis of the ureter, particularly at the anastomosis site, and external compression or kinking of the ureter due to hematomas and other fluid collections. There is inevitable bleeding at the time of transplant, and it is not unusual for clots to form. The majority of patients post-transplant will have either a urethral or suprapubic catheter to drain the bladder, or rarely a urinary diversion, and this should facilitate the passage of clots, though it is possible for clots to block the catheter and flushing of the catheter is often required in the first few days after the transplant. Inadequate drainage of urine can also be the result of dislodgement of the catheter. Many centers also routinely place a stent into the ureter of the allograft at the time of transplantation and this

generally remains in situ for 2–6 weeks to minimize the risk of stenosis or effects of external compression. External compression of the ureter may be caused by a hematoma, a urinoma, a lymphocele, stool, or any other mass in the vicinity of the graft. Ultrasound will usually be able to follow the length of the ureter and will detect any mass compressing it. Transplant ureters are also at risk of kinking, especially if a large adult donor has been used without appropriate trimming of the ureter. Rarely, further surgical intervention is necessary.

Beyond the early post-operative period, obstruction is more frequently encountered in patients with known bladder problems and in those with incomplete bladder emptying. Double voiding regimes, clean intermittent catheterization or indwelling catheter drainage may be necessary to relieve the obstruction.

Urine Leak

This potentially devastating complication is fortunately rare, and the incidence appears to be decreasing. Leakage is usually due to ureteral necrosis around the anastomosis site, and urine then collects in the abdomen. If an abdominal drain has been placed at the time of surgery, the drain fluid can easily be tested for the creatinine concentration, which would be comparable to that of the urine rather than the blood. If there is no drain, then fine needle aspiration of the fluid and measurement of the creatinine concentration will aid in the diagnosis. Occasionally, nuclear medicine imaging studies may also be considered. The adult literature has demonstrated poorer wound healing in patients treated with sirolimus and subsequent increased urine leak [186].

Investigation of Delayed Graft Function and Peri-Operative Allograft Dysfunction

If no urine is obtained post-operatively, then a systematic approach should identify the cause. Assessment of the patient, ensuring that there is adequate volume replacement to maintain a good blood pressure and central venous pressure is critical. The position of the urinary catheter should be assessed, and it should be checked for any blockage. A Doppler ultrasound will demonstrate the degree and pattern of renal perfusion. If the kidney looks well-perfused and the patient is well-hydrated, then the most likely cause of the delayed graft function (DGF) is acute tubular necrosis, although most would advocate an early biopsy to rule out hyperacute rejection.

If good urine volumes were present but then decrease, factors such as inadequate fluid replacement or a blocked catheter should be considered initially. These problems are common and are easily resolved. If the patient is assessed to be normo- or hypervolemic, then a trial of a loop diuretic may be appropriate. If there is still no response, then more serious complications such as urinary leak, graft thrombosis and hyperacute rejection need to be investigated. A Doppler ultrasound, with or without a mercaptoacetyltriglycine or diethylenetriamine pentaacetic acid scan, will assess the perfusion of the kidney. Ultrasound will also detect obstruction to the kidney, fluid collections around the kidney suggestive of a urine leak or lymphocele, and clots in the bladder. A renal biopsy is required to rule out rejection. In exceptional cases, surgical re-exploration is required to assess the viability of the kidney.

Treatment of Delayed Graft Function

By the most used definition of DGF, dialysis will be required. Data from the OPTN show that 50% recover adequate function by the tenth post-transplant day. The use of CNIs is often minimized or delayed until good graft function is obtained. These patients are often treated with ATG, until graft function improves, or for a maximum of 10 days, as an alternative to CNIs, as there is evidence to suggest less DGF with ATG [187].

Acute Rejection and Chronic Allograft Dysfunction

Acute rejection and chronic allograft dysfunction require clinical, immunological, and histopathological input to understand and appropriately

treat. With the advent of new techniques for detecting anti-HLA antibodies and a better understanding of histological changes, it is becoming easier to define the causes of acute rejection and chronic allograft dysfunction, although it is important to remember that more than one factor may be operating in any individual patient. Interstitial fibrosis and tubular atrophy (IFTA) are the final common pathway of chronic allograft dysfunction; however, early investigation may pinpoint the underlying mechanism involved and allow intervention prior to irreversible allograft fibrosis.

International data from single center reports and registries have shown improved long-term patient and renal allograft survival rates for children and young people after kidney transplantation, including the NAPRTCS [48]. Most studies have shown improvement inpatient and renal allograft survival rates over the last three decades, which may be due to changes in immunosuppressive drug regimens, improvements in HLA matching, and a reduction in cold ischemia times. Pre-emptive and living donor renal transplantation are preferred given improved outcomes for living donation as compared to deceased donation with donation after brain death (DBD) and donation after circulatory death (DCD). A national study from the United Kingdom showed 1-year DBD renal allograft survival for those transplanted from 2012 to 2016 was 98%, compared with 72% for those transplanted from 1987 to 1991 [188]. Within this cohort, renal allograft survival for first kidney only transplants at 1, 5, 10, 20 and 25 years were 89%, 79%, 65%, 42% and 33%, respectively. Superior survival with living donation was maintained throughout the study period with 25-year renal allograft survival at 33% compared with 31% from deceased donation ($p < 0.0001$). These are similar to long-term data published from the Dutch LERIC study; 20-year allograft survival was 49% and 29% for LD and DD, respectively [189]. The 20-year allograft survival in Norway of allografts children since 1970 was 45%; 52% of these allografts were pre-emptive and 84% were from LD [190].

Predictors of Pediatric Renal Allograft Survival

Renal allograft function is calculated using eGFR, which requires the plasma creatinine and height according to modified Schwartz or other formulae, although other serum markers such as cystatin C have been proposed as providing increased accuracy [191].

Living donation confers a distinct advantage over deceased donation as the process of brain death and longer cold ischemia may predispose to acute tubular injury and DGF. DGF, prior transplantation, primary renal disease, and degree of HLA matching appear to influence long-term allograft outcome [192]. Recipient age is a predictor for graft survival, with older children having better early allograft survival but worse 5-year allograft survival [193]. Pre-transplantation dialysis and early acute rejection adversely affect allograft survival [194]. Additionally, some studies have found a deceased donor age over 40 years and prolonged cold ischemia time to be predictive of reduced allograft survival [195].

Proteinuria is common after pediatric renal transplantation, occurring in up to 80% of patients and can be glomerular or tubular in origin. Proteinuria can be both a contributor to and sign of chronic allograft damage [196]. A reduction in nephron mass results in increased intra-glomerular pressure in the remaining nephrons, causing proteinuria, which is injurious to the kidney via glomerular and interstitial inflammation, resulting in interstitial fibrosis and glomerulosclerosis [192]. Proteins entering the interstitium are processed by dendritic cells [197]. It has even been postulated that activated dendritic cells may then predispose to the development of rejection [194]. Transplant glomerulopathy is associated with proteinuria, presumably linked to damage to the glomerular basement membrane following antibody mediated rejection [198]. The use of mammalian target of rapamycin inhibitors has also been associated with the development of proteinuria [199].

Chronic Allograft Dysfunction

Allograft lifespan can be influenced by a variety of factors including peri-implantation injuries, history of allograft rejection, cardiovascular disease, and (recurrent) infection—all of which may influence the rate of decline of renal allograft function. However, the contribution of each of these factors will vary in individual patients. Post-transplant factors can be divided into early or implantation stresses and later injuries to the allograft. It is likely that multiple factors operate in individual patients. Over the last decade, there has been an appreciation that repeated episodes of stress damage the allograft resulting in nephron loss. This cumulative burden of injury eventually results in allograft failure [200].

Pre-Implantation Injury

Long-term outcome data clearly demonstrate that LD transplantation confers a survival advantage compared with deceased donation. This is observed in living-related and unrelated donors, suggesting that reduction in cold ischemia time and avoidance of brain death are important factors. The process of brain death, through hemodynamic and neuro-hormonal changes, reduces the viability of DD kidneys, although optimal management of brain-dead donors and their kidneys can improve outcome [201–203].

Advanced donor age for living and deceased donors is associated with a worse long-term outcome in adult recipients, which may represent reduced functional renal mass, although other factors such as donor hypertension or arteriosclerosis may be important [204]. However, older donor age is associated with a greater risk of renal allograft failure for pediatric recipients. Donor organ quality is also important; more functioning nephrons lead to better outcomes. The presence of interstitial fibrosis on implantation biopsies (reflecting nephron loss) is predictive of late outcome as is glomerular size, which is an inversely related surrogate for renal mass [205–207]. Extended criteria donors are rarely used in pediatric practice, and include donors older than 60 years, or 50–59 years with two out of three of the following: hypertension, cerebrovascular cause of death or plasma creatinine >130 μmol/l (1.5 mg/dL), as they have a 70% increased risk of long-term allograft failure compared with standard criteria donors [208].

Implantation Injury

Cold ischemia, preservation injury and ischemia/reperfusion injury, with or without the effects of brain death, cause allograft injury and DGF, which may result in nephron loss if there is incomplete recovery. There is increased expression of cytokines, adhesion molecules and HLA molecules with ischemia, and DGF can be associated with acute rejection episodes and worse outcomes.

Post Implantation Injury

There are further stresses on the transplanted kidney, including acute or chronic rejection, recurrent disease, hypertension, hyperlipidemia, nephrotoxic medications, and bacterial and viral infections. These insults may cause further loss of nephrons with increasing IFTA. Rejection, as the major cause of chronic allograft dysfunction, is discussed in detail below.

The significant contribution of the immune system to chronic allograft dysfunction is supported by reduced allograft survival in the setting of previous acute rejection episodes, in highly sensitized patients, where there is de novo production of anti-donor HLA antibodies, and where there is evidence of under-immunosuppression.

Acute Allograft Dysfunction and Rejection

Acute allograft dysfunction or transplant acute kidney injury may result from pre-renal, renal, and post-renal conditions. The commonest pre-renal conditions include hypovolemia caused by dehydration (including viral gastroenteritis), hypotension and renal arterial or venous thrombosis, although thrombosis is rare after the immediate post-operative period. Intrinsic renal disease is more common with acute rejection, nephrotoxicity (including CNI nephrotoxicity) and infection (including bacterial infections, such as

transplant pyelonephritis, and viral infections) and recurrent and de novo glomerulonephritis (see above). Post-renal causes are detailed below and include transplant ureteric stent obstruction and dislodgement, ureteropelvic and ureterovesical junction obstructions, bladder dysfunction and rarely perirenal hematoma or fluid. Percutaneous renal transplant biopsies may be required to make the correct diagnosis; these are called indication biopsies as opposed to protocol or surveillance biopsies, which are routinely performed at a specific time point post-transplant.

Allograft Rejection

The Banff Classification was originally devised in 1991 and was introduced to standardize reporting of acute and chronic rejection (Table 68.3) [209]. The Banff criteria have subsequently been updated on a regular basis to reflect increased understanding of antibody-mediated rejection and place more emphasis on the type rather than the degree of rejection [210–212]. Four main types of acute rejection are defined: T cell mediated rejection (TCMR) with or without vasculitis and AMR with or without vasculitis [213]. Antibody mediated vascular rejection (AMR with vasculitis) is associated with a poor outcome. A better understanding of the underlying mechanisms of rejection will allow more appropriate treatment and hopefully better outcomes. There is improved long-term survival with aggressive treatment of early TCMR, as early TCMR can rapidly lead to renal allograft loss if left untreated. However, it may result in a degree of nephron loss and IFTA, which will still be evident in later percutaneous renal biopsies but will not have progressed.

Chronic Allograft (Late) Rejection

Chronic allograft dysfunction has been intensively studied over the last decade, resulting in increased understanding of late acute and chronic rejection. Rejection episodes occurring 3–6 months after transplantation are labeled acute or chronic depending on the speed of development, severity of allograft dysfunction and the

Table 68.3 Acute allograft rejection according to the Banff 2017 classification. (Table used with permission from Haas et al., 2018 [256])

Acute T cell–mediated rejection (TCMR)
• Ia >25% interstitial inflammation with moderate tubulitis (t2)
• Ib >25% interstitial inflammation with severe tubulitis (t3)
• IIa mild-to-moderate intimal arteritis (v1)
• IIb severe intimal arteritis (v2)
• III transmural arteritis and/or fibrinoid necrosis (v3)
Acute antibody-mediated rejection (ABMR): Should have all three criteria below
Histologic evidence of tissue injury:
• Acute tubular injury
• Microvascular inflammation (g > 0 and/or ptc > 0)
• Arteritis (v > 0)
• Thrombotic microangiopathy without apparent cause
Evidence of current/recent antibody interaction with endothelium:
• Positive C4d staining of peritubular capillaries
• Moderate microvascular inflammation (g + ptc ≥ 2)
• Increased expression of gene transcripts in biopsy tissue strongly associated with ABMR
Serologic evidence of donor-specific antibodies (DSA):
• Positive C4d staining/presence of ABMR-associated gene transcripts may substitute for DSA

Key: i0—No inflammation or in <10% of unscarred cortical parenchyma. i1—Inflammation in 10–25% of unscarred cortical parenchyma. i2—Inflammation in 26–50% of unscarred cortical parenchyma. i3—Inflammation in more than 50% of unscarred cortical parenchyma

t0—No mononuclear cells in tubules or single focus of tubulitis only, t1—Foci with 1–4 mononuclear cells/tubular cross section (or 10 tubular cells), t2— 5–10 mononuclear cells and t3—Foci with >10 mononuclear cells/tubular cross section or the presence of ≥2 areas of tubular basement membrane destruction accompanied by i2/i3 inflammation and t2 elsewhere. G: glomerulitis, none (g0), segmental or global glomerulitis in 75% of glomeruli (g3), PTC: peritubular capillaries- at least 1 leukocyte in ≥10% of cortical PTC but 10 leukocytes in most severely involved PTC (ptc3)

biopsy findings. Late acute rejection is associated with a worse outcome [214]. The timing of a biopsy for allograft dysfunction is predictive; indication biopsies (performed for allograft dysfunction) in adult recipients after 12 months are associated with worse outcome than a biopsy performed during the first post-transplant year [215]. Dorje et al. report similar findings with AMR; allograft survival at 4 years was 75% in those with early AMR in the first 3 months post-transplant, compared with 40% in those with AMR diagnosed after 3 months [216]. Non-adherence or suboptimal immunosuppression were more common in the group with later AMR.

There is increasing research on the link between late allograft dysfunction and subsequent allograft loss. Previously, used causes of allograft loss have often been imprecise diagnoses such as chronic allograft nephropathy (CAN) or IFTA [209, 217]. These terms describe the final common pathway of several different processes and have been shown to be unhelpful in determining the underlying cause of allograft failure. Recruitment to a large multicenter study of factors that affect long-term kidney transplant function was commenced in 2005 [218]. Biopsies performed for allograft dysfunction were frequently reported by local pathologists as showing CAN or CNI toxicity. However, further follow-up showed no difference in outcome for patients with or without a diagnosis of CAN. This study demonstrated that late allograft dysfunction in a previously stable allograft was associated with a high risk of renal allograft loss. Further reports showed that a diagnosis of CNI toxicity was associated with a reduced rather than increased risk of allograft failure, and, unexpectedly, a high incidence of antibody-mediated rejection was found on biopsies for late allograft dysfunction [219, 220].

A precise diagnosis of allograft failure was made in a detailed prospective study of adult kidney transplant recipients of whom 19% had allograft loss, which was correlated with findings on earlier indication biopsies, clinical and serological data [221]. The causes of allograft failure were rejection in 64% of cases, glomerulonephritis in 18%, polyoma virus in 7% and intercurrent events in 11%. The most common cause of allograft failure was AMR, with all allografts that failed from rejection having some degree of AMR, whereas no losses were attributable to TCMR alone. A substantial proportion of AMR losses were associated with non-adherence. Neither a diagnosis of IFTA alone without evidence of inflammation nor CNI toxicity were common causes of allograft failure in this study. Antibody mediated rejection is the most common cause of late allograft loss, and it is important to differentiate late acute rejection into TCMR or AMR to allow appropriate treatment.

Antibody Mediated Rejection

Endothelial inflammation and injury in the microvasculature of the kidney allograft is the underlying pathology in AMR [222]. This can be due to donor specific anti-HLA antibodies (DSA) causing direct toxicity to antigen expressing endothelial cells through activation of the classical complement cascade or through cell-mediated toxicity after binding to the Fc receptors of mononuclear cells [223, 224]. The spectrum of histological lesions range from mild changes with acute tubular necrosis to severe changes with vascular fibrinoid necrosis [225]. There is swelling of the injured endothelia in the glomeruli and peritubular capillaries, which are infiltrated with mononuclear cells. The Banff criteria for AMR include signs of microcirculatory inflammation and the presence of complement split product C4d staining, which reflects activation of the classical complement pathway [226]. The Banff criteria require both of these markers to be present for the diagnosis of AMR, with or without the presence of DSA, although it is now appreciated that C4d staining is not always present in AMR [227].

Chronic injury in AMR is characterized by remodeling of the microvasculature and larger arteries. There is multilayering of the basement membrane in the peritubular capillaries, often with associated secondary IFTA, with or without C4d staining. The changes on electron microscopy may be present before there are obvious changes on light microscopy. The glomeruli are enlarged, and the capillary walls are thickened

with duplication of the glomerular basement membrane causing double contours with interposition of mesangial matrix, usually with an increase in mesangial matrix. There may be subendothelial accumulation of deposits on electron microscopy. These chronic changes are referred to as transplant glomerulopathy (TG), which is associated with a poor outcome despite treatment [228]. There is now better understanding of the role of the endothelium and microcirculatory inflammation and repair in AMR [229].

The presence of C4d staining of peritubular capillaries has been associated with a worse outcome than C4d negative AMR, but the category of C4d negative AMR is now established and is well-recognized as a cause of allograft loss [230]. Deposition of C4d has been shown to have a high specificity but a poor sensitivity for AMR [231]. Fifty percent of AMR is missed if reliance is placed on the presence of C4d to make a diagnosis. Signs of microcirculatory injury, including glomerulitis, are a better predictor of late allograft loss than the presence of C4d.

Deposition of C4d on biopsy is associated with basement membrane multilayering, TG and the accumulation of mononuclear cells within the peritubular capillaries. Deposition of C4d in biopsies from low immunological risk patients which show normal glomerular morphology is associated with the development of TG on later biopsies. C4d deposits in the absence of other signs of AMR can be seen in ABO incompatible transplantation and may be a sign of accommodation [212, 232]. Molecular studies have shown that the presence of inflammatory cells in areas of fibrosis contribute to rejection and are predictive of outcome. It is therefore recommended that fibrotic areas should be included when calculating the degree of inflammatory infiltrate on a percutaneous renal biopsy [233]. Gene expression analysis has also proved useful in discriminating biopsies classified histologically as showing borderline histological changes of rejection into those patients with and without rejection [234]. However, there is the hope for point of care testing of biomarkers in pediatric renal transplantation to predict rejection in the future. Studies linking findings on indication biopsies with later allograft loss have used a broader diagnosis of AMR than traditional Banff criteria with the requirement for microcirculatory inflammation, DSA or C4d.

Donor Specific Antibody

The consequences of developing de novo DSA on allograft outcome has been known for some time [235]. In both adults and children, the natural history of de novo DSA in pKTR is well-documented, with evidence of complement activation leading to renal allograft injury [134, 236]. The development of sensitive solid-phase assays has helped to detect the presence of DSA and establish its role as a major cause of late allograft dysfunction and failure. The sensitivity of the assay and the cut-off median fluorescent intensity (MFI) used will affect the ability to distinguish de novo DSA from antibody present prior to transplantation. Using rigorous methods to exclude antibody already present in the recipient at the time of transplantation, no de novo DSA was detected prior to 6 months, 2% had developed DSA by 1 year and the median time to develop DSA was 4.6 years in adult kidney transplant recipients, although other adult studies have found that de novo antibodies can develop earlier [237, 238]. The prevalence of de novo DSA in pediatric renal transplant populations has been reported to be between 14 and 34% and can be associated with allograft loss [239].

HLA molecules are expressed on peritubular capillaries and can be upregulated during infectious or inflammatory processes by interferon gamma. This may result in cellular rejection or allow the expansion of B cells producing DSA. Early cellular rejection has been shown to be a risk factor for DSA development [240]. More intense peritubular capillaritis during cellular rejection is associated with the development of DSA. The degree of immunosuppression is important; reduction in immunosuppression or the use of less potent immunosuppressants is associated with the development of DSA. DSA occur more frequently with the use of cyclosporin than with tacrolimus, with everolimus compared to cyclosporin and with azathioprine compared to MMF [241]. HLA mismatching is a

predictor of the development of DSA, especially HLA class II mismatch. In addition younger age predicts development of DSA, which may reflect a more robust immune system in the young or non-adherence [242]. De novo DSA precedes the onset of allograft dysfunction by months or years. Most DSA is directed against class II HLA, including DQ and DP, which are not included in most matching algorithms. There are other non-DSA anti-HLA and non-HLA antibodies. Anti-HLA antibodies that are not donor specific have been reported to be pathogenic in some studies, whereas in other studies there has been no association with outcome [243]. The development of de novo DSA post-transplant has been associated with 10-year allograft survival that is almost 40% lower than those without DSA [244].

Ginevri has published a detailed study in pediatric renal transplant recipients [245]. Thirty-seven of 82 consecutive recipients of first allografts developed de novo anti-HLA antibodies; 19 had DSA (6 also had non-DSA) and 18 had non-DSA only. Two patients who had only HLA Class I mismatches developed only HLA Class I DSA. The other 17 had mismatches at both HLA Class I and class II; 11 developed HLA Class II antibody and 6 developed both HLA Class I and II. HLA Class II DSA were almost exclusively directed against DQ. In the non-DSA group, 15 developed mostly HLA Class I with or without HLA Class II antibodies that recognized cross-reactive epitope group specificities related to the donor mismatch. The MFI of the non-DSA were significantly lower than the MFI of the DSA. DSA appeared at a median time of 2 years post-transplant with a range of 3–60 months. DSA were more likely to remain detectable compared with non-DSA and were more common in patients receiving cyclosporin compared with tacrolimus. Renal allograft function decreased significantly in the DSA group during 4.3 years of follow-up. Five allografts were lost in the DSA groups; four were due to AMR. Seventeen (89%) DSA patients needed an indication biopsy compared to 44% in the non-DSA group and 11% in those with no antibody ($p < 0.0001$). Eleven of the biopsies showed AMR, and 8 were C4d positive. One recipient in the non-DSA group had evidence of microcirculatory inflammation in keeping with probable AMR. These data suggest that it is prudent to monitor DSA post transplantation.

Prevention and Treatment of Rejection

Prevention of chronic allograft dysfunction confers significant health and economic benefits and is likely to be a more successful strategy than treatment. Many preventative strategies have been touched on already, including the use of living donors, which carries an allograft survival benefit, as does the appropriate selection of deceased donors. Optimal management of the deceased donor can attenuate the effects of ischemia reperfusion injury [246]. Prevention and treatment of rejection is an important part of post-transplant management. In our opinion, the most effective way to prevent allograft rejection is through regular adherence counseling, increasing parent-patient engagement in post-transplant care, and close laboratory and clinical follow-up after transplant.

Early acute rejection is most likely to be TCMR and this is usually responsive to corticosteroid treatment and indeed recent improvements in early allograft survival have been attributed in part to newer, more potent immunosuppressants which have significantly reduced early acute rejection rates. Accurate diagnosis of early rejection episodes into either T or B cell-mediated with or without a vascular component is important in determining outcome.

The treatment of late AMR remains a challenge. The outcome after late AMR is worse than for early AMR, where good results have been obtained using PE or intravenous immunoglobulin (IVIG) and rituximab [247–250]. There are no RCT data available regarding the treatment of late AMR but a number of different agents have been tried. High-dose corticosteroids, IVIG, PE, IA, rituximab and bortezomib have been used [251]. Baseline immunosuppression is commonly augmented to include MMF and tacrolimus [252]. Varying results have been reported,

which are likely to be influenced by the baseline function of the allograft and the degree of injury that has already occurred by the time of AMR diagnosis [253]. Rituximab, used in combination with other therapies, and bortezomib both appear less effective for late AMR than early AMR [254]. Many reports describe reduced immunosuppression or non-adherence prior to the development of AMR; prevention of late AMR is likely to be a more effective strategy than treatment. Late TCMR seems more amenable to treatment and in studies of late allograft dysfunction does not appear to be a cause of allograft loss.

Adequate Immunosuppression

Late allograft dysfunction is often due to AMR with non-adherence or under-immunosuppression as the underlying mechanisms. Non-adherence and under-immunosuppression with lower doses of tacrolimus, cyclosporin and MMF may in part be related to a concern that calcineurin nephrotoxicity contributes to chronic allograft dysfunction. Calcineurin nephrotoxicity is a concern clinically, but not a frequent cause of allograft loss. The Mycophenolic Renal Transplant Registry of the de novo use of MMF showed that reductions in dose during the first-year post-transplant were associated with increased rejection, and if tacrolimus levels were also low, with increased allograft failure [255]. An observational analysis of over 25,000 low-risk, adult recipients showed that withdrawing maintenance cyclosporin, tacrolimus or MMF, or reducing the dose below certain thresholds after the first post-transplant year, was associated with a significant risk of allograft failure. These data indicate the importance of adequate immunosuppression for allograft survival.

Conclusion

Transplant planning and care require a thorough understanding of the underlying cause of ESKD and close monitoring for non-infectious complications in the post-operative period. In most instances, transplantation confers significantly reduced morbidity and mortality and improvements in quality of life. Rejection remains a lifelong concern for kidney transplants, as does the risk for disease recurrence in certain populations. For most, the risk of disease recurrence is low; however, exceptions are notable in the case of complement-mediated kidney disease where risk for disease recurrence may be greater than 50%. Most patients with recurrent disease due to glomerulonephritis still have generally equivalent patient and allograft survival compared to those with non-recurrent etiologies, such as CAKUT.

Despite scientific advances, the management of disease recurrence and allograft rejection in pediatric kidney transplant recipients remains challenging; however, emerging therapies for high-risk diseases, such as aHUS and C3G, provide hope for improved allograft survival amongst these pediatric kidney diseases at highest risk for recurrence. Our understanding of optimal treatment for both allograft rejection and recurrent disease is limited by the lack of systematic, randomized studies, particularly in pediatric patients. Systematic use of international registries and prospective multicenter collaborative studies is necessary to allow improvement in pre-transplantation risk evaluation and facilitate data-driven yet individualized post-transplantation management.

Prevention and Treatment of Infectious Complications in Pediatric Renal Transplant Recipients

Jodi M. Smith, Sarah J. Kizilbash, and Vikas R. Dharnidharka

Introduction

Over the last few decades, significant advances have been made in the outcomes of pediatric kidney transplant recipients, with marked improvement in patient survival and early allograft survival. However, the more potent immunosuppressive therapy that successfully reduced the incidence of acute rejection has resulted in a higher incidence of infectious complications [1]. This increase has manifested as (1) an increase in the total frequency of infection [2]; (2) infection becoming the primary reason for post-transplant hospitalization [3]; and (3) the successive emergence of new viral infections in the past several decades. Specifically, cytomegalovirus (CMV) infections have been common in kidney transplant recipients since the 1980s, followed by Epstein Barr virus (EBV) related post-transplant lymphoproliferative disorder (PTLD) since the 1990s, and BK virus associated allograft nephropathy (BKVAN) in the last 15 years. Infections are not only a significant source of morbidity and hospitalization, but they also can lead to graft loss and patient death. Even when adjusting for death, infections represent an additional risk factor for worse graft survival [4–6], thus in part accounting for the less significant improvement in longer-term allograft survival [7]. Excessive PTLD resulted in the early termi-

nation of a large multi-center immunosuppression trial in pediatric kidney transplantation in the US [8]. Hospitalizations due to infection occurred in 47% of children within the first 3 years after kidney transplant, higher than in adults with a kidney transplant or in children on dialysis [2]. Unlike adults, the total incidence of infections did not drop in children in more recent years. From 2019 onwards, the global SARS-COV-2 (COVID19) pandemic greatly affected organ transplant recipients.

Special Considerations in Pediatric Transplantation

Organ transplant recipients are at greater risk for infection than immunocompetent individuals. The immunosuppressive medications currently in use are non-selective in nature, suppressing immune responses to alloantigens, as well as to infectious organisms. An organ transplant is a major surgical procedure with the infection risks of any major surgery. Chronic kidney failure itself suppresses the immune system to some extent. Cytopenias are common post-transplant due to medication side-effects, and can raise the infection risk.

Further, children are exposed to some unique infection risks. Many of the main viral infections that occur post–transplant are associated with higher morbidity when they are primary infections. A primary viral infection is defined as infection in a recipient who is seronegative at the time of transplant, with no prior immunity. Reactivation infection occurs in the setting of a patient who is seropositive and has some prior immunity. Pediatric patients are at higher risk for primary infection due to higher rates of recipient seronegativity at the time of transplant. Recent US data demonstrated that approximately 50% of pediatric kidney transplant recipients were EBV seronegative and 65% were CMV seronegative at the time of transplant compared to 10% EBV and 40% CMV seronegativity among adults [9]. The grafts to children come most often from adult (therefore most likely seropositive) donors, thereby introducing the virus at transplant.

Viral Infections

Cytomegalovirus

CMV, now called human herpesvirus 5 (HHV5), a double-stranded DNA virus of the herpes virus family, is perhaps the single most important pathogen in solid organ transplantation [10]. CMV not only causes significant morbidity by direct infection, but its immunomodulatory effects also predispose to other infectious complications [10]. CMV infection and CMV disease are different from each other. CMV infection is defined as evidence of CMV replication regardless of symptoms (differs from latent CMV). CMV disease is defined as evidence of CMV infection with attributable symptoms. Three patterns of CMV infection may be seen post-transplantation: Primary infection, reactivation infection, and superinfection. Primary infection occurs in transplant patients who were CMV seronegative prior to transplant, most commonly via transmission from a graft from a seropositive donor [10–12]. Without preventative therapy, the incidence of CMV disease in such recipients is 50–65% [10]. Reactivation infection is due to activation of latent virus in seropositive recipients, while superinfection is activation of virus from a seropositive donor in a seropositive recipient. Infection with CMV usually presents in the first few months post-transplant and can manifest as CMV syndrome, characterized by fever, myalgias, malaise, leukopenia and thrombocytopenia, or CMV disease, in which there is clinical evidence of organ involvement by the infection [10, 13]. The transplanted kidney is at higher risk for CMV infection than are the native organs, but pulmonary, liver and gastrointestinal tract infection are common, regardless of the organ transplanted [14–16]. As stated above, in addition to causing direct infection, CMV has significant indirect effects,

including an increase in the overall state of immunosuppression leading to increased risk for opportunistic infection [10]. CMV infection has been demonstrated to increase the risk of EBV-associated PTLD [10, 16]. In addition, CMV and acute rejection are interrelated. CMV infection is a risk factor for acute rejection, while rejection leads to release of tumor necrosis factor, triggering the process that ultimately leads to CMV replication [17].

Prevention of CMV infection can be accomplished with either (1) universal prophylaxis: the administration of anti-CMV therapy to all patients except seronegative recipients of a seronegative organ; or (2) preemptive therapy: viral monitoring and initiation of the treatment dose of anti-viral medication when a certain positive threshold is reached. There is some controversy as to the optimal strategy, as both methods have advantages and disadvantages. Consensus guidelines from the American Society of Transplantation (AST), Kidney Disease: Improving Global Outcomes (KDIGO), and The Transplantation Society International CMV Consensus Group recommend universal prophylaxis for high risk patients (seronegative recipients of seropositive organs or seropositive recipients of seropositive organs in the setting of anti-T-cell antibody immunosuppression), based on the available data suggesting better graft survival and clinical outcomes [11, 12]. Preemptive therapy has not been well studied in pediatrics. Although several agents are available for prophylaxis, valganciclovir has revolutionized both CMV prevention and treatment [18]. It is a prodrug of ganciclovir and is approximately 60% bioavailable, which is tenfold more than ganciclovir [19]. While the dosing of valganciclovir is well established in adults, the dosing in pediatric patients is somewhat more complex due to the dependence on metabolic activation, renal clearance and variable absorption. Since 2009, the manufacturer recommends normalization of the adult dose for BSA and creatinine clearance. Other centers have employed a weight based approach. Due to the challenges, particularly in infants and young children, ganciclovir levels may be helpful to guide therapy. Leukopenia is a common side effect of valganciclovir therapy. The duration of prophylaxis is an area of debate. Consensus recommendations guide the duration of therapy based on the serostatus of the donor and recipient [11, 12] (Table 69.1). For CMV Donor (D)+/Recipient (R)- patients, 3–6 months of prophylaxis with oral ganciclovir or valganciclovir is recommended. For CMV R+ patients, 3 months is recommended but 6 months should be considered if anti-lymphocyte induction is used. No prophylaxis is recommended in the CMV D−/R- patient. In addition, treatment of rejection with antilymphocyte antibodies in at risk recipients (D+/R-) should prompt re-initiation of prophylaxis or preemptive therapy for 1–3 months [11, 12, 22]. For treatment of CMV disease in pediatric patients, IV ganciclovir is recommended [12]. Therapy should continue until the CMV is no longer detectable. Reduction of immunosuppression in life-threatening CMV disease is indicated in cases of persistent disease despite treatment.

Late onset CMV disease is defined as disease occurring after prophylaxis has been discontinued and has been reported in 25–40% of patients on universal prophylaxis [20, 23]. Late onset CMV is associated with significant morbidity and high mortality, underscoring the ability of anti-viral prophylaxis to delay but not prevent

Table 69.1 Recommendations for duration of CMV prophylaxis [20, 21]

CMVD+/R-	• 3–6 months of prophylaxis with oral ganciclovir or valganciclovir is recommended. • In addition, treatment of rejection with antilymphocyte antibodies in at risk recipients (D+/R-) should prompt re-initiation of prophylaxis or preemptive therapy for 1–3 months.
CMV D+/R+ CMV D−/R+	• 3 months is recommended but 6 months should be considered if anti-lymphocyte induction is used.
CMVD−/R-	• No prophylaxis is recommended.

Table 69.2 Expert recommendations regarding BK virus screening

	2003 Polyoma-virus associated nephropathy interdisciplinary group [24]	2009 AST infectious diseases group [25]	2009 KDIGO transplant work group [12]
Screening	Urine screening, various techniques, every 3 months till month 24 (grade A-II) and annually thereafter till fifth year post-transplant (grade B-III) or with allograft dysfunction Biopsy if urine BK DNA > 1×10^7, VP1 mRNA >6.5×10^5 or plasma DNA > 1×10^4	Urine screening every 3 months in first 2 years then annually until fifth year post-transplant (grade II-B). If plasma screening performed, then at monthly intervals Biopsy if urine BK DNA > 1×10^7, VP1 mRNA > 6.5×10^5 or plasma DNA > 1×10^4	Plasma BK nucleic acid testing monthly for first 3–6 months, then every 3 months till month 12, or if elevated serum creatinine or after treatment for acute rejection
Intervention	Various approaches discussed, none specifically endorsed	Reduce immunosuppression for presumptive BKVN (plasma BKV loads >1×10^4 for >3 weeks)	Reduce immunosuppression if plasma nucleic acid load persistently >1×10^4

Adapted from [139]

CMV. Thus, careful clinical follow-up and virologic monitoring is recommended after completion of prophylaxis.

Antiviral drug resistance should be suspected and tested for in the setting of a patient who has had cumulative ganciclovir exposure of more than 6 weeks and there are rising viral loads or progressive disease after 2 weeks at full dose [11]. Risk factors include prolonged antiviral drug exposure (median 5–6 months), ongoing active viral replication, lack of prior CMV immunity (D+/R-), and inadequate drug delivery. Currently, genotype testing includes the UL97 kinase and UL54 DNA polymerase, with the UL97 mutation appearing in 90% of cases.

The timing and frequency of screening for CMV is largely center-specific and influenced by donor and recipient CMV serostatus, as well as whether universal or preemptive therapy is employed. Published guidelines recommend regular monitoring using a quantitative viral load assay for the first year post-transplant; however, the duration and frequency may vary depending on the type of CMV prevention strategy [11, 12]. Table 69.2 summarizes the characteristics of many commonly used assays for the different viral infections. The recent development of an international standard for CMV is promising as it will permit determination of appropriate standardized trigger points for intervention and allow comparison among sites.

Epstein-Barr Virus

EBV is another herpes virus that causes significant morbidity post-transplantation. Distinctions are made between EBV infection and disease. Active, asymptomatic EBV infection is defined by the presence of a detectable EBV viral load as measured by a nucleic acid amplification assay. Uncommonly, asymptomatic infection may also be identified in lymphoid rich histopathologic specimens. EBV disease is defined by the presence of active EBV infection with symptoms or signs attributable to the virus. The spectrum of clinical manifestations of EBV in transplant recipients includes nonspecific viral syndrome, mononucleosis, lymphoproliferative disorders and malignant lymphomas.

Like CMV, EBV commonly infects immunocompetent people sometime in childhood and establishes a prolonged latency in reticuloendothelial cells. Thus, the patterns of infection are identical to CMV: primary infection (often from the graft of a seropositive donor), reactivation or superinfection. Again, like CMV, the primary infection in an immunosuppressed transplant recipient is more virulent. Unlike CMV, EBV infection does not seem to have many indirect effects except for the development of PTLD. PTLD is a major complication and is covered in detail in the next chapter. This section deals with EBV infection only.

Prospective viral surveillance studies revealed that subclinical EBV infection occurs in 35–40% of pediatric renal transplant recipients [6, 26]. In a recent cohort study of adult kidney transplant recipients, 40% had subclinical viremia [27]. EBV viremia often precedes the development of EBV disease and PTLD by 4–16 weeks [28, 29]. Thus, early identification of EBV viremia may allow for intervention that could prevent progression to EBV disease and PTLD. KDIGO recommends the following post-transplant EBV screening schedule for high risk D+/R- patients: once in the first week after transplant; at least monthly for the first 3–6 months; then at least every 3 months until the end of the first year with re-initiation of monitoring after treatment for acute rejection. While D−/R– patients might be at decreased risk of developing EBV disease compared to D+/R–, they are still at increased risk relative to R+ patients and therefore warrant close monitoring. Some centers may choose to measure EBV loads more frequently. Beyond the first year, selective monitoring, such as in those with persistently high viral loads or in those with higher than normal immunosuppression, may be performed based on center preferences. Some centers recommend continued monitoring for an indefinite period for all patients. For seropositive individuals, selective monitoring may be considered in the setting of increased immunosuppression or clinical concern.

The reader should note that PCR techniques to detect EBV DNA amplification vary greatly based on the type of sample and laboratory standards. Thus, PCR values from peripheral blood leukocytes and whole blood generally correlate with each other but not with PCR values from plasma [30, 31]. To date, there is no defined standard sample site for EBV. In practice, the most important strategy is to follow the viral load in the same lab using the same type of sample consistently over time and to be careful to not compare viral loads from one lab to another.

There is no universally accepted treatment for subclinical EBV infection post-transplant. Options include reduction of immunosuppression, antiviral therapy, intravenous immunoglobulin (IVIG), and monoclonal antibody therapy directed toward infected B lymphocytes [21, 29, 32–34]. Currently, the only consensus recommendation is for a reduction of immunosuppression in EBV seronegative patients with an increasing EBV viral load. The utility of antiviral therapy to prevent PTLD is controversial, with little evidence to support the role of acyclovir or ganciclovir in response to an elevated or rising EBV viral load without a concomitant reduction of immunosuppression. These agents seem to delay the onset of infection rather than reducing its incidence. Two studies suggest that anti-viral prophylaxis has an additional benefit of preventing the progression from EBV disease to PTLD [19, 35]. IVIG does not appear to be of added benefit [36]. Preemptive use of rituximab in response to subclinical EBV infection began in the hematopoietic stem cell population and has recently been reported in the adult kidney transplant population [37, 38]. It is important to remember, however, that children, in particular, can develop a chronic high load carrier state without ever progressing to PTLD [39–44]. Nevertheless, the majority of reports indicate that higher EBV PCR values are associated with a greater risk for subsequent PTLD [45–47]. An EBV vaccine, directed against an EBV-glycoprotein, was tested in the United Kingdom but failed [48]. Unlike with CMV, we are not aware of any cost-benefit analysis of EBV monitoring or preventative treatment strategies.

BK Virus and BKVAN

BK virus (BKV) was first isolated from the urine of a kidney transplant recipient in the 1970s [49], but it was not until the late 1990s that this virus emerged as a significant problem in kidney transplantation [50, 51]. BKV is a part of the polyoma group of viruses. Though this virus is not from the herpesvirus group, it shares the characteristics of herpesviruses of infecting most immunocompetent people during childhood and establishing a prolonged latency. Unlike the herpesviruses, the virus does not establish latency in reticuloendothelial cells but in the uroepithelium. This propensity for the uroepithelium is responsible for the clinical manifestations: hemorrhagic

cystitis in bone marrow transplant recipients and allograft nephropathy in kidney transplant recipients. The incidence of BKVAN in pediatric kidney transplantation appears to be the same as in adult kidney transplants at 3–8% [52–56]. Risk factors include the intensity of immunosuppression, recent treatment for acute rejection, and placement of a ureteral stent, though the data implicating specific immunosuppressive agents is conflicting [54, 57–59].

BKVAN and BKV infection are two separate entities. BKVAN is defined as the presence of virus in the renal parenchyma, with accompanying evidence of either tubulointerstitial nephritis or elevated serum creatinine, as defined by a working group of the AST [2]. BKVAN is more prevalent in the medulla of the kidney, so at least one core should be deep enough to include medulla. A negative biopsy result does not rule out BKVAN due to the possibility of sampling error and the focal nature of the infection, so sensitivity is not 100%. In cases where the biopsy is negative, but there is high clinical suspicion for BKVAN, a repeat biopsy may be indicated. The histologic patterns of BKVAN have been divided into three types, as reviewed by Liptak et al. and the AST Transplant Infectious Diseases Group [25, 60]: Type A has intranuclear viral inclusions only, Type B has additional acute inflammation but very little chronic fibrosis, and Type C has significant chronic fibrosis and atrophy. The value of this classification lies in its prognostic value of clinical outcomes: the incidence of progression to end-stage kidney disease (ESKD) was only 13% with Type A, 55% with Type B and 100% with Type C [61]. BKVAN represents a diagnostic challenge because the condition may resemble acute rejection. Symptoms are often minimal or absent. Serum creatinine elevations are found on clinical lab monitoring. Since the treatment of acute rejection (intensifying immunosuppression) is the opposite of the treatment of BKVAN (reduction in immunosuppression), making the correct diagnosis is critical.

Early identification of BKV infection (detectable viral load in blood or urine) may permit intervention that may prevent BKVAN. Data suggest that the BK viremia precedes BKVAN by a median of 8 weeks [24]. BKV viral load >10,000 copies/L has a high positive predictive value for BKVAN [59]. Indications for biopsy vary among centers but many include viral load >10,000 copies/L with or without an elevated creatinine.

Routine screening is the most important tool used to identify patients at risk for BKVAN. Various schedules of surveillance are shown in Table 69.3. Intervention options include reduction of immunosuppression and use of other agents such as cidofovir, leflunomide, or IVIG. Stepwise immunosuppression reduction is recommended for kidney transplant recipients with plasma BKV-DNAemia of >1000 copies/ml sustained for 3 weeks or increasing to >10,000 copies/ml, reflecting probable and presumptive BKVAN, respectively [64]. The approach to immunosuppression reduction varies among centers, with varying levels of supporting evidence, and includes the following: (1) switching from tacrolimus to cyclosporine (CSA) or sirolimus; (2) mycophenolate mofetil (MMF) to azathioprine or sirolimus or leflunomide; (3) decreasing tacrolimus (trough levels <6 ng/ml), MMF (dosing ≤1 g/day), and CSA (trough levels 100–150 ng/ml); or (4) decreasing tacrolimus or MMF (maintain or switch to dual therapy with calcineurin inhibitor (CNI) and prednisone, sirolimus/prednisone, MMF/prednisone) [12]. While the reduction of immunosuppression raises concerns about the unintended consequence of rejection, several studies have reported successful preemptive intervention with no increase in rejection [65, 66].

There are virtually no randomized controlled trials to test any of these strategies head to head for any of the viral infections. Anti-viral therapy against BKV is more complicated than for CMV or EBV, since acyclovir, ganciclovir or their analogues are not active against BKV. Cidofovir is one anti-viral drug that has been tried with some success [67, 68]. Higher doses of cidofovir can be very nephrotoxic. Probenecid in combination with the higher dose cidofovir or intermediate dose cidofovir prevents the nephrotoxicity [69]. Fluoroquinolones are not recommended for either prophylaxis or treatment [64].

Table 69.3 Recommended vaccinations for pediatric transplant candidates and recipients [62, 63]

Vaccine	Inactivated/live attenuated (I/LA)	Recommended before transplant[a]/ strength of recommendation	Recommended after transplant/ strength of recommendation	Monitor vaccine titers?	Quality of evidence
Influenza, injected	I	Yes/A	Yes/A	No	II

Adapted from (a) Advisory Committee for Immunization Practices 2013; (b) The American Society of Transplantation (AST) Handbook of Transplant Infections, 2011

[a]Whenever possible, the complete complement of vaccines should be administered before transplantation. Vaccines noted to be safe for administration after transplantation may not be sufficiently immunogenic after transplantation. Some vaccines, such as Pneumovax, should be repeated regularly (every 3–5 years) after transplantation

[b]Routine vaccine schedule recommended prior to transplant and as early in the course of disease as possible; vaccine poorly immunogenic after transplantation, and accelerated schedules may be less immunogenic. Serial hepatitis B surface antibody titers should be assessed both before and after transplantation to assess ongoing immunity

[c]Serologic assessment recommended if available

[d]Children older than 5 years should receive 23-valent pneumococcal polysaccharide vaccine. Children less than 2 years should receive conjugated pneumococcal vaccine. Those 2 years–5 years of age should receive vaccination based on age and number of previous immunizations with conjugated pneumococcal vaccine

[e]Vaccination with conjugated meningococcal vaccine recommended in United States for all children aged 11–12 years of age and adolescents at high school entry or 15 years of age, whichever comes first

[f]Not routinely administered. Recommended for exposures, or potential exposures due to vocation or avocation

[g]The indications for Bacille Calmette-Guérin administration in the United States are limited to instances in which exposure to tuberculosis is unavoidable and where the measures to prevent its spread have failed or are not possible

[h]Transplant recipients who are face-to-face contacts of a patient with smallpox should be vaccinated; vaccinia immune globulin may be administered concurrently if available. Those who are less intimate contacts should not be vaccinated

Varicella

Varicella-zoster virus (VZV) is the most infectious of the human herpesviruses. Primary infection with VZV results in chickenpox. Following primary infection, the virus remains in the body in a latent state from which it may be reactivated, resulting in cutaneous herpes zoster, or shingles. Most adult kidney transplant recipients have experienced primary infection in childhood and, therefore, are at risk for reactivation and the development of herpes zoster with the introduction of immunosuppressive medication post-transplant [70]. Historically many children were VZV naive at the time of transplantation and primary infection was a significant cause of morbidity and mortality [71, 72]. With the development of a safe and effective VZV vaccine, routine immunization of pediatric kidney transplant candidates has been documented to reduce the incidence of primary VZV infection post-transplantation [73]. Given these findings, it is recommended that all transplant candidates over 9–12 months of age receive immunization with the VZV vaccine [74]. Studies in children with chronic kidney disease and on dialysis suggest that two doses, rather than one, may be necessary to elicit protective antibody levels, so it is recommended that antibody levels be obtained at least 4 weeks following immunization, and a second dose given if necessary [74–76]. Although some studies have evaluated the use of this vaccine in post-transplant patients, both the American Academy of Pediatrics Committee on Infectious Diseases and the Centers for Disease Control and Prevention's Advisory Committee on Immunization Practices (ACIP) advise against the use of this live viral vaccine in immunocompromised patients [77, 78]. Thus, it is imperative that immunization be provided and protective antibody levels documented prior to transplant whenever possible.

Patients who are varicella-naive at the time of transplant, i.e. no history of chicken pox or VZV immunization, or fail to develop protective antibody after immunization, and who are exposed to varicella should receive prophylactic therapy. Previous recommendations included the delivery of varicella zoster immune globulin (VZIG); however, this product is no longer being manufactured [79]. In North America, an investigational VZIG product, VariZIG (Cangene Corporation, Winnipeg, Canada) has become available under an investigational new drug application and the ACIP recommends that use of this product be requested if an immunocompromised patient is exposed to varicella infection [79]. If this product is not available, IVIG, which contains some anti-varicella antibody, may be given. Any prophylactic therapy should be given as soon as possible, up to 96 hours after exposure. Patients who develop infection, either primary or secondary, should receive treatment with intravenous or oral acyclovir, with consideration of reduction of immunosuppression [12, 80, 81].

COVID-19

The coronavirus disease 2019 (COVID-19), characterized by significant respiratory and multiorgan disease, is caused by the novel severe acute respiratory syndrome coronavirus 2 (SARS–COV–2). This virus first emerged in December 2019 in Wuhan, China [82]. Droplets expelled during talking, coughing, sneezing, or eating are the most common mode of transmission. Transmission may also occur through aerosol; however, it is unclear if this is a significant mode of transmission outside of laboratory settings. Common symptoms of COVID-19 infection include fever, dry cough, shortness of breath, fatigue, myalgias, nausea and vomiting, diarrhea, headaches, weakness and rhinorrhea. Common complications include pneumonia, acute respiratory distress syndrome, liver injury characterized by elevation of liver enzymes, cardiac injury marked by troponin elevation, acute heart failure, myocarditis, prothrombotic coagulopathy, acute kidney injury, and acute cerebral vascular disease. Rare complications include cytokine storm and macrophage activating syndrome. Patients become contagious about 2–3 days prior to the onset of symptoms until about 8 days after symptom onset [82]. Nearly 80% of patients with COVID-19 have mild manifestations, 15% develop severe illness and 5% become critical.

Data are emerging on the impact of COVID-19 on kidney transplant recipients. The incidence of COVID-19 in solid organ transplant (SOT) recipients is 10- to 15-fold higher than in the general immunocompetent population and adult SOT patients with COVID-19 appear to be at higher risk of poor outcomes on the basis of their chronically immunosuppressed state and underlying medical comorbidities [67, 68]. Initial reports in pediatric kidney transplant recipients demonstrate a decreased risk for infection and less severe disease when compared to adult kidney transplant recipients [83, 84].

Transplant Candidate Considerations

Vaccination is recommended to occur prior to transplantation, ideally completing the vaccine series a minimum of 2 weeks prior to transplant. Living donor candidates should self-quarantine or follow strict social distancing for a 14 day period prior to the transplant. All candidates should also have a negative nucleic acid amplification test (NAT) documented prior to surgery.

Post-Transplant Vaccination

The AST recommends vaccination against SARS CoV-2 using the locally approved vaccines for pediatric kidney transplant recipients [85]. Information about COVID-19 vaccine responses in transplantation is rapidly evolving. However, antibody responses to COVID-19 vaccines in transplant recipients are diminished compared with the general population [86–97]. Data suggest that providing a third dose of mRNA vaccine to SOT recipients that have previously received two doses of mRNA vaccine can increase antibody titers to SARS-CoV-2 [98–100]. In a recent, double-blind, randomized placebo-controlled trial, a third dose mRNA vaccine provided 2 months after the second dose significantly increased antibody titers, neutralizing antibody, and cellular immune response to SARS-CoV-2 compared to a third dose placebo [94]. Based on this, a third dose of mRNA vaccine is recommended for SOT recipients who have previously completed a 2-dose mRNA vaccine series. The use of a third dose should, until further evidence is available, be based on individual patient's unique situation and must depend on local availability of vaccines and local regulations. In addition, vaccination is recommended for all eligible household and close contacts. Routine antibody testing following vaccination is not recommended by the FDA.

COVID-19 and Donor Considerations

The AST published guidelines for organ donor screening for COVID-19. All deceased donors should be tested for SARS-CoV-2 infection using RT-PCR from the upper respiratory tract within 72 hours, but ideally as close to organ recovery as possible. For donors previously known to have had COVID-19, organ acceptance can be considered if the following circumstances are met: negative SARS-CoV-2 RT-PCR testing from the respiratory tract, symptoms of COVID-19 have resolved, AND at least 21 days have transpired since the date of disease onset. Data regarding the safety of organ donation from donors with previous COVID-19 are limited at this time and consultation with transplant infectious disease experts is recommended. Living donors should be advised to follow universal masking precautions and strict social distancing for 14 days prior to donation. All living donors should undergo respiratory tract SARS-CoV-2 RT- PCR testing within 3 days of donation. Donors should be encouraged to self-quarantine after the preoperative COVID-19 test [101].

Bacterial Infections

Urinary Tract Infection

Urinary tract infection (UTI) is the most common bacterial infection in kidney transplant recipients, in both adults [102, 103] and children [104].

UTIs develop in 20–60% in the first year post-transplant and 40–80% by 3 years post-transplant [2, 102–105]. UTI is not only a cause of morbidity but is also associated with higher rates of graft loss and patient death [106, 107]. Early UTI (within 6 months of transplant) elevated the risk for graft loss in children, while late UTI did not [108]. The urogenital tract is the most common entry point for systemic sepsis [109]. Numerous risk factors have been identified for UTIs post-transplant. Urologic anomalies such as neurogenic bladder, urinary tract obstruction, vesicoureteral reflux, bladder augmentation, ureteral stents and intermittent catheterization have all been associated with an increased risk of UTI post-transplant [105, 110–112]. UTI risk is highest in the first 3–6 months post-transplant but some risk remains at later time points. While the organisms implicated are usually the same as in immunocompetent individuals, such as Enterobacter species (e.g., *Escherichia coli* and *Klebsiella)*, a higher percentage of UTIs in transplant patients are due to unusual organisms such as *Pseudomonas* species [113]. Clinical symptoms may include fever, dysuria, graft tenderness and foul-smelling or cloudy urine. In some patients, symptoms may be masked due to immunosuppression. A rise in serum creatinine may occur and can mimic acute rejection. UTIs can also precipitate acute rejection.

The diagnosis of UTI is usually made by urine culture, though patients on trimethoprim-sulfamethoxazole prophylaxis for *Pneumocystis jiroveci* may not demonstrate positive cultures. Treatment is with antimicrobial therapy. Initially, the antimicrobial prescribed should cover the common gram negative organisms, such as the beta-lactams or the quinolones [114]. Once the organism is known, the most specific and cost-effective antimicrobial can be prescribed. Treatment route and total duration are determined by the severity of infection, recipient age, and other risk factors. Kidney allograft pyelonephritis can be associated with bacteremia and significant morbidity. If allograft pyelonephritis is suspected, hospitalization and treatment with intravenous antibiotics for up to 14 days is recommended [12]. Shorter 5–7 day oral courses, as are used in immunocompetent individuals, can be used for milder cystitis episodes in older children [92]. KDIGO suggests that all kidney transplant recipients receive UTI prophylaxis with daily trimethoprim-sulfamethoxazole for at least 6 months post-transplant based on data showing a decrease in the frequency of UTIs [115]. For patients who are allergic to trimethoprim-sulfamethoxazole, the recommended alternative is nitrofurantoin. Currently, the available evidence does not support routine treatment of asymptomatic bacteriuria [114].

Other Bacterial Infections

Other bacterial infections, such as wound infections, line sepsis and pneumonia are seen with significant frequency in kidney transplant recipients. Wound infections and line sepsis are commonly due to gram-positive *staphylococcus* and *streptococcus*.

Pneumonia can be due to multiple etiologies (bacterial, viral or fungal), but bacterial pathogens are responsible for approximately 44% of cases [116]. In adult transplant recipients, cellulitis and bacterial abscesses are frequent problems, largely due to co-morbid diabetes mellitus. In general, these complications are less common in the pediatric population. The treatment of these infections is generally no different than standard treatment in immunocompetent hosts, though duration of therapy may be longer.

Bartonella henselae infection (also known as cat-scratch disease) has been reported in pediatric organ transplant recipients, including kidney transplants [117].This infection typically presents as fever and lymphadenopathy, and thus must be included in the differential diagnosis for PTLD. However, unlike PTLD, this infection is treated with antimicrobial therapy.

The incidence of *Mycobacterium tuberculosis* infection in kidney transplant recipients varies geographically, occurring in less than 2% of kidney transplant recipients in North America and Europe, but 5–15% in Asia and Africa [118–120]. This infection may present at any time post-transplant, but is most common in the first post-

transplant year [119]. *M. tuberculosis* infection presents with a myriad of symptoms, including weight loss, cough, fever and lymphadenopathy, again mimicking PTLD. The diagnosis of tuberculosis in the transplant recipient is similar to that in other populations, although the tuberculin skin test may be positive in only a third of kidney transplant recipients with tuberculosis [120]. Early diagnosis is best achieved by staining for acid-fast bacilli or using PCR from sputum, bronchoalveolar lavage or gastric aspirates. Interferon-gamma release assays such as QuantiFERON and T-SPOT.TB are alternative methods used to detect latent infection. Management of tuberculosis is complex and evolving and has long been directed by recommendations developed, updated and disseminated by expert panels [12, 120–122]. A four-drug regimen, similar to the regimen recommended in the general population, should be used in case of active tuberculosis after transplantation [123]. Rifampin is associated with numerous drug interactions through its activation of the CYP3A4 pathway which can impact levels of CNIs and mTOR inhibitors, sometimes necessitating higher CNI doses. Alternatively, rifabutin could be used instead of rifampicin given its milder interactions [123].

Other Infections

Pneumocystis Jiroveci Pneumonia

Pneumocystis jiroveci was previously known as *Pneumocystis carinii* and classified as a protozoal disease. The classification has evolved based on DNA sequence analysis such that *P. jirovecii* is now classified as a fungus. Human pneumocystis is now called jirovecii as *Pneumocystis carinii* only infects rats. *P. jirovecii* pneumonia (PJP) is an important opportunistic infection that has fortunately decreased in frequency due to the widespread use of sulfamethoxazole/trimethoprim prophylaxis in the immediate post-transplant period. Patients typically present with fever, dyspnea and nonproductive cough, interstitial infiltrate on chest x-ray and hypoxemia. Elevated lactate dehydrogenase and hypercalcemia are characteristic biochemical findings supporting the diagnosis. The diagnosis is established by demonstration of pneumocystis in lung secretions obtained from bronchoalveolar lavage or in tissue from lung [124]. Gomori stain or toluidine blue staining will demonstrate the cysts and Giemsa staining will identify the sporozoites. CMV infection is the major differential diagnosis. Many children may have dual infection, in which CMV infection predisposed to superinfection with *P. jirovecii*. Treatment recommendations include high dose intravenous trimethoprim-sulfamethoxazole, corticosteroids and a reduction in immunosuppression. Chemoprophylaxis with three times a week oral sulfamethoxazole/trimethoprim (5 mg/kg trimethoprim component/dose) has reduced the incidence of PJP from 3.7% to 0% [125]. Daily dosing may be easier for patient adherence and is recommended by KDIGO [12]. Prophylaxis is recommended in all transplant recipients for 3–6 months post-transplant. Some also advocate its use after anti-rejection therapy, particularly with anti-T cell antibodies.

Parasitic Infections

Although several parasitic infections have been reported in pediatric recipients of solid organ or bone marrow transplantation, there are few reports of such infections in pediatric kidney recipients. Several parasitic infections deserve mention, however, as they have been reported as transmitted by the transplanted graft in adult kidney transplant recipients. *Strongyloides stercoralis* is an intestinal nematode that infects tens of millions of people worldwide. It is endemic in tropical and sub-tropical regions. The highest rate of infection in the US is in the Southeast [126]. *S. stercoralis* may remain in the human intestinal tract without symptoms for decades, and then cause disseminated infection with the introduction of immunosuppressive medication post-transplant [126]. In addition, there are case reports of transmission of strongyloidiasis by kidney transplantation in an adult recipient [127]. Interestingly, CSA but not tacrolimus has effects

against *S. stercoralis* and may reduce the risk for disseminated strongyloidiasis [128, 129]. Active infection typically presents with cutaneous, gastrointestinal and pulmonary symptoms as well as eosinophilia [130]. With disseminated disease, fever, hypotension, and central nervous system symptoms may be present [130]. In uncomplicated infections, diagnosis is made by detection of larvae in stool, although 25% of infected patients may have negative stool examinations [131]. In disseminated disease, larvae may be found in stool, sputum, bronchoalveolar lavage fluid, and peritoneal and pleural fluid [126, 132]. Serologic testing using ELISA may also be of value, but may be falsely negative in immunocompromised hosts [132, 133]. Thiabendazole, previously the treatment of choice for *S. stercoralis,* has been replaced by ivermectin, with albendazole as an alternative [134].

Other parasitic infections reported in kidney transplant recipients as transmitted by the transplanted graft include Chagas' disease and malaria [126, 135, 136]. Chagas' disease is caused by *Trypanosoma cruzi* and is found only in the southern US, Mexico and Central and South America. The manifestations of Chagas' disease classically include megaesophagus, megacolon, and cardiac disease, although CNS involvement has been reported in kidney transplant recipients [135]. The diagnosis is routinely made serologically and treatment typically consists of benznidazole or nifurtimox. Post-transplant malaria, transmitted from donors living in high-risk areas, is a frequent occurrence [136]. The discussion of these infections is meant to illustrate the potential problem of parasitic infections post-transplant. Policies to screen potential recipients and donors for these and other parasitic infections should be based on the presence of risk factors, including residence in or travel to an endemic area.

Fungal Infections

In general, serious invasive fungal infections such as aspergillosis are less common in pediatric kidney transplant recipients than thoracic organ recipients. Candida is the most common organism affecting kidney transplant recipients, either as oral and esophageal thrush, vaginitis, nail infection or UTI. The diagnosis of thrush is by clinical examination or demonstration of hyphae on a smear. Candidal UTI is diagnosed by urine culture. Treatment for topical candida is by topical nystatin or clotrimazole. Prophylactic measures include oral clotrimazole lozenges, nystatin, or fluconazole for 1–3 months post-transplant and for 1 month after treatment with an anti-lymphocyte antibody [12]. Treatment of invasive disease typically requires amphotericin. Fluconazole may be used for treatment of less severe disease, or for infections that have stabilized after initial therapy with amphotericin. Dose adjustment and close monitoring of the levels of CNIs are necessary when fluconazole is used due to the drug-drug interactions. In addition, there are potential drug-drug interactions between CNIs and clotrimazole [137].

Immunizations

One of the cornerstones of preventative care in pediatrics is the delivery of routine childhood immunizations. Unfortunately, the complicated medical care required by many children with chronic kidney disease may result in only sporadic delivery of routine well-child care, including immunizations. Complete immunization is especially important in children with ESKD as they approach transplantation given the increased risk for vaccine preventable disease post-transplant. In general, children with chronic kidney disease should receive immunizations according to the recommendations for healthy children in the region. Because they may also be more susceptible to or at risk for more serious infection from pathogens that are not typically problematic in healthy children, candidates for or recipients of kidney transplantation may also benefit from supplemental or additional vaccinations [76]. Table 69.3 provides a list of vaccinations recommended specifically for pediatric transplant candidates and recipients. Because children with chronic kidney disease and on dial-

ysis may have sub-optimal response to many immunizations, or lose immunity prior to transplantation, it is important not only to ensure timely delivery of routine childhood immunizations, but also to monitor antibody titers or levels and revaccinate when indicated [138]. This is especially true of the live viral vaccines, including measles, mumps, rubella and varicella zoster vaccine, which are contraindicated in the immunosuppressed patient post-transplant.

In the post-transplant period, immunizations may be given after immunosuppressive medications have reached a baseline level, typically 6 to 12 months post-transplant. Again, live viral vaccines are generally contraindicated in the post-transplant period. Because the presence of immunosuppressive medications may impair response to vaccines, maximal protection requires universal immunization of health care workers, family members and household contacts [74]. In particular, annual immunization with injectable influenza vaccine is required [74].

Long-Term Outcome of Kidney Failure in Children

70

Jaap W. Groothoff

Introduction

> …The patient remained unconscious during dialysis, showing cramps from time to time ...suddenly he vomited, showing massive gingival bleeding...13 h the patient started shaking after a piece of wood had been placed in the device against the spatter of dialysate...an example of a smooth dialysis session….

These thrilling notes are from Willem Kolffs' thesis in which he describes the first dialysis sessions ever performed in humans. The experiments took place during World War II in Kampen, a small town in the Netherlands [1]. Only one of the 12 patients, notably a sympathizing Nazi, survived the treatment. After the war Kolff emigrated to the United States where he developed the first production artificial kidney, the Kolff Brigham Artificial Kidney, which laid the foundation for modern hemodialysis treatment.

Yet, it would take until the end of the 1960s before chronic kidney replacement therapy (KRT) became available on a routine basis for children with end-stage kidney disease (ESKD). Initially, many physicians were reluctant to start such invasive therapy in children. Among those who refused to start dialysis in children were some very distinguished pediatric nephrologists. As both the dialysis technique and supportive therapy improved during the 70s and 80s chronic renal replacement therapy in children became gradually more accepted. In particular, better nutrition, the introduction of bicarbonate-buffer replacing acetate in hemodialysis, the introduction of continuous cycling peritoneal dialysis, the use of recombinant human erythropoietin and growth hormone therapy, and the introduction of cyclosporine after transplantation contributed to a marked decrease in morbidity and mortality and increase of children taken into therapy.

Despite all these improvements in therapy, RRT in children remained controversial at least until the early nineties of the last century. Even today, many physicians feel uncomfortable in offering chronic RRT to young children and question whether it should be offered to all children, especially in case of multiple comorbidities [2]. The fear for acute casualties has been replaced by concerns about the long-term prospects for children on RRT. One of the first questions parents ask when confronted with the necessity of chronic dialysis or transplantation for their child is what his or her future will be like. Will he or she ever be able to participate in society as an independent individual and have an acceptable life?

Unfortunately, even to date few extensive data exist on long-term outcome. This chapter reviews the very few late outcome studies performed to

date. By definition, these data are based on outcomes of patients who started RRT in the early experimental years of dialysis and transplantation in children. Extrapolation of outcomes to the current generation of children on RRT is therefore hazardous as both the treatment quality and policies have importantly changed over time. Most western registry data show, for instance, a significant and continuous rise in pre-emptive transplantation rates in children over time [3–5]. Yet, despite all improvements, the most important problems of dialysis and transplantation have not been solved to date. Therefore, the situation of the first generation of now middle-aged patients with pediatric chronic renal replacement therapy may indeed give at least an impression of the potential threats for the current generation of children with ESKD.

Chronic Pediatric Renal Replacement Therapy in Developing Countries

A shortcoming of this review is that the reported data apply to patients from highly developed countries. Few data exist on the situation in resource limiting settings, but from the few existing reports it is obvious that the situation there is incomparable with that in developed countries. In some countries, chronic renal replacement therapy in children does not even exist at all. In an IPNA survey in 2017 among all countries with more than 300,000 inhabitants and a response rate of 80%, chronic RRT for children was reported to be absent in 10 out of 94 countries [6]. However, this is most likely an underreport, as nearly all not-responding countries were low-income countries. Also, the existence of a program for pediatric renal replacement therapy does not automatically imply access to RRT for all children. In China and India, for instance, the world's largest countries with 32% of the global childhood population, the estimated prevalence of pediatric RRT was in 2017 less than 10% of that observed in Western countries [6]. A recent report from Nigeria described outcomes of peritoneal dialysis in children aged 3–11 years for acute kidney injury after 18 months of follow up and reported 27.6% mortality [7]. A report from India mentioned 72% one-year survival, falling to 30% after 106 months of 66 children median aged 12.3 years on PD [8]. Another recent paper on country disparity within Europe showed that children on RRT from low-income countries have less access to transplantation but equal graft survival of those who received a kidney graft. Access to transplantation should also therefore be also the main aim for countries with limited financial means [9].

Course of Treatment Over Time

"A child with end-stage renal disease should receive a kidney transplant as soon as possible; a child that cannot be transplanted should not be started on chronic renal replacement therapy at all."

This paradigm has been a guideline for most pediatric nephrologists. Unfortunately, there are several circumstances in which dialysis is the only—temporary—option for children with ESRD. Moreover, as renal grafts may fail over time, the longer a patient is on RRT the higher is the chance that a patient will have a sequence of periods of living with a functioning graft alternating with periods on dialysis.

Most outcome studies have followed patients either on dialysis or after transplantation, ignoring the fact that most patients living with RRT for decades spend variable periods on both treatment modalities. The interpretation of such studies is troublesome, as it is the cumulative time spent on dialysis vs. the time with a functioning renal graft that predominantly affects the overall outcome.

In a long-term study of all 249 Dutch patients born before 1979 who started RRT before age 15 years between 1972 and 1992 with follow-up to 2010 (the LERIC study), patients spent on average 25.5 years on RRT. Of this cumulative time, 19.7 (0.03–39.6) years (77%) were spent with a functioning graft and 5.8 (0–36.5) years on dialysis. Among the 231 (93%) transplant recipients, 71 (31%) lived with a single transplant -not necessarily their first- for more than 20 consecu-

tive years, up to 37.2 years. Transplantation was performed twice in 84 patients (36.4%), three times in 43 (18.6%), four times in 8 (3.5%), five times in 1 (0.4%) and six times in 3 patients (1.3%). Patients changed treatment modality between 1 and 11 times during the study period. Only 2 of the 249 patients (0.8%) lived with a functioning graft during the entire follow-up (median survival 25.3 years) while 18 patients (7.2%) only received dialysis (median survival 3.7 years) [10].

In an equally long follow-up study using data of the Australian and New Zealand database (ANZDATA) concerning 1634 patients with RRT onset <19 years between 1963 and 2002, patients received RRT for on average for 11.3 years, of which 3.5 years were spent on dialysis and 7.8 years (69%) with a functioning graft [11]. The difference towards a longer time on dialysis in the latter study is probably explained by the 10 years earlier observation period [11].

Possibly, the average lifetime on dialysis may further decrease in the future as the last decade has shown a trend towards more pre-emptive transplantations in children, at least in the Western countries. All registry data show rises in rates of pre-emptive transplantation, varying from 26% in 1997–2001 to 32.9% in 2007–2011 in the United Kingdom ($p < 0.05$), from 10% to 25% between 1992 and 2007 in Canada and from 9.6% in 1985–1989 to 18.4% in 2000–2004 in the countries connected to the ERA-EDTA database [3–5]. According to the ANZDATA base, the proportion of children who underwent transplantation as the initial RRT modality had remained stable over time, being about 19–20% of all children starting RRT. On the other hand, the incidence of pre-emptive transplantation in children increased from 0.58 transplantations per million age related population (pmarp) in 1967–1971 to 1.65 transplants pmarp in 2002–2006 [12].

A recent report from the ESPN/ERA-EDTA database showed a 2% increase from 26.4 per million age-related population (pmarp) in 2007 to 32.1 pmarp between 2007 and 2016 of the prevalence of pediatric transplant recipients aged <15 years, with an unchanged incidence (5.5–6.6 pmarp), reflecting a better graft survival and promising a prolonged time on transplantation over time [13]. These shifts will certainly impact on the course of RRT as well as the impact on adult life in the current population of children with ESRD.

Impact of RRT Modality Over Time: Transplantation vs. Dialysis

All late outcome studies favor early transplantation in children with ESKD, which appears to have a beneficial effect on overall mortality, morbidity and psychosocial development. In the LERIC study, the cumulative duration of dialysis in relation to years with a renal graft was the strongest factor associated with nearly all adverse outcomes, especially with cardiovascular death, but also with impaired cognitive performance, loco motor disorders and social independency [10, 14–18]. The impact of dialysis on physical condition is also reflected by the sharp difference in physical health perception of dialysis and transplanted patients. On the other hand, the ANZDATA data showed that a short period of dialysis (up to 2 years) did not affect overall mortality, a finding that was confirmed by ERA-EDTA data on mortality in young adults with pediatric-onset ESKD [11]. None of the studies showed significant differences in outcome of peritoneal dialysis and hemodialysis.

Although dialysis is the most unfavorable mode of RRT, transplantation is associated with considerable late morbidity. Disabling co-morbidity was reported by 40% of all transplant recipients in the LERIC study of whom most patients were transplanted at time of investigation [19]. Apart from clinical bone disease, the most frequently reported disabling problems were severe daily headaches, tremors and severe itching, most of them appearing in transplanted patients. Malignancies, infection, hypertension related LVH and arterial wall stiffening are the most life-threatening problems after transplantation. Although current insight shows a much lower mortality in transplant recipients with childhood ESKD than in patients who remain on dialysis, with the passage of time the

'dark side of Camelot' may become more lucid. The longer the period of transplantation, the more patients become at risk for life-threatening infections and malignancies at relatively young age [20]. The current trend towards the use of more potent, and hence potentially more carcinogenic, immunosuppressive therapy may bear significant future consequences.

Mortality

According to long-term outcome studies, the overall mortality of patients with pediatric onset of chronic renal replacement therapy is about 30 times as high as among people of the same age without the need for RRT [10, 20–23]. Mortality rates per 100 patients decreased in most long-term outcome studies from 4.4 (ANZDATA) and 3.6 (LERIC) in 1972–1983 to 1.2–1.8 years after 1983 (ANZDATA, LERIC, Canadian Registry) [4, 10, 11, 20]. After on average 30 years of cRRT, the Dutch cohort study showed a U-shaped course of mortality risk over time: the added mortality risk, expressed as Mortality Rate Ratio, was extremely high during the first years of RRT in 72–'89, then decreased from 53 to 19.7 in the following period '90–'99, but increased again to 26.8 in the period '00–'10 [20]. After on average 30 years of RRT, mortality risk in the Dutch cohort study showed a U-shaped course over time: the added mortality risk, expressed as Mortality Rate Ratio, was extremely high in the 1970s and 1980s, decreased from 53 to 19.7 in the 1990s, but increased again to 26.8 in the first decade of this century [20]. This suggests that the added mortality risk may increase with ageing.

To some extent, these figures may overestimate the mortality risk for children currently on RRT as the dialysis technique certainly has improved over time and more children are transplanted pre-emptively. All studies on patients with ESKD indeed show a substantial decrease in mortality over the last 40 years, especially in the very young age groups. Yet, at the same time, this trend toward improvement of survival of ESKD has also slowed dramatically during the last 25 years [10, 11]. In fact, the survival trends are quite disappointing, considered the experimental nature of renal replacement therapy among children during the early years. Both McDonald's study on the ANZDATA and the Dutch cohort showed no increase in survival after 1983 [10, 11]. These outcomes are in line with other registry data. A Canadian registry study on survival rates of pediatric dialysis and transplantation since 1992 showed no improvement over time [4]. The USRDS data show a slightly different picture; here the mortality hazard ratio among transplanted patients decreased from to 0.83 in 1988–1994, dropped further to 0.77 in 1995–1997, stabilized between 1998–2001 and further dropped to 0.69 in 2002–2006. Yet, the latest figure might be biased by the maximum time to follow up as the authors also showed an increase of mortality with increasing time, becoming significant after 10 years of transplantation. Ageing and, more importantly, return to dialysis seem to explain this effect. Taken this into account, one can conclude that the actual mortality risk has not changed since the mid 90ies.

The lack of improvement might have been due at least partly to a shift towards acceptance of more severely disabled and younger children for chronic renal replacement therapy over the last two decades. Unfortunately, data on the referral and selection of children for chronic RRT do not exist, yet from oral communication this tendency over time towards accepting sicker children for chronic RRT accounts for most Western countries. Nevertheless, it is beyond discussion that the stable mortality rate over the last 20 years is unacceptably high.

Low-income countries that do offer chronic RRT to children show fewer favorite outcomes with respect to survival compared to high income countries. A recent report from the ESPN/ERA-EDTA database showed important disparities between European low- and high-income countries. A high-income country like France had a mortality rate (9.2) of more than 3 SDs better, in contrast to relatively low-income countries like Russia (35.2), Poland (39.9), Romania (47.4), and Bulgaria (68.6) had mortality rates more than 3 SDs worse than the European average. At the same time, the number of children on RRT was significantly lower in low income compared to high

income countries. Public health expenditure was inversely associated with mortality risk (per SD increase, aHR 0.69, 95% CI 0.52–0.91) and explained 67% of the variation in renal replacement therapy mortality rates between countries. Child mortality rates showed a significant association with renal replacement therapy mortality, albeit mediated by macroeconomics (e.g., neonatal mortality reduced from 1.31 [95% CI 1.13–1.53], p = 0.0005, to 1.21 [0.97–1.51], p = 0.10). After accounting for country distributions of patient age, the variation in renal replacement therapy mortality rates between countries increased by 21% [24].

Factors Associated with Mortality

Age of onset of RRT before 6 years, a long-time burden of hypertension, onset of RRT before 1982 and most significantly, the cumulative duration of dialysis during RRT were associated with premature death in the LERIC study. The risk ratios with respect to overall mortality of a relatively long period of dialysis and relatively long-standing hypertension were 7.2 and 3.1, respectively. Patients who started RRT between 1972 and 1982 had a 1.7-fold chance of premature death compared to those who started between 1982 and 1992, and patients aged below 6 years a 2.2-fold risk compared to older patients [10].

These outcomes are in line with those of the larger ANZDATA study and the Canadian Registry. In the ANZDATA study, the hazard ratio for death among those who started RRT before 12 months of age was 3.7 as compared to those who started at 15–19 years, and of those who started RRT between 1963 and 1972 the risk ratio was 4.2 compared to 1993–2002. In the Canadian study, the hazard ratio of patients aged younger than 1 year at onset of RRT and of those aged 2–10 were 7.8 and 1.5, respectively, compared to patients aged 10–18 years [4] (Fig. 70.1).

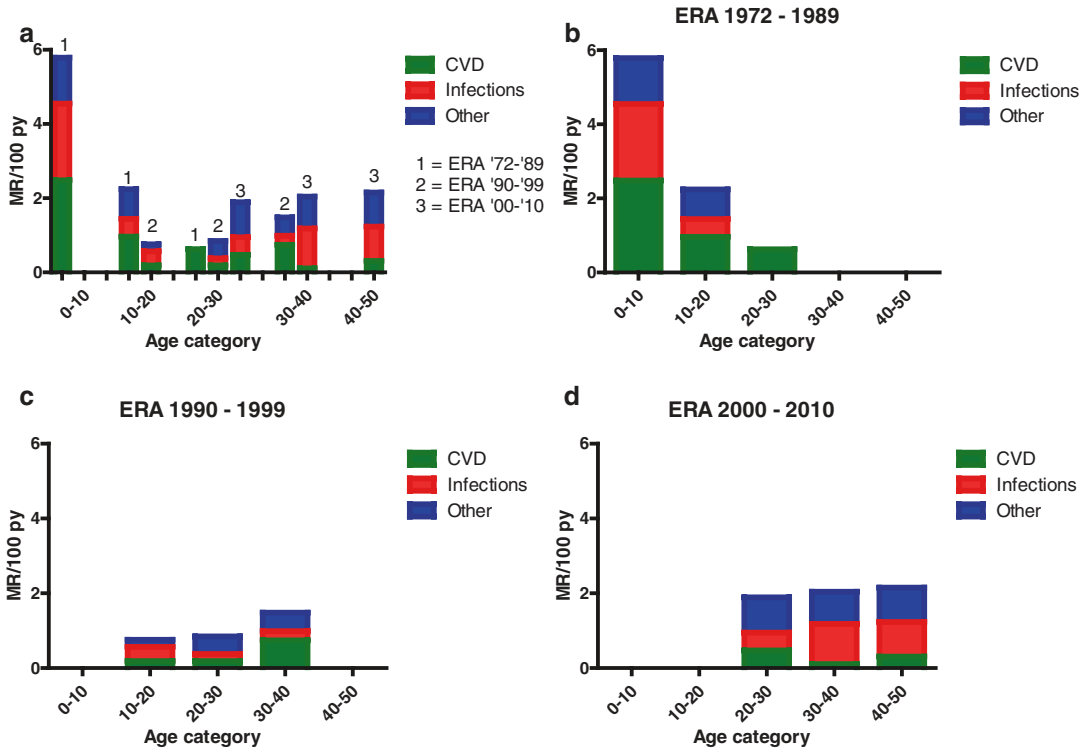

Fig. 70.1 CVD, infections and other causes related mortality rates per 100 persons in the LERIC Cohort (all Dutch patients with ESKD at age <15 years in 1972–1992 with follow-up to 2010) per age category per ERA (**a**), in the ERA 1972–1989 per age category (**b**) in the ERA 1990–1999 per age category (**c**) and in the ERA 2000–2010 per age category (**d**). (From Ref. [20]: Vogelzang JL et al, Nephrol Dial Transplant. 2013;28:2082–2089)

Rates of survival also varied with the type of renal replacement therapy. Overall mortality rates were 4.8 per 100 patient-years among patients receiving hemodialysis, 5.9 among those receiving peritoneal dialysis, and 1.1 among those with a functioning renal transplant. The Canadian Registry study showed that graft failure with return to dialysis was strongly associated with greater mortality risk in an adjusted model compared with a functioning graft (HR 7.2) [4]. According to both the ANZDATA and the ERA-EDTA registry study a short period of dialysis did not influence mortality; patients with pre-emptive transplantation had equal mortality to those with a maximum period of 2 years dialysis vintage [11, 13] (Fig. 70.2).

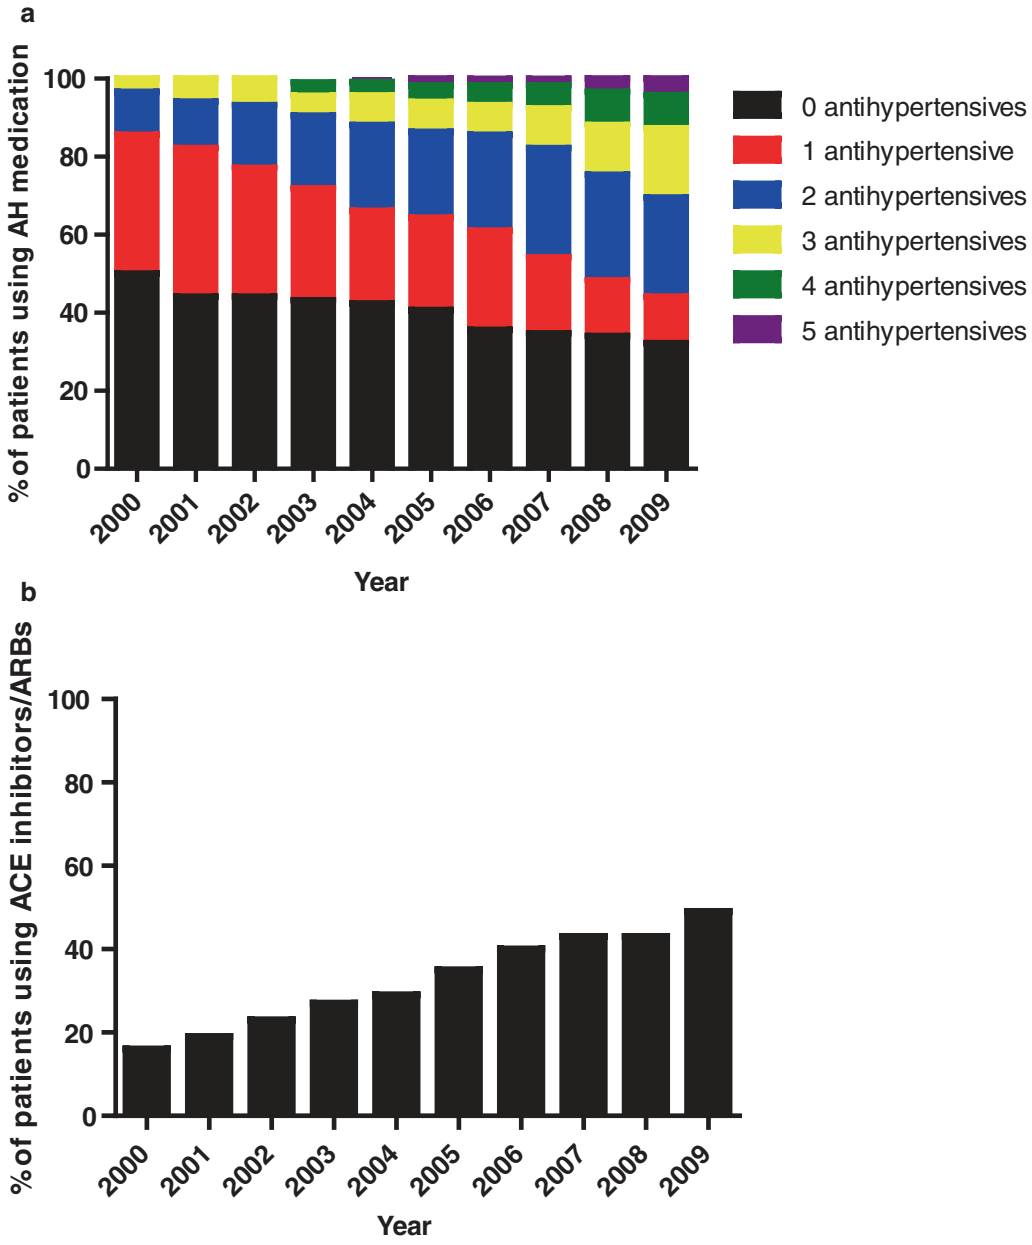

Fig. 70.2 Number of antihypertensive used per patient in each calendar years (**a**) and ACE-inhibitor (**b**) prescriptions in the LERIC Cohort (all Dutch patients with ESKD at age <15 years in 1972–1992 with follow-up to 2010) over time. Causes of Death

Cardiovascular disease accounts for most casualties in pediatric RRT, followed by infection and malignancies, at least according to most outcome studies. Between 35 and 50% of all deaths are attributed to cardiovascular disease [10, 11, 20, 22, 25–27] Although one has to be cautious in interpreting "cardiac death" as a genuine cause of death, these figures reflect the excess risk of cardiovascular disease in children with ESRD. Prolonged hypertension has been shown to be independently associated with increased morality [10]. Other recent studies show that left ventricular hypertrophy (LVH) occurs early in children with ESRD and that it is strongly associated with hypertension [28–30]. Mitsnefes et al. found that 69% of all children already had LVH at the onset of dialysis therapy which persisted for 2 years after transplantation in 56% and that regression of the LVH could be induced by controlling systolic blood pressure [28–30]. These data emphasize the pivotal role of blood pressure in both dialyzed and transplanted children. Both the ESPN registry and NAPTRCS have shown that uncontrolled hypertension occurs in 40–65% of patients [28, 31].

Despite the high prevalence of hypertension in transplanted patients, the overall cardiovascular profile of conventional dialysis is by far more adverse than that of kidney transplantation. In line with this notion, late outcome studies have identified extended time spent on dialysis as the strongest predictor for premature death from cardiovascular disease. Patients on dialysis who do not receive a transplant have a four times higher risk of death than transplant recipients; in patients who have spent more time on dialysis than with a renal graft, mortality rates are seven times higher [10, 11]. A long-term outcome report on pediatric transplant data of the USRDS showed that after the first post-transplant year, each additional year with a functioning graft was associated with a 16% decrease of cardiovascular mortality [32]. The same study showed a significant 6% increase in mortality risk for each year on dialysis prior to transplantation, whereas the ANZDATA and the ERA-EDTA data only found an increase in mortality risk of patients with a pre-transplant dialysis period of more than 2 years [11, 31, 32]. Nevertheless, the beneficial effect of transplantation on survival is beyond discussion.

In adults, increasing the intensity of hemodialysis, especially nocturnal hemodialysis, has shown to be effective in reducing cardiovascular disease, improve overall condition and quality of life and prolong survival [33]. Frequent hemodialysis ideally preformed as nocturnal home hemodialysis should be considered in children who cannot be transplanted and are long-time bound to dialysis treatment.

A younger age at onset of RRT was consistently identified as a considerable mortality risk factor across all studies [10, 11, 26, 32]. However, it is encouraging to notice that the survival of very young patients has improved over time. Considering the fact that more infants have been accepted for chronic RRT during the last 20 years, it seems that we indeed have overcome a great deal of the specific technical problems concerning delivering RRT to very young children, at least in terms of survival.

Trends Over Time in Causes of Death: From Cardiovascular Disease to Infections?

Up to the late 1990s, few physicians, internists as well as pediatric nephrologists were fully aware of the extreme cardiovascular burden that threatened their patients. Growing awareness and adjustment of therapy accordingly might be the basis of a remarkable trend in change of outcome according to some very recent data. In an extension of the Dutch LERIC study, a significant shift from cardiovascular disease to infections as main cause of death was found [20]. In this study following up to 2010 all Dutch patients with RRT onset before 15 years of age between 1972 and 1992, the overall mortality rate as well as the added risk to the overall population, the Mortality Rate Ratio (MRR), stabilized over time. At the same time, the MRR for cardiovascular death decreased from 660 in 1972–1989 to 70 in 1990–1999 and further to 20 in 2000–2010. Conversely,

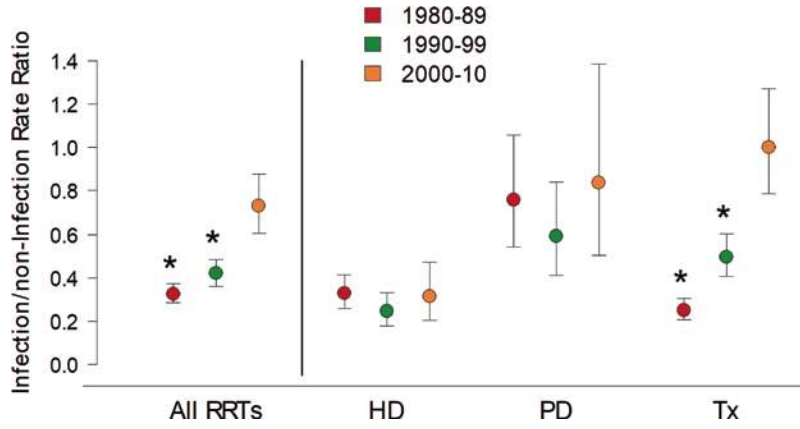

Fig. 70.3 Infection-non infection for Hospital Admission Rate Ratio according to decade and Renal Replacement Therapy modality in the LERIC Cohort. *p < 0.001 vs. decade 2000–2010. Whiskers represent 95% CI> *HD* hemodialysis, *PD* peritoneal dialysis, *Tx* transplantation (From Ref. [46]: Lofaro D et al, Pediatr Neph. 2016)

the MRR for infectious death showed a U-shaped curve; it decreased from 503 in 1972–1989 to 102 in 1990–1999 and increased again to 350 in 2000–2010. In the period 2000–2010, infections became the most prevalent cause of death (44%). In 2000–2010 cardiovascular mortality had decreased by 91% since 1972–1989 (p = 0.003) whereas infectious mortality had doubled over time, although not significantly (adjusted HR 2.12, p = 0.09) [20] (Fig. 70.3).

More recent data confirm this trend of infections gradually replacing cardiovascular disease as the most important cause of death. Recent USRDS data show a declining burden of cardiovascular mortality among the dialysis patients of all ages over the last years (MR 120 in 2001 to MR 83 in 2008 per 1000 patient years without changes in other causes of death over time (MR 100 per 1000 patient years in 1998, 2001 and 2008) [34]. This trend was similar in patients aged 20–44 years, with the cardiovascular MR declining from 40.5 per 1000 patient years in 2001 to 31.3 in 2008 [34]. Also ANZDATA showed decreasing cardiovascular mortality rates for all dialysis patients (MR 9.0 in 1992 to 6.4 in 2005 per 1000 patient years), but not among the younger patients aged 35–54 years [35].

Co-morbidity

Many studies have shown that end-stage renal disease affects many organs, especially the cardiovascular system and the loco motor system, and that it has an important impact on the overall physical condition of patients. Yet, very little data exist on the exact physical burden of pediatric ESKD later in life. In the LERIC study, 40% of survivors aged between 20 and 40 years. 75% being carriers of a functioning renal graft at time of investigation, indicated an important co-morbidity that significantly affected their activities of daily life, ranging from chronic fatigue to symptoms of cardiovascular disease or disabilities due to loco motor disorders [19].

Cardiovascular Disease

Asymptomatic cardiovascular disease, to an extent that it might induce sudden death, has been reported to be highly prevalent in transplanted as well as in dialysis patients with pediatric ESKD [10, 14, 18, 22, 30, 36, 37]. Yet, for transplanted patients, previous dialysis vintage is the strongest factor for developing cardiac and vascular abnormalities [10]. In a German single center late outcome study of 283 patients that had been transplanted between 1970 and 1997 and of whom 42 patients had died, in 50% of cardiovascular disease, CT scans were performed in 39 survivors, aged between 19 and 39 years [22]. Coronary artery calcifications were present in 92% of patients; calcium scores exceeded the 95th age- and sex-specific percentiles tenfold on average. Carotid IMT was significantly increased compared with matched control subjects. Both coronary calcium scores and IMT were associ-

ated with cumulative dialysis and ESKD time and the cumulative serum calcium-phosphate product [22]. In the Dutch LERIC study, nearly 50% of all living male and 40% of all female patients aged between 20 and 42 years were found to have moderate to severe left ventricular hypertrophy (LVH), 75% being transplanted at the time of investigation in 2000 [18]. Like LVH, cardiac valve calcification and arterial wall stiffening caused by media proliferation and secondary calcification are highly prevalent in young adults with childhood ESRD, both in dialysis and transplant recipients [14, 22]. All these abnormalities are associated with an increased risk of death. Coronary ischemia and cardiac conduction defects due to myocardial calcification are the most probable links between aortic valve calcification and mortality. Aortic valve calcification may occur early in ESKRD patients and reflects a more generalized artery disease with calcification of the coronary arteries and the myocardium [38]. Vascular calcification appears to already start at a young age. Eifinger et al. described coronary calcifications in 16-year-old dialysis patients [38]. Chronic hypertension, a high calcium phosphate product and a chronic state of inflammation are among the most important potential determinants of cardiovascular disease in ESKD [36, 39–41].

Yet, as previously discussed, increased awareness among physicians of the impact of pediatric ESKD on the cardiovascular system might profoundly change outcomes in the near future. To our surprise, we found in the extension of the LERIC study in 2010 that between 2000 and 2010, most people had died of infections and only 1 due to CVD [20]. Among the survivors, the prevalence of cardiovascular risk factors decreased from 41.3% in 2000 to 18.8% in 2010. The odds ratios in 2010 relative to 2000 for left ventricular hypertrophy, hypertension and hypercholesterolemia were 0.26, 0.22 and 0.04, respectively. The rate of non-fatal cardiovascular events dropped, although not significantly, from 1.75 in 1972–2000 to 0.95 in 2000–2010 per 100 patient years. RAS antagonists and cholesterol lowering medication were significantly more often prescribed in the period 2000–2010 (OR 7.4 and 11.5) [42]. Trends were similar among those who survived and those who did not survive the last decade. Although a causal relationship between the two cannot be inferred from this study, our data strongly suggest that strict blood pressure control, with preferential use of RAS antagonists, and reduction of dyslipidemia may be effective in reducing cardiac threat in patients with end-stage renal disease even after a long-lasting burden of cardiovascular disease (Fig. 70.4).

Infections

In adults, infections are the leading cause of death in the first year after kidney transplantation [43]. In a single center study, only 7 out of 129 consecutively transplanted patients did not have an infection for which medical intervention was necessary [44]. Urinary tract infections (69.8%) and CMV infection/reactivation were most prevalent. Yet, USRDS data show that infections, especially urinary tract infections are also highly prevalent much later after transplantation. In a retrospective cohort study on 28,942 Medicare renal transplant recipients the cumulative incidence of urinary tract infections was 60% for women and 47% for men at 3 years after transplantation. Late urinary tract infection was significantly associated with an increased risk of subsequent death (adjusted hazard ratio-AHR 2.93) and graft loss (AHR 1.85). The association of urinary tract infection with death persisted after adjusting for cardiac and other infectious complications, and regardless of whether urinary tract infection was assessed as a composite of outpatient/inpatient claims, primary hospitalized infections, or solely outpatient infections [44]. This contrasts somewhat with findings in children; according to USRDS data the risk for graft loss was increased for early but not late urinary tract infection. This finding might, however, be biased by a relatively short follow-up time [45].

Data on the prevalence of severe infections over a very long time in pediatric ESKD come from the LERIC study. This study shows an increasing importance of infections over time. Between 2000 and 2010, 34 out of 186 patients died; 44% of these died of infections in contrast to only 12% of cardiovascular disease. There was a 60% reduction of the number of hospitalizations over time, from 1202 in the period 1980–1989 to 484 in 2000–2010. This was entirely due to a reduction in non-infection-related hospitalizations by 74%, whereas infection-related hospitalizations in allograft recipients did not change at all. Consequently, the hospital admission incidence rate ratio of infections and other causes increased from 0.25 to 1.0 over time in transplanted patients [46]. Urinary tract infections (UTI) became more prevalent over time in transplanted patients; the UTI/non-UTI infections hazard rate ratio in transplanted patients for which hospitalization was required increased from 0.42 in 1980–1999 to 0.72 in 2000–2010 [46].

Most of the transplanted patients in LERIC have a relatively mild immunosuppression as compared to currently used strategies. In adult studies, there is some evidence suggesting that the incidence of infection is associated with the intensity of the immunosuppressive regime. Most studies show that the dose rather than the type of immunosuppression is responsible for the increased risk of infections. The ELITE (Efficacy Limiting Toxicity Elimination)-Symphony study compared outcome of either low-dose of ciclosporin, tacrolimus or sirolimus with standard dose ciclosporin and with equal MMF dose in both groups. Opportunistic infections were more common in the standard-dose ciclosporin group [47]. Infections were also more common if patients use a standard dose of ciclosporin as compared to low-dose ciclosporin combined with everolimus [48]. The TERRA (Tacrolimus Evaluation in Renal Transplantation with Rapamycin) study compared 0.5 mg with 2.0 mg sirolimus and equal dose tacrolimus in both groups; more infections were found in the 2 mg sirolimus group [49].

In conclusion, ageing in pediatric RRT goes with a high risk for premature death by infections. Urinary tract infections are probably the most prevalent late life-threatening infections. Lowering of the immunosuppressive load, especially in patients with a prolonged rejection-free period after transplantation, might help reducing the number of fatal infections in these patients.

Malignancies

Incidence

In young adults with pediatric ESKD, the cumulative incidence of cancer varies between 0.8 and 17%. Malignancy is believed to occur about ten times more frequently than expected for age [50–54]. The most prevalent forms of malignancies seen are non-Hodgkin lymphomas and above all,

skin cancer at older age. Cancer was found in 24 cases of all 536 transplanted children in Sweden since 1970 with a mean follow-up of 12.5 (0.04–34) years [52]. In a French single center study with 20 years follow-up, 16 malignancies were found in 219 kidney transplant recipients at a median age of 20.8 (4.1–36.5) years [53]. A large German long-term follow-up study of transplanted children with a mean follow-up of 13 years showed a relatively low percentage of malignancies of 2.6% [25]. In a long-term follow-up study on 187 renal transplant recipients who had reached adulthood at time of assessment, Bartosh et al. found 12% malignancies [50].

The NAPRTCS reported recently on the prevalence among "more than 10,000" pediatric transplant recipients since 1987 and found 35 cases of malignancy, including 5 cases of renal cell carcinoma [54]. The estimated prevalence of 72.1 cases per 100,000 person-years reflects a 6.7-fold increased risk compared with the general population [54].

Yet most studies suffer from a relatively short follow-up period and the distribution over time after onset of RRT suggests that most casualties might come at a later age. In the 10 years extension of the Dutch LERIC study, 54 (21%) of the originally 249 patients had developed 105 *de novo* malignancies after an average RRT time of 23 years (age survivors 30–50 years) [55]. In this study, the Cancer-free survival after 10, 20, 30 and 35 years of follow-up was 97%, 87%, 68% and 58% respectively. The mean age at malignancy diagnosis was 36.9 (range 11.1–50.4) years. The mean interval from first transplantation to diagnosis of cancer was 23.7 (range 0.1–36.2) years. Death was attributed to the malignancy in 13 out of the 54 (24%) patients who developed cancer at time of assessment [55].

Type of Cancer

Post-Transplant Lymphoproliferative Disease (PTLD)

The term Post-transplantation lymphoproliferative disorder (PTLD) stands for different types of lymphoid neoplasms that may develop after kidney organ transplantation. The World Health Organization (WHO) distinguishes four subtypes of PTLD: an early, a polymorphic, a monomorphic and a classical Hodgkin-lymphoma-like type, each with its different therapeutic approach. The risk of PTLD is biphasic in time. The highest incidence is within the first year after transplantation. These so-called early onset PTLD types are for 95% associated with Epstein-Barr virus (EBV) and have a relatively good prognosis. A second peak occurs after 5–10 years [56]. Late onset PTLD is related to the impact of relative high burden of immunosuppressive therapy most often independent from EBV and has a worse prognosis than the early onset form [56, 57]. PTLD occurs in about 0.8–2.8% in kidney transplant recipients [58–60].

Pathophysiology of EBV Associated PTLD

EBV-related PTLD occurs because of a de novo EBV infection or reactivation from latent B-cells driven by immunosuppressive therapy. An EBV-seronegative recipient who gets an allograft from an EBV-seropositive donor (D+/R-) may undergo a primary EBV infection, a situation which is the most important risk factor for PTLD. This explains why PTLD occurs 2–8 times more often in pediatric than adult transplant recipients [56, 61]. EBV is a lymphotropic virus which enters the B-lymphocytes during the initial infection and remains in the host nucleus in a state of latency for that individual's lifetime. This latent state is associated with EB nuclear antigen production and Latent Membrane Proteins which protect the B-cell from apoptosis and stimulate ongoing viral application which is controlled by a cytotoxic T cell driven EB specific surveillance. Impairment of this cytotoxic T-cell protection is believed to be essential for developing PTLD [62]. Lack of T-cell protection leads to uncontrolled viral replication and an increase of virus-carrying B-cells in the circulation [62]. Cytokine responses, induced by immunosuppression, may lead to uncontrolled B-cell proliferation and ultimately neoplastic PTLD.

Risk Factors for PTLD

Epstein-Barr Virus (EBV)

EBV seronegativity and the use of potent immunosuppressive therapy are the two most important PTLD risk factors. In children, over 70% of PTLD is EBV-associated. The risk of being EBV naïve has been established in various studies. Sero-negativity of EBV is associated with a 4–7 times overall increased risk and a 20 times increased risk with in the first years after transplantation [63–65].

CMV/Hepatitis C

Reports on the role of CMV and hepatitis C are conflicting. Studies from the 1990s have revealed a four-to-six-fold excess risk of PTLD of CMV sero-mismatch (i.e., a negative recipient and a positive donor) after non-renal transplantation [66]. A *de novo* CMV infection was associated with polyclonal B-cell proliferation. The same role has been suggested for hepatitis C [67], but neither the CMV nor the hepatitis C link could be confirmed by large registry reports from the USRDS and ANZDATA [60, 68].

Immunosuppressive Therapy

All longitudinal evaluations of the incidence of PTLD show a trend over time toward increased incidence and earlier onset of PTLD up to 2000–2005. The exact role of immunosuppressive drugs in this trend remains to be elucidated. The concurrent increase in potency of the immunosuppressive therapy and incidence of PTLD is obvious, but links between the use of specific drugs and PTLD are unclear. It is believed that MMF is of less influence than calcineurin inhibitors but that statement is not supported by hard evidence and even contradicted by some case reports [69]. The previously supposed protective effect of mTOR is also contradicted by recent data [70].

Other

Apart from the increased overall risk of children, UNOS data have shown that young male Caucasians were at greatest risk for PTLD [65] A complete HLA-DR mismatch associates with a twofold increased risk, probably as a result of the greater immunosuppressive requirements [71].

Monitoring and early detection. Elevated EBV levels in mononuclear cells or in plasma assessed by PCR is the key to early detection of PTLD. The most important monitor is serial EBV quantitative PCR assessment as a rising level is more predictive than a single positive EBV quantitative PCR. EBV+ PTLD most often occurs in the first 1–2 years post-transplant, so monitoring should be intensified during this period [72]. Unfortunately, there is no standardized assay for EBV quantitation. Thresholds for elevation of the EBV load therefore differ per individual lab [72]. A negative EBV PCR does not exclude PTLD. Unexplained anemia, leukopenia or thrombocytopenia and high uric acid and LDH levels are non-specific abnormalities that are associated with PTLD or another malignant blood or lymph disease. Patients should be checked for tonsil abnormalities; if they do occur, a biopsy is indicated. Radiological monitoring includes MRI, CT and positive positron emission tomography (PET) scanning to evaluate the spread of PTLD. In case of CNS involvement, a lumbar puncture with cerebral spinal fluid (CSF) analysis (EBV PCR in CSF fluid) is indicated. Histopathologic examination of the tumor can only determine the definitive diagnosis.

A new development in monitoring is the detection of a certain viral load as proxy for decrease of immuno-competence [73]. Data of a study in 96 heart and lung transplant recipients suggest that a high anellovirus load may be indicative of over-immunosuppression. In line with this, metagenomic shotgun sequencing of tissues from PTLD patients showed that more than 50% of the specimens contained anellovirus sequences, and the anellovirus levels, but not EBV levels, were associated with death within 5 years in a univariate analysis [74]. This presumes that virome changes, and even specific viruses such as anellovirus, may provide indirect measures of the immune status which can promote the development of EBV+ PTLD.

Therapy/prevention of PTLD. Reduction of immunosuppressive therapy in case of an increase in EBV load in EBV-seronegative recipients and

incase of EBV disease in all recipients is the first step in preventing PTLD (KDIGO level 2D and 1C) [75]. Rituximab is the cornerstone of 1e first line therapy of PTLD. In a multicenter trial, 152 transplant recipients with CD20 + PTLD that was unresponsive to immunosuppression reduction, were initially treated with 4 doses of weekly rituximab. In case of complete remission, rituximab treatment was continued with another 4 gifts; other patients received 4 R-CHOP courses. The overall response and CR rates were 88% and 70%, respectively; the most significant prognostic factor respect to overall survival and time to progression was the response to the first 4 courses of rituximab with [76].

Skin Tumors

Skin cancer is the most frequent malignancy after transplantation, also after pediatric transplantation, but hardly occurs in childhood. Most tumors only become manifest 10–15 years after transplantation. According to IPTTRS data, 16 out of 101 skin cancers found in pediatric solid-organ transplant recipients developed during childhood [77], 10 of them being squamous cell carcinomas (predominantly of the lower lip) and 6 melanomas. Death occurred in 8 patients, five from squamous cell carcinoma and three from melanoma [77].

The mean age at onset of skin cancer has been reported to be about 27 years [51, 54, 77–79]. However, recent data of the LERIC study shows that most tumors occur at later age. In the Dutch study, the risk for non-melanoma skin cancer (NMSC) was over 200 times higher than in the age-related population. Of all 249 patients, 63 had died in 2000 and 97 in 2010. At that time, 39 patients had developed 82 non-melanoma skin cancers (78% of all tumors). The mean age at developing a NMSC was 39 (range 22–50) years [55].

UV exposure and human papilloma virus (HPV) in combination with immunosuppression are thought to be the most important causative factors for the development of post-transplant skin tumors. UV radiation is probably one of the most important factors [78] This explains the extremely high incidence in Australia, a country with a majority of genetically ill-protected Caucasian people and a very high sun exposure, with a 93% proportion of skin cancer among all post-transplant malignancies [80]. Sun protection is therefore of utmost importance, in combination with Vitamin D supplementation to avoid Vitamin D deficiency.

Skin cancer may appear in the absence of any pre-existing skin lesion, but is often preceded by actinic keratosis, which suggests the involvement of HPV in its pathogenesis. Additional evidence for the role of HPV comes from a study on post-transplant squamous cell carcinomas (SCC) that occurred in a cohort of 500 allograft recipients; HPV DNA could be detected in nearly 50% of all SCC [81, 82].

Calcineurin inhibitors have been regarded as most important immunosuppressive drugs that may increase the risk of skin cancer [83]. CNIs may express their oncogenic effect by interference with the p53 pathway and nucleotide excision repair and by promotion of malignant cell differentiation [84, 85]. In contrast, mTOR inhibitors have anti-tumor properties. Indeed, several studies have showed that diversion to mTOR in transplanted patients with NMSC could prevent the occurrence of new tumors [86, 87]. A recent study showed that the combination of low dose CNI and sirolimus could also be effective as prevention against new tumors [88].

Squamous cell carcinoma and basal cell carcinoma (non-melanoma skin cancers, NMSC). Squamous cell carcinoma (SCC) accounts for more than 50% of all skin cancers after transplantation. The ratio of basal cell carcinoma (BCC) to SCC is reversed in transplant patients compared with the general population in which basal cell carcinoma is the most common one. SCC was 81 times more prevalent in a cohort of Danish renal allograft recipients than in the general population [82]. The predominance of SCC over basal cell carcinoma (BCC) is more pronounced in pediatric than in adult transplant recipients (SCC: BCC 2.8:1 vs. 1.7:1) [77]. SCC is for the most part found in parts of the body exposed to daylight [80]. In pediatric transplant recipients, lip cancers account for 23% of all skin cancers [77].

Skin cancers may develop rapidly, and recurrences are common. In the LERIC study NMSC was most common to recur and/or metastasize of all malignancies. Including metastases, 114 NMSC (78 SCC and 36 BCC) occurred in 39 patients at a mean age of 39 (21.8–50.4) years [55]. The Incidence Rate and Incidence Rate Ratio's for SCC were 1.5 and 744, respectively. The IRR was 992 in the 25–30 and 2610 in the 45–50 year age group. Two patients died of SCC; far more patients had important morbidity because of SCC metastases.

Melanoma

Melanoma seems to be more prevalent in pediatric than in adult transplant recipients (12 vs. 5%) [77]. The Dutch cohort study counted 5 melanomas on 105 malignancies, occurring at a mean age of 29 years [55]. Data of the IPTTRS and the Dutch cohort study suggest an earlier onset of melanoma compared to NMSC. The IPTTRS noted 25% of deaths were due to melanoma [55, 77].

Melanocytic nevi, a risk factor for melanoma, may develop in excess after transplantation [89]. In transplantation, melanoma can be transmitted by the donor. Any person with a history of melanoma should be excluded from donation [90]. It has been speculated that growth hormone use might increase the growth rate of melanocytic nevi, but to date no association between GH therapy and the occurrence of melanomas has been found [91]. Sun protection and removal of suspect nevi are the most important protective measures.

Kaposi's Sarcoma

Kaposi's sarcoma is caused by HHV8 virus infection. The Norwegian study found 3 times more Kaposi Sarcoma's in kidney transplant recipients than in the general population [92]. The IPTTRS reported 2% Kaposi sarcoma's, nearly all of which occurred during childhood [78]. Only one child presented with skin cancer. All had various visceral localizations. The age of occurrence ranged from 5 to 17 years, the onset was typically within a few months after transplantation. Six of the eight reported patients had a fatal outcome.

Other Tumors

There are very few data on other solid tumors after pediatric renal transplant recipients. The NAPRTCS transplant registry found a rate of non-lymphoproliferative solid tumors of 72.1 per 100,000 person-years which implies a 6.7-fold increased risk compared with the general pediatric population (10.7 cases per 100,000 person-years). Non-LPD malignancy was diagnosed in 35 subjects at a median of 726 days post-transplant. The most common type of malignancy was renal cell carcinoma. No specific type of immunosuppression was identified as a risk factor [54]. In the LERIC study, 9 solid non-skin/non lymphoproliferative tumors were found, consistent with 158 per 100,000 patient years, at a mean age of 41.7 years [55]. All 9 tumors were from different origin.

Other Somatic Co-morbidities

Bone disease and motor disabilities. Whereas cardiovascular disease and infections have proven to be the most life-threatening co-morbidities, chronic fatigue in dialysis patients and motor disabilities as a result of metabolic bone disease are the most frequently reported daily problems of young adults with childhood ESRD [16, 19, 50]. As expected, in a cohort of patients that has grown up in the pre-growth hormone era, more than two-thirds of the LERIC patients were severely growth retarded [16]. A more surprising and more worrisome finding was the extent and severity of clinically manifest metabolic bone disease that we found in the LERIC patients. More than one-third had daily complaints or disabilities related to metabolic bone disease. About 18% were disabled as a result of bone disease [16]. Very few data exist on this evidently underexposed problem. Although conclusive evidence is lacking, most of these problems seem to be related to chronic inactivity, inadequately managed CKD-MBD, a high burden of corticosteroids and an increased total duration of renal

replacement therapy [93]. Bone mineral densities (BMD) are lower than −2.5 SDS in over 50% of adult patients with childhood ESRD [16]. However, in a 10-year extension of the LERIC study, no association of low BMD with clinical bone disease, such as fractures, daily pain or motor disabilities, could be found (unpublished data).

Itching is a frequently mentioned complaint of both dialysis and transplanted patients [94].

Psychosocial Consequences

Cognitive Functioning

Neurocognitive dysfunction is a well-recognized complication of pediatric CKD. Many studies have found evidence of several neuropsychological deficits, including IQ, academic achievement, memory, and executive functioning [95–99]. This deficit is reflected by cognitive dysfunction at adult age. Cognitive and learning impairment is also more prevalent in middle-aged adult patients with childhood ESKD than in the age-matched population [15, 100]. In the LERIC study mean IQ scores of adults aged 20–40 years with childhood ESKD were on average ten points lower than in the aged matched Dutch population, which is in line with the results of IQ studies performed in children [15, 101, 102]. Impaired schooling and cognition appear to be induced by a long period of dialysis during youth. The LERIC study found no difference in intellectual performance between patients who were on dialysis and those who were transplanted by the time of investigation. In theory, chronic aluminum intoxication as a result of chronic use of aluminum-containing phosphate binders could have influenced the cognitive development of our patients. Yet, no evidence was found for this [15]. On the contrary, the compatible results of recent IQ studies in ESRD children indicate that abandoning aluminum-containing phosphate binders has not shown beneficial effects on intellectual development [15, 103]. Most deficits are found in tasks requiring concentration, memory and most of all general knowledge. Consequently, early educational intervention in young patients on dialysis might prevent most of these impairments. In spite of improvements in identification and treatment, CKD causes both direct and indirect insults to a variety of organ systems. In contrast with the Dutch study, the educational attainment of pediatric transplanted patients with a median age of 25.7 years in a Swedish study was in line with the general population. The problem of this study is that 40% of the cohort did not participate and no information about the characteristics of these non-participants was provided [104].

Previous studies of children with CKD suggest that toddlers and children with CKD are at increased risk for delays in neuro-cognitive development [105]. In a large North American study (CKiD) on 386 children with CKD 2–4 (mean GFR 41), the overall neuro-cognitive functioning was within the average range for the entire group, but 21% to 40% of participants scored at least one SD below the mean on measures of intelligence quotient (IQ), academic achievement, attention regulation, or executive functioning. A higher GFR was associated with lesser risk for poor performance on measures of executive function. Significant proteinuria was associated with lower verbal IQ, full-scale IQ, and attention scores [106].

In an accompanying analysis, CKiD cohort participants with hypertension scored lower on visual-spatial organization, planning, constructive abilities, and nonverbal reasoning [107]. Results from these studies highlight the importance of recognizing neurocognitive dysfunction in children with CKD early on because of the significant impact it may have on school performance and the opportunity it presents for prompt intervention [108].

Quality of Life

Transplant Patients

According to most studies, adult patients with a functioning renal graft achieve normal scores on self-assessment of mental and physical health for most domains. In the LERIC study, data on quality

of life were assessed in 2000 in 131 of 186 surviving patients aged 20–40 years with mean onset of RRT at age 11 years. In transplanted patients, only scores on social functioning and general health perception were slightly lower than in the age related general Dutch population. All other scores were within the normal range [17]. Equally good outcomes were found in an Italian follow up study on transplanted patients at aged 18–34 years who were transplanted a median age of 15 years [109]. In contrast, a study from Japan noted lower mean scores, especially of those related to the mental quality of life, in kidney allograft recipients of the same age [110]. Remarkably, in this study, nearly all scores of hemodialysis patients awaiting transplantation appeared to be similar to those of transplanted patients. In contrast, dialysis patients not awaiting transplantation (i.e. not on a transplant waiting list for medical or personal reason) had much lower scores [110]. Most available studies emphasize the improvement of the quality of life after renal transplantation [111–113]. However, for some young adults, transplantation not always had the wellness and health that they hoped it would have, as was shown in a more recent review on adult perspectives of living with kidney failure. Young adults with pediatric ESRD most often have a driving desire to *be* "normal," whereas those diagnosed later in early adulthood often feel an "unbearable loss" and hope *to return* to their previous state of "normal" [114].

Dialysis Patients

Not unexpectedly, in the LERIC study patients aged 20–40 years with pediatric onset of ESRD who were on dialysis at time of assessment indicated more often an impaired quality of life than the general population in all physical domains: activities that require good physical condition (Physical Functioning), social activities that require a good physical condition = Role Limitations due to physical health (Role Physical), social functioning (SF), general health perception (GH) and the so-called physical component summary (PCS). Yet the same patients reported an impaired quality of life for the mental domains equally or even less often than aged-matched Dutch citizens [17].

These results sharply contrast with data derived from dialysis patients with onset of ESRD in adulthood [115–117]. Patients with adult onset of disease appear to have a substantially poorer quality of life, particularly in Physical domains and General Health perceptions, but also in domains related to the mental quality of life.

In the LERIC study, outcomes of patients on dialysis were compared with age-matched dialysis patients with adult-onset ESRD from the NECOSAD-2 study. The latter concerned Dutch patients who were only on RRT since 1 year. In all domains except one, scores of NECOSAD patients were significantly lower than those found in the general population, whereas the LERIC dialysis patients had normal mental scores [17].

The high scores on mental health in LERIC are on the other hand consistent with findings in other studies of adolescents and adults with chronic illness since childhood, including sickle cell patients, cystic fibrosis and asthma [118–120]. Different expectations of life and different coping strategies by children and adults may explain the difference in mental status of patients with pediatric and those with adult onset of disease. Carr et al. have reasoned that health-related quality of life is to a large extent based on the difference between health expectations and health experiences [121].

Effect of Age at Assessment

Quality of Life (QoL) scores seem to be age dependent to some extent. At both late adolescent and very old age, patients score on average lower than at middle age [111, 122–124]. Using another scoring system, a Finnish group assessed QoL at young adult age years in 21 patients transplanted at very young age (mean 2.4 years) and found significantly lower scores than in age-matched controls, contrary to the Dutch and Italian late outcome studies. Significantly lower scores were found regarding mobility, usual activities, mental functioning and vitality [123]. There was a clear tracking effect, as scores per patient were comparable to those measured 10 years before. These outcomes mimic more the QoL scores found in children with ESRD [125].

Trend Over Time

Most favorable outcomes in transplanted patients are reported after at most 10–20 years of follow up. The QoL assessment in the Dutch LERIC study was repeated in 2010 after a mean duration of about 30 years of RRT in surviving patients aged by then 30–50 years. The scores in physical domains were significantly lower in 2010 than in 2000. These concern limitations of daily activities and social participation by physical impairment or pain ('Physical Functioning,' 'Role Physical' and 'Bodily Pain') as well as General Health perception. The decrease of physical QoL over time also accounted for transplanted patients [126]. The deterioration of physical QoL is partly explained by a normal effect of ageing in line with the trend in the general population as older age is an important negative predictor of perceived physical health status [124].Nevertheless, the ongoing decay superposed on lower scores on some domains could become a significant problem for these patients in the near future, adversely influencing their social functioning. In the LERIC study, one transplanted woman aged 32 years illustrated this by questionnaire comments: "Much more often than 10 years ago, even when I was on dialysis, I feel very tired nowadays, reason why I recently have decided to stop working for a while."

According to the same study, all domains relating to psychosocial functioning had remained stable over the last 10 years.

Co-morbidity was associated with an increased risk of impaired QoL in the domains 'Physical Functioning,' 'Role Physical' and 'Bodily Pain.' Having disabilities was associated with an increased risk of impaired QoL regarding Physical Functioning, Vitality and Bodily Pain. Notably, the current RRT modality at time of investigation was not correlated with impaired QoL in any domain. However in case lifetime on dialysis exceeded lifetime on renal transplant, there was an increased risk of impaired participation in social activities by physical strain.

Regarding the socio-demographic variables, being employed appeared to be associated with a lower risk of impaired QoL in the domains of Physical Functioning, Vitality and General Health perception. Having offspring was associated with a lower risk of impaired QoL regarding Social Functioning and an income equal to or above the national average of €2500 (about $ 3200) gross per month was associated with a lower risk of RP [126].

Although in line with positive outcomes on mental health perception for other chronic diseases of childhood with shorter follow-up time, the universally high scores on mental health after 30 years of RRT with a concurrent decline in physical health and subsequently physical QoL are striking. Nearly 80% of patients stated that their disease had brought them something positive in life. The perceived benefits of having ESRD included more satisfaction with (small things in) life, having developed a sense of perseverance and positive responses from friends and relatives [126].

Social Outcome

Employment

A review from a social work perspective of data on late social consequences of pediatric kidney transplantation showed a significant impact on many aspects of social development including education, peer/intimate relationships, employment and overall well-being. Young adults, kidney transplanted at childhood, are more likely to live with their parents and less likely to have a partner. Social isolation, fear to disclose their disease status to peers and difficulties to establish intimate relationships are more prevalent than in the general population [127].

Social outcome was assessed in the LERIC study in 2000 and in 2010. In 2000, 67.4% was employed, about 85% for more than 50% time equivalent [128]. Involuntary unemployment occurred in 19.1% vs. 6.4% in the Dutch population. Most patients (53%) had low skilled and only 10% had high skilled professions, a situation significantly different from the average Dutch population [128]. In 2010, 61.8% were employed of whom 81.8% had at least 50% full time equivalent paid work. However, different from the situation in 2000, there was a very significant difference

between patients on dialysis of whom only 31.3% were still employed, and transplanted patients [126]. Apart from dialysis as RRT modality, having motor disabilities was the most important risk factor for becoming unemployed. Patients also mentioned increasing chronic fatigue as an important reason for becoming unemployed. Some patients, however, reported that their employment contract was not renewed as a direct result of the disclosure of their dialysis patient status to the employer. Unemployment was related to patients' low subjective health perception, an apparent failure to adjust to their disease, rather than to their objective physical condition, or to whether they were transplanted or on dialysis [126]. Among 42 transplanted patients aged 20–38 years in a Swedish long-term follow up study 54% were part-time or full time employed, 14% were unemployed (compared to 5.3% in the general population, $p = 0.059$) and 21% received education [104].

A positive change was a significant trend towards more highly educated occupations. Also the educational level had on average increased over time. Among the patients, 22.1% had completed a high vocational training or scientific degree, compared to 31.2% in the general Dutch population ($P > 0.05$) [126] 34.8% of the patients had an income equal to or above the national modal income of €2500 (about US$ 3200) gross per month, a significantly smaller proportion compared to the general population (61.1%) [126].

In a very recent French outcome study of 624 patients transplanted in childhood, fewer patients than expected had a high-level degree (Q3-year university level: 14.8 vs. 30.2% general population) and fewer women had a baccalaureate degree (49.2 vs. 76.5%), but these differences were less marked than in the Dutch study [129, 130]. Mean incomes were much lower than in the French population [130]. While the distribution of professional occupations was representative of the French society, more patients were unemployed (18.5% vs. 10.4%; $p < 0.01$). Independent factors for poor social outcome with respect to professional career were ESRD onset in infancy, the presence of co-morbidity and disabilities, a low educational level of the parents or patient, female gender and being (again) on dialysis at time of assessment [130]. Interestingly, patients less often had a permanent contract than the average French employee (66.8 vs. 81.8%) [130]. This might reflect the observed reluctance of employers against a long-term professional commitment with renal patients, as also observed in the LERIC study. The relatively good overall outcome of the French study might be slightly biased by the fact that more non-responders than responders had graft failure at time of investigation and that the cumulative duration on dialysis was also higher in the non-responder group [130].

Interestingly, nearly 50% of the French transplanted patients indicated to have suffered from discrimination, either at school (60.8%), from employers (27.8%) or work colleagues (19.9%) and even from friends (19.3%) [130]. In the Dutch cohort, 35.2% of patients lost their job between 2000 and 2010, in 32.3% because they were fired—sometimes as part of a 'reorganization' and in 45.2% for medical reasons. In 12.1%, employers indicated that the disease state of the patient influenced their achievements. About 21% of patients felt that their disease had a significant negative influence on their professional achievements and career [126].

Partnership and Independency

In the first evaluation of the LERIC study in 2000 patients showed to have significant difficulties in finding a partner. Of all 144 patients, 31.9% lived alone, 34% lived with a partner, and 49 (34%) still lived with their parents. The odds ratio of living with parents, as a measure of dependency, vs. living alone or with a partner was 3.3 (95% CI, 2.3–4.7) for LERIC patients compared with age-matched Dutch inhabitants [128]). The odds ratio of living with a partner was 0.3 (95% CI, 0.2–0.4) for LERIC patients compared with age-matched Dutch controls. These figures are in line with those of the French follow-up study of pediatric transplanted patients of the same age as the LERIC study at time of assessment (31.1% partnership, 35.7% living with parents) [130]. In 2010, the situation in the LERIC cohort was completely changed: 67.4% was married or lived with a partner and 28 (31.5%) had offspring compared to respectively 74.4% ($P > 0.05$) and 64.8%

($P < 0.05$) in the general population [126]. This delay in starting a relationship could reflect a genuine delay in sexual maturity or a late 'social maturity' as has been described in patients with a chronic illness [131]. Patients with disabilities and patients from Southern more than from Northern European countries tend to remain living with their parents [25, 101, 126, 129, 130]. In an older study, patients reported on average successful partnerships after pediatric kidney transplantation, but fewer than in the general population had children and 40% reported not to be sexually active [132]. Men appear to have problems finding a life partner more often than women [129, 132].

Conclusions

Although the prospects of end-stage kidney disease in children have improved over the last 30 years, the risk for premature death remains extremely high and adult life comes with considerable physical troubles. Cardiovascular disease has been recognized for more than a decade as most important threat in pediatric ESKD. Recent data indicate that adjusted therapeutic approaches and changes in lifestyle may be very effective in reducing the risk for premature cardiac death in this population. On the other hand, physicians should be aware for a potential increase in life-threatening infections and malignancies as a result of more potent immunosuppressive therapy after transplantation. Co-morbidities, most importantly motor disabilities have an important impact on social life in adulthood, especially with respect to finding a job and a life partner. Despite all physical discomfort, the mental health perception of adult patients with pediatric ESKD is remarkably good. Most patients are highly motivated to fully participate in society and to join the work force, well-adjusted to their situation.

In appreciation of the insights gained from long-term outcome research in patients with childhood-onset ESKD, the following should be the principles of modern pediatric renal replacement therapy in order to optimize late outcomes in these patients: Reduction of RRT time on dialysis to the absolute minimum; propagation of pre-emptive and living-related transplantation; personalization of immunosuppressive therapy; aggressive prevention of CKD bone-mineral disease in order to avoid later motor disabilities; timely start of intensified dialysis regimes (preferably frequent nocturnal home hemodialysis) in patients who are not eligible for transplantation; and finally, active and early stimulation of development towards independency.

A Patient's Story

"I am 41 years old, live with my boyfriend in this beautiful apartment. Currently I am in between 2 jobs, partly because, over the last few years, I often feel quite exhausted, despite the fact that I have a well-functioning renal graft at this moment.

I used to work as a radio reporter at the local radio of Utrecht and as a stand-up comedian. The radio work was very exciting, making documentaries and interviews that was actually my dream as a young girl. My father was photographer. As a Moluccan son of a military servant of the Dutch Indian (former "Dutch India"— currently Indonesia), he moved to Holland in the fifties where he met my mother. She worked as a nursery-class teacher and has Dutch as well as Russian-Jewish blood. Combativeness and urge for moving both run in the family.

I was 3 years old when I turned ill. I remember having a sore throat and getting medicines that didn't work. I felled extremely tired, but our house doctor was not impressed, everybody feels occasionally tired. It took months before they realized that something was wrong. Then, I was hospitalized for 3 months, where I had to stay in bed and live on an awful diet. Later, they transferred me to the Sophia Children's (university) Hospital of Rotterdam

where the doctors told me that my kidneys were very sick and would slowly get ruined. Gradually the troubles came. I blew up like a balloon for which I felt awfully ashamed. At school I was abused, children called me a stupid Chinese. Between my third and 11th year, I was more often in the hospital than at home. At a certain time, my mother quit her job to join me at the hospital as she always did, unlike my father.

I do not know why they have waited so long with starting dialysis, because in a way it came as a relief. I had to dialyze 3 times per week for 4–5 h per time. Fortunately, my doctors were wonderful. They gave me much attention and explained everything to me. After 6 months, I got my first transplantation. That kidney lasted 10 years. Once in a while I had to go to the hospital for treatment of a rejection. At age 22, when I had entered university to study Dutch language, I was back on dialysis. I had never noticed that my kidney function was deteriorating, which is a frightening experience. Even today I am still nervous about my creatinine when I have am at the out clinic.

Then I got problems with my shunt. I had to turn to peritoneal dialysis. Not a big deal, but very tiresome to combine with my study. Luckily, I was rid of my dialysis hang-over. I have never understood how people could drive home themselves after a hemo session. I was always exhausted, even though I nicely kept my diet and fluid restriction. I have always experienced the day of dialysis as a totally wasted day. Actually, you only lived 3 days per week. With PD, things were different; I was freer, changed bags on the train, airplane, airfield, whatever. At first, I felled embarrassed to do so, but very rapidly it became quite normal.

The hospital feels like my second home; it is all very familiar, the smell of the ward, the nurses, the smell of antiseptics, the idea that you can drop down and people will help you immediately. I always thought that if I would get a child, I would call her Sophia, after the name of the hospital. I never regretted to go to the hospital. There were always people that I knew very well and who always paid attention to you. That is a very particular thing. Up to your 18th, people always listen to you and treat you as a person and suddenly at the internal department you become a number and you have to do everything by yourself. Behave as a mature person, but not too clever or candid!

Later I have learned to speak freely about my disease but when I entered university, nobody knew about my illness, even not when I was back on dialysis. I dialyzed in the evening, so I always had to find an excuse for not joining my friends at the pub or the movie. At first this was not a big problem. Many people had a job in the evening, but then friends started asking questions about my scars, so I had to disclose my disease, which actually turned out to be a big relief.

During my school time at home, I always felt extremely tired after a hemo session—there was no EPO at that time -, yet my mother always forced me first to clean my room or do a little job, before she allowed me to lie down. Later I have learned to appreciate her behavior. Many parents treat their sick children as princesses, which I think is disastrous. Most of the times, you are spared anyway. I always got attention from everybody. People were always worried about me, always asked about me, even the most distant acquaintances of my parents. That was a big frustration for my sister. So, even although my parents try to avoid it, I got pampered by my environment. The first time, that I realized this was at work, where nobody new about my situation. I could be heavily upset when people did not understand why I was not willing to work over-time or demanded a day off. I always thought, ‘man, if you would know my situation ...’ Later, I sometimes used by illness when I thought that people were whining.

When I started working at the radio, I told nobody at work about my situation. I just wanted to work for a maximum of 20 h a week and I thought it was of no once business to know why. Unfortunately, I got problems with my knees which was due to bone necrosis caused by long time prednisone use. I had to be operated and to disclose my disease status. My direct colleagues were all shocked and people started to behave differently. You could feel that they thought, that lady will be out for a long time, so we probably have to look for someone else. And with all those medicines, this will of course happen more often. These things were never openly discussed, but suddenly things were taken out of my hands and my contract was not extended. I received a letter in which I was thanked for everything, they wished me good luck and appreciated how I had handled my disease. But I learned my lesson. Never disclose your disease if not absolutely necessary to your employer!

During my time at the university, I first realized how awful it is not to be able to comply with the activities of your friends. They really could feel offended when I turned down their invitations to go out at evening. As in my world, everybody knows that there are good and bad days and that if you feel good, you want to enjoy your day which always means that you have to pay for it the next day.

I think that I am less ambitious than my healthy peers, that I am more realistic and easier pleased with small things. I have no driving license, I am not married, I rent my house, have no children. I have probably consciously avoided all these obligations, yet the thought of never having children is most depressing. Currently my graft function is too bad, my doctor advised against it. I do not see it as a problem to have a child with my disease, even when I would have to start dialysis again.

Getting mad is my biggest fear. When I was 29 years old, I got psychotic. I had visions how my parents must had felt when I got sick and religious delusions. I thought that I had special medical gifts and I was convinced to be pregnant of a twin. I was isolated for 3 weeks in a psychiatric hospital, because I was intruding other patients with my special medical gifts. When I recovered I realized that it was all due to a strange chemical reaction inside my head and not due to some unprocessed emotions. I always thought that to be bull shit. In the seventies, I had to encounter a pediatric psychologist and had to talk about my disease, how I dealt with it. She noticed from my drawings that I drew too many clouds, clearly a sign that I could not express my anger. Me, not able to show anger, that was totally absurd! She showed me that I was observed from a one-way screen by at least 10 people. One of the most terrible things you could do to a child! Every time, I was at the hospital afterwards, I checked the room for one-way screens. Anyway, the point was that I had no anger, I just liked the doctors. I was never sad when I had to go to the hospital. I always stood immediately ready with my suitcase. I was eager to help the doctors and was never afraid of the blood punctures. I always stuck out my arm and told the doctor what I thought would be the best vein to attack with the needle. To some extent, it was nice to return, as it was part of my family, I knew all the nurses and doctors and there were funny things to do on the ward. The worst thing about it was the sadness of my parents.

The psychosis has changed my attitude. I previously thought that I could rationally solve all my problems, now I have learned to be more honest. It has taught me that nothing is certain in life. And then suddenly, I was asked my former employer at the radio if I would be interested to come back. The work at the radio really helped me to overcome my psychosis."

Drugs and Toxins

Drug Use, Dosing, and Toxicity in Kidney Disease

71

Matthias Schwab, Simon U. Jaeger, and Guido Filler

Abbreviations

ABC	ATP binding cassette
AIN	Acute interstitial nephritis
ATN	Acute tubular necrosis
BSA	Body surface area
CL	Clearance
GFR	Glomerular filtration rate
LSS	Limited sampling strategy
MATE1	Multidrug and toxin extrusion protein 1
MDR	Multidrug resistance
MRP	Multidrug resistance-associated proteins
OAT1	Organic anion transporter 1
OAT3	Organic anion transporter 3
OATs	Organic anion transporters and organic cation transporters
OCTs	Organic cation transporters
PAH	Paraminohippuric
SCr	Serum creatinine
SLC	Solute carrier

Introduction

The interplay between xenobiotics (including most drugs) and the living organism (in this context the patient) is traditionally viewed from two perspectives, and this chapter is organized along them:

- How does the organism (patient) affect the drug? *Pharmacokinetics* or *drug disposition* are the terms used to describe the body's handling of drugs. This topic includes drug dosing in kidney disease and it will be discussed in the section "Drug Handling by the Kidneys: Principles of Pharmacokinetics/Drug Disposition."
- How does the drug affect the organism (patient)? *Pharmacodynamics* describe the drug's effects, i.e., both desired (therapeutic) and unwanted (adverse) effects. This topic includes most aspects of nephrotoxicity, and it will be discussed in the section "Drug Injury to the Kidney: Nephrotoxicity."

Drug Handling by the Kidneys: Principles of Pharmacokinetics/ Drug Disposition

Generally, the effects of drugs depend on the concentration at the site of action. The concentration is a result of the way and speed at which the body deals with the drug.

Obviously, drug handling by the organism is time-dependent and quantitative. This is why numbers are useful to describe a drug's pharmacokinetic features and why equations provide the most appropriate tools to describe the underlying processes [1].

Drug handling by the organism includes processes that are usually encompassed by the LADME acronym—*l*iberation, *a*bsorption, *d*istribution, *m*etabolism, and *e*xcretion. While liberation, absorption and distribution are rarely critical for individual variation of pharmacokinetics, elimination is the central process that, with repeated administration of drugs at steady state, determines the relationship between dose (D) and concentration (C_{ss}).

Clearance is the best parameter to describe the body's overall capacity of eliminating a specific xenobiotic. Clearance is defined as the volume (usually plasma) that is cleared of the compound within a particular period of time. The usual units of expression are liter per hour (L/h) or milliliter per minute (ml/min).

$$\frac{D \cdot F}{\tau} = C^{ss} \cdot Cl \qquad (71.1)$$

- D = dose
- F = bioavailability
- τ = dose interval
- C_{ss} = concentration at steady state
- Cl = clearance

Clearance determines the maintenance dose rate required to achieve a target plasma concentration of a drug, and therefore its effect, at steady state.

As a consequence, dose reduction is required to avoid toxic concentrations (C^{ss}) in individuals and situations with impaired clearance (Eq. 71.1). For the selection of the dose that is appropriate for a specific patient, it is important to consider by which route the drug leaves the body and whether or not that particular organ works properly.

The bile and the urine provide aqueous environments for xenobiotics to leave the body from systemic circulation. Xenobiotics need to be water-soluble to take these routes. It is the biological purpose of metabolism, predominantly in the liver, by chemical alteration to facilitate water solubility of xenobiotics. While the majority of drugs first undergo hepatic metabolism, some other drugs, which are water-soluble by themselves, skip metabolism and are excreted unchanged via the bile or urine. Xenobiotics with a molecular weight of less than 400 to 500 g/mol undergo excretion via the kidneys [2–4]. Larger molecules prefer the biliary route for excretion.

While the liver is important for both metabolism and biliary excretion, the kidneys are essential for excretion and thus have a predominant role in disposing xenobiotics. Most drugs, before leaving the body by the kidney route, undergo metabolism. In fact, some drugs (e.g., allopurinol, morphine, meperidine) have active metabolites which are cleared by the kidney.

Kidney drug clearance is the net result of three processes, i.e., glomerular filtration, tubular secretion, and tubular reabsorption (Eq. 71.2).

$$\text{Renal clearance} = \text{glomerular filtration} + \text{tubular secretion} - \text{tubular reabsorption} \qquad (71.2)$$

Glomerular Filtration of Drugs

The extent of a drug's glomerular filtration depends heavily on its binding to plasma proteins. The proteins that are relevant for drug binding, i.e., albumin and α1-glycoprotein, do not cross the glomerular membrane unless the patient is nephrotic. Thus, the protein-bound component cannot be filtered, and only the free fraction (f_u, fraction unbound) undergoes glomerular filtration. Beyond this, functional integrity of the glomeruli, the drug's molecular size, and kidney plasma flow (which is a marker of nephron endowment) determine glomerular filtration.

Glomerular filtration rate (GFR) and Cl are equal for drugs that are not bound to proteins and do not undergo secretion and reabsorption (Eq. 71.2). Inulin is an example of an exogenous substance without plasma protein binding; assessment of its clearance is the gold standard of measuring GFR [5].

For drugs and drug metabolites primarily eliminated by glomerular filtration, drug elimination declines as kidney function decreases and drug will accumulate if the dosing regimen is not adjusted. There are not many drugs that are subject to exclusive glomerular filtration; most drugs are actually excreted through active tubular transport.

Tubular Secretion of Drugs

As outlined above, most drugs excreted by the kidneys are eliminated by active tubular transport. Organic anion transporters (OATs) and organic cation transporters (OCTs) have an important role in the excretion of drugs. They are members of the solute carrier (SLC) transporter family. The energy required for the transport is provided by a gradient of the drug to be transported or by a co-transported ion (e.g., sodium).

In addition to OATs and OCTs, ATP binding cassette (ABC) transporters are important. Hydrolysis of ATP provides the energy. ABC transporters that are important for the renal elimination of drugs are some multidrug resistance (MDR) proteins, i.e., MDR1 (ABC1), multidrug resistance-associated proteins (MRP), i.e., MRP2 (ABCC2), MRP4 (ABCC4) and MRP5 (ABCC5), and BCRP (ABCG2). Figure 71.1 gives an overview of the localization of SLC transporters in human proximal tubule epithelial cells.

The active kidney tubular secretion of drugs and drug metabolites by relatively nonspecific anionic and cationic transport systems in the proximal tubule contribute substantially to the amount of drug eliminated by the kidney. The tubular secretion of basic and acidic drug molecules involves three steps:

1. *Drug uptake from blood by transporters in the basolateral membrane*

   At least two systems perform the basolateral uptake of organic acids into the tubular cell, a Na^+-dependent (linked to Na^+/α--ketoglutarate co-transport and subsequent exchange of α-ketoglutarate with organic anions by OAT1) and a Na^+-independent anion transporter. The basolateral uptake of organic cations with primary, secondary, tertiary, or quaternary amine structure is mediated by OCTs and depends on membrane potential. OCT2 is responsible for the uptake of numerous drugs such as cimetidine, famotidine, ranitidine, metformin, and cisplatin.
2. *Drug diffusion through the cytosol*
3. *Drug transport into the lumen by transporters in the brush-border membrane*

   The efflux of organic acids is performed by OATs such as OAT4. Two organic cation antiporters, OCTN1/2 (organic cation transporter novel), organize the efflux of organic cations. OCTN2 physiologically mediates the reabsorption of L-carnitine and thus organizes the homeostasis of the kidney carnitine pool. MDR1, localized in the luminal membrane of the proximal tubule, is involved in the secretion of lipophilic basic and neutral drugs (e.g., anthracyclines, vinca alkaloids, taxanes, quinidine, and digoxin). Other ABC transporters, such as MRP2 and MRP4, transport glucuronides. Interactions by competition may occur with the simultaneous administration of drugs which are substrates of these transporters.

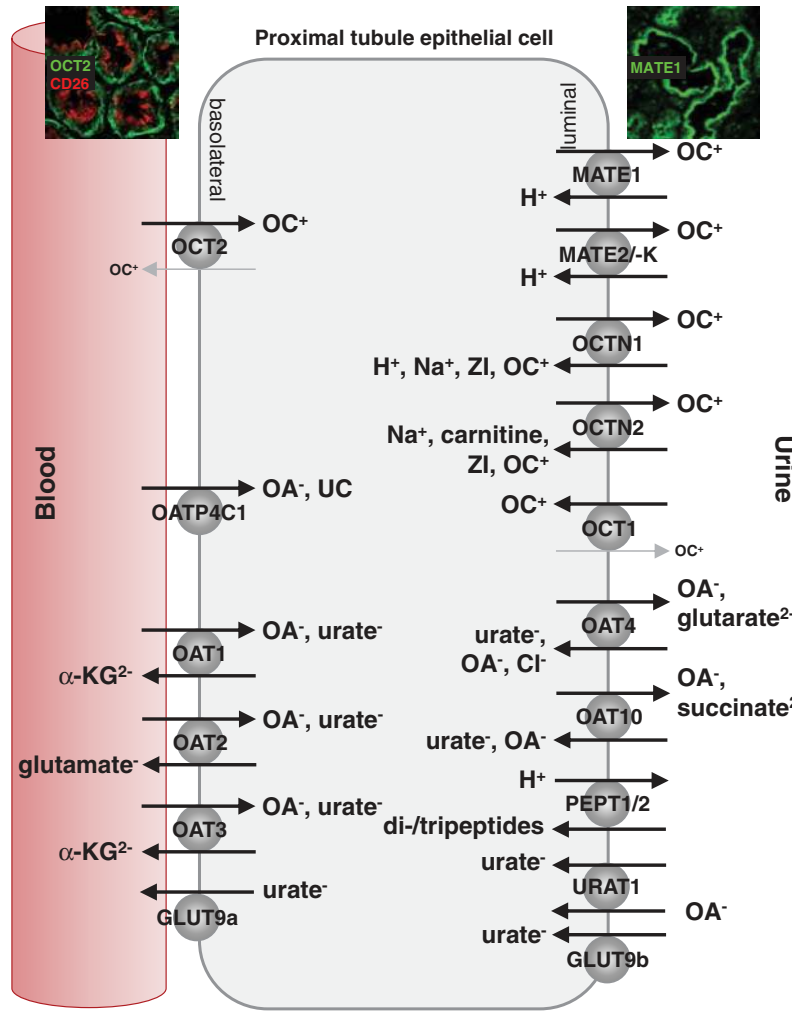

Fig. 71.1 Localization of solute carrier transporters in human proximal tubular epithelial cells implicated in drug-related nephrotoxicity. Representative immunofluorescence pictures show localization of organic cation transporter 2 in the basolateral membrane and *MATE1* in the luminal membrane of proximal tubule epithelial cells in cryosections from human kidney. *Cl* − chloride, *MATE1* multidrug and toxin extrusion proteins 1, *OA* − organic anion, *OC* + organic cation, *UC* uncharged compound, *ZI* zwitterion, *α-KG2* α-ketoglutarate. (Modified from Fisel et al. [6])

Thus, cimetidine, by inhibiting the OCT2-mediated uptake of cisplatin into tubular cells, reduces its nephrotoxicity. This transport system is an elimination pathway for many drugs such as penicillins. For instance, probenecid competitively inhibits the tubular secretion of organic anions such as penicillins. In consequence, plasma levels of weak organic acids such as penicillins will increase.

Tubular Reabsorption of Drugs

As the filtered urine becomes increasingly concentrated in the proximal tubule, a concentration gradient towards the intercellular space and vascular lumen develops. As a result, lipophilic compounds are reabsorbed to a larger degree.

Reabsorption is the passive diffusion of nonionized (non-charged) drug from the filtrate into the kidney tubular cell. Reabsorption of acids and bases depends on their pK_a and urinary pH. Basic urine (e.g., urine pH > 7.5) favors the ionized form of acidic drugs and limits their reabsorption, whereas reabsorption of basic drugs is enhanced in basic urine because the nonionized form of the drug is favored. Alteration of urinary pH thus affects the renal clearance of acidic and basic drugs because predominance of ionized drug reduces their tubular reabsorption. This intervention, together with increasing urinary flow ("forced diuresis"), has

been used in the past to treat intoxications. With hemodialysis and hemofiltration, safer and more effective methods of elimination are available now.

Kidney Failure Induced Alterations in Drug Disposition

Kidney dysfunction affects the disposition of renally cleared drugs. The clinical significance of decreased kidney function on a drug dosing regimen is a function of:

- the therapeutic index (TI), i.e. the amount of a therapeutic agent that causes the therapeutic effect relative to the amount that causes toxicity. The TI varies widely among drugs. Drugs with a high TI such as penicillins have a wide therapeutic window, have less side effects and are considered to be less toxic. Drugs with a low therapeutic index such as aminoglycosides or vancomycin require therapeutic drug monitoring to achieve plasma concentrations in the therapeutic window and limit toxicity and adverse effects of the drug.
- the percentage of total drug elimination that is due to renal clearance. E.g., the angiotensin converting enzyme inhibitor fosinopril is subject to both kidney and liver clearance and will not accumulate in kidney failure, whereas Enalapril is exclusively cleared by the kidneys and will accumulate with worsening kidney function [7].
- the degree of kidney failure.

The most difficult task is obtaining an accurate assessment of kidney function, e.g., GFR [5]. The GFR is estimated by measuring the rate at which the kidney removes a substance from the blood (e.g., kidney clearance). Endogenous compounds (e.g., creatinine, cystatin C) [5, 8], exogenous compounds that are specifically administered to measure the GFR (e.g., inulin), or compounds primarily eliminated by glomerular filtration that are administered as part of clinical care (e.g., gentamicin or vancomycin) are used for measurement.

Age-Related Development of Kidney Function

The developmental increase in GFR involves active nephrogenesis, a process that begins at 9 weeks and is complete by 36 weeks of gestation, followed by postnatal changes in blood flow, both to the kidney and inside the kidney [9, 10] (Fig. 71.2). In the postnatal period, the mean arterial pressure increases, consequently altering the glomerular hydraulic pressure and increasing the GFR. When GFR is indexed to body surface area, GFR increases rapidly after birth in term neonates from 10 to 15 ml/min/1.73 m^2 in the first days of life to values of 90–110 ml/min/1.73 m^2 at the age of 12–18 months [2, 3]. In preterm infants GFR rises more slowly and reaches adult values only by 2 years of age [11, 12].

Similarly, to the above-mentioned factors, tubular secretory pathways are immature at birth and gain full capacity during the first year of life [14]. In preterm neonates sodium excretion for example is inversely correlated to gestational age, mostly due to tubular immaturity [15]. Also, loss of bicarbonate and glucose may necessitate supplementation in preterm neonates. Other tubular functions are impaired such as organic cation transporters (OAT); these have been reported to mature functionally over the first weeks of life and reach adult levels around 7–8 months post-partum. For example, para-amino hippurate (PAH), a substrate of OAT1, is used as a marker for blood flow as the tubular secretion is approximately 100% at first pass through the nephron. PAH is therefore used to test for drug-induced inhibition of OAT1 that would lead to a reduced uptake of PAH. The expression of the luminal drug transporter P-glycoprotein changes significantly during maturation, as illustrated by the threefold difference in digoxin dosing between children and adults. Of note, the inter-individual variation in tubular maturation seems to be much greater than the variations seen in GFR maturation. As these tubular transport mechanisms play an important role in drug excretion, preterm birth can be expected to have an impact on kidney drug handling, although different mechanisms are impor-

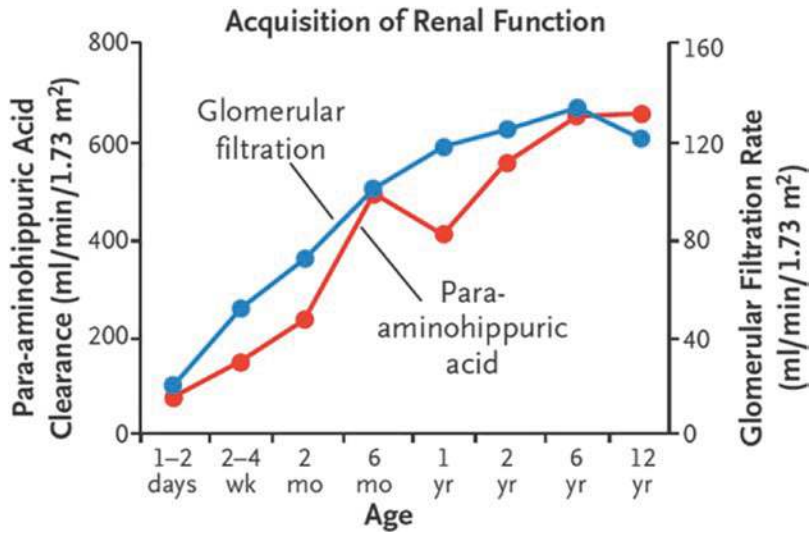

Fig. 71.2 Summary of the effect of postnatal development on the processes of active tubular secretion—represented by the clearance of para-aminohippuric acid and the glomerular filtration rate, both of which approximate adult activity by 6–12 months of age. (From Kearns et al. [13])

tant for different drugs and the actual impact may be difficult to predict.

Dialysis

The impact of dialysis on drug disposition is determined largely by the extent of drug removal by the dialysis procedure. During dialysis, drug clearance is a composite of ongoing drug removal by kidney, hepatic, and other intrinsic clearance pathways and the additional clearance provided by dialysis.

The physicochemical properties of a drug such as molecular size, protein binding, and volume of distribution largely determine its dialyzability [16, 17]. Additional factors specific to the dialysis prescription such as the type of dialyzer and blood/dialysate flow rates can also impact drug removal.

In general, drug removal is considered clinically significant when >25% of the administered dose is removed by dialysis. Only a drug present within the systemic circulation in the unbound form is available for removal by dialysis. Uremic solutes that accumulate in CKD are known to increase the free fraction of some drugs, making them more easily dialyzable.

High-flux dialyzers can remove drugs with molecular weights of up to 40,000 Da. Failure to recognize the extent of dialytic drug removal and provide supplemental dosing is needed can result in underdosing and therapeutic compromise. For instance, vancomycin (~1450 Da) is cleared minimally with conventional low-flux dialysis but is extensively removed by high-flux dialyzers (dialytic clearance between 45–131 ml/min with high-flux polysulfone dialysis membranes) [18, 19]. Other drugs that exhibit the same characteristic include carbamazepine, cisplatin, daptomycin, fluorouracil, ranitidine, and valproic acid.

Drugs cannot be directly removed from tissue stores but must be redistributed from the tissue sites into the vascular space to be available for elimination by any dialysis procedure. Drugs that have a small V_d (e.g. <0.7 L/kg) are generally restricted to the blood compartment and therefore more accessible for removal during dialysis. In contrast, drugs with a large V_d are distributed into the tissues and are generally minimally impacted by dialysis. Although drug usually moves from the blood compartment to dialysis fluid, drug can also be absorbed from the dialysis fluid into the blood compartment when the dialysis fluid drug concentration exceeds the serum concentration. The bidirectional movement of drugs is exploited for the antibiotic treatment of peritonitis in patients on peritoneal dialysis where therapeutic blood concentrations can be achieved by intraperitoneal administration.

Drugs with a large V_d are also more susceptible to the rebound effect following dialysis.

Examples of drugs with a substantial rebound effect include gentamicin and vancomycin. Gentamicin concentrations rebound by up to 25% several hours following the completion of a dialysis session [20]. Vancomycin exhibits a similar rebound as plasma concentrations decrease by 38% immediately following dialysis but are only 16% lower than the pre-dialysis concentration 5 h post-dialysis [21].

The efficiency of drug removal is greatest for hemodialysis, followed by continuous kidney replacement therapies (CKRTs), and least by peritoneal dialysis. Although drug removal by CKRT and peritoneal dialysis is less efficient than hemodialysis, the total drug removal may be equivalent because CKRT and peritoneal dialysis are performed for a longer period of time.

Guidelines for Drug Dosing in Children with Kidney Failure

The optimal drug prescription for a child with kidney failure considers the multiple factors impacting drug disposition and response and is best achieved by using an individualized approach. Although drug lists and dosing tables can be helpful to identify those drugs that require attention in children with kidney failure (Table 71.1), such guidelines fall short when it comes to providing dosing recommendations because optimal therapy must be individualized according to the degree of kidney failure, concurrent medications, and developmental factors—all of which can impact the disposition of a drug. Table 71.1 should be interpreted with caution since systematic clinical data from trials in children of different age groups and across wide GFR ranges are still limited.

Thus, the provision of safe and effective therapy in children with kidney failure is best accomplished using an individualized systematic approach (Fig. 71.3). The design of a successful therapeutic regimen begins with an estimate of the child's residual kidney function and an estimate of the relative contribution of kidney elimination to the total drug elimination obtained from the literature. Reference books such as the *Pediatric Drug Handbook*, *Physicians' Desk Reference*, and *Micromedex* are excellent sources for information on drug disposition—and most references are available as electronic documents that can be used on hand-held devices for point-of-care therapeutic decisions.

Although children receiving dialysis by definition have very poor kidney function, it is inappropriate to assume that there is no kidney elimination because many children maintain a significant amount of residual kidney function. Failure to account for the continued kidney elimination of drug may result in insufficient drug dosing and therapeutic failure. If one assumes that drug protein binding, distribution, and metabolism are not altered to a clinically significant degree in kidney failure (an assumption likely true for most drugs), a dosing adjustment factor Q can be estimated using the following equation (Eq. 71.3):

$$Q = 1 - \left[\text{fraction renal elimination} \cdot \left(1 - \frac{\text{child's } Cl_{cr}}{\text{normal } Cl_{cr}} \right) \right] \tag{71.3}$$

- Cl_{cr} = creatinine clearance [ml/min/1.73 m^2]

The appropriate dose amount or dosing interval for a child with reduced kidney function is generated by applying the dosing adjustment factor Q to either the normal dose amount (Q × normal dose = adjusted dose) or normal dosing interval (normal dosing interval + Q = adjusted dosing interval). The dosage adjustment factor estimates the change that occurs in elimination associated with kidney failure but does not account for any additional clearance by dialysis. If appropriate, supplemental doses may be required to replace the dialysis-related drug losses.

Whether a change is made in the dose amount or dosing interval depends on the therapeutic goal

Table 71.1 Drug dosing guidelines for common therapeutic agents according to Filler et al. [22]

Drugs	Normal DOSE/day Not to exceed adult dose	Dose at GFR 50–30	Dose at GFR 30–10	Dose at GFR < 10	MW	Plasma protein binding	%eliminated by kidney	Elimination t ½ with normal GFR

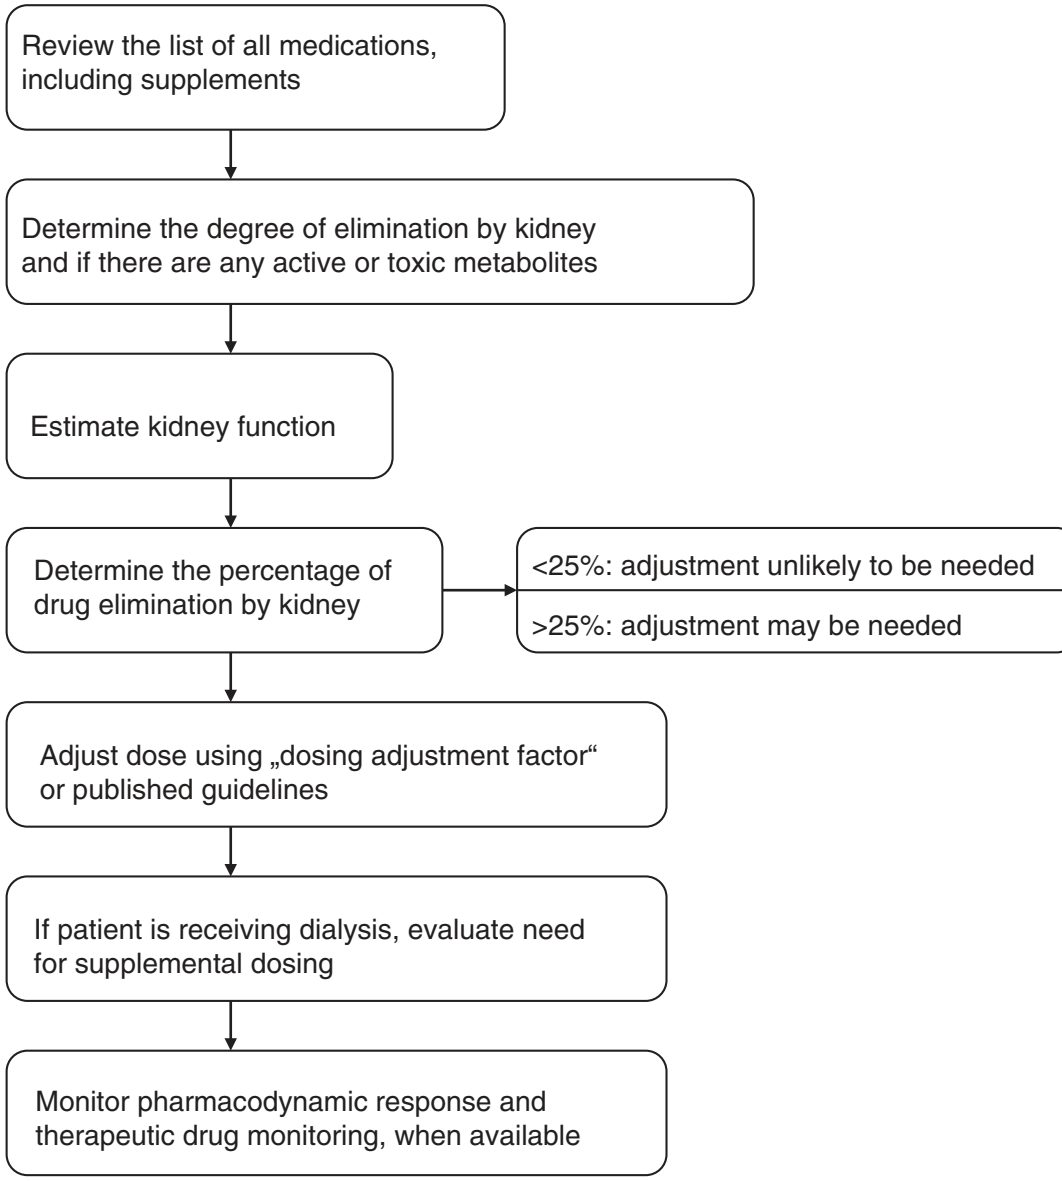

Fig. 71.3 Guidelines for drug dosing in children with kidney failure

and relationships between drug concentrations and clinical response and toxicity. In general, increasing the dosing interval will increase the variation between peak and trough blood concentration and would be most appropriate for drugs whose effects are based on achieving a certain peak drug level (e.g., aminoglycosides). In contrast, a decrease in variations between peak and trough blood concentration will be observed when a normal dosing interval is maintained but the dose amount is decreased. This dosing adjustment would be most appropriate for drugs that should be maintained at a relatively stable blood concentration, such as cephalosporins or blood pressure medications.

Once the prescribed drug dosing schedule has been adjusted for kidney failure, a supplemental dose or dosing adjustment may be required for children receiving dialysis when >25% of a drug is removed during the dialysis procedure.

Supplemental dosing is given to replace the amount of drug removed by dialysis and may be achieved as a partial or full dose administered after hemodialysis, or an increase in the dosing amount or frequency in children receiving peritoneal dialysis or CRRT. When possible, routine maintenance drugs should be provided after hemodialysis. Guidelines for drug dosing during dialysis are available in selected references [16].

The determinants of drug disposition and action in children with kidney failure and on dialysis are frequently altered such that changes in the dosing regimens are necessary to avoid toxicity or inadequate treatment. In view of the many factors capable of altering both the disposition and action of a given drug, it is important to individualize drug therapy for the known alterations associated with age, kidney failure, and dialysis.

Therapeutic Drug Monitoring

Humans are not equal, and it is increasingly appreciated that this inequality pertains to pharmacokinetics also. Much of what carries the label "personalized medicine" is related to pharmacokinetics.

Target concentration strategy is a concept where pharmacokinetics plays a critical role. This strategy is useful as an adjunct in initiating and monitoring drug therapy when certain criteria are met. Most important is a close concentration-response relationship, which means the plasma concentration of a drug must correlate quantitatively with the intensity or probability of therapeutic or toxic effects across the patient population. The strategy becomes particularly attractive when a therapeutic endpoint is difficult to quantify, i.e., with the non-occurrence of epileptic seizures. The strategy is ideal when the aim is to maintain a therapeutic effect for which a systemic exposure within a given range is necessary. Drug administration in a constant-rate input or multiple-dose regimens is possible when the potential for organ toxicity or rejection may be predicted from the trough or peak concentration.

Multiple dosing regimens are usually based on the total body clearance such that the dosing rate is taken as the product of the clearance and the desired steady-state plasma concentration of the drug. For drugs eliminated by the kidneys, it is widely accepted that the kidney clearance is proportional to GFR [23].

For drugs with a narrow therapeutic index and poor correlations of trough levels with efficacy and adverse effects, limited sampling strategy (LSS) models have been developed to estimate the area under the concentration time curve. Ting et al. published different LSS approaches [24]. Many LSS studies utilize blood sampling within the first 4 h (C2 and C4) or the first 8 h (C1, C4, and C8) postdose with multiple regression analysis.

Drug Injury to the Kidney: Nephrotoxicity

Kidney dysfunction and toxicity secondary to medications are common, but the real incidence of drug-induced nephrotoxicity is difficult to determine. Approximately 18% of acute tubular necrosis (ATN) or acute interstitial nephritis (AIN) cases can be attributed to nephrotoxic medication. The incidence of nephrotoxic injury due to antibiotics such as aminoglycosides is even higher, up to 36% [25].

Fortunately, most episodes of drug-induced kidney injury, if diagnosed and treated early, are reversible, with *a restitution ad integrum* after cessation of the causing medication. Chronic kidney damage may occur with prolonged exposure to drugs such as analgesics and calcineurin inhibitors and will lead to chronic tubulointerstitial inflammation, papillary necrosis or prolonged proteinuria. A close follow-up is necessary to avoid kidney failure [26].

Nephrotoxic drugs require therapeutic drug monitoring (TDM) to maintain a balance between efficacy and toxicity. This is particularly important if a drug has a narrow target range, significant pharmacokinetic variability, a reasonable relationship between plasma concentration and clinical effects, an established therapeutic win-

dow, and availability of a cost-effective assay. Most places offer TDM for aminoglycosides (acute tubular necrosis), vancomycin (acute interstitial nephritis), calcineurin inhibitors (cyclosporine: acute tubular necrosis, chronic interstitial nephritis, thrombotic microangiopathy; tacrolimus: acute tubular necrosis), antifungal drugs (amphotericine: acute tubular necrosis, distal tubular renal acidosis), antiepileptic drugs (mostly not nephrotoxic), lithium (chronic interstitial nephritis, glomerulonephritis, rhabdomyolysis), and digoxin (not nephrotoxic) [27]. For some drugs like acyclovir (acute interstitial nephritis, crystal nephropathy) [28] or ganciclovir (crystal nephropathy), which should have TDM, this is not widely available. It is important not note that toxicity may be more related to the area under the time concentration curve (AUC) than the pre-dose trough level. For instance, switching from BID dosing of cyclosporine to TID dosing may substantially reduce the AUC [29]. Some other drugs may not be increasing the active drug, but rather metabolites, which then account for toxicity. An example is mycophenolic assay, where the main metabolite mycophenolic acid glucuronide (MPAG) accumulates with decreased kidney function, rendering it intolerable with low eGFR [30].

An increasing number of observational studies report on early drug-related nephrotoxicity in humans. The investigations concern nephrotoxicity from antibiotics (particularly aminoglycosides), angiotensin-converting enzyme (ACE) inhibitors, non-steroidal anti-inflammatory drugs and antifungal agents [31]. Also, there is growing interest in the long-term effects of drugs on the neonatal kidney. A recent up-to-date summary of nephrotoxic drugs with particular impact on children highlighted additional underlying pathophysiological mechanisms [32]. Figure 71.4 summarises the clinically relevant information. In the following paragraph we describe selected mechanisms of drug nephrotoxiciy and include some examples of nephrotoxic drugs.

Regarding toxic effects on nephrogenesis drugs administered to pregnant women and to neonates born preterm may influence kidney development. Nephrogenesis ceases at approximately 36 weeks gestation in humans so that most toxic effects on nephrogenesis may be expected in treatment with drugs during pregnancy. In premature-born neonates nephrogenesis has not completed at time of birth. Many of them will be treated with drugs in the vulnerable phase of kidney development. An adequately functioning RAS is essential for kidney development. The use of angiotensin converting enzyme inhibitors (ACEIs) in pregnancy can therefore negatively influence nephrogenesis and lead to neonatal kidney failure (ACEI fetopathy). Mutations in genes coding for renin, ACE and AT1 cause autosomal recessive kidney tubular dysgenesis and fetal hypotension [33]. Both inherited and acquired defects of the RAS can alter kidney hemodynamics with deleterious effects on kidney development.

Aminoglycosides are well-known for their nephrotoxic effect on the developing fetal kidney. These drugs will result in tubular alterations and low nephron number. Offsprings of pregnant rats treated with aminoglycoside are born with lower nephron numbers and subsequently develop glomerulosclerosis with aging. Unfortunately these drugs are still commonly used as first-line treatment of infections in premature neonates although alternative treatment options with less adverse effects on nephrogenesis are available, such as cephalosporins and carbapenems [34, 35].

Pathophysiologic Mechanisms of Drug Nephrotoxicity

Direct Tubular Cell Toxicity

This damage is at least in part dose-dependent, is generally of surreptitious onset (with symptoms often undetected in the early stages), and is characterized by acute tubular necrosis (with loss of a proportion of kidney proximal tubular cells). This mode of toxicity is typical for the aminoglycosides, where it has been reported in 20–35% of exposed children [25], and for antivirals such as aciclovir, foscarnet, cidofovir, adenovir and tenofovir [36]. Cisplatin induced nephrotoxicity is

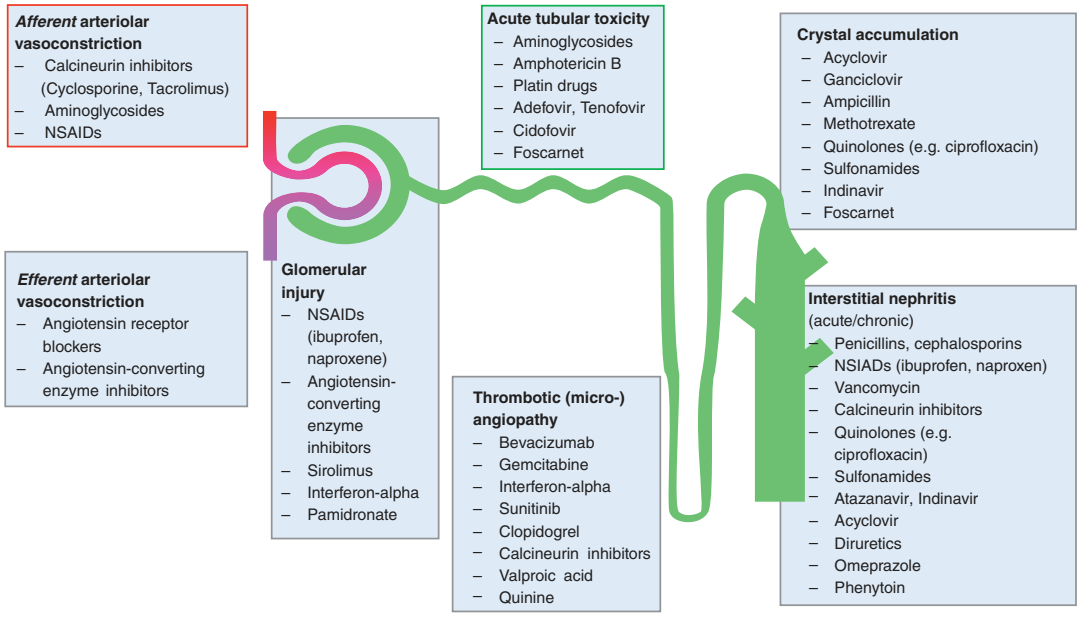

Fig. 71.4 Nephrotoxic drugs in children with related pathophysiological mechanisms. Modified from Tjon and Teoh [32]

frequent (up to 80%) [37] and linked to the accumulation of toxic metabolites with subsequent inflammation and cellular damage. The cyclophosphamide analogon ifosfamide causes proximal tubular dysfunction (Fanconi syndrome) in up to 30% of exposed children and the toxic damage is conferred by the metabolite chloroacetaldehyde. Other drugs associated with this type of damage are amphotericin B, calcineurin inhibitors, methotrexate, pamidronate, pentamidine, and cocaine.

Generally, transient enzymuria and a Fanconi-like syndrome are early signs of proximal tubular damage. These often remain undetected but may be followed by urine sediment disorders (granular, hyaline, and cellular casts) and kidney failure.

Acute Interstitial Nephritis and Immunologically Mediated Kidney Toxicity

Immunologic kidney toxicity is mediated by inflammation of the interstitium and tubules. It occurs on an allergic basis in an idiosyncratic, dose-independent manner with a predominance of lymphocytes, monocytes, eosinophils and plasma cells within the interstitium, and active urinary sediment [38]. Clinical and laboratory signs such as fever, rash and eosinophiluria are rare (<10%) and therefore, if indicated, the diagnosis can be confirmed with certainty only by kidney biopsy. Interstitial nephrotoxicity is typical of antibiotics such as beta-lactams, quinolones, rifampin, macrolides, sulfonamides, vancomycin, most NSAIDs, diuretics (thiazides, loop diuretics, and triamterene), anticonvulsants (phenytoin), cimetidine and ranitidine, allopurinol, and antivirals (acyclovir, indinavir, atazanavir), etc.

If acute interstitial nephritis is diagnosed, potential nephrotoxic drugs should be discontinued immediately.

Chronic interstitial nephritis is more complex and associated with drugs such as calcineurin inhibitors (cyclosporin A, tacrolimus) and carmustine. In contrast to acute interstitial nephritis, the prognosis of chronic interstitial nephritis is rather poor. Data from post-transplant patients treated with cyclosporine indicate a high frequency of cyclosporine-induced interstitial nephrotoxicity resulting in chronic rejection [39].

Arteriolar Vasoconstriction

Decreased kidney blood flow and GFR due to dose-dependent reversible vasoconstriction affecting primarily the afferent but also the efferent arterioles (prerenal dysfunction with intact tubular function) is the main pathophysiogical mechanism of acute kidney toxicity typical for calcineurin inhibitors, NSAIDs, angiotensin-converting enzyme (ACE) inhibitors, and angiotensin receptor blockers. The synthesis of strong vasoconstrictors such as angotensin II, leukotrienes and endothelin is stimulated and endothelial nitric oxide concentrations are reduced.

Prostaglandins contribute to the regulation of kidney perfusion and GFR—with their vasodilating properties opposing the action of vasoconstrictive substances. Thus, subjects suffering from conditions associated with high levels of vasoconstrictive substances (such as hypovolemia, cardiac failure, sepsis, and hypertension) may develop kidney damage when treated with NSAIDs which induce a reduction of prostaglandin synthesis.

Kidney dysfunction associated with antihypertensive therapy is a result of excessive lowering of blood pressure. Since kidney blood flow and kidney perfusion are maintained during treatment with ACE inhibitors despite the adverse effects on glomerular function, kidney function readily returns to pretreatment levels when the drug is discontinued.

Crystal Accumulation

The pH-dependent precipitation of insoluble crystals in the distal tubular lumen is a nephrotoxic mechanism occurring mostly with antiviral drugs (e.g. acyclovir, ganciclovir), sulphonamides, methotrexate, indinavir, etc. Crystalluria after fluoroquinolone administration is rare, and may occur in the condition of dehydration. Among the factors that increase the likelihood of kidney crystal deposition, severe volume contraction is the most important. Uric acid and calcium phosphate crystals contribute to tumor lysis associated nephrotoxicity after chemotherapy for malignancies.

Proteinuric Glomerular Dysfunction

Some drugs can cause nephrotic range proteinuria due to podocyte toxicity. These include NSAIDs, captopril, interferon-alpha, pamidronate, MTOR inhibitors (sirolimus, everolimus), tiopronin, etc. Discontinuation of the drug usually leads to resolution of proteinuria, although irreversible lesions have also been reported.

Vascular Injury/Thrombotic Microangiopathy

Thrombotic microangiopathy has been associated with a wide range of drugs, including cyclosporin A, tacrolimus, gemcitabine, clopidogrel, sunitib, valproic acid, bevacizumab, etc. The main pathologic finding is presence of hyaline thrombi in the microvessels of many organs, including glomerular thrombosis. The manifestations can include fever, hemolytic anemia, thrombocytopenic purpura, kidney dysfunction, central nervous system involvement (thrombotic thrombocytopenic purpura, TTP), and predominance of kidney failure with anemia and thrombocytopenia (hemolytic uremic syndrome).

Alterations of Fluids and Electrolytes

Examples of alteration of fluids and electrolytes are excess of sodium and water removal; metabolic alkalosis and hypokalemia induced by excessive use of diuretics; and hyperkalemia and metabolic acidosis secondary to pharmacologic hyporeninemic hypoaldosteronism as induced by NSAID and tacrolimus.

Other Mechanisms

Additional specific mechanisms of drug nephrotoxicity include osmotic nephrosis (related mainly to mannitol and immunoglobulins) and rhabdomyolysis (e.g. codein, corticosteroids). Osmotic nephrosis is characterized by vacuoliza-

tion and swelling of renal proximal tubular cells as consequence of glucose and sucrose reabsorption by pinocytosis. Thrombolytic agents often disrupt or dissolve protective thrombi covering ulcerated plaques, thereby releasing cholesterol plaques into the circulation leading to occlusion of small-diameter arteries of the kidney (i.e., arcuate and interlobular arteries, terminal arterioles and glomerular capillaries). Cholesterol embolization with anticoagulants, such as warfarin and heparin, or thrombolytic agents (streptokinase and tissue-plasminogen activator) is sometimes observed weeks or months after initiation of therapy.

Ten Rules for Prevention of Drug-Induced Kidney Damage

- **Rule 1**: **Alternatives**. *Do not use nephrotoxic drugs if alternatives are available*.

- The simplest way to prevent drug-induced nephrotoxicity is to avoid the use of these drugs. Knowledge of drug safety is a useful element for preventing iatrogenic dysfunction. Lack of nephrotoxicity is one of the parameters to be considered in the choice of drug therapy. Before prescribing a potentially nephrotoxic drug, the risk-to-benefit ratio and the availability of alternative drugs should be considered.

- Nephrotoxic drugs should be avoided whenever possible, especially in high-risk situations. Critically ill children are not ideal candidates for potentially nephrotoxic drug treatment, although pediatricians may not always have valid alternative choices. E.g., aminoglycosides have two unique pharmacodynamic properties: their postantibiotic effect and concentration-dependent killing. However, aztreonam is a reasonable alternative to aminoglycoside therapy in children and low-birth-weight infants with gram-negative infections at risk of nephrotoxicity.
- **Rule 2: High-Risk Patients**. *Do not use nephrotoxic drugs in high-risk patients.*
- Chronic kidney failure and a preexisting kidney injury are major risk factors for most nephrotoxins. Diabetes mellitus increases vulnerability to aminoglycosides, nonsteroidal anti-inflammatory drugs (NSAIDs), and ACE inhibitors. Sepsis itself is a major risk for nephrotoxicity. Significant volume depletion is a risk factor for NSAID-induced nephrotoxicity.
- Volume management is essential for prevention. Generally, pretreatment hydration can reduce the nephrotoxic potential of many drugs, including amphotericin B, aminoglycosides, NSAIDs, cisplatin, and indinavir. A "diuretic holiday" (a period off diuretics) is suggested before starting an ACE inhibitor. Modifiable risk factors should be corrected. In many cases, patients are routinely prehydrated before the administration of a nephrotoxic drug. In such cases, it is mandatory to accurately monitor urine output and avoid intravascular volume overload.
- Novel biomarkers such as kidney injury molecule-1 (KIM-1) may be helpful to early identify children with aminoglycoside-induced tubular toxicity (see Chap. 51) [25].
- **Rule 3: Choice of Compound**. *Choose the least nephrotoxic compound.*
- For the kidney, netilmicin is better than gentamicin, teicoplanin is better than vancomycin, and lipid formulations of amphotericin B are better than conventional formulations. Ceftazidime seems the safest cephalosporin for the kidney. Analgesics other than NSAIDs are preferred in children with compromised hemodynamic status or volume depletion.
- **Rule 4: Dosage and Monitoring**. *Use correct dosage and therapeutic drug monitoring, if required*.
- The correct drug dosage should be prescribed. For many years, it has been debated whether TDM of aminoglycosides and vancomycin will decrease toxicity—especially at the kidney level. Probably it depends on the patient population, with high-risk patients benefiting more. However, a tailored TDM is generally associated with lower nephrotoxicity.
- **Rule 5**: **Concomitance**. *Do not use concomitant nephrotoxic drugs*.

- Specific combinations of drugs (such as cephalosporins and aminoglycosides, cephalosporins and acyclovir, and vancomycin and aminoglycosides) may result in synergistic nephrotoxicity. The combination aminoglycoside-vancomycin is believed to increase the nephrotoxic risk up to sevenfold.
- **Rule 6**: **Duration**. *Limit the duration of treatment*.
- Prolonged duration of treatment has been associated with increased aminoglycoside and amphotericin B nephrotoxicity. In adult studies, aminoglycoside-related nephrotoxicity may reach approximately 55% of cases according to the duration of the treatment (high risk with duration >10 days). Moreover, repeated courses of aminoglycoside therapy a few months apart can enhance nephrotoxicity.
- **Rule 7**: **Diagnosis**: *Seek to diagnose kidney damage early*.
- Kidney function (and particularly the GFR) should be frequently monitored during the administration of a potentially nephrotoxic drug. Cystatin C, a marker of glomerular function in the "creatinine blind range" (GFR 60 to 90 ml/min/1,73m^2), and urinary biomarkers of nephrotoxicity (microglobulins, enzymes, and growth factors) can be used for early noninvasive identification of kidney damage occurring in the course of drug therapy. Moreover, they are helpful in establishing its extent and monitoring its time course.
- **Rule 8**: **Damage**. *Stop drug administration if damage occurs*.
- In many cases, the most important first step in treating drug-induced nephropathy is to stop the offending drug. This is true in many cases, such as for acute interstitial nephritis, nephritic syndrome, drugs associated with TTP-HUS, and obstructive nephropathy.
- **Rule 9**: **Pediatric Drugs**. *Use caution when using new drugs in pediatrics*.
- It is important to be cautious in administering drugs to children outside the terms indicated in the product license (off-label use as regards the dose, age group, route of administration, different indication) or in an unlicensed manner (formulations modified, extemporaneous preparations, imported medicines, chemicals used as drugs).
- The lack of approval for pediatric use does not imply a drug is contraindicated or disapproved. It simply means that insufficient data are available to grant approval status and the risks/benefits balance (including nephrotoxicity) cannot be evaluated.
- This suggestion should be extended to obstetricians because increasing reports of kidney damage in newborns are related to drugs administered to the mother.
- **Rule 10**: **Kidney Failure Dosing**. *Modify dose and/or interval dosing in kidney failure*.

- Normal kidney function is important for the excretion and metabolism of many drugs. Kidney failure alters drug clearance and requires modification in dosage regimens to optimize therapeutic outcome and minimize the risk of toxicity. This is a key point for prevention and is recommended as an essential component of any computer-based prescription system to minimize medical errors and adverse drug events, including drug-induced nephrotoxicity.

Acknowledgement For this current chapter, parts of two chapters from the edition 2014 (Chap. 64 on Drug Use and Dosage in Kidney Failure by Dr. Douglas L. Blowey and Chap. 65 on Causes and Manifestation of Nephrotoxicity by Dr. Vassilios Fanos and Dr. Laura Cuzzolin) have been used.

Introduction

Complementary therapies have been described as "health care approaches that are not typically part of conventional medical care or that may have origins outside of usual Western practice" [1]. Thus complementary therapies are a term that includes a diverse range of products and practices (e.g., natural health products [NHPs], massage therapy, acupuncture, etc.) used in the prevention or treatment of illness or the promotion of health and well-being.

The distinction between conventional medicine and complementary therapies is not always well defined or fixed [1]. As complementary therapies do not have a well-demarcated border, the inclusion or exclusion of dietary modifications, vitamins, and prayer/spirituality as complementary therapies remains unresolved [2]. This chapter focuses on evidence regarding NHPs, traditional Chinese medicine (TCM), and massage therapy. First, we review core relevant concepts, including definitions, epidemiology of complementary therapy use (including reasons for use and lack of disclosure), NHP quality and regulation, and legal and ethical issues related to the use of complementary therapies.

Natural Health Products, TCM, and Massage Therapy

In Canada, NHPs are defined in the *Natural Health Products Regulations* as vitamins and minerals, herbal medicines, homeopathic remedies, traditional medicines such as TCMs, probiotics, and other products like amino acids and essential fatty acids [3]. In the United States (US), these products are more commonly referred to as "dietary supplements" [4].

TCM is an ancient medical system that includes acupressure, acupuncture, breathing exercises, NHPs, moxibustion, oriental massage, qi gong, and tai chi [5]. An important concept in TCM is qi, a life energy with various mental, physical, and spiritual manifestations. This energy is said to flow throughout the body, along the meridian system, allowing for the integration of internal organs and other body structures. If one's qi is flowing in an orderly fashion, the person is healthy. Disorderly flow causes disease. One of TCM's aims is to restore the orderly flow of qi (Table 72.1) [9].

Yin-yang is another important concept in TCM, in which yin and yang represent opposing but complementary qualities [10]. The philosophical and physiologic implications of yin-yang imbalance in TCM theory are complicated and beyond the scope of this chapter. It can be confusing; for example, the term *kidney* in TCM has a very different meaning than it does in conventional Western medicine. In TCM theory, it does not imply the physical organ; instead, in TCM theory, the kidney's main function is to store energy that governs conception, growth, development, sexual maturation, reproduction, and pregnancy [10].

Table 72.1 Principles of selected Traditional Chinese Medicine (TCM) therapies

Therapy	General principles
Acupressure	Pressing and/or massaging various acupuncture points (acupoints) using fingers, palms, elbow, feet or special devices on the body's meridians [6].
Acupuncture	The Chinese art of stimulating the pathways of energy (14 main meridians plus branches) by puncturing, pressing, heating, using electrical current, or using herbal medicines [7].
Moxibustion	Moxibustion is the process where dried moxa herb (a mugwort) is burned usually just above but sometimes directly on the skin over acupuncture points. The herb may be in the form of incense sticks or wool [8].
Oriental massage	A wide range of therapeutic techniques involving the manipulation of muscles and soft tissues, including kneading, rubbing, tapping, friction, vigorous or relaxing, deep or superficial [7].
Qigong	Exercises aimed at bringing about harmony, as well as improving health and longevity. Healing methods involve breathing, movement, the mind, and the eyes [7].
Tai chi	Balanced gentle movements, incorporating a combination of meditation and breathing, are designed to dissolve physical and karmic layers of tension in both the physical body and the energy body, and to open up the spiritual space inside [7].

In massage therapy, pressure is used to manipulate the body's soft tissues to impact the circulatory, lymphatic, musculoskeletal, and nervous systems, and in so doing enhance the body's self-healing ability [11]. Aromatherapy generally refers to the use of massage therapy in conjunction with aromatic plant extracts, also known as essential oils [12].

Epidemiology of Complementary Therapy Use

There is widespread use of complementary therapies worldwide [13] with varying prevalence rates: 10–40% in different European countries; 40–60% in the USA [14]; 49% in Australia; 75% in Africa, and between 21.6–90% in Saudi Arabia [15, 16]. A US survey of complementary therapies use in the past 12 months found that 4 in 10 adults and 1 in 9 children and youth had used complementary products or therapies [17]. In a Canadian 2011 survey (n = 2001), 71% of respondents reported using one or more NHPs [18], while in a 2016 survey 56% of Canadians reported having used at least one complementary therapy in in the last 12 months [19]. The prevalence of complementary use tends to be higher among individuals with conditions that are chronic, serious, or recurrent [20–22]. A systematic review reported that prevalence rates for complementary therapy use among children/adolescents range from 10.9% to 87.6% for lifetime use and from 8% to 48.5% for current use [23]. The review also found variance in lifetime prevalence by type of complementary therapy: homeopathy 0.8–39% (highest in Germany, United Kingdom, and Canada) and herbal medicine use 0.8–85.5% (highest in Germany, Turkey, and Brazil) [23].

There is a high prevalence of complementary therapy consumption among adult renal patients. The use of complementary therapies in the previous 6 months among patients (N = 278) at a nephrology outpatient clinic in India was 66.3% [24]. A Saudi cross-sectional study (N = 315) reported that 54.9% of chronic kidney disease (CKD) patients were current complementary therapy users [15]. An earlier survey in Egypt reported a similar complementary therapy prevalence rate (52%) among outpatient nephrology clinic attendees (N = 1005) [25]. In a German survey, regular complementary therapy use was reported by 57% of dialysis patients (n = 119) and 49% of kidney transplant patients (n = 45) [26]. In a Thai survey of 421 adults with CKD, 45% had used NHPs in the past year, and a 2004 US survey found 29% of CKD patients used NHPs (n = 250) [27]. A Canadian study reported that 45% of patients (n = 100) with CKD had used NHPs [28], and 25.2% of 206 CKD patients in a Turkish study reported having used complementary therapies at least once following their renal diagnosis [29].

Parents who use complementary therapies are likely to offer these to their children. Although no complementary therapies prevalence studies among pediatric kidney patients were identified, studies show the main predictors of complementary therapy use to be higher parental income and education, older children [23], female children and the existence of comorbid medical condition [30]. The prevalence of complementary therapy use increases to over 50% in children who have chronic [31, 32] recurrent or incurable conditions [22]. For adults and children, complementary therapy use often occurs in combination with conventional care [32].

Reasons for complementary therapy use may include a desire to improve and cure the disease [31]; having an expectation of benefits of complementary therapies; and dissatisfaction with conventional medicine due to lack of cure, side effects, or higher costs [27, 33, 34]. Some adults mention long wait times and insufficient time spent with their physician as reasons for using complementary therapies. Many complementary therapy users value the long appointments that complementary therapy practitioners provide and feel their concerns can therefore be addressed more thoroughly [34, 35]. Other commonly cited reasons for complementary therapy use include increased personal control regarding treatment, and the perception of complementary therapies

as more natural, and therefore safer, than Western medical treatments [27, 33].

Despite common use, many physicians remain unaware about their patients' complementary therapies use. Only 20% to 65% of families discuss their complementary therapies use with their physician [22]. A US complementary therapies user study (N = 7493) found that 42.3% (n = 3094) did not discuss complementary therapies use with their primary care physicians [36]. Among adults with kidney disease, non-disclosure of complementary therapy use can be as high as 72% [37]. Lack of disclosure usually occurs because patients may not think it is relevant, healthcare providers do not ask, concerns about the healthcare provider's knowledge regarding complementary therapies or patients feel their healthcare provider would disapprove of their complementary therapies use [36, 38, 39].

Regulation of complementary therapy practices varies significantly within and among countries [13, 40]. For example, the regulation of complementary therapy practices within the US is inconsistent (some complementary therapy practices are regulated in some states, and not others). Different states can have different requirements for practitioners or different regulations regarding scope of practice [41]. In the United Kingdom, with the exception of osteopaths and chiropractors, most complementary therapy providers are largely unregulated [41, 42]; conversely, in Canada, regulation of chiropractors, naturopaths, homeopaths, osteopaths, TCM practitioners, acupuncturists, and massage therapists often varies by province [41]. In Canada, various provincial professional medical bodies have produced guidelines that address how physicians should deal with complementary therapies and practitioners [43, 44].

Natural Health Product Quality and Regulation

NHPs have complex product quality issues. Heterogeneity in product quality is common for various reasons. For example, for any given herbal product (e.g., *Echinacea*) there may be several plant species (*Echinacea purpurea, Echinacea pallida, Echinacea angustifolia)* with different phytochemical constituents and different physiologic effects [9]. Moreover differences in growing conditions, time of harvesting, parts used (e.g., aerial vs. root), and extraction methods used to prepare the herbal product may vary, compounding differences within and among manufacturers [45]. Some manufacturers have tried to reconcile this problem by standardizing some herbal products to a marker compound specific to that particular plant [46].

NHP product quality suffers from issues related to species misidentification, adulteration, and contamination. Various techniques, including microscopy, mass spectrometry and, more recently, DNA barcoding have been used to identify NHP quality issues [47]. Using DNA barcoding techniques, Newmaster and colleagues [46] found that 59% of herbal products sold on the North American herbal market were contaminated, and McCutcheon's [48] examination of Chinese herbal medicines found that 7% to 23.7% were adulterated [48]. Other reports of NHP quality concerns include a case of neonatal androgenization reported in Toronto where a pregnant mother consumed what she believed to be Siberian ginseng, but was actually Chinese silk vine [48].; herbal products being contaminated with bacteria, fungi, herbicides, and heavy metals; and cases of adulteration of NHPs with pharmaceutical agents [49]. Some herbal products have been found to be mislabeled, a problem that is often associated with the absence of regulation [48]. A 2003 US study found that 10% (6 of 59) of products marketed as *Echinacea* actually contained no *Echinacea* [50, 51].

Different regulatory approaches have been adopted internationally with regard to NHPs, In the US, the 1994 Dietary Supplements and Health Education Act reclassified NHPs as dietary supplements (i.e., neither food nor drug), and thereby exempted them from the usual safety and regulatory rules set by the Food and Drug Administration (FDA).[41, 52] As such, dietary supplements can be marketed without proven safety or efficacy, and it is the responsibility of the FDA to demon-

strate that a supplement is unsafe, which can be challenging. In Canada, Health Canada's Natural and Non-prescription Health Products Directorate regulates NHPs under the NHPs Regulations. Although Health Canada has not attempted to standardize NHPs, its regulations demand that manufacturers meet label claims and eliminate contamination and adulteration from products sold in the Canadian marketplace [3]. In order to help consumers to select and safely use NHPs, Health Canada has proposed regulation amendments to make NHP labels easier to read and understand [3]

Legal and Ethical Considerations

A number of legal and ethical considerations surround the use of complementary therapies. While many patients report that complementary therapy use helps them feel better, use of complementary therapies may delay the use of known effective treatment. Physicians should always inquire about complementary therapy use, monitoring high-risk patients such as those on dialysis, and consider the possibility of NHP-drug interactions as many patient mix NHPs with prescription medications. Clinicians may be hesitant to encourage the use of complementary therapies, as it is unfamiliar [53]. A survey of clinicians (N = 195) in Quebec found that 86.7% believed it was their role to advise patients on complementary therapies, but only 33.1% reporting being able to do so [54] Studies show that most medical students believe that integrative medicine information and education is important to their future practice and improves patient care [55].

Medical school curriculum is evolving to include more information about complementary therapies. For example, a Thai survey found that 50% of medical schools had integrated traditional, complementary, and alternative medicine training in their curriculum [56]. In the US over 50% of medical schools now include some complementary therapies education in their curriculum, with the majority of courses offered as electives [57–59]. At the same time, the number of US hospitals that offer complementary and integrative medicine as an ancillary clinical service has increased, with different hospitals addressing issues related to scope of practice, licensure and malpractice liability differently in their models of integrative health care [57]. There are over 12 residency programs that offer board-certified fellowships (by the American Board of Integrative Medicine or the Academic Consortium for Integrative Medicine and Health) in Integrative Medicine, with opportunities for elective residency experiences in the US [60]. Across North American, there has also been an increase in academic pediatric integrative medicine programs that develop and promote evidence-based integrative approach within Children's hospitals [22]. In Canadian medical programs, few formal courses on complementary therapies are offered as part of medical training [55]. Established in 2008, the Academic Consortium for Integrative Medicine and Health is a group of more than 70 universities, many of which offer educational courses for students and continuing education courses for practicing providers [55].

If a patient expresses interest in using complementary therapies for his or her illness, the physician should review the literature and advise accordingly. If there are sufficient safety and efficacy data, physicians may choose to recommend complementary therapies or refer their patient to a licensed complementary therapy provider [21] (see Fig. 72.1). If efficacy is uncertain, but the therapy is likely to be safe, patients may choose to try the therapy while their clinician continues to monitor them. If a therapy is felt to be unsafe, the patient should be advised to discontinue its use [9].

This chapter reviews the best available evidence with regard to NHPs, TCM and massage therapy. When pediatric evidence is unavailable, evidence from studies conducted among adults is discussed. Because limiting research by language can promote bias, our searches were conducted without language restriction.

It is important to highlight that the methodological quality of randomized controlled trials (RCTs) examining complementary therapies have been assessed and found equivalent to that

Fig. 72.1 Potential malpractice liability risk associated with complementary and integrative medical therapies [61]. (Used with permission from Cohen MH, Eisenberg DM. Potential physician malpractice liability associated with complementary and integrative medical therapies. Ann Intern Med. 2002;136(8):596–60)

of conventional interventions, while complementary therapies' systematic reviews have tended to be of better quality than those of conventional therapies [62, 63]. While this is reassuring regarding the overall quality of complementary therapies evidence, there have been calls for improvement in specific areas, such as Chinese TCM studies [64].

Nephrotic Syndrome

Various studies have examined complementary therapy treatments in children with nephrotic syndrome, including TCM and dietary modification. We identified several RCTs and systematic reviews of Chinese herbal medicines in the treatment of children with nephrotic syndrome.

TCM

Deng and colleagues [65] have published a systematic review that investigates the effect of Chinese medicine prescription on nephrotic syndrome.

Feng and associates [66] performed a Cochrane review that examined the benefits and harms of administering Huangqi or Huangqi formulations alone (oral solution or intravenous injection) or in addition to other drug therapies in treating nephrotic syndrome [66]. Haungqi is a traditional Chinese herbal medicine and is a root of *Huangqi membranaceus* (Fisch) Bge. var. *mongholicus* (Bge) Hsiao or *Huangqi membranaceus* (Fisch) Bge. or *Hedysarum polybotrys* Hand. –Mazz (fam. *Leguminoseae)* [66]. Haungqi and its formulations have been used commonly for nephrotic syndrome in China [66]. In the review, nine Chinese studies (n = 461 participants) were included; five included children only, one study was of adults only and three studies included both adults and children. Compared to control interventions, Huangqi and Huangqi formulations were found to have positive effects in treating nephrotic syndrome by increasing plasma albumin and reducing urine albumin excretion, blood cholesterol, triglycerides. At 3 months, more patients who had taken Huangqi showed improvement (relative risk (RR) 0.41, 95% confidence interval (CI) 0.20 to 0.84). However, due to small sample sizes and other methodological concerns including lack of blinding and unclear randomization, the evidence was insufficient to support the use of Huangqi formulations for the treatment of nephrotic syndrome. No adverse effects of Huangqi formulations were reported.

A previous systematic review [67] examined various interventions for preventing infections in children with nephrotic syndrome. Twelve studies (n = 762), all carried out in China, were included. Nine studies assessed prophylactic pharmacotherapy (e.g., intravenous immune globuli, Bacillus Calmette-Guerin) compared to placebo, no or other treatment. Three studies investigated the efficacy of the Chinese medicinal herbs tiaojining (one study) and Huangqi (astragalus) granules (2 studies). Tiaojining is a compound of six primary Chinese medicinal herbs (Shengdi, Zhimu, Zexie, Shanyurou, Xianlinpi, and Baihuasheshecao) associated with immunomodulation effects. *Huangqi astragalus* granules contain astragalus polysaccharides, astragaloside, amino acids and various microelements associated with improved immune function. The authors noted that the trials included in the review were of very poor methodological quality because most studies did not describe the methods used for randomization, blinding or withdrawals.

We describe here the three RCTs included in the Wu et al. [67] review that investigated the efficacy of Chinese medicinal herbs for nephrotic syndrome, one about tiaojining and two about Huangpi (astragalus) granules. The first study evaluated the efficacy of tiaojining for reducing the risk of infection among children with nephrotic syndrome (n = 60; aged 1–13 years) [68]. Children in the treatment group received 8 weeks of prednisone combined with various doses of tiaojining 3 times/day based on their age. Children in the control group received prednisone for the same duration. At the end of treatment tiaojining was effective in preventing infection, with a relative risk (RR) of 0.59 (95% CI 0.43 to 0.81, p = 0.001). No adverse events or safety data were presented.

The second study was a parallel group RCT in which 92 children (aged 2–13.7 years) were assigned to either prednisone in combination with Huangpi granules (dose between 7.5 and 15 g b.i.d. based on age) or control (prednisone) for 3 months [69]. The third study was a smaller parallel RCT, which allocated 38 children (aged 1.5–7 years) to either prednisone with 15 g of Huangqi granules for 3–6 months or control (prednisone only) [70]. When both studies were combined, Huangqi granules showed a significant beneficial effect (RR 0.62, 95% CI 0.47 to 0.83) in reducing the risk of infection in children with nephrotic syndrome. Both studies reported that no adverse events were observed. Although these findings seem promising, these studies had methodological limitations and no recommendations for use can be made without larger and better designed studies.

Tripterygium wilfordii Hook F (TwHF) is a traditional herbal medicine that has been used as an immunosuppressive agent to decrease proteinuria and preserve kidney function [71]. A systematic review published in 2013 evaluated the benefits of taking two standardized types of TwHF (ethanol-ethyl acetate extract and chloroform methanol extract only) alone or in combination with other drug therapies in primary nephrotic syndrome patients. The review included 10 Chinese RCTs (9 involving adults only and one involving both adults and children) with 630 patients. The main outcomes measured were complete or partial remission. Treatment with TwHF was administered for 4 to 8 weeks at dosages ranging from 0.5 mg/kg/day to 2.0 mg/kg/day, while the follow-up period ranged from 3 to 18 months. In 4 trials (n = 293) comparing TwHF to control, TwHF significantly increased complete or partial remission. The evidence was not statistically significant when comparing TwHF to prednisone or cyclophosphamide. No serious adverse events of TwHF were observed. The authors concluded that TwHF may have an add-on effect on remission in patients with primary nephrotic syndrome. The authors had major concerns regarding the poor quality of the included studies and called for better studies with larger sample size and adequate follow-up.

Standardised TwHF preparations are purported to be less toxic and have fewer serious adverse effects than non-standardised preparations [72]. Some common adverse events associated with standardised TwHF include gastrointestinal tract disturbances, leukopenia, thrombocytopenia, rash, skin pigmentation, and malfunction of the reproductive system [73]. These adverse effects reportedly resolve after adjusting the dose or discontinuing TwHF treatment [66, 74]. In Chinese clinical practice, many physicians are unwilling to use TwHF in children due to potential reproductive system complications [75]. Serious adverse events associated with use of non-standardized TwHF include severe liver dysfunction, aplastic anaemia, and death [72]. More evidence is needed regarding long-term use and safety of TwHF in children with nephrotic syndrome before recommendations can be made for its clinical use.

An earlier RCT carried out by Wang et al. (2005) [76] compared the effects of Tripterygium glycosides with that of cyclophosphamide in 80 children (aged 1–13 years) with relapsing primary nephrotic syndrome. Children in the experimental group (n = 39) received 1 mg/kg of tripterygium glycosides orally 2 or 3 times each day for 3 months. The control group (n = 41) received 10 mg/kg/day of cyclophosphamide by intravenous pulse over 3–6 months. All children also received tapering doses of prednisone over a period of 12–18 months. After follow-up for 3–7 years, no significant differences in the relapse rates in the two groups were observed ($p > 0.05$). The researchers concluded that treatment with tripterygium glucosides and prednisone was as effective as cyclophosphamide and prednisone, although this study was not designed as an equivalence trial. More side effects were reported in the control (n = 21) than the experimental group (n = 2), but in both groups symptoms resolved after treatment was discontinued. The control group side effects included one case of rising guanosine triphosphate (GTP) levels, 3 cases of transient leukocytopenia, 11 cases of alopecia, and 6 cases of gastrointestinal disturbance. The experimental group had a case of transient leukocytopenia and another of rising GTP. Safety information regarding tripterygium glycosides beyond this trial are unknown; therefore, more studies are needed.

The efficacy of Chai-Ling-Tang (Sairei-to), a preparation of 10 Chinese medicinal plants, was evaluated in 69 children (aged 5–12 years) with steroid-dependent nephrotic syndrome [77]. Over 3 weeks, children in the experimental group (n = 37) received tapering doses of prednisone until they had protein-free urine and consistent doses of Chai-Ling-Tang for 1.5 years. The control group (n = 32) received tapering doses of prednisone plus 2.5 mg/kg/day of cyclophosphamide for 8 weeks. All study participants were monitored for at least 2 years. No significant differences were reported between the experimental and control group in terms of outcomes measured, including relapse time, time to absence of

proteinuria, amount of prednisone intake, and side effects. Chai-Ling-Tang was therefore equivalent to cyclophosphamide in treating steroid-dependent nephrotic syndrome. The authors suggested that Chai-Ling-Tang could be used as an alternative where patients are either non-responsive or have severe side effects from cyclophosphamide. Beyond this RCT, the safety of Chi-Ling-Tang is not known. More research is needed before any considerations for its routine clinical use in pediatric patients with nephrotic syndrome.

Immunoglobulin A (IgA) Nephropathy

There has been a substantial amount of research conducted on the effectiveness of omega-3 fatty acids (O3FA) as a therapy for individuals with IgA nephropathy (IgAN). Most of the research comes from studies involving adult patients, with a few that included children. There are also RCTs that assessed the usefulness of TCM and Vitamin E in IgAN patients.

Omega-3 Fatty Acids

A 2017 meta-analysis [78] of 9 RCTs (N = 444) evaluated the effects of O3FA on renal function and subsequent end-stage kidney disease (ESKD) events in patients with IgAN (7 RCTs) and CKD (2 RCTs). Two trials were in the US, 2 in Japan, 3 in Europe and 2 in Australia. Participants ranged from 23 to 106 patients, and follow-up ranged from 2 to 76.8 months. O3FA supplementation was significantly associated with both a lower risk of proteinuria (SMD: −0.31; 95% CI: −0.53 to −0.10; p = 0.004) and ESKD (RR: 0.49; 95% CI: 0.24 to 0.99; p = 0.047). There was no evidence to suggest that O3FA has an effect on creatinine clearance (CrCl) and estimated glomerular filtration rate (eGFR). There was no mention of adverse effects in this meta-analysis. The limitations of the meta-analysis included pooled data (due to unavailability of data), and not having sufficient relevant trials to conduct subgroup analyses for ESKD or examine for publication bias [78].

Chou et al. (2012) [79] conducted a meta-analysis to evaluate the effects of O3FA on GFR and proteinuria in IgAN. The review included 5 RCTs reported between 1989 and 2009 and included 233 adults. One hundred and sixteen patients received O3FA and 117 patients received no treatment (3 studies) or placebo (2 studies). Patients received therapy for 6–48 months. There was no significant difference in renal function between O3FA and control groups. No significant differences in renal function or proteinuria were observed when analysis was based on comparing patients who received high (> 3 g/day) and low (≤ 3 g/day) O3FA doses. In addition, no dose-effect relationships between O3FA and renal function or proteinuria were observed. This meta-analysis included a small number of RCTs with study design limitations that included small sample size, short duration and variable stages of renal disease. The authors concluded that there was no evidence to suggest that O3FA has significant effects on renal function compared to controls.

An earlier meta-analysis published in 2009 [80] combined evidence from 17 RCTs to determine the effectiveness of n-3 long-chain polyunsaturated fatty acid (n-3 LCPUFA; also known as OSFA) supplementation on change in urine protein excretion and GFR in 626 adults with various chronic kidney conditions [80]. The underlying conditions in the patients were IgA nephropathy (5 trials), diabetes (7 trials), lupus (1), and kidney disease of mixed etiology (3). One trial included in the review did not report the underlying kidney disease of the study participants. Four of the IgAN trials included in this review were the same studies included in the 2012 meta-analysis [58]. The dose of n-3 LCPUFAs administered ranged from 0.7 to 5.1 g/day and follow-up was 6 weeks to 48 months. Supplementation with n-3 LCPUFA significantly reduced urine protein excretion compared to control, but there was no effect on GFR. Side effects were reported in 5 of the 17 trials and included; gastrointestinal side effects including nausea, fish aftertaste, and smell/taste of fish on eructation [80].

In a US based double blind RCT, Hogg et al. [81] compared the efficacy of prednisone or O3FA

to placebo in 96 children and young adults with IgAN. A total of 23 patients were randomly assigned to receive O3FA 4 g/day (1.88 g/day of eicosapentaenoic acid, 1.48 g/day docosahexaenoic acid) for 2 years. Another 33 patients received alternate day prednisone at 60 mg/m^2 for 3 months, then 40 mg/m^2 for 9 months and 30 mg/m2 for 12 months. The last group of 31 patients received placebo. The main outcome measure was time to failure, defined as an eGFR ≤60% of baseline. The investigators found no differences with respect to time to failure between the three groups. Significantly more patients in the prednisone group compared to the placebo group experienced heartburn (48 vs. 16%; p = 0.018), and increased appetite (73 vs. 32%; p = 0.001). Other adverse events such as weight gain and anxiety were not statistically different between the two groups.

The current body of evidence assessing the efficacy of fish oils for the treatment of IgAN is from relatively small trials. More evidence from large, randomized, double-blind, placebo-controlled studies is required. Fish oils are considered extremely safe for adults when taken in recommended doses. Common adverse effects of fish oil supplements include fishy after-taste and gastrointestinal complaints such as nausea and dyspepsia [82]. Fish oil ingestion above 3 g/day may result in an increased risk of bleeding, especially in patients taking warfarin [82]. Based on this safety information, the inclusion of fish oils at recommended dosages in the treatment of adult IgA patients may be considered. The potential use of fish oils in children warrants further examination.

TCM

An RCT conducted in pediatric patients (n = 62) found that treatment with both TCM and Western medicine improved symptoms in pediatric patients with renal biopsy diagnosed IgAN [83]. Children (aged 5–14 years) were randomized to receive TCM and Western medicine (n = 34) or Western medicine only (n = 28) for 6 months. The Western medicine group took dipyridamole, captopril, common threewingnut, prednisone or cyclophosphamide according to their illness condition. Based on the clinical features, a range of TCM preparations such as Huang Qi (RadixAstragali seu Hedysari), Jian Qu (Massa Medicata Fermentata Fujianensis), fresh Mao Gen (Radix Rubi Parvifolii) and Lu Gen (Rhizoma Phragmitis) were prescribed, leading to considerable variability in TCM preparations and dosing used between patients. Eight children dropped out from the study; 2 from the TCM group and 6 from Western medicine group. After 6 months of treatment, there was no significant difference in efficacy between the two groups. The cure plus marked effect rate in the group treated with both TCM and Western medicine was higher compared to the group treated with Western medicine alone. One adverse event occurred in a patient who received TCM and Western medicine: the patient had increased alanine aminotransferase, which returned to normal after 1 week of "liver-protecting treatment" (not specified).

Safety information regarding TCM beyond the adverse effect described in the study is unknown. More studies and safety information are required before TCM herbals can be recommended for routine clinical use.

Vitamin E

A pilot double-blind, placebo-controlled trial found reduced protein/creatinine ratios in 55 children with early or mild IgAN (biopsy-proven) who were given vitamin E as antioxidant therapy [84]. Children were randomized to receive placebo (n = 28) or vitamin E capsules (n = 27). The dose of vitamin E amount was 400 IU/day if they weighed less than 30 kg and 800 IU/day if they weighed more than 30 kg. Thirty-eight patients completed 1 year of the follow-up, with no side effects reported in either the vitamin E or the placebo group. At study conclusion, there was no significant difference in GFR or in hematuria. The urine protein to creatinine ratio was significantly better in the vitamin E group (0.61; 1.37 mg/mg) vs. the placebo group (0.24; 0.38 mg/mg; p = 0.013). This small pilot study supports the use of vitamin E in pediatric patients with mild IgAN. However, larger studies investigating the long-term treatment effects of taking vitamin E in patients with mild to severe IgAN are needed.

Vitamin E is generally considered to be a safe, inexpensive product, with no clinically relevant side effects [84] when taken at recommended dosages for short periods of time.

Urolithiasis

A number of studies have assessed complementary therapies for urolithiasis and renal colic. The research has mainly focused on adults and the efficacy of acupuncture, with one study each investigating the efficacy of massage and probiotics in treating urolithiasis.

Acupuncture

Acupuncture involves the insertion of fine sterile needles into specific acupuncture points on various parts of the body.

A systematic review investigated the role of complementary therapies (including acupuncture) in decreasing analgesia requirement and alleviating anxiety during extracorporeal shockwave lithotripsy (ESWL) [85]. The systematic review included only studies published in English; they had sample sizes from 35 to 100 patients. In the five studies (4 RCTs and 1 prospective design without a control), 235 adult kidney stone disease (KSD) patients received different types of acupuncture: electro-acupuncture (2 studies), sham acupuncture and electro-acupuncture (2 studies), sham acupuncture, electro-acupuncture and auricular acupuncture (2 studies), and unspecified acupuncture (one study) d. The primary outcome measures across the studies were visual analogue scale (VAS) for pain and the State-Trait Anxiety Inventory (STAI) for anxiety. Four studies reported a statistically significant lowered pain and/or anxiety score. Two studies also reported a decrease in analgesia or opiate use. No major or minor side effects were noted with the use of acupuncture. The reviewers concluded that acupuncture reduced pain as well as anxiety and should be considered for use in outpatient urological procedures [85].

An RCT [86] in Turkey compared the efficacy of diclofenac, acetaminophen and acupuncture in treating urolithiasis-driven renal colic. Adult patients (N = 121) were divided into 3 groups: Group A (n = 40) was treated with 1 g of intravenous acetaminophen over 15 min, Group B (n = 41) was treated with acupuncture applied to the urinary bladder meridian points the side with acute renal colic pain (UB-21 to 24, UB-45 to 48), and Group C (n = 40) was treated with a 75-mg intramuscular injection of diclofenac sodium. VAS and verbal rating scale (VRS) were used to assess drop in pain intensity after 10, 30, 60, and 120 min. After 10 min, the largest decrease in VAS and VRS scores was observed in patients who received acupuncture ($p < 0.05$). At subsequent intervals (30, 60, and 120 min) either diclofenac or acetaminophen had higher decreases in VAS and VRS scores compared to acupuncture. Adverse effects were reported in individuals who received acetaminophen (one patient had an allergic reaction and another reported dizziness and vomiting) and diclofenac (one patient had rash, and 2 patients had abdominal burning/pain). No adverse effects were reported in the patients that received acupuncture treatment. The authors concluded that acupuncture is a viable alternative treatment modality for renal colic.

A RCT conducted in Tunisia [87] randomized 115 renal colic patients into two groups. The first group (n = 61) received 0.1 mg/kg intravenous morphine every 5 min until the pain score as measured using the VAS dropped by at least 50% of its baseline value. The second group (n = 54) received a 30-min acupuncture session where needles were inserted to urinary bladder meridian points on the side of the pain (UB21–24, UB26, UB45–49). VAS was used to assess pain intensity at baseline and at 10, 20, 30, 45, and 60 min after treatment. From the tenth minute until the end of the intervention, acupuncture was associated with a faster and higher analgesic effect compared to morphine ($P < 0.05$). Forty-two side effects (namely, dizziness, nausea and vomiting and drowsiness) were reported in the morphine group compared to 3 (1 needle blockage and 2 reports of itching/rash/bleeding at needle insertion point) in the acupuncture group ($P < 0.001$). The investigators suggested that acupuncture rep-

resents an effective alternative treatment for patients with high risk of adverse events due to morphine and its use be further assessed [87].

A Chinese RCT evaluated the clinical effects of body and auricular acupuncture compared to medication in treating renal colic in 60 participants (aged 16–45 years) [88]. Renal colic patients in the intervention group received body acupuncture (acupoints: bilateral Zusanli (ST36), Yanglingquan (GB 34), and Ashi points on the affected side) and auricular acupuncture (ear points: Shenmen (TF 4), Kidney (CO 10), and Bladder (CO 9) for 30 min). Patients in the medication group received an intramuscular injection with pethidine 50 mg and atropine 1 mg. Pain relief and analgesic effects were measured using a patient numeric rating scale. Patients in both groups reported reduced pain. The total effective rate was higher in the acupuncture group (89.7%) than in the medication group (77.4%); ($p < 0.05$). The researchers concluded that acupuncture could be used as an alternative to pethidine and atropine in treating renal colic.

Hodzic et al. (2007) [89] investigated whether acupuncture could lower or replace the need for analgesics in ESWL of kidney stones in adult patients (aged 17–85 years) in Germany. The control group (n = 78) received 50 mg pethidine plus 10 mg diazepam. Patients randomized into the treatment group (n = 86) received acupuncture at various acupoints. The main outcome was self-rated pain scores. Pain sensation was rated prior to ESWL and for every minute until 21 min after the therapy started, and for 10 min after therapy stopped. All patients who reported a pain sensation higher than 5, received analgesics delivered intravenously. Twenty percent of recruited patients refused acupuncture treatment and were excluded from the study. There was no mention of adverse events. The mean pain score throughout the treatment was significantly less for the treatment group (2.6) vs. the control group (3.2) ($p < 0.0001$). Acupuncture was reported to provide significantly more effective analgesia than pethidine and diazepam. It is important to note that 23% (n = 20) of patients in the acupuncture group needed additional pain medication [89].

Another RCT assessed the clinical effectiveness of electro-acupuncture compared to a combination of tramadol and midazolam in relieving pain during outpatient ESWL [90]. Thirty-five adults with kidney stones were allocated to undergo lithotripsy with a third generation lithotriptor following treatment with either electro-acupuncture (treatment group; n = 17) or tramadol/midazolam (control group; n = 18) for sedation and analgesia. For patients in the treatment group, the same licensed acupuncturist administered 20-min electro-acupuncture stimulation with 2–4 Hz frequency for 30 min prior to ESWL. Patients in the control group received treatment with tramadol (1.5 mg/kg) 30 min before the start of lithotripsy and midazolam (0.06 mg/kg) 5 min before ESWL. The main outcome, pain intensity, was measured using a VAS. Although the electro-acupuncture group was found to have lower VAS compared to the medication group, this finding was not statistically significant. Similarly, there was no significant difference in stone-free rates between the two groups. There were no adverse effects in the electro-acupuncture group. Participants in the control group experienced moderate adverse events such as orthostatic hypotension and dizziness, which did not warrant their removal from the study. The authors concluded that electro-acupuncture is an effective alternate pain relieving method without any demonstrable side effects.

In an earlier RCT, Lee and colleagues [91] investigated the effect of acupuncture compared to a conventional analgesic (Avafortan, which has since been discontinued) in the treatment of 38 adult males with renal colic from urolithiasis [91]. Patients were randomized to either receive acupuncture treatment (n = 22), or an intramuscular injection of Avafortan (n = 16). Renal colic pain scores were evaluated before treatment and 30 min following treatment. There was no significant difference in the reduction in mean pain score between the two groups, but acupuncture had a significantly faster analgesic onset than Avafortan ($p < 0.05$). Nearly half (n = 7) of the Avafortan group experienced side effects; 3 cases of skin rash, 2 cases of tachycardia and one case

of facial flushing and drowsiness. Patients in the acupuncture group did not experience any adverse effects. The authors contended that acupuncture could be a good alternative for the treatment of renal colic.

Serious adverse events associated with acupuncture are rare. In a prospective survey of 229,230 patients (mean age 46 years) 8.6% patients reported experiencing at least one adverse event [92]. Bleeding (6.1% of patients) and pain (1.7% of patients) were the most common adverse events reported. A systematic review evaluating the safety of pediatric needle acupuncture calculated a mild adverse event incidence per patient of 168 in 1422 patients (11.8%; 95% CI: 10.1% −13.5%). In the review, adverse events included bleeding, pain, bruising and worsening of symptoms. Although rare, serious adverse events associated with acupuncture in children have occurred such as infections, thumb deformations, cardiac rapture (a fatal consequence of myocardial infarction) and hospitalization [64]. Some of the acupuncture related serious adverse events may have been avoidable as they were likely caused by substandard practice. The evidence suggests pediatric acupuncture is safe where it is performed by appropriately trained acupuncture practitioners [64, 93].

Massage

A retrospective RCT assessed the use of vibration massage therapy after ESWL in 103 adults with lower caliceal stones [94]. Patients in the experimental group (n = 51) received ESWL and 20- to 25-min sessions of vibration massage therapy (applied at a speed of 3800 rpm) in 2-day intervals for 2 weeks. The control group (n = 52) received ESWL alone. The stone-free rates in the experimental and control groups were 80% and 60%, respectively ($p = 0.003$). The rate of stone recurrence was significantly higher in the control group than in the experimental group ($p = 0.0006$). However, there were more reports of renal colic in the experimental group ($p = 0.03$) than in the control group. No trials investigating the use of vibration massage therapy in children were identified.

While therapeutic massage generally carries a low risk of complications, information pertaining to the safety of vibration massage is unknown.

Probiotics

Probiotics have been described as live microorganisms which can provide a health benefit to the host when ingested in adequate amounts [95].

A small pilot study investigated whether a mixture of freeze-dried lactic acid bacteria could reduce oxaluria in 6 adults with idiopathic calcium oxalate urolithiasis and hyperoxaluria [96]. During a 4-week period, all patients received 8×10^{11} freeze-dried lactic acid bacteria (*L. acidophilus, L. plantarum, L. brevis, S. thermophilus, B. infantis*) and did not eat foods rich in oxalate (e.g. spinach, chocolate, peanuts, cocoa and rhubarb). There was a significant decrease in 24-h oxalate excretion compared to baseline ($p < 0.05$). The treatment was associated with a mean reduction in oxaluria of approximately 30 mg/day [96]. The reduced levels were sustained for at least 1 month after the end of treatment.

Probiotics are generally safe in healthy individuals, and some probiotics (*L. acidophilus*, *Lactobacillus* GG, *Saccharomyces* sp.) have been found safe for use in children, when administered in appropriate doses [97]. Case reports of serious infections including bacteremia, fungemia, endocarditis, liver abscess, septicemia and meningitis have been associated with probiotics [95, 98]. The risk of adverse effects associated with probiotics is high in patients that are immunocompromised, including those with indwelling medical devices [95, 98].

Urinary Tract Infections

Various NHPs have been used as a prophylaxis for urinary tract infections (UTIs) including cranberry, probiotics and vitamin A. The evidence evaluating the efficacy of cranberry juice in pediatrics is increasing, while the number of pediatric trials evaluating probiotics and vitamin A remains limited. Studies often have small sample sizes and other methodological limitations.

Cranberry

In vitro evidence suggests that proanthocyanidins (tannins) and fructose found in cranberries have antibacterial activity [98] via preventing bacteria from adhering to the walls of the bladder and thus decrease the development of UTIs [99].

In 1998 Jepson and colleagues [100] published a systematic review of cranberry trials for the prevention of UTIs which they updated in 2004, 2008 and in 2012 [101]. The 2012 update included 24 studies which compared the effectiveness of cranberry in different forms and combinations (concentrate juice, tablets, liquid concentrate syrup and capsules/tablets) to placebo, no treatment, water, methenamine hippurate, antibiotics or lactobacillus. Due to design and data shortcomings, 11 studies were excluded, leaving 13 studies (2462 participants) for the meta-analyses. Studies were analysed together and separately by participant subgroups (e.g., children with first or subsequent UTI, participants with a history of recurrent lower UTI, and pregnant women). Cranberry products did not significantly reduce the risk of repeat UTI across the combined 13 studies (overall RR 0.86, 95% CI 0.71 to 1.04) or any subgroup populations analysed. Although not significant, the pediatric subgroup analysis, which compared cranberry juice to placebo/control, suggested the greatest effect (RR 0.48, 95% CI 0.19 to 1.22). Many of the studies reported low compliance and a high number of withdrawal/dropout due to problems with the palatability/acceptability of the cranberry product, mainly the cranberry juice. The authors concluded that cranberry products compared to placebo was not effective in most population groups, and that any benefit in sub-groups is likely very small.

The three pediatric RCTs included in the review are described. The largest pediatric RCT investigating the efficacy of cranberry juice in preventing UTI recurrences was performed in Finland and involved 263 children (1–16 years) with a verified UTI in the previous 2 months [102]. Children were randomized to receive 1 or 2 daily doses of up to 300 ml per day of cranberry juice containing 41 grams cranberry concentrate (n = 129) or placebo (n = 134) for 6 months and monitored for UTI recurrences over 12 months. Nearly 45% of participants in this study were toddlers, the mean age being 3.8 years (standard deviation (SD) 2.5) in the cranberry group and 4.5 years (SD 2.9) in the placebo. Eight children were excluded from the study due to protocol violations leaving 255 children included in the analysis. There were no significant differences observed in the proportion of children that had at least one UTI after entering the study; 20 vs. 28 children in the intervention and controls, respectively. The UTI incidence per person-year at risk was 0.16 episodes lower in the cranberry group (95% CI, 2.31 to −.01; p = 0.035) [102]. Twenty-seven children dropped out: 16 from the cranberry group and 11 from the placebo group. The authors only cited the main reason for withdrawal, which was reluctance to drink the juice (7 from the intervention and 6 from the placebo groups).

The second RCT [103] compared the effectiveness of cranberry juice vs. *Lactobacillus* in preventing the recurrence of UTIs in 84 girls (aged 3–14 year; mean age 7.5) in Italy. The girls were randomized to receive, for a 6-month period, either: a daily 50 ml dose of cranberry juice containing 7.5 g of cranberry concentrate and 1.7 g of lingonberry concentrate juice in 50 ml of water, without sugar additives (n = 28); 100 ml of *Lactobacillus* drink containing 4×10^7 cfu of *Lactobacillus* GG/100 ml on 5 days a month (n = 27); or control (n = 29). Four children dropped out due to poor compliance to the protocol, two from the control group and one from each of the other groups. During the 6 months of observation, reduction in UTIs was significant ($p < 0.05$) for the cranberry group compared to the other groups: UTI occurrence was 5/27 (18.5%) in the cranberry group; 11/26 (42.3%) in the *Lactobacillus* group; and 18/27 (48.1%) in the control group.

The third RCT [104] recruited children (aged 1 month to 13 years) with more than two UTIs in the last 6 months. Children (n = 192) in the treatment group received a nocturnal dose of 0.2 ml/kg of cranberry syrup (5 ml of the syrup contained 36 mg of highly bioactive proanthocyanidin (PACs); n = 75). Children in the control group

ingested 0.2 ml/kg of a color-masked suspension of trimethoprim at a concentration of 8 mg/ml just before the evening meal (n = 117) for a year. The incidence of UTIs was 18.9% (n = 18) in the trimethoprim group (95% CI:11%–26.3%) and 8.4% (n = 8) (95% CI: 2.8%–13.9%) in the cranberry group. However, there was no significant difference between the two groups. Adverse reports included: gastrointestinal intolerance (5 in the trimethoprim group and 2 in the cranberry group) and a case of rash in each group. The authors concluded that cranberry syrup was non-inferior to trimethoprim in preventing recurrent UTIs.

In 2015 Durham and colleagues evaluated the use of cranberry products for the prevention of UTIs in pediatric patients in a literature review. Of the eight trials reviewed: 3 were in healthy children [102, 103, 105] and 5 in children with underlying urogenital abnormalities [104, 106–109]. The literature review concluded that cranberry products may be an effective option for preventing recurrent UTIs in healthy children, while in children with anatomical abnormalities the findings were inconclusive. In two trials that compared the effectiveness of cranberry juice to antibiotics in children with underlying urogenital abnormalities, cranberry juice was found to have comparable efficacy to antibiotics [104, 108]. This finding is important as cranberry juice could be an alternative to the use of antibiotics at a time when overuse of antimicrobial agents and antibiotic resistance is on the rise [110].

A Taiwanese RCT [111] not included in the previously described reviews evaluated the effects of highly concentrated cranberry juice in preventing repeat UTI's in boys aged 6–18 years (55 uncircumcised and 12 circumcised). Over a 6-month period, uncircumcised boys in group A (n = 28) drank 120 mL of cranberry juice daily and in group B (control) drank placebo. A third control group C of circumcised boys also drank a placebo juice. The main outcome was a confirmed urine culture of symptomatic UTI. The results showed that recurrent UTI's was 25%, 37% and 33.3% in groups A (cranberry), B and C, respectively. No adverse effects were observed in the study. The findings support the use of concentrated cranberry juice to reduce the number of repeated episodes of UTI in uncircumcised boys compared to placebo (in circumcised and uncircumcised boys).

Cranberry products (mostly as juice) have been observed to decrease the risk of UTIs in healthy children, and in children with urogenital abnormalities cranberries appear to be just as effective as antibiotic prophylaxis. The primary adverse effects reported by children following cranberry juice intake are mild: sour taste and a lingering aftertaste [99]. No serious adverse effects have been reported from cranberry fruit; however, large intake of cranberry products should be used with caution to prevent the potential for gastrointestinal distress and diarrhea. The use of sweetened cranberry products should be used with caution in diabetic and overweight individuals as it unnecessarily exposes them to carbohydrates and calories [110].

It is safe to use cranberry in clinical practice; however, it is important to note that information regarding the amount and concentration of proanthocyanidins (PACs) in commercially available cranberry juice products may not be known. In addition, PACs are degradable molecules, which means the manufacturing data and storage practices are crucial factors in determining the bioavailability of PACs.

Probiotics

A RCT compared the effect of probiotic and placebo in preventing UTIs in children (4 months to 5 years) with uncomplicated UTI [112]. Children (N = 181) were randomized to receive a probiotic mixture of Lactobacillus acidophilus, Lactobacillus rhamnosus, Bifidobacterium bifidum, and Bifidobacterium lactis (n = 91) or placebo (n = 90) for a total of 18 months of therapy. The primary outcome measure was being UTI free (composite cure) during the study period. At 18 months, compared to children who received placebo, the composite cure was significantly (p = 0.02) higher in children treated with probiotics (96.7% vs 83.3%, respectively). The researchers reported that there were no specific adverse events among the participants who received the probiotic mixture during the course of therapy.

The findings by Sadeghi-Bojd (2020) [112] are consistent with those reported in an RCT [113] that compared probiotic to antibiotic prophylaxis for the prevention of UTIs in 129 children with persistent primary vesicoureteral reflux (VUR) for 1 year prior to the study [113]. Children were randomized to receive probiotics twice daily (*Lactobacillus acidophilus* 10^8 colony forming units (cfu) twice a day, n = 60) or once a day antibiotic (trimethoprim/sulfamethoxazole 2/10 mg/kg, n = 60) at bedtime. The incidence of UTIs was 18.3% in the probiotic group and 21.6% in the antibiotic group, but the difference was not statistically significant. Two children from the probiotic group and one from the antibiotic group dropped out due to noncompliance. The authors concluded that probiotics prophylaxis was as effective as antibiotic prophylaxis in preventing UTIs in children with persistent primary VUR [113].

An earlier double blind RCT assessed whether probiotics could prevent UTIs in 585 preterm infants (birth weight < 1500 g or gestational age < 33 weeks) [114]. Newborns were randomized to receive standard milk enriched with 6×10^9 cfu of *Lactobacillus* GG (n = 295) or standard milk with placebo (n = 290) once a day beginning with the first feed and continued until they were discharged (mean 48 days). The occurrence of UTIs in the babies receiving probiotic-enriched milk was less compared to that observed in the control group (3.4% vs. 5.8%). This difference was, however, not statistically significant.

Unlike the above studies a meta-analysis that included 10 studies (N = 2865; 61.5% boys) found no beneficial effect of probiotics in preventing UTIs (RR = 0.94; 95% CI 0.85–1.03; p = 0.19) and recurrence (RR = 0.93; 95% CI 0.85–1.02; p = 0.14) in children and adolescents [115]. When probiotics were used as adjuvant therapy to antibiotics, the incidence of UTI was reduced (RR = 0.92; 95% CI 0.85–0.99; p = 0.02). The studies in the meta-analysis included children with the following characteristics: admitted into intensive care (4 studies, n = 1681); with vesicoureteral reflux (3 studies, n = 333); first-time UTI (1 study, n = 80), preterm (1 study, n = 585) and preterm with acute pyelonephritis (1 study, n = 186). The outcomes measured were incidence of UTI (5 studies), recurrence of UTI (4 studies), and both were evaluated in one study. The meta-analysis had several limitations (7 studies were of poor quality) that prevent generalizing the findings. Moreover, most studies were conducted in preterm infants or children that were admitted into intensive care.

An earlier 2015 [116] systematic review (N = 725) that included 9 trials (4 included children) comparing the effectiveness of probiotic use to no treatment, placebo or antibiotics in children and adults with complicated UTI also reported no significant benefit for probiotics. Adverse effects reported in the studies included diarrhoea, nausea, vomiting, constipation, and vaginal symptoms. The reviewers noted that most studies had small sample sizes and poor methodological reporting limiting rigorous evaluation [116].

Current evidence on the efficacy of probiotics in preventing or reducing the recurrence of UTI in children is inconclusive. Additional research with larger sample sizes is needed to provide more conclusive evidence and to answer many unresolved questions such as what is the most effective probiotic strain, the ideal combination of strains, effective doses, and the safety of long-term use.

Vitamin A

Vitamin A has anti-inflammatory properties, which in animal studies have been demonstrated to reduce the damage to kidneys after glomerulonephritis [117].

An Iranian RCT evaluated the efficacy of vitamin A supplementation in combination with antibiotics for improving UTI symptoms and preventing renal scarring in girls (N = 90, aged 2–12 years) with acute pyelonephritis (APN) [118]. Children were randomized to receive 10 days of oral vitamin A (n = 36) or placebo (n = 38) in addition to antibiotics during the acute phase of infection. Sixteen girls were lost to follow-up. The main outcomes were duration of UTI symptoms during trial treatment period and

renal scarring as measured by 99 mTc-DMSA scan. The duration of fever (vitamin A: 1.8 days, placebo: 3.1, p = 0.0026), urinary frequency (1.3 vs. 2.8, p = 0.003) and poor feeding (2.3 vs. 4.2, p = 0.005) were significantly less in the vitamin A group than in the placebo group. The vitamin A group showed renal lesion improvement on DMSA scan compared to the placebo group: 63.8% (23 patients) vs. 21% (8 patients), respectively (P < 0.0001) [118] No vitamin A intolerance or adverse effects were observed in the study. The researchers concluded that vitamin supplementation was effective in improving UTI clinical symptoms and reducing scarring following APN, but called for larger studies with longer follow-up.

A meta-analysis [119] of four studies assessed the efficacy of vitamin A administration in addition to antibiotic therapy on renal damage in children aged 1–144 months (N = 248) after APN (120 in the experimental group and 128 in the control group). Three studies were performed in Iran and one was performed in China. The doses and duration of vitamin A were slightly different across studies. Vitamin A was inversely associated with renal damage (relative risk 0.53, 95% confidence interval 0.43–0.67) when compared with placebo after an average follow-up of 5 months. Although vitamin A may have a preventive effect on renal damage in children with APN, these findings need to be further investigated because the few studies in the meta-analysis were of low methodological quality (risk of selection and attrition bias) [119].

A small Turkish RCT not included in the meta-analysis [119] examined the effectiveness of a high dose of vitamin A in preventing UTIs in 24 children (mean age 6.3 ± 1.09 years) with non-complicated lower recurrent UTI [120]. All children received 10 days of antimicrobial therapy and were also randomly assigned to vitamin A (n = 12) or placebo (n = 12). After eradication of infection, children in both groups received antimicrobial prophylaxis and were followed for 1 year. Among children who received vitamin A supplementation, the recurrence rate of UTIs was reduced from 3.58 to 0.75 (p = 0.002) in the first 6 months. During the same period, UTI recurrence rate in the placebo also decreased, but was not statistically significant. There was no mention of adverse events. The authors concluded that vitamin A may have a beneficial role as an adjuvant for treatment of recurrent UTI [120].

Vitamin A is safe at usual doses; however, when taken at more than 25,000 IU, toxicity may include elevated intracranial pressure, severe liver injury (cirrhosis), bone and cartilage damage, and diarrhea [121]. Because vitamin A is fat soluble, it can be stored in the human body and released long after it is taken. There have been two reports of vitamin A toxicity in two hemodialysis patients who had consumed large quantities of vitamin A. The two patients had serum vitamin A levels of 220 ug/dl and 380 ug/dl respectively (normal vitamin A is between 30–95 ug/dl) [122].

Larger and adequately designed studies are needed to confirm whether vitamin A is an effective prophylaxis that alleviates renal scarring (damage) and to determine what dosage is safe for long-term use in the prevention of UTIs in children.

Vitamin D

Vitamin D is known to have an effect on bone and mineral homeostasis in the human body. What is not yet known is its immunoregulatory role in enhancing the body's defenses against bacterial and viral infections [123].

A 2014 small RCT [124] in Iran investigated the effect of Vitamin D supplementation on prevention of recurrent UTI in 68 children and adolescents. Study participants either received Vitamin D (1000 IU/daily) (n = 33) or placebo (n = 32) for 6 months. The differences in the frequency of UTIs was not significantly different between the two groups studied (P = 0.72). There was no mention of adverse effects. The author concluded that vitamin D at the dose levels taken in this study had no significant effect on preventing recurrent UTI, and suggested that more research is required with higher doses of vitamin D and longer follow-up [124].

Chronic Kidney Disease

Complementary therapies that have been used to treat symptoms associated with CKD include NHPs such as folic acid, L-arginine, rhubarb, and various TCM herbal medicines. More conventional approaches have included evaluations of a low-protein diet.

Folic Acid

One of the leading causes of death among CKD patients is cardiovascular disease. Some research has been conducted to evaluate the effects of folic acid supplementation on endothelial function and homocysteine levels. Bennett-Richards et al. [125] performed a crossover RCT involving 25 children (aged 7–17 years) with CKD, who over an 8-week period received 5 mg/m^2 of folic acid per day, followed by an 8-week washout period, and 8 weeks of placebo [125]. Twenty-three children completed the study. During the folic acid phase, homocysteine levels decreased (10.3 mol/L to 8.6 mol/L, p = 0.03), while no decrease in levels was observed during the placebo period. In addition, during the folic acid phase, endothelial-dependent flow-mediated dilatation improved significantly from 7.21 (2.8%) to 8.47 (3.01%) (p = 0.036). The authors speculated that, although folic acid supplementation in adults with CKD have largely been negative, the positive finding in children may be linked to the timing of treatment because atherosclerosis in children is at an earlier stage of its natural history. Folic acid is safe when taken at recommended dosages. More studies in pediatric populations are needed with relevant clinical outcomes before folic acid supplementation can be recommended in pediatric CKD.

Oral L-Arginine

In a crossover RCT, Bennett-Richards et al. [126] examined the effect of dietary supplementation with oral L-arginine on the response of the endothelium to shear stress in 21 children (aged 7–17 years) with CKD and documented endothelial dysfunction. During the treatment phase, each child received 2.5 g/m^2 or 5 g/m^2 of oral L-arginine three times a day for a 4-week period. This was followed by a rest period of 4 weeks and then 4 weeks of placebo. Twenty-one children completed the study as 4 children withdrew (2 due to L-arginine taste complaints, one due to L-arginine related nausea and another received a renal transplant). After the treatment phase, a significant rise in levels of plasma L-arginine was observed; however, there was no significant change in endothelial-dependent dilation. Hence, dietary supplementation with L-arginine was not useful in the treatment of children with CKD. L-arginine at the dosage used resulted in some children experiencing metabolic side effects, namely increased urea and extracellular acidosis [126]. The authors suggested that this could have also contributed to the negative results observed in the study.

Rhubarb

A systematic review that included 18 randomized and quasi-randomized trials (n = 1322) assessed the use of rhubarb in adult patients with CKD [127]. The included trials compared different forms of rhubarb, including tablets and decoctions, to conventional medicine (e.g. captopril) and TCM herbs. The doses and parts of the plant used were not specified. Rhubarb was found to be significantly more effective in treating CKD than conventional medicine alone. However, there was no significant difference in effectiveness between rhubarb and other TCM herbs for treating CKD. Although rhubarb was effective in reducing the symptoms of CKD, it was not possible to determine whether it could slow or stop long-term progression due to the small number of patients. Half the included trials reported adverse events, but these were not described.

Rhubarb is possibly safe for most people when used for short periods (i.e., less than 8 days) and in low doses [128]. Rhubarb has been associated with side effects such as abdominal pain and diarrhea [128]. Long-term use of rhubarb can result in several adverse effects, including electrolyte depletion, edema, colic, atonic colon, and hyperaldosteronism. Rhubarb leaves contain oxalic acid and are considered toxic if ingested [128]. Patients with renal disorders should be cautious and monitored closely when using rhu-

barb as potential electrolyte disturbances may occur [128]. Individuals with renal stones are not advised to consume rhubarb because of its high oxalate content [129]. Rhubarb safety and dosing information for children is limited and not conclusive.

TCM Herbs

The effectiveness of TCM herbs as a supplement treatment to conventional drugs in the treatment of CKD was assessed in an RCT including 248 adults [130]. For a year, the TCM group (n = 120) received conventional drugs (including prednisone and furosemide) in combination with 5 different herbal decoctions which were individualized in terms of type used and dosage. The TCM herbs were selected to supplement the kidney (as described by TCM theory) and invigorate blood flow. Details related to the composition of the TCM herb decoctions can be found in the original article. The control group (n = 128) received conventional medicine for a year. Significant differences between the two groups were found in improved symptoms (92.5% for TCM vs. 49.2% for control group, $p < 0.01$) and in improved CRCL (56 ml/min for TCM vs. 37 ml/min for control group, $p < 0.01$). There was no mention of side effects in the study, and safety information regarding the various TCM herbs used is unknown. Further research is required to determine if the results can be replicated in children.

Protein Restriction

A Cochrane review [131] assessed the effectiveness of a protein-restricted diet in delaying the start of maintenance dialysis and maintaining nutrition in children with CKD. The review included 2 studies (250 children) which compared outcomes for 124 children receiving a protein restricted diet to 126 children on a control diet. The protein-restricted diet given to children was equivalent to the lowest safe protein intake recommended by the World Health Organization (0.8 to 1.1 g/kg/day). The reviewers found no significant differences in the number of renal deaths (RR 1.12, 95% CI 0.54 to 2.33), progression of kidney disease as measured by CRCL at 2 years (mean difference 1.47, 95% CI −1.19 to 4.14) or growth. Thus, the authors concluded that reducing protein intake does not appear to have a significant impact in delaying the progression to ESKD in children. A major limitation for this review was that only two studies were identified. Of these, one had a small sample size (n = 24) and the larger study (n = 226) had significant loss to follow-up [131].

The larger study included in the above systematic review was a multicenter randomized trial involving 226 children (aged 2 to 18) with CKD from 25 pediatric nephrology centers across Europe [132]. After a 6 month run in period, children were first stratified into one of two groups (progressive or non-progressive disease). They were then further stratified into 3 renal disease groups. Children were then randomly assigned into either a diet or control group. Over a 2-year period, the intervention group received a low protein, 0.8 to 1.1 g/kg of protein a day, with adjustments made for age, while the control group had no protein intake restrictions. After 2 years in the study, 112 participants agreed to continue for an additional year. GFR was estimated every 2 months by CRCL. No statistically significant differences in the decline of CRCL were found, suggesting little value in protein restriction in pediatric CKD. There was significant loss of follow-up. No adverse effects were reported, including growth impairment due to the protein-restricted diet.

The smaller study included in the protein diet restriction systematic review was a multicenter RCT which evaluated the effect of a low-protein intake in a group of 24 infants (aged 8 months) with CKD [133]. Infants were randomized to receive a low protein (1.4 ± 0.3 g/kg/day, (protein: energy ratio 5.6%) or control protein (2.4 ± 0.4 g/kg/day, protein: energy ratio10.4%) formula for 10 months. During the 2-month run-in period prior to randomization, all infants were fed formula with intermediate protein (protein: energy ratio of 8%). An assessment of GFR over time could not be conducted due to the short follow-up period and lack of progression to ESKD in patients. At 18 months, the low protein group had significantly lower standard deviation scores

for length compared to the control group (−2.6+ 1.2 vs. −1.7 + 1.4),raising safety concerns of a low protein diet in this young population. It is recommended that extra caution be employed when considering any protein restrictions until larger prospective RCTs provide more data on efficacy and safety in children. Although there were no dropouts due to adverse events, 2 infants from each group had possible protein deficiency (based on poor weight gain) or excess protein (defined as blood urea nitrogen (BUN) greater than 80 mg/dl or BUN/serum creatinine ratio greater than 60). These infants were given their individual group formula combined (50:50) with the intermediate (8%) protein: energy ratio formula until the end of the study.

Rheum Officinale

Rheum officinale (Da Huang, a medicinal herb) is a type of rhubarb from the family *Polygonaceae*, and has been used by TCM practitioners for its strong cathartic action, and more recently, to delay progression of CKD [134].

A systematic review [134] which examined the effectiveness of *Rheum officinale* (Da Huang) in treating or preventing the progression of CKD found no evidence to recommend its use. The systematic review included 682 patients from 9 studies. Seven of the trials compared *Rheum officinale* with no treatment and 2 compared it to captopril. The main outcome was changes in two blood markers that indicate progression of CKD: serum creatinine (Cr) and BUN. Compared with no treatment, *Rheum officinale* had a positive effect on Cr (MD −87.49 μmol/L, 95% CI −139.25 to −35.72) and BUN (MD −10.61 mmol/L, 95% CI −19.45 to −2.21). The studies had various methodological shortcomings that included lack of reporting on group allocation or blinding (all studies) and small or relatively small sample size (all studies). Only one small trial (n = 30) reported on adverse effects: two-thirds of the study participants experienced diarrhea when taking more than 3 g/day of *Rheum officinale*. Despite the seemingly positive results, the authors highlighted that there was no high quality evidence to indicate that treatment with *Rheum officinale* can improve CKD or delay its progression. Well-designed RCTs are needed to better assess if there are benefits from *Rheum officinale* for CKD patients. More safety information about *Rheum officinale* is also needed.

Topical Herbal Medicine

Zhang H et al. [135] evaluated if the topical application of herbal medicine delays the progress of renal disease and improves its complications in CKD patients. The review included 23 trials, all published in Chinese, that compared external use of herbal medicine (e.g. herbal paste, herbal body/foot bathing or fuming) with no treatment, placebo, or conventional treatment. Commonly prescribed ingredients in the herbal paste and bathing formulas were Radix et Rhizoma Rhei (Da huang), Radix Salviae Miltiorrhiza (Dan shen), Rhizoma Chuanxiong (Chuan xiong), Radix Angelicae Sinensis (Dang gui), and Radix Astragali (Huang qi). The authors suggested that herbal paste and bathing or fuming treatment may be effective in delaying renal disease progression, improving kidney function, and improving some kidney complications in CKD patients. However, because of the low quality and poor reporting practices of the included trials, the authors were unable to reach a more definitive conclusion. Instead, they expressed a need for the current findings to be confirmed through larger, well-designed clinical trials with longer follow-up (greater than the 2 weeks to 2 months employed in the majority of studies included in the review) and appropriate primary outcome measures (GFR, ESKD, and all-cause mortality).

Bicarbonate

An open label RCT found that supplementation with bicarbonate was effective in slowing progression of CKD and in improving the nutritional status of 134 adults attending a predialysis clinic in the United Kingdom [136]. Patients were randomized to receive 1.82 ± 0.80 g/day oral supplementation with sodium bicarbonate (n = 67) or usual care (n = 67) for 2 years. The main primary and secondary outcomes were change in CrCl and dietary protein intake, respectively. Side effects were similar between the two groups, and

included worsening of hypertension and edema. A small proportion (6.5%) of patients in the supplementation group did not like the taste of bicarbonate. Compared with the control group, decline in CrCl was significantly slower in patients who received bicarbonate supplementation (5.93 vs. 1.88 ml/min 1.73 m^2; $p < 0.0001$). Fewer patients supplemented with bicarbonate developed ESKD (6.5 vs. 33%; relative risk 0.13; 95% confidence interval 0.04 to 0.40; $p < 0.001$). Compared to the control group, nutritional status, as measured by dietary protein intake, also improved significantly in the bicarbonate supplementation group ($p < 0.007$). The observed benefits and tolerability of bicarbonate supplementation, inexpensive and simple strategy, warrants further investigation of efficacy and safety through multi-centre double-blind RCTs in adults and children.

Traditional Chinese Medicine (TCM)

A meta-analysis of 39 Chinese RCTs investigated the efficacy and safety of TCM alone or in combination with Western medicine in reducing the risk of kidney damage in children (N = 3643) with Henoch-Schönlein Purpura (HSP) [137]. The RCT had a follow-up period between 2 weeks and 1 year and interventions included TCM self-preparation, TCM differentiation, Xijiao Dihuang Decoction, and Chinese patent medicines. In 7 RCTs (n = 582), adverse effects were significantly ($p < 0.05$) higher in children in the control 7.6% (20 cases of 263 patients) than treatment group 3.5% (12 of 319 patients). TCM significantly ($P < 0.01$) improved the treatment effect (OR: 4.31, 95% CI [3.34, 5.57], reduced the risk of kidney damage (RR: 0.36; 95% CI [0.21, 0.61], and rate of HSP recurrence (RR: 0.43, 95% CI [0.34, 0.54]. Although this study showed that TCM is an effective treatment for HSP, the RCTs included had several limitations, including small sample size, inconsistent follow-up, and poor to moderate quality of some of the studies. Large multi-centre trials are required to confirm these results.

A prospective, controlled, open-label study [138] of 150 children (aged 5–16 years) with HSP and proteinuria examined the efficacy and effectiveness taking a Traditional Chinese herbal decoction Qingre-Lishi-Yishen Formula (QLYF). All (N = 150) children received oral glucocorticoid and cyclophosphamide intravenous pulse regimen (Western medicine), and 100 of the 150 also received QLFY (integrated therapy). Children were followed up for 2 years. The main outcome measures were: adverse events and short- and long-term clinical effects. Compared to children that received the Western medicine only, children who received the integrated therapy had lower adverse event rates of respiratory infection, urinary infection, hepatoxicity, poor appetite, cardiotoxicity, and neutropenia($p < 0.05$). The integrated therapy group also had lower levels of 24-h urine protein, urine blood cell count, occurrence of secondary TCM syndrome, and recurrence rate ($p < 0.05$).

Zhang et al. [139] and Ding et al. [140] published a protocols for a large multi-centre prospective studies to investigate the effectiveness and safety of Chinese Herbal Medicine (CHM) for the treatment of HSP in children [139, 140]. These findings are not yet available for inclusion in this review.

Uremic Pruritus

Although no pediatric studies were identified, various complementary therapies, such as acupuncture, acupressure, thermal therapy, homeopathy and aromatherapy, have been evaluated in the treatment of uremic pruritus in adults undergoing dialysis.

Acupuncture

Kim and associates [141] examined the effectiveness of acupuncture for uremic pruritus in patients with ESKD. Their review included three parallel RCTs, a controlled clinical trial, and two uncontrolled observational studies (case series). Needle acupuncture was assessed in four studies and electro-acupuncture in 2 studies. All studies used standardized acupuncture protocols, and primary endpoints such as the pruritus score and symptom relief were measured. Although all the included trials reported beneficial effects of acupuncture, the majority of studies had high risk of

bias as measured by the Cochrane criteria. The authors also cited publication bias as a potential limitation to the review and considered the evidence insufficient and inconclusive to support the usefulness of acupuncture as effective treatment for uremic pruritus in patients with ESKD.

Evidence from the three RCTs included in the above systematic review will be described, starting with the most recent study which investigated the efficacy of applying acupuncture at a single acupoint in treating refractory uremic pruritus in 40 hemodialysis patients (mean age of 62 years) in China [142]. Patients allocated to receive intervention had a 1-inch 34-gauge acupuncture needle inserted at Quchi (LI11) for an hour three times a week for a month. Patients in the control group had a 1-inch 34-gauge needle inserted 2 cm lateral to the Quchi (LI11) acupoint, for the same time period. The main outcomes captured through a pruritus score questionnaire included severity, distribution and frequency of uremic pruritus and related sleep disturbance. Outcomes were measured before and after 1 month and 3 months of treatment. Within the acupuncture group compared to baseline (38.3 ± 4.3), pruritus scores significantly decreased after acupuncture at 1 month (17.3 ± 5.5) and 3 months (16.5 ± 4.9; $p = 0.001$). Pruritus scores were not significantly different in the control group at 38.3 ± 4.3, 37.5 ± 3.2 and 37.1 ± 5, respectively. Two patients from the acupuncture group and one in the control group experienced elbow soreness which resolved after 1 day, and three patients in the acupuncture group had minimal bleeding. The authors concluded that acupuncture at the Quchi (LI11) acupoint was an easy, safe and effective means of relieving uremic pruritus.

An earlier study compared the effects of needle acupuncture to oral antihistamine for uremic pruritus in 68 adult hemodialysis patients (mean age 43.6) [143]. Patients in the intervention group (n = 34) received 30-min acupuncture sessions twice a week for 4 weeks. The control group (n = 34) received 4 mg of chlorpheniramine and a topical dermatitis ointment (no ingredient details were provided) three times daily for 2 weeks. Patients were then observed for the alleviation of pruritus. A significantly higher effective rate of 95% was observed in the acupuncture group, compared to an effective rate of 70.6% in the control group ($p < 0.01$). In the acupuncture group, this improvement was maintained in 16 patients for 3 months and 18 patients for 1 month. Once treatment administration stopped, uremic pruritus recurred in all patients in the control group.

The largest study included in the systematic review compared the efficacy of acupuncture to oral calcitriol in treating uremic pruritus in 150 hemodialysis adult patients [144]. Patients in the intervention group (n = 80) received acupuncture for 20 min, twice or three times per week for a total of 16 weeks. During the same period, the control group received oral calcitriol. Within group changes in the acupuncture and control group were similar, with an 88% response rate. No adverse events occurred in this study.

Adult efficacy and safety data for acupuncture are promising and some clinicians may want to consider including acupuncture for patients with uremic pruritus.

Acupressure

Acupressure is part of TCM and involves pressing and/or massaging various acupuncture points on the body [145].

A non-randomized control trial published in 2013 investigated the effect of acupressure on uremic pruritus in 78 adult patients receiving hemodialysis [146]. Using a transcutaneous electrical nerve stimulation (TENS), acupressure apparatus patients in the intervention group (n = 38) received acupressure at the SP6, ST36, SP10, and LI11 points three times/week for 6 weeks and a total of 18 sessions. Patients in the control group received no acupressure. Outcome points were captured using a VAS and a pruritus score. The presence or absence of adverse effects was not reported. Mean VAS and pruritus scores significantly decreased at week 6 ($p < 0.001$) in the acupuncture group compared to the control group. This decrease showed a stable trend in weeks 12 and 18 ($p > 0.05$). Throughout the study, patients in the acupuncture group were also observed to use less medication than the control ($p < 0.001$). Acupressure was concluded

to be effective in reducing pruritus in hemodialysis patients.

An earlier RCT also showed that acupressure decreases pruritic symptoms in 60 adult dialysis patients [145]. Patients in the treatment group (n = 30) received 15–20 min sessions of acupressure three times a week for 5 weeks, either immediately before or after dialysis. The control group (n = 30) received no other treatment. Between the acupuncture and control groups, significant differences in mean pruritus scores at 6, 12 and 18 weeks after baseline were found, with the acupressure group having lower scores ($p < 0.0001$).

Acupressure is believed to be quite safe as it is a non-invasive procedure that does not involve needle insertion. Some clinicians may choose to consider it in treatment in their patients with uremic pruritus.

Thermal Therapy

A RCT that employed convenience sampling [147] compared the effectiveness of thermal therapy to non-thermal therapy on uremic pruritus and biochemical parameters in 49 hemodialysis patients. For various reasons, 8 patients (thermal group = 3, non-thermal group = 5) dropped out of the study, leaving 41 patients. The intervention group (n = 21) was treated with 40 °C thermal therapy with far infrared rays, a type of electromagnetic wave with a wavelength of 4 ~ 1000 μm [147], at the Sanyinjiao (SP6) acupoint once a day for 15 min on 2 days a week for a total of 18 sessions. The control group (n = 20) had a plain adhesive patch placed on the same acupoint plus routine care. Uremic pruritus improved in both groups, with a larger decrease in pruritus scores in the thermal group ($p < 0.001$) as compared with the non-thermal group. There was, however, no difference in pruritus scores between the two groups. No side effects related to the intervention were observed. The effectiveness of thermal therapy for uremic pruritus treatment warrants further investigation.

Homeopathy

Homeopathy is the use of substances that cause a particular symptom (e.g., rash) in healthy individuals to treat unwell patients with the same symptom (e.g., "like cures like"), with the belief that progressive dilution of the substance strengthens the remedy. Cavalcanti et a1 [148] performed an RCT to evaluate the effect of individualized homeopathic treatment on uremic pruritus in 20 adults from 5 dialysis centres. The experimental group (n = 11) received a homeopathic treatment and the control group (n = 9) were given placebo. All patients were assessed individually by a homeopath that was free to change the prescription based on reassessments of the patients after treatment had begun. During the study, 40 homeopathic medications were prescribed and each patient in the homeopathic group received more than one type of homeopathic remedy. At each point of observation, that is after 15, 30, 45, and 60 days of follow-up, pruritus scores were found to have decreased significantly ($p < 0.05$) in the treatment group. However, at the end of the study, post-treatment pruritus scores between the two groups were not significantly different. The authors concluded that homeopathy may be a valuable option in relieving uremic pruritus.

Side effects associated with homeopathy are generally rare and not severe. Some side-effects reported include allergic reactions and symptom aggravation [149].

Aromatherapy

A pre and post-clinical study [150] using convenience sampling assessed the effect of aromatherapy on pruritus relief in 24 adult patients receiving hemodialysis. Over a 2-week period, participants received 6 sessions of 7 min of hand massage in the non-fistulated hand with 3–5 ml of lavender, mint, and tea tree oils at 5% concentration. Four patients withdrew from the study; two objected to the oil odor, one had incontinence linked to the greasy oil sensation, and one patient was lost to follow-up. In the twenty patients that completed the study, the average pruritus score decreased significantly from 7.40 (1.18) at pre-intervention to 5.85 (1.69) at post-intervention ($t = 5.43$, $p < 0.001$), suggesting that aromatherapy can significantly relieve pruritus in hemodialysis patients.

A previous study also showed positive results when using aromatherapy and massage for the treatment of uremic pruritus in 29 adult dialysis patients [151]. Patients in the experimental group (n = 13) received aromatherapy (lavender or tea tree oil) using massage 3 times a week for 4 weeks. The control group (n = 16) received no treatment. In the experimental group, the mean pruritus score decreased significantly from 5.69 (*SD* = 1.25) before treatment to 2.69 (*SD* = 1.03) after treatment ($p < 0.001$). Pruritus scores were significantly lower in the experimental group vs. the control group ($t = 6.60$, $p = 0.001$) after the treatment period. The investigators suggested that the massage component of the aromatherapy may have confounded the findings and recommended future studies also provide massage to the control group.

Some aromatherapy oils have been linked to adverse effects such headache, nausea, and allergic reactions [12]. Although aromatherapy was found to be useful in the studies discussed with mild adverse effects, generalization and application of this therapy for uremic pruritus still requires further investigation using better designed studies with larger sample sizes and longer follow-up periods.

Chinese Herbal Bath Therapy

A meta-analysis [152] of 17 RCTs (N = 970; study sample size ranged from 24 to 156 adult patients) assessed the efficacy of Chinese herbal bath therapy (CHBT) in the treatment of uremic pruritus in adult hemodialysis (HD) patients. In CHBT, decoction or extract of Chinese medicine is poured into warm water and then patients bathe in it [152]. Patients in the treatment group bathed in baths that included 11 Chinese herbs for a period ranging between 2 weeks and 3 months (mean = 4.7 weeks). During the same time period, the control group used standard medical treatment alone or in combination with sham CHBT, clean hot water bath, or calamine lotion. At the end of the treatment period, the outcomes measures were pruritus level (measured using the VAS or the symptom score scale) and the total effective rate. None of the RCTs mentioned adverse events. CHBT plus basic treatment significantly ($p < 0.00001$) reduce the VAS score (MD = −2.38; 95% confidence intervals [CI], −3.02 to −1.74) and the symptom score (MD = −8.42; 95% confidence intervals [CI], −12.47 to −4.36) and had a higher total effectiveness rate (risk ratio [RR] = 1.46; 95% CI, 1.31 to 1.63). The authors noted that the quality of RCTs was poor to moderate. The majority of studies suffered from unclear randomization and concealment, lack of blinding and selective reporting [152].

Although findings suggest CHBT improves pruritic symptoms in individuals with uremic pruritus further investigation, with better designed (large sample size, randomization) studies is warranted to determine efficacy and safety.

End Stage-Renal Disease (ESKD)

Studies have investigated the efficacy of complementary therapies such as O3FA, acupuncture and acupressure, in reducing fatigue and depression and improving the quality of sleep and life among adult patients with ESKD. The findings from these studies suggest some positive effects and warrant further examination in pediatric populations.

O3FA

A multi-center clinical trial conducted in Iran investigated the efficacy of O3FA on inflammatory markers, namely C-reactive protein and tumor necrosis factor-alfa (TNF-α), in 45 patients with ESKD (aged 15–63 years) [82]. For 2 months, study participants received 3 g of O3FA per day (1 g omega-3 Pearl 3 times a day). Nine patients withdrew from the study: 5 for personal reasons; 2 underwent kidney transplantation and one died. After 2 months, TNF-α serum levels decreased significantly from 6.91 ± 15.25 to 2.35 ± 8.02, $p = 0.038$ among the 37 patients who completed the study. Adverse effects associated with O3FA included nausea, diarrhea and an unfavorable smell. The authors concluded that O3FA has a positive effect in reducing inflammatory markers in ESKD patients, but acknowl-

edged that a larger study with a longer duration of treatment was needed. Future studies would benefit from the addition of a control group, randomization, and blinding.

Acupressure

A recent double blind RCT conducted in two hospitals in Iran found that acupressure in conjunction with routine care improves the sleep quality of ESKD adult patients [153]. Over 4 weeks, patients in the intervention group (n = 22) received routine care and acupressure on the Shenmen (He7) and He Gu (Li4) points in the hands and Sanyingjao (sp6) point in the feet, while the control group (n = 22) received routine care only. After the intervention, significant differences between the acupressure group and the control group were recorded for the global Pittsburgh Sleep Quality Index score ($p < 0.001$) and all sleep quality indices: subjective sleep quality ($p < 0.001$), sleep latency ($p < 0.001$), sleep duration ($p < 0.001$), sleep efficiency ($p = 0.006$), sleep disturbance ($p < 0.001$), the use of sleeping medication ($p = 0.028$), and daytime dysfunction ($p < 0.001$). Although these preliminary findings support the effectiveness of acupressure in improving sleep quality in ESKD adult patients, the study was small and would benefit from replication.

Kim et al. [154] conducted a systematic review of the evidence from 7 RCTs of acupressure in the management of symptoms in patients with ESKD. In the studies, acupressure was used to alleviate sleep disorder, muscle cramps, uremic pruritus, fatigue, and depression experienced by ESKD patients. Acupressure treatment was compared to usual care (n = 3), sham acupressure (n = 2), transcutaneous electrical stimulation (n = 1), sleep medication (n = 1) or an undefined control (n = 1). Across 6 RCTs the follow-up period ranged between 4–18 weeks from baseline, while in one study only the immediate effects of acupressure were reported. Although in 5 trials there were some suggested benefits of acupressure compared to usual care (n = 3), sleep medication (n = 1), and undefined control intervention (n = 1), the authors could not draw any definitive conclusions regarding the efficacy of acupuncture until larger trials with clearer methodology and better reporting were conducted. None of the studies included in the review reported any adverse events. Six of the 7 trials included in the systematic review will be briefly described. One trial which evaluated acupressure for uremic pruritus was described in an earlier section of this chapter.

Dai and associates [155] investigated the therapeutic effect of lower extremity point massage for improving quality of sleep in 82 ESKD patients with sleep disorders. Patients in the treatment group (n = 42) received 20 to 30 min lower extremity point massage, once a day, for 4 weeks. During the same time period, patients in the control group (n = 40) took 1 mg of estazolam tablets orally half an hour before sleep. Patients who received acupressure reported significantly better sleep quality and lower rates of sleep disturbance-related disorders than patients in the control group.

A double-blind RCT by Tsay et al. [156] allocated 105 adult ESKD patients experiencing sleep disturbances to either receive manual acupressure (n = 35), placebo (n = 32), or control (n = 31). The acupressure group received 14 min of acupoint massage during hemodialysis three times a week for 4 weeks. The placebo group received sham acupressure, which involved massage on non-acupoints 1 cm from the meridian, at the same frequency and duration as the acupressure group. The control group received only standard care. Sleep quality and quality of life scores as measured by the Pittsburgh Sleep Quality Index in the acupressure group were significantly improved compared to the usual care (control) group, but not when compared to the placebo (sham acupressure) group.

Tsay et al. [157] conducted another RCT, this time to examine the effect of acupressure, transcutaneous electrical acupoint stimulation (TEAS) and routine care on sleep quality, depression and fatigue in 108 adult patients with ESKD. Over 4 weeks, patients in the acupressure (n = 36) and TEAS group (n = 36) received manual acupressure for 20 min 3 times weekly plus usual care for a total of 12 sessions. The control group received usual care only. Sleep quality,

fatigue and depression were significantly improved in the acupressure and TEAS group compared to the control group. No differences were observed between the acupressure and the TEAS group.

In yet another study, Tsay [158] compared the effect of acupressure, placebo and control on fatigue in 106 ESKD patients. Patients in the acupressure group (n = 35) received acupressure massage 3 times a week for 4 weeks, and the placebo group (n = 35) received a massage at locations with no acupoints at the same frequency as the acupressure group. The control group (n = 36) received no intervention. Patients in the acupressure group had significantly lower scores of fatigue than patients in the control group, but no difference was observed between the acupressure and placebo group. The authors concluded that acupressure provided an alternative method for health care providers to use to manage ESKD patients with fatigue.

A smaller study also found positive effects of acupressure on fatigue and depression in 58 hemodialysis patients [159]. Over a 4-week period, patients either received 12 min of acupressure (n = 28) plus 3 min of lower limb massage three times a week or routine care (n = 30; control group). After the 4-week study period, fatigue ($p = 0.04$) and depression ($p = 0.045$) were significantly improved among patients that received acupressure compared to patients who received routine care (control). The authors noted that the lack of a sham acupressure group meant that a placebo effect could not be ruled out.

Another study included in the review was a small RCT which examined the effects of acupressure plus routine care (n = 23) or routine care alone (control; n = 21) on pain associated with muscle leg cramps in 44 hemodialysis patients [160]. Routine care included stopping ultrafiltration and providing hypertonic solution. Patients in the acupressure group received acupressure at acupoints for 1 to 2 min. The rate of treatment response (pain resolving time ≤ 8 min) was significantly ($p < 0.01$) greater among the acupressure group compared to the control group.

Summary

A substantive body of evidence regarding the use, efficacy and safety of complementary therapies exists and is growing. This chapter examined current research evidence on interventions used to prevent or treat symptoms associated with kidney conditions with a specific focus on pediatric patients. The information provided allows for better informed discussions between medical/health care providers and patients or families with an interest in using complementary therapies for their children. The information provided can be used as a guide or resource by pediatric health care providers as they treat patients with kidney disease and consider seeking and referring patients to relevant local qualified complementary therapists.

Environmental Nephrotoxins

73

Jie Ding and Ruth A. Etzel

There are a large number of environmental chemicals that are potentially toxic to the kidneys [1]. Children may be exposed to these chemicals in toys, consumer products, household pesticides, and as contaminants of food and drink. This chapter will provide information about some of the chemicals that the pediatrician should consider when a child presents with renal injury of unknown etiology. In order to determine the possibility of exposure to nephrotoxic chemicals, a careful environmental history should be performed as part of the complete history and physical examination [2, 3]. Table 73.1 lists agents that should be considered in the environmental history. Table 73.2 shows the most likely site of renal injury for selected toxicants [4].

Table 73.1 Environmental toxicants and renal dysfunction

Ammonia	Acute nephrotoxicity, oliguria, hematuria
Arsenic	Cortical necrosis, hematuria, leukocyturia, glucosuria
Barium	Renal insufficiency, hemoglobinuria, degeneration of kidney, acute renal failure
Cadmium	Acute renal failure, necrosis of tubular cells, Fanconi syndrome
Carbon tetrachloride	Acute renal failure, aminoaciduria, oliguria
Chloromethane	Albuminuria, proteinuria, anuria, increased serum creatinine and serum BUN
Chromate and chromium (VI)	Necrosis of tubular cells
Copper sulfate	Necrosis of tubular cells
Fluoride	Interstitial nephritis
Lead	Chronic nephropathy, Fanconi syndrome, renal insufficiency
Methyl parathion	Acute nephrotoxicity
Mercury	Glomerular dysfunction, acute nephritic syndrome
Naphthalene	Tubular necrosis, oliguria, anuria, proteinuria, hemoglobinuria, increased serum creatinine and serum BUN
Pentachlorophenol	Renal tubular degeneration, metabolic imbalance
Thallium	Proteinuria, decreased creatinine clearance, increased blood urea
Uranium	Chronic nephritis, renal sclerosis
1,2 dibromomethane	Acute nephrotoxicity
1,2 dichloromethane	Acute nephrotoxicity
1,2 dichloropropane	Acute nephrotoxicity

Cadmium

Cadmium is nephrotoxic [5]. Cadmium has a biological half-life of 10–30 years in humans. At birth, cadmium is present only at very low levels, but the whole-body cadmium burden can reach 20–30 mg by the age of 50 years and in people with occupational exposure it can reach 200–300 mg. Cadmium concentrates in the kidneys. Increased proteinuria is the earliest sign of cadmium nephropathy. A study of children 6–17 years of age living near a previous zinc smelter in Pennsylvania showed that urine concentrations of *N*-acetyl-β-D-glucosaminidase, alanine aminopeptidase and albumin were positively associated with the children's urine cadmium concentrations, but the findings did not remain statistically significant after adjusting for urinary creatinine and other potential confounders [6]. Food is the major source of cadmium for children. A study in France showed that a high proportion of children exceeded the tolerable weekly intake of cadmium in the diet during the first 3 years of childhood [7]. A study in Mexico documented an association between early-life dietary cadmium exposure and kidney function in 9-year-old children [8]. Cadmium is estimated to contribute, along with other metals, to the global burden of foodborne disease [9]. Children may also be exposed to cadmium by drinking water, inhalation of cadmium-containing particles from ambient air or cigarette smoke, ingestion of contaminated soil and dust, or use of inexpensive metal jewelry containing cadmium [10, 11].

The primary route of excretion is through the urine. The rate of excretion is low, in part because cadmium binds tightly to metallothionein, a transport and storage protein synthesized in response to cadmium and zinc exposure, preventing excretion into the tubules. In addition, the majority of filtered cadmium is reabsorbed in the renal tubules.

Clinical Effects

Acute and Short-Term Effects

Large oral exposure can produce renal toxicity. A tragic episode of industrial dumping of cadmium into the environment occurred in the Jinzu and Kakehashi river basins in Japan, leading to contamination of locally grown rice. This event produced widespread human exposure and a syndrome of renal disease coupled with brittle bones referred to as "Itai-itai" (ouch-ouch) disease. The disease was particularly common among women [12, 13], perhaps because of their higher prevalence of iron deficiency and, therefore, greater cadmium absorption.

Chronic Toxicity

Cadmium is well recognized as a toxicant in occupational exposures. Chronic occupational exposures most commonly produce renal toxicity; microproteinuria is one of the earliest signs.

Epidemiological studies among people living in cadmium-polluted areas of Japan have documented that ß2-microglobulinuria regularly occurs following a lifetime accumulation of 2000 mg cadmium or more [14]. Cui et al. reported early renal effects from cadmium exposure in children and adults living in the tungsten-molybdenum mining areas of South China [15]. Kidney damage also may occur at lower levels of cadmium; a study by Wang et al. in China suggested that adverse tubular renal effects (increased levels of *N*-acetyl-β-D-glucosaminidase and β2-microglobulin) occur in children even at the current low cadmium levels in the Chinese general population [16].

Diagnosis

While the cadmium concentration in blood reflects recent exposure, urinary cadmium concentration more closely reflects total body burden because cadmium accumulates in the kidney and is considered the gold standard measure of cumulative exposure. Twenty-four–hour urine collections are standard, but spot urine measures in conjunction with urinary creatinine to adjust for urine volume can also be used to assess exposure. However, the kidney is also a prime target of cadmium toxicity, and if renal damage from cadmium exposure occurs, the excretion rate may increase sharply and urinary

cadmium concentrations will no longer reflect body burden.

In adults, 24-h urinary cadmium excretion should be <10 μg/g of creatinine. There is no child-specific standard. On the basis of data from the National Health and Nutrition Examination Survey, the geometric mean urinary cadmium concentration in children 6–11 years of age is 0.075 μg/L per gram of creatinine. From occupational monitoring studies, the first signs of renal abnormalities in adults typically occur at 2 μg/g of creatinine and include microproteinuria—in particular, β_2-microglobulin and α_1-microglobulin are spilled. At urinary cadmium concentrations of 4 μg/g of creatinine, enzymes such as *N*-acetyl-B-glucosaminidase (NAG) are found in urine; signs of more significant glomerular damage (such as albumin in the urine and decreases in glomerular filtration rate) are seen. In the final stages of cadmium nephropathy, glycosuria, wasting of calcium and phosphate, and altered calcium metabolism are seen [17].

Prevention of Exposure

There is no effective treatment for cadmium toxicity or exposure, thus prevention of exposure is important. Chelation therapy has been shown to mobilize tissue cadmium and increase renal cadmium concentrations, increasing renal toxicity. Children younger than 6 years should not be given or allowed to play with inexpensive metal jewelry. Cadmium should also not be used in consumer products unless absolutely necessary, particularly not in products designed to be used by or with children. Reducing children's exposure to secondhand smoke has obvious health benefits beyond reducing cadmium exposure. Consumption of liver and kidney from exposed animals are potential sources of high dietary cadmium. Exposure to environmental cadmium can be prevented by reducing environmental levels in soil, in water used to irrigate food crops, and by reducing drinking water levels of cadmium. Cadmium concentrations in drinking water supplies are typically less than 1 μg/L (1 part per billion).

Lead

Exposure to high levels of lead causes kidney damage. Children may be exposed to lead in a variety of ways in and near their homes [18]. Studies of adolescents working in auto shops in low and middle income countries and children living near lead smelters have documented significant increases in urinary biomarkers of kidney tubular dysfunction such as *N*-acetyl-β-D-glucosaminidase, retinol binding protein, and α-1-microglobulin [19–23].

Chronic exposures to low levels of lead also cause proximal tubular injury characterized by proximal tubule nuclear inclusion bodies that progresses to tubulo-interstitial disease and fibrosis. Lead accumulation eventually results in decreased renal clearance, tubular reabsorption and glomerular filtration rate [24]. The association between blood lead and lower estimated GFRs has been documented in a representative sample of US adolescents who participated in the third National Health and Nutrition Examination Survey (1988–1994). More than 99% of the adolescents had blood lead levels below 10 μg/dL. Adolescents with lead in the highest quartile (>3 μg/dL) had 6.6 mL/min/1.73 m^2 lower estimated GFR compared to those in the first quartile (<1 μg/dL) [25].

Diagnosis

The exposure history is essential to making a diagnosis of lead poisoning. When taking the history of exposure, it is important to document the occupation and hobbies of the parents and all home occupants, age of the home, and use of ceramic dishes and fold medicines. Essential questions in the environmental history are shown in Table 73.3. The physical examination should include careful evaluation and documentation of hearing, language, and other developmental milestones. It is rare to see a purplish line on the gums (lead line), but if present it usually indicates severe and prolonged lead poison-

Table 73.3 The Environmental History—focus on lead

When obtaining the environmental history of a child with suspected lead poisoning, the following questions and actions should be included:
• What is the age and general condition of the residence or other structure (school) in which the child spends time?
• Is there evidence of chewed or peeling paint on woodwork, furniture or toys?
• How long has the family lived in that residence?
• Have there been recent renovations or repairs to the house or building?
• Are the windows new?
• Are there other sites at which the child spends significant amounts of time?
• What is the condition or composition of indoor play areas?
• Do outdoor play areas contain bare soil that may be contaminated?
• How does the family attempt to control dust and dirt?
• Does smoke or dust come from external sources close to the building?
• Are there any point sources near the home, such as smelters, metallurgic industries, battery recycling activity (even inactive) or open burning of waste?
• What was the previous use of the land before the building was constructed?
• To what degree does the child exhibit hand-to-mouth activity?
• Does the child exhibit pica?
• Are the child's hands washed before meals and snacks?
• Has anyone in the household ever had lead poisoning?
• What are the occupations of adult household members?
• Are the clothes and shoes used for working activities brought into the house or washed with the home laundry?
• Is the family or any member of the family involved in scavenger activities?
• Is there any work done with lead—For example, car battery recycling, radiator repairs or recuperation of metals—In or around the home?
• What are the hobbies of household members? For example, do they include fishing and preparing weights, working with ceramics or stained glass, hunting and preparing shots for guns, or handicraft activities that use tin or lead solders?
• Are painted materials or waste materials burned in household fireplaces or used as combustibles?
• Are there any local idiosyncratic sources or uses of lead?
• Does the child receive or have access to imported food, food of unsecure origin, cosmetics or folk remedies?
• Is food prepared or stored in glazed pottery or metal vessels?
• Does the family use foods stored in soldered cans?

ing [26]. The best index of exposure is a measurement of blood lead concentration [26]. Suggested laboratory tests to evaluate lead poisoning include a blood lead concentration, CBC with peripheral smear, BUN and creatinine level, and urinanalysis (looking for proteinuria, glucosuria, and aminoaciduria, seen in acute poisoning). In 2012 the US Centers for Disease Control and Prevention defined a reference level of 5 μg/dL to identify children with exposure to lead [27].

Management

Management of lead poisoning includes finding and eliminating the source of the lead, instructing the parents in proper hygienic measures (personal and household), and following up closely. Assessing the nutritional status of the child is important because iron and calcium deficiencies enhance the absorption of lead and aggravate pica [26]. Because most children in the United States with higher blood lead concentrations live in or frequently visit a home with lead paint, successful therapy depends on eliminating the child's exposure. Management that does not control environmental exposure to lead is inadequate. A thorough investigation of the child's environment and family lifestyle for sources of lead should be undertaken.

Deteriorated lead paint is the most common source of exposure in the United States. Other sources that should be considered include table-

ware, cosmetics such as surma and kohl, home remedies, dietary supplements of calcium, tap water, and parental occupation. Some children have elevated blood lead levels without access to lead paint. Blood lead levels should fall after the child reaches 2 years of age, and a stable or increasing blood lead level after that age is likely to be due to ongoing exposure. Specific attention should be paid to treating iron deficiency and ensuring adequate calcium and zinc intake.

Chelation therapy for children with blood lead levels of 20–44 μg/dL may reduce blood lead concentrations but has not been documented to reverse or diminish cognitive impairment or other behavioral or neuropsychological effects of lead [28]. If the blood lead level is greater than 45 μg/dL and the exposure has been controlled, treatment should begin. A pediatrician experienced in managing children with lead poisoning should be consulted [29].

Mercury

Mercuric salts are usually colorless or white crystals or intensely colored yellow or red powders; they include mercuric oxide (antiseptic and disinfecctant), mercuric cyanide and mercuric oxide (topical antiseptics), and mercuric nitrate (used in working with felt). Mercurous salts are typically colorless, white or light yellow powders; they include mercurous acetate (antibacterial agent), mercurous chloride or calomel (cathartic, diuretic, antiseptic, and antisyphilitic agent), mercurous nitrate (used to blacken brass) and mercurous oxide (used to make electrical batteries) [30].

Children may be exposed to mercury through uses of mercury compounds at home or in school, or in working environments such as small scale artisanal gold mining [31]. Residents in the gold mining communities and downstream of the gold mining communities consume fish that may be heavily contaminated with methylmercury, and it impacts their kidney function [32]. Mercury is used in skin-lightening creams, Chinese traditional medicine (especially for rheumatoid arthritis), and hair-dyeing agents. In a study of 509 infants exposed to phenylmercury fungicide on cloth diapers [33] urinary excretion of gamma-glutamyl-transpeptidase increased in a dose-dependent manner when urinary mercury exceeded approximately 220 μg/L. This effect was completely reversible and was no longer detectable when the children were re-examined 2 years later.

Acute mercury poisoning presents with acute tubular necrosis, especially with involvement of the proximmal tubules. Chronic low-dose exposure to mercuric salts or elemental mercury vapor can present with edema, proteinuria and normal renal function. Chronic mercury exposure can induce an immunological form of glomerular disease. This form of mercury injury to the kidney is a common form of mercury-induced nephropathy [34–36]. Findings of this membranous nephropathy may include thickened glomerular basement membrane and mildly proliferative mesangial cells and deposits of IgG1 subclasses along the glomerular capillary loops [37].

Diagnosis

The exposure history is essential to making a diagnosis of mercury poisoning. When taking the history of exposure, it is important to document the occupation and hobbies of all home occupants, use of medicines, folk remedies and antiseptics. Essential questions in the environmental history are shown in Table 73.4. A 24 h urine specimen collected in an acid-washed plastic container is appropriate for patients who have been chronically exposed to elemental mercury or mercury salts. A first morning void can provide a close approximation of a 24-h collection, particularly if it is adjusted for the concentration of the urine (using the amount of creatinine present).

A urine mercury concentration of less than 8 μg/L in adults is considered background [37]. Urinary mercury concentrations from 12 to 100 μg/L are associated with subtle changes on some tests, even before overt symptoms occur. Background or toxic urinary mercury concentrations have not been determined for children [30].

Table 73.4 The Environmental History—focus on mercury

When obtaining the environmental history of a child with suspected mercury exposure, the following questions and actions should be included:
• What are the occupations and hobbies of adult household members?
• Has there been recent application of mercury-containing caulks, latex paints, and other materials in constructing or renovating homes and other buildings?
• Has there been recent use of folk medicines? (these may contain mercury compounds.)
• Has there been a recent move? (previous tenants may have spilled mercury.)
• Has there been recent use of cosmetics containing mercury? (mercury is contained in some mascaras and wave fixatives and some skin lighteners sold outside the US.)
• Has there been use of over-the-counter preparations such as nasal sprays, contact lens solutions, and topical antiseptics?
• Has there been use of elemental mercury in a school laboratory?
• Has the child been playing with mercury? (children are attracted to elemental mercury because of its unique properties.)

Management

Proper management includes finding and eliminating the source of the mercury. When a patient has ingested mercury salts, the goals of therapy are to remove mercury from the body and to prevent dehydration and shock. Inorganic mercury can be removed from the gastrointestinal tract by emesis, catharsis or lavage. It is imperative that adequate intravenous fluids be administered to prevent dehydration and to reduce the concentration of mercury in the kidneys. BAL or another appropriate chelating agent should be administered immediately; its usefulness depends on rapid administration [30].

Prognosis

If mercury exposure ceases, complete remission is expected [37].

Uranium

Exposure to uranium can damage the proximal tubules of the kidney [38]. A case series described a family in Connecticut, who discovered that their private well was contaminated with naturally occurring uranium. Twenty four hour measurements of urine uranium were obtained on all 7 family members, but only the youngest child (age 3) had an elevated β-2-microglobulin excretion rate [39]. They had lived in the house for the previous 5 years, and the 3-year-old had derived a major portion of her nutritional intake from infant formula that was prepared by mixing powdered formulas with contaminated well water. Soil and water can also become contaminated from depleted uranium in areas where armed conflict has occurred.

Diagnosis

The exposure history is essential to making a diagnosis of uranium poisoning. When taking the history of exposure, it is important to document the source of the family's water. If the child lives in an area where armed conflict has occurred, the physician should inquire if children play in areas where depleted uranium penetrators have impacted, if children have ingested heavily contaminated soil, and if a buried penetrator feeds uranium directly into a well. Environmental movement of depleted uranium from buried penetrators into local water supplies is likely to be very slow. Over decades levels of uranium could increase in local water supplies [40].

Urine analysis for uranium is the best test to determine whether a patient has been exposed to large amounts of uranium.

Management

Because well water used for drinking or to reconstitute infant formula may be contaminated with uranium, families who use well water should consider having the water tested. Most large municipal water supplies maintain uranium levels less than the U.S. EPA maximum contaminant level of 30 μg/L.

Table 73.5 Characteristic renal manifestations of exposure to selected pesticides

Manifestation	Characteristic of these poisonings	Occurs with these agents
Proteinuria	Inorganic arsenicals	Cadmium compounds
Hematuria	Copper compounds	Phosphorous
Sometimes leading	Sodium fluoride	Phosphides
To oliguria	Naphthalene	Phosphine
Acute renal failure	Borate	Chlorophenoxy compounds
With azotemia	Nitrophenols	Creosote
	Pentachlorophenol	Organotin compounds
	Sodium chlorate	
	Sulfuryl fluoride	
	Paraquat	
	Diquat	
	Arsine	
	Ethylene dibromide	
Dysuria, hematuria, pyuria	Chlordimeform	
Polyuria	Cholecalciferol	Fluoride
Hemoglobinuria	Naphthalene	
	Sodium chlorate	
	Arsine	
Wine-red urine (porphyrinuria)	Hexachlorobenzene	
Smoky urine	Creosote	
Glycosuria		Organotin compounds

Pesticides

Many pesticides are toxic to the kidney; pesticides such as paraquat and diquat are particularly toxic [41]. Paraquat and diquat are bipyridyl herbicides that are widely used, primarily in agriculture and by government agencies and industries for control of weeds [42].

When humans are exposed to these herbicides the proximal convoluted tubules show vacuolation and cell necroses [43, 44]. Proteinuria, hematuria, glucosuria or all of the features of the Fanconi syndrome may occur. Severely poisoned patients develop acute oliguric renal failure. Characteristic manifestations of poisoning with other pesticides are shown in Table 73.5.

Diagnosis

Pesticide poisonings may go unrecognized because of the failure to take a proper exposure history. The exposure history is essential to making a diagnosis. When taking the history of exposure, it is important to document the location of the family's home and the occupation and hobbies of all home occupants. Essential questions in the environmental history are shown in Table 73.6.

Table 73.6 Environmental History—focus on pesticides

When obtaining the environmental history of a child with suspected exposure to pesticides, the following questions and actions should be included:
• Are pesticides (e.g., bug or weed killers, flea and tick sprays, collars, powders, or shampoos) used in your home or garden or on your pet?
• Has anyone in the family worked with pesticides that they might have brought home?
• Does parent or any household member have a hobby with exposure to pesticides?
• Has the patient ever lived near a facility which could have contaminated the surrounding area (plant, dump site)?
• Does the patient's drinking water come from a private well, city water supply and/or grocery store?
• If pesticides are used:
– Is a licensed pesticide applicator used?
– Are children allowed to play in areas recently treated with pesticides?
– Where are the pesticides stored?
– Is food handled properly (e.g., washing of raw fruits and vegetables)?

Management

If poisoning with paraquat or diquat is suspected based on the environmental history, a simple colorimetric test can be used to identify paraquat and diquat in the urine, and to give a rough indication of the magnitude of absorbed dose [42]. To one volume of urine add 0.5 volume of freshly prepared 1% sodium dithionate (sodium hydrosulfite) in 1-normal sodium hydroxide (1.0 N NaOH). Observe color at the end of 1 min. A blue color indicates the presence of paraquat in excess of 0.5 mg/L. Both positive and negative controls should be run to ensure that the dithionate has not undergone oxidation in storage [42]. Diquat in urine yields a green color with the dithionate test. Both paraquat and diquat can also be measured in blood and urine [42]. Treatment should be managed in conjunction with a pediatric toxicologist, and includes immediate gastrointestinal decontamination with an adsorbent such as activated charcoal, Bentonite, or Fuller's Earth (2 gm/kg for children under 12 years.)

Arsenic

Arsenic has been classified as a known human carcinogen [10]. Children's most common exposure to arsenic is from contaminated drinking water. Other major sources of children's exposure are foods including rice, organic rice syrup, other grains, fruits, and juices [45].

Chronic exposure to arsenic is associated, in a dose-related fashion, with an increased risk of bladder cancer [10, 46–53]. Arsenic also has been associated with an excess risk of cancers of the kidney [10, 54–56]. The chronic consumption of water contaminated with arsenic in a concentration of 500 parts per million is associated with an estimated risk of 1 in 10 people developing bladder cancer. At a concentration of 50 parts per billion (ppb), cancer mortality is estimated to be in the range of 0.6 to 1.5 per 100, or approximately 1 in 100. At 10 ppb, the US Environmental Protection Agency drinking water standard since 2006, the risk of bladder cancer is 1–3 per 1000 [57].

Infancy and childhood appear to be susceptible periods during which exposure to arsenic can have lasting effects [58]. Exposure to arsenic during pregnancy and childhood is associated with a greater risk of increased occurrence of kidney cancer than exposure during adulthood [59].

Diagnosis

The exposure history is essential to making a diagnosis of arsenic poisoning. When taking the history of exposure, it is important to document the source of the family's water.

Management

Because well water used for drinking or to reconstitute infant formula may be contaminated with arsenic, families who use well water should consider having the water tested. Most large municipal water supplies maintain arsenic levels less than the EPA standard of 0.010 mg/L.

Ochratoxin A

Exposures to certain ochratoxins can cause kidney damage. Ochratoxins are natural toxins produced by fungi including *Aspergillus ochraceus*, *Aspergillus ostianus*, and *Penicillium verrucosum* that grow on cereal grains (barley, oats, rye, corn and wheat) and contaminate foods and drinks such as milk powder, coffee, wine and beer [60]. Ochratoxin A is a potent nephrotoxin [61]. Outbreaks of **Balkan nephropathy**, a fatal, chronic renal disease occurring in limited areas of Bulgaria, the former Yugoslavia, and Romania, have been linked with exposure to ochratoxin A [62–65]. Levels of ochratoxin A are elevated in the blood of patients with Balkan nephropathy [66].

In the United States, ochratoxin exposure is highest in infants and young children who consume large amounts of oat-based cereals [67]. Infants may also be exposed through breast milk if the mother has consumed foods contaminated with ochratoxin [68, 69].

Although the primary route of children's exposure to ochratoxin has previously been assumed to be through ingestion, there is grow-

ing evidence that inhalation can be an important route of exposure [70]. A case report linked exposure to ochratoxin A to focal segmental glomerulosclerosis in a 5-year-old girl who was diagnosed after presenting with enuresis. The child had a significantly elevated urine concentration of ochratoxin A (9.1 parts per billion (limit of detection 2.0 parts per billion). She probably had been exposed to ochratoxin from a home environment that was water damaged and moldy [71].

Apart from its nephrotoxicity, chronic exposure to ochratoxin A is associated with tumors of the upper urinary tract in adults. In view of substantial evidence from animal experiments supporting the carcinogenicity of ochratoxin A, the substance is categorized as possibly carcinogenic to humans (Group 2B) [66].

Diagnosis

The exposure history is essential to making a diagnosis of kidney damage from ochratoxin. When taking the history of exposure, it is important to collect a dietary history and to carefully document the condition of the home environment, with special attention to a history of the child's exposure to water damaged and moldy indoor areas.

Management

Investigations are ongoing to study the use of aspartame, a structural analogue of ochratoxin A and phenylalanine, in preventing the toxic effects of ochratoxin A exposure on the kidneys [72]. Aspartame competitively prevents the binding of ochratoxin to serum albumin. Investigations are also being conducted to study ways to reduce the genotoxic effects of ochratoxin. The quantity of DNA adducts that are induced by ochratoxin A in animals can be reduced dramatically by pretreatment of the animals with aspirin and indomethacin, which inhibit prostaglandin H synthase [73].

Aristolochic Acid

Aristolochic acids belong to the *Aristolochia* genus of plants which are often used as herbal medicines [74]. The kidney injury caused by aristolochic acids was identified from a group of women who used the herbal weight-loss regimen *Guang Fang Ji*, which contains aristolochic acid [75]. The kidney disease caused by exposure to aristolochic acids is now formally termed **aristolochic acid nephropathy**. Cases of aristolochic acid nephropathy have been reported in Europe [76–81], the United States [82] Australia [83], Japan [84], Korea [85], China [86, 87], Taiwan [86], and Hong Kong [88]. In addition, some cases of Balkan endemic nephropathy have documented exposure to aristolochic acid [89]. In the area close to tributaries of the Danube River in Bosnia, Bulgaria, Croatia, Romania, and Serbia there is a weed, *A. Clematitis.* Seeds of this weed contain aristolochic acid. The contamination of wheat flour with the seed has been associated with some cases of Balkan endemic nephropathy. Many studies show an association between the exposure with high- dose and/or long-lasting aristolochic acid exposure and kidney disease as well as urothelial cancer. The mechanism for aristolochic acid nephropathy might be apoptosis in tubular cells, whereas the urothelial cancer might be caused by DNA adducts [90].

Diagnosis

There is no specific diagnostic feature for aristolochic acid nephropathy. However, a clinical inquiry for the possible use of herbal medicines containing aristolochic acid should be taken in patients with unexplained progressive decline in glomerular filtration rate.

Patients with aristolochic acid nephropathy usually have proximal tubular dysfunction, such as glycosuria and low molecular weight proteinuria. Urinalysis reveals few erythrocytes and leukocytes, and mild proteinuria. Anemia often is unusually prominent relative to the degree of GFR impairment.

Ultrasonography usually demonstrates contracted kidneys. Unfortunately, there are no defined biomarkers for diagnosing aristolochic acid nephropathy.

Kidney biopsy reveals extensive interstitial fibrosis associated with tubular atrophy and low numbers of chronic inflammatory cells. The most

specific pathologic feature is that injury decreases from the outer to the inner cortex [91–93].

Although no strict criteria for diagnosing aristolochic acid nephropathy are available, a set of criteria allowing the definite, probable and possible diagnosis of aristolochic acid nephropathy has been proposed [94]. A definite diagnosis can be made in the patient with impaired renal function and any 2 of 3 additional findings: renal pathology demonstrating hypocellular fibrosis decreasing from the outer to the inner renal cortex, phytochemical analysis proving the intake of products containing aristolochic acid, or the detection of AA–DNA adducts in renal or urinary tract tissue. If only one of the additional findings is present in patients with impaired renal function together with urothelial cancer at the time of presentation, a probable diagnosis can be made. A possible diagnosis can be made in patients with unexplained renal dysfunction and a history of taking herbal medicines likely containing aristolochic acid.

Management

There are no randomized clinical trials supporting an evidence-based therapeutic strategy. The discontinuation of ingestion of products containing aristolochic acid is certainly essential. A study on steroid treatment for aristolochic acid nephropathy showed significant slowing of progressive renal failure in 12 patients [95].

Melamine

The Chinese Epidemic

In 2008, an epidemic of melamine contamination from formula milk was associated with urinary tract stones in young children in China. Nearly 230,000 children were diagnosed with urinary stones revealed through a targeted screening program. Melamine contamination was detected in 22 commercial brands of formula. The level of melamine in contaminated formula was 2.5 mg/kg in many brands of milk powder, exceeding the estimated tolerable daily intake level (0.063 mg/kg body weight) multifold [96]. It appeared that melamine was added to milk powder to boost the protein content, because melamine is 66% nitrogen by mass.

Non-epidemic Exposures

Melamine is prevalent in the environment and the effects of low-level exposures to children have not been clarified. A study in the US found concentrations of melamine and cyanuric acid in children's urine to be higher than levels reported in children from other countries [97]. Cyanuric acid was associated with increased KIM-1 concentrations, suggesting kidney injury.

Pathogenesis of Renal Injury Induced By Melamine-Related Urinary Stones

Almost all the available data on the toxicology and toxicokinetics was obtained by animal experiments that included dogs, cats, rats and mice. Melamine and cyanuric acid are not metabolized and are eliminated from the kidneys unchanged [98–100]. Crystals form mostly in the distal tubules from melamine and cyanuric acid [101–103].

Kidney injury is thought to be induced by the crystals or via obstruction of urine flow [101–104]. In a study of rats administered a diet containing melamine, stone formation was associated with injury to renal tubular epithelial cells, apoptosis and inflammation [105]. Gut microbiota can convert melamine to cyanuric acid *in vitro*, implicating a role of intestinal microbiota in the pathogenesis of melamine-related renal injury [106].

Clinical Manifestations

Three quarters of the children with urinary stones caused by melamine-contaminated formula in the Chinese epidemic were asymptomatic [107]. A few patients presented with dysuria, hematuria, and unexplained crying when urinating; these patients usually had obstruction caused by urinary stones. A small portion of patients (about 5%) with acute obstructive renal failure caused by melamine-induced urinary stones presented with nausea, vomiting, edema and anuria [108].

Infants were the major victims because of their high exposure to milk powder formula. However, the age at diagnosis of melamine-

associated urinary stones ranged from 1.5 months to 10 years [108]. The incidence of melamine-associated urinary stones was 3.1 times higher in male than in female subjects; the excess risk of males was most marked in boys younger than 1 year of age [109, 110].

Diagnosis

The exposure history is essential to making a diagnosis of melamine-associated urinary stones. When taking the history of exposure, it is important to document the feeding mode, formula brand, duration and amount of daily feeding.

Ultrasonography of the kidneys along with the ureters and the bladder is the first choice to detect stones, hydronephrosis and obstruction caused by melamine-associated calculi [111–113]. The location and number of stones should be reported. Abdominal X-ray and CT urography can be performed if the stone or hydronephrosis cannot be confirmed by ultrasonography [114].

Management

The management of melamine-related urinary stones in the Chinese epidemic included a conservative treatment approach, extracorporeal shock wave lithotripsy and surgical intervention. The decision regarding the approach usually was made by taking into account symptoms, stone size, stone numbers and location, etc. In children with non-obstructive melamin-related stones smaller than 4 mm without serious clinical symptoms, only oral fluid prescription was increased [113]. In case of stones larger than 4 mm, management included infusion of fluids, forced diuresis and urinary alkalization aiming for urine pH between 6.0 and 6.5. A follow-up study after 4 years showed that among 45 children treated conservatively melamine-related urinary stones had disappeared in 34 children, partially discharged in six, were unchanged in four and had grown in size in one child [115]. Hence, the vast majority of children with melamine-related stones without serious clinical symptoms, recovered with time.

Many medical teams opted for extracorporeal shock wave lithotripsy (ESWL) for children with a single melamine-related urinary stone who failed conservative treatment. In a cohort of 189 young children ESWL was performed on stones 3.8–25 mm in size located in the renal pelvis (n = 141), proximal ureter (n = 17), mid ureter (n = 5), or distal ureter (n = 26). Most children (95%) required only one lithotripsy session. During 28 months of follow-up there was not a single case with a severe complication of lithotripsy [116].

Few children (5.6% according to a meta-analysis of 2164 cases) underwent surgical intervention because of failure of conservative treatment or obstructive kidney failure [108]. Surgery included minimally invasive percutaneous nephrolithotomy using ureteroscope and pneumatic intracorporeal lithotripsy, and lithotripsy with cystoscopy or ureteroscopy.

Per- and Polyfluoroalkylated Substances

Per- and polyfluoroalkylated substances (PFAS) are synthetic chemicals that repel both water and fat and are highly heat resistant. These substances are used in many consumer products including stain-repellant fabrics and carpets, food packaging, floor care and cleaning products and personal care products. Their half-life in humans is several years. PFAS are eliminated via the kidneys by tubular excretion. PFAS are suspected to cause cellular and tubular histological changes in the kidneys via oxidative stress, enhanced endothelial permeability and other molecular pathways [117].

Few studies addressed the relationship of PFAS exposure with children's kidney function. A study of children found an eGFR decrease of 0.75 mL/min/1.73 m^2 decrease per quartile increase in per-fluorooctanoic acid (PFOA) concentration [118]. Two pediatric studies linked serum PFA concentrations to high uric acid levels [119, 120]. A study among adolescents and young adults in Taiwan who had abnormal urinalysis found that children with CKD had higher serum PFUA concentrations [121]. Given their renal mode of elimina-

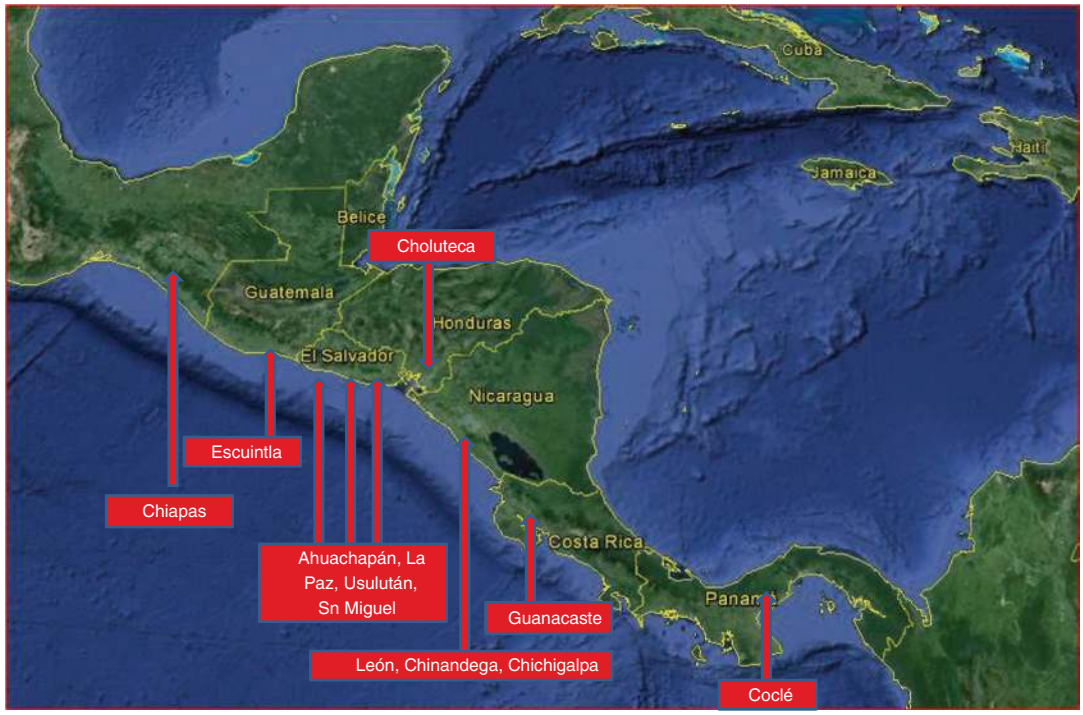

Fig. 73.1 Locations of studies of chronic kidney disease of unknown etiology in Central America. (Courtesy of Dr. Juan Jose Amador of Boston University)

tion, it is still controversial whether CKD may be the cause rather than the consequence of PFAS accumulation. However, in a recent long-term follow-up study in pre-diabetic adults, baseline PFAS concentrations were inversely correlated with long-term eGFR, with a reduction by 2.3 mL/min/1.73 m^2 per PFAS concentration quartile [122].

Chronic Kidney Disease of Unknown Etiology

Among young adults (primarily men) in Central American countries, an epidemic of non-proteinuric chronic kidney disease of unknown etiology has been occurring for at least the past 25 years on the Pacific coast (see Fig. 73.1). Young men working in the sugarcane fields appear to be most severely affected [123–126]. There is some evidence that the initial damage may be occurring at an early age [127]). A urine dipstick study conducted in the city of León among 423 pre-school children documented some level of proteinuria in 51% of the children in the study and hematuria in 20% [128].

Similar epidemics have been reported in Sri Lanka, India, and Egypt [129–131]. Investigators have evaluated the potential role of a variety of medicines, agrochemicals, arsenic, leptospirosis, and heat and strenuous labor combining to cause volume depletion, but a definitive etiology has not yet been identified [132–141].

Diagnosis

This is a diagnosis of exclusion. A thorough occupational and exposure history are essential if considering a diagnosis of chronic kidney disease of unknown etiology. When taking the history of exposure, the clinician should document the parents' occupation, and whether the child accompanies the parents to work. Adolescent work history should be obtained. Inquiries should be made about the source of the family's water.
