Preface

We are delighted to welcome you to the new edition of Pediatric Kidney Disease. As in the previous versions of this textbook, our goal has been to bridge the gap between multivolume "library-level" books and numerous pocket handbooks available in our specialty. We hope that Pediatric Kidney Disease will continue to be the standard textbook for reference to busy clinicians, who need to obtain an up-to-date, easy-to-read, review of virtually all kidney disorders that occur in children.

Following a critical review of the previous edition and the downloadable figures of each chapter, the table of contents was revised to optimally reflect the needs and expectations of our readers. One-third of the chapters were written by new authors. For chapters with unchanged authorship, each author was asked to thoroughly update the materials, which has resulted in extensive revisions of most chapters. A number of new topics have been included, such as metabolic disorders affecting the kidney, pediatric kidney tumors, sickle cell nephropathy, diabetic kidney disease, and strategic choices in kidney replacement therapy.

For all chapters, we have requested the authors to ensure the relevance and clinical usefulness of their chapter for busy pediatric and pediatric nephrology clinicians as well as the multidisciplinary team members. We hope that the included material and its presentation are of value and will contribute to the expansion of knowledge in the field of pediatric nephrology.

1 Antenatal Assessment of Kidney Morphology and Function

Khalid Ismaili, Benedetta D. Chiodini, Marie Cassart, and Karim Khelif

Introduction

Due to high patient expectations and demand, obstetrical two-dimensional (2D) ultrasound (US) is now a routine component of the care of pregnant women in most Western countries. In Europe, three sonographic examinations are performed, one in each trimester [1]. In other countries, including the United States and Canada, only one second-mid-trimester examination is performed routinely, with first-trimester or third-trimester examinations performed in case of specific indications [2]. Assessment of the fetal genitourinary tract is part of every routine fetal US examination. Congenital abnormalities of the kidney and urinary tract (CAKUT) make up one of the largest groups of congenital anomalies amenable to neonatal care, affecting 0.2–2% of all newborns [1]. Moreover, dramatic changes have occurred in the management of these children, and nowadays, CAKUTs are mostly found in asymptomatic infants and the treatment applied is mainly preventive with a low rate of surgical procedures performed during the last decade [3]. Also, the antenatal detection and postnatal follow-up have brought new insights into the natural history of many CAKUTs [4, 5].

Fetal Imaging Methods

Ultrasound is the first line imaging technique used in antenatal diagnosis. It has now been nearly four decades since its first use to evaluate the fetus and it is presently accepted as a safe and noninvasive imaging modality. The transducers most commonly used are curvilinear sector transducers (3–8 MHz), which have good penetration of the sound beam and allow for a visualization of the whole fetus. Higher frequency linear transducers (5–10 MHz) or transvaginal probes are used to achieve high resolution scans in near fields. The transducers most frequently used in daily clinical practice are multifrequency probes which allow for harmonic, three-dimensional and Doppler flow imaging. *3D imaging* is mostly used for the study of the face and vertebral column [6], the other organs are well depicted by C

imaging. Hence, 3D imaging is currently not routinely performed for urinary tract and kidney diseases. *Doppler imaging* is useful to evaluate the vascularization of the organs and the fetal well-being [2].

MR imaging of the fetus is a more recent technique. The examinations are performed on 1.5–3 T magnets. Although no deleterious effects on the fetus have been demonstrated to date [7], MR imaging is generally avoided during organogenesis in the first trimester. *MR imaging* is mostly performed in order to establish a more precise diagnosis where US cannot completely depict the suspected malformation or anomaly. The advantages of MR imaging are the larger field of view and the better contrast resolution which allow for a better characterization of the anatomy of the organs. The indications mostly concern the brain but it is presently extended to the fetal digestive and urinary tracts in specific indications [8]. Depending on local practice, sedation can be given to the mother before the examination to reduce fetal movement. Contrast media are not currently used due to the lack of data concerning potential side effects in pregnant women and fetuses [9]. Fast sequences (20 s) are performed in different planes and can be repeated in case of fetal movements. In urinary tract and kidney diseases the indications of fetal MR imaging are closely circumscribed; they will be illustrated in the next paragraphs.

The Normal Urinary Tract

Bladder

Urine starts to be produced during the ninth week of fetal life. At that time, the urine is collected in the bladder, which can be visualized as a fluid-filled structure within the fetal pelvis. During the second and third trimester, the fetus normally fills and partially or completely empties the bladder approximately every 25 min and the cycle can be monitored during the sonographic examination [10]. The bladder can easily be located by its outline of umbilical arteries, which are identifiable on color Doppler.

Kidneys

Endovaginal probes can be used to visualize fetal anatomic structures earlier than with transabdominal US. Thus, the fetal kidneys can be seen at around 11 weeks endovaginally and around 12–15 weeks with transabdominal probes. During the first trimester, the kidneys appear as hyperechoic oval structures at both sides of the spine (their hyperechogenicity can be compared with that of the liver or spleen) [11]. This echogenicity will progressively decrease and during the third trimester the cortical echogenicity will always be less than that of the liver or spleen. In parallel with the decrease of echogenicity, corticomedullary differentiation will appear at about 14–15 weeks. It should always be visible in fetuses older than 18 weeks (Fig. 1.1). Prominent pyramids should not be misinterpreted as calyceal dilatation.

Growth of the fetal kidneys can be evaluated throughout pregnancy. As a rule, a normal kidney grows at about 1.1 mm per week of gestation.

Evidence of Normally Functioning Urinary Tract

Besides visualization of the bladder and normal kidneys, assessment of the urinary tract should include an evaluation of the amniotic fluid volume. After 14–15 weeks, two thirds of the amniotic fluid is produced by fetal urination and one third by pulmonary fluid. A normal volume of

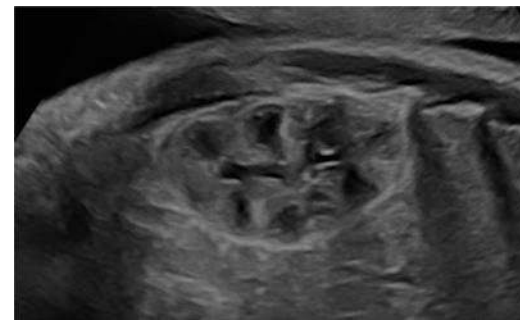

Fig. 1.1 Normal third trimester fetal kidney. Sagittal US scan of the kidney with clear visibility of the corticomedullary differentiation

ALGrawany

amniotic fluid is required for the proper development of the fetal lungs. This can be confirmed by measuring thoracic diameters or thoracic circumference [12].

Ultrasound Findings as Evidence of Abnormal Fetal Kidney and Urinary Tract

Abnormal US appearance of the kidneys as a pathophysiological base of CAKUT have been described extensively [13, 14]. Anomalies of the urinary system detected in utero are numerous; they can include anomalies of the kidney itself, of the collecting system, of the bladder and of the urethra. In addition, they can be isolated or in association with other systems. Therefore, the sonographic examination should be as meticulous as possible in order to visualize the associated features. These findings, among others, will determine the prognosis.

Abnormal Renal Number

Renal agenesis refers to the complete absence of one or both kidneys without identifiable rudimentary tissue [15].

Bilateral renal agenesis is part of Potter's syndrome and is incompatible with extrauterine life. The diagnosis is based on the absence of renal structure and the presence of oligohydramnios after 15 weeks of gestation. Pulmonary hypoplasia is invariably associated and leads to death from respiratory failure soon after birth. In this context, enlarged globular adrenals should not be mistaken for kidneys [16]. The use of color Doppler may help demonstrate the absence of renal arteries and subsequently confirm the diagnosis [17].

Unilateral renal agenesis is more common (1 in 500 pregnancies), usually asymptomatic and incidentally detected. This situation usually has no significant consequence on postnatal life as long as the solitary kidney shows compensatory hypertrophy [18]. The pathogenesis of renal agenesis is mostly due to a failure of the formation of the metanephros. In addition, interruption in vascular supply and regression of a multicystic dysplastic kidney (MCDK) may also lead to renal agenesis in the fetal period [19]. An investigation after birth is necessary to confirm the status of the remnant kidney and to look for possible associated anomalies such as hearing deficits, ear pits, coloboma, cleft lip or palate, single umbilical artery, syndactyly, microphallus, cryptorchidism, duplicated Mullerian structures, and ectopic ureteral insertion [18, 20]. In the long term, blood pressure and urinalysis should be monitored, in order to detect high blood pressure and/or microalbuminuria due to compensatory glomerular hyperfiltration. Children with congenital injury to the solitary kidney are at higher risk of adverse outcome, with a median time to chronic kidney disease of 14.8 years [21].

Abnormal Location of Kidney

Ectopic kidney, especially in the pelvic area, is part of the differential diagnosis of the "empty renal fossa" in the fetus and may represent 42% of these cases [18]. The diagnosis of horseshoe or crossed fused kidneys can also be assessed in utero through the demonstration of renal parenchyme crossing the midline in horseshoe kidney (Fig. 1.2) or attached to the lower pole of the normally positioned contralateral kidney, i.e. crossed fused renal ectopia [22]. An ectopic kidney is usually small and somewhat malrotated with numerous small blood vessels and associated ureteric anomalies. Ectopic kidneys may be asymptomatic, but complications such as ureteral obstruction, infection, and calculi are common [23]. Therefore, at birth, the anomaly has to be confirmed by US or by MRI and a voiding cystourethrography (VCUG) may be useful in complex cases.

Abnormal Renal Echogenicity

Hyperechogenicity of the fetal kidney is defined by comparison with the adjacent liver or spleen. This is difficult to assess in the first and second

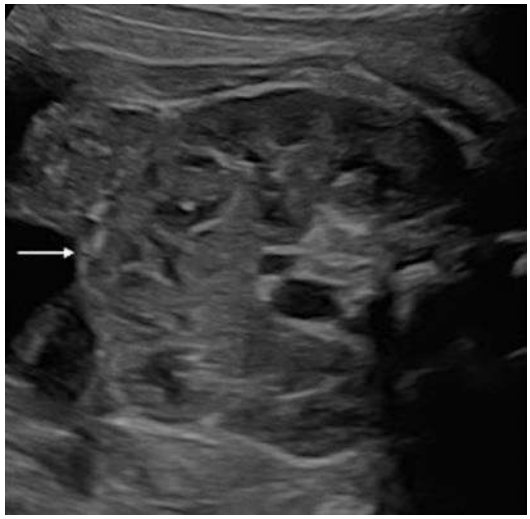

Fig. 1.2 Horseshoe kidney. Axial US scan on the fetal abdomen showing the parenchymal bridge crossing the midline (arrow)

trimester as the kidney is "physiologically" hyperechoic (or isoechoic at the end of the second trimester). It is easier to characterize after 28–32 weeks as the renal cortex by that time should be hypoechoic compared to the liver and spleen [11]. Increased echogenicity of the renal parenchyma is nonspecific and occurs as a response to different changes in renal tissue [24]. Interstitial infiltration, sclerosis and multiple microscopic cortical and medullary cysts may account for hyperechogenicity even in the absence of macrocysts. The detection of hyperechoic kidneys represents a difficult diagnostic challenge and generates significant parental anxiety due to the uncertain prognosis [25, 26]. The differential diagnosis must be based on kidney size, corticomedullary differentiation, the presence of macrocysts, the degree of dilatation of the collecting system and the amount of amniotic fluid [27]. The diagnosis must also take into account the familial history, the presence of associated anomalies and/or aberrant karyotype and genetic diseases [25]. Metabolic disorders should also be added to the long list of causes of hyperechoic kidneys in children (Fig. 1.3): tyrosinemia, galactosemia, fructosemia, mitochondrial disorders, glutaric aciduria, carnitine

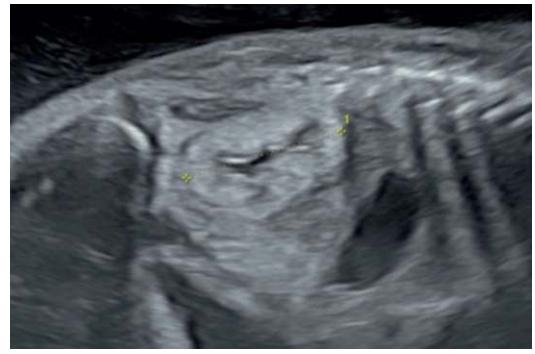

Fig. 1.3 Hyperechoic undifferentiated kidney. Sagittal US scan of the left kidney of a fetus with post natal diagnosis of nephrocalcinosis

palmitoyltransferase II deficiency, congenital disorders of glycosylation, and peroxisomal disorders can all be accompanied by hyperechoic kidneys [28].

So far, the outcome of fetal hyperechoic kidneys can only be accurately predicted in severe cases with significant oligohydramnios [26, 27]. For some patients, the characteristic US patterns will appear after birth or even later. A follow-up is therefore mandatory. It should be stressed that some cases remain unsolved and have to be considered as normal variants [25, 27]. Table 1.1 provides information on the spectrum of renal disorders associated with fetal hyperechoic kidneys.

Abnormal Renal Size

Measurements of the kidneys must be systematic whenever an anomaly of the urinary tract or amniotic fluid volume is suspected. It is therefore important to have standards for renal size and volume measurements covering the complete gestational age range, because renal pathology often presents late in pregnancy [31]. Small kidneys most often correspond to hypodysplasia or damaged kidneys from obstructive uropathy or high-grade vesicoureteral reflux (VUR) [32, 33]. Enlarged kidneys may be related to urinary tract dilatation, renal cystic diseases or tumoral involvement.

Urinary Tract Dilatation

Fetal renal pelvis dilatation is a frequent abnormality that has been observed in 4.5% of pregnancies [34]. Pyelectasis is defined as dilatation of the renal pelvis whereas pelvicaliectasis and hydronephrosis include dilatation of calyces. In practice, these terms are interchanged and used as descriptions of a dilated renal collecting system regardless of the etiology [35].

The third-trimester threshold value for the anteroposterior (AP) renal pelvis diameter of 7 mm is certainly the best prenatal criterion both for the screening of urinary tract dilatation and for the selection of patients needing postnatal investigation [35, 36].

There are several theories that account for the visibility of the renal pelvis during pregnancy. The distension of the urinary collecting system may be simply a dynamic and physiologic process [37]. The size of the fetal renal collecting system is highly variable over a 2-h period [38]. The tendency of renal pelvis dilatation to resolve spontaneously is supported by normal postnatal renal appearances reported in 36–80% of cases followed up after birth [39, 40]. However, prenatally detected renal pelvis dilatation may be an indicator of significant urinary tract pathologies [41]. The likelihood of having a clinically significant uropathy is directly proportional to the severity of the hydronephrosis [35]. A summary of the literature describing the postnatal uronephropathies found in neonates who presented with fetal renal pelvis dilatation is given in Table 1.2. The incidence and type of pathology varies considerably between studies, reflecting the differences in prenatal criteria and the variability in postnatal assessment. The two main pathologies found are pelviureteric junction stenosis and VUR. US is the first examination to perform after birth [46]. In babies diagnosed in utero with renal pelvis dilatation, the presence of persistent renal pelvis dilatation or other ultrasonographic abnormalities (such as calyceal or ureteral dilatation, pelvic or ureteral wall thickening and absence of the corticomedullary differentiation) and signs of renal dysplasia (such as small kidney, thinned or hyperechoic cortex or cortical cysts) should determine the need for further investigations [47, 48]. In cases when the urinary tract appears normal on neonatal US examinations, no further evaluation is needed [39]. Based on our own experience [34, 39, 49, 50], we propose an algorithm for a rational postnatal imaging strategy (Fig. 1.4). Using this algorithm, we found that very few abnormal cases escaped the work up and that the risk of complications was very low.

Renal Cysts

Renal cystic diseases should be suspected not only in the case of obvious macrocysts but also in the case of hyperechoic kidneys [51]. Cysts may be present in one or both kidneys. Their origin may be genetic, and they may occur as an isolated anomaly or part of a syndrome. Familial history is of a great importance for the diagnosis [51].

Obstructive renal dysplasia and MCDK are the most common entities in which macrocysts can be detected. Obstructive renal dysplasia is associated with urinary tract obstruction that may have resolved at the time of diagnosis, leaving the cystic sequelae behind as the unique evidence that a urinary flow impairment ever existed [11]. In this condition, the cysts measure less than 1 cm and are located within the hyperechoic cortex (Fig. 1.5) [51]. MCDK is discussed further under Renal Causes of Fetal Renal Abnormalities in this chapter. Although rare, isolated cortical cysts may be seen in utero. They may persist after birth or regress spontaneously [52].

The most frequent genetically transmitted cystic renal diseases are the autosomal dominant polycystic kidney diseases and abnormalities of the hepatocyte nuclear factor-1β (HNF1B) encoded by the *TCF2* gene [53]. HNF1B diseases are typically associated with bilateral cortical renal microcysts as well as other renal parenchymal abnormalities including MCDK and renal dysplasia [53]. HNF1B plays an important role in the early phases of kidney development [54]. Both the type and the severity of the renal disease are variable in children with HNF1B mutations. Their

range from severe prenatal renal failure to normal renal function in adulthood. There is no obvious correlation between the type of mutation and the type and/or severity of renal disease. Furthermore, the inter- and intrafamilial variability of the phenotype in patients who harbor the same mutation is high, making genetic counseling particularly difficult in these families [55]. Cystic kidneys are also part of many syndromes (Tables 1.1 and 1.3) with many associated anomalies that are sometimes typical of the underlying pathology.

Renal Tumors

Fetal renal tumors occur only rarely. Mesoblastic nephroma represents the most common congenital renal neoplasm [65]. It is a solitary hamartoma with a usually benign course. Mesoblastic nephroma appears as a large, solitary, predominantly solid, retroperitoneal mass arising and not

ALGrawany

AD autosomal dominant, *AR* autosomal recessive

separable from the adjacent kidney. It does not have a well-defined capsule and may sometimes appear as a partially cystic tumor [11]. In case of a tumor with multiple cysts, a MCDK should be considered first. Mesoblastic nephroma frequently coexists with polyhydramnios although the reason for this association remains unclear [65]. Fetal Wilm's tumor is exceptionally rare and may be indistinguishable from mesoblastic nephroma on imaging [66]. Another differential diagnosis is nephroblastomatosis, which appears either as hyperechoic nodule(s) or as a diffusely enlarged hyperechoic kidney [67]. Renal tumors have to be differentiated from adrenal tumors and intra-abdominal sequestrations [68].

Bladder Abnormalities

On fetal US examinations, the bladder should always be seen from the tenth week of gestation. Nonvisualization of the bladder in the setting of oligohydramnios is highly suspicious of a bilateral severe renal abnormality with decreased urine production. It is important to carefully analyze the kidneys in order to exclude agenesis or dysplasia associated with poor outcome.

Nonvisualization of the bladder with an otherwise normal sonogram (kidneys and amniotic fluid) may be due to physiologic bladder emptying cycle in the fetus. Normal repletion should be checked within the following 20 min. Persistent non visualized bladder can be due to its inability to store urine, for example in cases of bladder or cloacal extrophy [69]. In this context, no bladder is seen between the two umbilical arteries. Bladder extrophy or cloacal malformations represent a diagnostic challenge on US, and MRI may help to define the pelvic anatomy of the fetus [70].

Enlarged bladder in the first trimester has a poor prognosis. Most of the cases are secondary

to urethral atresia or stenosis, some are part of a syndrome (such as Prune Belly), or associated with chromosomal anomalies. Later in pregnancy, megabladder is defined as a cephalocaudal diameter superior to 3 cm in the second trimester and to 5 cm in the third trimester. Megabladders are mainly due to outflow obstruction or to a major bilateral reflux [71]. It is often difficult to make a clear distinction between both abnormalities, as they may be associated. An irregular and thickened bladder wall is suggestive of an outflow obstruction. Megacystis-microcolon hypoperistalsis (MMH) syndrome is another differential diagnosis that carries a very poor prognosis [72]. It can be excluded by MRI during the third trimester because the colon is well visualized at that time.

Assessment of Fetal Renal Function

In utero, excretion of nitrogenous waste products and regulation of fetal fluid and electrolytes balance as well as acid-base homeostasis are maintained by the interaction of the placenta and maternal blood [73]. Thus, the placenta functions as an in vivo dialysis unit. Several parameters have been used in the evaluation of renal function in fetal life. However, since fetal homeostasis depends on the integrity of the placenta, it is very difficult to assess the functional status of the fetal kidney. Furthermore, changes in the volume or composition of fetal urine may in many instances reflect the condition of the placenta rather than the condition of the fetal kidney [74]. However, exact diagnosis of the renal abnormalities and accurate prediction of the renal function after birth are important tasks, because during parental counseling parents often want to know if their child will have renal failure and whether or not surgery or other aggressive therapies will be performed. Therefore, in addition to using fetal renal sonography to determine potential fetal renal anatomical abnormalities, it is important to assess function as accurately as possible.

Amniotic Fluid Volume

During the first trimester of gestation the placenta (chorion and amniotic membrane) is the principal source of amniotic fluid, while after 15 weeks the volume of amniotic fluid is maintained by fetal urine production. Therefore, the assessment of the quantity of amniotic fluid after 15 weeks constitutes the initial step in the evaluation of the fetal urinary tract. Abnormal amounts of amniotic fluid must alert the sonographer to search meticulously for renal and urinary tract anomalies [75]. Assessing amniotic fluid volume is difficult and mostly subjective. However, the four-quadrant sum of amniotic fluid pockets (amniotic fluid index) provides a reproducible method for assessing amniotic fluid volume with interobserver and intraobserver variation of 3–7% [76].

Various cut-off criteria have been suggested for definition of oligohydramnios by amniotic fluid index, including less than 3rd percentile [77], or 5th percentile for gestational age [76]. Oligohydramnios of any cause typically compresses and twists the fetus, thus leading to a recurrent pattern of abnormalities that has been called the oligohydramnios sequence [12]. Oligohydramnios may be caused by decreased production of fetal urine from bilateral renal agenesis or dysplasia, or by reduced egress of urine into the amniotic fluid due to urinary obstruction [78]. Other causes may be fetal death, growth retardation, rupture of the membranes, or post-term gestation (Table 1.4).

In cases of bilateral obstructive uropathy, the evaluation of amniotic fluid by the amniotic fluid index seems to be the most reproducible and inexpensive method to predict renal function after birth [79]. An amniotic fluid index less than the 5th percentile is generally associated with an adverse perinatal outcome [76, 79]. Yet, an amniotic fluid index between the 5th and 25th percentiles should be considered as a warning sign since it may be a subtle indication of renal impairment, especially early in gestation when ultrasonographic signs of renal dysplasia may not be present and when fetal urinalysis is not available [79].

AL Grawany

Table 1.4 Causes of oligohydramnios and polyhydramnios

	Origin	Pathologies
Oligohydramnios	Uronephropathy	Bilateral renal agenesis Bilateral renal dysplasia Autosomal recessive polycystic kidney disease Bilateral obstructive uropathy Bilateral high-grade reflux Bladder outlet obstruction
	Other	Premature rupture of membranes Placental insufficiency Fetal death Fetal growth retardation Twin-to-twin transfusion (twin donor) Maternal drug intake: prostaglandin synthase inhibitors, angiotensin-converting enzyme inhibitors, cocaine Postmaturity syndrome
Polyhydramnios	Uronephropathy	Renal tumors, especially mesoblastic nephroma Bartter syndrome Congenital nephrotic syndrome Alloimmune glomerulonephritis
	Other	Maternal diabetes Maternal drug intake: lithium Multiple gestations Twin-to-twin transfusion (twin recipient) Fetal infections: rubella, cytomegalovirus, toxoplasmosis Fetal gastrointestinal obstructions: esophageal atresia, duodenal atresia, gastroschisis Fetal compressive pulmonary disorders: diaphragmatic hernia, pleural effusions, cystic adenomatoid malformations, narrow thoracic cage Neuro-muscular conditions: anencephaly, myotonic dystrophy Cardiac anomalies Hematologic anomalies (fetal anemia) Hydrops fetalis Fetal chromosome abnormalities: trisomy 21, trisomy 18, trisomy 13 Syndromic conditions: Beckwith-Wiedeman syndrome, achondroplasia No evident cause

Finally, one of the most devastating consequences of oligohydramnios, especially before 24 week's gestation, is pulmonary hypoplasia [80]. Traditional explanations suggest that oligohydramnios causes pulmonary hypoplasia either by compression of the fetal thorax [80] or by encouraging lung liquid loss via the trachea [81]. However, since several morphogenetic pathways governing renal development are shared with lung organogenesis, this sequence is put into question. Some reports suggest that abnormal lung dysplasia may precede the advent of oligohydramnios in fetuses with intrinsic defects of renal parenchymal development [82].

Polyhydramnios, also referred to as hydramnios, is defined as a high level of amniotic fluid. Because the normal values for amniotic fluid volumes increase during pregnancy, this definition will depend on the gestational age of the fetus. During the last 2 months of pregnancy, polyhydramnios usually refers to amniotic fluid volumes greater than 1700–1900 mL. Severe cases are associated with much greater fluid volume excesses. The two major causes of polyhydramnios are reduced fetal swallowing or absorption of amniotic fluid and increased fetal urination (Table 1.4). Increased fetal urination is typically observed in maternal diabetes mellitus, but it may be associated with fetal renal diseases as mesoblastic nephroma [65], Bartter syndrome [83], congenital nephrotic syndrome [84] and alloimmune glomerulonephritis [85].

Fetal Urine Biochemical Markers

The healthy fetus produces hypotonic urine. In case of kidney damage, proximal tubular function is harmed and urine osmolality increases. Fetal urine biochemistry was first introduced four decades ago as an additional test to improve prediction of renal function after birth [86]. Thereafter, investigators started to establish gestational age-dependent reference ranges for various biochemical parameters of fetal urine [87]. Rapidly, two important pitfalls emerged in this area of research. Initially, biochemical markers were analyzed either from amniotic fluid or bladder sampling based on the debatable assumption that both liquids have nearly identical composition. Subsequently, a practice has emerged whereby reference ranges are only taken from bladder or fetal urinary tract sampling. The second pitfall involved the pertinence of the use of urinary solutes that are filtered by the glomerulus and reabsorbed by the tubules. These solutes express a tubular damage rather than a compromised GFR and it is therefore questionable if they can accurately predict renal function.

Fetal urine biochemistry is currently used especially in dilated uropathies because of technical difficulties of sampling fetal urines from a nondilated urinary tract, as seen in the majority of nephropathies. β2-microglobulin is the most widely used fetal urinary marker, although other compounds such as calcium, chloride and sodium may also be of interest; prognostic values of these markers are outlined in Table 1.5. Most fetal urine studies agree on some points [88, 89]: (1) fetuses with renal damage (dysplasia) show increased urinary solute concentrations; (2) a combination of β2-microglobulin and cystatin C or chloride exhibits better accuracy than the measurement of any single electrolyte; (3) the predictive accuracy of the proposed parameters is, however, far from perfect.

Novel approaches to fetal urine biochemistry such as proteomics and metabolomics may yield novel markers that may improve the usefulness of this technique in the near future [95]. The ongoing European ANTENATAL study was designed to validate a fetal urine peptide signature proposed by Buffin-Meyer in order to predict postnatal renal function in fetuses with posterior urethral valves [96, 97]. The final results are expected in 2023.

Fetal Blood Sampling

Fetal blood sampling poses probably greater risks than urine sampling, but it allows a more accurate evaluation of fetal glomerular filtration rate (GFR) [94, 98, 99]. In the fetus, creatinine cannot be used as a marker of GFR because it crosses the placenta and is cleared by the mother. This is not the case for α1-microglobulin, β2-microglobulin and cystatin C, which have been used to predict renal function in uropathies and nephropathies (Table 1.6). This technique may be helpful, especially in cases where fetal urine is difficult to sample. It is however unlikely that fetal serum

Table 1.5 Fetal urine biochemical markers of postnatal prognosis

	Normal limits [90]	Good prognosis [91–93]	Moderate renal failure at age 1 year [94]	Poor prognosis (neonatal death or termination of pregnancy) [92–94]
Na^+	75–100 mmol/L	<100 mmol/L	59 mmol/L (54–65)	121 mmol/L (100–140)
Ca^{2+}	2 mmol/L		2 mmol/L (1.5–2.5)	2 mmol/L (1.5–2.5)
Cl^-		<90 mmol/L	57 mmol/L (52–62)	98 mmol/L (85–111)
β2 microglobulin	<4 mg/L	<6 mg/L	6.8 mg/L (4.2–9.4)	19.5 mg/L (11–28)
Cystatin C		<1 mg/L	0.47 mg/L (0.05–4.75)	4.1 mg/L (0.45–13.1)
Protein		0.22 g/L (0.09–0.97)		0.28 g/L (0.06–13.5)
Osmolarity	<200 mOsm/L	<210 mOsm/L		

Table 1.6 Fetal serum biochemical markers of postnatal prognosis

	Controls [98]	Bilateral hypoplasia and dysplasia [99]	Bilateral uropathies [100]
Outcome		Good prognosis	Postnatal renal failure
β2-microglobulin	4.28 mg/L (2.95–6.61)	3.2 mg/L (1.5–3.7)	5.3 mg/L (3.5–7.2)
Cystatin C	1.67 mg/L (1.12–2.06)	1.43 mg/L (1.09–1.86)	1.95 mg/L (1.56–4.60)
α1-microglobulin			60.5 mg/L (31.8–90.1)

α1-microglobulin, β2-microglobulin and cystatin C will overcome the limitations associated with fetal urinalysis [98]. The only clinical useful information emerging from the studies performed to date is that fetal serum β2-microglobulin remains the best marker of renal function; however its helpfulness is questionable outside extreme values (less than 3.5 mg/L good outcome; more than 5 mg/L poor outcome) [100].

Ultrasound-Guided Renal Biopsies

Ultrasound-guided renal biopsy would theoretically allow precise definition of the extent of renal damage in obstructed and primarily dysplastic kidneys [101]. However, this is an invasive procedure with a high rate of failure in obtaining an adequate sample [94]. Furthermore, a focal needle aspiration is not representative of the whole kidney parenchyma since renal dysplasia is patchily distributed.

Specific Renal and Urinary Tract Pathologies

Causes of fetal abnormalities of the kidney and urinary tract may be considered as prerenal, renal and postrenal.

Pre-renal Causes of Fetal Renal Abnormalities

Intrauterine Growth Restriction (IUGR)

Intrauterine growth restriction (IUGR) complicates up to 10% of all pregnancies. It is associated with a perinatal mortality rate that is six to ten times higher when compared to normally grown fetuses and is the second most important cause of perinatal death after preterm delivery. The cause of IUGR is multifactorial. Worldwide, maternal nutritional deficiencies and inadequate utero-placental perfusion are among the most common causes of IUGR.

IUGR caused by placental insufficiency is often associated with oligohydramnios due to reduced urine production rate in these fetuses. This phenomenon is probably due to chronic hypoxemia that leads to the brain-sparing redistribution of oxygenated blood away from non-vital peripheral organs such as the kidneys [73]. As a consequence, fetal renal medullary hyperechogenicity may develop between the 24th and the 37th weeks of gestation due to tubular blockage caused by Tamm-Horsfall protein precipitation, and may be a sign of hypoxic renal insufficiency [102]. IUGR complicated by renal medullary hyperechogenicity suggests a more serious state, because these fetuses have a higher risk of pathological postnatal clinical outcome, such as neonatal mortality (8%), fetal distress leading to cesarean section (36%), transfer to intensive care unit (64%), and perinatal infection (24%) [102]. IUGR not only leads to a low birth weight but it might also reprogram nephrogenesis, which results in a low nephron endowment. According to the hyperfiltration hypothesis, this reduction in renal mass is supposed to lead to glomerular hyperfiltration and hypertension in remnant nephrons with subsequent glomerular injury with proteinuria, systemic hypertension and glomerulosclerosis in adult age [103].

Renal Vein Thrombosis

Renal vein thrombosis is the most common vascular condition in the newborn kidney and represents 0.5/1000 of admissions to neonatal intensive care units [104]. Factors predisposing a neonate

AL Grawany

to renal vein thrombosis include dehydration, sepsis, birth asphyxia, maternal diabetes, polycythemia and the presence of indwelling umbilical venous catheter [104]. In addition, prothrombotic abnormalities may be present in more than 40% of these babies, such as Protein C or S deficiency, Factor V Leiden mutation, Lupus anticoagulant and Antithrombin III deficiency [105].

Renal vein thrombosis may also occur in utero. However, the origin of the thrombosis is not always obvious. Sonographically, the fetal kidney appears somewhat enlarged; the cortex may appear hyperechoic and without corticomedullary differentiation (Fig. 1.6a). Pathognomonic vascular streaks may be visible in the interlobar areas. Thrombus in the inferior vena cava is a common association [11]. Color Doppler US may be used in addition to grey-scale examination in the assessment of renal vein thrombosis. In the early stages of renal vein thrombosis, intrarenal and renal venous flow and pulsatility may be absent and renal arterial diastolic flow may be decreased, with a raised resistive index. Collateral vessels develop very rapidly (Fig. 1.6b) and in most cases there are no consequences on further renal development [106]. After birth, the hyperechoic streaks and the thrombus are calcified. This feature helps differentiate antenatal from postnatal onset of the renal vein thrombosis [106].

The Twin-To-Twin Transfusion Syndrome

The twin-to-twin transfusion syndrome complicates 10–15% of monochorionic twin pregnancies [107]. The etiology of this condition is thought to result from an unbalanced fetal blood supply through the placental vascular shunts, with the larger twin being the recipient and the smaller twin the donor [108]. The twin-to-twin transfusion syndrome is defined by the existence of a oligo-polyhydramnios sequence (that is, the deepest vertical pool being 2 cm or less in the donor's sac and 8 cm or more in the recipient's sac) [107]. Additional phenotypic features in the donor include a small or nonvisible bladder and abnormal umbilical artery Doppler with absent or reverse end-diastolic frequencies. In addition to the neonatal complications of growth restriction, up to 30% of donors have renal failure and/or renal tubular dysgenesis due to the chronic renal hypoperfusion state in utero [107]. In the recipient, confirmatory features include large bladder, cardiac hypertrophy and eventually hydrops. Risk of renal failure in the recipient twin is considerably smaller than in the donor twin. This can be seen as one fetus dying and vascular resistance dropping significantly to cause reversed blood transfusion from the recipient twin to the dead fetus, resulting in hypovolemia and anemia in the live fetus [109].

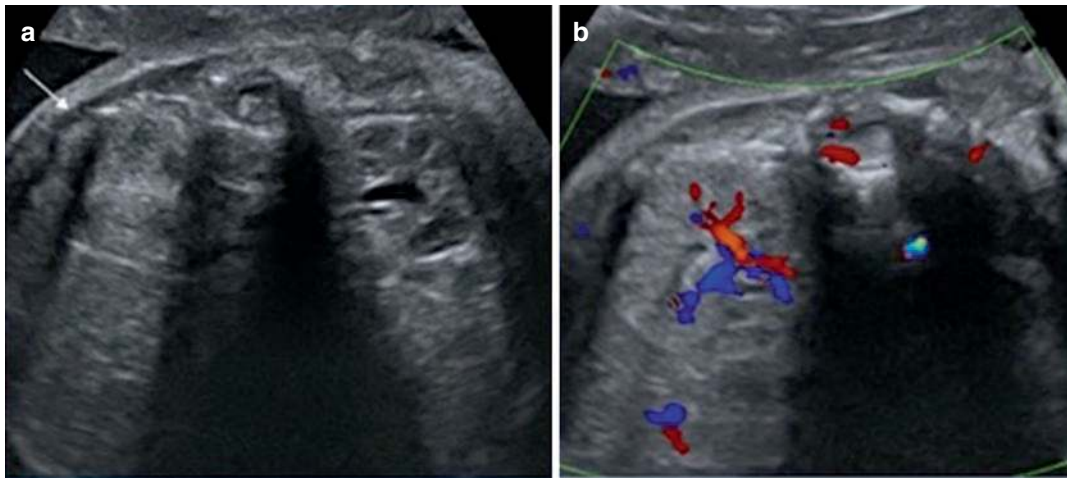

Fig. 1.6 Right renal vein thrombosis. (**a**) Axial US scan showing differences of size and echogenicity of both kidneys. The right kidney is enlarged and hyperechoic (arrow). (**b**) Axial US scan showing normal renal arterial and venous flow on the right kidney attesting of rapid revascularisation

Maternal Alcohol/Drug Intake

Mother's alcohol and/or drug consumption can in certain cases affect fetal kidney function or cause congenital kidney anomalies.

Alcohol

Based on both animal and human studies, it has been suggested that children with fetal alcohol syndrome (FAS) should be screened for renal anomalies [110]. The kidneys of children exposed prenatally to ethanol (with or without FAS) were smaller as compared to children with no evidence of alcohol exposure in utero [110]. Recent studies from Portugal have found an association between alcohol consumption during pregnancy and a decreased kidney function later in childhood, especially in overweight schoolchildren [111].

Renin-Angiotensin System (RAS) Antagonists

Administration of angiotensin converting enzyme inhibitors (ACEIs) and angiotensin type I receptor blockers (ARBs) can severely affect renal development and function at any gestational age. RAS inhibitors lead to tubular dysgenesis, oligohydramnios, growth restriction, neonatal anuria and stillbirth [112–115]. In one study almost 9% of children exposed to ACEIs during the first trimester (but not later in pregnancy) showed major congenital anomalies (cardiovascular, central nervous system and renal malformations) at a rate 2.7 times that among unexposed infants [113]. The renal anomalies are thought to be caused both directly by antagonism of the fetal intrarenal renin-angiotensin system and indirectly by fetoplacental ischemia resulting from maternal hypotension and a drop of fetal-placental blood flow [73]. Pregnancies exposed to RAS blockers and complicated by oligohydramnios are associated with the highest rate of adverse pregnancy outcomes. Combined monitoring of amniotic fluid volume evaluation and fetal serum β2-microglobulin may be helpful in the management of these pregnancies [116].

Nonsteroidal Antiinflammatory Drugs (NSAID)

Cyclooxygenase type 1 (COX-1) inhibitors such as indomethacin, the most common NSAID used as a tocolytic, definitely reduce urine output and may lead to oligohydramnios and renal dysfunction [73]. It was hoped that cyclooxygenase type 2 (COX-2) inhibitors would target COX-2 activity and potentially spare COX-1-specific fetal side effects. However, COX-2 expression is higher in fetal as compared to adult kidneys and may even occur constitutively in fetal kidney tissue [73]. Sulindac and nimesulide administration has therefore been linked both to constriction of the ductus arteriosus and oligohydramnios [117].

Cocaine

Maternal cocaine use adversely influences fetal renal function by hypoperfusion and thus influences the fetal renin-angiotensin system. It is also associated with oligohydramnios as well as other fetal vascular complications leading to higher renal artery resistance index and a significant decrease in urine output [118]. However, and contradicting a widely held belief [119], a prospective, large-scale, blinded, systematic evaluation for congenital anomalies in prenatally cocaine-exposed children did not identify any increase in the number or consistent pattern of genitourinary tract malformations [120].

Immunosuppressive Medications During Pregnancy

Historically, physicians discouraged pregnancy in female kidney transplant recipients, due to concerns for maternal, graft, and fetal health [121]. Nevertheless, a large number of women with transplanted organs have completed pregnancies [122]. Although some immunosuppressants such as corticosteroids, cyclosporine and azathioprine have been shown to be teratogenic in animals, case reports and registry records have not identified any consistent malformation patterns in children of allograft recipients [123–126] (Table 1.7). On the contrary, the use of mycophenolate mofetil (MMF) during pregnancy has been

Table 1.7 In utero malformations caused by the exposure to immunosuppressive drugs used in kidney transplant recipients

Immunosuppressive drugs	Congenital malformations	References
Corticosteroids	In animals: increased risk of cleft palate. In humans: no increased prevalence of congenital malformations even at high doses.	[123]
Calcineurin inhibitors	In animals: skeletal retardation in cyclosporine exposure. In humans: no increased prevalence of congenital malformations.	[124, 125]
Azathioprine	In animals: various congenital malformations. In humans: safe in pregnant women.	[126]
Mycophenolic acid	In animals: wide range of teratogenic and fetotoxic effects; high miscarriage rate. In humans: congenital malformation prevalence of 26% (orofacial defects, hypoplastic nails, short fifth finger, corpus callosum agenesis, myelomeningocele, hydronephrosis, atrial septal defect, and tracheo-esophageal atresia).	[127–129]
Rapamicin inhibitors (mTOR)	In animals: high risk of intra-uterine growth retardation, impaired skeletal ossification, and miscarriage. In humans: few studies, no congenital malformations reported.	[130]
ATG	No data available	[131]
Basiliximab	No data available	[131]
Rituximab	No data available	[131]
Belatacept	No data available	[131]

clearly associated with teratogenicity in humans [127–129] (Table 1.7). Therefore, European best practice guidelines recommend that women receiving MMF switch to another drug and wait at least 6 weeks before attempting to conceive [131, 132].

Primary Congenital Kidney Anomalies

CAKUT is the most common cause of pediatric kidney failure [133]. CAKUT is highly heterogeneous, and the etiologic factors are not completely understood. These conditions are genetically variable and encompass a wide range of anatomical defects, such as renal agenesis, renal hypodysplasia, pelviureteric junction stenosis, and VUR. Mutations in genes causing syndromic disorders, such as *HNF1B* and *PAX2* mutations, are detected in only 5–10% of cases [134]. Familial forms of nonsyndromic disease have also been reported [135], further supporting a genetic determination such as *ACTA2* and *CHRM3* genes in Prune belly syndrome, *HPSE2* and *LRIG2* genes in Ochoa syndrome, among many others (Table 1.8). However, owing to locus heterogeneity and small pedigree size, the genetic cause of most familial or sporadic cases remains unknown [135].

Multicystic Dysplastic Kidney (MCDK)

These kidneys contain bizarrely shaped tubules surrounded by a stroma, that includes undifferentiated and metaplastic cells (for example, smooth muscle and cartilage). According to Liebeschuetz [155] the prevalence of MCDK is about 1 in 2400 live births, which is higher than other reports [156]. MCDK is usually unilateral and presents a typical US pattern: multiple noncommunicating cysts of varying size and nonmedial location of the largest cyst, absence of normal renal sinus echoes, and absence of normal renal parenchyma [157]. MCDK may also develop in the upper part of a duplex system or be located in an ectopic position. Unilateral isolated MCDK carries a good prognosis but careful examination of the contralateral kidney is essential because there is a high incidence of associated pathologies, many of which may not be detected until birth [158]. These associated malformations include ectopic ureteral insertions more commonly in the semi-

Table 1.8 Genes implicated in urinary tract malformations

Urinary tract malformation	Genes implicated	Mutated protein
Bladder extrophy	*ISL1* [136]	Transcription factor potentially involved in formation of the bladder and urethra
Branchio-oto-renal syndrome	*EYA1* [137]	Transcriptional co-activator required for eye morphogenesis
	SIX1 [138]	Homeobox protein similar to *EYA* gene product
Campomelic dysplasia (sex reversal, megaureter)	*SOX9* [139]	Transcription factor modulating smooth muscle in the ureter
Diverse kidney malformations	*TCF2* [140]	Transcription factor widely expressed in renal tract epithelia
Megaureter	*TBX18* [141]	Transcription factor affecting ureter morphogenesis
	TSHZ3 [142]	Transcription factor modulating smooth muscle
Primary VUR, Ehler-Danlos	*TNXB* [143]	Extracellular matrix protein found in the urinary tract
Posterior urethral valves	*BNC2* [144]	Basonuclin 2, a zinc finger containing protein implicated in epithelial maturation
Prune belly syndrome, megacystis microcolon intestinal hypoperistalsis	*ACTA2* [145]	Smooth muscle contractile protein
	ACTG2 [146]	Smooth muscle contractile protein γ2-actin
	CHRM3 [147]	M3, the main acetylcholine receptor in detrusor smooth muscle
	MYH11 [148]	Smooth muscle contractile protein called myosin heavy chain 11
	MYLK [149]	Myosin light chain kinase modifying myosin in smooth muscle cells
	MYOCD [150]	Transcription-related protein needed for the expression of smooth muscle contractile proteins
Renal hypodysplasia, primary VUR	*NRIP1* [151]	Nuclear receptor transcriptional cofactor that modulates retinoic acid transcriptional activity
Small kidneys, VUR, optic nerves malformation	*PAX2* [152]	Transcription factor widely expressed in the developing ureter and kidney
Urofacial-Ochoa syndrome	*HPSE2* [153]	Heparanase 2, a protein probably modulating growth factor signaling in bladder nerves
	LRIG2 [154]	Leucine-rich-repeats and immunoglobulin-like-domains 2 probably modulating growth factor signaling in bladder nerves

nal glands in boys and (hemi)vagina in girls. These ectopic insertions should be searched in utero but are more obvious after birth. An early diagnosis has a relevant clinical impact and leads to better management of the children and planning of further surgery in symptomatic cases [159]. The distinction between MCDK and cystic renal dysplasia associated with urinary tract obstruction may be difficult, especially in the absence of hydronephrosis. This distinction, although helpful in terms of diagnosis, may be somewhat artificial in terms of prognosis, since in either case, the affected kidney has no or minimal functional capacity.

Autosomal Recessive Polycystic Kidney Disease (ARPKD)

ARPKD belongs to the family of cilia-related disorders, has an incidence of 1 in 20,000 live births and may cause fetal and neonatal death in severe cases [160, 161]. Mutations in the *PKHD1* fibrocystin gene are usually demonstrated in this disease [162]. Yet, since some patients survive the neonatal period with few or slight symptoms, different combinations of *PKHD1* gene mutations and its resulting changes in the fibrocystin/

polyductin protein structure may at least partially explain the phenotypic variance [163]. The disease is characterized by marked elongation of the collecting tubules that expand into multiple small cysts. The cystic dilatation of the tubules is variable and predominates in the medulla. The outer cortex is spared since it contains no tubules. The classical in utero pattern of ARPKD includes markedly enlarged (+4 SD) hyperechoic kidneys without corticomedullary differentiation (Fig. 1.7). This appearance can be observed in the second trimester. The patterns may evolve and the size of the kidneys may continuously increase during the third trimester. Oligohydramnios and lung hypoplasia may be present, and therefore the prognosis is extremely poor.

Another presentation of ARPKD is of reversed corticomedullary differentiation with large kidneys (+2 to +4 SD). This finding is probably related to increased interfaces within the medullae and to the presence of material within the dilated tubules [164]. It is an important observation since there are few other causes of reversed corticomedullary differentiation. Liver involvement, typical of the condition, is usually impossible to demonstrate in utero. The differential diagnosis includes the glomerulocystic type of autosomal dominant polycystic kidney disease, Bardet-Biedl syndrome in which polydactyly is present [58] and other rare entities such as bilateral renal tumors, medullary sponge kidney, bilateral nephroblastomatosis, Finnish-type congenital nephrotic syndrome, medullary cystic disease, or congenital metabolic diseases (that is, glycogen storage disease or tyrosinosis). Oligohydramnios and absence of urine within the bladder would suggest ARPKD over all these rare entities.

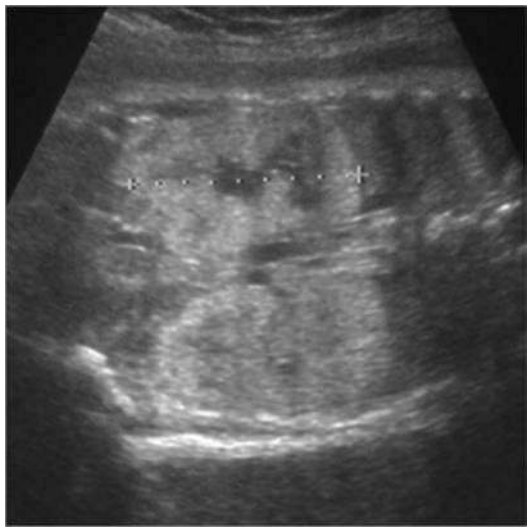

Fig. 1.7 Autosomal recessive polycystic kidney disease. Third trimester-coronal scan through the kidneys that appear large (+3 SD), and hyperechoic

Autosomal Dominant Polycystic Kidney Disease (ADPKD)

ADPKD is a common hereditary kidney disease, with 1/1000 people carrying the mutation. The pathological abnormality consists of a cystic dilatation of all parts of the nephron, which causes the kidneys to enlarge while the cortex and medulla become replaced by cysts, thus leading to end-stage renal failure [164, 165].

There are two major types of ADPKD: type I is caused by mutations in the *PKD1* gene on chromosome 16p13.3 and accounts for 85–90% of cases [164], and type II is caused by mutations in the *PKD2* gene on chromosome 4q21-22 and accounts for 10–15% of cases [165]. Other ciliopathy genes are likely to be involved since some obvious cases have none of these mutations. Although the age of clinical onset of this disorder is typically in the third to fifth decade of life, early manifestations during childhood or young adult age are now well described [166]. It is however unknown whether early diagnosis of ADPKD can enable earlier management and improve outcomes [167].

There may be different presentations in utero. In most cases, the kidneys are not grossly enlarged, but the corticomedullary differentiation is increased due to cortical hyperechogenicity. In this type of ADPKD, cysts are unusual in utero; they will develop after birth. Markedly enlarged kidneys resembling ARPKD are another pattern that can be encountered in utero and suggests either the homozygous presentation of ADPKD or the glomerulocystic type of ADPKD [168]. In these presentations of the disease renal failure may be already present in utero or at birth [163].

AL Grawany

Renal Hypoplasia and Dysplasia

Renal dysplasia refers to abnormal differentiation or organization of cells in the renal parenchyma and is characterized histologically by the presence of primitive ducts and nests of metaplastic cartilage [32, 33]. Hypoplasia is a reduction of the number of nephrons in small kidneys (below −2 SD) (Fig. 1.8) [33]. Hypoplasia may coexist with dysplasia and the diagnosis is inferred from the hyperechoic appearance on US caused by the lack of normal renal parenchyma and structurally abnormal small kidneys [32, 33]. As in most cases the diagnosis is made by US examination, the spectrum of renal dysplasia includes inherited or congenital causes of renal hypoplasia, renal adysplasia, cystic dysplasia, oligomeganephronic hypoplasia, reflux nephropathy and obstructive renal dysplasia [32]. Cases with oligohydramnios have the poorest outcome [169].

A number of developmental genes have been implicated in the pathogenesis of hypodysplastic kidneys [134]: *EYA1* and *SIX1* causing autosomal dominant branchio-oto-renal syndrome [137, 138], *HNF1B/TCF2* associated with autosomal dominant renal cysts and diabetes syndrome [140, 170], and *PAX2* causing autosomal dominant renal-coloboma syndrome [152].

After birth, the prognosis depends on the residual renal function at 6 months of age. Infants with a GFR below 15 mL/min per 1.73 m^2 are at high risk to require early renal replacement therapy [32].

Fig. 1.8 Unilateral renal hypoplasia. Sagittal US scan through a small-sized right kidney: 18 mm at 31 weeks: between calipers

Congenital Nephrotic Syndrome

Congenital nephrotic syndrome (CNS) is defined as proteinuria leading to clinical symptoms in the first 3 months after birth. Infantile nephrotic syndrome manifests later, in the first year of life. However, these definitions are arbitrary as the time of onset ranges from fetal life to few years of age [171]. Moreover, CNS is a heterogeneous group of genetic disorders with variable clinical presentations and progression to end-stage renal failure [172, 173]. In a recent cohort study on renal transplanted infants weighing ±15 kg, CNS represented 35% of cases [174].

Congenital nephrotic syndrome of the Finnish type (CNF) is characterized by autosomal recessive inheritance and is caused by mutations in the nephrin gene (*NPHS1*) [175]. Most infants are born prematurely, with low birth weight for gestational age. The placenta is enlarged, weighing more than 25% of newborn weight. Edema is present at birth or appears within a few days due to severe nephrotic syndrome. In utero, the observation of hydrops fetalis and increased nuchal translucency reflects massive proteinuria [176, 177]. Most of the α-fetoprotein measured in the amniotic fluid is produced by fetal urine [178]. CNF should be suspected in front of an α-fetoprotein concentration exceeding 250–500 mg/L (mean normal values: 16.3 mg/L at 15 weeks of gestation; 8.1 mg/L at 20 weeks of gestation) [179].

Other cases of prenatally diagnosed congenital nephrotic syndrome have been reported, including Podocin gene (*NPHS2*) mutations [180], Pierson syndrome [181, 182], *PLCE1* gene mutations [183], secondary nephrotic syndrome due to CMV or other intrauterine infections [184] and massive proteinuria in offsprings of mothers with homozygous deficiency for the metallomembrane endopeptidase [85].

Postrenal Causes of Fetal Renal Abnormalities

Dilatations of the renal pelvis, calyces and ureters are the principal signs of impaired urinary flow on antenatal ultrasound scanning.

Pelvicoureteric Junction Stenosis

Pelvicoureteric junction stenosis occurs in 13% of children with antenatally diagnosed renal pelvis dilatation [39] and is characterized by obstruction at the level of the junction between the renal pelvis and the ureter. The anatomical basis for obstruction includes intrinsic stenosis/valves, peripelvic fibrosis, or crossing vessels. Sonographic diagnosis depends on the demonstration of a dilated renal pelvis in the absence of any dilatation of ureter or bladder. It should be particularly suspected when severe (greater than 15 mm) dilatation is seen, when the cavities appear round shaped and in the presence of a perirenal urinoma [35, 185] (Fig. 1.9). The anomaly is twice as common on the left side and twice as common in boys than in girls [186]. Prognosis may be poor in bilateral cases associated with oligohydramnios and hyperechoic parenchyma. The postnatal management of these children still remains a controversial topic among the nephro-urologic community [187]. It involves close monitoring of both sonomorphological and functional criteria assessed by radionuclide renogram including renal transit limited to the cortical area, differential function and output function (drainage pattern) [188–191]. Importantly, while the wait-and-see approach has gained wide acceptance, the decision to follow up those neonates conservatively requires some level of vigilance and clear parental consent and cooperation in order to avoid any evitable complications including renal functional deterioration [192].

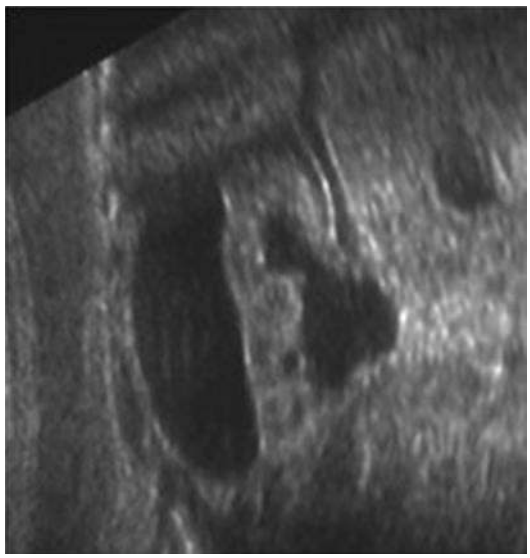

Fig. 1.9 Pelvicaliceal dilatation and perirenal urinoma in a fetus with pelviureteric junction stenosis. Coronal US scan through the right fetal kidney

Vesicoureteric Reflux (VUR)

VUR is defined as the retrograde flow of urine from the bladder upward within the ureter, sometimes extending into the renal pelvis, calyces and collecting ducts. Fetal renal pelvis dilatation can signal the presence of VUR in 11% [39] to 30% [193] of cases with the lower figure being more realistic. Making a precise diagnosis of VUR in utero is difficult. However, intermittent renal collecting system dilatation during real-time scanning (Fig. 1.10) or pelvicaliceal wall thickening are sonographic criteria highly suggestive of this diagnosis [194]. Although some children with high-grade, prenatally diagnosed VUR may have associated renal dysplasia [5, 194], VUR related to fetal renal pelvis dilatation was found in a large and prospective study to be of low-grade in 74% of cases with a high rate of 2-year spontaneous resolution (91%) [5]. Furthermore, in the absence of infections, reflux is not per se associated with progressive kidney injury [5]. The systematic use of VCUG in those babies is therefore questionable, especially since parents are frequently reluctant to consent to an invasive and uncomfortable examination for their child [195].

Uretero-Vesical Junction Obstruction (Megaureter)

In utero, under normal conditions, the ureters are not visualized. Megaureter should be suspected in the presence of a serpentine fluid-filled structure with or without dilatation of the renal pelvis and calices (Fig. 1.11). The ureter may be dilated because of obstruction at the level of the junction between the ureter and the bladder or as a result of nonobstructive causes including high-grade reflux. The differential diagnosis relies on VCUG. Megaureter could also be encountered in fetuses and/or newborns with neurogenic bladder or posterior urethral valves. In those cases, specific treatment strategies should be directed

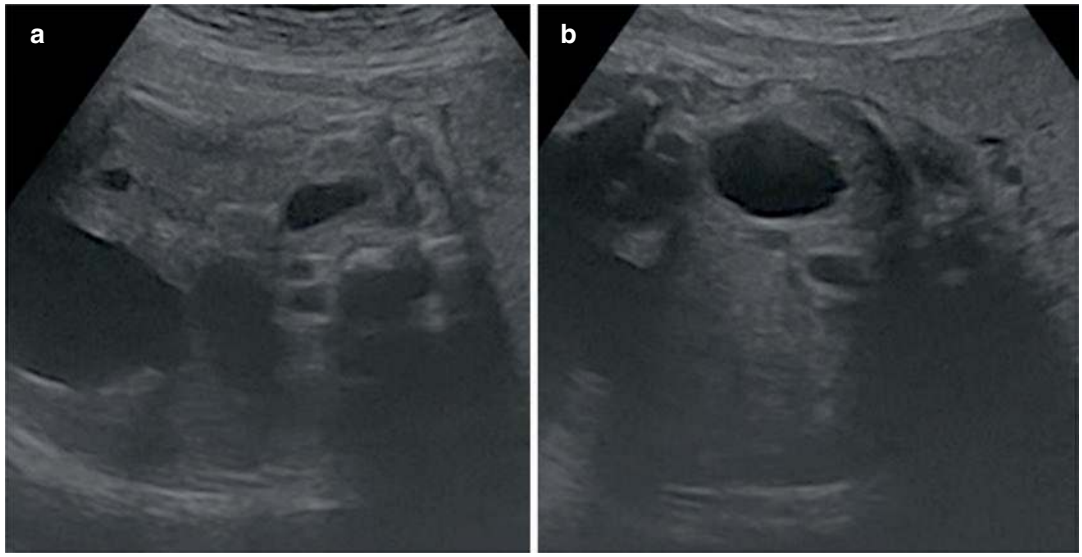

Fig. 1.10 (**a** and **b**) Fetal vesicoureteral reflux. Transverse scans of the fetal abdomen. Intermittent renal collecting system dilatation during the same antenatal ultrasound examination only visible in figure **b**, due to vesicoureteral reflux

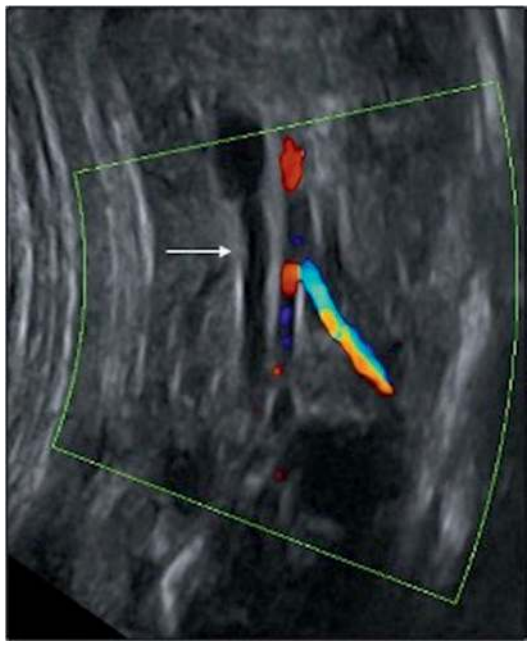

Fig. 1.11 Megaureter. Coronal scan of the fetal abdomen showing a fluid-filled structure (arrows) laterally to the aorta corresponding to a dilated ureter

toward the underlying condition. Prognosis of primary megaureter is generally good since most cases resolve spontaneously between ages 12 and 36 months [196]. However, in children with high-grade hydronephrosis, or a retrovesical ureteral diameter of greater than 1 cm, the condition may resolve slowly and may require surgery [196].

Duplex Kidneys

Duplication of the renal collecting system is characterized by the presence of a kidney having two pelvic structures with two ureters that may be completely or partially separated [197]. Most cases with non-dilated cavities have no renal impairment and should be considered as normal variants [4]. However, a proportion of duplex kidneys may be associated with significant pathology, usually due to the presence of VUR or obstruction. Fetal urinary tract dilatations are related to complicated renal duplication in 4.7% of cases [39]. VUR usually involves only the lower pole ureter in 90% of cases. Compared to single-system reflux, duplex system VUR tends to be of a higher grade with a high incidence of lower pole dysplasia [198]. Obstructive ureteroceles are associated with the upper pole ureter in 80% of cases, although obstruction of the upper pole may also occur secondary to an ectopic insertion or an isolated vesicoureteric junction obstruction (Fig. 1.12a) [198, 199]. In utero, duplex kidneys are highly suspected in the presence of two separate noncommunicating renal

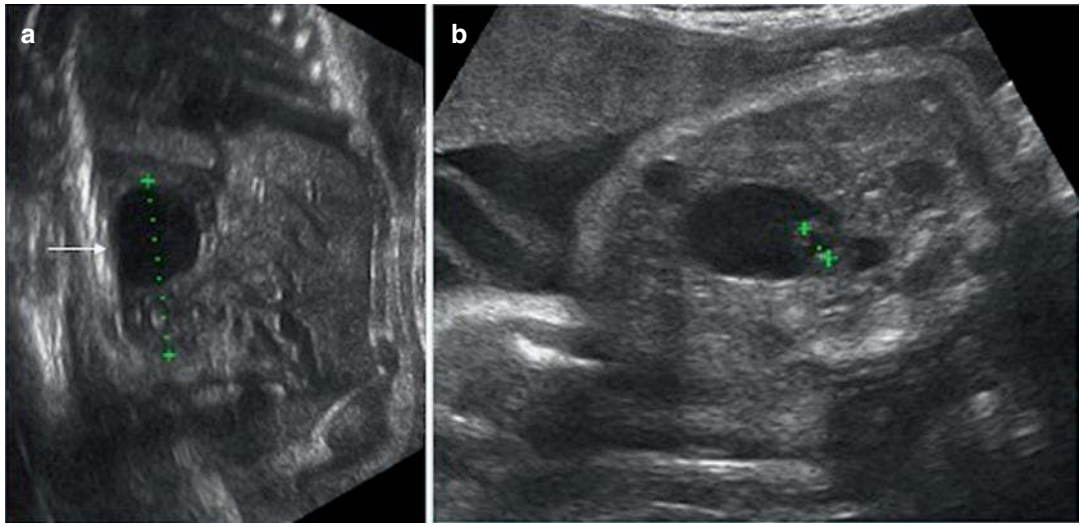

Fig. 1.12 (**a**) Fetal duplex kidney with dilatation of the upper pole (arrow). Sagittal US scan through the fetal kidney. (**b**) Fetal bladder with ureterocele (between crosses). Axial US scan through the fetal bladder

pelves, dilated ureters, cystic structures within one pole, and echogenic cyst in the bladder, representing ureterocele (Fig. 1.12b) [199, 200]. After birth, the classical radiological workup of abnormal duplex kidneys is based on US and VCUG [4]. Most people agree that the surgical approach to complicated duplex systems is largely predicated on the function of the affected renal moiety and the presence or absence of function [4].

Bladder Outlet Obstruction

When bladder obstruction is suspected in the first trimester, the most common causes are Prune Belly syndrome or fibrourethral stenosis, which is mainly associated with chromosomal and multiple congenital anomalies and carries a very poor prognosis [201]. In the second trimester, the most common cause of lower urinary tract obstruction in male fetuses is posterior urethral valves, which are tissue leaflets fanning distally from the prostatic urethra to the external urinary sphincter. The failure of the bladder to empty during an extended examination and the presence of abnormal kidneys and oligohydramnios must raise suspicion of posterior urethral valves. On occasion a megabladder with a thickened wall may be seen (Fig. 1.13a), and the dilated posterior urethra may take the aspect of a keyhole (Fig. 1.13b). In extreme cases in utero bladder rupture may be observed with extravasation of urine resulting in urinary ascites. This phenomenon was thought to be a protective pop-off mechanism, although recent reports provided evidence against this hypothesis [202].

In many cases there is only a partial obstruction, and amniotic fluid volume can be maintained throughout pregnancy. In some cases, spontaneous rupture of valves appears to occur in utero with the reappearance of cyclical emptying of the bladder. The most reliable prognostic indicators of poor renal functional status are presentation before 24 weeks, oligohydramnios, increased cortical echogenicity, and the absence of corticomedullary differentiation [203, 204].

The prognosis in severe cases is often relatively easy to predict, and perinatal death will occur secondary to pulmonary hypoplasia and renal failure [204]. The renal parenchymal lesions may be secondary to the obstruction but also to associated high-grade reflux. In partial obstruction, however, the outcome is less predictable, and late morbidity most commonly takes the form of end-stage renal failure, which affects 15–30% of individuals some time in childhood [205]. Once the prognosis has been determined

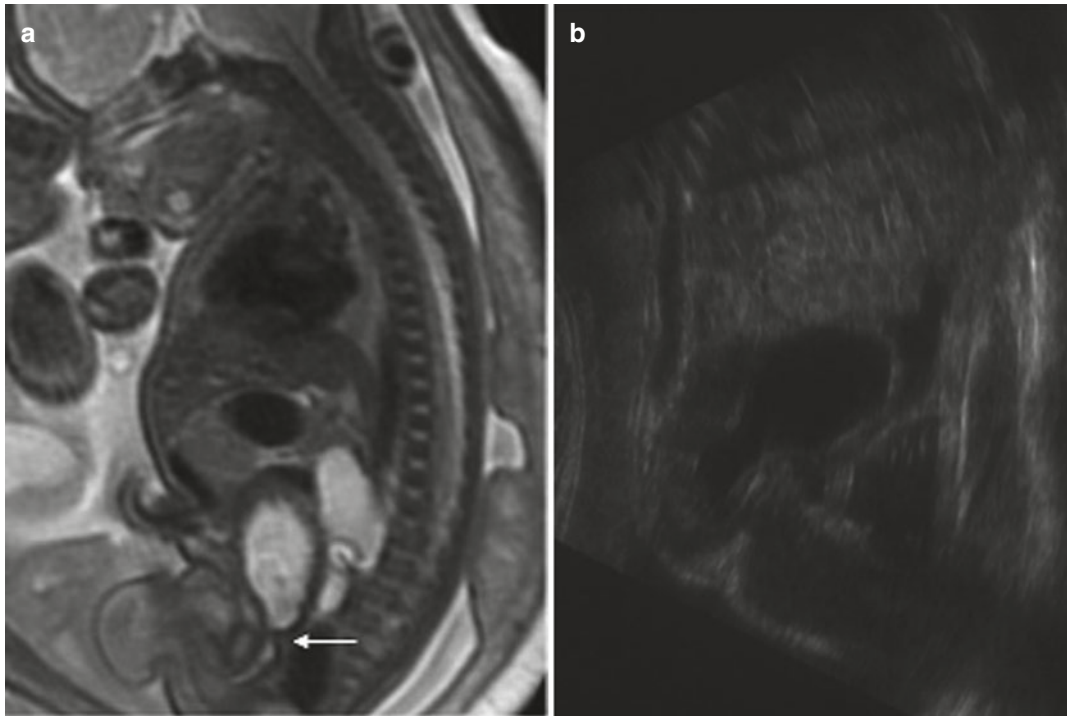

Fig. 1.13 (**a**) Fetal urethral valve with thickened bladder wall. Posterior urethral dilatation (arrow). Sagittal MR image on the fetal pelvis. (**b**) Megabladder. Third trimester scan. Huge enlargement of the fetal bladder due to posterior urethral valves. The key-hole sign is present

as accurately as possible, management of these cases should be performed in a fetal medicine and pediatric surgery reference center. In each new case, the great variability of presentation makes participation of different specialists necessary in the difficult decision-making process. Various options should be considered, including in utero follow-up with planned postnatal management (sustained medical treatment or palliative care), termination of pregnancy, and occasionally, in utero therapy [50].

Fetal Intervention for Lower Urinary Tract Obstruction

There was considerable interest in fetal intervention for obstructive uropathies in the 1980s and 1990s, which was revolutionary at that time. In utero intervention was thought to improve neonatal outcome by restoring amniotic fluid levels, thereby allowing normal pulmonary maturation and eventual renal function [206, 207]. A variety of in utero therapeutic approaches to bladder outflow obstruction have been tried. Expectably, the open surgical technique of **fetal vesicostomy** was not free of risks and has been abandoned due to significant fetal loss, premature uterine contractions and maternal morbidity [206, 207].

Direct endoscopic ablation of urethral valves is a more recent technique and requires the introduction of an endoscope into the fetal bladder, leading to ablation of the valves either by laser, saline irrigation or mechanical disruption using guide wire [208]. Direct visualization of the valves, however, is difficult, and it may be hard to avoid damage to surrounding tissues.

Vesicoamniotic shunting is performed under US guidance using a pigtail shunt, which when inserted leaves one end in the fetal bladder and the other in the amniotic space. This technique, which was first reported in 1982 [209], is

preferred to bladder drainage by serial vesicocentesis. A previous systematic review to assess the effectiveness of bladder drainage (vesico amniotic shunting or vesicocentesis) showed that fetal bladder drainage increased survival [210]. However, the studies identified in this systematic review were small, heterogeneous, observational, and non-randomized trials and so the potential for bias in these results was substantial. In addition, using survival alone as a marker of efficacy in these patients was misleading, since most of the survivors were left with significant renal morbidity. End-stage renal failure was present in 40% of those children who survived [90]. After decades of absence of serious clinical research, Rachel Morris and colleagues orchestrated and published in *The Lancet* in 2013 the results of the PLUTO (Percutaneous vesicoamniotic shunting in Lower Urinary Tract Obstruction) trial, in which fetuses with fetal lower urinary tract obstruction were randomly assigned to either vesicoamniotic shunting or conservative management [211]. Thirty-one women with singleton pregnancies complicated by lower urinary tract obstruction were included in the trial, with 16 allocated to the vesicoamniotic shunt group and 15 to the conservative management group. Unfortunately, the trial was stopped early because of poor recruitment after only about 20% of the planned 150 pregnancies were randomly assigned during a 4-year period. Although the results of PLUTO results have to be interpreted with caution due to the premature termination of the study and the small number of patients [212], postnatal survival was three-times higher in the fetuses receiving vesicoamniotic shunting. However, only two of seven shunted survivors had normal renal function at age 1 year. These results suggest that the chance of newborn babies to survive with normal renal function is very low irrespective of whether or not vesicoamniotic shunting is done. These findings are in line with results from studies in animals, which have shown that renal damage occurs rapidly after the onset of obstruction and might be only partly reversible [213].

In conclusion, the evidence available so far suggests that intrauterine shunting of an obstructed urinary tract will improve perinatal survival but does not carry any advantage with regards to the rescue of postnatal kidney function and long-term renal survival.

Laboratory Evaluation of Renal Disease in Childhood

2

Damien Noone and Valérie Langlois

Assessment of the Urine

Urinalysis

The American Academy of Pediatrics stopped recommending routine yearly urinalysis as a screening tool for chronic kidney disease (CKD) in otherwise healthy school-aged children over a decade ago [1]. Nonetheless, the value of the urinalysis in the evaluation of kidney disease should not be underestimated in certain patient populations. Important information can be learned from this simple, quick, inexpensive test when used in the appropriate setting. Commercially available reagent strips can be used to screen the urine for pH, specific gravity (SG), protein, blood, glucose, ketones, leukocytes, and nitrates. Urine specimens should be fresh and clean-voided midstream in older children. If analysis cannot be done within 4 h, then the sample needs a preservative and/or to be stored at 4 °C or lower (−20 or −80 °C) to maintain the integrity and prevent degradation of the specimen. The variations in pH and osmolality of the urine can cause particles within the urine to lyse. Various preservatives can be used, e.g., boric acid (changes urinary pH), sodium azide (to prevent bacterial overgrowth), formaldehyde (causes false positive leucocyte esterase), mercury salts and chlorhexidine [2].

Depending on urine concentration, the urine color varies from pale yellow to amber. Red or tea colored urine suggests the presence of blood, hemoglobin, myoglobin, porphyrin, non-pathologic pigments (beets, food color) or certain medications. Blue to green is suggestive of the presence of biliverdin or Pseudomonas infection.

The urine is normally clear, but can be cloudy in the presence of leukocytes, epithelial cells, bacteria, or precipitation of amorphous phosphate or urate. Unusual urine odor can lead to the diagnosis of rare metabolic disorders such as maple syrup urine disease (maple syrup odor), phenylketonuria (musty odor) or hypermethioninemia (fishy odor).

SG reflects the urinary concentrating and diluting capability of the kidney. In normal conditions, it reflects the patient's hydration status. However, with abnormal kidneys, a very low SG may represent a concentrating defect. It may be useful in distinguishing pre-renal states from intrinsic renal disease. SG usually ranges from 1:001 to 1:035 and can be measured using a urinometer or a refractometer, but more commonly using the reagent strips. The reagent strip test is based on pKa change of polyelectrolytes in relation to ionic concentration [3].

Urinary pH usually ranges from 5.0 to 8.5 depending on the acid-base balance of the body and can be estimated using the reagent test strip.

However, precise measurements need to be obtained using a pH meter with a glass electrode, particularly when <5.5 or >7.5. Urinary pH is important in the diagnosis of renal tubular acidosis and monitoring the treatment for prevention of urinary stones.

Glucose is not usually present in the urine. Glucose is freely filtered at the glomerulus and reabsorbed in the proximal tubule via a sodium-coupled active transport mechanism. Glucosuria can be seen when the serum glucose is above the renal threshold, or due to isolated renal glucosuria or generalized proximal tubular dysfunction (Fanconi syndrome). Normal values for maximal tubular glucose reabsorption (TmG) in children vary from 254 to 401 mg/min/1.73 m^2 [4]. Reagent test strips are usually impregnated with the enzyme glucose oxidase and only detect glucose. Other sugars can be detected by the copper reduction test such as Clinitest Tablet (Ames Co.). A false negative glucose can occur with high dose vitamin C and in the setting of elevated ketones [2].

Ketone bodies are formed during the catabolism of fatty acids and include acetoacetic acid, β-hydroxybutyric acid, and acetone. Most reagent strips for ketones are based on a color reaction with sodium nitroprusside and are sensitive for acetoacetic acid but will not detect β-hydroxybutyric acid or acetone.

Strip tests detect leukocyte esterase, an enzyme found in neutrophils. Nitrites indicate the presence of bacteria capable of reducing dietary nitrate, such as *Escherichia coli*, *Enterobacter*, *Citrobacter*, *Klebsiella*, and *Proteus* species. A positive urinalysis for both leucocytes and nitrites is suggestive of bacteriuria or a urinary tract infection (UTI), and if both are negative then a UTI is unlikely. If either are positive, then a further confirmatory urine culture is required [5, 6]. Samples should be processed rapidly to avoid degradation of esterases and false negative results [7]. For children under the age of two, urinalysis is less reliable for the diagnosis of UTI [6]. For infants less than one year of age, microscopic presence of moderate bacteria and >10 white cells/high powered field is more accurate in diagnosing a UTI [6]. An alkaline pH or the ingestion of beets can cause a false positive leukocyte esterase and there may be a false negative in the setting of high urinary glucose, protein or with antibiotics. There may be a false negative nitrite when the urine SG is high, with ascorbic acid ingestion (reducing agent), if the child eats insufficient fruits and vegetables to provide the nitrate substrate in the urine or if the incubation time is too short due to urinary frequency [2, 8]. The accuracy of urinary nitrites in the diagnosis of UTIs in those under age 2 years has been recently called into question; they miss UTIs in about 75% of young children [8].

Hematuria is defined as the presence of >5 red blood cells (RBCs) per high power field in centrifuged urine. The presence of RBCs can only be confirmed by microscopic evaluation of fresh urine. Reagent strips detect RBCs, myoglobin, and hemoglobin because all contain a heme moiety. As with nitrite detection, ascorbic acid can cause a false-negative due to it being a strong reducing agent. The supernatant of a centrifuged urine containing red blood cells will be clear yellow as opposed to being pink if the urine contains hemoglobin or myoglobin. The morphology of the cells can help determine their origin. The presence of dysmorphic red blood cells suggests glomerular hematuria.

Urine Microscopy

"…the ghosts of dead patients that haunt us do not ask why we did not employ the latest fad of clinical investigation. They ask us, why did you not test my urine?"—Sir Robert Grieve Hutchison (1871–1960) [9].

Microscopic evaluation of fresh urine (within 1–2 h) is extremely valuable in the evaluation of renal disease. Ideally, 10 mL of urine is centrifuged at 1500 rpm for 5 min, and about 9.5 mL is decanted off. The remainder is gently agitated; a single drop is placed on a glass slide; and a cover slip is added. The urine sediment is examined at low (×10) and high (×40) magnification for the presence of casts, cells, and crystals. Although hyaline (containing primarily uromodulin) and granular casts can be seen in normal states, cel-

lular casts are pathologic. Granular casts contain degraded cell lysosomes and other debris from degenerated renal tubular epithelial cells and typically reflect tubular injury or acute tubular necrosis. Red blood cell casts are pathognomonic of glomerular disease and white blood cell (WBC) casts can be seen with pyelonephritis or post-infectious glomerulonephritis [10].

Crystals are rarely seen in fresh urine but appear after the urine stands for a period. Uric acid, calcium oxalate, amorphous urate, cystine, tyrosine, leucine, and cholesterol crystals are usually found in acid urine. Uric acid and calcium oxalate crystal can be seen in normal and pathological conditions. Amorphous urate crystals are of no clinical significance. Cystine, tyrosine, leucine, and cholesterol crystals are always relevant. Cystine crystals (colorless and hexagonal) are present in patients with cystinuria, leucine crystals can be associated with maple syrup urine disease, methionine malabsorption syndrome and severe liver disease. Tyrosine crystals also occur in severe liver disease, tyrosinosis, and methionine malabsorption syndrome. The presence of cholesterol crystals can indicate excessive tissue breakdown, or nephritic or nephrotic syndrome [3]. Triple phosphate, calcium carbonate, ammonium biurate, amorphous phosphates and calcium phosphate crystals are usually found in alkaline urine. Calcium carbonate and amorphous phosphate are of no clinical significance [10]. Many drugs are associated with crystalluria, including acyclovir, amoxicillin, atazanavir, ciprofloxacin, methotrexate, sulfadiazine, triamterene and vitamin C [10].

The association of urinary eosinophils with acute interstitial nephritis (AIN) was first reported by Galpin et al. [11] and became widely accepted as supportive of a diagnosis of AIN. Hansel's stain replaced Wright's stain, the latter being ineffective when urine pH was <7, and the former revealing the bright red granules of eosinophils. However, eosinophiluria may be seen in a variety of conditions, including prostatitis, cystitis, and glomerulonephritis, limiting the sensitivity and positive predictive value of the test. Compared to the gold standard of kidney biopsy, eosinophiluria lacks sensitivity and specificity, and cannot distinguish AIN from acute tubular necrosis. Hence, it really has no diagnostic utility [12].

Automated microscopy that uses laminar flow digital imaging technology can classify and count cells (RBCs, WBCs and epithelial cells) and particulate matter (bacteria, yeasts and crystals) in uncentrifuged urine. Urine particle flow cytometers can quantify cells more accurately than manual urine microscopy [13].

Urinary Protein Excretion

In the normal state, most of the filtered low molecular weight (MW) proteins (MW < 40,000) are reabsorbed in the proximal tubules. Proteins of higher MW, such as albumin (MW = 60,000), are not usually filtered. Tamm Horsfall proteins are secreted by the tubular cells in the ascending thick limb of the loop of Henle and are the main protein found in normal urine.

In disease states, increased amount of protein can be found in the urine and may reflect damage in the glomerular barrier (glomerular proteinuria) or impaired tubular reabsorption (tubular proteinuria). In glomerular proteinuria, albumin, which is not usually present, is the dominant protein. β2-microglobulin, α-1-microglobulin, and retinol-binding protein are markers of tubular proteinuria.

Proteinuria can vary by age, sex, ethnicity and body mass index [14, 15]. In the first month of life, proteinuria is 4–5 times higher than in older infants, perhaps reflecting the evolving maturity of the tubules, and the 90th percentile for urinary albumin/creatinine ratio (UACR) in the neonatal period was reported as 17.5 (90% Confidence Interval 7.1–79.7) mg/mmol in one study [16]. Normative ranges for UACR at different ages are presented in Table 1 [17].

The 2012 KDIGO Clinical Practice Guideline for the evaluation and management of CKD recommends, in order of preference, a UACR, a urine protein/creatinine ratio (UPCR), reagent strip urinalysis for total protein with automated reading and, finally, a reagent strip with manual reading for assessment of proteinuria. All should ideally be done on an early morning urine speci-

men [18]. It is not usually necessary to obtain a timed urine collection. A standard urine dipstick can be used to detect increased total urine proteins and albumin-specific dipsticks are acceptable to detect microalbuminuria. Microalbuminuria refers to albumin excretion above the normal range, but below the level of detection of the standard urine dipstick. UACR or UPCR ratio should be done within 3 months of a positive dipstick to confirm albuminuria or proteinuria, respectively. Post-pubertal children with diabetes of 5 or more years' duration should have urine albumin measured by albumin-specific dipstick or UACR, and this should be performed annually [19, 20].

Urine dipstick can provide an estimate of proteinuria and is most sensitive for albumin. False positive dipstick can be the result of prolonged immersion of the reagent strip, alkaline urine (pH > 7.5), presence of pyuria, bacteriuria or mucoprotein and penicillin [21]. A false negative can occur in very dilute urine [2].

Twenty-four-hour urine collections have long been the gold standard for quantification of urine protein excretion. The adequacy of the collection is verified by quantifying the total creatinine content of the sample, which should be about 15–20 mg/kg in females and 20–25 mg/kg in males [22]. However, collection in young children often requires catheterization and is not practical. First morning urine for UPCR is generally accepted as being valid in the assessment of proteinuria in children [18]. A recent study confirmed that UPCR is positively correlated with 24-h urine protein in children, and the cutoff of UPCR <0.2 g/g corresponds to normal protein excretion and the cutoff UPCR ≥2 g/g is nephrotic-range proteinuria [23].

Twenty-four-hour urine protein excretion of <4 and >40 mg/m^2/h is normal and nephrotic-range proteinuria, respectively. Normal urinary albumin excretion is between 30–300 mg/day on a 24-h collection, 20–200 μg/min in an overnight collection and 3–30 mg/mmol on a first morning urine sample (Table 2) [24]. There can be significant diurnal variation in proteinuria in children and adolescents that is generally not considered pathological and resolves by adulthood. Orthostatic proteinuria is defined as an elevated protein excretion in the upright position, but normal excretion in the recumbent position. It can be assessed on a split 24-h urinary protein assessment [22]. Previous studies reported an incidence of 2–5% [22]; however, a study using 24-h total urinary protein excretion found a much higher incidence of 19.8% in a cohort of 91 children [25]. The original studies had used dipstick analysis [22], spot UPCR [26] or timed collections of less than 24 h [25, 27].

In 2006, Mori et al. [28] measured the UPCR in a cohort of Japanese children with urinary tract abnormalities or glomerular disorders and found that it varies according to body size and composition, reflecting muscle mass. They suggested that evaluation of UPCR should also consider body height, because as height and therefore muscle mass (denominator) increases, the ratio will decrease. A normative range for urinary protein excretion for the different sexes and as height and body surface area increases remains to be defined [28]. Kim et al. [29] proposed urine protein-to-

Table 1 Mean urinary albumin excretion, expressed as a albumin/creatinine ratio [17]

Age	Spot urine (mg/mmol)
Neonates	5.24
1–3 months	5.01
4–6 months	4.06
7–23 months	1.76
2–4 years old	1.34
3–19 years old	3

Table 2 Reference values for urinary protein excretion [19]

	24 Hour collection (mg/m^2/h)	24 Hour Collection (mg/m^2/day)	Spot urine protein/creatinine (mg/mg)	Spot urine protein/creatinine (mg/mmol)
Normal range				
6–24 months	<4	<150	<0.5	<50
>24 months		<150	<0.2	<20
Nephrotic	>40	>3 g/1.73 m^2/day	>2	>200

osmolality ratio as an alternative test to 24-h urinary protein excretion. Urinary protein-to-osmolality corrects for hydration status, can be used in children with decreased muscle mass, and has now been validated in two further pediatric populations against both spot UPCR and 24-h urinary protein excretion [30, 31]. In children, a spot urinary protein-to-osmolality ratio above 0.33 and 1.75 mg/L/mOsm/kg represents abnormal proteinuria and nephrotic-range proteinuria, respectively [31].

Standard urine dipstick tests are primarily sensitive to detect albumin. Screening for low MW protein can be done by the sulfosalicylic acid test. The addition of sulfosalicylic acid to the supernatant of centrifuged urine will cause cloudiness in the presence of any protein in the urine. A negative reagent strip test with a positive sulfosalicylic acid test is suggestive of low MW proteinuria. Urine protein electrophoresis can confirm the diagnosis. A false positive sulfosalicylic acid test can be produced by radiographic contrast, penicillin, cephalosporins, sulfonamide metabolites and high uric acid concentration [21].

Assessment of Renal Function

Glomerular Filtration

Glomerular filtration rate (GFR) is the most commonly used measure of kidney function and is used to classify various stages of CKD (Table 3) [18]. It can be quantified by measuring the clearance rate of a substance from the plasma. The substance can be endogenous or exogenous. It is often referred to as the "marker". Different markers such as inulin, creatinine, iothalamate, iohexol, ethylenediaminetetraacetic acid (EDTA) and diethylenetriamine pentaacetic acid (DTPA) are available. The ideal marker must have a stable plasma concentration, should be filtered, but not reabsorbed, secreted, synthesized or metabolized by the kidney so that the amount filtered equals the amount excreted.

Table 3 NKF-K/DIGO 2012 Classification of the stages of chronic kidney disease in children greater than 2 years of age [38]

Stage	Description	GFR (mL/min/1.73 m^2)
1	Kidney damage with normal or increased GFR	>90
2	Kidney damage with mild reduction of GFR	60–89
3a	Moderate reduction of GFR	45–59
3b	Moderate to severe decrease of GFR	30–44
4	Severe reduction of GFR	15–29
5	Kidney failure	<15

The renal clearance of the substance x (Cx) can be obtained by multiplying the urinary concentration of substance x (Ux) times the urinary flow rate in mL/min (V) divided by the plasma concentration of substance x (Px).

$$Cx = Ux * V / Px$$

Inulin

Determination of urinary inulin clearance during a continuous intravenous infusion is considered the "gold standard" method for measurement of GFR. Inulin has all the properties of an ideal marker. Inulin is inert and not synthesized or metabolized by the kidney. It is freely filtered by the glomerulus, and not secreted or reabsorbed in the tubules [32].

The measurement of urinary inulin clearance requires a constant intravenous infusion to maintain a constant level of inulin over a period of 3–4 h. After an equilibration period, timed urinary specimens and plasma are collected every 30 min and urinary and plasma inulin is measured to calculate urinary inulin clearance. The mean clearance of the 4–5 measurements determines the individual's GFR [33]. Urinary catheterization in young children is often required. To avoid this cumbersome procedure, two methods of plasma inulin clearance have been developed: the continuous infusion method and the single bolus method [34, 35]. The continuous infusion method is based on the concept that once a marker has reached steady state in the plasma and the volume of distribu-

tion is saturated, the rate of elimination of the marker will equal the rate of infusion (RI).

The clearance of the marker can then be measured [34]

$$Cx = RI\,x\,/\,Px$$

The equilibration period can take more than 12 h in certain situations. To avoid this long period, a bolus can be given prior to the infusion to reach steady state more rapidly.

After a single bolus injection, 10–12 blood samples are collected up to 240 min after injection and the inulin concentration measurements are used to construct a plasma concentration versus time curve (plasma disappearance curve). Plasma clearance of inulin can be calculated by dividing the dose by the area under the plasma concentration-time curve. This method has been shown to give accurate results in adults [36]. van Rossum et al. developed and validated sampling strategies to minimize the number of blood samples, making it more acceptable for children [37]. He concluded that two (at 90 and 240 min) to four samples (at 10, 30, 90, 240 min) allow accurate prediction of inulin clearance in pediatric patients with a non-significant bias and good imprecision (<15%) [37]. The single bolus injection method tends to overestimate GFR (average 9.7 mL/min 1.73 m^2), but the difference between the two methods becomes smaller at lower GFR (less than 50 mL/min/1.73 m^2) [37].

Although measurement of inulin clearance remains the gold standard for assessment of GFR, most laboratories cannot routinely measure inulin, which makes this test unpractical. Furthermore, simple, rapid determination of GFR is often needed in clinical practice.

The KDIGO 2012 Clinical Practice Guideline for the Evaluation and Management of Chronic Kidney Disease recommends the use of serum creatinine and a pediatric-specific GFR estimating equation which incorporates a height term in the initial assessment of pediatric renal function [38].

Serum Creatinine

Creatinine is an amino acid derivative produced in muscle cells. Its production increases in proportion to muscle mass, it is freely filtered, and about 10% of the creatinine found in urine is secreted by the proximal tubules. Tubular secretion varies between and within individuals [39]. Creatinine is used as a measure of renal function. In the past, laboratories used different measurement methods and the lack of standardization was clinically significant. In 2006, the National Kidney Disease Education Program published recommendations to improve creatinine measurement [40]. It is now recommended that creatinine measurements in all infants and children utilize methods that minimize confounders and that are calibrated against an international standard [38].

Creatinine Clearance (Ccr)

Creatinine clearance measurement has been widely used and correlates well with inulin clearance within the normal range of GFR [41]. Creatinine has the advantage of being an endogenous marker, which precludes the need to use an injection. However, as GFR declines the percentage of secreted creatinine increases; therefore, Ccr at low GFR will significantly overestimate true GFR [42]. In order to decrease tubular secretion of creatinine and obtain a creatinine clearance more reflective of the true GFR, cimetidine can be given in patients with renal disease since cimetidine decreases tubular secretion of creatinine [43, 44]. The cimetidine protocol involves the administration of cimetidine (20 mg/kg to a maximum of 1600 mg divided twice daily for a total of five doses) prior to assessment of urinary creatinine clearance. For the 24 h prior to the test, the patients were placed on a meat-free diet. Dose adjustments in cimetidine according to renal function are advised and the complete protocol is reported [45].

Equations to Predict GFR

Schwartz [46] and Counahan [47] first developed equations to predict GFR. In the clearance formula, the numerator UCr × V is the excretion rate of creatinine; in steady state this must equal the rate of production. Since the rate of production is a function of muscle mass, Schwartz tested different variables of body size to provide the best correlation with GFR measured by creatinine clearance. The body length had the best correlation. The GFR can be estimated using the equation known as the Schwartz formula:

$$\mathrm{GFR}\left(\mathrm{mL/min/1.73\ m^2}\right) = \mathrm{K} * \mathrm{Ht/PCr}$$

where K is a constant determined by regression analysis for different ages, Ht = height in cm and PCr = plasma creatinine.

Following the standardization of creatinine measurement, the pilot study for the Chronic Kidney Disease in Children (CKiD) study showed that the Schwartz formula overestimates GFR when compared to measured iohexol [48]. This was attributed to the fact that creatinine values determined by enzymatic creatinine assays are lower than those determined by the Jaffe method [49].

Subsequently, a number of new equations have been developed and validated. Many of these new equations were developed using a "gold standard" other than inulin and may overestimate GFR. Furthermore, the precision and accuracy of each equation may not be the same at all GFR levels, depending on which populations were used for validation. As per KDIGO, currently the most robust pediatric estimated GFR (eGFR) formula derived using iohexol disappearance and creatinine measurements, which were measured centrally and calibrated and traceable to international standards, is from the CKiD study [38, 50, 51].

The most common creatinine-based formulas recommended for use in clinical practice is the updated bedside Schwartz formula also known as the CKID 2009 equation [50]

$$\mathrm{eGFR}\left(\mathrm{mL/min/1.73\ m^2}\right) = 41.3 \times \mathrm{height\ (m)\,t/Scr(mg/dL)}$$

or

$$\mathrm{eGFR}\left(\mathrm{mL/min/1.73\ m^2}\right) = 36.5 \times \mathrm{height(cm)/creatinine(\mu mol/L)}$$

The CKID 2009 equation was validated in a population consisting primarily of children aged 8–15 years of age with reduced GFR and used creatinine as the marker.

Equations based on multivariate analyses are superior to those using univariate analysis. However, in some situations, a univariate equation might be preferred. For example, since creatinine is highly dependent on muscle mass, a cystatin C based equation may be preferable in patients with reduced muscle mass.

In 2012, the CKiD study group developed an improved equation to estimate GFR by adding cystatin c and urea as filtration markers and sex as additional variables [51].

$$\mathrm{eGFR}\left(\mathrm{mL/min/1.73\ m^2}\right) = 39.8 * \left[\mathrm{ht(m)/Scr(mg/dL)}\right]^{0.456} \left[1.8/\mathrm{cystatin\,C(mg/L)}\right]^{0.418}$$
$$\left[30/\mathrm{BUN(mg/dL)}\right]^{0.079} \left[1.076^{\mathrm{male}}\right] \left[\mathrm{ht(m)}/1.4\right]^{0.179}$$

Cystatin C

Cystatin C is a low MW protein (MW = 13.36) member of the cystatin superfamily of cysteine protease inhibitors. It is produced at a stable rate by all nucleated cells. Cystatin C is freely filtered by the glomerulus and metabolized after tubular reabsorption [52]. Since it is not excreted in the urine, its clearance cannot be calculated.

Cystatin C is less influenced by age, gender and muscle mass than creatinine [53]. Levels decline from birth to one year of age then remain stable until about 50 years of age. However, cystatin C levels may be influenced by cigarette smoking, high c-reactive protein, steroid use and thyroid disorders [54–56]. One pediatric study showed that for children with CKD stage 3–5 the intrapatient coefficient of variation of cystatin C was significantly lower than serum creatinine and proposed that cystatin C is a better tool for longitudinally monitoring patients with advanced CKD [57]. Equations based on cystatin c and/or creatinine using different variables can be found in Table 4.

Some of the equations were developed using height as one of the variables whereas some are height independent to allow quick estimation of GFR when patient height is not available [58, 59]. These equations were externally validated against the gold standard single injection inulin clearance. The eGFR Pottell was superior to the eGFR-BCCH and comparable to the eGFR Schwartz [60]. Pottel developed an equation to be used in children, adolescents and young adults since none of the previous equations were validated for adolescent and young adults [61]. KDIGO suggest that measuring cystatin C based eGFR (not serum cystatin C) could be undertaken in adults with a creatinine-based eGFR of 45–59 mL/min/1.73 m^2 who do not have markers of kidney damage, such as proteinuria, in an attempt to confirm CKD. No specific recommendation for pediatrics or equation was made [38].

Since 2010, standards of measurement for cystatin C have been developed by the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) to reduce variability. The National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) recommends that eGFR based on cystatin C use an equation that was developed using data from measurement procedures that were standardized to the certified reference. This new IFCC-standardized assay increases measured cystatin C significantly and can thus affect the validity and reliability of GFR estimating equations [62]. The CKiD equation was one such equation initially affected by the change in standardization, but cystatin C values are now standardized to the appropriate IFCC reference. To correct older results to the new IFCC concentrations the value is multiplied by 1.17 [63].

Table 4 Equations to estimate GFR

Name	Equation to estimate GFR	Reference method used to derive
	Height dependent	
Updated Bedside Schwartz [50]	eGFR(mL/min/1.73 m^2) = 41.3[Height (m)/Scr (mg/dL)] or eGFR(mL/min/1.73 m^2) = 36.5[Height (cm)/Scr (μmol/L)]	Iohexol
Updated CKiD [51]	eGFR(mL/min/1.73 m^2) = 39.8[ht (m)/Scr (mg/dL)]$^{0.456}$[1.8/CysC (mg/L)]$^{0.418}$[30/BUN (mg/dL)]$^{0.079}$[1.076^{male}][ht (m)/1.4]$^{0.179}$	Iohexol
	Height independent	
Pottel [59]	eGFR(mL/min/1.73 m^2) = 107.3/[Scr (mg/dL)/Q] where Q is the median serum creatinine concentration for children based on age and sex Median serum creatinine (mg/dL) = 0.0270 × age + 0.2329 To express serum creatinine concentration in μmol/L, multiply by 88.4	Inulin
Modified BCCH equation [58]	eGFR(mL/min/1.73 m^2) = Inverse ln of: 8.067 + (1.034 × ln[1/SCr (μmol/L)]) + (0.305 × ln[age (years)]) + 0.064 if male	Iothalamate
Filler [223]	eGFR(mL/min/1.73 m^2) = 91.62[1/CysC]1.123	TcDTPA

Pediatric and adult equations for eGFR were developed using different datasets. The equations don't align at the transition from adolescent to adult. The CKiD equation generally underestimates GFR whereas the CKD-EPI equation, which is recommended for eGFR in adults, tends to overestimate GFR in young adults. Therefore, to improve the estimation of GFR in adolescent and younger adults, Pierce et al. modified the CKiD 2009 bedside estimation of GFR to include sex and age and used a dataset with patients 1–25 years old. The two equations, one for creatinine and one for cystatin C, are known as the CKiD U25 [64].

Bjork et al. also tried to improve the accuracy of eGFR in children and young adults [65]. They first established sex specific creatinine growth curves for children and young adults. These curves can be used to project childhood levels of serum creatinine to corresponding adult levels. Using the estimated adult creatinine, he then developed a modified CKD-EPI equation, the CKD-EPI 40, to improve precision and accuracy for both children and young adults at all measured GFR levels. This allows the use of the same equation for most patients without artificial change when transitioning from adolescent to adult care. However, the cohorts used for validation were from 4 European countries and may not be generalized to non-European populations or specific ethnic groups.

Other Methods

KDIGO suggests measuring GFR using an exogenous filtration marker when more accurate GFR will impact the treatment decisions. Since inulin is not widely available, other markers can be used.

Iohexol and Iothalamate

Iohexol is a safe nonionic low osmolar contrast agent (MW 821). It is eliminated exclusively by the kidneys, where it is filtered, but not secreted, metabolized, or reabsorbed. It has less than 2% binding to protein. Therefore, it makes it an ideal marker of GFR and a good alternative to the use of radiotracers that are not suitable for some patients and require special handling, storage and disposal. Iohexol and iothalamate have similar kinetic profiles, but iohexol has a lower allergic potential [66].

Clearance of iohexol correlates well with measured inulin clearance [48, 66–68]. Gaspari et al. [69] showed a highly significant correlation between GFR measured by the plasma clearance of iohexol (using a two-compartment open–model) and the GFR measured by urinary inulin clearance.

EDTA, DTPA Nuclear GFR

GFR can be accurately measured using a radioactive tracer such as Chromium 51 (51Cr) EDTA or technetium 99m (^{99m}Tc) DTPA in children. The most accurate method is based on the plasma disappearance curve after a single bolus injection, fitted by a double exponential curve. The clearance of the radiotracer is calculated as the injected dose divided by the area under the curve [70]. The initial "fast curve" represents the diffusion of the radiotracer in its distribution volume whereas the late slow exponential curve represents its renal clearance. The two-compartment model requires serial blood sampling to obtain an accurate plasma disappearance curve. In general, the more numerous blood samples that are acquired over time, the more accurate the calculated GFR value will be. However, to avoid excessive blood sampling, two simplified methods have been proposed for routine clinical use in children [71].

The Slope-Intercept Method

The slope-intercept method requires two blood samples acquired 2 and 4 h post injection and is based on the determination of the late exponential curve. An algorithm must be used to correct for overestimation of the clearance because this method neglects the early exponential curve. Late blood sampling (between 5 and 24 h) is recommended to improve the accuracy in patients with renal clearance below 10–15 mL/min/1.73 m^2.

The Distribution Volume Method

This method only requires one blood sample acquired at 2 h post injection. It appears to be valid for children of any age except for those with very poor renal function (GFR < 30 mL/min/1.73 m^2) [70].

One major limitation of these methods is decreased accuracy in the presence of significant edema. In such situations, the disappearance of the tracer will be influenced by its diffusion into an expanded extracellular volume, artifactually elevating the calculated GFR. Infiltration of the radiotracer at the injection site can also cause artifactual elevation of GFR.

The effective dose of radiation is approximately 0.011 mSv/examination regardless of the age of the child for Cr-EDTA and twice as high with low GFR (<10 min/1.73 m^2). It is 0.1 mSV/examination for Tc-DTPA [70].

Assessment of Tubular Function

Fluid filtered by the glomerulus (plasma ultrafiltrate) enters the proximal tubule where 60–65% of the filtrate will be reabsorbed [72]. In disorders of the proximal tubule, excessive amount of the solutes will be found in the urine. The fractional excretion of sodium and tubular reabsorption of phosphate can be used to assess the integrity of the proximal tubules. Detection of glucosuria and aminoaciduria can also be indicative of a proximal tubular disorder in certain situations.

Fractional Excretion of Sodium (FeNa)

This is one of the most used tests of tubular integrity. There is no "normal" for fractional excretion of salt. It must be interpreted in the context of each patient's sodium and volume status.

In the face of hyponatremic dehydration the appropriate response will be conservation of sodium and water. Therefore, the fractional excretion of salt will be low, usually with a FeNa <1% in children and less than 2.5% in neonates. The urinary sodium concentration will be <20 mEq/L in children and <30 mEq/L in neonates. The FeNa can be useful in distinguishing prerenal, assumed reversible acute kidney injury (AKI) as first shown in a seminal paper in 1976 where patients who recovered from their acute oliguria had a FeNa <1%, and those that didn't recover after volume resuscitation had a FeNA >3% [73]. If tubular damage has occurred, such as in acute tubular necrosis, the fractional excretion of sodium will be inappropriately elevated. The FeNa will be >2% in children and >2.5% in neonates. Urinary sodium will generally be more than 30 mEq/L.

However, FeNa is unreliable in certain situations, such as when patients are on diuretic therapy, receiving intravenous saline or in patients with salt losing tubulopathies or CKD [74, 75]. The FeNa may be substituted by FeUrea, as urea is less influenced by diuretics, because urea reabsorption is mostly dependent on passive forces [76]. A FeUrea <35% implies prerenal AKI; it is >50% if there is intrinsic AKI. High FeNa combined with FeUrea >35% has a 95% negative predictive value for intrinsic AKI [77].

The FeNa can be calculated as below:

$$\text{FeNa} = \frac{\text{U}(\text{Na}) * \text{PCr}}{\text{PNa} * \text{UCr}} * 100$$

UNa = urinary concentration of sodium
PCr = plasma creatinine
PNa = plasma sodium
UCr = urinary creatinine

Tubular Reabsorption of Phosphate (TRP)

Eighty-five to ninety-five percent of phosphate is usually reabsorbed in the proximal tubule [72]. Phosphate transport is primarily regulated by the plasma phosphate concentration and parathyroid hormone, which alter the Na^+-phosphate carrier activity.

The normal tubular reabsorption of phosphate (TRP) is greater than 85% and can be calculated:

$$\text{TRP\%} = 1 - \frac{\left(\text{UPO}_4 * \text{PCr}\right)}{\left(\text{PPO}_4 * \text{UCr}\right)} * 100$$

UPO_4 = urinary concentration of phosphate
PCr = plasma creatinine
PPO_4 = plasma concentration of phosphate
UCr = urinary concentration of creatinine

The renal tubular maximum reabsorption rate of phosphate to glomerular filtration rate (TmP/GFR) was initially described by Bijvoet using phosphate infusion [78]. Its initial use was for diagnosis of hypercalcemia, parathyroid disorders and renal handling of phosphate. Although it is no longer used for evaluation of hypercalcemia, it can still be helpful for evaluation of hypophosphatemia. A nomogram [79] and algorithm [80] were derived from the initial infusion data of Bijvoet and can be used to calculate the TmP/GFR ratio from the TRP. The algorithm is less prone to error and therefore recommended instead of the nomogram [81]. Basically, if the TRP is ≤0.86 then TmP/GFR = TRP × P_p (where P_p = plasma phosphate) and if >0.86 then TmP/GFR = 0.3 × TRP/[1 − (0.8 × TRP)] × P_p [80, 81].

Glucosuria

Filtered glucose is usually almost completely reabsorbed in the three segments of the proximal tubule. Glucose is transported across the apical membrane by secondary active transport dependent on the sodium electrochemical gradient generated by the Na–K ATPase. Two sodium-glucose transporters are found in the proximal tubule. SGLT2, in the early proximal tubule, has high capacity and low affinity for glucose and SGLT1, found in segments 2 and 3, has high affinity and low capacity [82].

The plasma glucose at which glucose reabsorption is maximal is defined as the *threshold for glucose* and the transport capacity when the threshold is reached is called the maximal tubular glucose reabsorption (TmG).

In presence of glucosuria, it is important to determine the serum glucose concentration.

The presence of isolated glucosuria with normal serum glucose concentration is usually a result of familial renal glucosuria. Mutations of *SGLT2* were first described by Santer et al. [83]. Isolated glucosuria with elevated serum glucose is suggestive of diabetes.

The antidiabetic SGLT2 inhibitors enhance both urinary glucose and urate excretion, but the mechanism behind the uricosuric effect remains to be fully elucidated and is possibly related to an indirect effect of the glucosuria on the expression of the urate transporter, URAT1 [84].

Transtubular Potassium Gradient (TTKG)

Potassium is secreted in the late distal and cortical collecting tubules in response to aldosterone. The transtubular potassium gradient is an indirect measure of the activity of the potassium secretory process in the cortical distal nephron and reflects the action of aldosterone. It is an important component of the evaluation of hyperkalemia and hypokalemia.

It can be calculated using the formula proposed by West [85].

$$\text{TTKG} = \frac{\text{UK} \div \left(\text{Uosm} / \text{Posm}\right)}{\text{Ppotassium}}$$

UK = urinary potassium concentration
Uosm = urinary osmolality
Posm = plasma osmolality

The urinary sodium concentration should exceed 25 mmol/L. This ensures sodium reabsorption is not limiting potassium secretion, and urine osmolality should exceed plasma osmolality.

The luminal potassium of the terminal cortical collecting duct is estimated by dividing the urinary potassium by the urine/plasma osmolality since the luminal potassium concentration is influenced by removal of water in the medullary segments. The serum potassium is an estimate of the peritubular potassium concentration.

TTKG appears to be a good indicator of aldosterone activity in both normal children and in children with hypoaldosteronism and pseudohypoaldosteronism. A TTKG below 4.1 in children or 4.9 in infants is indicative of a state of hypoaldosteronism or pseudohypoaldosteronism [86]. Ethier et al. define expected values of TTKG under stimuli that are known to modulate excretion of potassium. The expected value during hypokalemia induced from a low potassium diet is less than 2.5 and during acute potassium loading is greater than 10.0 [87]. It may also be useful in distinguishing aldosterone deficiency from resistance by repeating the calculation after initiation of mineralocorticoid therapy [88]. Kamel and Halperin have recently questioned the validity of the TTKG because one of the principal assumptions involved in calculating the TTKG, that the majority of osmoles in the medullary collecting ducts are not reabsorbed, is incorrect, as this is where urea recycling occurs. If more urea is reabsorbed, then the TTKG may overestimate the potassium excretion. As the amount of urea being recycled and excreted in the cortical collecting duct cannot be measured to provide a correction for the formula, the TTKG is no longer considered a valid test [89]. Instead, the urinary potassium to creatinine ratio calculated on spot urine can be used. The expected urine potassium/urine creatinine (UK/UCr) ratio in a patient with hypokalemia should be less than <1.5 mmol K/mmol creatinine, whereas the appropriate renal response to hyperkalemia would be a UK/UCr ratio >20 mmol K/mmol creatinine [89].

Aminoaciduria

In the normal state, most of the amino acids are reabsorbed in the proximal tubule. Sodium dependent cotransporters are responsible for the transport of glycine and glutamine whereas sodium independents carriers are responsible for the transport of neutral amino acids (leucine, isoleucine and phenylalanine), cystine and dibasic amino acids (ornithine, arginine and lysine). Mutation in *SLC3A1*, which encodes a protein responsible for the transport of cystine and the dibasic amino acids, is the cause of cystinuria (type I/I) [90, 91].

The cyanide–nitroprusside test is an easy way to detect urinary amino acids which contain a free sulfhydryl group or disulfide bond such as cystine, cysteine, homocystine and homocysteine and can diagnose cystinuria in the evaluation of nephrolithiasis [3]. Generalized aminoaciduria is usually associated with Fanconi syndrome.

Assessment of Acid Base Status

Total Carbon Dioxide (Total CO_2) and Bicarbonate (HCO_3^-)

Total CO_2 content of blood, plasma or serum consists of an ionized (bicarbonate and carbonate) and a non-ionized (carbonic acid) fraction. The ionized fraction includes HCO_3^-, CO_3^{2-} and carbamino compounds. The non-ionized fraction contains H_2CO_3 and physically dissolved (anhydrous) carbon dioxide. Total CO_2 measurement typically includes both of these fractions.

HCO_3^- results obtained from a blood gas analyzer is a calculated parameter. First, pH and pCO_2 are measured and then HCO_3^- is calculated using the Henderson-Hasselbalch equation:

$$\mathrm{pH} = \mathrm{pK1} + \log\left[\left(\mathrm{HCO_3^-}\right) \div \left(0.03 * \mathrm{pCO_2}\right)\right]$$

pK1 is usually equal to 6.1.

Discrepant values from calculated arterial bicarbonate and measured venous total CO_2 can be seen, especially in acutely ill pediatric patients who are prone to large fluctuations in pK1 [92].

Reference range for total CO_2 varies between 17 and 31 mEq/L depending on age.

Total CO_2 (tCO_2) and bicarbonate are reduced in the presence of acidosis. K/DOQI clinical practice guidelines for Bone metabolism and Disease in Children with CKD [93] recommends that serum level of tCO_2 be measured. Serum levels of tCO_2 should be maintained at ≥22 mmol/L in children over 2 years of age, and ≥20 mmol/L in neonates and young infants below age 2.

Maintaining the serum tCO_2 in the normal range, as suggested by K/DOQI, may also be desirable for better growth in children with CKD [94].

Serum Anion Gap (SAG)

The serum anion gap (SAG) is used in the interpretation of metabolic acidosis to determine if there are additional unmeasured anions contributing to the acidosis. It is the difference between the most abundant cations and anions measured in the blood. The serum anion gap is calculated as follows.

$$\mathrm{SAG} = \mathrm{Na}^{+} - \left[\mathrm{Cl}^{-} + \mathrm{HCO3}^{-}\right]$$

Potassium is generally not included in most references. However, if the serum K is significantly high or low, then it will alter the SAG. Reference values reported vary and depend on the method of quantification of the electrolytes by individual laboratories. A typical normal range is 8–16 with a mean of 12 ± 2 [95]. Correction for the serum albumin, a major anion, is advisable as the SAG changes by 2.5 mEq/L for every g/L change in serum albumin. Corrected SAG can be calculated by using the Figge equation as follows [96]:

$$\text{Corrected SAG} = \text{SAG} + 0.25 \times \left(\text{normal albumin} - \text{measured albumin}\left[\text{g / L}\right]\right)$$

or

$$\text{Corrected SAG} = \text{SAG} + 2.5 \times \left(\text{normal albumin} - \text{measured albumin}\left[\text{g / dL}\right]\right)$$

Not correcting for albumin, especially when it is low, may lead to an increased anion gap metabolic acidosis being missed in a significant number of cases [97].

Urine Anion Gap

The urine anion gap is normally positive (range 30–50 mmol/L) because there is excretion of unmeasured anions such as phosphate and sulfate. The urine anion gap can be used clinically as an indirect measurement of ammonium production by the distal nephron. Because ammonium is not routinely measured in most laboratories, clinicians need an index of ammonium secretion to use in the evaluation of normal anion gap metabolic acidosis. This was initially proposed by Goldstein et al. [98] and its clinical usefulness was also shown later by Batlle et al. [99]. In the setting of metabolic acidosis, ammonia production by the kidney is increased and ammonium is excreted into the urine with chloride.

If an excess of ammonium is present, the sum of sodium and potassium will be less than the chloride since ammonium is an unmeasured cation. This test presupposed that the chloride is the predominant anion in the urine balancing the positive charge in urine NH_4^+.

Therefore, the urine anion gap can be calculated by the equation:

$$\text{Urine anion gap} = \left(\mathrm{Na} + \mathrm{K}\right) - \mathrm{Cl}$$

A negative urine anion gap suggests gastrointestinal loss of bicarbonate or renal bicarbonate loss whereas a positive urine anion gap suggests the presence of impaired distal urinary acidification [99].

The urine anion gap cannot be used in volume depletion with a urine sodium concentration of less than 25 mmol/L; when there is increased excretion of unmeasured anions such as ketoacid or hippurate; or in neonates.

Urine Osmolar Gap

Halperin et al. [100] proposed the urine osmolar gap in addition to urine anion gap to ascertain

the etiology of normal or increased anion gap metabolic acidosis as well as mixed metabolic acidosis. The urine osmolar gap was defined as the difference between the measured urine osmolality and the sum of the concentration of sodium, potassium, chloride, bicarbonate, urea, and glucose. Normally this gap is 80–100 mOsmol/kg H_2O. Values >100 mOsmol/kg indicate increased urinary ammonium salts, the normal response to a metabolic acidosis [101]. A lower urine osmolar gap occurs in patients with dRTA.

Calculation of the urine osmolar gap is helpful in excluding glue sniffing, which causes a normal anion gap metabolic acidosis. A high urinary concentration of the unmeasured ions ammonium and benzoate will increase the osmolar gap, and can lead to a false exclusion of RTA as the cause of acidosis [102].

Urine-Blood pCO_2 (U-B pCO_2)

U-B pCO_2 can be used for the evaluation of normal anion gap metabolic acidosis with a positive urine net charge to differentiate between deficient ammonium production versus poor hydrogen secretion [103, 104]. The pCO_2 should be measured in alkaline urine. With adequate hydrogen secretion in the distal tubule, the hydrogen will couple with HCO_3 to form H_2CO_3 and then dissociate into CO_2 and H_20.

Kim et al. [105] evaluated the diagnostic value of the U-B pCO_2 in patients diagnosed as having H^+-ATPase defect dRTA based on reduced urinary NH_4^+ and absolute decrease in H^+ ATPase immunostaining in intercalated cells. U-B pCO_2 during sodium bicarbonate loading was less than 30 mmHg in all patients with H^+ ATPase defect dRTA.

General Biochemistry

Serum Sodium

The reference range for plasma sodium varies with age and method of measurement used. The following reference range for serum sodium is recommended by the Canadian Laboratory Initiative in Pediatric Reference Intervals (CALIPER) database group and the Australasian Association of Clinical Biochemists (AACB); birth to <7 days 132–147 mmol/L, ≥7 days to <2 years 133–145 mmol/L, ≥2 to <12 years 134–145 mmol/L, and ≥12 to adult 135–145 mmol/L [106, 107]. Serum sodium outside that range can have serious consequences.

Hyponatremia is the result of excess free water or sodium loss. The former is usually associated with expended extracellular fluid, while the latter is often seen with volume contraction. Hyponatremia with normal serum osmolality is usually the result of hyperlipidemia, hyperproteinemia, or hyperglycemia. Most laboratories now measure serum sodium with ion-specific electrodes and the measurement will not be affected by hyperlipidemia and hyperproteinemia. In the presence of hyperglycemia every 3.4 mmol/L increment in glucose will reduce serum sodium by 1 mmol/L because of water shift from the intracellular space to the extracellular space.

Hypernatremia is usually secondary to water deficit, either because of poor intake or increased water loss such as in diabetes insipidus or mellitus. Salt intoxication is a less common cause of hypernatremia.

Serum Potassium

Approximately 98% of body potassium is located intracellularly. Cell potassium concentration is about 140 mmol/L, whereas normal range for serum potassium varies between 3.2 and 6.2 mmol/L, depending on age. Reference range varies with the method used and age of the child. In infants, the upper limit of normal can be as high as 6.2. The upper limit then progressively decreases to about 5.0 to reach the "adult" level. Reference ranges vary depending on the methodology [108].

Hyperkalemia can be the result of intracellular to extracellular shift in the presence of acidosis, beta blockers, or cellular breakdown; decreased excretion in renal failure, hypoaldo-

steronism or pseudohypoaldosteronism; and, less commonly, with increased potassium intake. Pseudohyperkalemia is defined as a serum K^+ that exceeds plasma K^+ by 0.4 mmol/L on a sample processed within 1 h of venipuncture (delay results in glucose depletion, and less ATP generation, which is the energy source of the sodium-potassium pump) and maintained at room temperature (lower temperatures inhibit the pump leading to potassium leak out of cells). It can occur with prolonged tourniquet use, mechanical factors, excessive crying and respiratory alkalosis, potassium EDTA contamination (associated also with hypocalcemia), leukocytosis, erythrocytosis and thrombocytosis. During the clotting process activated platelets degranulate and release potassium [109, 110]. The benign, dominantly inherited familial pseudohyperkalemia presents as hyperkalemia when the potassium is measured at or below room temperature, but no hyperkalemia when the potassium is measured at normal body temperature [111]. It has recently been linked to mutations in an erythrocyte porphyrin transporter, *ABCB6*, on chromosome 2 [112].

Hypokalemia not associated with diarrhea or emesis is mostly seen in renal tubular disorders such as Fanconi's syndrome, Bartter's syndrome, and Gitelman's syndrome and in hyperaldosteronism.

Serum Calcium, Phosphorus, and Calcium-Phosphorus Product

Evaluation of calcium, phosphorus and calcium phosphorus product is reviewed in detail in the guidelines published by K/DOQI [18, 93]. Representative normal values for serum phosphorus, ionized calcium and total calcium are in Table 5. Pseudohypocalcemia may be seen with gadolinium based contrast agents or in thrombocytosis [113]. The serum phosphate may appear falsely low after mannitol infusion and falsely elevated with hyperbilirubinemia, hyperlipidemia, amphotericin administration or if the sample is taken from a central line that has been treated with tissue plasminogen activator [113].

In CKD, serum levels of phosphorus should be maintained at or above the age-appropriate lower limits and no higher than the age–appropriate upper limits. For children with CKD stage 5, the serum level of phosphorus should be maintained between 3.5–5.5 mg/dL (1.13–1.78 mmol/L) during adolescence and between 4–6 mg/dL (1.29–1.94 mmol/L) for children between the ages of 1–12 years.

Calcium in blood exists in three fractions: protein-bound calcium, free (ionized) calcium and calcium complexes. Total measured calcium should be corrected if serum albumin is abnormal to better reflect the ionized calcium. The following formula can be used:

Table 5 Normal values for serum phosphorus, blood ionized calcium concentrations (adapted from [93])

	Serum phosphorus			Total calcium	
Age	mg/dL	mmol/L[a]	Blood ionized calcium (mM)	mg/dL	mmol/L[b]
0–3 months	4.8–7.4	1.55–2.39	1.22–1.40	8.8–11.3	2.20–2.83
1–5 years	4.5–6.5	1.45–2.10	1.22–1.32	9.4–10.8	2.35–2.70
6–12 years	3.6–5.8	1.16–1.87	1.15–1.32	9.4–10.3	2.35–2.57
13–20 years	2.3–4.5	0.74–1.45	1.12–1.30	8.8–10.2	2.20–2.55

[a] Serum phosphorus converted from mg/dL to mmol/L using a factor of 0.3229
[b] Serum calcium converted from mg/dL to mmol/L using a factor of 0.250

ALGrawany

$$\text{Corrected calcium } (\text{mg/dL}) = \text{total calcium } (\text{mg/dL}) + 0.8 \times [4 - \text{serum albumin } (\text{g/dL})]$$

Ionized calcium is affected by pH since hydrogen ion displaces calcium from albumin. A fall of 0.1 unit in pH will cause an approximately a 0.1 mEq/L rise in the concentration of ionized calcium. As serum ionized calcium is not routinely measured at most institutions, K/DOQI guidelines are based on corrected total calcium. Levels should be maintained within normal range for the laboratory and preferably toward the lower end in CKD stage 5. The serum calcium-phosphorus product should be maintained at <55 mg^2/dL^2 (4.4 $mmol^2/L^2$) in adolescents greater than 12 years and <65 mg^2/dL^2 (5.2 $mmol^2/L^2$) in younger children [93].

Serum Albumin

Serum albumin is used to assess the nutritional status in children with or without renal disease. Although it is used as a measure of the nutritional state of an individual, it can be affected by non-nutritional factors, especially in children with CKD, such as infection, inflammation, hydration status, peritoneal and urinary losses [114]. Children with low serum albumin should be assessed for protein-energy malnutrition if not losing protein.

Serum Uric Acid

Serum uric acid varies with both age and gender [115, 116]. An elevated serum uric acid is much less common in childhood as compared to adulthood, and in contrast to adults where gout is the primary cause, hereditary disorders of purine biosynthesis account for the majority of cases in children. These include a deficiency of the enzyme hypoxanthine-guanine phosphoribosyltransferase (Lesch-Nyhan syndrome) and hereditary xanthinuria [117]. Hyperuricemia is also found in familial juvenile hyperuricemic nephropathy in association with mutations in the uromodulin gene [118]. The combination of hyperuricemia, anemia, early onset kidney failure and hypotensive or presyncopal episodes should raise suspicion of the recently described disorder associated with a mutation in the renin gene [119]. The renal cysts and diabetes syndrome caused by mutations in the gene for hepatocyte nuclear factor 1β (*HNF1β*) is also associated with hyperuricemia [120]. Patients with *HNF1β* mutations may also present with hypomagnesemia [121].

The kidney is the primary site of excretion of uric acid. The fractional excretion of filtered urate is 15–30% in children compared to 10% adults [122]. Hyperuricemia can be seen in AKI, tumor lysis syndrome, and secondary to certain drugs such as thiazide diuretics, salicylates and cyclosporine [116]. In dehydration, serum uric acid correlates significantly with weight change, and increased significantly with dehydration severity in one study [123].

There is ongoing debate and uncertainty as to whether there is a causal link, or merely an association, between hyperuricemia and hypertension or CKD progression [124, 125]. Uric acid may be a clinically useful marker in the management of essential hypertension in adolescents and young children, where there is some evidence that even in preschool children those with higher serum uric acid have higher blood pressures [126–128]. A pediatric study of over 100 patients with CKD found that 70% of children with an eGFR <60 mL/min/1.73 m^2 had uric acid levels above the normal range [129]. A subsequent analysis including over 600 children and adolescents from North America found that those with hyperuricemia progressed faster to CKD [130].

Drugs that lower serum uric acid include allopurinol and rasburicase. In addition, the angiotensin receptor blocker losartan is uricosuric [131], and could be beneficial in hypertensive patients with hyperuricemia [125]. Allopurinol can increase xanthine and hypoxanthine levels, leading to xanthinuria and xanthine stones. It is also associated with severe dermatological reactions in children.

Urinary Calcium

Measurement of calcium excretion should be part of the evaluation of patients with hematuria, nephrocalcinosis and renal stones and can often be useful in the assessment of children with frequency, dysuria, urgency and recurrent UTI [132]. Urinary calcium excretion varies with age, being highest in infancy and reaching its nadir during puberty.

Hypercalciuria is usually defined as a urinary calcium excretion of more than 4 mg/kg/day based on the study of Ghazali and Barratt [133]. However, several authors have studied urinary calcium excretion and published reference ranges in their study population [134–138].

A spot urinary calcium/creatinine ratio (usually collected on the second morning fasting urine specimen) correlates well with 24-h calcium excretion, especially for children with normal muscle mass. They can be used clinically; however, they are more likely to be affected than a 24-h collection by factors such as recent dietary calcium intake [139]. Sodium, protein, phosphorus, potassium, and glucose intake can influence calcium excretion. There is no apparent seasonal variation of urinary calcium/creatinine ratio in children as seen in adults [140]. A 24-h urine collection for calcium assessment is typically stored in acidified bottles containing hydrochloric acid to prevent the crystallization of calcium oxalate although this may not be necessary [141]. For those who have reduced muscle mass, a urinary calcium/osmolality ratio predicts hypercalciuria with better sensitivity and specificity than a urine calcium/creatinine ratio [142, 143].

Urinary Sodium

Measurement of urinary sodium excretion should be assessed in children with hypercalciuria. Polito et al. found that urinary sodium excretion and 24-h urinary sodium/potassium ratio (U Na/K) was higher in children with hypercalciuria [144]. Twenty-four-hour urinary sodium can also be used to assess dietary sodium intake in adults on a low sodium diet for the treatment of hypertension where a target 24 h intake of 50–100 mmol/day is recommended [145].

Urinary Magnesium

Magnesium is a known stone inhibitor as it forms complexes with oxalate and reduces supersaturation. Thirty-nine percent of children with calcium oxalate stones in one series had hypomagnesuria defined as magnesium excretion less than 1.2 mg/kg/24 h [146]. Urinary reference limits for Mg/Cr can be found in Table 6.

Urinary Citrate

Citrate inhibits calcium-oxalate and calcium-phosphate crystal nucleation, growth and aggregation. In normal circumstances, citrate is freely filtered at the glomerulus with a 65–90% reabsorption rate. Systemic acidosis, potassium depletion, starvation and acetazolamide therapy decrease urinary citrate. Citrate excretion is age and sex related. Mean molar excretion of citrate is higher in infants than in older children, and in infants is higher in females than males (Table 7) [147].

Table 6 Urinary reference limits for urinary magnesium/creatinine (adapted from [224])

	Urinary Mg/Cr	
	mol/mol (mg/mg)	
Age in year	5th Percentile	95th Percentile
1/12–1	0.4 (0.10)	2.2 (0.48)
1–2	0.4 (0.09)	1.7 (0.37)
2–3	0.3 (0.07)	1.6 (0.34)
3–5	0.3 (0.07)	1.3 (0.29)
5–7	0.3 (0.06)	1.0 (0.21)
7–10	0.3 (0.05)	0.9 (0.18)
10–14	0.2 (0.05)	0.7 (0.15)
14–17	0.2 (0.05)	0.6 (0.13)

Table 7 Mean molar citrate/creatinine ratio based on [147]

Urinary citrate/creatinine	Girls	Boys
Infants	1.9	0.63
Childhood	0.27	0.33
Adolescence	0.32	0.28

Citrate excretion of more than 1.6 mmol/1.73 m^2 in girls and more than 1.9 mmol/1.73 m^2 in boys is considered normal [148].

Hypocitraturia, either alone or in association with hypercalciuria, is an important risk factor for nephrolithiasis in children [149, 150]. In one study, hypocitraturia defined as citrate excretion <320 mg/1.73 m^2/24 h [1.66 mmol/1.73 m^2/24 h] was observed in 60.6% of children with calcium oxalate stones [146]. A study in a stone-forming adult population suggests that urinary calcium to citrate ratio >0.25 mg/mg is predictive of lithogenesis [151].

Urinary calcium-to-citrate ratio >0.326 mg/mg has been found in children to predict stone formers in a random urine sample [152]. Furthermore, urinary calcium-to-citrate ratio calculated on 24-h collection can also distinguish between solitary and recurrent calcium stone forming children. The mean urinary calcium-to-citrate was 0.41 mg/mg in those with a single stone episode and 0.64 mg/mg in recurrent stone formers as compared to the mean of 0.33 mg/mg seen in normal children without stones [153]. Hypocitraturia is also recognized as a major risk factor for nephrocalcinosis in very low birth weight infants [154] and after kidney transplantation [155].

Urinary Oxalate

Urinary oxalate excretion is significantly increased in primary hyperoxaluria type I (PH I), PH II and PH III and in secondary hyperoxaluria. In PH I, there is excessive endogenous production of oxalate caused by a deficiency of hepatic alanine:glyoxylate amino transferase (AGT), which catalyzes the peroxisomal conversion of glyoxylate to glycine and in PH II, a deficiency of cytosolic glyoxylate reductase/hydroxypyruvate reductase (GRHPR), an enzyme that catalyzes the reduction of glyoxylate and hydroxypyruvate as well as the dehydrogenation of glycerate [156, 157]. PH III is due to a defect in a hepatocyte specific mitochondrial enzyme, 4-hydroxy-2-oxoglutarate aldolase (HOGA) [158].

The secondary forms are due to increased intestinal absorption of oxalate due to malabsorptive states or impaired vitamin status. Reference values for oxalate/creatinine can be found in Table 8.

Patients suspected of having abnormalities in oxalate metabolism should have more extensive studies, including measurement of oxalate, glycolate and L-glycerate and in some cases liver biopsy to assess the activity of AGT and GRHPR.

Elevated oxalate and glycolate is associated with PH1; however, normal glycolate is found in 25% of subject with PHI. Elevated urinary oxalate and L-glycerate is the typical finding of hyperoxaluria type II, but likewise elevated L-glycerate is not always present. Genetic analysis is now considered the gold standard for diagnosis and liver biopsy, to measure intrahepatic enzyme levels, is generally reserved for patients in whom no mutation can be found [156, 157].

Table 8 Urinary reference limits for calcium/creatinine, oxalate/creatinine, urate/creatinine [224, 225]

	Urinary calcium/creatinine		Urinary oxalate/creatinine		Urinary urate/creatinine	
	mol/mol (mg/mg)[a]		mol/mol (mg/mg)[a]		mol/mol (mg/mg)[a]

[a]Conversions have been performed with higher precision, then rounded for this presentation [224, 225]

Urinary Uric Acid

Increased urinary uric acid excretion can present with microscopic hematuria, abdominal and/or flank pain, dysuria, gravel and macroscopic hematuria. About half of patients with hyperuricosuria (HU) will have microlithiasis on ultrasonography [159]. HU may be defined by urine uric acid concentration corrected for creatinine clearance >0.53 mg/dL/GFR [160]. The excretion varies with age, being highest in infants. However, a simpler estimate of urinary urate excretion can be calculated from the urine urate/creatinine ratio. Reference values for urine urate/creatinine can be found in Table 8.

Assessment of the Renin-Angiotensin-Aldosterone System

Renin is a proteolytic enzyme predominantly formed and stored in the juxtaglomerular cells of the kidney. Renal hypoperfusion and increased sympathetic activity are the major physiologic stimuli to renin secretion [72]. When released in the circulation, renin cleaves angiotensinogen to produce a decapeptide angiotensin I. Angiotensin I is then converted to an octapeptide, angiotensin II, by the angiotensin I-converting enzyme. Angiotensin II is a potent vasoconstrictor and promotes salt and water retention. The converting enzyme is mainly located in the lung, but angiotensin II can be synthesized at a variety of sites, including the kidney, luminal membrane of vascular endothelial cells, adrenal gland and brain. Angiotensin II promotes renal salt and water reabsorption by stimulation of sodium reabsorption in the early proximal tubule and by indirectly activating aldosterone biosynthesis in the zona glomerulosa of the adrenal cortex.

Measurement of plasma renin activity may not reflect the tissue activity of the local renin-angiotensin system.

Assessment of the renin-angiotensin-aldosterone system may be required in the evaluation of hypokalemia/hyperkalemia, adrenal insufficiency, and hypertension, see Table 9.

Renin

Renin release is dependent on renal tubular sodium concentration, renal perfusion pressure and beta-adrenergic vascular tone. The enzymatic activity of renin can be measured. It is expressed as the amount of angiotensin I generated per unit of time and is expressed in pmol or ng of generated angiotensin I per mL of plasma.

The "normal values" for plasma renin activity (PRA) are highly dependent on sodium intake, time of day, posture, age and methodology [161]. PRA varies inversely with age in infants and children. Reference values derived from measurement of PRA in 79 children age 1 month to 15 years in supine position were published in 1975 [162].

PRA can be useful in the management of hypertension to distinguish between a volume dependent hypertension, where renin is suppressed, and hypertension mediated by excess

Table 9 Assessment of the renin-angiotensin-aldosterone system

	PRA	PAC	PAC/PRA	BP	Potassium
Primary hyperaldosteronism	Decrease	Increase	Very high >20–50	High	Low
GRA	Decrease	Increase	High	High	Normal or low
Renin-secreting tumor	Increase	Increase		High	Low
Bartter' syndrome	Increased	Increased		Normal	Low
Renovascular disease	Increased	Increased	<10		
Apparent mineralocorticoid excess, Cushing, licorice ingestion	Low	Low		High	Low

PRA plasma renin activity, *PAC* plasma aldosterone concentration, *BP* blood pressure, *GRA* glucocorticoid remediable hypertension

renin secretion. A value less than 0.65 ng/mL/h suggests renin suppression, while a value above 6.5 ng/mL/h implies excess renin. This can help guide appropriate therapy [163].

During renal angiography, renal vein renin sampling may be done to predict feasibility of correcting hypertension or to identify which kidney contributes to the hypertension. A ratio of the renal vein renin from the diseased kidney (R) to the renal vein renin from the normal or less diseased contralateral kidney (RC) above 1.5 (R/RC >1.5) is considered significant, and there is greater probability that blood pressure will improve after surgery. A RC/infrarenal inferior vena cava ratio less than 1.3 further supports the presence of a lesion that may respond to repair. Segmental veins within a kidney may also be sampled [164–168].

Aldosterone

Aldosterone is synthesized in the zona glomerulosa of the adrenal gland. It regulates electrolyte excretion and intravascular volume, mainly through its effects on the distal tubules and cortical collecting ducts of the kidneys, where it acts to increase sodium reabsorption and potassium excretion [169].

Aldosterone is measured by radioimmunoassay. Like renin, it is dependent on sodium intake, posture and time of the day. Serum aldosterone concentration is highest at the time of awakening and lowest shortly after sleep onset. Hyperaldosteronism should be sought for in children with hypertension, hypokalemia and metabolic alkalosis [170].

Plasma Aldosterone Concentration (PAC) to Plasma Renin Activity Ratio

The PAC/PRA ratio is a screening test for hyperaldosteronism prior to confirmation with a suppression test. Patients should not be taking aldosterone receptor antagonists, ACE inhibitors and angiotensin receptor blockers for 3–6 weeks, and hypokalemia needs to be corrected prior to the test. Any medication that stimulates renin production, such as diuretics, may lead to a false negative result. False positives can be expected with the reduced renin and increased salt and water retention of renal impairment. The patient needs to be in the seated position for 10–15 min after ambulating for at least 2 h, and midmorning is considered the best time to perform the test [171]. The mean normal value is 4–10 compared to more than 30–50 in patients with primary hyperaldosteronism [172].

Endocrine Testing Relevant to Nephrology

ADH/Copeptin

Arginine vasopressin (AVP) or antidiuretic hormone (ADH) is one of the key hormones in the regulation of salt and water balance. The measurement of ADH can be helpful in the diagnosis and work-up of sodium disorders. However, due to its structural instability, very short plasma half-life, and long laboratory processing time, its use in clinical practice is limited. Copeptin is a well-established ADH surrogate. It is secreted in an equimolar amount to ADH and can be easily measured in plasma or serum. The distribution of copeptin levels in pediatric cohorts indicate a range between 2.4 and 8.6 pmol/L [173].

The distribution of plasma copeptin in percentiles in a population of children without disturbance of the AVP system can be found in a study published in 2021 [174]. Finally, measuring copeptin after infusion of 3% saline to induce hypernatremia of at least 150 mmol/L (hypertonic saline infusion test) may have greater diagnostic accuracy for diabetes insipidus (plasma copeptin <4.9 pmol/L) and primary polydipsia (plasma copeptin >4.9 pmol/L) than the indirect water-deprivation test [175].

Biochemical Testing for the Diagnosis of Pheochromocytoma

Typical testing of patients suspected of having pheochromocytoma includes measurement of catecholamines and metanephrines in the urine and plasma. Plasma and urinary metanephrines are recommended as they are more reliable, with the best negative predictive value. This is because metanephrines are produced continuously by the pheochromocytoma, whereas catecholamines are only intermittently secreted. Plasma metanephrines are most often measured using high-performance liquid chromatography coupled with either electrochemical detection or mass spectrometry. The sensitivity of plasma free metanephrines to diagnose pheochromocytoma is 97% and has a specificity of between 80 and 100%. Twenty-four-hour measurement of urinary fractionated metanephrines has similar sensitivities and specificities. Plasma metanephrines should ideally be obtained when the patient is fasting and has been in the supine position for at least 30 min to avoid sympathoadrenal activation. False positives due to interference with the analytical methods can be seen with acetaminophen, mesalamine and sulfasalazine. Alternatively, there may be false positives caused by drugs that affect metabolism or secretion, of catecholamines, such as caffeine, cocaine, amphetamines, ephedrine, venlafaxine (serotonin-noradrenaline reuptake inhibitor), tricyclic antidepressants, dihydropyridine calcium channel blockers, doxazocin and phenoxybenzamine [176].

Complement Pathway Assessment

The complement system consists of at least thirty plasma membrane proteins that provide an innate defense against microbes and an adjunct or complement to humoral immunity [177, 178]. The complement system is divided into three major pathways: classical, lectin and alternative. The lectin pathway is activated by the binding of lectin (which has a similar structure to C1q) to sugar residues on the surface of a pathogen and the alternative pathway which is an amplification loop for C3 activation is activated by polysaccharide antigens, aggregated IgA, injured cells or endotoxins. The classical pathway is activated by the binding of C1q to the Fc portion of antibody. The alternative pathway is a constitutively active and amplifiable system. Plasma factor H and factor I are important fluid phase complement regulators of the alternative pathway, while CD46 (membrane cofactor protein), CD55 (decay accelerating factor) and CD59 (protectin) are the principal surface bound regulators. Each of these three pathways lead to the deposition of an activated C3 fragment (C3b), inducing the final steps of the complement cascade, which include opsonisation, phagocytosis, induction of inflammation, and formation of the membrane attack complex (MAC) and cytolysis [179]. A fourth pathway by which thrombin can directly activate C5 and thus the terminal complement cascade was also identified and links the complement and coagulation cascades [180]. However, the significance of this pathway in the pathogenesis of disease is still unclear. There is an evolving spectrum of kidney diseases now recognized as being either complement-mediated or having complement dysregulation as part of their pathogenesis, and these will be discussed in a later chapter.

Evaluation of the complement system, or *complement analysis*, plays an integral part in the diagnosis of various infectious, inflammatory and autoimmune diseases as well as many glomerular diseases caused by either overactivity, or loss of regulation, of the complement system. Much progress has been made not just in the understanding of the role of complement in the pathogenesis of these diseases, but also in the quality and standardization of the methods of complement analysis [179, 181]. Concentrations of C3, C4 and C1q can be quantified by immunological methods. Glomerular disease associated with activation of the classical pathway will typically have a low C4 and C3, whereas disease associated with activation of the alternative pathway will have a low C3 and normal C4. Serial assessment of complement proteins can also be helpful in monitoring disease activity in immune complex mediated disease such as lupus. C4 is less likely to normalize because one or more C4 null genes

are common in SLE; therefore, patients in remission can continue to have low C4. However, C3 is sensitive to change in disease activity [182]. The normal range for C3 varies considerably between laboratories [182]; therefore, no normal values are provided in this chapter.

There are functional assays that assess the total hemolytic activity of the entire classical (CH50) and alternative (AH50) pathways [181]. All nine components (C1–C9) are required to have a normal CH50, a test which in the past assessed the ability of the patient's serum to lyse sheep erythrocytes optimally sensitized with rabbit antibody, but now typically uses a synthetic liposome coated with antibody instead of erythrocytes [181]. A suppressed CH50 suggests a deficiency or consumption of one or more component, or complement activation and consumption of complement proteins. The CH50 is useful to diagnose hypocomplementemic states (for example congenital C2 deficiency) that would be missed if only C3 and C4 were measured.

AH50 is a functional assay of the alternative pathway. The assay typically used erythrocytes from rabbit, guinea pig or chicken, and the classical pathway is kept inactive by the addition of a calcium chelator (EGTA). Suppressed AH50 suggests a deficiency or consumption of one or more components of the alternative pathway. Depressed or absent AH50 activity, in the presence of a normal CH50, suggests a deficiency in an alternative pathway component (such as C3, C5, C6, C7, C8, C9, factor D, factor B, properdin or the regulators factor H or factor I). When the AH50 is normal, but the CH50 is absent, then there might be a classic pathway deficiency such as C1q, C2 or C4, or the presence of a C1 inhibitor. When both CH50 and AH50 are depressed this reflects either a late component deficiency or a setting of complement consumption and one should measure C3, C5–C9 as well as levels of factor H and I [183].

When a complement-mediated disease is suspected, more in-depth analysis of the complement system can be performed. The International Complement society provides guidelines for modern complement analysis [179]. There are a number of steps in order to complete a thorough analysis of the complement system including (1) functional assays of global complement pathway function, with the CH50, AH50 and lectin pathway (assessed by semiquantitative enzyme-linked immunosorbent assay [ELISA]), (2) analysis of individual complement components/proteins, such as C3, C4 and C1q, (3) analysis of key complement regulators such as CFH, CFI and C1-INH, (4) detection of complement activation or split products such as C3dg, C3a, Bb, sC5b-9, typically measured by ELISA in the serum, urine or tissues, (5) measuring auto-antibodies to various complement components, to the C3 convertase (C3 nephritic factor), or to the alternative pathway regulator CFH (anti-CFH) and (6) genetic analysis for mutations in C3, CFB, CFH, CFI, CD46/MCP, now linked to various diseases including atypical hemolytic uremic syndrome, membranoproliferative glomerulonephritis and antibody-mediated rejection.

The measurement of complement split products such as C3a, C3d, C4d or Bb and the soluble form of the membrane attack complex (sC5b-9) have allowed more sensitivity and accuracy in defining whether it is the classical, alternative, or terminal common pathway that is involved, and monitoring the degree of complement activation. Measuring these split products, and in particular sC5b-9, can be useful to ensure complete complement inactivation by complement inhibitors such as eculizumab [181].

Laboratory Assessment of Various Glomerulopathies

Antineutrophil Cytoplasmic Antibodies (ANCA)

Antineutrophil cytoplasmic antibodies (ANCA) are IgG autoantibodies directed against constituents of primary granules of neutrophil and monocyte lysosomes. They were first described in 1982 in patients with pauci-immune glomerulonephritis [184]. Indirect immunofluorescence (IIF) and ELISA are the most widely used techniques to detect ANCA. By IIF, two major immunostaining patterns can be seen: the dif-

fuse granular cytoplasmic pattern with central accentuation known as C-ANCA and the perinuclear pattern which is defined as perinuclear fluorescence with nuclear extension known as P-ANCA. Diffuse flat cytoplasmic staining without interlobular accentuation can also be seen and is termed atypical C-ANCA. Atypical ANCA includes all other neutrophil-specific or monocyte-specific IIF reactivity, most commonly a combination of cytoplasmic and perinuclear fluorescence. Proteinase 3 and myeloperoxidase are two antigenic targets associated with vasculitis. The cytoplasmic pattern usually suggests the presence of serum proteinase 3 ANCA (PR3-ANCA), whereas the perinuclear pattern with nuclear extension is usually associated with myeloperoxidase ANCA (MPO-ANCA). Occasionally, antinuclear antibodies can give a false positive P-ANCA and this can be avoided by fixing the neutrophils with formalin rather than ethanol [185]. ELISA is used in addition to prove the presence of myeloperoxidase and proteinase 3 ANCA [186]. In order to enhance specificity, both IIF and ELISA have been recommended.

More novel assays for ANCA confirmation include capture ELISAs, high sensitivity or anchor ELISAs and automated immunoassays, the latter able to provide a result in under an hour, have become more widespread [187]. There are now several commercially available antigen-specific immunoassays that detect antibodies (IgG) to either MPO or PR3. These include first, second (monoclonal antibody capture-based) and third generation (peptide anchor-based) ELISA as well as fluorescent-enzyme immunoassays, chemiluminescent, or multiplex bead assays. These assays have excellent comparative performance with area under the curve (AUC) ranging from 0.92 to 0.98, better than those for IIF in recent studies [188, 189]. Current guidelines now recommend using a high-quality antigen-specific immunoassay to screen for MPO- or PR3-ANCA given that the turnaround time is faster and the cost is lower [190].

Antibodies to several azurophilic granule proteins (lactoferrin, elastase, cathepsin G, bactericidal permeability inhibitor, catalase, lysozyme and more) can cause a P-ANCA staining pattern. The ELISA will determine the specific antibody responsible. Only anti-PR3 or anti-MPO antibodies, however, are clinically relevant [191].

ANCA measurement should only be done for patients who are strongly suspected of having vasculitis. Clinical indications for ANCA testing can be found in the International Consensus Statement on Testing and Reporting of Antineutrophil Cytoplasmic Antibodies [186]. Compliance with guidelines for ANCA testing would decrease the number of false positives, which may lead to misdiagnosis and potentially harmful treatments [192].

Granulomatosis with polyangiitis (GPA), microscopic polyangiitis, Churg-Strauss syndrome, renal limited vasculitis and drug induced ANCA-associated vasculitis are associated with positive ANCA. C-ANCA anti-PR3 ANCA suggests a diagnosis of GPA whereas P-ANCA anti-MPO associates more with MPA and Churg Strauss syndrome. ANCA are positive in 70–95% of patients with GPA and MPA, but only about 40% of patients with a diagnosis of Churg Strauss syndrome are positive [191].

ANCA can also be positive in non-vasculitic disease such as anti-glomerular basement membrane disease, inflammatory bowel disease, neoplasia, and other autoimmune disorders. Both PR3 and MPO ANCA may be found with infectious conditions such as tuberculosis, leprosy, HIV and subacute bacterial endocarditis. Various drugs can also be associated with ANCA positivity. These include propylthiouracil, hydralazine, penicillin, sulfonamides, quinolones, thiazides, and allopurinol [193].

Correlation with disease activity was first recognized by van der Woude et al. in 1985 [194]. Although the diagnostic value of ANCA is not disputed, the utility of measuring serial ANCA to monitor disease course, response to treatment or relapse prediction has overall been disappointing [191, 195]. A patient in clinical remission whose titers are rising, have returned to positivity or that remain persistently positive should be followed very closely as they may be at increased risk for relapse [190]. A rise in ANCA may be predictive of an imminent relapse, but this is not universal and may be limited to certain subgroups

of patients, though this remains to be clarified. MPO-ANCA carries worse renal and adult patient survival [196, 197]. Relapse is more common with PR3-ANCA, especially if there is persistence of PR3 positivity after induction therapy [198–200].

Some progress in terms of the so called ANCA negative vasculitides has been made recently with the discovery of pathogenic versus naturally occurring MPO epitopes, previously undetectable by conventional testing [201]. In the future, epitope specificities may prove useful in distinguishing varying disease characteristics in ANCA-associated vasculitides [202].

Kain et al. detected antibodies against human lysosome-associated membrane protein-2 (LAMP-2), a protein localized to the same neutrophil granules as PR3 and MPO, in over 90% of patients with ANCA-associated vasculitis and glomerulonephritis [203]. These autoantibodies may only be present early post diagnosis and disappear with the initiation of immunosuppressive therapies and disease remission; however, their relevance as a pathological or serological marker is yet to be determined [204–206]. LAMP-2 ANCA titers have been detected by ELISA and typically coincide with MPO- or PR3-ANCA positivity in a cohort of children with systemic vasculitis, but this is just preliminary data that needs validation [207].

Antinuclear Antibodies (ANA) and Anti-doubled Stranded DNA (Anti-dsDNA)

ANAs are autoantibodies directed against chromatin and its individual components, including dsDNA, histones and some ribonucleoproteins [208]. Although ANAs are frequently found in children without a rheumatic disease [209], they have been associated with several systemic autoimmune diseases, including systemic lupus erythematosus (SLE), scleroderma, mixed connective tissue disease, polymyositis, dermatomyositis, rheumatoid arthritis, Sjögren's syndrome, drug induced lupus, discoid lupus, and pauciarticular juvenile chronic arthritis. They are also occasionally seen in autoimmune disease of the thyroid, liver and lungs as well as chronic infectious disease such as mononucleosis, hepatitis C infection, subacute bacterial endocarditis, tuberculosis and HIV, and some lymphoproliferative disorders. They do not always signify disease and 13.8% of the population over age 12 have detectable ANAs, with ANA positivity increasing with age and more common in females [210].

Different types of ANAs are known and classified based on their target antigens. Antibodies can be directed against dsDNA, individual nuclear histones, nuclear proteins, and RNA-protein complexes. As some of these antibodies are more specific for a particular disease, they are helpful tests for diagnosis. They are also used for monitoring disease activity. A positive ANA may also precede disease onset [211].

In most laboratories, ANAs are measured by an indirect immunofluorescence assay using a human epithelial cell tumor line (Hep2 cells) as the antigenic substrate. Different staining patterns can be seen, reflecting the presence of antibodies to one or a combination of nuclear antigens. The patterns are neither sensitive nor specific for a single disease. In general, a homogenous or chromosomal pattern is more likely in healthy individuals and in those with SLE, whereas a speckled or extrachromosomal pattern implies antibodies against extractable nuclear antigens (ENA) such as Smith antigen. A nucleolar pattern may suggest systemic sclerosis. It is important to emphasize that anti-dsDNA antibodies associated with SLE may also present a speckled or nucleolar pattern [212]. These different immunofluorescent staining patterns may correlate with disease manifestations in SLE. For instance, proliferative lupus nephritis is more commonly associated with a homogenous pattern and organ damage may be less likely with the speckled pattern in SLE [213]. A nuclear, coarse speckled, rather than a dense fine speckled pattern on immunofluorescence, may signify an autoimmune rheumatic disease [214]. This will need further validation before being employed in more widespread clinical practice [215].

The titer of ANAs can be helpful clinically. A negative ANA makes a diagnosis of SLE or mixed

connective tissue disease very unlikely. ANAs in the sera of a normal healthy childhood population using Hep-2 cells as substrate is reported as 6% [216], and 16% at screening dilutions of 1:20 [217]. In healthy individuals, ANA titers above 1:40 are found in 32%, above 1:80 in 13% and above 1:320 in 3% [218].

The presence of a titer >1:640 should raise the suspicion of an autoimmune disease. If no diagnosis is made, the patient should be followed closely. Lower titers with no clinical sign or symptoms of disease are much less worrisome. In one study, no rheumatic disease was diagnosed in patients with ANA titers <1:160. Unless there is a high pretest likelihood of a rheumatic disease, a positive ANA has a very low positive predictive value [219].

Anti-dsDNA are relatively specific for SLE and fluctuate with disease activity [220].

Anti-nucleosome antibody is the earliest marker for the diagnosis of SLE. It is also a superior marker of lupus nephritis [208]. Among those with SLE, the prevalence of anti-nucleosome antibodies was higher in those with renal disease (58%) compared to those without nephritis (29%) [221]. Antibodies to the Smith antigen, which is a nuclear non-histone protein, are very specific for SLE but insensitive.

In SLE, autoantibodies to the complement component C1q are strongly associated with proliferative lupus nephritis, correlate with disease severity, can herald the onset of nephritis and be used to monitor response to therapy [220, 222]. Anti-dsDNA are also strongly associated with nephritis in SLE [220].

3 Imaging and Radiological Interventions in the Pediatric Urinary Tract

Bernarda Viteri, Seth Vatsky, Amy Farkas, Mohamed Elsingergy, Richard D. Bellah, and Erum A. Hartung

Introduction

Imaging plays an important role in the diagnosis and monitoring of many diseases of the kidney and urinary tract in children [1–4]. Both congenital and acquired diseases of the urinary tract are imaged using a variety of modalities, and in many cases it is the imaging study that offers a diagnosis or at least narrows what may begin as a lengthy differential diagnosis. Radiography, excretory urography, contrast fluoroscopy, ultrasonography (US), computed tomography (CT), magnetic resonance imaging (MRI) and nuclear scintigraphy have all been used to assess the urinary tract, each with its own relative strengths and weaknesses. In some cases, two or more complementary modalities will be necessary to narrow the differential diagnosis. It is important not only to know the most appropriate modality for the investigation of a patient, but also to understand the risks and benefits associated with the various modalities. In this chapter, we provide an overview of these imaging modalities and their associated risks and benefits and present examples of their application in the evaluation of children with kidney and urinary tract abnormalities.

Imaging-Associated Risks

Ionizing Radiation

Several of the modalities used in urinary tract imaging employ ionizing radiation. It is well known that exposure to radiation has deleterious effects, including a strong association between exposure to radiation (particularly at doses reached in CT) and subsequent development of malignancies [5, 6].

The use of medical imaging that exposes patients to ionizing radiation has been increasing. Medical radiation, on average, accounts for the same radiation dose as background radiation in the United States [7]. The use of ionizing radiation is of particular concern in children due to their increased susceptibility to its negative effects. Compared to adult patients, pediatric

patients have a higher lifetime radiation risk and higher relative dose for a given radiation exposure [5]. To decrease risks to children, it is important to minimize use of ionizing radiation when possible and employ radiation dose reduction strategies applicable to imaging modalities.

Fluoroscopy is an important imaging modality in the evaluation of pediatric genitourinary diseases, as voiding cystourethrography (VCUG) and retrograde urethrography provide necessary anatomic and functional information. A wide variation of radiation doses has been observed in pediatric fluoroscopy [8]. Technical considerations to reduce dose during imaging acquisition include proper collimation and position of patient close to the imaging receptor [9]. Further strategies include the removal of anti-scatter grids for smaller pediatric patients and use of grids for larger pediatric patients [10]. Fluoroscopy units can also be adjusted to optimize settings for pediatric patients, including the automatic brightness control [10]. A pulsed frame rate rather than continuous fluoroscopy can be used without sacrificing imaging quality with considerably less radiation exposure [11].

CT is used for the evaluation of pediatric stone disease and genitourinary trauma and is often the imaging modality of choice in the emergent setting. While CT represents 17% of radiologic procedures in the United States, it accounts for almost 50% of medical radiation [12], highlighting the importance of CT dose optimization. Dose mitigation strategies are of particular importance in the CT evaluation of genitourinary diseases, as the effective doses for pediatric CT of the abdomen and pelvis are the highest when compared to other scans such as head, chest, and spine [13]. Size-based protocols are essential for the reduction of pediatric radiation dose [14]. These protocols factor the patient size into the parameters used to acquire CT images, such as the tube voltage and tube current. Use of a lower tube voltage can cause a substantial dose reduction, and automated tube voltage selection systems can optimize the tube voltage and corresponding tube current based on the scout image [12]. Iterative reconstruction is a method of data processing that refines the raw data and reduces noise, allowing decrease in the radiation dose necessary to acquire diagnostic quality images [12].

When available, dual energy CT (DECT) can also provide further dose reduction when multiphase contrast examinations are necessary. DECT is performed by scanning a patient with two x-ray tubes operating at different energies, one at a low energy and one at a high energy. DECT can be acquired with a dose comparable to conventional single source CT, but the image acquisition at different energies enables differentiation of structures based on atomic number rather than beam attenuation [15]. This data allows the virtual creation of an unenhanced phase, allowing a multiphasic examination without additional radiation dose. Applications of DECT for CT urography have been explored, demonstrating sufficient image quality with radiation dose reduction [16].

Intravenous Contrast Agents

Risks associated with the administration of intravenous (IV) contrast agents include contrast-induced nephropathy and adverse contrast reactions [17, 18]. The risk of post-contrast acute kidney injury (PC-AKI), defined as acute kidney injury (AKI) occurring within 48 h of IV administration of iodinated contrast media, has been controversial in recent decades. Observational studies designed to evaluate the association between iodinated CT contrast administration and PC-AKI have had conflicting results, likely due to differences in institutional contrast-enhanced CT protocols, variances in strategies for propensity matching, and discrepant subgroup sample sizes with different baseline kidney function [19–24]. Despite recent contributions to the pediatric literature by McDonald et al. [23] and Gilligan et al. [24], knowledge of the risk of PC-AKI in children remains limited.

Nephrotoxicity associated with gadolinium-based contrast agents for MRI has also been described, though the overall consensus is that the risk is low when used at approved doses, even in patients with kidney dysfunction [25, 26].

Another potential risk of IV contrast administration is nephrogenic systemic fibrosis (NSF) [27, 28], which has been described with the use

of an older generation of gadolinium-based contrast agents in patients with kidney failure. This rare though significant side effect has limited gadolinium use in patients with advanced chronic kidney disease (CKD) [26]. Nevertheless, the risk of NSF is thought to be lower with newer macrocyclic gadolinium-based agents (e.g. gadobutrol, gadoteridol, gadoterate) [29]. There may also be a risk of gadolinium deposition throughout the body as studies have proven deposition in the bone, brain, and skin but further study is required to determine the clinical significance, if any [30–32]. Rarely, severe reactions to gadolinium-based contrast agents can occur [33].

Potential risks associated with US contrast agents are discussed in the subsequent section, "Contrast-Enhanced Ultrasonography."

Sedation and Anesthesia

Due to the scan times associated with some imaging modalities, some children will require sedation or general anesthesia, and these risks must also be considered when choosing an imaging modality [34, 35]. In some cases, techniques such as "feed and wrap" can be used to obtain high quality images in infants for specific studies such as functional MR urography [36].

Ultrasonography

US is arguably the most important part of the pediatric imaging armamentarium. Its main strengths are that it does not use ionizing radiation and sedation is very rarely required.

The most common indications for US of the kidneys and urinary tract include: urinary tract infection (UTI) [37–39], follow-up of antenatally diagnosed hydronephrosis, evaluation of a palpable mass, assessment for vascular abnormalities (including renal artery stenosis), assessment of medical kidney diseases, screening of patients at known risk to develop kidney neoplasms (for example Beckwith-Wiedemann syndrome and other cancer predisposition syndromes) [40], and assessment for possible urinary obstruction. US can also assess other findings noted on antenatal imaging such as kidney agenesis, ectopia, dysplasia or mass.

The US examination can be tailored in many ways to suit the patient and clinical situation. A patient who is upset or frightened can be scanned lying next to a parent or in the arms of a parent, which can alleviate some anxiety. Coupled with a calm and reassuring environment and various distractions (e.g. toys, music, videos, computer tablets), this setting often allows for the performance of a satisfactory diagnostic study. The need for sedation is extremely rare but may be considered on a case-by-case basis.

The patient can be scanned in various positions (supine, prone, decubitus) depending on the scenario. In fact, altering position can at times be helpful particularly in determining if a structure such as a calculus is mobile. In some situations, the US examination can be repeated after an intervention has been performed in order to determine whether it was successful or resulted in a complication. One can study the urinary tract before or after voiding, after placement of a bladder catheter, ureteral stent or nephrostomy catheter, and throughout a kidney biopsy procedure. These repeated examinations can be done without concern for the effects of radiation.

In general, the smaller body habitus of children allows for excellent US imaging of the kidneys and urinary tract. However, US of the urinary system can be suboptimal in some larger teenagers or obese children. Scanning of the kidneys is performed mainly with curved array transducers for assessment of kidney length and to examine the status of the kidney parenchyma, pelvicalyceal system, ureters, and bladder. These images can be supplemented with those obtained with a high-resolution linear transducer, which offers superior spatial resolution but is limited in penetration depth. For that reason, high-resolution US is particularly well suited to neonates, infants and younger children. In older children, the distance between the transducer and the kidneys may preclude this type of higher resolution examination.

The kidneys are ovoid organs that typically lie in the retroperitoneal renal fossae, although they can be ectopic. Their lengths can be measured and compared with published nomograms [41–43] (Fig. 3.1). Growth of the kidneys can be followed on serial examinations; however, it is important to keep in mind that kidney lengths can

AL Grawany

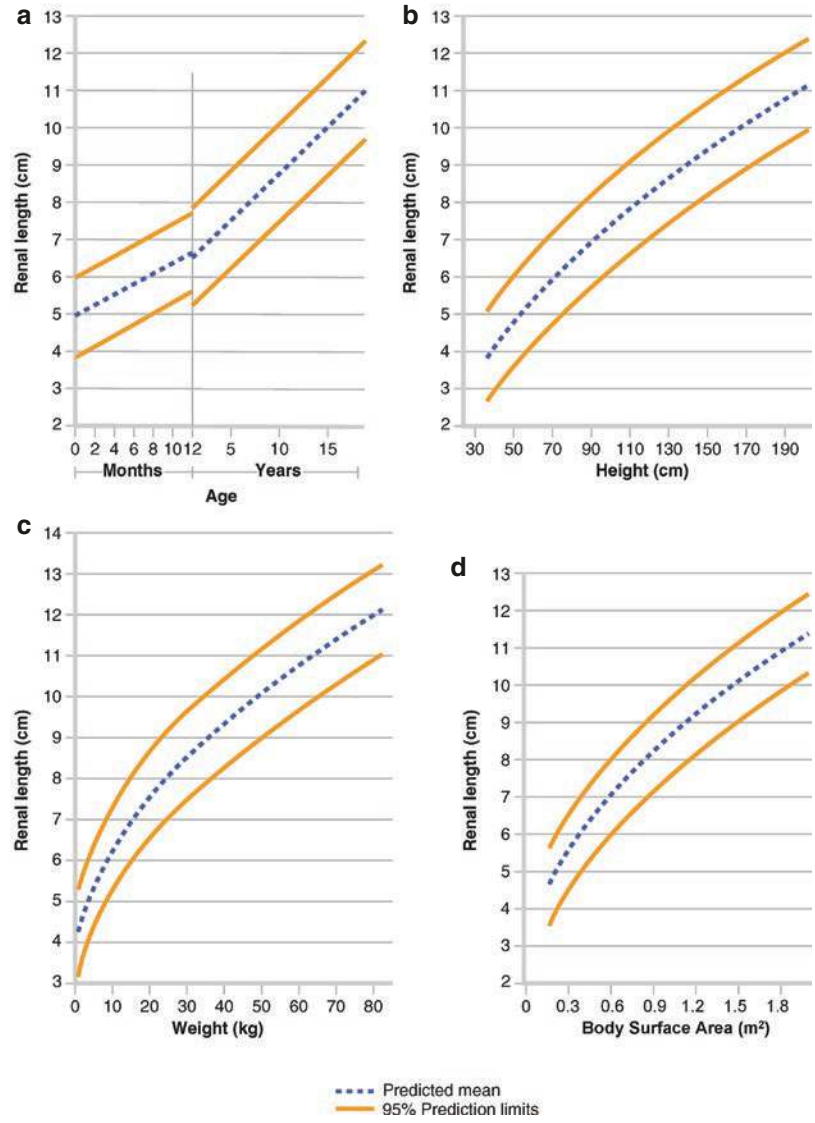

Fig. 3.1 Nomograms for kidney size. Nomograms delineate the predicted mean and 95% prediction limits of kidney length as a function of (**a**) age, (**b**) height, (**c**) weight, and (**d**) total body surface area

occasionally be over- or under-measured depending on the circumstances of the examination. Retardation in kidney growth can be a sign of ongoing insult such as vesicoureteral reflux [44].

Greyscale US

In healthy children there is a difference in echogenicity between normal kidney cortex and the medullary pyramids, with the former more echogenic and the latter more hypoechoic (Fig. 3.2). This difference is termed *corticomedullary differentiation.* The echogenicity of the kidney cortex can be compared to an internal and adjacent

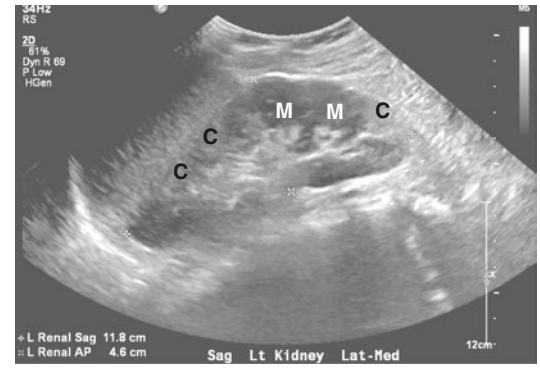

Fig. 3.2 US of normal kidney. Greyscale longitudinal US image of a 12-year-old child showing normal left kidney with relatively more echogenic cortex (C) and hypoechoic medulla (M)

standard—that is, the right kidney is compared to the liver, and the left kidney to the spleen. One must, however, ensure that this reference organ (the liver or spleen) is normal. The pattern of normal kidney echogenicity varies in childhood. In the neonate, the kidney cortex can be isoechoic or even hyperechoic compared to the liver and the renal pyramids are often profoundly hypoechoic, which can make corticomedullary differentiation quite marked [45] (Fig. 3.3a). By the time the child is several months of age the kidney cortex should be hypoechoic compared to the echogenicity of the liver [45, 46]. Any alteration in cortical echogenicity after that age suggests intrinsic kidney disease. The medullary pyramids, particularly in the neonate, can be so hypoechoic that they can be mistaken for a dilated collecting system. There are exceptions to the hypoechogenicity of the renal pyramids, the majority of which relate to disease states such as medullary nephrocalcinosis. The most common exception, however, seen in many neonates may be the transient increase in pyramidal echogenicity, which has been attributed to precipitation of Tamm Horsfall proteins [47]. In addition, there may be lobulation of the kidney outline, especially in neonates. This should not be confused with scarring. The notching of normal lobulation tends to be seen in the portion of the cortex between pyramids (Fig. 3.3b), whereas focal scarring tends to occur in portions of the cortex directly overlying the pyramid.

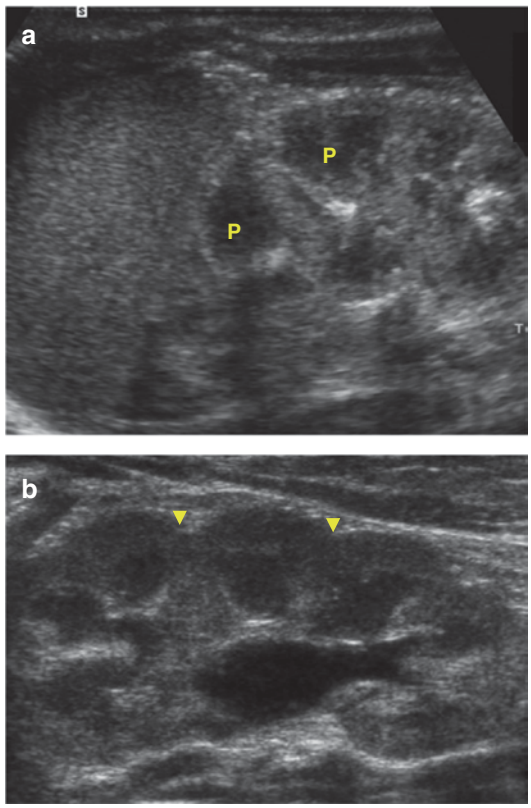

Fig. 3.3 US of normal neonatal kidney. (**a**) Greyscale longitudinal US image of a neonatal kidney showing hypoechoic pyramids (P) and hyperechoic cortex when compared to the liver with prominent corticomedullary differentiation. (**b**) Neonatal kidney showing "lobulations" (arrowheads) between pyramids

The degree of kidney collecting system dilation can be assessed both qualitatively and quantitatively. Measurement of pelvic dilation can be assessed at the level of the kidney hilum—or just beyond it in the case of an extrarenal pelvis. Classification of urinary tract dilation (UTD) is discussed in more detail later in this chapter in the section "Applications of Diagnostic and Interventional Radiology Techniques: Neonatal Diseases." A full bladder can exaggerate the degree of dilation. It is therefore prudent to assess the pelvic diameter after voiding if the bladder is overdistended. If the ureter is dilated, its diameter can be assessed along its course, although it can be visualized most reliably proximally and distally (Fig. 3.4). Overlying bowel gas often obscures the midportion of the ureter. The thickness of the wall of the intrarenal collecting system, ureter or bladder can also be assessed. Thickening of the urothelium anywhere along the urinary tract can be associated with, though is not pathognomonic for, infection or inflammation. Urolithiasis can be diagnosed as an echogenic focus with distal acoustic shadowing [48] and/or with twinkle artifact on color Doppler. The degree of obstruction caused by a calculus can also be assessed with US.

Color Doppler

Color Doppler and pulsed Doppler interrogation of the kidneys can be used to assess vascularity of the kidneys. The study can assess the

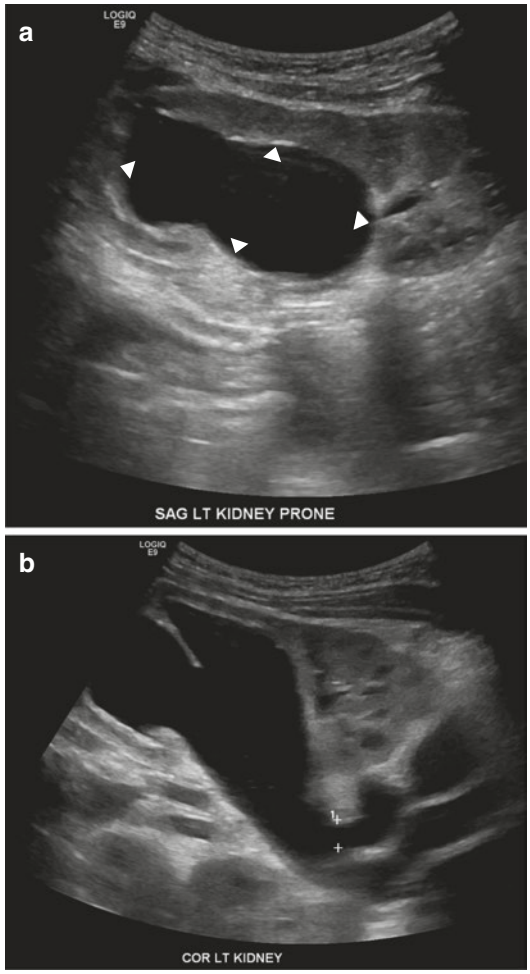

Fig. 3.4 US of urinary tract dilation and ureteral dilation. (**a**) Greyscale longitudinal US image of a 1-year-old child with congenital hydronephrosis of the left kidney showing marked dilatation of the upper pole collecting system (arrowheads) and thinning of the parenchyma with a relatively normal lower pole. The upper pole pelvis and calyces are markedly dilated. (**b**) The ureter is markedly dilated and tortuous with a proximal diameter of 0.53 cm (cross marks)

vessels from the ostia of the main renal arteries and veins through the arcuate vessels in the kidney parenchyma. Indications for Doppler evaluation include suspicion of renal arterial or venous thrombosis [49], arterial stenosis [50], trauma [51], infection [52], acute tubular necrosis, and transplant rejection [53]– though the role in the evaluation of rejection remains controversial [54].

Contrast-Enhanced Ultrasonography

Contrast-enhanced US (CEUS) is an innovative imaging modality that utilizes non-nephrotoxic microbubbles as an IV US contrast agent (UCA). UCAs consist of a gas core with lipid monolayer stabilizing shell no bigger than a red-blood cell. UCAs are currently approved by the United States Food and Drug Administration for IV use in cardiac and hepatic US, and for intravesical use in the evaluation of vesicoureteral reflux (VUR) in children. Despite being "off-label" in the United States, its kidney applications have grown in recent years, including evaluation of kidney trauma, masses and cysts, as well as to guide procedures [55–59]. CEUS is more sensitive in detecting perfusion abnormalities than Doppler (Fig. 3.5), as CEUS enhances the vascular echo signal through the use of a purely intravascular contrast agent, rather than detecting the Doppler shift, which is highly dependent on many technical factors such as speed of acquisition, angle of imaging, depth of imaging, and frequency [60]. CEUS in clinical practice provides dynamic information about an organ, such as microvascular perfusion, potential quantification of blood flow, and perfusion characteristics of masses and cystic lesions [61–63]. For example, inflammatory processes of the kidneys such as acute pyelonephritis and glomerulonephritis will show hyper-enhancement whereas scarred kidneys present with focal areas of hypo-enhancement. In the evaluation of lesions, cysts show no enhancement while solid lesions do. Moreover, malignant lesions usually enhance avidly and "wash out" because of their nearly complete arterial blood supply and abnormal arteriovenous shunts throughout. In kidney transplantation, CEUS has been able to detect early features of acute allograft dysfunction in the setting of acute tubular necrosis, rejection, cortical necrosis and other vascular complications such as local areas of hypoperfusion (Fig. 3.5) [64–66].

CEUS can also provide real-time images for guidance of interventional procedures, such as percutaneous drainage and biopsy, by providing

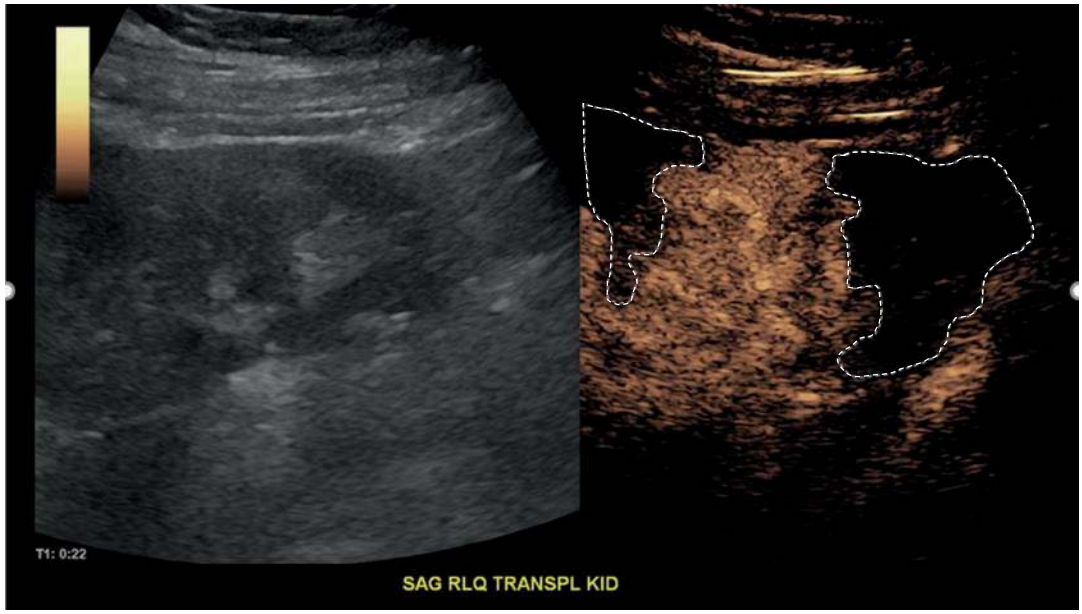

Fig. 3.5 Contrast enhanced US (CEUS) of kidney transplant. CEUS of a transplant kidney in an adolescent recipient showing lack of perfusion in the lower one third of the kidney along with a wedge-shaped perfusion defect in the anterior aspect of the upper-pole (dashed lines), highly suggestive of kidney infarction

evidence of communication between cavities or flow from the placed catheter into the region of interest. It can also be used during percutaneous nephrostomy and thermal ablation of tumors [56]. CEUS can also allow bedside evaluation of organ perfusion and lymphatic leakage without the need for ionizing radiation [67].

Post-acquisition quantification of perfusion or relative enhancement are, to date, a work in progress with no standardization but with promising preliminary results [68, 69]. Additionally, given that most US machines that have the capability to perform CEUS also perform conventional US, one can simultaneously evaluate images with both modalities.

Contrast-Enhanced Voiding Urosonography (ceVUS)

A special application of CEUS is contrast-enhanced voiding urosonography (ceVUS), an US-based alternative to evaluate for VUR or urethral pathology [70, 71]. CeVUS, like fluoroscopic VCUG, evaluates the urinary tract with contrast administration via a bladder catheter, but uses an US scanner for evaluation. Benefits of ceVUS include a more child-friendly imaging environment and lack of ionizing radiation. The detection of microbubbles within a ureter or kidney collecting system indicates VUR, which is graded similarly to VCUG [70, 72, 73]. ceVUS has been shown to be more sensitive in detecting VUR, with a higher grade of reflux in up to two thirds of patients, and as good for the evaluation of the urethra when compared to VCUG (Fig. 3.6) [74, 75]. CeVUS can also be used in the evaluation of posterior urethral valves (PUV) and urethral trauma [72, 76]. Moreover, in therapeutics, intraoperative applicability of ceVUS has improved the success rate of minimally invasive sub-trigonal injection procedure (Deflux®) for resolution of VUR by approximately 20% [77].

US Contrast Safety

US contrast agents have a good safety profile for intravesical use. The most common side effects relate to the urethral catheterization, with no known side effects from the actual US contrast agent [70].

Over two decades of experience with IV US contrast administration in thousands of pediatric

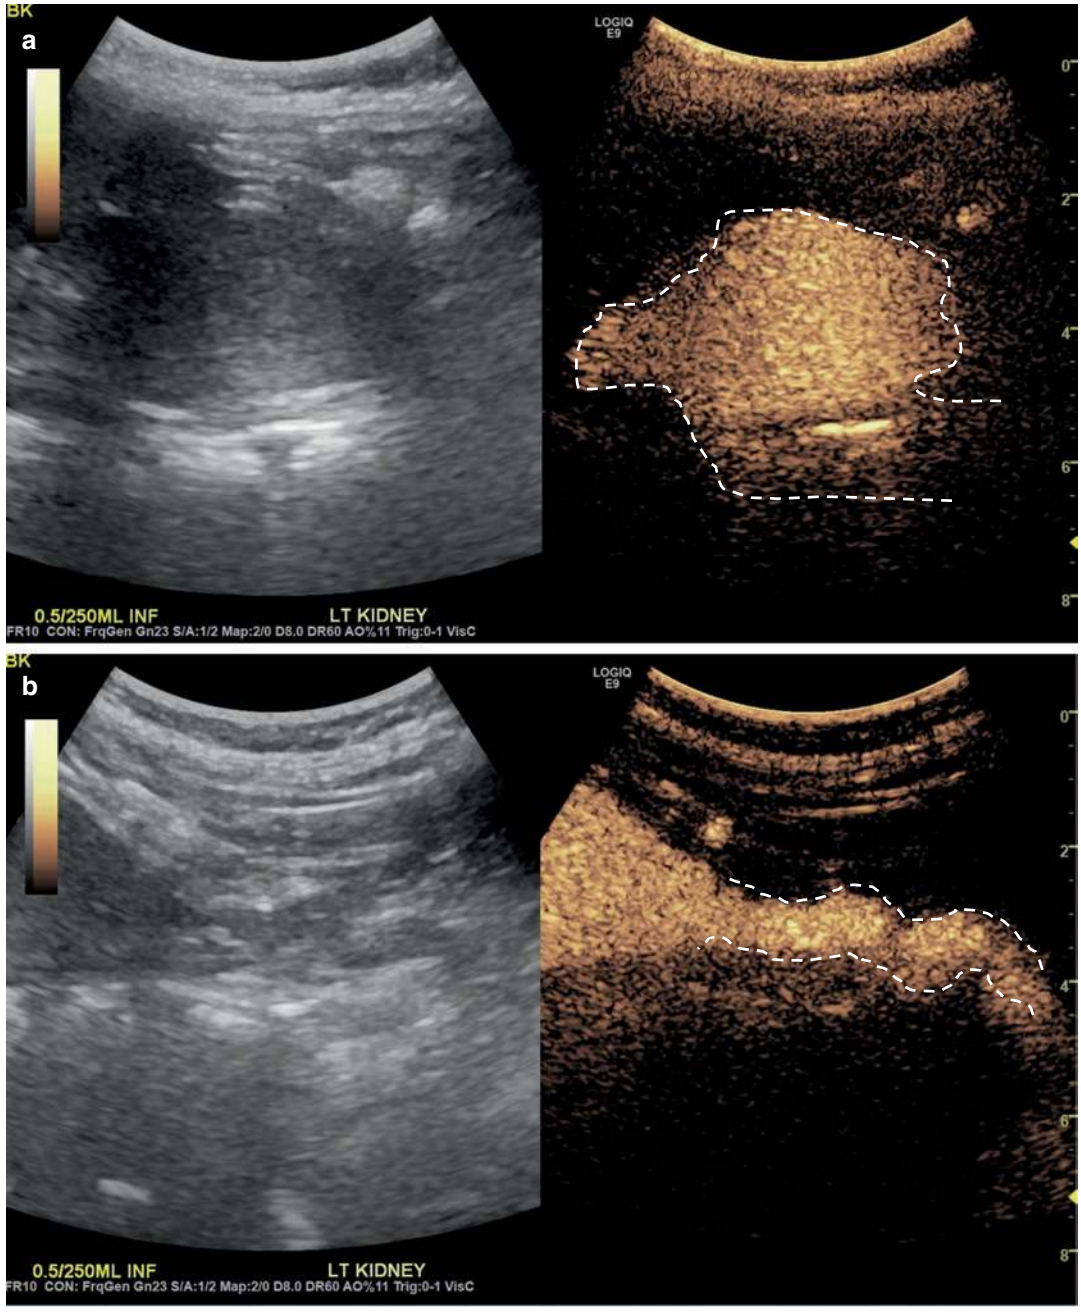

Fig. 3.6 Contrast enhanced voiding US (ceVUS). (**a**) CeVUS of a 4-year-old child shows grade 4 reflux to the left kidney. The renal pelvis and calyces are dilated (dashed lines). (**b**) The left ureter is moderately dilated and tortuous (dashed lines)

patients in Europe, Asia, and most recently in the United States, has shown a good track record of safety. Specifically, in over 1900 reported IV US contrast exams in children, two children had severe allergic reactions that were successfully treated [78–81]. Other reactions reported in children include tachypnea, unusual taste, mild itching and hives, and other minor reactions that did not require treatment [78–83]. Nausea and headache are the most common reactions associated with the administration of the commercially available US contrast agents Lumason® (approved in the United States) [84] and SonoVue (approved in Europe and Asia) [85].

Voiding Cystourethrography

VCUG has traditionally been the study of choice for diagnosing VUR and assessing the anatomy of the bladder and urethra. Indications include UTI [39], antenatally or postnatally diagnosed hydronephrosis, and suspected PUV, among others. At most institutions, sedation is not administered. In our experience, the examination can be performed without sedation in the vast majority of children, given proper explanation and reassurance.

A catheter is placed via the urethra into the bladder using aseptic technique; alternatively, a suprapubic catheter or appendicovesicostomy (Mitrofanoff) can be used if present. The bladder is filled with water soluble contrast under the pressure of gravity until pressure within the bladder induces micturition. The amount of contrast used will vary according to the patient's age and bladder capacity. If a child is unable to void on their own, the bladder can be drained via the catheter in situ. If the child is reticent or unable to void, warm water applied to the perineum can induce voiding. Some children will not void on the fluoroscopy table despite a variety of maneuvers. In these cases, the micturition phase of the study is not possible and the sensitivity of the study to detect reflux is diminished. In some institutions an image is taken after the child has been allowed to void in the toilet. At some institutions a single cycle of filling and voiding is performed. At others, two or three cycles are the routine [86]. This latter method, termed *cyclic VCUG*, has demonstrated greater sensitivity in detecting reflux, but results in a higher radiation dose compared to the single cycle method. In all cases, care is given to minimizing the dose of ionizing radiation [87].

Exact views obtained will vary between institutions, but all will include images of the bladder that will allow for assessment of its wall characteristics and detection of structural abnormalities such as diverticula, ureteroceles or urachal abnormalities. These images should demonstrate whether there is any reflux into the ureters. Images of the urethra will be obtained during voiding, either with the catheter in place or after its removal depending on the practice of the institution and the individual radiologist. At our institution an image of the urethra is obtained with the catheter in place as well as after its removal, thus ensuring an image of the urethra in cases in which the child stops voiding just as the catheter is removed. An image of the renal fossae will assess for any reflux to the level of the kidneys, characterize the collecting system anatomy (duplex or not) and assign a grade to that reflux [88]. The system of the International Reflux Study in Children classifies reflux into five grades. Reflux into the ureter alone is classified as Grade I. When contrast fills the intrarenal collecting system but without dilation, it is classified as Grade II. Grades III–V demonstrate progressive dilation of the ureter, pelvis and calyces [88] (Fig. 3.7).

Complications related to VCUG are similar to those encountered in any catheterization of the bladder, with infection and trauma being the most common. At our institution, we do not administer prophylactic antibiotics unless there is a clinical indication for procedure related prophylaxis. If the examination is positive and the patient is not on long-term antibiotic prophylaxis, a prompt communication of the results to the referring clinician is appropriate. One can also encounter urinary retention post-procedure.

Nuclear Medicine

Nuclear medicine is a modality that comprises a variety of examinations for evaluating the pediatric urinary tract. Nuclear medicine techniques differ from other imaging modalities in that they focus on function rather than detailed anatomic structure. As a result, nuclear imaging plays an important complementary role to other modalities, particularly to the structural evaluation obtained with US.

The physical principles of how scintigraphic images are generated also differ from those of other imaging modalities. Rather than transmitting x-rays through the patient as is done with fluoroscopy, radiography and CT, nuclear medicine introduces a radioactive tracer into the patient's body. An Anger camera is then positioned adjacent to the patient, and images are created by detecting the gamma-rays emitted from the patient's own body. In nuclear urinary tract imaging, depending on the specific examination being performed, the radiopharmaceutical can be injected IV to be extracted by the kidneys, or can be instilled via catheter into the bladder. Radiation doses in nuclear medicine examinations of the urinary tract are lower than those encountered in CT and lower or comparable to those in fluoroscopy.

Most pediatric patients do not require sedation, as they are either cooperative in lying still on the scintigraphy imaging table or are infants small enough to be safely restrained with swaddling. However, if a child is anticipated to have difficulty lying still for at least 30 min, sedation can be considered. Rarely, general anesthesia is necessary to perform a successful examination.

Urinary tract imaging comprises over half of the examinations performed in a typical pediatric nuclear medicine department. The most common clinical indications for performing nuclear kidney imaging examinations include UTI, ante- or post-natally detected hydronephrosis, vesicoureteral reflux, suspected urinary obstruction, and suspected impairment of kidney function.

Overview of Radiopharmaceuticals

Technetium-99m (99mTc) is the radionuclide (i.e. gamma-emitting isotope) that is used to label most radiopharmaceuticals in urinary tract imaging. It emits a 140 keV gamma-ray and has a physical half-life of 6 h.

Technetium-99m pertechnetate is the base form of 99mTc that is obtained from a portable generator unit found in any nuclear medicine radiopharmacy. 99mTc-pertechnetate can be used to radiolabel other pharmaceuticals using commercially available labeling kits. Other radiopharmaceuticals routinely used in nuclear urinary tract imaging are described in Table 3.1.

Table 3.1 Radiopharmaceuticals routinely used in nuclear urinary tract imaging

	Use	Mechanism of action	Imaging analysis
Glomerular filtration agents			
DTPA			
99mTc-diethylenetriaminepentaacetic acid	• Calculate GFR	Measuring the rate of DTPA extraction from plasma by serial blood sampling provides an accurate estimate of GFR. Approximately 90% of DTPA is filtered by the kidneys into the urine within 4 h after IV injection [126].	Kidney imaging can be performed using 99mTc-DTPA, providing additional information on excretion and drainage, as well as the ability to plot dynamic renogram time-activity curves.
EDTA			
51Cr-ethylenediaminetetraacetate	• Calculate GFR (standard GFR agent used in Europe)	Due to better radioisotope binding to the tracer, 51Cr-EDTA produces slightly higher values for GFR than 99mTc-DTPA. However, this difference is small (5% or less) and is not considered to be clinically relevant [284].	Kidney imaging is not performed with 51Cr-EDTA as it does not emit gamma-rays of suitable energy levels for imaging.
Tubular secretion agents			
MAG3			
99mTc-mercaptoacetyltriglycine	• Agent of choice for functional kidney imaging • Split kidney function • Detect obstruction • Evaluate kidney transplant allografts	MAG3 is cleared predominantly (95%) by the kidney tubules [126]. MAG3 clearance is proportional to effective kidney plasma flow.	Better image quality as the extraction fraction of MAG3 is more than twice that of DTPA, resulting in a much higher target-to-background ratio.
Kidney tubular fixation agents (cortical agents)			
DMSA			
99mTc-dimercaptosuccinic acid	• Agent of choice to detect cortical scarring	Binds to sulfhydryl groups of proximal kidney tubules after filtration [126]. Only 10% is excreted into the urine during the first several hours after IV injection.	Produces excellent high-resolution images of the kidney cortex without interference from urinary activity. Is the preferred cortical imaging agent.
GH			
99mTc-glucoheptonate	• Early imaging evaluates kidney perfusion, urinary excretion and drainage • Late imaging at 1–2 h visualizes kidney cortex	Cleared by the kidneys through both tubular secretion and glomerular filtration, with 10–15% remaining bound to the kidney tubules at 1 h after injection.	99mTc-GH has less cortical binding affinity than 99mTc-DMSA.

Direct Radionuclide Cystogram (DRC)

Direct radionuclide cystography (DRC) has good sensitivity to detect VUR, but provides very little anatomic detail for detecting bladder and urethral abnormalities [89, 90]. DRC is performed in a similar manner to VCUG, except the bladder is filled with a 99mTc-based radiopharmaceutical and an Anger camera is used for imaging, often for several cycles of filling and voiding. DRC can be used as a complementary modality to VCUG [89–91]. Typically, VCUG is the primary modality to evaluate for VUR in patients with febrile UTI or hydronephrosis [92]. Subsequently, DRC may be used as a follow-up examination to determine if VUR has resolved or is persistent, including post-operative evaluation after ureteral reimplantation surgery or minimally invasive sub-trigonal injection procedure (Deflux®). DRC can also be performed as a primary screening examination to detect reflux in asymptomatic patients with a small kidney or solitary kidney, or who have a family history of VUR (first degree relative, i.e. parent or sibling).

Indirect Radionuclide Cystogram

An alternative test for the detection of VUR reflux is the indirect radionuclide cystogram (IRC) [93–102]. This examination should be reserved for children >3 years of age [103] in whom bladder catheterization is impossible. IRC is performed by injecting 99mTc-mercaptuacetyltriglycine (MAG3) IV, then acquiring continuous dynamic images of the kidney and bladder during bladder filling and voiding. The patient must be able to remain still during imaging and to void on command after bladder filling. Regions of interest are drawn over the intrarenal collecting systems and the ureters, and time-activity curves are plotted. A sudden increase in activity in the renal pelvis and ureter indicates the presence of VUR.

Direct vs. Indirect Radionuclide Cystogram

There is ongoing debate regarding whether direct vs. indirect radionuclide cystography is preferable for detecting VUR. In theory, IRC is a better mimic of physiologic slow antegrade bladder filling, whereas DRC involves rapid retrograde bladder filling via a catheter, which some believe induces artificial reflux. Others assert that this higher sensitivity of DRC (up to 95%) [104] is an advantage, and may be a better comparator to prior VCUG results due to the same method of bladder filling. Patients with abnormal kidney function may have insufficient excretion of radiotracer during IRC, resulting in lower sensitivity ranging between 32% and 81% [94, 97, 104–106]. In practice, there is a high rate of failure of IRC due to the inability of children to remain still while voiding or the inability to void at all during image acquisition [107]. In the case of a negative IRC examination, a subsequent DRC or VCUG may be needed to confidently exclude vesicoureteral reflux [103].

Kidney Cortical Scan

Cortical scintigraphy with 99mTc-dimercaptosuccinic acid (DMSA) is a highly sensitive examination for the detection of both acute lesions (i.e. pyelonephritis) and late sequelae (i.e. permanent parenchymal scarring) in children with UTI. Acute lesions of pyelonephritis can take up to 6 months to resolve scintigraphically. Therefore, permanent scarring can only be reported when the DMSA scan is performed at least 6 months after the acute infection. If less than 6 months have elapsed since the acute infection, any cortical defects should be interpreted as either resolving pyelonephritis or potential scar. Therefore, kidney cortical scintigraphy should only be performed within 6 months of an acute infection if there is an acute need to document kidney involvement. Otherwise, a repeat scan will likely be needed later to exclude

permanent scarring [39, 103, 108–110]. When requesting a DMSA scan, it is helpful for the referring physician to note the date of the most recent UTI.

Kidney scarring tends to occur at the upper and lower poles due to the round-shaped orifices of the compound papillae at these locations. The simple papillae at the mid-poles have slit-like orifices that are less prone to reflux of infected urine. Kidney cortical defects are reported as unilateral or bilateral, single or multiple, small or large, with or without loss of parenchymal volume. Permanent scarring tends to cause loss of parenchymal volume (Fig. 3.8), whereas acute infection does not. If present, a dilated renal pelvis can also be visualized. DMSA cortical scintigraphy is more sensitive than IV pyelography and US for the detection of both acute lesions and permanent scarring [52, 109, 111, 112].

Other causes of cortical defects on DMSA scan include kidney cysts and masses. Normal variations in appearance of the kidney cortex can include indentation by the adjacent spleen, fetal lobulation, columns of Bertin, duplex kidney, and malrotated kidney. Kidney cortical scans are often useful in confirming the diagnoses of horseshoe kidney, ectopic kidney, or cross-fused renal ectopia when US is equivocal (Fig. 3.9).

Images are acquired 2–3 h after injection of 99mTc-DMSA. Planar images are acquired in the posterior, and right and left posterior oblique positions. In infants, additional pinhole images may be acquired that offer higher spatial resolution. In older, sufficiently cooperative children, additional single photon emission computed

AL Grawany

tomography (SPECT) images may be acquired to improve spatial resolution [113–117]. SPECT iterative reconstruction algorithms can further improve spatial resolution, or maintain spatial resolution with a lower administered dose of radiopharmaceutical [118]. However, the clinical significance of any additional small cortical defects detected by these higher-resolution methods is unclear [119–125].

Functional Kidney Imaging and Renography

Functional kidney imaging uses dynamic image acquisition to evaluate kidney perfusion, uptake, excretion, and drainage of radiotracer by the urinary system. Renography refers to the process of plotting the radiotracer activity in the urinary system as a function of time, resulting in renogram (time-activity) curves. A large amount of information can be acquired with functional kidney imaging. For example, abnormal perfusion can suggest arterial stenosis or occlusion; delayed uptake and excretion of radiotracer suggest parenchymal disease; and poor drainage of radiotracer into the bladder can suggest obstructive uropathy or over-compliance of the collecting system. Functional kidney imaging can be custom-tailored for specific clinical problems. For example, a diuretic challenge can be administered to more sensitively evaluate for urinary obstruction (see below).

Although 99mTc-DTPA is widely used for functional kidney imaging, 99mTc-MAG3 is preferred due to its higher extraction fraction and better target-to-background ratio. This advantage is particularly important in patients with impaired kidney function or urinary obstruction, and in very young patients with immature kidney function.

Immediately after the injection of radiotracer, imaging of kidney perfusion can be performed. The patient lies supine with the camera positioned posteriorly. Radiotracer activity should reach the kidneys about 1 s after the tracer bolus in the abdominal aorta passes the renal arteries; there should be symmetric perfusion of the kidneys [126]. Over the next 20–30 min, imaging of kidney function is performed. Maximal parenchymal activity is seen normally at 3–5 min after injection (T_{max}) [126]. Urinary activity in the renal pelvis is typically seen by 2–4 min after injection (calyceal transit time); however, there is no widespread consensus on what constitutes a normal calyceal transit time [127]. There should be prompt drainage of tracer into the bladder, with less than half of the activity at T_{max} remaining in the renal pelvis by 8–12 min after injection ($T_{1/2}$) [126].

Renogram curves are generated by plotting the activity within regions of interest drawn around each kidney. The renogram is a graphic representation of the uptake, excretion, and drainage phases of renal function, and the curves for each kidney should be reasonably symmetric. Patients should be well-hydrated, preferably with IV fluids, when functional kidney imaging is performed, as dehydration will result in an abnormal renogram with globally delayed function and slow drainage.

Diuretic Renogram

In the setting of urinary collecting system dilation not due to VUR, the possibility of urinary tract obstruction must be considered. Diuretic renography performed with furosemide is useful in determining the presence of a high-grade obstruction at the ureteropelvic junction (UPJ) or the ureterovesical junction (UVJ). Diuretic renography is commonly used to evaluate the results of surgery in patients who have undergone pyeloplasty for ureteropelvic junction obstruction.

Diuretic renography is performed as described above for dynamic kidney imaging, with the additional step of administering IV hydration and furosemide to cause maximal urine flow through the collecting system. The dose of furosemide is usually 1 mg/kg, with a maximum dose of 40 mg [128]. The timing of the furosemide administration varies among institutions, as several diuretic

protocols have been described, validated, and debated in the literature [103, 129, 130]. The most commonly used protocols are: "F+20" (furosemide is given 20 min after radiotracer if normal spontaneous drainage has not occurred [131]; this protocol is endorsed by the American Society of Fetal Urology); "F−15" (furosemide is injected first, followed 15 min later by radiotracer; this protocol is the widely-used European standard) [128]; and "F0" (radiotracer and furosemide are injected immediately following one another) [132, 133]. Dynamic images are acquired from the time of radiotracer injection for approximately 20 min. In the case of the F+20 protocol, an additional 20 min of imaging is performed after injection of furosemide.

Bladder catheterization is not always necessary but should be performed in patients who are not toilet-trained, or who have known hydroureter, VUR, bladder dysfunction, or PUV. In this subset of patients, back pressure from urine in the bladder may cause a false-positive result.

In the absence of urinary obstruction, there is rapid drainage of radiotracer from the renal pelvis into the bladder to a minimal residual by 20 min. In quantitative terms, a drainage half-time, $T_{1/2}$, of less than 10 min usually means the absence of obstruction.

In an obstructed system, the drainage of radiotracer from the collecting system will be slow. In this case, a $T_{1/2}$ of greater than 20 min indicates obstruction (Fig. 3.10). When $T_{1/2}$ ranges between 10 and 20 min, this is usually considered an equivocal result, and a follow-up examination will typically be performed to see if the drainage remains unchanged, normalizes, or becomes frankly obstructed.

When UPJ obstruction is suspected, the above drainage parameters are used when analyzing a region of interest drawn around the renal pelvis. These values can also be applied to the ureter and to a region of interest combining the ureter and renal pelvis when UVJ obstruction is suspected.

If a large amount of radiotracer remains in the renal pelvis and/or ureter at the end of dynamic imaging, the patient can be positioned upright to void if possible. A final static image can then be acquired to see if the postural/gravitational effect caused additional drainage [103].

Pitfalls are common in the interpretation of diuretic renography. Poor kidney function from prolonged, severe obstruction can result in poor accumulation of radiotracer in the collecting system, making the renogram difficult or impossible to interpret. A very dilated, overly-compliant, but non-obstructed collecting system may have a prolonged $T_{1/2}$ because the capacious collecting system easily accommodates a large urine volume [128, 130]. This "reservoir effect" can be observed in the setting of primary megaureter, and in patients who have undergone successful pyeloplasty for UPJ obstruction.

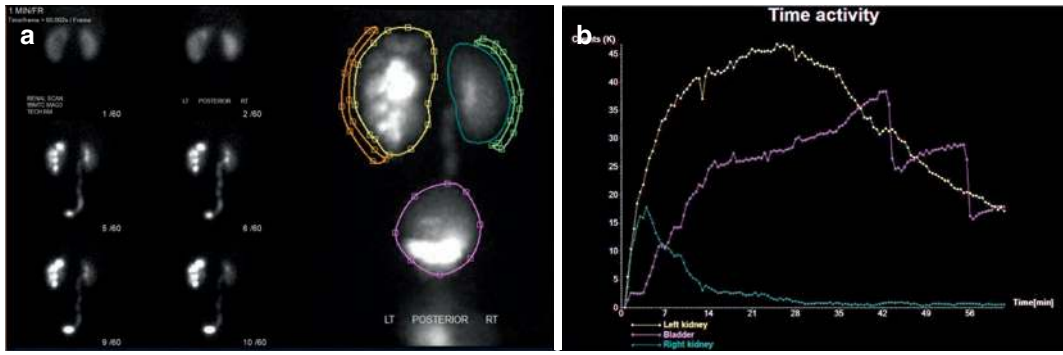

Fig. 3.10 MAG3 diuretic renogram. (**a**) MAG3 renogram of a 27-month-old girl with a history of congenital hydronephrosis shows prompt blood flow to both kidneys. (**b**) Time-activity curves shows significant urine stagnation on the left side at 25 min (white curve), which responds poorly to furosemide administration with a prolonged half-clearance time. Normal clearance of radiotracer of right kidney (blue curve)

Computed Tomography

CT is often the imaging modality of choice for evaluation of blunt or penetrating genitourinary trauma and may be used in the evaluation of stone disease or neoplasm. The indication for imaging determines the CT protocol and the need for the administration of IV contrast.

In the evaluation of trauma, IV contrast should be administered unless there is a contraindication. Obtaining a CT in the arterial phase, when contrast opacifies the arterial structures, can evaluate for arterial injury such as dissection or pseudoaneurysm, as well as active arterial hemorrhage. A delayed phase CT, obtained approximately 10 min after contrast administration when the contrast has been excreted into the collecting system, can be obtained if there is a suspicion for a collecting system injury, and will show extravasation from the collecting system when injured. A dedicated cystogram, or retrograde filling of the urinary bladder with contrast after placement of a catheter, can be performed if there is concern for bladder injury, as routine CT of the abdomen and pelvis is not sensitive for the detection of bladder injury [134].

Multiphasic CT evaluation with a single contrast bolus may offer increased clinical certainty to detect vascular extravasation (Fig. 3.11), devascularization and urinary leak, but results in increased radiation dose because multiple CT scans must be obtained at different time points corresponding with the structures that are opacified by the contrast [135, 136]. Double and triple split bolus techniques can opacify multiple structures during a single CT acquisition, reducing radiation dose [137–139].

Although rarely the initial imaging modality in the work-up of urinary tract disease, CT contributes significantly to the imaging of children with suspected urinary tract disorders. Indications include neoplasia [140], trauma [141, 142], severe infections [143] and occasionally complex questions regarding anatomy [144] (although MRI often would be the preferred modality). Though US is the mainstay of imaging urolithiasis in children, CT can be useful in cases that on US are equivocal or non-diagnostic.

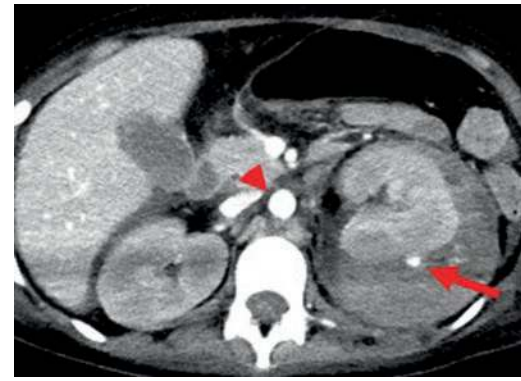

Fig. 3.11 Contrast enhanced CT of vascular extravasation. Arterial extravasation from the kidney on CT in a 14-year-old female following kidney biopsy. Contrast-enhanced axial CT image obtained in the arterial phase demonstrates opacification of the aorta (arrowhead) and remainder of the arterial system. There is arterial enhancement external to the left kidney (arrow) within a large perinephric hematoma, consistent with active arterial extravasation

CT allows for cross sectional imaging of the urinary tract and has the ability to reconstruct images in any plane for analysis. CT also provides excellent resolution of the urinary tract structures. The addition of IV contrast to the CT imaging allows for even greater accuracy in the detection of disease. Newer generations of CT technology provide higher spatial and temporal resolution and importantly can be done in many instances without sedation or general anesthesia, which may be required for MRI.

On unenhanced scans, the kidneys demonstrate similar attenuation to the normal liver or spleen. They are surrounded by a variable amount of retroperitoneal fat depending on the age and health status of the child. Administration of contrast results in a reliable pattern of enhancement beginning in the renal cortex, followed by enhancement of the renal pyramids, and later by opacification of the pelvicalyceal system, ureters and bladder.

The ability of CT to differentiate between tissues of various densities allows for the detection of hydronephrosis, calcifications (Fig. 3.12) and diseases extending into the perinephric fat even without the administration of IV contrast. With the addition of IV contrast, however, one can detect individual lesions of the kidney paren-

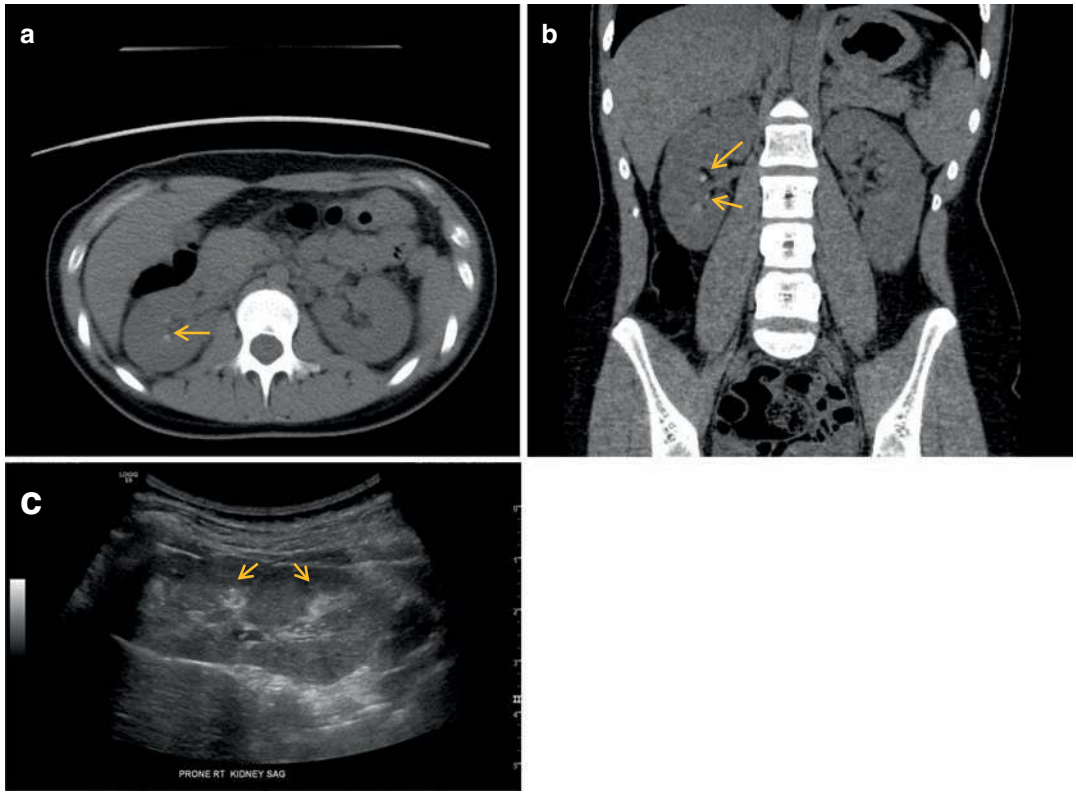

Fig. 3.12 Nephrocalcinosis. (**a**) Axial and (**b**) coronal planes of non-contrast CT of 17-year-old child showing variable hyperattenuation in multiple medullary papilla (arrows), which gradually decreases in density more proximally along the expected course of the medullary tubules. (**c**) Greyscale US shows diffuse increased echogenicity of the medullary pyramids. This is most suggestive of medullary calcifications (nephrocalcinosis)

chyma, such as cysts, tumors or nephroblastomatosis; focal areas of diminished enhancement, such as foci of pyelonephritis (Fig. 3.13) or contusion/laceration (Fig. 3.14); and global abnormalities of enhancement, such as is evident in renal artery stenosis (RAS) or thrombosis.

When ordering a CT examination, potential risks, including radiation exposure and possible contrast-induced nephropathy, must be considered and balanced with potential benefits such as avoidance of sedation or anesthesia.

Magnetic Resonance Imaging

MRI, like US, is uniquely suited to the imaging of children due to avoidance of ionizing radiation. Although radiofrequency energy is

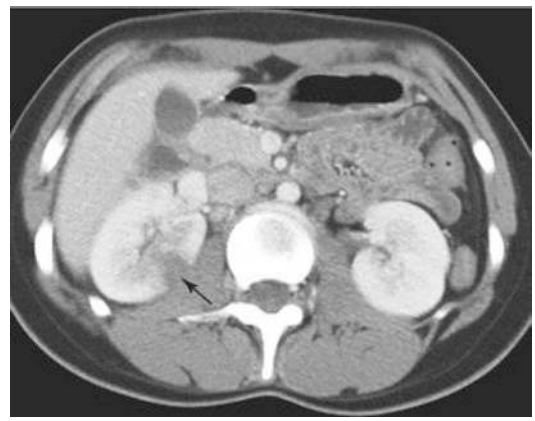

Fig. 3.13 Contrast enhanced CT for pyelonephritis. Contrast-enhanced CT at the level of the kidneys demonstrates an area in the posteromedial aspect of the right kidney with diminished enhancement (arrow), consistent with the clinical suspicion of pyelonephritis

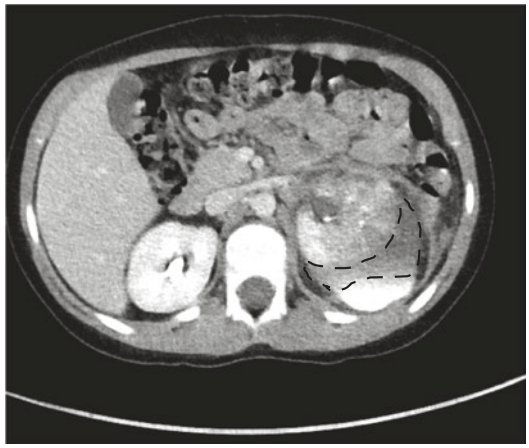

Fig. 3.14 Contrast enhanced CT of kidney laceration. Contrast-enhanced CT at the level of the kidneys demonstrates an area of diminished enhancement in the inferior aspect of the left kidney (dashed line), consistent with a laceration bisecting the lower pole of the kidney

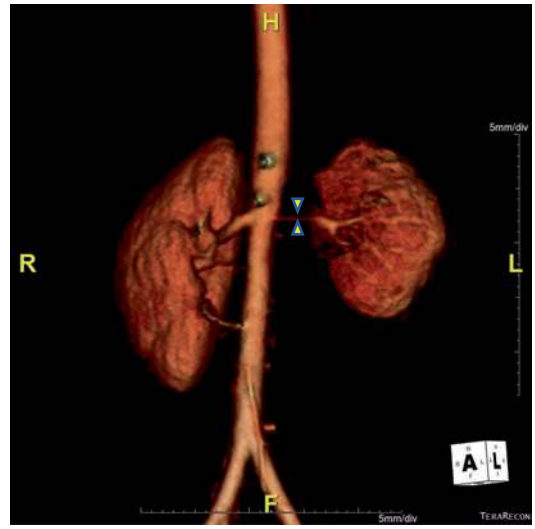

Fig. 3.15 MR angiography (MRA) of renal artery stenosis. MRA in a patient with hypertension showing stenosis in the left main renal artery (arrow heads)

imparted, MRI has not been shown to have the deleterious potential of CT. For that reason, MRI is often preferred over CT for children. However, longer scan times with MRI may necessitate sedation or general anesthesia in patients who are not able to lie still, such as children younger than 6 years and in those with development delay or claustrophobia [145]. In addition, access to an MR scanner remains limited in some regions of the world.

The superior tissue characterization of MRI makes it a powerful tool in assessing diseases of the urinary tract. Administration of gadolinium-based IV contrast can provide improved visualization but may be associated with risks such as NSF as discussed previously. For patients in whom gadolinium contrast is contraindicated, MRI without contrast can still provide detailed structural imaging of the urinary system.

MRI is particularly well suited in assessing neoplasms and tumor-like conditions of the kidneys [146, 147] including nephroblastomatosis [147]. MRI can help to characterize lesions, for example by demonstrating necrosis and hemorrhage in lesions such as Wilms tumor or renal cell carcinoma, or areas of fat in angiomyolipomas [148, 149]. Calcifications, however, are not as reliably seen with MRI as with CT.

As in adults, MRI can be used to assess the renal arteries and veins in children. Bland (non-tumor) thrombosis can readily be demonstrated, as can tumor extension into the vessels [150, 151]. MR angiography (MRA) can be used to assess for RAS in patients with hypertension [152–155] (Fig. 3.15). However, MRA may not be sensitive enough to definitively exclude RAS even in adults [156], and is additionally challenging in children due to their smaller vasculature. MRI can also be used in the assessment of infection [157–159] and trauma [160, 161]. Research is ongoing in adults and children into the application of additional advanced MR sequences in the kidney, such as diffusion-weighted MRI, diffusion tensor imaging, arterial spin labeling, and MR elastography [162–165].

Magnetic Resonance Urography

Magnetic resonance urography (MRU) is an advanced imaging technique that provides detailed anatomic information without ionizing radiation. The optimal visualization of the collecting system on MRU allows differentiation of complex genitourinary anatomy and evaluation

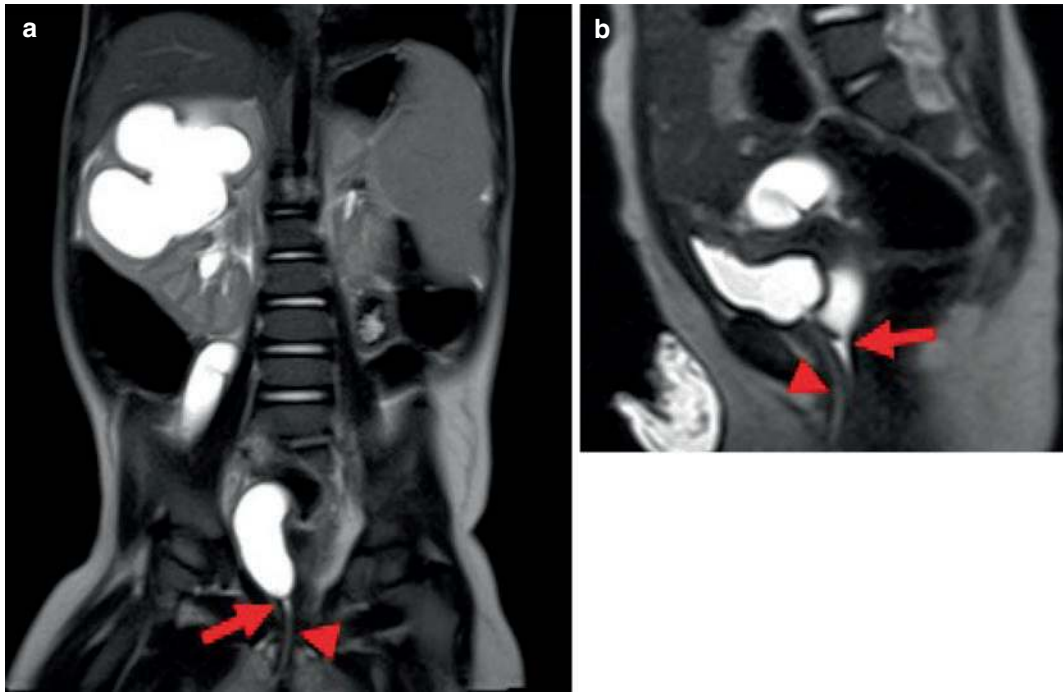

Fig. 3.16 MR urography (MRU) of ectopic ureter. Ectopic ureteral insertion on MRU in a 2-year-old with urinary tract infections. (**a**) Coronal and (**b**) sagittal T2-weighted images demonstrate a right-sided duplicated collecting system, with a markedly dilated upper pole system ectopically inserting into the urethra (arrows). A Foley catheter is in place (arrowheads), which demarcates the position of the urethra

of the course and insertion of the ureters (Fig. 3.16). This anatomic detail is provided by heavily T2-weighted, high spatial resolution two-dimensional and three-dimensional images [166]. With optimization of the imaging protocol, scan times with MRU can be reduced to 30 min [167].

Multiple technical factors of MRU must be considered and planned. Patients receive IV hydration and furosemide prior to imaging to distend the urinary tract and improve visualization [166]. A Foley catheter is often placed, allowing patients to tolerate the examination without the discomfort of needing to void. If evaluation of the bladder is necessary, the Foley catheter can be clamped during the examination to distend the bladder and allow better assessment. Patient positioning is also an important consideration, as patients with a dilated collecting system may need to be placed in a prone position to facilitate drainage of the system [167].

Functional information including differential kidney function, cortical transit time, calyceal transit time, and renal transit time can also be discerned with functional MRU (fMRU). Functional information coupled with delineation of anatomy is invaluable for treatment decisions and surgical planning [166]. If fMRU is desired, patients cannot have a contraindication to gadolinium contrast, as contrast enhancement and excretion provides the functional assessment.

MRU may require sedation in children younger than 6–10 years of age [166]. In infants, MRU without sedation is feasible using the "feed and wrap" technique [36]. In unsedated patients, motion robust sequences including radial volumetric interpolated breath-hold examination (VIBE) and periodically rotated overlapping parallel lines with enhanced reconstruction (PROPELLER) can be used. Respiratory or navigator gating can also be used to further improve image quality.

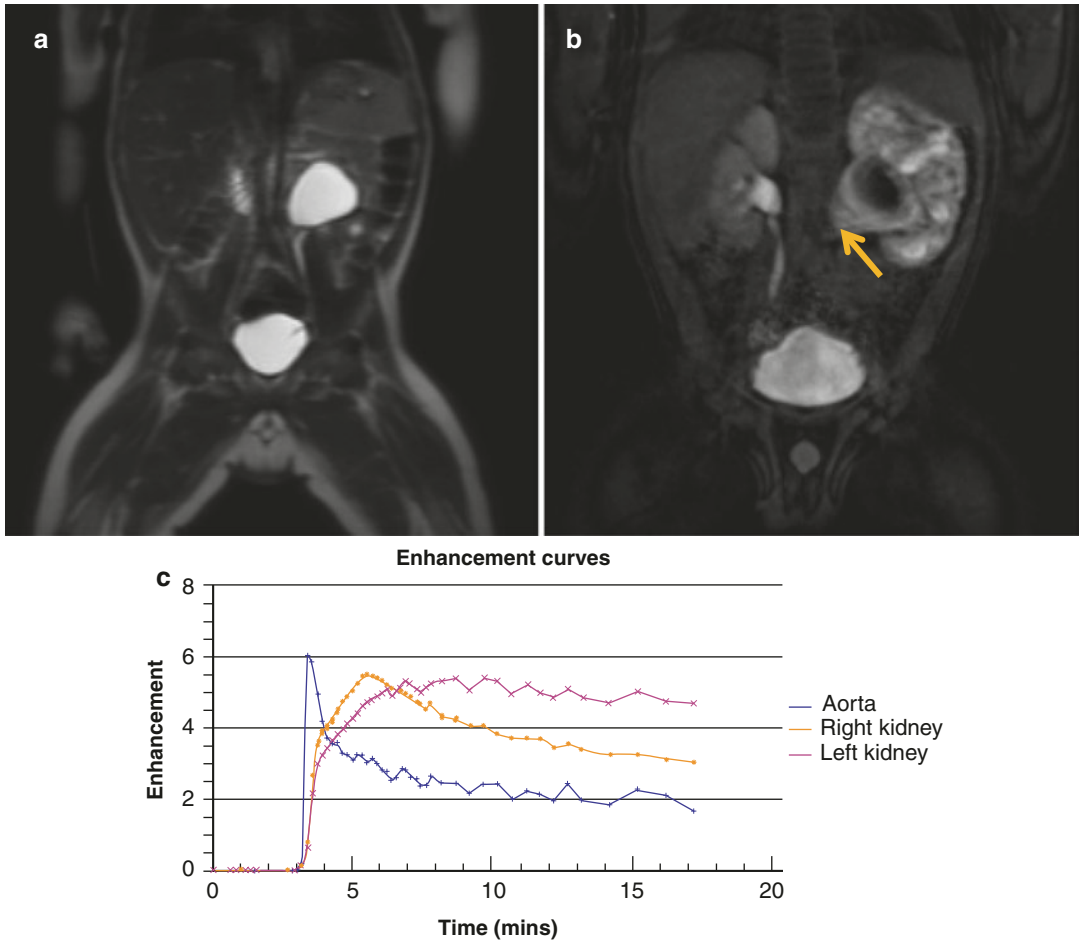

Fig. 3.17 Functional MR urography (fMRU). An 8-month-old boy with left ureteropelvic junction (UPJ) obstruction. (**a**) Coronal T2-weighted and (**b**) post-contrast VIBE images show left hydronephrosis with transition at the level of left UPJ (arrow). (**c**) Signal intensity versus time curves demonstrate asymmetric perfusion and excretion of contrast agent. The curve of the right kidney (blue line) is normal, and the left kidney (green line) reveals a dense delayed nephrogram and delayed excretion

MRU can be used to distinguish a capacious non-obstructed system from a UPJ obstruction. A UPJ obstruction should demonstrate delayed renal transit time correlating with the obstructed system (Fig. 3.17). MRU can confirm that the level of the obstruction is at the UPJ rather than at the level of the ureter, as seen with ureteral strictures. Additionally, arterial and venous phase postcontrast images can evaluate for crossing vessels as the etiology of the UPJ obstruction [166], a necessary step in surgical planning. MRU can also be used for postoperative reevaluation for UPJ obstruction following pyeloplasty or vessel reimplantation [168].

Radiography

Radiography is the oldest modality used in the evaluation of urinary tract disease, but its utility is limited. The normal urinary tract is not sufficiently different in tissue density compared to the surrounding abdominal and pelvic structures to be properly evaluated using radiography alone. There may, however, be cases in which there is sufficient retroperitoneal fat to outline the kidneys on plain radiographs and even assess their relative sizes. A kidney mass or severely hydronephrotic kidney might be detected by the presence of a soft tissue mass, calcification or fat, and

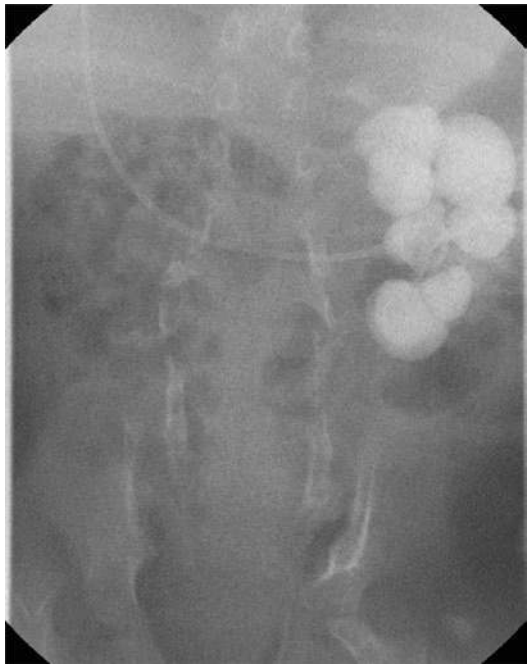

Fig. 3.18 Radiograph of staghorn calculus. Abdomen posteroanterior radiograph showing a radio-opaque staghorn calculus occupying the pelvis and collecting system of the left kidney

displacement of adjacent structures. A full bladder can also be seen as a midline structure in the pelvis, which will occasionally displace bowel loops out of the pelvis.

Calculi in the urinary collecting system can at times be seen on radiography depending on their composition [169–171] (Fig. 3.18). Nephrocalcinosis may also be detected depending on the degree of involvement [172]. Radiography is the mainstay of imaging for bone changes associated with advanced CKD, such as renal osteodystrophy [173].

Radiographs can also be beneficial in determining the correct positioning of various drainage catheters and stents. Most catheters and stents are sufficiently radio-opaque to be visible on radiographs (Fig. 3.19).

Overall, however, the role of radiography has largely been supplanted by the cross-sectional imaging modalities (US, CT and MRI) and by nuclear medicine.

Fig. 3.19 Radiograph of ureteral stent. Abdomen posteroanterior radiograph showing right ureteral stent (arrows), which appears radiopaque

Excretory Urography

Excretory urography (IV pyelography) relies on the administration of IV contrast to enhance the urinary tract relative to the remainder of the abdominal tissues [174–177]. Excretory urography was historically used to delineate and characterize the anatomy of the urinary tract, but has now largely been supplanted by other imaging modalities such as US, CT, MRI and nuclear medicine [178–181]. Current applications for excretory urography can include evaluation for ectopic ureters and diagnosis of urothelial disorders and papillary necrosis [182–184].

Retrograde Urethrography

Though retrograde urethrography is rarely performed, it remains useful in the evaluation of suspected acute trauma or stricture to the male urethra, [185] and both congenital and acquired urethral abnormalities [186–188] (Fig. 3.20). The examination involves placement of a balloon tipped catheter into the distal urethra and careful

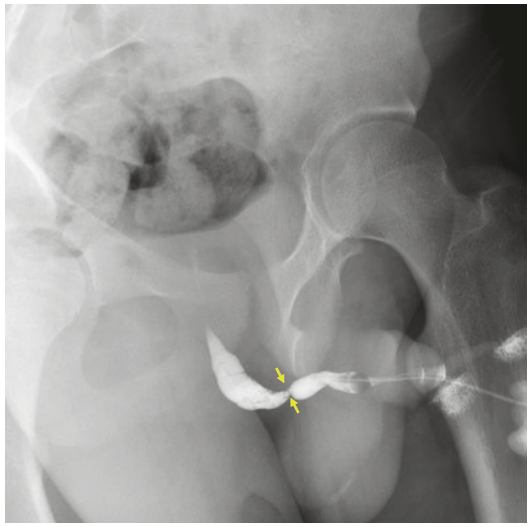

Fig. 3.20 Retrograde urethrogram. Retrograde urethrogram showing bulbar urethral stricture (arrows)

inflation of a balloon in the fossa navicularis. Images of the urethra are taken in an oblique projection during a hand injection of water-soluble contrast. Due to the presence of the external sphincter, the posterior urethra is usually not optimally assessed as part of this study but rather can be imaged during voiding after filling the bladder directly.

Interventional Radiology

Minimally invasive image-guided techniques are increasingly available and integrated into the diagnosis and treatment of pediatric kidney disease. Imaging innovations such as improved US imaging resolution and low radiation dose fluoroscopy and angiography allow for detailed evaluation and guidance in even the smallest patients. The development of pediatric interventional radiology (IR) as a subspecialty has resulted in innovative techniques specifically designed for application in children. Finally, innovative design has resulted in a greater selection of pediatric specific or applicable devices, allowing for application of adult techniques that were previously unavailable in children because of the technical limitations of devices designed for larger patients.

Patient Evaluation and Preparation

Pediatric patients frequently require deep procedural sedation or general anesthesia for minimally invasive image guided procedures, creating greater complexity for the performing proceduralist and health care system. Therefore, many pediatric institutions have adopted care teams with an additional care provider (critical care physician, nurse anesthetist, anesthesiologist) to monitor and manage the patient's sedation/anesthesia during genitourinary interventions, allowing the interventional radiologist to focus solely on the procedural goals. Patients must be screened for anesthetic risks and triaged appropriately to a team that can manage acute sedation or airway complications.

Procedure-specific evaluation includes review of the relevant presentation, medical history, goals of therapy, and allergies. Complete pediatric-specific guidelines for pre-procedure labs and anticoagulation protocols are not currently available from the Society of Pediatric Interventional Radiology, but pediatric literature increasingly incorporates guidelines published by the Society of Interventional Radiology (SIR). Pediatric interventional radiologists may use the SIR adult recommendations for procedural preparation or can develop institution-specific guidelines and protocols [189, 190]. Because of the robust blood supply of the kidneys, most interventions are considered at high risk for bleeding, and therefore anticipation of bleeding and/or the need for transfusion should be considered [189].

Facilities and Equipment

Proper equipment management and sterile technique are critical to reduce infectious complications. The portability of US, which has robust applications and favorable anatomic detail in the pediatric population, allows for the potential of bedside procedures. However, this increased portability should be used deliberately, as the IR suite frequently offers easier access and space to perform patient resuscitation in emergencies and adjunctive imaging modalities that can prevent complications and shorten procedures.

Types of Interventions

Pediatric renal interventions are often divided into two large subsets, vascular and non-vascular, and will be described in more detail in the next section, "Applications of Diagnostic and Interventional Radiology Techniques" Vascular interventions involve trans-arterial access to the renal arteries via the umbilical, femoral, brachial or radial artery. This technique can be utilized to treat renovascular hypertension, kidney hemorrhage in the setting of trauma, and benign kidney tumors using angioplasty, stenting or embolization. Non-vascular interventions frequently involve direct access to the collecting system of the kidney, ureter or bladder to address infection or obstruction. US guidance has become the standard of care for kidney biopsy and will be discussed specifically in a later chapter [191].

Applications of Diagnostic and Interventional Radiology Techniques

Neonatal Diseases

The increase in antenatal imaging (US and to a much lesser degree MRI) and prenatal detection of urinary tract abnormalities has resulted in a commensurate increase in postnatal imaging in the work-up of antenatal findings. The most common indications for postnatal imaging are follow-up of antenatally diagnosed UTD and renal ectopia, agenesis or dysplasia. US is the most common initial study to determine whether two kidneys are present, their location and the status of the parenchyma and collecting system. An increase in parenchymal echogenicity, loss of corticomedullary differentiation, parenchymal loss or scarring, and cyst formation can be signs of underlying kidney disease.

In many institutions, the initial postnatal US will be done after the first 48 h of life to avoid missing hydronephrosis during the relative dehydrated state of the newborn period and the non-distended state of the collecting system. The UTD classification system, described in further detail below, is used to quantify the degree of dilation. The region of dilatation helps to localize a urinary tract obstruction. Dilatation of only the pelvicalyceal system suggests UPJ obstruction [192] (Fig. 3.21); if the ureter is also dilated, UVJ obstruction may be present [193]; if the bladder is distended and perhaps trabeculated, the obstruction may involve the bladder outlet or urethra (Fig. 3.22) [194]. Any degree of pelvicalyceal and/or ureteral dilatation can also be due to VUR.

The work-up of a dilated collecting system may vary among institutions, but in general focuses on screening for VUR, obstruction, and other congenital anomalies of the kidneys and urinary tract (CAKUT). VCUG can be used to assess for VUR or urethral obstruction due to PUV or stenosis. If VCUG does not reveal VUR or PUV, nuclear medicine diuretic renography can assess for any degree and level of urinary obstruction.

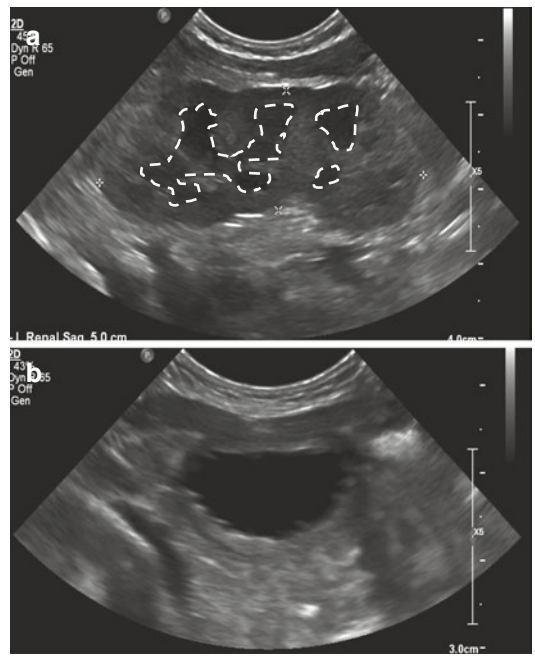

Fig. 3.21 US of urinary tract dilation (UTD) due to ureteropelvic junction (UPJ) obstruction. UTD due to UPJ obstruction in a 2-month-old male. (**a**) Longitudinal greyscale US image of the left kidney demonstrates marked central and peripheral calyceal dilation (dashed line) with minimal renal parenchyma. (**b**) The urinary bladder is markedly distended with thickened bladder wall (arrow heads)

Urinary Tract Dilation Classification System

The UTD classification system is a multidisciplinary consensus intended to standardize the terminology used to describe and quantify the degree of pre- and postnatal UTD and to propose a management scheme based on risk stratification. The UTD classification system is based on the US findings of anterior-posterior renal pelvic diameter (APRPD), calyceal dilation, kidney parenchymal thickness, kidney parenchymal appearance, bladder abnormalities, and ureteral abnormalities [195].

Prenatally detected UTD is stratified into low risk (UTD A1) or increased risk (UTD A2–3) based on gestational age and US findings. Low risk patients have an APRPD of 4 to <7 mm at 16–27 weeks gestation and 7 to ≤10 mm at ≥28 weeks gestation, with central or no calyceal dilation. An increased APRPD of ≥7 mm at 16–27 weeks gestation or ≥10 mm at 28 weeks gestation is classified as increased risk. Additional findings such as peripheral calyceal dilation, parenchymal thinning, abnormalities of the parenchymal appearance, bladder abnormalities, ureteral abnormalities, and unexplained oligohydramnios classify patients as increased risk, with the classification based on the most concerning finding present.

As previously mentioned, initial postnatal US is typically performed greater than 48 h after birth to avoid underestimation of UTD due to dehydration. Patients that may require evaluation prior to 48 h after birth include those with oligohydramnios, urethral obstruction, bilateral high-grade dilation, or if there are concerns about patient compliance with postnatal evaluation. Low risk (UTD P1) patients have an APRPD of 10 to <15 mm and central calyceal dilation. APRPD of ≥15 mm, peripheral calyceal dilation, or ureteral abnormalities increase patient risk to the intermediate (UTD P2) category, whereas abnormal kidney parenchymal appearance or thickness and bladder abnormalities increase patient risk to the high (UTD P3) category.

The UTD classification system has been associated with clinical outcomes, with higher risk scores being associated with genitourinary diagnoses and need for surgical intervention [196].

Other Congenital Abnormalities of the Kidneys and Urinary Tract

Many other types of CAKUT can be diagnosed with antenatal or neonatal imaging. Multicystic dysplastic kidney (MCDK) is characterized by multiple non-communicating cysts with no identifiable normal kidney parenchyma [197, 198]. It is thought to arise either due to prenatal renal pelvic ureteral atresia or abnormal interaction between the ureteric bud and metanephric blastema [198]. Demonstration of the lack of communication between the cysts differentiates this process from pelvicalyceal dilation. Imaging can also demonstrate agenesis, ectopia, and horseshoe or cross-fused kidneys. Again, US is the preferred initial imaging modality, although in some cases the findings are discovered inciden-

tally on other modalities (including DMSA renal cortical scintigraphy).

The presence of a duplicated collecting system can be inferred on US when the renal sinus echo complex is interrupted by a band of renal cortical tissue, though it can be difficult to distinguish this pattern from a prominent column of Bertin [199]. The presence of a duplex collecting system may be associated with obstruction (usually of the upper moiety) and/or reflux (usually of the lower moiety) according to the Weiger-Meyer rule [200]. This rule states that in a duplicated collecting system, the upper moiety is drained by a ureter, which inserts ectopically and the lower moiety is drained by a ureter that inserts orthotopically, with the former often obstructed by a ureterocele and the latter demonstrating VUR. These entities (obstruction and VUR) can coexist in the same patient.

Ureteroceles can be found using almost any modality but are most commonly diagnosed on US or VCUG [201]. Ureteroceles can occur with ectopic ureters or at the normal ureterovesical junction (termed orthotopic or simple ureteroceles), and like ectopic ureteroceles can be obstructive or non-obstructive [202].

Neonatal Renovascular Conditions

Conditions affecting the renal vasculature in the neonate, including thrombosis of the renal arteries or veins, can be assessed with Doppler US imaging of the vessels and kidneys. Associated thrombosis of the aorta and inferior vena cava (IVC) can also be assessed. If a central catheter is present, which can predispose a patient to thrombosis, its position can best be assessed with abdominal radiographs, although the catheters can also be seen with US. If a thrombus has occurred, recanalization can be assessed sonographically after anticoagulation or thrombolysis. Occasionally, residual thrombus can calcify and be visible as a linear hyperechoic structure, either along the vessel wall in major vessels or within the renal parenchyma in small vessels. Follow-up kidney US can also assess for any long-term sequelae of thrombosis, such as atrophy, abnormal parenchymal echogenicity or cyst formation.

Interventional Radiology in the Neonate

In most cases, neonatal UTD is managed surgically (ablation of PUV, ureteral reimplantation, pyeloplasty) or conservatively. Occasionally, urgent decompression of the upper urinary tract is necessary to prevent further injury to the kidney and allow postponement of definitive surgical intervention in the presence of significant comorbidities or prematurity [203].

Percutaneous nephrostomy (PCN) allows for rapid decompression of the upper urinary tract and is broadly used to treat urinary obstruction and infection in adults and children. The procedural success rate is consistently high (> 95%) in multiple case series in both neonates and larger children [203–207]. PCN is performed by placing the patient in the prone or semi-prone position and localizing the kidney using US. Periprocedural antibiotics are used routinely for infected systems and are recommended for all cases by SIR Quality Improvement Guidelines [190], although there is practice variation in antibiotic use for non-infected systems [206]. In cases with collecting system dilation, a "single stick" technique is employed to place a hollow tip or sheath needle into the collecting system via a peripheral calyx. Positioning within the collecting system is confirmed with a combination of US needle tip localization, return of urine via the needle hub, and injection of agitated saline, US contrast or iodinated contrast. Once peripheral access is confirmed, a guide wire is placed into the collecting system and coiled or advanced into the ureter or bladder. The tissues are then dilated over the wire and a pigtail drainage catheter is placed into the collecting system and secured (Fig. 3.23). In nondilated systems, a "two stick" technique may be used to access the central collecting system with a hollow tip needle to allow for distension and easier access to a peripheral calyx without endangering the central vasculature. An elegant modified technique for PCN in neonates has been described by Koral et al. that accommodates for their unique anatomy and tissue density [208]. Major complications are best avoided by using US guidance, avoiding central puncture of the renal collecting system, and using

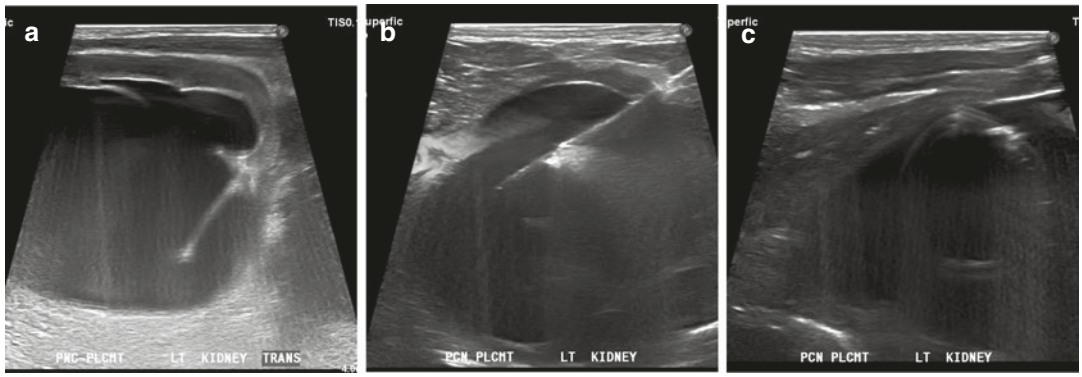

Fig. 3.23 Percutaneous nephrostomy (PCN). PCN placement in a 22-day old infant due to bilateral hydronephrosis and left sided urinoma with worsening abdominal distension despite bladder decompression. (**a**) Greyscale US showing a markedly dilated left kidney collecting system with parenchymal thinning. (**b**) The collecting system was accessed using a 21-gauge micro-puncture needle (**c**) Subsequently a 5 French Dawson-Mueller catheter was placed into the collecting system with US guidance

caution during tissue dilation with a supportive guide wire. In the immediate post-placement period, hemorrhage can occur due to central entry into the collecting system or inadvertent creation of an arterial fistula. Injury to the collecting system or ureter can occur due to needle or wire perforation during wire positioning or dilation, resulting in a urinoma. Sepsis is a feared complication in the setting of an infected collecting system. Appropriate antibiotic coverage and minimizing collecting system distension and manipulation during initial treatment of the infected system is recommended to reduce the risk of sepsis. Overall, the risk of major complication is the pediatric populations ranges from 0% to 9% [205, 209].

Retrograde placement of ureteral stents is less common in neonates than in older patients, as the size and rigidity of commercially available stents creates technical challenges.

Urinary Tract Infections and Vesicoureteral Reflux

The clinical management of UTI and VUR will be discussed more fully in later chapters. Multiple imaging modalities can contribute to the evaluation and management of UTI and VUR, including US, VCUG, ceVUS, and nuclear medicine. Imaging can help to identify urologic abnormalities such as obstruction or VUR, guide management strategies (e.g. need for antibiotic prophylaxis or surgical intervention such as ureteral reimplantation), and can aid in characterizing the extent of infection and potential complications (e.g. pyelonephritis, abscess, and kidney scarring). Clinical practice guidelines for imaging in pediatric UTI vary somewhat between international organizations [39, 210–212] but there are several unifying themes: (1) defining criteria for obtaining imaging based on risk factors for underlying urologic abnormalities (based on factors such as age, number of UTIs, and severity of symptoms); (2) using kidney and bladder US as the initial imaging method to assess for anatomic abnormalities; (3) evaluating for VUR in selected patients; and (4) using additional modalities such as DMSA based on various clinical criteria.

Kidney and bladder US can identify UTD that could suggest obstruction or reflux, evaluate bladder anatomy (e.g. wall thickness, bladder emptying [213]), and detect signs of either acute infection or sequelae of previous infection (e.g. scarring or global volume loss). Acute pyelonephritis can be associated with urothelial thickening [214], kidney enlargement [215], alterations in parenchymal echogenicity [216], or increased echogenicity of the renal sinus [217]. Focal bac-

terial nephritis (acute lobar nephronia) can resemble a kidney mass [218]. Echogenic debris in the collecting system can suggest, but is not pathognomonic for, infection. In patients with fungal UTI, particularly those who are immunosuppressed or have indwelling catheters, US can be used to assess for kidney parenchymal infection and the presence of fungal balls of the collecting systems.

Evaluation for VUR and urethral abnormalities such as PUV is most commonly performed using pulsed fluoroscopic VCUG. However, ceVUS is increasingly being used in some centers. Both VCUG and ceVUS can assess for the presence of VUR, whether it occurs during filling or voiding, and its severity in the five-grade system as described previously. Grading of VUR is similar between VCUG and ceVUS [73]. VCUG and ceVUS can also be used to assess for other anatomic abnormalities, including duplicated collected system, calyceal diverticula and PUV.

DMSA kidney cortical scintigraphy can be used to detect pyelonephritis and scars, both of which will appear as photopenic or "cold" areas. The distinction between acute pyelonephritis and scarring therefore depends on clinical signs and symptoms, as well as comparison with prior DMSA if available. If cortical defects persist beyond 6 months after clinical resolution of the acute infection, they are considered to be permanent scars that can predispose to CKD and hypertension [219].

Although contrast-enhanced CT (CECT) is the preferred imaging modality for acute pyelonephritis is adults [220], it is generally reserved for selected situations in children to minimize radiation exposure (for example, children with equivocal US findings at centers where MRI is unavailable, or when the risk of sedation for MRI is considered greater than that of radiation and IV contrast). CECT findings in acute pyelonephritis can include kidney enlargement and parenchymal hypodensities that can be wedge-shaped, linear, or patchy [220] (Fig. 3.13). The "striated nephrogram" is considered a classic finding of acute pyelonephritis, but can also be seen in other conditions such as renal vein thrombosis or ureteral obstruction [221].

MRI provides excellent anatomic definition of the kidneys without exposure to ionizing radiation. Contrast-enhanced MRI is generally considered to be the reference imaging technique for children with suspected acute pyelonephritis, but newer diffusion-weighted imaging sequences also appear to have comparable performance without the need for gadolinium contrast [222].

Interventional Radiology Techniques in UTI

Infection in the obstructed renal collecting system is considered a medical emergency and an indication for urgent decompression by stenting or percutaneous therapy. The need for minimally invasive decompression is less clear in infection occurring from ascending bacteria, direct spread from an adjacent source or hematogenous disseminated infection of the non-obstructed system.

Intraparenchymal kidney abscess and perinephric abscess are frequently grouped together in treatment algorithms. In general, collections smaller than 3 cm may be managed effectively with medical therapy alone, but percutaneous US-guided drainage may be advised in larger collections, immunocompromised or critically ill patients, or failure to improve despite appropriate antibiotics [223, 224] (Fig. 3.24).

Pyonephrosis refers to purulent material within the collecting system, and historically has been an indication for percutaneous drainage because of the risk of severe urosepsis with any extraneous manipulation. When collecting system decompression is indicated, US-drain placement, similar to PCN placement, is the technique of choice.

Neoplasm

Most kidney neoplasms in children present as a large palpable mass detected by the parent or physician. The initial imaging modality is most often US, which can suggest the renal origin of an abdominal mass by demonstrating extension of kidney tissue around the mass—the so-

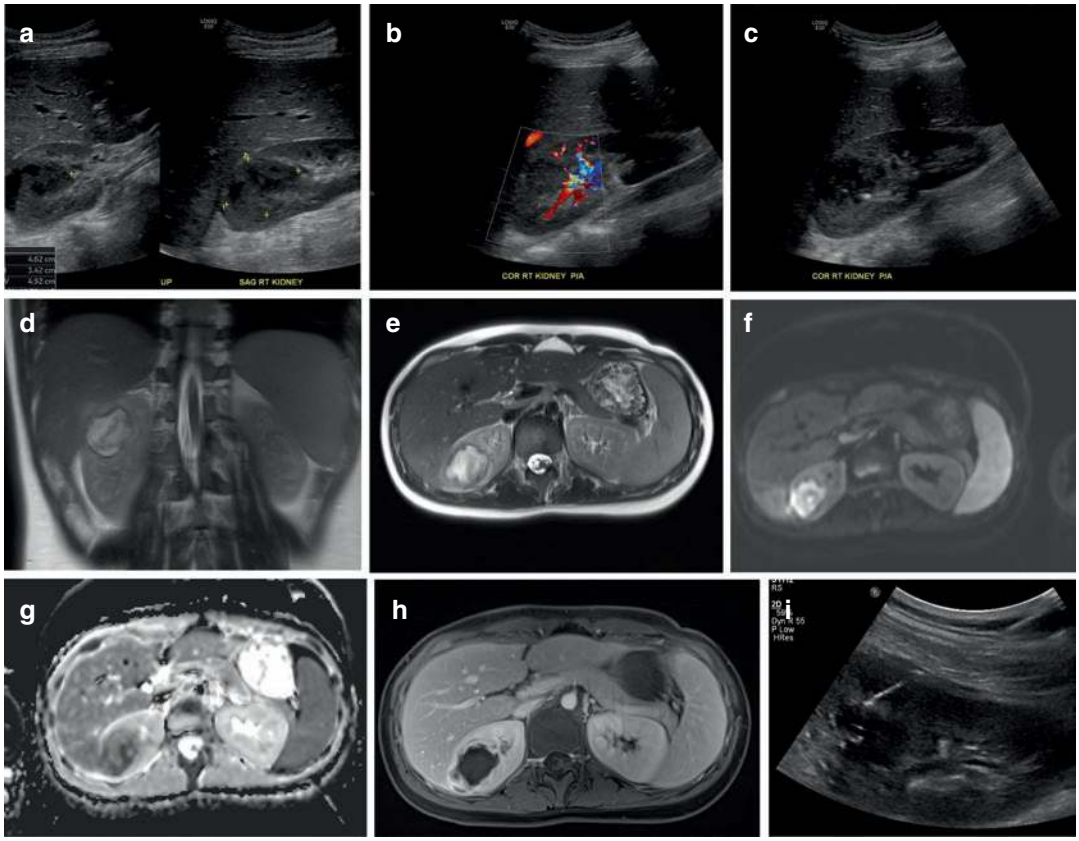

Fig. 3.24 Kidney abscess. 17-year-old female with acute pyelonephritis and increasing right flank pain despite appropriate antibiotic therapy. (**a–c**) US images with a heterogenous hypovascular expansile lesion of the right upper pole, with distortion of the adjacent vasculature and color Doppler signal. The collection was aspirated under US guidance (**i**)

called "claw sign" (Fig. 3.25). US can differentiate solid from cystic or necrotic areas, demonstrate if hemorrhage or calcification is present, and determine whether the tumor involves the renal vein or IVC or extends into the heart. Once an US confirms the presence of a tumor, CT or MRI can better assess the size, extent, involvement of adjacent structures, and spread, and are particularly useful for Wilms tumor staging [225–227]. Although CT and MRI are relatively equivalent in assessing the primary kidney mass, CT is the modality of choice to assess for lung metastases. If the tumor has a propensity to metastasize elsewhere, then appropriate imaging modalities (CT or MRI of the brain, bone scan, etc.) can be performed.

Interventional Radiology in Pediatric Kidney Tumors

Interventional techniques can be applied in the management of pediatric kidney tumors in various situations. Percutaneous biopsy of Wilms tumor has been controversial since its use has been attributed to upstaging tumor classification in some staging systems [228] and it may not be necessary in patients with classical imaging presentation. Therefore, image guided diagnosis should be discussed with a pediatric oncologist before proceeding with a biopsy (Fig. 3.26). The technique for a targeted mass biopsy is similar to that of a non-targeted renal biopsy, although localization of a representative sample is critical. Adjunctive techniques, including image fusion and CEUS, can be helpful for targeting smaller lesions or obtaining viable tissue for pathologic analysis [229].

Rarely, a malignant kidney tumor can present with acute hemorrhage. Similar to kidney trauma, angiography and embolization can be useful either independently or in conjunction with surgery to stabilize patients and reduce blood loss [230].

Careful differentiation of kidney tumors from adrenal masses is critical prior to performing a biopsy. Tissue requirements for characterizing neuroblastoma are more extensive than other masses, necessitating larger coring needles and a greater number of samples for gene sequencing. Adrenal lesions, such as pheochromocytoma, can have catecholamine activity, and may result in hypertensive crisis if instrumented without alpha blockade [231].

The most common benign neoplasm of the kidney is angiomyolipoma (AML). In children, AML is seen almost exclusively in tuberous sclerosis complex (Fig. 3.27a, b), rather than as an independent lesion as seen in the middle-aged female population. These hamartomatous lesions are at risk for hemorrhage regardless of size, with increased risk in larger lesions or in the presence of intranidal aneurysm [232, 233]. Multiple lesions can be treated medically with mammalian target of rapamycin (mTOR) inhibitors, although embolization and partial nephrectomy have long been critical components of therapy. Embolization involves arterial access, renal angiography and microcatheter selection of the tumor vascularity of the AML (Fig. 3.27c, d) [233–235]. Liquid (dehydrated alcohol), glue (n-BCA) or particulates (PVA or Embospheres@) are administered until vascular stasis is achieved, resulting in tumor necrosis and lesion shrinkage over subsequent months [236].

Ablation therapy is a newer method of treating kidney tumors and has generally been accepted to treat small malignancies while preserving kidney parenchyma. In general, a probe is placed percutaneously into the target lesion and energy is imparted to the surrounding tissue to incur target

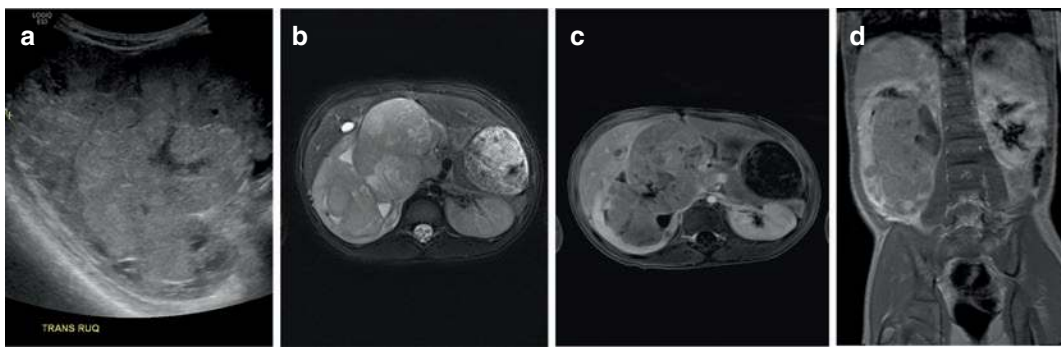

Fig. 3.26 Kidney mass. 6-year-old female with right abdominal mass. (**a**) Greyscale US demonstrates a heterogenous vascular mass expanding and distorting the contour of the right kidney. (**b**) T2, (**c**) post-contrast axial T1, (**d**) coronal MRI of the abdomen confirms a lesion arising from the right kidney. Staging evaluation confirmed metastatic spread to the lungs, therefore percutaneous biopsy was obtained for tissue diagnosis to guide presurgical chemotherapy

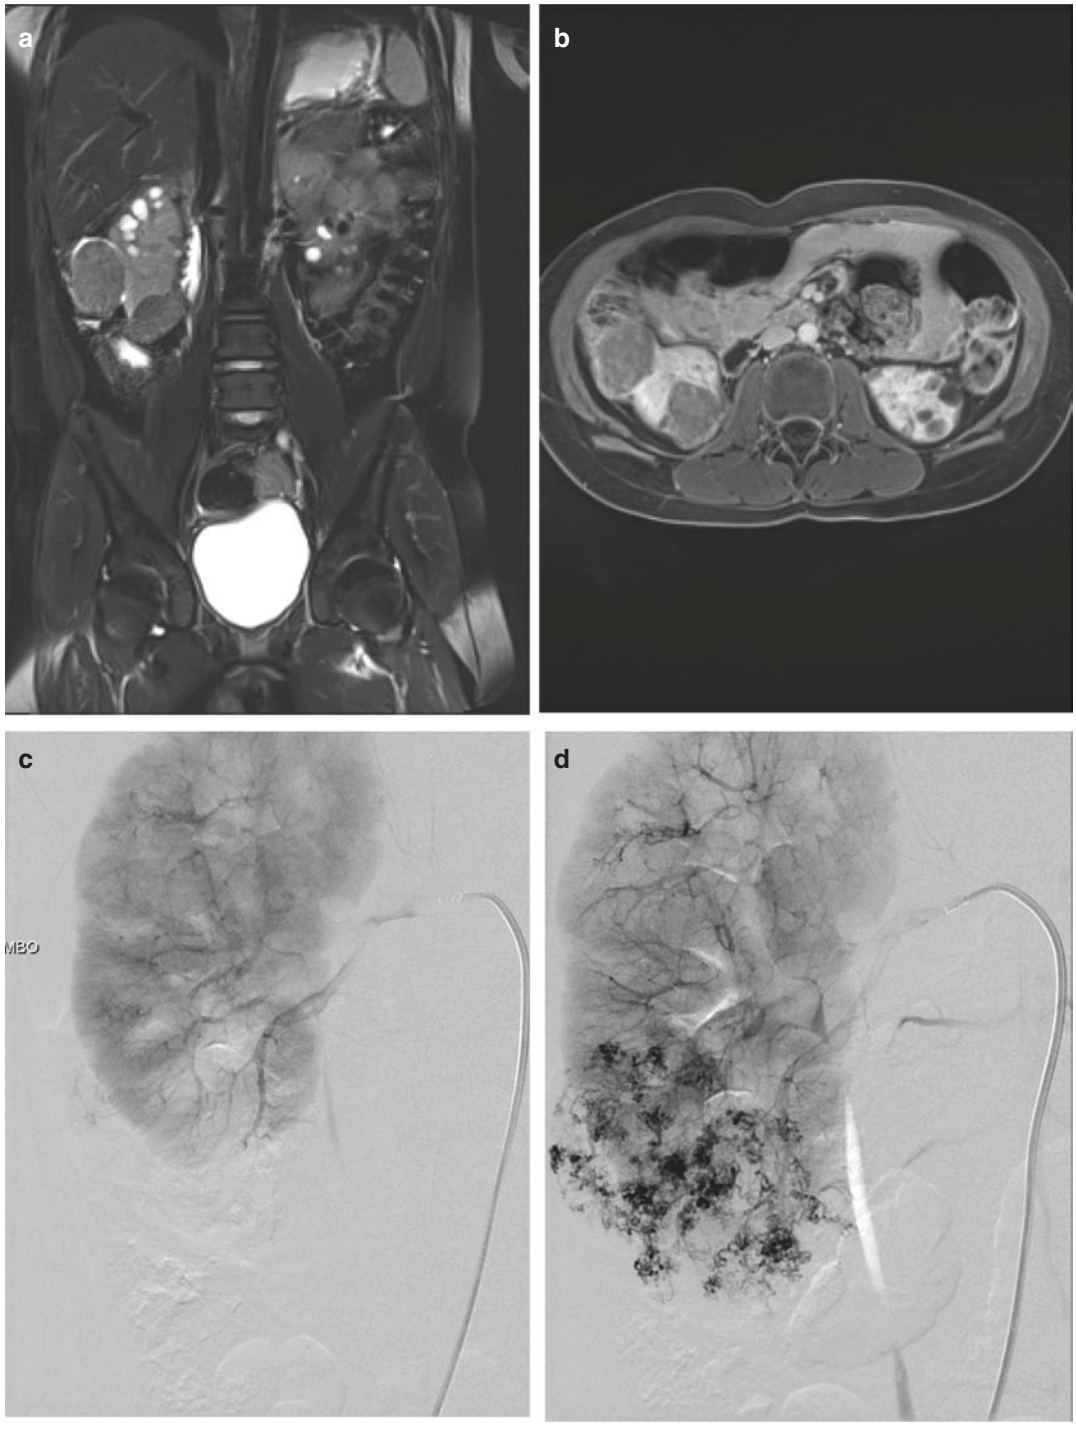

Fig. 3.27 Kidney angiomyolipoma. (**a**) Coronal T2 and (**b**) axial post contrast T1 abdominal MRI in a 12-year-old with tuberous sclerosis demonstrating interval growth of two pedunculated lesions from the lower pole of the right kidney. (**c**) Catheter directed angiography confirms angiomyolipoma with characteristic "cork-screw" vasculature. (**d**) Following particle embolization, the abnormal vasculature is no longer present and adjacent kidney parenchyma is preserved

cell injury and apoptosis. Currently, cryotherapy is commonly used in the GU system [237, 238], although radiofrequency ablation and microwave are also reported as effective for treatment of small kidney tumors. The primary limiting factors are proximity to critical structures or vascularity that can result in heat or cold sump, preventing target lesions reaching threshold damage.

Trauma

Due to the relatively large size of the kidneys compared to body size, decreased protection from the rib cage, and increased pliability of Gerota's fascia and capsule, there is increased frequency of kidney injury following blunt abdominal trauma in children and adolescents [239].

Imaging of trauma to the urinary tract has been studied extensively and remains a topic of debate [240]. In the acute setting, the imaging evaluation of the injured child is determined by the extent and type of injury as well as the practice of the particular institution [141, 241]. In some institutions, evaluation of trauma to the abdomen begins with abdominal US to assess for free fluid and obvious visceral injuries [242, 243]. At other institutions, CT is the modality of choice in the initial assessment [92, 142, 240]. The decision as to which modality is used will depend on the clinical situation. US has a high sensitivity in detecting intraperitoneal fluid; however, in the setting of trauma, the presence of fluid is not an absolute indication for surgery. Moreover, there can be injury to the urinary tract without the presence of free fluid [244]. CT, on the other hand, can accurately assess for the presence of free fluid and assess the solid and hollow abdominal viscera.

US imaging is effective for evaluating the kidneys and can be useful in triaging patients (FAST exam), in lower acuity patients, and to monitor patients following initial characterization of injuries [135]. US is not considered the primary study for trauma because of the lower sensitivity for kidney contusions and lacerations, operator dependence, length of the study, and patient discomfort in the acutely injured patient. The adjunctive use of US contrast shows promise for increasing the sensitivity for parenchymal and vascular injury, but is not yet widely utilized and does not overcome the drawbacks of length of study and operator dependence [136].

US can depict a kidney laceration or contusion as a focal area of abnormal echotexture. The area can be hypoechoic, isoechoic or hyperechoic to the remainder of the kidney depending on the contents of the area and the stage of the evolution of the injury. US can also characterize the quality and amount of perinephric fluid (blood, urine or both) and follow the appearance to assess whether the collection is diminishing, remaining stable or increasing in size. Doppler US of the kidneys can assess both for areas of kidney parenchymal ischemia due to vascular interruption and for arterial or venous thrombosis and pseudoaneurysm formation. Renal vascular injury can also be visualized with nuclear medicine functional renal imaging, with non-perfused regions of the kidney appearing as cold defects.

CT is often the modality of choice in the evaluation of abdominal trauma, since most pediatric kidney injuries are related to blunt trauma and are associated with additional organ injuries [245]. Imaging is indicated in the setting of clinical suspicion based on mechanism or hematuria on presentation. As described previously in the section "Computed Tomography," IV contrast is generally used in the evaluation of trauma, and multiphase imaging can offer increased sensitivity to detect vascular disruptions or urinary leak. The appearance of the kidneys, particularly their patterns of enhancement on CT, can allow diagnosis of kidney contusions and lacerations. Areas devoid of enhancement, particularly if they are regional, suggest infarction. Perinephric and/or periureteral fluid can also be assessed. Delayed imaging may show disruption of the collecting system if dense contrast is seen outside of the collecting system (Fig. 3.28). CT cystography has also been used to assess for injuries to the urinary bladder and urethra.

In the past IV urography was used extensively in the evaluation of urinary tract trauma but is

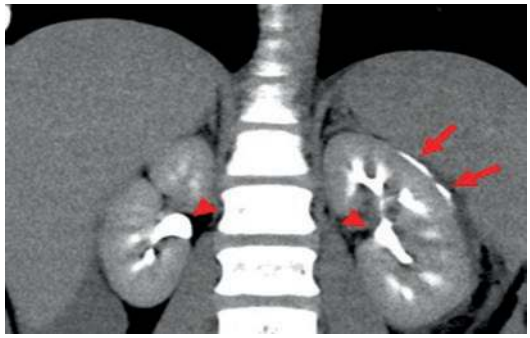

Fig. 3.28 Contrast enhanced CT (CECT) for trauma. CECT of collecting system injury in a 13-year-old following a snowboarding accident. CECT image obtained in the delayed phase shows opacification of the collecting system (arrowheads). There is contrast accumulation outside of the collecting system of the left kidney (arrows), compatible with collecting system injury

seldom used today. Fluoroscopic studies (retrograde urethrography and cystography) are, however, still used extensively in the imaging of bladder and urethral injury.

Interventional Radiology in Kidney Trauma

The American Association for the Surgery of Trauma (AAST) Organ Injury Scale (or the European Classification System) classifies kidney injury on a scale from grade I to V based on the depth and extent of injury, involvement of vascular structures, and urinary tract injury (Table 3.2). Most pediatric kidney injuries fall in grade I, II or III, and are frequently managed conservatively (Figs. 3.29 and 3.30) [246, 247]. Analysis of trauma registries and additional case series have described increased rates of surgical or interventional management within grades IV and V (Fig. 3.31) [246–248].

The goal of kidney trauma management is first to preserve life and second to preserve kidney integrity and function. The confined retroperitoneal space allows for tamponade of most hemorrhage when the facial plains remain intact. Initial patient instability frequently dictates the need for immediate operative intervention. However, delayed decompression of hemorrhage into the kidney collecting system or into the peritoneal space can result in refractory anemia and the need for persistent transfusion in the initially stable or stabilized patient. Patients requiring >3 transfusions in the initial 24–48 h should be deemed unstable, and angiographic intervention or surgery should be considered. Injury to the collecting system and ureter is a critical component of the trauma evaluation, as urine leak and urinoma can result in morbidity. Grade I–III injuries as well as most grade IV injuries can be successfully managed conservatively or with percutaneous or endoscopic therapy [249, 250].

When available, image guided intervention can successfully manage refractory hemorrhage while preserving kidney parenchyma. Trauma registries have demonstrated a high rate of nephrectomy when early surgery is performed for hemorrhage in the pediatric population [248]. Embolization can be performed rapidly and has been shown to be effective in salvaging

Table 3.2 American Association for the Surgery of Trauma (AAST) kidney injury scale (2018 revision)

AAST grade	Imaging criteria
I	Subcapsular hematoma and/or parenchymal contusion without laceration
II	Perirenal hematoma confined to Gerota's fascia Parenchymal laceration ≤1 cm in depth without urinary extravasation
III	Parenchymal laceration >1 cm without urinary extravasation or collecting system rupture Any injury in the presence of a kidney vascular injury or active bleeding contained within Gerota's fascia
IV	Parenchymal laceration extending into urinary collecting system with urinary extravasation Renal pelvis laceration and/or complete ureteropelvic disruption Segmental renal vein or artery injury Active bleeding beyond Gerota's fascia into the retroperitoneum or peritoneum Segmental or complete kidney infarction(s) due to vessel thrombosis without active bleeding
V	Main renal artery or vein laceration or avulsion of hilum Devascularized kidney with active bleeding Shattered kidney with loss of identifiable parenchymal renal anatomy

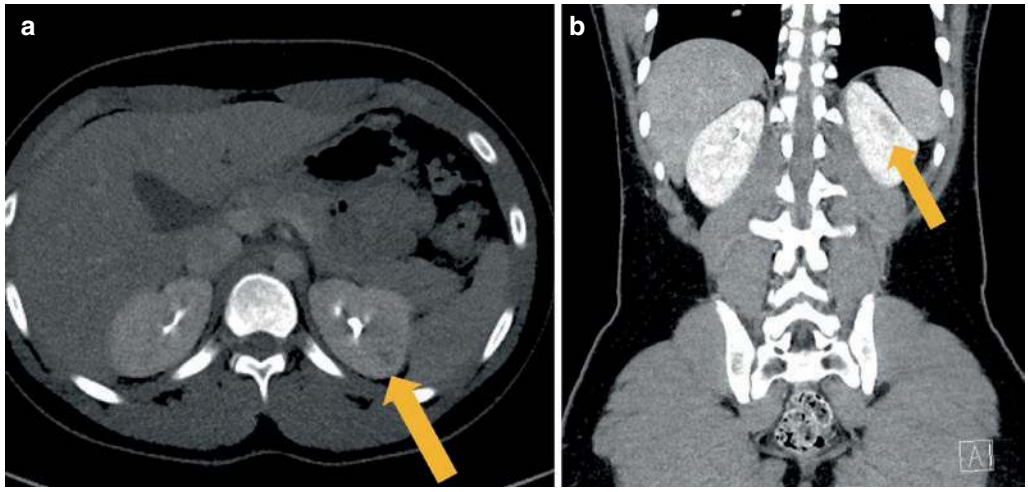

Fig. 3.29 Grade I left kidney parenchymal contusion on contrast enhanced CT. (**a**) Axial and (**b**) coronal contrast enhanced CT showing small focal hypoattenuating area (arrows) in the left interpolar region suggestive of grade I kidney contusion

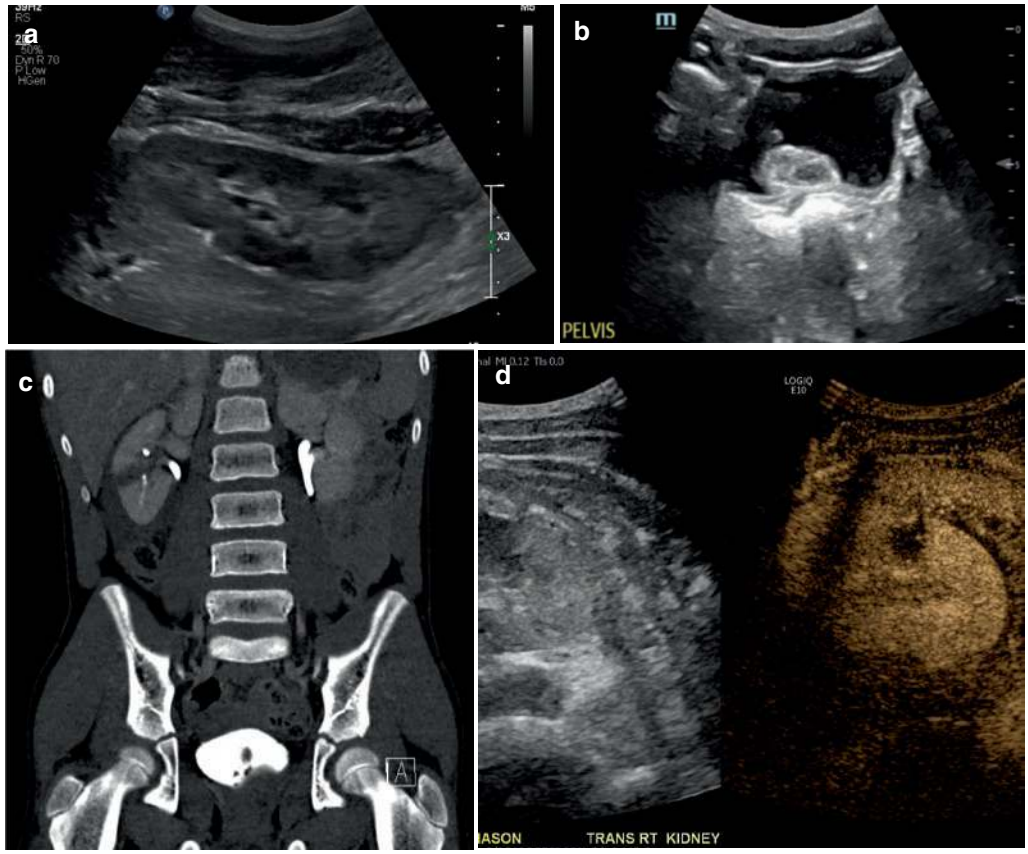

Fig. 3.30 Grade III right kidney injury. (**a**) Greyscale US of the right kidney shows increased lower pole echogenicity and a band of hypoechoic tissue at the juncture between the interpolar region and lower pole. (**b**) Bladder US provides visual confirmation of hematuria with a blood clot. (**c**, **d**) Contrast enhanced CT and US more accurately depict the extent of this Grade III right kidney injury

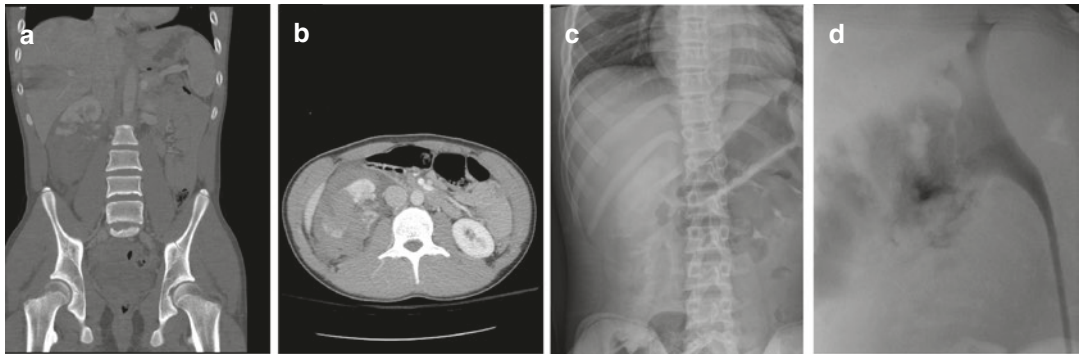

Fig. 3.31 Grade IV right kidney injury. Adolescent male following sports injury to the right flank. (**a**, **b**) Coronal and axial contrast enhanced CT angiography show a complex right kidney laceration involving the collecting system. Excretory phase imaging was not obtained. (**c**) Abdominal radiograph shows persistent contrast in the right kidney parenchyma with amorphous density in the perinephric tissues. (**d**) Retrograde ureterogram confirms urine leakage from the right kidney collecting system that was managed with placement of an endoscopic ureteral stent

the kidney without nephrectomy [245]. Embolization can be performed with a variety of agents, although temporary agents (such as Gelfoam®) and coils are the most common. A secondary procedure may be required if bleeding persists and has been shown to be beneficial for kidney salvage according to national trauma data bank [251].

Renovascular Hypertension

Imaging plays a critical role in identifying and managing renin-mediated renovascular hypertension. Renovascular hypertension can be described by stenosis location, extent and syndromic or non-syndromic association. Renovascular hypertension, once thought to be a rare cause of hypertension in children, has received growing attention in the past decade and is reported as a cause of hypertension in 10% of children with hypertension [252].

RAS can be unilateral or bilateral, involving the main, main branch or segmental renal arteries. Additionally, renal perfusion can be affected by upstream short or long segment stenosis of the lower thoracic or abdominal aorta. This distribution of disease, named middle aortic syndrome (MAS), can be isolated or can occur in combination with renal artery involvement.

Commonly identified causes for renovascular hypertension and MAS in children include fibromuscular dysplasia (FMD), vasculitis, neurofibromatosis type I, and Williams syndrome. However, the underlying cause is often difficult to confirm because of the overlapping imaging appearances, and the presumed diagnosis is made based on a combination of clinical and imaging features. For instance, "burned out" or senescent vasculitis can have imaging features identical to FMD. Additionally, the classically described "beaded string" appearance of FMD in adults is uncommon in children. In the young patient, the angiographic appearance of FMD is commonly a short segment uniform stenosis secondary to the involvement of both the intima and media within this age group.

Non-invasive imaging is critical for evaluating renovascular hypertension and determining the need for further intervention. US is the mainstay as it offers moderately high-resolution images with a combination of anatomic features and vascular flow assessment (Fig. 3.32) [253]. Differences in kidney lengths of >1 cm in the presence of hypertension may suggest main RAS and deserve additional evaluation. Established criteria for diagnosing RAS include direct visualization of stenosis, *parvus et tardus* wave form [acceleration time (time from onset of systole to peak systolic velocity) of >70 ms], main renal

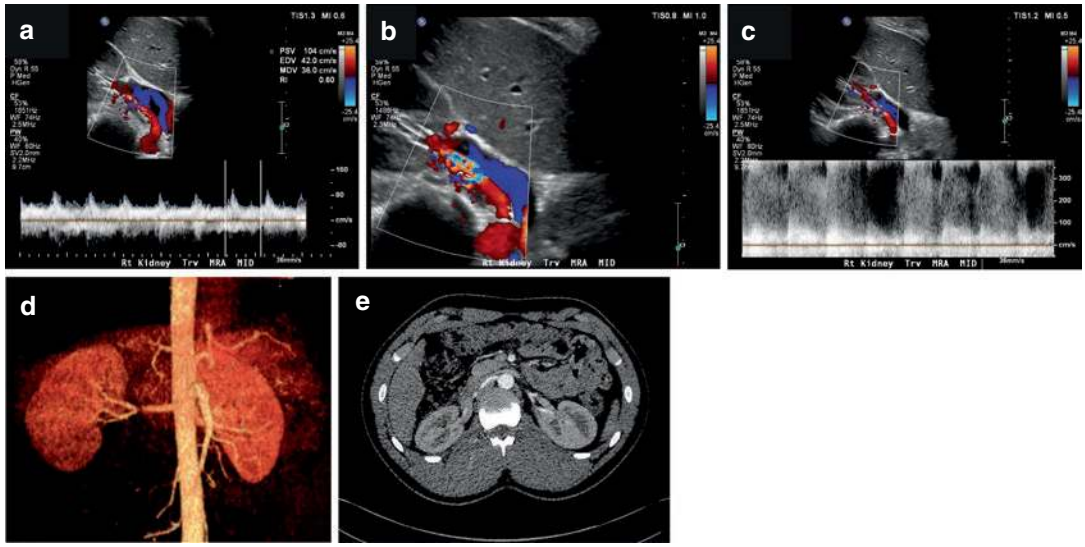

Fig. 3.32 Doppler US and CT angiography (CTA) of renal arteries. 16-year-old male with newly detected hypertension without hereditary risk factors. (**a–c**) Doppler US shows increased flow velocities in the mid- to distal right renal artery with aliasing on Doppler tracing and velocities in excess of 180 cm/s. (**d**, **e**) Contrast enhanced CTA confirms a short segment stenosis of the right renal artery, just proximal to a bifurcation into the upper and lower main branch renal arteries

Table 3.3 US criteria for renovascular hypertension (adapted from Dillman et al. [254])

US characteristic	Criteria suggesting renovascular hypertension
Kidney size	Asymmetric kidney lengths with difference of >1 cm
Doppler waveform	*Parvus et tardus* waveform Acceleration time of >70 ms
Main renal artery peak systolic velocity (PSV)	>180–200 cm/s
Renal-aortic (velocity) ratio (RAR)	>2.3–3.5
Renal-intrarenal (velocity) ratio (RIR)	>5

artery peak systolic velocity (PSV) of >180–200 m/s, main renal artery to aortic PSV ratio (RAR) of >2.3–3.5, or main renal artery to intrarenal artery PSV ratio (RIR) of >5 (Table 3.3) [254, 255]. Unfortunately, the sensitivity for RAS on Doppler US is low at 63–73% [256, 257].

CT angiography (CTA) (Fig. 3.32d) and MR angiography (MRA) (Fig. 3.15) have better sensitivity for detecting RAS, reported in the range of 93–94% and 77–93% respectively [256, 257]. Improved detection rates need to be balanced with the potential risks of ionizing radiation (for CTA) and sedation or anesthesia (for MRA). CTA image acquisition is much faster than MRA, and therefore conducive for non-sedated exams in the school-age child. Dose reduction, motion tolerant and image enhancement technology in newer MRI scanners will potentially offer no radiation exposure while maintaining image quality. However, currently MRA remains susceptible to even small amounts of motion that can occur in both sedated and non-sedated patients.

Catheter directed angiography remains the gold standard for the diagnosis of renovascular hypertension when there is a suggestive history and absence of non-invasive imaging findings [257]. In patients with appropriate histories as many as 40% of patients will have findings of clinically significant stenosis on angiography. Once identified, the lesion can be treated using angioplasty, stenting or ethanol ablation.

Angioplasty has, however, been the mainstay of endovascular therapy for renovascular hypertension and MAS. Lesions are confirmed with

aortography or selective renal angiography, crossed using supportive wires and treated with balloon angioplasty following heparinization (Fig. 3.33). Adjunctive devices such as drug-eluting and cutting balloons have reportedly improved outcomes in small series [258–260]. Branch segmental artery stenoses may be difficult to traverse and current limitations of angioplasty devices may preclude treatment. In these cases, directed ethanol ablation may offer a mechanism to reduce renin secretion from the affected area of kidney parenchyma [261].

Angioplasty using a combination of traditional, high pressure and cutting balloons has high rates of technical angiographic success, up to 94% in reported series [262]. Features associated with favorable technical and clinical outcomes include short segment stenosis (<10 mm), and residual stenosis of <10% following angioplasty [259, 262]. Clinical responses vary among children and are lower than comparable disease in adults. This is most pronounced in FMD, where angioplasty alone has been reported to be beneficial in 93–98% of adult patients. In contrast, pediatric cases series have reported benefit in 56–72.8% of cases and cure in 23–39% of cases. Variability in the response rates may be due to regional variation and heterogenous disease etiology [259, 262, 263].

Renal artery angioplasty is well tolerated with infrequent life-threatening complications, even in the pediatric population. Potential complications include contrast toxicity (contrast-induced nephropathy), thrombosis, stent migration, vascular spasm, dissection, perforation and resulting hemorrhage with imminent threat to the kidney. Contrast toxicity is best managed by setting weight-based contrast notifications throughout the procedure and maintaining patient hydration. Hemorrhagic complications are more frequent when using cutting angioplasty balloon but can be treated with angioplasty as either a temporizing or a definitive therapy. Covered stent deployment is reserved for cases refractory to angioplasty and when appropriate sized devices are available but is associated with higher rates of re-stenosis [263]. If hemorrhage continues after a trial of balloon occlusion, then urgent engagement of the surgical team may be the only remaining option. Surgical interventions have been reported for primary or salvage therapy in the event of failed angioplasty or restenosis [264].

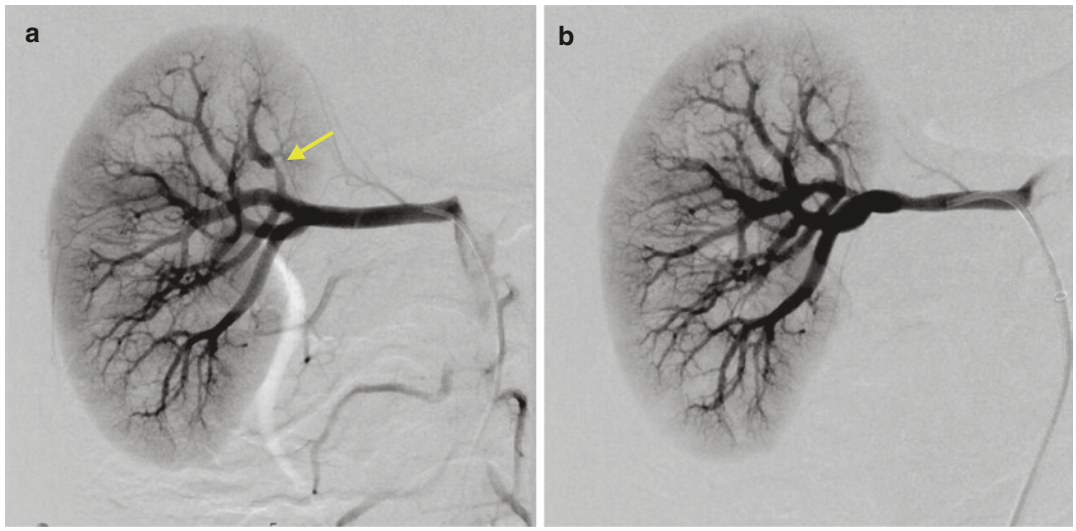

Fig. 3.33 Catheter directed angiography. Catheter directed angiography in a 9-year-old male with newly detected hypertension without hereditary risk factors. (**a**) Focal segmental branch stenosis in right upper pole with wedge-shaped parenchymal perfusion defect. (**b**) Repeat angiography following right upper pole segmental angioplasty showing improved lumen diameter and perfusion

Cystic Kidney Diseases

Kidney cysts can be seen at any age in the pediatric group. Cysts can be sporadic and unassociated with any systemic disease or may occur in a wide range of genetic and non-genetic diseases [265–267].

Kidney and bladder US is the primary imaging modality recommended for initial assessment of kidney cysts in children [267]. On US, a kidney macrocyst will appear anechoic with an imperceptible wall, whereas multiple microcysts may manifest as heterogeneous parenchymal echogenicity (e.g. "salt-and-pepper sign" in autosomal recessive polycystic kidney disease [ARPKD]) or just increased echogenicity without distinct cysts (Fig. 3.34) [267]. When distinct macrocysts are present, important characteristics to note include the number of cysts, location (e.g. cortical, medullary), sizes of larger cysts, and whether any complex features such as septations or debris are present [267]. The collecting system should be identified to ensure that a calyceal diverticulum or dilated calyces are not confused with cysts [267].

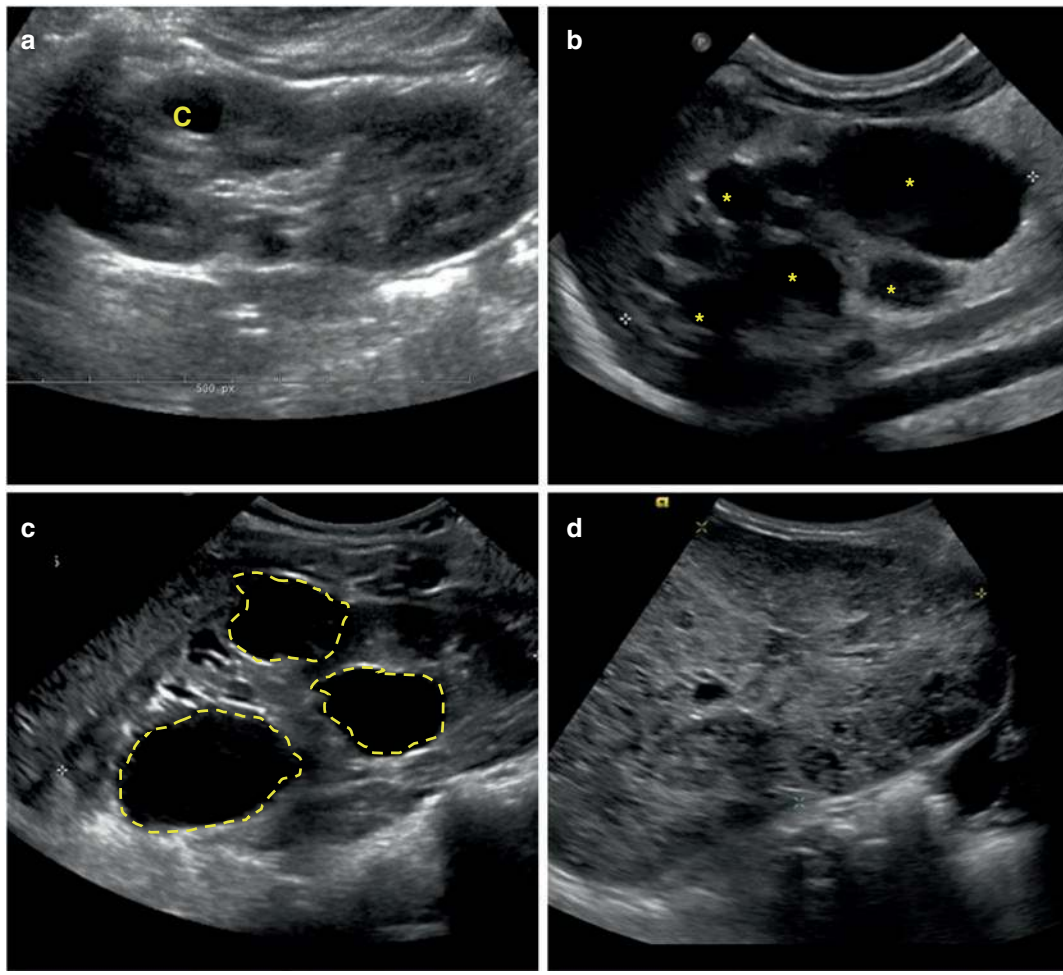

Fig. 3.34 US of cystic kidney diseases. US appearance of kidney cysts. (**a**) Simple cyst (c); (**b**) Multicystic dysplastic kidney, with numerous disorganized cysts (*) without intervening normal parenchyma; (**c**) ADPKD, with enlarged kidney with multiple macrocysts (dashed lines); (**d**) ARPKD, with numerous microcysts causing "salt-and-pepper" appearance of parenchyma and few resolvable cysts

Other imaging modalities such as CT or MRI are not routinely recommended for initial evaluation of kidney cysts in children due to cost and availability, as well as due to associated risks of ionization radiation (for CT) and need for sedation in younger children (for MRI). However, CT or MRI may be indicated in select circumstances, such as evaluation of complex cystic lesions with suspicion for malignancy or detection of angiomyolipomas in patients with tuberous sclerosis [267].

On CT, a cyst will have attenuation equal or near that of simple fluid and will have an imperceptible wall. There should be little to no change in the attenuation of the cyst after contrast administration. The Bosniak classification system was developed to assess the risk for malignancy based on cyst appearance on CT in adults, using factors such as cyst wall thickness, presence of septa, calcifications, or solid components, and degree of enhancement [268]. Studies in children suggest that modified versions of the Bosniak classification based on US appearance of cysts can adequately stratify malignancy risk [269–271]. CEUS also appears promising to classify kidney cystic lesions in native and transplant kidneys [57, 61, 62].

Non-genetic causes of kidney cysts in infants and children include cystic dysplasia, multicystic dysplastic kidney [272], medullary sponge kidney [273], cystic tumors or malformations, cystic nephroma, and solitary simple or acquired cysts [265, 267, 274]. Although simple cysts are common in adults, the reported incidence of simple cysts in children is as low as 0.2% [274]. Solitary cysts can also result from previous insult to the kidney, such as trauma or infection. In most cases of solitary cysts, the appearance of the remainder of the kidney is often normal.

Genetic causes of kidney cysts include autosomal dominant polycystic kidney disease (ADPKD), ARPKD, *HNF1B*-associated disease, nephronophthisis, and other genetic ciliopathies [267]. ADPKD is characterized by the development of multiple macrocysts throughout the kidney cortex and medulla (Fig. 3.34c), with progressive enlargement of the cysts and the kidneys throughout the lifetime [275, 276]. ARPKD is typically characterized by enlarged, echogenic kidneys, sometimes with visible macroscopic cysts or dilated tubules predominantly in the medulla. Echogenic foci and the "twinkling sign" suggestive of calcifications can also be seen (Fig. 3.34d) [267, 277]. Juvenile nephronophthisis is characterized by relatively normal-sized or small kidneys with increased echogenicity and often cysts at the corticomedullary junction [267]. Imaging is also useful to assess for other complications or extra-renal manifestations of genetic cystic kidney diseases, such as angiomyolipomas in children with tuberous sclerosis, liver fibrosis in children with ARPKD, or liver cysts in children with ADPKD [278].

Kidney Stones and Nephrocalcinosis

Kidney Stone Imaging

US is typically the first-line modality in the evaluation of pediatric stone disease. Kidney stones can range from a few millimeters in size in a renal calyx to several centimeters in size filling the renal pelvis (staghorn calculus) (Fig. 3.35). They are most reliably detected by US when present in the kidney or bladder but may also be seen in the ureter when not obscured by overlying bowel gas. Kidney stones appear on greyscale US as echogenic foci, which may produce acoustic shadowing deep to the location of the stone. Small stones may be difficult to differentiate from vessels or portions of renal sinus fat, particularly if distal shadowing is not present. The twinkle artifact, or presence of alternating colors, is an imaging feature of kidney stones on color flow Doppler US (Fig. 3.35). Proper optimization of US settings is necessary to detect smaller stones, particularly in the selection of the focal zone and pulse repetition frequency. In addition to detecting stones, US may also assess for UTD suggestive of urinary obstruction due to stones. The bladder can also be evaluated for ureteral jets, the absence of which is suggestive of obstruction.

CT may also be indicated in the evaluation of stone disease if the US is equivocal or non-diagnostic. CT has a higher sensitivity than US

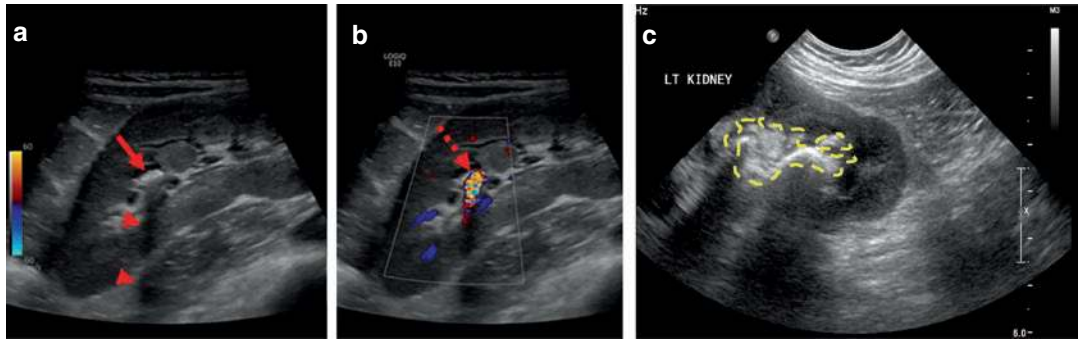

Fig. 3.35 US of kidney stones. (**a**) Greyscale longitudinal US of a non-obstructing stone, appearing as an echogenic focus (arrow) in the upper pole of the kidney with posterior acoustic shadowing (arrowheads). (**b**) Color Doppler longitudinal US demonstrates twinkle artifact (dashed arrow) associated with the echogenic focus, compatible with a kidney stone. There is no urinary tract dilation to suggest obstruction. (**c**) Obstructing staghorn calculus demonstrated by a large echogenic focus (dashed outline) occupying the collecting system of the left kidney

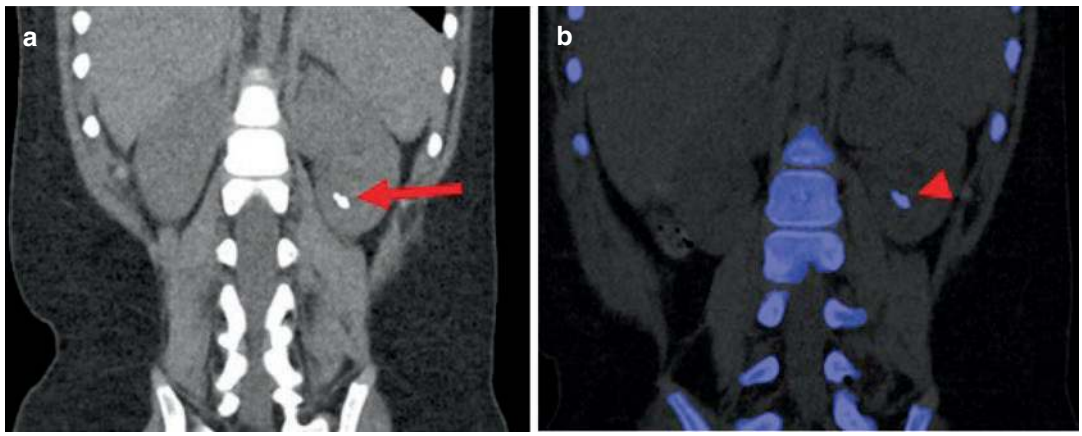

Fig. 3.36 Dual-energy CT (DECT) for detecting kidney stone composition. Non-obstructing kidney stone on DECT in an 8-year-old female. (**a**) Coronal DECT images demonstrate a dense focus in the left kidney lower pole (arrow), compatible with stone. (**b**) Color coding demonstrates that the stone is blue, correlating with non-uric acid/urate-composition, which is compatible with a cystine or calcium-based stone

for the detection of stones smaller than 3 mm [279], and can detect nearly all stones, except for matrix stones or medication stones, such as indinavir stones [280]. CT may also be necessary to evaluate for ureteral stones that may not be visualized on US, as well as complications of stone disease, including abscess and pyonephrosis. Stone evaluation is further enhanced by DECT, which can be used to determine stone composition based on the attenuation ratios (Fig. 3.36). Determining stone composition can help guide management, as certain compositions are less amenable to extracorporeal shock wave lithotripsy, and knowledge of the stone composition can help guide dietary recommendations and medical management [281]. In children, kidney stone size and Hounsfield attenuation values on CT have been shown to predict successful shock wave lithotripsy [282].

Nephrocalcinosis

US is often the modality of choice to assess nephrocalcinosis. While cortical nephrocalcinosis can be seen, it is a rare finding in children [283]. Medullary nephrocalcinosis is well described in children and can be accurately diagnosed and fol-

lowed using US. Typically, medullary nephrocalcinosis appears as echogenic pyramids, often outlining the rim of the pyramid, with a normal appearing cortex (Fig. 3.12c). A pattern of peripheral increased echogenicity followed by progression toward the center of the pyramid has been described as the Anderson-Carr progression of nephrocalcinosis [172].

Conclusion

The role of radiologic imaging and interventions in the diagnosis and treatment of diseases of the kidneys and urinary tract continues to evolve. US, CT, MRI, and nuclear medicine remain the most common modalities for assessing the urinary tract, while new technologies such as CEUS, ceVUS, and MRU are starting to change practice patterns. Interventional radiology is playing an increasing role in the management of urinary tract and renovascular disease. Close collaboration between nephrologists, urologists, and radiologists will continue to allow optimal care for children with kidney and urinary tract abnormalities.

Acknowledgement The authors express their gratitude to Drs. Ruth Lim and Jeffrey Traubici, whose excellent work in the previous edition laid the foundation for this chapter.

4 Molecular Diagnosis of Genetic Diseases of the Kidney: Primer for Pediatric Nephrologists

Aoife Waters and Mathieu Lemaire

Introduction

Over the past decade, remarkable advances have been made in our understanding of the human genome through the development of genotyping arrays and next-generation sequencing techniques. These technological advances have allowed us to examine the consequences of various types of genomic variations on the phenotype of patients in an unparalleled manner. Identification of mutations in novel genes associated with rare renal diseases has forced dramatic pathophysiological revisions owing to the discovery of links to unexpected biochemical pathways or structural scaffolds. These provide not only a firm molecular diagnosis for hitherto "idiopathic" conditions, but also offer hope for new therapeutic strategies for diseases that would otherwise have an unfavourable prognosis. The last few years have witnessed great improvements in our understanding of the role of common genetic variation in the pathogenesis of complex renal diseases, although the promises of clinical utility are far from reality. In this chapter, we will outline developments made in various fields related to genomic medicine, with a particular emphasis on how these will translate into the daily clinical practice of pediatric nephrologists.

General Genetic/Genomic Concepts

Deoxyribonucleic Acid (DNA)

In 1962, the Nobel Prize in Medicine was awarded to Watson and Crick together with Maurice Wilkins for their discovery of the structure of deoxyribonucleic acid (DNA). DNA is a critical participant in the execution and regulation of biological processes that are critical for living organisms to develop and survive. Constituting the double helix structure of DNA are two twisting, paired strands that are packed full of information via the systematic arrangement of four nucleotide bases—adenine (A), thymine (T), guanine (G), and cytosine (C)—the "genetic alphabet" [2]. Opposite strands anneal together specifically, via the pairing of bases: A binds to T, and C to G. If one strand's nucleotide sequence reads ATTCGG, the other strand will read TAAGCC; we refer to these as the positive and negative strands, respectively.

Gene

A gene refers to segments of DNA that carry the sequencing code for all building blocks necessary for cells to thrive. Two sequential processes are key: transcription and translation. Transcription is the process by which a ribonucleic acid (RNA) strand is made to match exactly the nucleotides that make up a particular gene. It is critical to preserve both nucleotide identity and order because it is a key determinant of the function of RNAs. The most well-known RNA molecule made this way is the messenger RNA (mRNA): it is the key player in the translation (or encoding) of proteins. During this process, which occurs in ribosomes, the sequence of mRNA molecules is read in triplets of nucleotides, known as codons, and this specifies which amino acid we add next during protein synthesis (Fig. 4.1). The recent discovery of a dizzying array of noncoding RNA molecules has added an unexpected level of complexity: the RNA world is much more than mRNAs [3]. We are only starting to understand how these noncoding RNAs carry cellular functions by themselves, without requiring translation into proteins [4].

Genome

A genome represents an organism's complete DNA sequence. The Human Genome Project, an international effort to sequence the entire human genome (6 billion nucleotides), was completed in 2001 after more than 10 years of work and billions in research funding [5]. DNA from 13 anonymous individuals of European descent was used to build what is now referred to as the human ref-

Amino acid properties: Nonpolar | Polar | Basic | Acidic | Nonsense

Fig. 4.1 DNA codons and associated amino acids. The three nucleotides (codons) that make up the 20 different amino acids (and stop signal) are presented, along with the single-letter database codes. To obtain the various codons, one simply needs to integrate the value of the first (left), second (top) and third (right) bases. To obtain the RNA codons, Key properties of amino acids are indicated in the color legend at the bottom. (Figure credits: Modified from Wikipedia, https://en.wikipedia.org/wiki/DNA_and_RNA_codon_tables#Translation_table_1)

erence genome. In principle, the human reference genome should be a repository containing a representative whole-genome sequence for a prototypical human. After the publication of the draft sequence in 2001 [6], a high-quality reference sequence followed in 2004 [7]; the Genome Reference Consortium continues to improve the quality and coverage of low-complexity, repetitive, and hard to resolve regions [8].

While the exact number of genes remains unknown, most experts estimate that there are ~20,000 protein-coding genes that occupy about 1% of the human genome. Other constituents of the genome include RNA genes, regulatory sequences, and repetitive DNA sequences. Ongoing research by the Encyclopedia of DNA Elements (ENCODE) project suggests that ~80% of the human genome is functionally active: non-protein-coding DNA must be implicated in a significant number of regulatory processes including gene-gene regulation, gene-protein interactions and the transcription of nontranslated RNA [9].

Genetic vs. Genomic

It is now common, but incorrect, to use the terms "Genetic" and "Genomic" as synonyms. The former refers to investigations restricted to a small number of genes at once, while the latter applies to tests that involve genome-wide interrogation.

Other Omics

Many other "-omics" sciences are actively developed in parallel to genomics, such as proteomics [10], transcriptomics [11], epigenomics [12], and metabolomics [13]. New forms of -omics are still emerging: for example, epitranscriptomics, which is the study of mechanisms that regulate RNA functions [14], is relevant to novel forms of nephrotic syndrome [15, 16]. The new frontier is to study one or more omics patterns at single-cell resolution [17]: it is widely anticipated that it is a key development to better understand the pathophysiology of many kidney diseases [18]. Eventually, these methods will be combined to provide holistic insights into organ or cell functions [19]. It is, however, beyond the scope of this chapter to cover these methods in any detail.

Variations in the Genome

Several different classes of DNA sequence variations are observed when comparing the genomes of different individuals. A variation may also be classified as a mutation, which is defined as a change of the nucleotide sequence when compared to the human reference genome; a mutation is not necessarily pathogenic. These alterations may be caused by a number of mechanisms, including unrepaired DNA damage (caused by mutagens such as radiation or chemicals), DNA polymerase errors during replication, or insertion or deletion of DNA segments by mobile genetic elements. Below, we will describe the different kinds of mutations after a short discussion on their key characteristics. Implicit to these discussions is that these mutations are all germline, which means that all cells of an individual carry the mutation, and this mutation is passed on to subsequent generations according to Mendel's law of allele segregation. This contrasts with somatic mutations that are only present in a restricted subset of cells. The concept of somatic mosaicism will not be covered further here: it has relevance well beyond that of cancer genetics [20], most notably in nephrology, for autosomal dominant polycystic kidney disease [21].

How to Assess Genomic Variations

One of the key features that will allow genomic medicine to flourish in the clinic is the ability to reliably assess whether a given mutation is likely to affect protein function or not. When appraising a particular mutation, there are a number of important characteristics to consider systematically before deciding on its pathogenic potential [22]. A recent review reveals that the nephrology literature is replete with spurious gene-disease associations, or "diagnoses of uncertain significance" [23]. Below, we will briefly describe four such characteristics, including frequency, location, mutation type, and conservation. This section introduces many key concepts that will be used frequently throughout this chapter. Please refer to Fig. 4.2 for an illustration of the various concepts.

Is the Allele Common or Rare?

The first consideration is to assess how frequently the mutation is observed in the general population. The minor allele frequency (MAF) is the most useful piece of information for this. It is calculated by dividing the number of mutant alleles in a sample by the number of wild-type alleles (each individual has two alleles since humans are diploid organisms). MAF data for common variants is easily retrieved from online databases, such as dbSNPs. The MAF for rare and common variants should be less than 1% and between 1% and 49%, respectively; the major allele frequency is usually more than 50%. This concept is important because common mutations are expected to have a low probability to cause rare conditions. The frequency of deleterious alleles is expected to remain low in the general population because of reduced reproductive fitness and natural selection.

Coding vs. Non-coding Variants

The second distinction relates to the location of the mutation in the genome: is it in a region that is involved in protein coding or not? Because we have rich knowledge about protein-coding DNA (exons) and their functions, most studies and clinical tests tend to focus on these regions of the genome, collectively known as the exome. "Non-coding" DNA, which is composed of intronic and intergenic segments, does not contain only "junk" DNA as this is where one finds a host of regula-

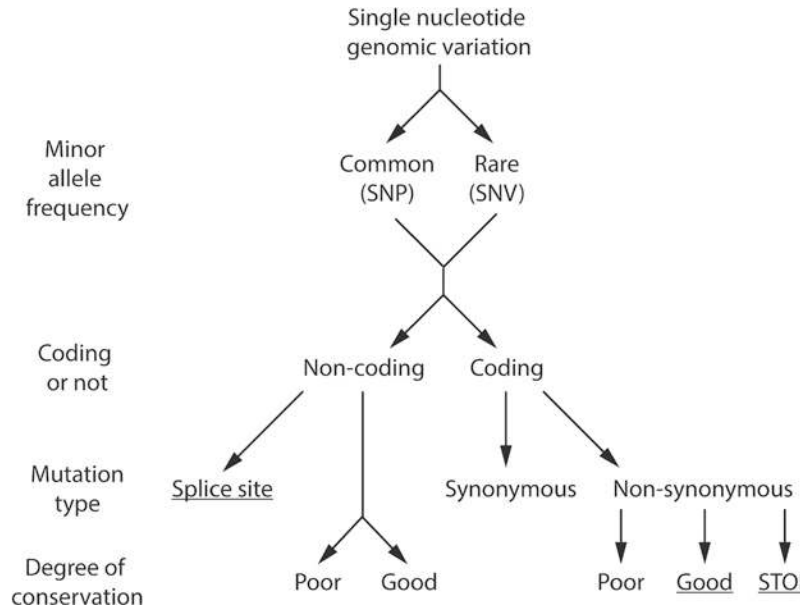

Fig. 4.2 An approach to assess a mutation. We present a simple workflow to assess mutations that include four steps. These are based on allele frequency, mutation location and type and degree of conservation. Underlined terminal nodes indicate the mutations most likely to cause human disease

tory elements such as promoters, enhancers, silencers and insulators, as well as microRNAs. There is mounting evidence that there is in fact no such thing as junk DNA as 80% of the entire genome plays an important role one way or another [24].

There is one type of intronic mutation that has a special status in clinical genetics: splice site mutations that change key nucleotides in one of the specific sites that are critical for splicing introns during the processing of precursor mRNA into mature mRNA. Abolishment of a splicing site results in the retention of introns in mature mRNA molecules and leads to the production of aberrant proteins (for an example relevant to nephrology, see Mele et al. [25]).

Mutation Types

Third, it is important to determine if an exonic mutation will result in the insertion of different amino acids in the encoded protein, in which case it is referred to as a nonsynonymous substitution (see Fig. 4.3). These changes are important in clinical genetics because they are most likely to alter the function of the encoded protein. To determine if a nonsynonymous mutation may be pathologic, one needs to assess if the physicochemical properties of the original amino acid are preserved (size, charge, and polarity) and the degree of amino acid conservation (see next section).

There are three instances where a substitution will be expected to be deleterious without requiring these analyses. First, changing any amino acid to a nonsense (or stop) codon will result in the production of a truncated protein. Second, substituting a start codon (which is always a methionine) for any other amino acid will cause problems because protein translation cannot be initiated properly: no protein is produced. Third, any mutations at a stop codon will also cause problems because the protein made will be longer than the wild type, and as a result, it will include extra amino acids that may interfere with the proper function of the protein.

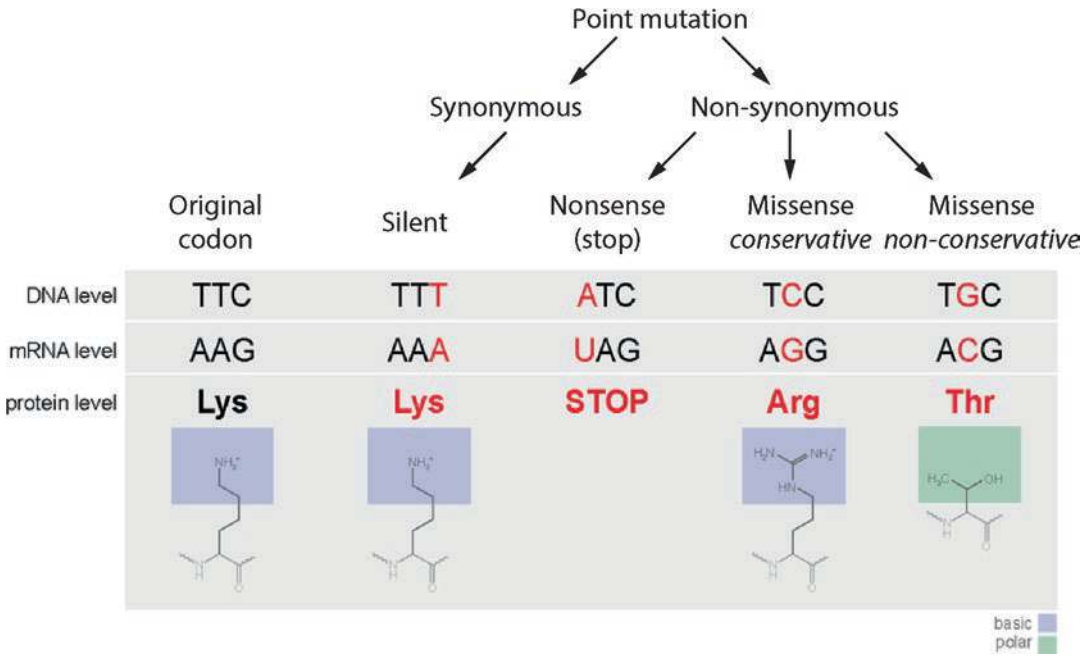

Fig. 4.3 Different types of point mutations. This figure illustrates how a single point mutation in a given codon can change the encoded amino acid in many ways. A conservative missense mutation is one that keeps some or all of the original amino acid properties intact. (Figure credits: Modified from Wikipedia, https://en.wikipedia.org/wiki/Synonymous_substitution)

Mutations that do not result in an amino acid change are referred to as synonymous variants (this is possible because many amino acids are generated from different codons; see Fig. 4.1). They are also known as silent mutations since in most instances (but not always [26]), they have little to no effect on the function of the encoded proteins.

Degree of Conservation

Finally, one needs to determine if the mutation occurs at a genomic position that is highly conserved when compared to the genomes of other species. It is possible to make this comparison rapidly since we have the entire genomic sequences of many different species (e.g., from humans to mice, frogs, and fruit flies). This analysis is most meaningful for coding segments because one can directly compare the amino acid sequences of the same protein in different organisms (orthologs) [27].

Such comparisons support the notion that the degree of interspecies amino acid variation is indirectly proportional to the functional importance of the amino acid. For example, key residues within the catalytic domain of protein kinases are conserved as a functional unit among all kinases of any species [28]. Kinases are enzymes that transfer a phosphate group from ATP to tyrosine, serine, or threonine residues on target proteins. Other approaches are needed to assess mutations found in noncoding regions because nearly all positions are poorly conserved across species [29].

Single Nucleotide Polymorphisms

Strictly speaking, an SNP is a single base substitution at a specific genomic locus which makes this position different from that of the Human Reference Genome [30]. However, common usage has SNPs also defined as a "common variant" on the basis of a population minor allele frequency of >1%. Single nucleotide mutations may occur anywhere in the genome. That the bulk of SNPs are located in noncoding segments is hardly surprising since they constitute ~99% of the genome. As discussed above, the vast majority of SNPs have long been thought to be benign because they are so common. However, the lack of clear clinical significance does not mean that SNPs are useless far from it.

Over the years, geneticists have long used a variety of genetic markers to study human genetic variation with greater depth and accuracy. SNPs emerged as the genetic marker of choice around 2000. It was preceded by three other "generations" of markers: restriction length fragment polymorphisms (~1980), variable number of tandem repeats (~1985), and short tandem repeat polymorphism (~1989) [31]. The rise of SNPs as markers is in large part due to the momentum created by the HapMap project [32], which aimed to catalogue millions of SNPs in hundreds of subjects from many ethnicities [33]. This resulted in marked improvements in the reliability, efficiency, and cost of high-throughput SNP genotyping (see the section below).

SNPs proved to be invaluable to study haplotype patterns in humans. Haplotypes are genomic segments on a chromosome that are defined by a combination of alleles that are consistently inherited together. This phenomenon is termed linkage disequilibrium (LD) [34] since these alleles are linked to each other more often than not because recombination events occur outside of the LD block. Because of the low diversity of genetic variation within LD blocks, genotyping a subset of SNPs provides a fingerprint of the underlying haplotype without having to genotype all alleles: these are known as "tag SNPs"[35]. The concepts described here will be useful for the sections on linkage analysis, homozygosity mapping, and genome-wide associations.

Single Nucleotide Variants

Single nucleotide variants (SNV) are often defined as alleles with a minor allele frequency of <1% in the general population. SNVs are found throughout the genome, both in noncoding (introns, intergenic segments) and coding (exons)

regions. As described earlier, coding SNVs exist in two "flavours": synonymous and nonsynonymous variants. Since there is almost no selective pressure on synonymous variants, they are expected to be scattered anywhere in the genome. In contrast, nonsynonymous variants are often enriched in well-conserved amino acid positions owing to the strong selective pressure they sustain. As a result, it is not surprising that highly penetrant disease-causing variants in monogenic conditions are overwhelmingly nonsynonymous SNVs. It is commonplace to refer to disease-causing SNVs as pathogenic mutations [36]: this topic will be covered in the section on Mendelian conditions.

When dealing with a rare condition, one needs to determine whether the mutation is truly rare (or novel) by interrogating a variety of publicly available variant databases such as dbSNPs [37]. Most of these resources have been generated using samples from subjects of European descent. As a result, interpretation of variants from patients that are not "European" is problematic because usually, one does not have access to the optimal control group. This phenomenon, called population stratification, makes the search for pathogenic mutations more challenging because variants that are common in one population may be rare (or even absent) in another [38]. Hence, the validity of the interpretation of pathogenicity for a given variant is deeply impacted by the patient's ethnic background. The magnitude of this problem will be lessened as more non-European subjects are sequenced through various efforts worldwide [39].

An additional layer of complexity comes from the fact that reported ethnicity is notoriously unreliable [40]. This is particularly true in localities where multiethnic families are common: the genetic makeup of a patient may be much more complex than predicted based on recent family history [41]. For example, some self-identified "Europeans" have substantial genomic portions that are derived from African ancestors, whereas 99% of the genome of some self-identified "African Americans" is of European origin [42]. To circumvent this problem, researchers use unbiased measures of ethnicity that rely on the SNPs genotyping data (such as principal component analysis) [43]. This approach is, however, not routinely used by clinical diagnostic laboratories to draw conclusions about the presence or absence of pathogenic mutations.

Structural Variations

We define structural variation as any genomic change that implicates more than a single base substitution at once. There are typically 5000–10,000 structural differences when comparing the genomes of two unrelated, apparently healthy individuals [44]. dbVar is a database equivalent to dbSNPs, but for variants >50 bp in length [45]. Below, we will briefly describe the most common types of structural variations while also providing, whenever possible, examples from the renal literature. We are only starting to grasp the magnitude, complexity, and ramifications of structural variations in human biology and diseases [46]. We still believe it is worthwhile for pediatric nephrologists to understand these topics since they will undoubtedly become "household" terminology in the clinic soon.

Insertions and Deletions (Indels)

There are two major types of structural variations that involve short genomic segments that are less than 1000 base pairs. These include situations where nucleotides are added or removed, which are respectively, known as insertions and deletions. Structural variants that affect more than 1000 base pairs are known as copy number variations (discussed in the next section).

Some events involve very short segments that are located within an exon. Whether such an alteration is deleterious for proteins depends largely on the number of nucleotides involved and the position of the alteration relative to the coding sequence. Any change that disrupts the normal sequence of bases is likely deleterious (it is key to remember that codons always include three bases) [47]. For example, any insertion that is not a multiple of three in terms of base number (for example, insertion of a single A) will dramatically change the interpretation of the mRNA

sequence: its reading frame will be shifted, and the protein produced, truncated (Fig. 4.4a). In contrast, after insertion of three bases (for example, insertion of AGGACG), it simply adds a few extra amino acids to the protein (in this case, arginine "AGG" and threonine "ACG"). This type of alteration is usually benign because if it does not alter the way the mRNA sequence is "read" after the insertion (i.e., the amino acid sequence of the rest of the protein is unchanged).

Frameshift mutations are commonly found in genes known to cause Mendelian conditions affecting the kidney. Insertion of a single cystine residue in the gene mucin1 (*MUC1*) was recently found in multiple unrelated families with medullary cystic kidney disease type 1 using a unique combination of sequencing and bioinformatic techniques [48]. What is fascinating about this story is that while multiple linkage studies pointed to a small genomic segment on chromosome 1 (where *MUC1* is located) [50], the disease-causing mutations remained elusive even to next-generation sequencing approaches. Indeed, for all families, the C insertion lies in an exon that is enriched in C residues, thereby making it very difficult to distinguish *bone fide* mutations from sequencing errors [48] (see Fig. 4.4b).

For structural events involving slightly larger segments (for example, deletion of two exons), the functional consequences are related to either the absence of an important domain (e.g., these exons contain a kinase domain) or an aberrant

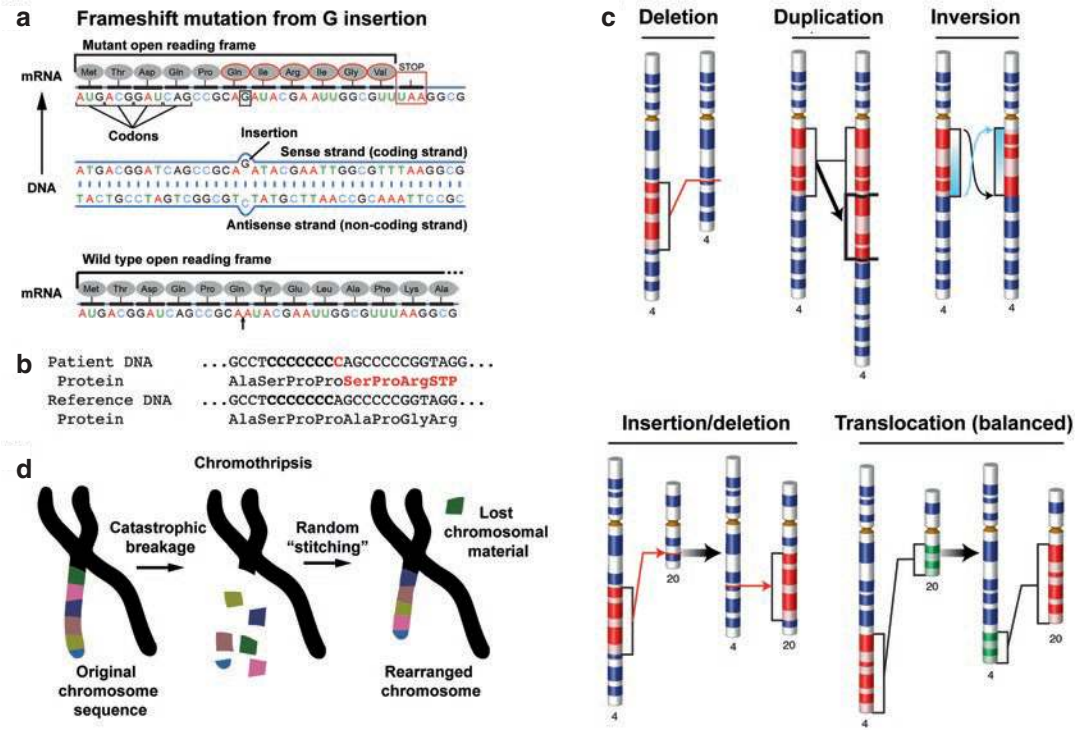

Fig. 4.4 Structural variations. Illustration of various types of structural variations. (**a**) Illustration of the impact of insertion of a single base in a coding exon. The shift in the reading frame causes a major change in the amino acid sequence. The encoded protein is truncated because a new stop codon is created by the frameshift. (**b**) Example of a C insertion (red) in a genomic segment that is highly enriched in cystine (bold). The impact on the amino acid sequence is presented below the DNA sequences. (**c**) Examples of large-scale structural changes. (**d**) This schematic presents the model by which the process of chromothripsis is explained. tertiary protein structure (e.g., direct linking of the flanking exons results in a misfolded protein). These types of events are relevant to many conditions managed by nephrologists. For example, small deletions in *COL4A5* are described in patients with Alport syndrome [51], and a large duplication of the complement factor H-related protein 5 gene (*CFHR5*) gene is described in many patients with *C3* glomerulopathy [52].

Copy-Number Variations

Large-scale insertions or deletions are collectively referred to as copy-number variants (CNV; see Fig. 4.4c). They are detected using the same microarray-based technologies used for GWAS studies [53]. Most CNVs are predicted to be benign since the majority are common in the general population. Large hemizygous or homozygous deletions, especially when rare and leading to abrogation of a single gene, are the simplest CNVs to interpret phenotypically. Indeed, this copy number loss is equivalent to a gene knockout. Studies on patients with a large deletion of the X chromosome led to the discovery of *CLCN5* as the first molecular mechanism causing Dent's disease in an affected female with nonrandom X-inactivation [54]. Similar events were critical to the identification of *COL4A4* and *NPHP1* as the disease-causing genes for Alport syndrome [55] and nephronophthisis [56], respectively. Some syndromes associated with large chromosomal defects, such as Turner syndrome (loss of the X chromosome [57]) or Down syndrome (gain of chromosome 21 [58]), can also be associated with renal defects.

It is not straightforward to predict the functional impact of other types of CNVs, even those strongly associated with human diseases. In most instances, gene dosage is thought to be reflected proportionally in the levels of gene expression [59]. For example, mRNA and protein expression is higher when there is a copy number gain; important, the amino acid sequence of this protein is unchanged. The most prominent example of this in the renal literature comes from studies on the genetic basis of lupus nephritis: SLE patients with low copy numbers (0 or 1 per chromosome) of the gene encoding Fc receptor for IgG (*FCGR3B*) were more likely to develop kidney disease than those who had more than 1 [60]. It was recently shown that patients with congenital kidney malformations are much more likely to harbour large and rare heterozygous CNVs in any region of the genome when compared to unaffected controls [61]. Tumour-specific copy number gain and loss have been observed in clear cell renal cell carcinoma, particularly when there is no germline mutation in the gene VHL [62].

Copy-Neutral Variations

Copy-neutral variation, defined as genomic alterations that do not affect the overall number of copies of genes, includes inversion and translocation (see Fig. 4.4c). These may cause the disease in several ways. The function of genes may be abnormal if the inversion/translocation is accompanied by random loss of parts of the rearranged genomic segment that play an important role (i.e., it is "unbalanced"). Balanced copy-neutral variations can also be pathogenic. Indeed, if the boundaries of the structural change occur in the middle of a gene, it may disrupt the normal transcription of that gene (since contiguous exons are now far apart). Even if gene integrity is preserved, aberrant gene expression may be observed because of interference with the function of regulatory elements such as promoters, enhancers, silencers, insulators [63].

There are only a few examples of patients with renal conditions caused by balanced copy-neutral variations [64–66]. A unique type of disease-causing copy-neutral variation was also found by exome sequencing in a rare form of pheochromocytoma: the affected patient had homozygous *MAX* mutations because of uniparental disomy (a process by which two copies of a chromosome come from a single parent) [67]. One explanation for the apparent rarity of copy-neutral variants as the cause of disease is that commonly used genomic techniques are unable to detect these types of rearrangements. Thus, clinicians who have patients with a clear phenotype but without mutations in the known gene(s) should consider asking for copy-neutral variation testing.

Chromothripsis

Recent advances in DNA sequencing and bioinformatics now allow interrogation of genomes at an unprecedented resolution: it was instrumental in the discovery of yet another type of structural variation, namely, chromothripsis (which means chromosomes shattered to pieces). Chromothripsis is suspected when a chromosome is found to harbour two or more complex structural rearrangements (see Fig. 4.4d). This phenomenon was first described as a type of somatic structural variation present only in cancer cells [68]. Many similar reports followed shortly thereafter, suggesting that this mechanism is common in tumours [69]. The current working model states that chromothripsis arises from a single catastrophic event causing shattering of one or more chromosomes followed by the formation of a chromosome-like structure via random stitching of the fragments [70]. Chromothripsis was recently described in renal cell carcinomas [71].

Of utmost interest for pediatricians is the fact that a chromothripsis-like phenomenon has been reported as *a de novo* germline variation in patients with congenital diseases [72, 73]. Recent evidence suggests that the underlying mechanism is analogous to that described for cancer cells; the main difference being that the shattering process is much more circumscribed in so-called "constitutional chromothripsis"[74]. Chromothripsis was recently described as potentially causal in a child with multiple congenital anomalies, including vesicoureteral reflux [75]. However, there is still plenty to learn about the biological relevance of this process. Indeed, genetic investigations of a child with congenital anomalies ultimately uncovered parentally transmitted germline chromothripsis that was unlikely to be causal: besides his mother, 9 healthy carriers were found in this three-generation kindred [76].

Haploinsufficiency

Haploinsufficiency refers to a situation where adequate gene expression to preserve normal cell function requires the presence of two wild-type alleles being actively transcribed (diploid organisms have two copies of all autosomal genes) [77]. Disease occurs when one of the two alleles is absent or dysfunctional owing to a deletion event or a deleterious mutation, respectively [78]. Such conditions may arise *de novo* or via inheritance from an affected parent. Given their extreme dependence on gene dosage, it remains unclear why negative selection has not resulted in the disappearance of haploinsufficient genes [79].

There are several conditions that affect the kidneys that are driven by abnormalities in haploinsufficient genes. The most common is RCAD syndrome (renal cysts and diabetes) syndrome, a condition caused by either a heterozygous mutation in HNF1B or by the 17q12 microdeletion syndrome (this segment includes HNF1B) [80]. RCAD syndrome is characterized by its striking phenotypic variability among affected individuals (even between first-degree relatives with the same genotype) [81]. Recent data suggest that this phenomenon may be due to epigenetic modifications in many genes that occur in response to the haploinsufficiency state [82]. Other examples of haploinsufficient conditions that pediatric nephrologists should be aware of include SON deficiency syndrome [83] and various forms of CAKUT [84–86].

Modes of Inheritance

An allele is one of a number of copies of the same gene or locus. Every person has two copies of every gene on autosomal chromosomes, one inherited from the mother and one inherited from the father. The occurrence of two copies of the same allele results in a homozygous genotype for that allele, whereas the presence of two different alleles results in a heterozygous genotype for each allele. How recessive or dominant genotype

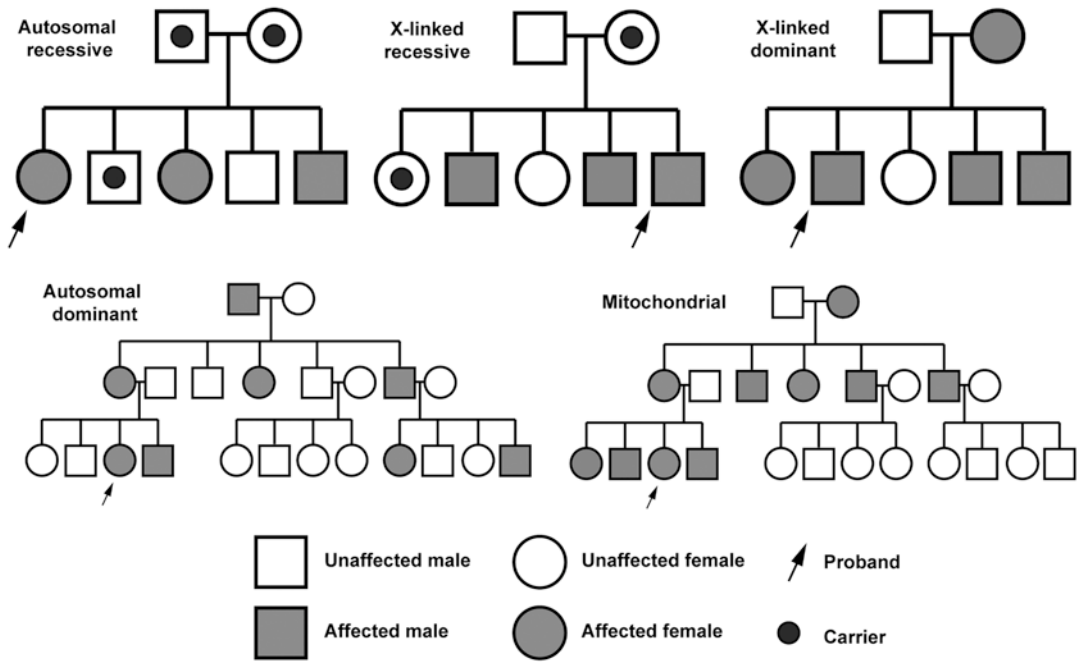

Fig. 4.5 Examples of pedigrees for most common types of inheritance. Examples of classic pedigrees for kindreds with patterns of inheritance consistent with autosomal recessive, autosomal dominant, X-linked recessive, X-linked dominant and mitochondrial

interactions can influence the expression of the characteristic traits of the underlying genetic variation are described in the following sections. Please see Fig. 4.5 for pedigrees displaying the typical inheritance patterns, and the sections below for clinical examples.

Dominant Genotypes

Dominant genotypes are seen when the heterozygous genotype is associated with phenotypic expression. Dominant genotypes arise when one allele dominates by masking the phenotypic expression of the other allele at the same genetic locus. For example, where a gene exists in two allelic forms (designated A and B), a combination of three different genotypes is possible: AA, AB, and BB. If AA and BB individuals (homozygotes) show different forms of some trait (phenotypes), and AB individuals (heterozygotes) show the same phenotype as AA individuals, then the allele A is said to dominate or be dominant to or show dominance to allele B, and B is said to be recessive to A. If instead, AB has the same phenotype as BB, B is said to be dominant to A. There are many autosomal dominant conditions that are relevant to pediatric nephrologists, such as autosomal dominant polycystic kidney disease (ADPKD) [87], tuberous sclerosis complex [88], or renal cyst and diabetes (RCAD) syndrome [80].

Recessive Genotypes

Recessive genotypes are seen when the homozygous genotype and not the heterozygous genotype are associated with phenotypic expression. Thus, both parents have to be carriers of a recessive trait in order for a child to express that trait. If both parents are carriers, there is a 25% chance for each child to show the recessive trait in the phenotype. Thus, if the parents are closely related (consanguineous), the probability of both having inherited the same allele is increased and as a result, the probability of children showing the

recessive trait is increased as well. Most pediatric nephrologists will regularly manage patients with autosomal recessive conditions that affect the kidneys, including cystinosis [89], autosomal recessive polycystic kidney disease [90], Bartter syndrome [91], or pseudohypoaldosteronism type 1 [92].

X-Linked Inheritance

X-linked inheritance means that the gene causing the trait, or the disorder is located on the X chromosome. Females have two X chromosomes, while males have one X and one Y chromosome. X-linked recessive (XLR) inheritance is a mode of inheritance in which a mutation in a gene on the X chromosome causes the phenotype to be expressed (1) in males (who are necessarily hemizygous for the gene mutation because they have only one X chromosome) and (2) in females who are homozygous for the gene mutation (i.e., they have a copy of the gene mutation on each of their two X chromosomes). Carrier females who have only one copy of the mutation do not usually express the phenotype, although differences in X chromosome inactivation can lead to varying degrees of clinical expression in carrier females since some cells will express one X allele and some will express the other.

In contrast, X-linked dominant (XLD) conditions occur when a single mutated X-linked allele is responsible for the manifestations of the disorder: as such, both males and females are usually affected. The exact pattern of inheritance varies, depending on whether the father or the mother has the trait of interest. All daughters, but no son of an affected father, will have the same condition. In addition, the mother of an affected son would be expected to be affected. Examples of X-linked dominant conditions that primarily affect the kidneys include nephrogenic diabetes insipidus [93], and Dent Disease [94]. X-linked Alport syndrome can be either dominant or recessive [95]. X-linked hypophosphatemia is a rare X-linked recessive condition caused by mutations in *PHEX* [96].

Mitochondrial

Inheritance from a single parent can give rise to disease (uniparental isodisomy). Some renal phenotypes arise solely by maternal inheritance and are characterized by mitochondrial dysfunction. Mitochondrial DNA (mtDNA) is derived from the mother because it exists in much higher concentrations in ova compared to sperm. Furthermore, sperm mtDNA tends to get degraded in fertilized ova and sperm mtDNA fails to enter the ovum in several organisms. Most patients with mitochondrial cytopathies will present with evidence of proximal tubular dysfunction; it can also be associated with a distal tubulopathy, or even a glomerulopathy [97].

Genetic/Genomic Methods

SNPs Genotyping

Because of the unique properties of SNPs, there has been considerable interest in developing high-throughput technologies that would allow simultaneous testing of a large number of SNPs cheaply and reliably. The starting point is always a solution containing the patient's fragmented DNA. The two most successful approaches apply this solution to a microarray seeded with specific oligonucleotide probes directed against the sequence surrounding the target common variants (with minor allele frequencies of at least 1%).

The first method relies on non-enzymatic hybridization of single-stranded DNA with probes: a perfect match generates a light signal, but a fragment harbouring a variant does not. The second uses DNA polymerase to add one of four fluorescent-labelled nucleotides (A, C, T, or G), thus extending the probe by one base specifically at the SNPs locus. SNPs genotyping was rapidly adopted by investigators as the method of choice to investigate the links between common genetic variants and human disease [98].

Current estimates show that a typical human genome (3 billion base pairs in total) harbours 5

million SNPs: this corresponds to roughly 1 SNP every ~1000 bases. While early versions of these arrays contained <100,000 SNPs scattered throughout the genome, current platforms routinely interrogate 1–2 million SNPs at once (1 SNP every ~2000 bases). This means that we currently have unprecedented precision in our assessment of common genetic variation. As described below, SNPs genotyping has proved useful for many types of investigations, such as assessment of linkage, genome-wide association, ancestral heritage, and copy-number variations. The most recent application of this technology is the generation of polygenic risk scores to estimate the likelihood that a given individual will experience a specific clinical outcome based on genome-wide SNPs data [99]. The polygenic risk profiling tools developed to predict renal outcomes may soon be used in clinical practice [100].

Linkage Analysis

For decades, genetic linkage analysis has proved to be a powerful method to uncover short genomic segments that contain disease-causing genes for Mendelian conditions. The concepts of co-segregation, phase, linkage disequilibrium, and haplotype, which were described above, are central to this analysis (see Fig. 4.6). The goal is to identify nonrandom segregation of disease phenotypes with discrete chromosomal segments [101]. When performed with the current technology, the first step is to obtain dense SNPs geno-

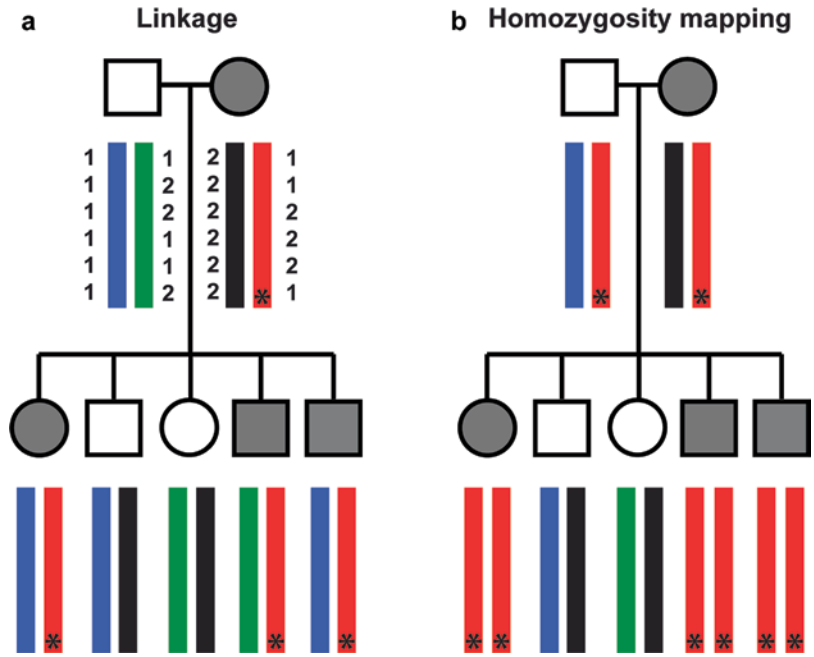

Fig. 4.6 Linkage analysis and homozygosity mapping. (**a**) Illustration of linkage analysis, with the disease haplotype (genomic segment harbouring the disease-causing mutation) in red. If an autosomal dominant pattern of inheritance with complete penetrance is suspected, all (and only) affected individuals should share the pathogenic heterozygous haplotype. Each coloured segment represents different haplotypes because they harbour different sequences of alleles at similar genomic positions (in this case, 6 loci are shown, each with 2 possible alleles, 1 or 2). (**b**) Homozygosity mapping seeks to identify homozygous segments that are present only in affected individuals (red). While a consanguineous union increases the probability of an autosomal recessive condition, outbred parents may share short genomic segments because of very distant common ancestors

typing data for all individuals in the family that provided a blood sample. Genotyping platforms typically record genotypes for millions of common variants (minor allele frequency >1% in the general population) that are scattered throughout the genome. On that basis, this approach is often referred to as a "genome-wide linkage scan."

Next is the identification of all series of contiguous SNPs that travel together (haplotypes) in all affected individuals, but not in healthy relatives (see Fig. 4.6). Using this approach, one can confidently exclude most of the genome and focus efforts on the incriminated genomic segments, which may contain any number of candidate genes (from zero to many). One key concept to understand is that the SNPs used for linkage analysis almost never turns out to be the disease-causing variant *per se* since the common variants on the SNPs genotyping platform cannot be the primary cause for a rare Mendelian condition. These SNPs are called tag SNPs because they effectively flag specific genomic segments (haplotypes) that contain the rare disease-causing variant.

The larger the number of samples from affected and unaffected individuals, the higher the precision of linkage analysis. This approach is thus most fruitful when dealing with a large kindred with multiple affected individuals, and it is not useful when dealing with families with a single affected individual. Obtaining a large number of blood samples from unaffected first-degree relatives is also key as one can exclude a larger number of "healthy" haplotypes. Combining linkage analysis performed on two or more unrelated kindreds with similar phenotypes allows for narrowing down the number and length of the target genomic segments since the disease-causing gene must lie within the segment that is shared between kindreds (if caused by mutations in the same gene).

Up until recently, most genes associated with Mendelian conditions were discovered using linkage analysis. This is true for renal conditions as well. Nowadays, gene discovery projects are done with whole-genome and whole-exome sequencing using analytical procedures that often include linkage analysis (see the section below) [102]. Instead of using common variants as genomic markers for the disease locus, one can directly find the disease-causing mutation (which is expected to be rare or novel since the disease under scrutiny is rare).

Homozygosity Mapping

Genetic analysis of consanguineous families with multiple individuals exhibiting a similar disease phenotype is in theory simpler than for outbred kindreds because of a much higher prior probability that the disease follows an autosomal recessive pattern of inheritance (see Fig. 4.6) [103]. Homozygosity mapping [104], which is the method of choice in this context, is a version of linkage analysis that is streamlined by restricting the playing field to genomic segments that are homozygous only in affected individuals [105]. The entire set of homozygous segments has been termed the "autozygome" because autozygosity refers to homozygosity in the context of consanguinity [106]. This method relies on identity-by-descent because one would expect to find a single founder mutation that originated from a common ancestor. As in traditional linkage analyses, testing of unaffected parents and siblings is critical to make sure that only affected individuals carry recessive genotypes (monogenic disorders typically have complete penetrance).

Ideally, the homozygosity mapping points to a single homozygous genomic segment. Interestingly, homozygosity mapping is at times problematic when investigating highly inbred families because there may be many shared homozygous segments [107]. Alternatively, isolated communities can accumulate distinct pathogenic mutations in the same gene, resulting in the unexpected identification of affected individuals with compound heterozygous mutations despite being the product of a highly consanguineous union. The main example for this exceptional scenario is relevant to pediatric nephrologists since it stems from research on congenital nephrotic syndrome [108, 109]. There is evidence from the renal literature that homozygosity mapping may also be useful to investigate a sub-

ject from an outbred family for whom a recessive pattern of inheritance is suspected [110].

Since most of these conditions are first diagnosed clinically during childhood, pediatricians should know about this approach. The history of kidney disease genetics is replete with examples of successful applications of identity-by-descent methodology to identify novel disease-causing genes. While homozygosity mapping is better known as a research method for gene discovery, it is emerging as a critical tool for clinical genetics as well. It is particularly useful when dealing with patients from consanguineous unions that have a condition with many possible genetic causes [111]. For example, this approach reduced diagnostic costs and streamlined patient care when applied to a large number of patients with a clinical diagnosis of Bardet-Biedl syndrome [112].

Genome-Wide Association Studies

In many ways, a genome-wide association study (GWAS) is very similar to a linkage study. Indeed, both test to see if there is a statistical association between any of 1–2 million SNPs and a particular trait that may be recorded as a variable that is either continuous (systolic blood pressure, in mmHg) or dichotomous (hypertension: yes or no) [113]. There are two major differences between these study designs [114]. First, while the focus of linkage studies is on families with affected and unaffected individuals, GWAS methodology actively prohibits the inclusion of close relatives in the same study to avoid bias. Second, linkage and GWAS studies use the same set of tag SNPs to flag haplotypes harbouring rare disease-causing mutations or common risk alleles, respectively.

Anyone reading an article reporting on the results of a GWAS for the first time is usually struck by the extremely low p-values required to identify valid associations: the typical genome-wide significance threshold for GWAS studies is 5×10^{-8}. Such low p-values are necessary to minimize the chances of reporting false-positive associations, which become increasingly common as the number of tests performed increases [115]. While on a different scale, this concept should be familiar to physicians ordering lab tests. The new p-value threshold is simple to calculate: 0.05 divided by the number of tests performed (in this case 1×10^{-6} SNPs). When reading an article, it is good practice for physicians to systematically calculate the number of tests performed and independently calculate the corrected p-value threshold, if applicable.

Flag SNPs with p values below the set threshold identify target haplotypes, each of which usually contains many genes. It is important to realize that a GWAS does not make it possible to pinpoint which of the genes contained in the haplotype is the culprit. This is critical because it influences the way GWAS results are reported in the literature. Early on, the tradition was to name a significant haplotype after one of the genes it contained, often based on the authors' best guess of pathogenic potential. This approach has backfired in the past because significant resources were allocated to the incorrect gene (see Box 4.1 for an exemplar taken from annals of Nephrology research history). Because of this problem, the authors now make it clear that the genes associated with haplotypes are merely signposts [116].

Box 4.1: The MYH9 vs. APOL1 Story

One of the best examples of an educated guess that misfired is from the nephrology literature. Simultaneous reports from two independent teams found a very strong genome-wide association between the haplotype containing the gene encoding myosin heavy chain 9 (*MYH9*) and glomerular disease in African-American adult patients [117, 118]. This was a reasonable guess given that many associated SNPs were clustered near or within *MYH9*, and given that autosomal dominant mutations in *MYH9* cause diseases with a complex, multisystemic phenotype that include an Alport-like glomerulonephritis that often leads to end-stage renal disease [119]. However, sequencing of all *MYH9* exons did not reveal the underlying risk allele(s).

Taking a deeper look at similar cohorts, a third team finally solved the riddle: the associated risk alleles were in a distinct gene named *APOL1*, located on the same haplotype [120]. These renal risk alleles are common in African Americans because they also confer a positive advantage via more efficient *APOL1*-dependent killing of trypanosome parasites. A prospective study later confirmed that African-American individuals harbouring the *APOL1* alleles do indeed have a higher risk of progression to ESKD or CKD over time [121]. Despite tremendous efforts to better understand the relationship between *APOL1* variants and kidney disease, the pathophysiology remains elusive [122, 123].

Polymerase Chain Reaction

Polymerase Chain Reaction (PCR) is the method of choice to amplify specific DNA segments. Most current DNA sequencing technologies depend on PCR amplification to generate a reliable signal that is translated into the DNA sequence itself through various ingenious means (see Fig. 4.7). PCR takes advantage of a DNA polymerase enzyme that is highly resistant to heat such that it is still functional following multiple rounds of heating/cooling. Heat is necessary to break the double-stranded DNA into single strands that can then be copied by the DNA polymerase using the supplied deoxynucleotide (dNTPs). The reaction also requires primer pairs that are synthesized in the laboratory: these are made out of a series of ~20 nucleotides that

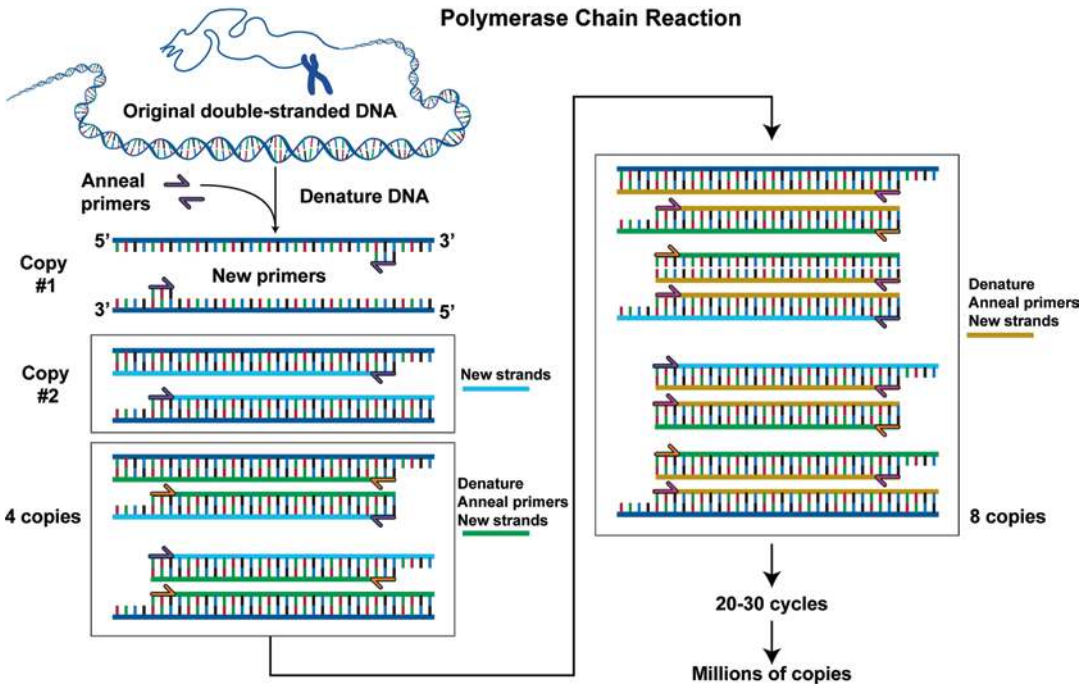

Fig. 4.7 Polymerase chain reaction. Illustration of the amplification process that occurs when DNA is subjected to PCR. Specific oligonucleotide primers, heat-resistant DNA polymerase and unlabelled nucleotides are added to the solution containing the starting DNA. The mix is subjected to heat to denature DNA. Once the temperature is reduced, the primers anneal to single-stranded DNA segments and new strands are synthesized by DNA polymerase enzyme. The first cycle generates two new strands, the second cycle four new strands. Ultimately, millions of copies of this segment are generated after 20–30 cycles. (Figure credits: Modified from NHGRI Image Gallery, https://www.genome.gov/genetics-glossary/Polymerase-Chain-Reaction)

match a very specific region of the genome. Now that the human reference genome is well established, it is simple to design primer pairs located around the target genomic segment of interest that is no more than 1000 base pairs in length.

The main drawback of PCR-based methods is that the DNA polymerase sometimes inserts the wrong nucleotide at a given position during the copying process. When one such amplified segment is subjected to DNA sequencing, one could be mistaken to think that it is a mutation when in fact there is none in the original DNA. It is thus important to validate all mutations deemed "pathologic" via PCR reamplification of a fresh sample of DNA followed by Sanger sequencing (method discussed below). The reason this step is useful is that most of these errors occur at random, which means that the same mistake is very unlikely to be observed at the same locus in a separate experiment.

DNA Sequencing Technologies

DNA sequencing determines the precise order of the four bases adenine, guanine, cytosine, and thymidine in a single strand of DNA. Sequences of individual genes or clusters of genes, full chromosomes, or the whole genome have greatly facilitated our understanding of the basic biological mechanisms of human disease. DNA sequencing was first developed in the 1970s [124] and a rapid sequencing method using the 'chain termination Method' was developed by Sanger in 1977 [125].

Sanger Method

DNA replication requires the presence of a single strand of DNA template, dNTPs, DNA polymerase, and DNA primers. Under normal conditions, the 3′-OH terminus of the dNTPs facilitates the formation of a phosphodiesterase bond between two nucleotides catalysed by the enzyme, DNA polymerase. The 'chain termination method' relies on the incorporation of dideoxy NTPs (ddNTPs) lacking a 3′-OH terminus such that the extension of DNA thereby ceases during the replication process (Fig. 4.8). Fluorescent-labelled ddNTPs are employed in automated sequencing methods which rely on wavelength determination to identify the different ddNTPs in a given sequence [126].

Next-Generation Sequencing Methods

Sanger sequencing can be laborious and expensive. A number of new sequencing technologies called next-generation sequencing (NGS) technologies have been developed that have significantly reduced the cost and time required for sequencing [127]. Unlike the Sanger method where a single predefined target is required for each sequencing reaction, NGS platforms allow for the sequencing of many millions of target molecules in parallel (Fig. 4.9). DNA molecules are immobilized on a solid surface and are sequenced in situ by stepwise incorporation of fluorescent-labelled nucleotides or oligonucleotides. "Clusters" of identical DNA are generated by the clonal amplification of template DNA, hence the term 'massive parallel deep sequencing' used to describe NGS. Platforms vary, with some covering fewer genomic regions than others, some are able to detect a greater total number of variants with additional sequencing, while others capture untranslated regions, which are not targeted by other platforms [128].

Massive parallel sequencing has greatly facilitated investigations of variations within the human genome. In January 2008, the 1000-Genome Project was launched with the objective of establishing a detailed catalogue of human genetic variation [129]. Utilizing the genomic sequences of 2500 anonymous participants from a number of different ethnic groups worldwide and using a combination of methods including low-coverage genome sequencing and targeted resequencing of coding regions, the primary goals of this project were to discover SNPs at frequencies of 1% or higher in diverse populations; to uncover rare SNPs with frequencies of 0.1–0.5% in functional gene regions; and to reveal structural variants, such as copy number variants, insertions, and

It is available: https://en.wikipedia.org/wiki/Sanger_sequencing)

deletions. The pilot project involving more than 1000 genomes was completed in May 2011 [130]. This resource is publicly available and can be used by researchers to identify variants in regions that are suspected of being associated with the disease. By identifying and cataloguing most of the common genetic variants in the populations studied, this project has generated data that will serve as an invaluable reference for clinical interpretation of genomic variation.

All rights reserved)

Third Generation Sequencing Methods

Newer or 'third generation' approaches have emerged that aim to sequence a single DNA molecule in real-time without prior amplification. The potential benefits of using single-molecule sequencing are minimal input DNA requirements, elimination of amplification bias, faster turnaround times, and longer read lengths that allow for some haplotyping of sequence information.

Whole-Exome Sequencing

Owing to the fact that about 85% of all disease-causing mutations in Mendelian disorders are within coding exons, the recent application of massive parallel deep sequencing with exon capture has shown the efficacy of this technique for the rapid identification of mutations in single-gene disorders [131, 132]. Almost 15 years have now passed since the targeted enrichment of an exome by hybridization of shotgun libraries was first described [133]. Two years later, the targeted capture and massively parallel sequencing of the exomes of 12 humans was published [134]. The following year, the first reports emerged on the use of whole-exome sequencing in gene identification [135]. Since then, investigators have discovered the genetic etiology of hundreds of Mendelian diseases.

Exome sequencing involves the targeted resequencing of all protein-coding sequences, which requires 5% as much sequencing as the whole human genome (Fig. 4.10) [134]. As the majority of Mendelian disorders are due to mutations that disrupt protein-coding sequences, the use of exome capture to identify allelic variants in rare monogenic disorders is well justified. Furthermore, highly functional variation can also be accounted for by changes in splice acceptor and donor sites, the sequences of which will also be targeted by exome capture.

The major advantage of whole-exome sequencing is that virtually all variants within

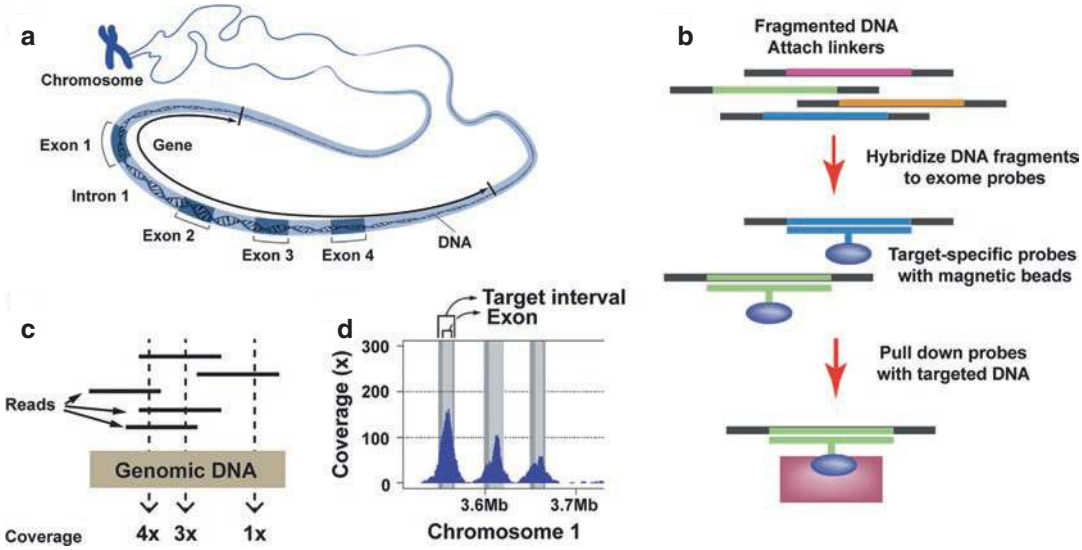

Fig. 4.10 Whole-exome capture and sequencing. (**a**) Representation of a gene and its exons and introns. (**b**) Illustration of the exome capture process. In this case, the oligonucleotide probes designed to specifically anneal to all exons in the genomes are in solution. They are easily pulled out from the solution, the probes are linked to magnetic beads. Another exome capture system has probes attached to a microarray. (**c**) Illustration of the concept of reads and coverage for a small genomic segment. These are key concepts in genomics. (**d**) Illustration of the skewed distribution of read coverage with exome capture to the exonic segments. (**d**) Dr. Murim Choi, Seoul National University)

an individual's genome are uncovered simultaneously. This allows for direct examination of the list of variants and candidate gene selection in the presence or absence of mapping studies. Variant listing depends on several factors that depend on the technology used. For example, the type of capture kit, the sequencing platform, and sequencing depth can influence the variant listing. Additionally, the lists produced will depend on the alignment algorithms and the stringency settings of the bioinformatics tools employed for identifying variants. Capture kits are continuously improving, initially covering 27 Mb and 180,000 coding exons to now up to 62 Mb of the human genome and over 201,121 coding exons. Each platform uses biotinylated oligonucleotide baits complementary to the exome targets to hybridize sequencing libraries prepared from fragmented genomic DNA. These bound libraries are enriched for targeted regions by pull-down with magnetic streptavidin beads and then sequenced.

Whole-Genome Sequencing

Whole-genome sequencing (WGS) involves sequencing the complete DNA sequence encompassing all 6 billion nucleotide bases in 23 chromosome pairs of a diploid human genome [136]. The main difference between WGS and WES is that WGS covers the entire genome, including all exons [137]. As a result, it includes the exome and allows the detection of mutations in noncoding DNA elements that are missed by WES. While we cannot efficiently analyse such mutations right now, it is fair to assume that we will be in a good position to do so in a few years. Once the tools exist to assess noncoding variants, re-analysis of "negative" WGS datasets would be very simple. On the other hand, patients who underwent WES studies that proved uninformative (i.e., no causative coding variant was identified) would have to be studied again with WGS.

Yet another significant advantage over WES is the much improved ability to uncover various types of CNVs, such as insertions, duplications, and deletions [138]. This is possible because of the introduction of paired-end mapping of sequence reads: a CNV is flagged when the 75 bp reads generated from both ends of genomic fragments of known length (~300 bp) are aligned farther (or closer) than anticipated (Fig. 4.11) [139]. The earliest example of genome-wide CNV interrogation using WGS data revealed 1000 large structural variations per genome, which is much more than anticipated [140]. However, the gold standard for a thorough investigation of structural variations remains comparative genomic hybridization (CGH) microarray techniques.

We will use one of the first published WGS studies (based on James Watson's DNA) to illustrate how comprehensive is the dataset created [141]. More than 100 million high-quality short-read sequences were produced, containing a total of 24.5 billion DNA bases. This allowed the investigators to "read" every base of Watson's genome on average seven-times—this is referred to as the "coverage", and the higher it is, the more confident you are that the mutations identified are true. After processing the data with various bioinformatics tools, a total of 3 million high-quality variants were ultimately identified, of which ~10,000 were nonsynonymous mutations (0.3%). More than 65,000 insertions and twice as many deletions were also found in these data.

When compared to WES, one of the biggest challenges of WGS is the substantially larger volume of data generated (estimated to be over 1 TB per genome). This has significant implications because the raw aligned data will typically be stored long-term. The issue is that sequencing costs have decreased much more rapidly than the costs associated with the infrastructure necessary to store and process these data [142]. For example, even when Watson's team was done processing his data back in 2008 [141], they would have to keep the data indefinitely in case reanalysis was deemed necessary. Consequently, teams interested in implementing WGS as opposed to WES have to be ready to face significant challenges with regards to storing data.

Another big challenge is the much higher number of variants identified in a WGS dataset. Indeed, it is not easy to pinpoint the disease-causing variant from the many hundreds of variants that remain after various bioinformatics

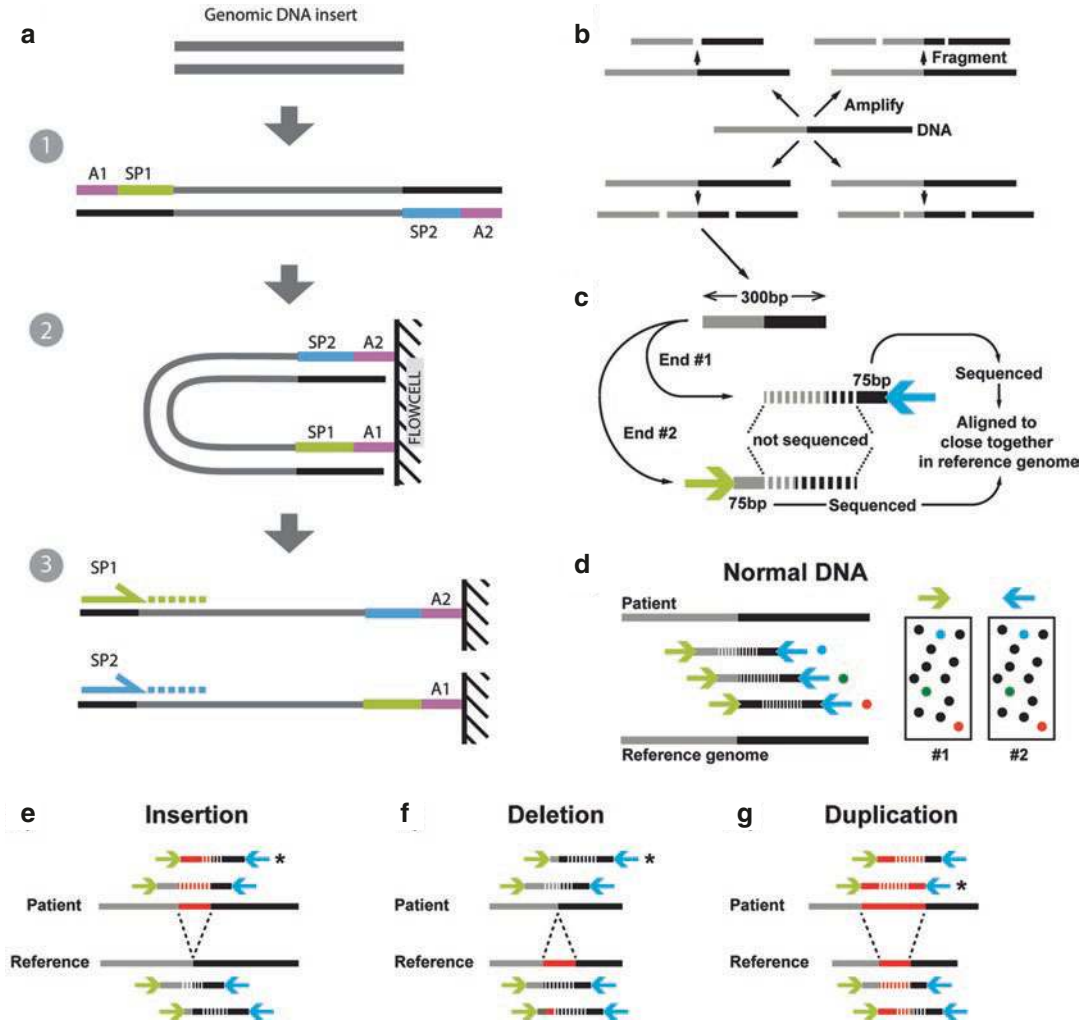

Fig. 4.11 Paired-end sequencing to detect structural variations. (**a**) Preparation DNA sample for standard next-generation sequencing using paired-end. Genomic DNA from the patient were amplified and then fragmented into small pieces. Only fragments with lengths ~200–250 base pairs are selected for sequencing (genomic DNA inserts). The steps described are as follows: (1) Adapter (A1 and A2) with sequencing primer sites (SP1 and SP2) are ligated onto DNA fragments; (2) Template clusters are formed on the flow cell by bridge amplification; (3) Clusters are then sequenced by synthesis from the paired primers sequentially. (**b**) Illustration of amplification of DNA, random fragmentation of amplified segments; in this case, fragments of similar sizes are illustrated. (**c**) Illustration of the two-step process leading to paired-end sequencing. The fragment size selected for is 300 base pairs, and 75 base pairs are sequenced at each end. The dotted lines represent segments that are not directly sequenced in that fragment. (**d**) Schematic showing how paired-end reads from a small genomic region from a patient with normal DNA align to the reference genome. The right-hand side shows the position of the clusters from which the data for each read come from. Each DNA fragment is linked to a specific cluster on the flow cell, thus linking the first and second sequencing data. Also shown are examples of how paired-end sequencing is useful to identify for insertions (**e**), deletion (**f**) or duplications (**g**). (Figure credits: Panel **a**: Figure modified from the original Illumina® paired-end sequencing workflow. All rights reserved)

filters. In comparison, one has to investigate ~50–100 coding variants after filtering WES data.

Furthermore, it will be essential for accurate and comprehensive characterization of disease phenotypes to greatly assist the analysis of an individual's phenotype. It has been shown that the presence of bi-allelic variants can greatly influence a disease phenotype and the data generated by WGS will likely increase our understanding of the molecular intersection of biologically relevant pathways.

As whole-genome is still expensive, currently over £2000 per genome, whole-exome sequencing remains the preferred strategy for molecular genetic diagnosis as this remains a more cost-effective strategy than Sanger sequencing in genetically heterogeneous conditions. However, limitations exist with both technologies and the major challenges posed by both strategies will involve the logistics of delivering genome sequence information to clinicians and how we as clinicians use the data, and how patients and their families deal with the incidental findings.

Clinical Implementation in Nephrology

Finding Pathogenic Mutations for Mendelian Disease

Nowadays, most pediatric nephrologists will send blood samples for genetic testing a few times a year for patients with a wide range of conditions. This may be done to establish a firm molecular diagnosis for a patient, to verify if the relatives are carriers. Non-invasive techniques are also emerging to obtain an antenatal molecular diagnosis from maternal blood [143]. The interested reader is directed to a recent review on the topic of genetic testing applied to nephrology [144].

The first set of investigations is usually to sequence genes known to cause a particular condition to uncover possible pathogenic mutations. Until recently, this was done using PCR amplification and Sanger sequencing of all exons of these genes. However, when the number of genes under investigation is less than 50, the same diagnostic procedure is usually now done using targeted exome sequencing because it is fast, cheap, customisable, widely available, and reliable [145]. The difference between the targeted exome and the whole exome lies in the number of genes investigated at once: all known genes known to cause disease X vs. all genes of the genome. This approach has been applied to various groups of kidney diseases with great success [146]. A gene panel was designed to allow for the rapid discovery of pathogenic mutations in ~4500 genes relevant to genetic conditions with neonatal or infantile onset: "RapSeq" includes many genes that cause renal diseases [147].

Whole-exome sequencing is usually reserved for conditions caused by >50 genes, cases that remain undiagnosed using targeted sequencing panels, or for patients with atypical phenotypes. Recent data suggest, however, that the added benefits of whole-genome sequencing may result in this approach soon becoming the standard test [148]. A clear advantage and yet another challenge of this approach is the ability to interrogate all genes and all noncoding regions at once, and the improved yields for structural variations.

The simplest scenario is when a mutation identified in your patient is described in other patients with the same phenotype. Unfortunately, the alternative scenario is much more common: the report states that there is a variant of "uncertain significance" in one of the genes tested. This means that the genetic testing company, using a systematic approach to evaluate novel variants, cannot determine with high certainty that your

AL Grawany

patient's mutation is causal [149]. With a little extra work, it is however possible to provide families with more information about the pathogenic potential of the variant. We provide a case that illustrates what a pediatric nephrologist can do to evaluate such a report (see clinical vignette). It emphasizes the usefulness of simple concepts that were discussed earlier in this chapter, such as co-segregation, allele frequency, and amino acid conservation.

Physicians need to be prepared to revisit the diagnosis since databases are evolving and should make this clear to the patient and his/her parents. Current protocols used by leaders in the field stipulate systematic rechecks of all datasets every 6 months, with automatic reporting to the ordering physician if new findings emerge [150, 151]. This is critical because as public databases are populated with an increasing number of pathogenic variants over time, the output of bioinformatic analyses performed changes. Table 4.1 shows the significant increase in the number of pathogenic genotypes in HGMD between 2012 and 2020 for congenital nephrotic syndrome caused by *NPHS1* mutations. Thus, an initial negative report from next-generation sequencing testing may yield a firm molecular diagnosis later on. A recent study on millions of genetic tests done for hereditary forms of cancer found that ~25% of variants of uncertain significance were later confidently labelled as pathogenic or benign [152].

Since the criteria for a mutation to be deemed pathogenic are very stringent, one may assume that the interpretation of such a mutation is unlikely to be overturned. However, the curation of mutation databases is surprisingly unreliable: sequencing of ~438 target genes in 52 parent-child trios revealed that ~25% of mutations flagged as "likely pathogenic" (on the basis of being already described as such) were likely to be benign since they were found in healthy, asymptomatic parents [153]. To address this issue (and many others in the field), the NIH created the Clinical Genome Resource, or ClinGen [154]. This group devised a comprehensive and systematic approach to evaluate the robustness of all gene-disease and mutation-disease causal links [155]. The assessment of renal genetic conditions will soon improve as ClinGen recently established a Clinical Domain Working Group on tubulopathies, and another one focused on kidney cystic and ciliopathy disorders (https://peds--renomics.clinic/ClinGen-kidney).

Clinical Vignette

A young patient with a clinical diagnosis of congenital nephrotic syndrome spent many months as an inpatient. Since the parents are first cousins, an autosomal recessive form of CNS was expected; the patient has a 2-year-old female sibling that is apparently healthy (Fig. 4.12). There is no prior family history of CNS. A few months back, your colleagues made sure to send blood samples from all first-degree relatives for genetic testing of the usual CNS gene panel, which includes Sanger sequencing of the genes *NPHS1* and *NPHS2*. You are seeing the patient and his parents today in the clinic to discuss the report issued by the diagnostic laboratory.

Table 4.1 Change in the number of pathogenic *NPHS1* mutations in HGMD between 2012 and 2020

	Yearly data for *NPHS1* in HGMD database								
Mutation types	2012	2013	2014	2015	2016	2017	2018	2019	2020

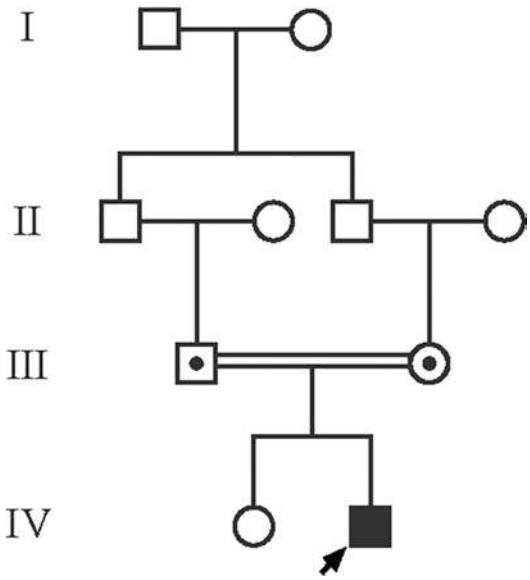

Fig. 4.12 Pedigree for a patient with Congenital Nephrotic Syndrome. Black and white symbols represent affected and unaffected subjects, respectively. Black dots and double lines denote heterozygous carriers and consanguineous unions, respectively. Black arrowhead identifies the proband

The report highlights potentially relevant alterations. The homozygous mutation in *NPHS1* (c.2276 T>C; p.I759T) is considered a "variant of uncertain significance" (VUS) because it has not been described before in other patients with CNS. It is important to note that mutations should always be described with "c." and "p.", which are the base change relative to the cDNA (mRNA) and the resulting amino acid change in the encoded protein, respectively. Not surprisingly, for a novel variant, there are no *in vitro* studies that have tested its functional impact experimentally. We confirmed that the two healthy parents and the unaffected sibling were heterozygous carriers: thus, the pattern of cosegregation is consistent with this mutation being potentially pathogenic. In preparation for our meeting with the family, we decided to investigate further to see if this mutation could be pathogenic. Indeed, finding a convincing mutation in a gene known to be associated with CNS would help our team provide a more accurate prognosis while also providing some closure for the family [156].

First, we visited the public version of the Human Gene Mutation Database (HGMD [157]) to make sure that this mutation remained novel (free registration required for access; Fig. 4.13a). We then confirmed that conclusion using ClinVar (Fig. 4.13b) [158]. These two resources present comprehensive lists of mutations causing Mendelian conditions curated by experts. A major advantage of ClinVar is that it also provides information on the variant of interest if it was reported as VUS by any genetic testing facility or if there are any data in control databases, such as the gnomAD browser (see the bottom of Fig. 4.13b) [159] or dbSNPs [37]. As shown in Fig. 4.13b (bottom panel), ClinVar also reported that the Broad Institute Rare Disease Group reported an unrelated case of congenital nephrotic syndrome with *NPHS1* p.I759T in compound heterozygosity.

To get a better understanding of the pathogenic potential of this variant, we also consulted gnomAD [159]: it was observed in the heterozygous state in 4 out of >125,000 individuals that were all of South Asian descent (like our patient; Fig. 4.13c). This database includes whole-exome and whole-genome data from adults that are unlikely to have a severe pediatric syndrome [159]. Another port of entry to access all this information is dbSNPs [37], particularly if the report includes the rs# associated with the variant (in our case, rs775313529; Fig. 4.13d).

The gnomAD page for the variant includes a wealth of information [159], including the likelihood of it being pathogenic based on two of the most widely used prediction tools, Polyphen [160] and SIFT [161]. There are now dozens of such bioinformatic tools, all claiming to be better than the others. All evaluate the pathogenic potential of missense mutations by using information about the degree of amino acid conservation between various species, the predicted impact of the specific amino acid change (based on physicochemical properties of amino acids, such as size, charge, and polarity) compounded by some advanced computing methodologies (machine learning). An alternative approach is to use software like Condel [162] because it inte-

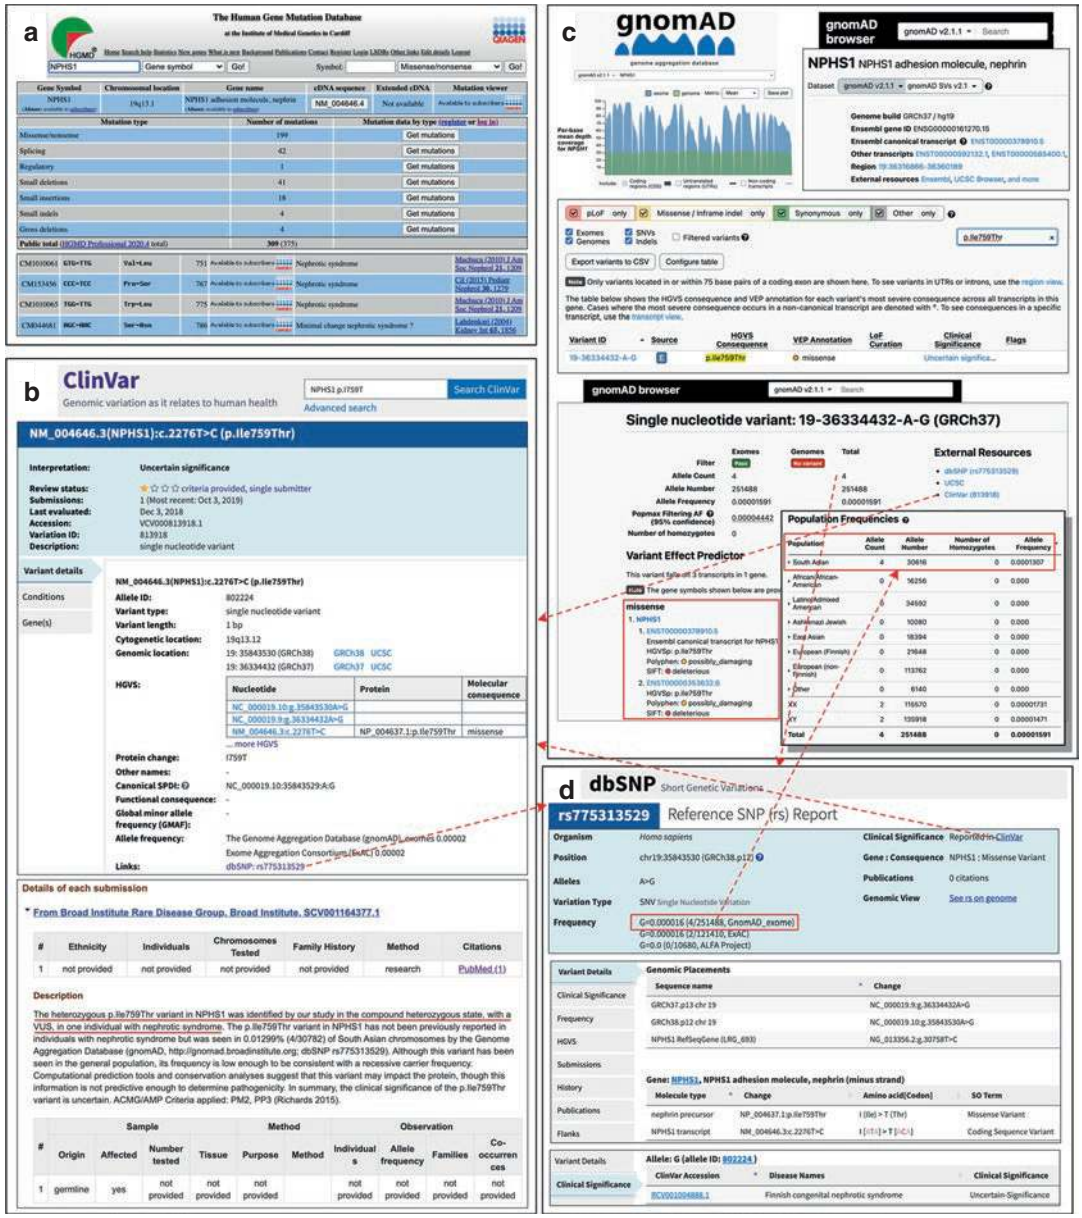

Fig. 4.13 Assessing a variant of uncertain significance in *NPHS1*. (**a**) A visit to the HGMD website suggest that the variant *NPHS1* p.I759T has yet to be reported in a patient. (**b**) While the ClinVar website corroborates this finding, it also suggest that there is one report of a patient with the same variant in the context of compound heterozygosity. (**c**) Data from gnomAD suggest that variant is rare and is only described in South Asian individuals. (**d**) dbSNP is the simplest point of entry to all these data if the genetic test report include the rs#. Note that most of these resources are densely linked to each other (red arrows)

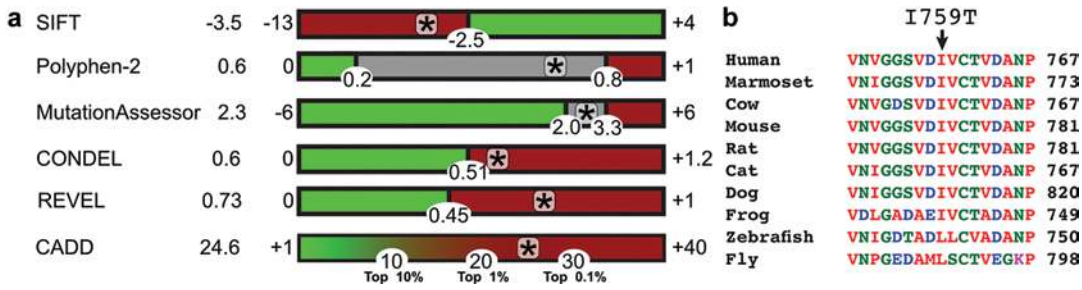

Fig. 4.14 Assessing mutations for pathogenicity with various prediction softwares. (**a**) The ranges of scores for SIFT, Polyphen2, MutationAssessor, Condel, REVEL and CADD. For a mutation to be considered as pathogenic, its score should lie in the red zone of the score gradients. Because all softwares use slightly different inputs and analytical methods, it is not unusual to generate contradictory predictions for the same mutation. (**b**) Multiple species protein sequence alignment was done using BLAST shows that position I759 is well conserved down to the fruit fly (note: leucine and isoleucine are interchangeable). Each letter represents an amino acid; the number on the right-hand side indicates the position of the last amino acid of the series presented in a given ortholog

grates the outputs of Polyphen [160], SIFT [161] and MutationAssessor [163] (Fig. 4.14a). Newer tools that attempt to further refine the output include CADD [164] and REVEL [165] (Fig. 4.14a). Interestingly, the isoleucine at position 759 is well conserved across orthologs, down to the fruit fly (Fig. 4.14b).

Overall, it is likely that this VUS will soon be upgraded to "pathogenic" on the basis that it was found in two unrelated patients with congenital nephrotic syndrome, familial cosegregation analysis was consistent with a recessive mode of inheritance (as expected), the mutated amino acid is well conserved, the mutation is only observed in the heterozygous states with very low MAF in South Asians (0.01%), and most prediction softwares predict that p.I759T should be deleterious.

Genetic Heterogeneity

Genetic (or locus) heterogeneity is recognized when a particular phenotype may be caused by mutations in different genes. Nephronophthisis is one of the best examples of locus heterogeneity in the renal literature, with disease-causing mutations reported in ~30 genes (Table 4.2). Functional studies have shown that the majority of the proteins encoded by these genes are localized and play important roles at the centrosome, basal body, and cilia. This led to the proposition that these structures are central in the pathogenesis of nephronophthisis [166]. It is important to note that locus heterogeneity is common among many monogenic renal conditions, such as atypical hemolytic-uremic syndrome [167], nephrotic syndrome [168], distal renal tubular acidosis [169], Dent's disease [170], or primary hyperoxaluria [171].

Pleiotropy is the mirror image of genetic heterogeneity: mutations in the same gene cause different phenotypes. Incidentally, nephronophthisis also provides many well-documented cases of pleiotropy (Table 4.1). For example, the study of patients with unique phenotypes within the nephronophthisis spectrum using whole-exome sequencing led to the identification of novel candidate genes that were previously associated with completely distinct disorders, such as *SLC4A1* or *AGXT* [172]. The first gene, which encodes the anion exchanger 1 protein, was previously associated with hereditary spherocytosis [173] or distal tubular renal acidosis [169], while the second one is a well-established cause for primary hyperoxaluria (it encodes an enzyme involved in glyoxylate metabolism) [171].

Interestingly, a substantial number of patients with nephronophthisis (~40%) remain genetically undefined. The same is true for many other renal conditions. This will prove to be a fertile

ground to display the utility of whole-exome and/or whole-genome sequencing and will undoubtedly lead to the identification of many other unexpected candidate genes [174, 175].

Finding Risk Alleles for Complex Diseases

One of the promises of genomic medicine is for knowledge about a patient's genome to play a central role in the management of complex medical conditions. Classic examples of complex diseases include essential hypertension, diabetes mellitus type 2, steroid-sensitive nephrotic syndrome, and congenital malformations of the kidney and/or urinary tract. For example, pediatric nephrologists could optimize the prevention and/or treatment of steroid-sensitive nephrotic syndrome, thus realizing the guiding principles of personalized medicine. While this will undoubtedly change the face of clinical medicine, as described below, we are unfortunately years away from enacting this scenario.

In contrast to Mendelian conditions that are caused by highly penetrant mutations in a single gene, complex diseases are not rare and are caused by multiple factors. Detailed epidemiological

studies have shown that for many of these conditions, environmental and genetic factors are the major determinants of trait expression. Current models implicate the interaction of multiple low penetrance variants in many genes. These are based on studies of heritability, defined as the fraction of phenotypic variation that is likely explained by genetic variation [176]. Heritability is estimated from the phenotypic correlations among related individuals, using families with multiple affected individuals as well as twin studies. A prime example of a complex trait with high heritability is adult essential hypertension [177].

Finding the genetic basis for complex traits could have significant public health implications. First, it may help identify at-risk individuals early on, thereby perhaps allowing for the prevention of long-term, largely preventable health consequences. Second, it may be an important tool to decide the type and dose of medication that is best suited for a given patient, which would be a major advance towards the realization of personalized medicine. Below, we will discuss the two competing theories of complex trait genetics and the methodologies employed to find associations, while providing examples from the renal literature.

Complex Diseases: Associated with Common and/or Rare Variants?

There are two predominant explanatory models of complex disease genetic causation: the complex disease, common variants (CDCV) and the complex disease, rare variants (CDRV) hypotheses (see Fig. 4.15) [178]. Both assume that multiple genes are implicated in the pathophysiology of common traits. The first hypothesis states that the genetic landscape of common traits mostly comprises common variants (minor allele frequency >1%), each with a very small contribution to the overall phenotype. The alternative hypothesis suggests that rare variants (minor allele frequency <1%) with larger effects are largely responsible. Up until recently, the technology to perform the comprehensive genomic analyses required to unravel the genetic architecture of complex diseases did not exist: the predominant working model was CDRV.

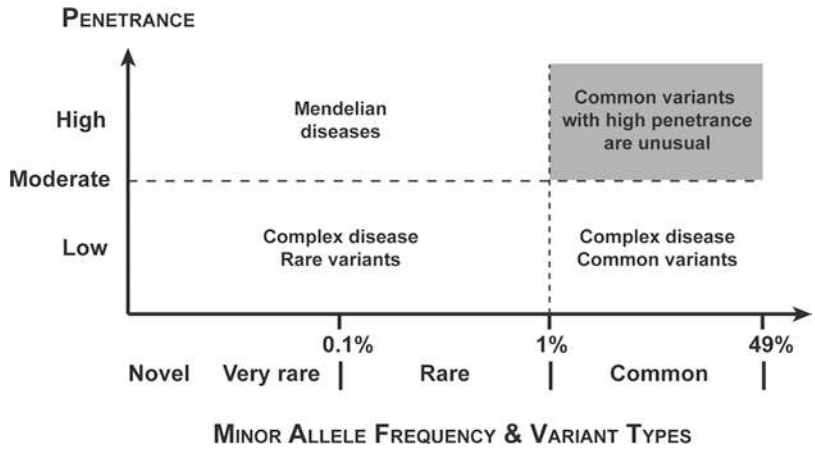

Fig. 4.15 The relationship between minor allele frequency and penetrance to explain the genetic basis of complex diseases. This graph illustrates the relationship between minor allele frequency and penetrance of phenotype. Typically, common variants that have a phenotypic effect have low penetrance. On the other hand, rare variants are expected to result in a much higher penetrance. This is due to the fact that penetrance is one of the main factors driving the selective pressure for/against a particular phenotype. Most variants identified thus far for Mendelian conditions are in the left upper quadrant, while those associated with complex diseases fit in the right lower quadrant

The CDCV hypothesis was the first to be tested rigorously owing to technological and methodological developments related to SNPs genotyping. This opened the gates for a flurry of genome-wide association scans (GWAS) performed on common SNPs. Reliable investigations of the CDRV hypothesis were beyond reach until the emergence of cheap high-throughput sequencing and the development of exome capture.

Clinical Implications of Genome-Wide Association Studies

Most of the GWAS studies focused on renal conditions include only adult subjects [113]. Some studies were focused on dichotomous disease outcomes, such as hypertension, diabetic nephropathy, IgA nephropathy, CKD, ESKD/FSGS and kidney stones [113]. Others tested the association with relevant continuous variables like blood pressure, eGFR, serum creatinine, creatinine clearance, albumin-to-creatinine ratio, or serum cystatin C [113]. Unfortunately, there are few variants showing robust association with a given trait that is replicated across distinct studies. These SNPs typically explain very little of the phenotypic variability observed in patients: this phenomenon, which is not unique to nephrology studies, has been termed "missing heritability" [179]. Many of these studies have, however, provided unique insights into the biological pathways that cause disease that were hitherto immune to detection [180].

There are now a few published GWAS that enrolled children with kidney disease [181]. As a result of this research lag, children may not benefit from the realization of genomic medicine as rapidly as adult patients [182]. Indeed, it is likely that advances percolating from adult studies will not translate into concrete measures for children for two main reasons. First, the important pediatric public health problems that could be addressed "genomically" are not on the adult medicine "radar" (e.g., nephrotic syndrome). Second, even when diagnoses are congruent (e.g., hypertension), it is unclear how useful results from large adult studies will apply to pediatric care since the underlying pathophysiology is often distinct (due to growth and development) [183, 184].

Thankfully, this state of affair is changing. The first GWAS, which included more than one thousand children with CKD, was inconclusive because of low power [185]. A number of small GWAS (sample sizes <500) focused on nephrotic syndrome yielded statistically significant SNPs, particularly in the HLA genes [186–189]. The largest GWAS published in 2020, which included many of the subjects from earlier cohorts, confirmed this association and also uncovered new loci of interest in the regions of *NEPHS1-KIRREL2* and *TNFS15* [190].

Source of Missing Heritability: Rare Variants?

A substantial proportion of the genetic contribution to complex traits thus remains unexplained. The next logical step is to determine the impact of rare variants on such phenotypes using whole-genome or -exome sequencing [191]. Unfortunately, because the variants are rare, the sample sizes required to draw conclusions are prohibitively large (10,000–100,000 subjects at a minimum) [192, 193]. As a result, few studies testing the CDRV hypothesis have been published [194]. Other aspects that could also play a role in the pathophysiology of complex traits include epigenetic factors [195], gene-gene interactions (epistasis) [196], and/or gene-environment interactions [197]. An alternative explanation recently put forward is that heritability may have been overestimated all along [198]. Finally, the complexity of the underlying genetic architecture of these diseases may be such that it is not possible to unravel with our current experimental tools [199].

Pharmacogenetics/Pharmacogenomics

Most current studies attempt to link genetic polymorphisms in a small number of genes with

known functions in drug metabolism. As such, they establish the pharmacogenetic profiles for patients. Very few studies, particularly when enrolling pediatric subjects, perform pharmacogenomic profiling, which involves genome-wide interrogation. One of the major promises of personalized medicine is that drug prescriptions will be tailored based on a patient's pharmacogenetic profile. This promise is within reach because of the extensive knowledge accumulated about two of the key determinants of drugs' pharmacokinetic and pharmacodynamics properties.

First, a group of enzymes add specific chemical groups to the parent compound: this way, drugs are metabolized to their active form, or they are modified to enhance excretion. Cytochrome P-450 oxidases (CYP) and uridine diphosphate-glucuronosyltransferase (UGT) are two of the most prominent families of enzymes of this class. The second class are transporters that mediate the efflux of drugs outside of cells, thereby limiting their therapeutic benefits. Many great examples are provided by transporter proteins that are part of the ATP-binding Cassette (ABC) superfamily. The other key development is the increasing knowledge about the physiological impact of SNPs in genes encoding proteins that play important roles in both of these processes. Below, we will describe issues that relate specifically to the realization of pharmacogenetics for pediatric nephrology patients, while also providing concrete examples from the literature.

Four main issues plague the field of pediatric pharmacogenetics in general. First, the vast majority of pharmacogenetics studies are done exclusively on adult subjects. Unfortunately, these findings cannot be directly extrapolated to children because of the impact that growth and development have on pharmacologic parameters. Second, there are currently very few studies reporting specifically on the association of genetic polymorphisms with pharmacologic parameters in pediatric subjects. Third, the predictive power of most pediatric studies is effectively limited by small sample sizes (typically less than 100). Finally, all studies conducted thus far are retrospective and have not been able to test if the inclusion of pharmacogenetic data influences outcomes. It is therefore not surprising that there are currently very few tests that are ready for prime time for pediatric patients.

In both adult [200] and pediatric nephrology [201], the most active research in pharmacogenetics relates to key agents used in current renal transplantation cocktails. Calcineurin inhibitors were logical candidates for such studies since they have proved to be valuable as steroid-sparing agents but are known to cause significant level-dependent nephrotoxicity. A single study with 104 pediatric kidney transplant recipients treated with cyclosporin showed no evidence that genotyping for polymorphisms in genes from the CYP and ABC families helped optimize patient care [202]; these results largely echo the consensus opinion derived from similar adult studies [200]. In contrast, the implementation of pharmacogenetic profiling is probably closer to reality for tacrolimus: testing for polymorphisms in *CYP3A5* identified in adult studies [200] were found to be predictive when tested in 30 teenage kidney transplant recipients [203]. There are also data from two small studies on pediatric kidney transplant recipients treated with MMF that report promising associations with UGT polymorphisms that require corroboration [204, 205].

Two additional hurdles will complicate the implementation of pharmacogenetics specifically in renal transplant protocols. First, the benefits of genotyping above and beyond the current gold standard will have to be demonstrated. This may prove a difficult task since therapeutic drug monitoring (TDM) of various immunosuppressive medications allows personalization of doses within days to weeks [200]. There is evidence that at least in adult patients, pharmacogenetics leads to more rapid optimization of drug dosage, but it does not appear to translate into better outcomes [206]. Second, the ability of any predictive indices, including pharmacogenetics, to impact clinical outcomes will always be hampered by the polypharmacy that is inherent to most renal transplant drug cocktails because of complex drug-drug interactions [200].

Warfarin is yet another medication relevant to pediatric nephrologists that has been extensively studied for pharmacogenetic applications.

Studies in adult subjects have shown that polymorphisms in the genes encoding the target of warfarin, *VKORC1* (vitamin K epoxide reductase complex subunit 1) or its main metabolizing CYP (*CYP2C9*) are helpful to predict warfarin disposition [207]. Data emerging from pediatric studies testing the same polymorphism are unfortunately not as clear [208].

While pharmacogenetics offers the potential of individualized treatment strategies, it is critical to obtain solid evidence of clinical utility before widespread clinical implementation. A great source of information for interested physicians is the Clinical Pharmacogenetics Implementation Consortium (CPIC), a project aimed at addressing "some of the barriers to the implementation of pharmacogenetic tests into clinical practice".

Barriers to Implementation in the Clinic

There is a lot of hype and high expectations that remain largely unrealistic. Apart from the diagnosis of rare diseases and some rare applications in pharmacogenomics, the real-world impact of genomics has yet to be shown in the clinic. Notwithstanding the knowledge limitations that are inherent in the implementation delays, there are a number of other issues that will hamper this process, some of which are discussed below.

Patients' Health Literacy and Numeracy

Adequate health literacy skills are necessary for patients to understand a discussion about genomic issues and to appropriately consent for testing. Health literacy is defined as "the degree to which individuals can obtain, process, and understand the basic health information and services needed to make appropriate health decisions" [209]. A survey of general US adults demonstrated poor health literacy in ~30–40% [210]. Not surprisingly, the situation is even worse when these skills are assessed in the context of genomics issues [211]. Apparent familiarity with genetic concepts is common in adults, but physicians should be alert to the fact that understanding of basic genetic concepts is often limited [212].

Health numeracy skills are also critical for patients to grasp the predictive nature of most discussions that relate to genomic health decisions. Indeed, statistics and probabilities are an integral part of these discussions. Health numeracy is defined as "the degree to which individuals have the capacity to access, process, interpret, communicate, and act on numerical, quantitative, graphical, biostatistical, probabilistic health information needed to make effective health decisions" [213]. A recent survey revealed that ~50% of adult subjects have basic or minimal numeracy skills [210]. In contrast to health literacy, this subject has been little studied [211].

While these issues cannot be ignored, they should not jeopardize patient care. Given that time is limited in the clinic, it may not be possible for the treating physician to spend time explaining basic concepts. The critical point is to rapidly assess if the patient (or their caretaker) has at least a basic understanding of the issues at stake and take measures to try to address perceived inadequacies. If the family has access to the Internet and is motivated to learn independently, the physician may provide the address of reputa-

ble websites focused on teaching basic genetic concepts to a general audience (see the list below).

Physicians' Health Literacy and Numeracy

Another important issue that is emerging is the gap between what physicians will need to know to implement genomic science in clinical practice, and what they actually know [1, 214]. Given the scarcity of healthcare professionals with expertise in genetics and genomics [215], which is unlikely to change in the next few years, it is possible that these inadequacies may hamper the deployment of genomic medicine when it is ready for widespread implementation. There are many resources in the literature [1], in print and online (see the list below) that may help bridge that gap for practicing physicians.

While most physicians agree that a good understanding of basic statistical concepts is necessary in contemporary medicine, very few feel confident of their own skills [216]. This is a long-standing problem that has been repeatedly documented in Europe and North America [217–219]. Up until recently, these skills were deemed important by physicians espousing the principles of evidence-based medicine. The advent of genomic medicine will hopefully trigger a renewed interest for physicians to acquire basic quantitative skills. Medical schools have adapted their curricula to reflect these changes such that current physicians-in-training will be better prepared [220–222].

Test Costs and Gene Patents

Both governmental programs and insurance companies will usually agree to defray the costs of tests that are ordered by physicians, are relevant to the patient's condition, and may lead to a con-

crete change in the plan of care. Ideally, the cost of tests would not play a major role in this decision, but up until recently, it did for a few genetic tests that were prohibitively expensive (thousands of dollars). These high prices were driven in large part by the strict enforcement of gene patents held by a few companies. For example, the price of BRCA1 and 2 tripled once the company Myriad Genetics decided to exercise a strict monopoly on its gene patents [223].

Since ~40% of the human genes have been patented [224], this has the potential to be a major hurdle in the development of personalized medicine based on genomic testing [225]. This situation changed dramatically following the US Supreme Court judgment that invalidated the gene patents held by Myriad Genetics [226].

Demonstration of Efficacy and Cost-Effectiveness

With the gene patent barriers now down and cheap sequencing being available, the next big obstacle to the promised widespread clinical implementation of genomic tests [227] will be the demonstration of efficacy and cost-effectiveness for common conditions [228]. At the request of the CDC, a committee of experts proposed to use a specific set of criteria to assess whether a particular genetic test ought to be implemented in the clinic. It is referred to as ACCE, an acronym that reflects the four criteria that need to be fulfilled: Analytical validity, Clinical validity, Clinical utility, and associated ethical, legal, and social implications.

As seen in Fig. 4.16, this is an ambitious task that requires the integration of data from many different spheres of expertise. Genomic tests will also need to be analysed using the ACCE multifaceted approach: this will likely prove to be a lengthier process since, in theory, each gene-disease combination will undergo a similar in-depth examination. The CDC also formed another committee, named Evaluation of Genomic Applications in Practice and Prevention (EGAPP), that is aimed at the prospective integration of published data within the ACCE framework [229].

It is sobering to review the most up-to-date EGAPP recommendations, which are focused only on common diseases with a significant public health burden: there is “insufficient evidence to recommend for or against the use” of well-studied genetic tests for breast cancer, cardiovascular disease, depression, diabetes, and prostate cancer [230]. In fact, only genetic testing for KRAS mutations in colorectal cancer fulfils all requirements. Children are typically not mentioned in articles on this topic; if they are mentioned, it is as part of the subjects that are excluded [231].

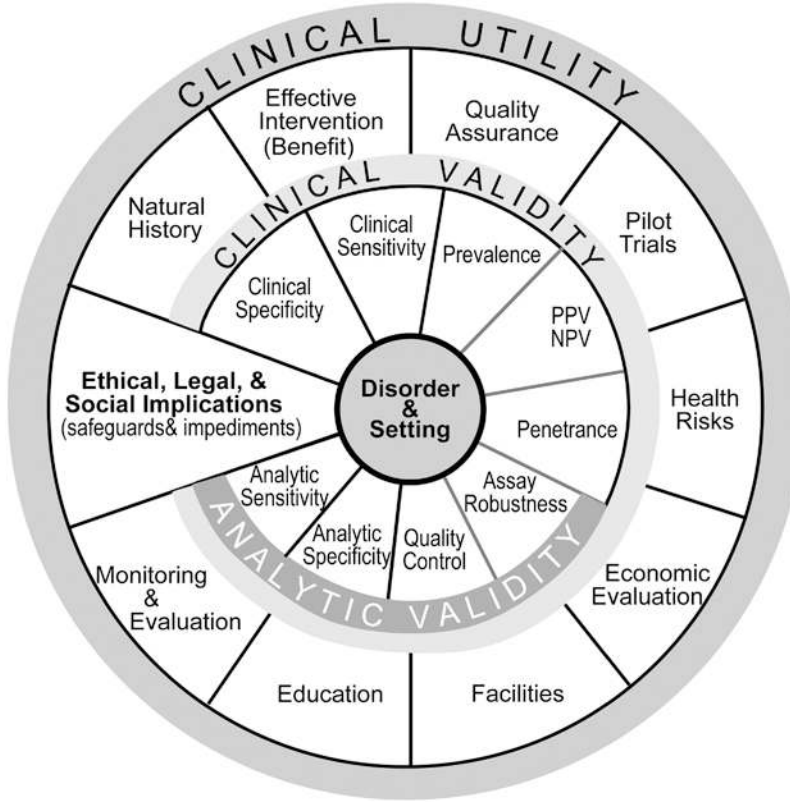

Fig. 4.16 Illustration of the ACCE framework used to evaluate genetic tests. Evaluation of genetic tests with ACCE is based on four criteria: analytic validity, clinical validity, clinical utility and associated ethical, legal and social implications (ELSI). It is meant to be an up-to-date source of information for policymakers to allow informed decision-making. This figure illustrates the various components that are studied for each category. Analytical validity is defined as how accurately and reliably the test measures the genotype of interest. Clinical validity is defined as how consistently and accurately the test detects or predicts the intermediate or final outcomes of interest. Clinical utility is defined as how likely the test is to significantly improve patient outcomes. ELSI is defined as the ethical, legal, and social implications that may arise in the context of using the test. (Figure credits: CDC, https://www.cdc.gov/genomics/gtesting/acce/index.htm)

Ethical and Legal Issues

As the clinical use of sequencing technologies becomes increasingly widespread, practicing nephrologists should expect to have to deal with a new set of issues when discussing results with their patients. With the price of whole-exome and/or exome sequencing decreasing over time, these technologies have now supplanted current approaches that are more targeted, such as Sanger sequencing. This is a dramatic change in practice since clinicians will now have to deal with genome-wide data that are not restricted to genes known to be associated with a given condition. With these changes comes a complex set of issues that every physician is likely to encounter in the near future. These include dealing with mis-attributed paternity and handling incidental genetic findings. Physicians should also be able to discuss how genomic medicine may affect patient privacy and how these results may lead to genetic discrimination. Below, we provide a brief introduction to these concepts that will provide interested physicians with a good starting point or springboard to learn more about these topics. The interested readers are directed to more in-depth reviews on these topics [232, 233].

Mis-attributed Paternity

One important consideration when performing genetic testing is to be cognizant of the fact that misattributed paternity, also referred to as non-paternity, is observed in ~10% of tested individuals (range 1–30%) [234]. In the clinical arena, this problem will be encountered in two main scenarios. First, in the context of HLA testing when assessing parents as potential organ donors [235]. The other situation is when diagnosing a genetic condition, particularly if it is a recessive disease and the father does not harbour the mutation [236].

The treating team should strongly consider consulting a medical geneticist or a genetic counsellor since they are trained to handle these situations. In addition, they can help to calculate and interpret the paternity index, the most useful measure of paternity testing [237]. This method relies on genotyping of 10–15 additional loci for each member of the trio, the assumption being that: each parent shares ~50% of the variants with their child. Rarely, a paternally inherited de novo mutation may explain these findings when paternity testing confirms that the father is indeed genetically related to the patient.

In most jurisdictions, there are no guidelines, rules, or laws that dictate what a clinical team should do in these circumstances. Proponents of nondisclosure emphasize the importance of non-maleficence, while those that advocate for disclosure invoke respect for patient autonomy and truth telling [238]. Treating physicians should be aware that nearly all genetic specialists in the US [239] or abroad [240] have consistently favoured disclosure, but only to the mother. This was also the recommendation from a report published by the Institute of Medicine in 1994 [241].

Medically Actionable Variants

Another dilemma that stems from the introduction of genome sequencing in the clinic is how incidental genomic findings, also known as "incidentalomas", should be handled. This dilemma is particularly acute when dealing with so-called "medically actionable pathologic mutations". These are defined as variants in genes known to be associated with severe Mendelian diseases for which there is good evidence of benefit from specific preventive measures or therapies. A debate on whether one has a duty to report such findings has been raging for a few years in the genetic research community: a recent consensus opinion states that such findings should be reported to subjects who have a priori consented to receive information about incidental findings [242]. The debate is now overflowing to the clinical world.

Recently published policy guidelines put forth by the American College of Medical Genetics recommend mandatory reporting of variants found via clinical sequencing and deemed to be likely pathogenic in 57 genes associated with 24 monogenic conditions [243]. In stark contrast to the research guidelines mentioned above, these incidental findings would have to be reported to patients even if they did not consent to receive this information. While providing valuable information to patients and their families, the enactment of these guidelines would add extra work that may not be accommodated easily by the current clinical workforce. Interrogation of whole-genome sequencing data from 500 Caucasians and 500 African-American "healthy" adults revealed that ~1–3% of subjects tested harbour at least 1 mutation in one of these genes [244]. Adjudication of which incidental findings are actionable is not straightforward [245].

Importantly for pediatricians, these recommendations make no exception regarding children, even for genes that cause adult-onset conditions [243]. This suggestion is based on the fact that it may be critical for the parents themselves to know about these incidental findings. It is predicted that more restricted reporting of such variants will be recommended for children once clinical sequencing becomes more widespread: indeed, this argument will be moot when the parents also have their own sequencing data [243]. Table 4.3 provides a list of genes that are relevant to the practice of pediatric nephrologists: all follow an autosomal dominant pattern of inheritance and are the primary cause for a variety of cancers [243]. A recent study on more than 2000 adults

Table 4.3 Conditions and/or syndromes with clinically actionable mutations that are relevant to pediatric nephrologists

Conditions	Gene	OMIM #	Patients affected	Mode of inheritance	Clinical impact
VHLS	VHL	193300	Child/adult	AD	Known and expected
MEN type 1	MEN1	131100	Child/adult	AD	Known and expected
MEN type 2	RET	171400, 162300	Child/adult	AD	Known
HPPS type 1	SDHD	168000	Child/adult	AD	Known and expected
HPPS type 2	SDHAF2	601650	Child/adult	AD	Known
HPPS type 3	SDHC	605373	Child/adult	AD	Known and expected
HPPS type 4	SDHB	115310	Child/adult	AD	Unknown
TSC type 1	TSC1	191100	Child	AD	Known and expected
TSC type 2	TSC2	613254	Child	AD	Known and expected

NF type 2	NF2	101100	Child/adult	AD	Known and expected

HPPS hereditary paraganglioma-pheochromocytoma syndrome, *MEN* multiple endocrine neoplasia, *NF* neurofibromatosis, *TSC* tuberous sclerosis complex, *VHLS* von Hippel-Lindau syndrome

with CKD who underwent exome sequencing revealed that 1.6% had a medically actionable variant [144].

Privacy

All physicians are keenly aware that patient privacy is paramount. Most are also cognizant of data that could be used as unique identifiers: name, birth date, home address, social security number, etc. When stripped of these data, samples or datasets are deemed deidentified. Like most pediatric subspecialists, pediatric nephrologists routinely take care of patients with very rare conditions. For such patients, it is unclear how "deidentified" the information really is if the diagnosis is part of the data that may be shared. For example, the inclusion of this information in public databases could lead to the de facto identification of a specific patient, particularly if the condition is associated with a visible phenotype. For this reason, some jurisdictions have added rare (UK) or unique (USA) characteristics of patients to the list of unique identifiers [246].

One recent challenge to the privacy of patients stems from the emergence of genomic medicine because genomic data is not considered as a unique identifier per se. This is likely to become even more challenging as the pressures from the research community grow to have as many genomes available publicly as possible [247]. Given the fact that humans differ at ~0.1% of the 3.2 billion bases of the genome, and given a world population of 6 billion, current estimates show that genotyping data from 30 to 80 alleles would be sufficient to provide unique genomic fingerprinting for every individual [248]. This number is amazingly small when compared to the datasets from whole-exome and whole-genome sequencing, which provide thousands of such alleles. Thus, reidentification of a deidentified dataset is simple if one can genotype a sample obtained from an individual that may then be used to find a perfect match against all available genomic datasets (or near-perfect match for close relatives).

In a recent tour-de-force, it was shown that it is possible to trace the original subject linked to a particular genomic dataset by combining the analysis with data from publicly available genealogical databases [249]. The "investigator hackers" were able to do this with the following publicly available information in hand: whole-genome sequencing data, gender (males), age when the samples were provided, and state where the men lived at the time (Utah).

As front-line responders deal with keen parents who are very likely to use the internet to find health information [250], pediatricians should be prepared to answer questions about the impact of genomic medicine on the privacy of their patients. The current status is that there is still considerable uncertainty in the field, but the consensus

appears to be that complete deidentification of genomic datasets is far more complex than expected [251].

Genetic Discrimination

The rapid developments in the sequencing and analysis of genomic information have forced a debate about the potential real-life consequences for patients when it is used in the clinic [252]. The reporting of diagnostic and/or incidental findings opens the door to genetic discrimination, which is defined as an "adverse treatment that is based solely on the genotype of asymptomatic individuals" [253].

Knowledge about genetic or familial risks for a variety of diseases has been used to justify health insurers' refusal of at-risk patients [254] or employers' dismissal of potential or current employees [255]. Most European countries have enacted legislation against this type of discrimination since the 1990s [256]. The US congress followed suit in 2008 with the passage of the Genetic Information Nondiscrimination Act (GINA) [257]. Canada remains the only G8 country without such legislation, and Canadians are routinely refused life and/or disability insurance because of genetic risk factors [258]. Similar problems also occur in other developed nations with national health care systems, such as Japan [259] or Australia [260].

All pediatricians ordering genetic tests for their patients should seek information about the current legal framework in their country as these may have immediate implications for the family as a whole. These issues should ideally be discussed with the family before ordering the tests.

Direct-to-Consumer Testing of Presymptomatic Minors

The first direct-to-consumer (DTC) genetic testing companies started to operate more than 10 years ago. Up until recently, they existed in a legislative void: because the tests used were developed internally (known as "home brews"), they are exempt from the tight regulations that apply to most diagnostic tests [261]. As a result of this, they were able to offer tests of questionable value, without oversight and without interaction with a healthcare professional before or after testing [262]. Once it became clear that thousands of people were paying for these services, regulatory bodies in many countries started to pay closer attention to the products offered by these companies [263], but changes in regulation have been slow to come [264]. The interested reader is directed to recent exhaustive reviews for more details on this complex topic [265, 266]. In this discussion, we will focus on issues that relate to DTC testing when applied specifically to children.

Many direct-to-consumer (DTC) genetic testing companies, most notably 23andMe, agree to perform pre-symptomatic or predictive genetic testing on children [267]. This is in direct contradiction with the professional guidelines promulgated by most professional organizations, which state that such tests should only be performed once the child can provide informed consent for themselves [268]. Additional concerns raised by the behaviour of DTC companies are that there is no requirement for these findings to be medically actionable (i.e., at a minimum, a way to prevent or treat the condition must exist to offer such tests to minors) [267]. The FDA has been investigating to determine whether tighter regulations are necessary for these companies.

A pediatrician should expect to be asked for advice regarding performing DTC genetic testing on their patients, or they may be asked to help interpret the results of such tests [269]. It may also lead to new consultations for asymptomatic children because a number of renal conditions are included in mainstream DTC reports (for example, carrier status for ARPKD, primary hyperoxaluria type 2, and tyrosinemia type 1). Since DTC companies do not spend time explaining the ethical and legal issues that stem from such testing (discussed above), the onus will be on the treating physician to do so. Unless clinically indicated, pediatricians should strongly consider refraining from ordering additional diagnostic tests triggered solely from the results

of DTC genetic testing as the clinical validity of many of the findings has yet to be established [270]. In a significant turn of events, the US Federal Drug Administration (FDA) asked 23andme to stop marketing these tests to consumers starting in November 2013; the FDA will now require DTC genomic companies to undergo regulatory clearances that are typical for genetic tests used in the clinic.

Glossary

Alleles Alternative forms of a gene at the same locus.

Alternative splicing Formation of diverse mRNAs through differential splicing of an mRNA precursor.

Autosome Any chromosome (1–22) other than the sex chromosomes X and Y.

cDNA, complementary DNA DNA sequence that contains only exonic sequences and was made from an mRNA molecule.

Centimorgan Length of DNA that on average has 1 crossover per 100 gametes.

Cis Location of two genes/changes on the same chromosome.

Codon Three consecutive bases/nucleotides in DNA/RNA that specifies an amino acid.

Compound heterozygote Individual with two different mutant alleles at a locus.

Consanguineous Mating between individuals who share at least one common ancestor.

Conservation Sequence similarity for genes present in two distinct organisms or for gene families; can be detected by measuring the sequence similarity at the nucleotide (DNA or RNA) or amino acid (protein) level.

Crossover Exchange of genetic material between homologous chromosomes during meiosis.

Digenic inheritance Two genes interacting to produce a disease phenotype.

Diploid Chromosome number of somatic cells.

Domain Segment of a protein associated with a specialized structure or function.

Dominant Trait expressed in the heterozygote.

Downstream Sequence that is distal or 3′ from the reference point.

Empiric risk Recurrence risk based on experience rather than calculation.

Epigenetics Term describing non-mutational phenomena (e.g., methylation and acetylation) that modify the expression of a gene.

Euchromatin Majority of nuclear DNA that remains relatively unfolded during most of the cell cycle and is therefore accessible to transcriptional machinery.

Exon Segment of a gene (usually protein-coding) that remains after splicing of the primary RNA transcript.

Expressivity Variation in the severity of a genetic trait.

Genotype Genetic constitution of the organism; usually refers to a particular pair of alleles the individual carries at a given locus of the genome.

Germline Cell lineage resulting in eggs or sperm.

Germline mutation Any detectable, heritable variation in the lineage of germ cells transmitted to offspring while those in somatic cells are not.

Gonadal (germline) mosaicism Occurrence of more than one genetic constitution in the precursor cells of eggs or sperm.

Haplotype Group of nearby, closely linked alleles inherited together as a unit.

Heterozygote Person with one normal and one mutant allele at a given locus on a pair of homologous chromosomes.

Homozygote Person with identical alleles at a given locus on a pair of homologous chromosomes.

Imprinting Parent-specific expression or repression of genes or chromosomes in offspring.

Intron Segment of a gene transcribed into the primary RNA transcript but excised during exon splicing, thus does not code for a protein.

Isodisomy, uniparental Inheritance of two copies of one homologue of a chromosome from

one parent, with loss of the corresponding homologue from the other parent.

Karyotype Classified chromosome complement of an individual or a cell.

Lyon hypothesis (X inactivation) Principle of inactivation of one of the two X chromosomes in normal female cells (first proposed by Dr. Mary Lyon).

Mendelian Following patterns of inheritance originally proposed by Gregor Mendel.

Monogenic disorder Caused by mutations in a single gene.

Mosaicism Occurrence of more than one genetic constitution arising in an individual after fertilization.

Multifactorial disorder Caused by the interaction of multiple genetic and environmental factors.

Mutation Change from the normal to an altered form of a particular gene that has harmful; pathogenic effects.

Oligogenic inheritance Character that is determined by a small number of genes acting together.

Penetrance Frequency with which a genotype manifests itself in a given phenotype.

Phenotype Visible expression of the action of a particular gene; the clinical picture resulting from a genetic disorder.

Pleiotropy Multiple effects of a single gene.

Polymerase chain reaction (PCR) Amplification of DNA using a specific technique that allows analysis of minute original amounts of DNA.

Polymorphism Usually used for any sequence variant present at a frequency greater than 1% in a population.

Recessive A trait expressed only when both alleles at a given genetic locus are altered.

Recombination Separation of alleles that are close together on the same chromosome by crossing over of homologous chromosomes at meiosis.

SNPs (single nucleotide polymorphism) Usually used for any sequence variant present at a frequency greater than 1% in a population.

Somatic Involving the body cells rather than the germline.

Syndrome, genetic Nonrandom combination of features.

Teratogen Any agent causing congenital malformations.

Trans Location of two genes/changes on opposite chromosomes of a pair.

Transcription Production of mRNA from the DNA template.

Translation The process by which a protein is synthesized from an mRNA sequence.

Tools for Kidney Tissue Analysis

5

Anette Melk

Introduction

The gold standard for renal tissue analysis is the kidney biopsy. It is routinely performed to allow histological diagnoses of kidney diseases and determine the extent of damage in native and allograft kidneys. However, there has been controversy over the use and interpretation of kidney biopsies. Issues include sampling errors and reproducibility between different observers. More importantly, histopathological assessment has failed to predict progression or regression of kidney diseases reducing the value of kidney biopsies as a guide for clinical therapeutic approaches. Because of this, researchers have always tried to use new methods in order to add more validity and prognostication. Needle biopsies were performed already in the 1930s, but kidney biopsies as clinical diagnostic tool were introduced in the 1960s when Jones silver stain and the new techniques of electron microscopy (EM) and immunofluorescence (IF) became available. In the 1970s, immunohistological methods were applied to identify, localize and semi-quantify immune deposits, extracellular matrix proteins and cellular infiltrates. The developments in the late 1980s and 1990s have been focused on methods to measure RNA and DNA. With the ongoing advances in kidney imaging this non-invasive, indirect technique may become the ultimate way of analyzing kidney tissue in the future.

Kidney Biopsy

Indication

There are multiple indications to perform a kidney biopsy. The most frequent indications for native kidney biopsies in the pediatric population are nephrotic syndrome, non-nephrotic range proteinuria, asymptomatic hematuria and acute kidney injury [1, 2]. Other indications are unexplained kidney failure, nephritic syndrome, and potential kidney involvement in case of systemic diseases. Kidney transplant biopsies are performed in case of allograft dysfunction, suspected rejection, virus-associated nephropathy, and suspected *de novo* or recurrent kidney diseases. Some transplant centers advocate for the use of protocol biopsies in pediatric kidney transplantation [3, 4].

Absolute contraindications to kidney biopsy include uncorrected severe coagulopathy, uncontrolled severe hypertension, active renal or perirenal infection, or a skin infection at biopsy site. The following conditions represent relative contraindications to kidney biopsy: complex anat-

omy of the kidney that may increase the risk of the biopsy (e.g. multiple cysts, anatomical abnormalities as in horseshoe kidneys), small kidneys or the presence of a solitary native kidney.

Procedure

In children, kidney biopsies were done using open exposure of the kidney until 1962 when White in England and in 1970 Metcoff in the United States described a modified needle biopsy procedure for children including infants [5–7]. Today percutaneous kidney biopsies in children are done under ultrasound guidance and have become a routine procedure. A report on the 22-year experience on 9288 native kidneys biopsies (715 from children) from the Norwegian Kidney Biopsy Registry came to the conclusion that the percutaneous kidney biopsy is a low-risk procedure at all ages [8]. However, in case of contraindications or after failed attempts at percutaneous kidney biopsy, open (surgical), laparoscopic or transvascular biopsies may be performed.

Despite differences in details, the procedures for a kidney biopsy are relatively standardized. In preparation for the biopsy the patient and the parents have to be informed about the possible risks of the biopsy and the potential therapeutic consequences. For safety, laboratory values that should be obtained include hemoglobin, platelet count, prothrombin time, partial thromboplastin time and bleeding time if uremic. In addition, serum creatinine, electrolytes and a urine dip stick analysis are useful as baseline parameters in case of occurring complications. Prior to performing the biopsy the nephrologist should be aware of the patient's kidney anatomy. Ultrasound examination is used to exclude contraindications.

Small children will receive general anesthesia. In larger children the procedure can safely be performed with mild sedation allowing for cooperation of the patient, but many centers use general anesthesia even in larger children. Briefly, the patient is placed in prone position with a foam roll under the upper part of the abdomen. The kidneys are localized by ultrasound from the back. The kidney, of which the lower pole is easiest to reach, is chosen for biopsy. In most cases, this will be the right kidney. The exact position of the kidney during inspiration is determined and after marking the intended entry position of the needle on the skin, the skin is cleaned with an antiseptic solution. If the patient is only sedated, the skin, the subcutaneous tissue and the muscle are infiltrated with a local anesthetic. After a small incision, the needle mounted on the semi-automated spring loaded biopsy gun is carefully introduced under ultrasound guidance until the kidney is almost reached. Manually operated needles have been widely replaced by biopsy guns because of the easier use and lower complication rates. The patient is then advised to take a breath and hold the air. In case of general anesthesia, the anesthetist will hold the patient in deep inspiration. The needle is quickly advanced to the capsule of the kidney and the biopsy is taken (Fig. 5.1). Ideally, the whole procedure is followed on the ultrasound screen to visualize the path of the biopsy needle.

After the procedure, the patient usually stays in bed for 24 h with compression of the puncture site. However, during the past several years, kidney biopsies have been performed on an outpatient basis, where stable patients are discharged after about 8 h [9]. To assure brisk diuresis the patient receives either a glucose/sodium chloride solution intravenously and/or is asked to drink a lot. Urine is collected in single portions and is examined with urine dip sticks. Hemoglobin levels and ultrasound controls are performed in most centers after 4–6 h and after 24 h. Hourly controls of blood pressure and heart rate have to be done.

The primary major complication remains macroscopic hematuria that occurs in 0.8–12% of biopsies performed in pediatric patients. Other complications may include subcapsular or perirenal hematoma, possible need for transfusion, infection, and pain requiring medication. Arteriovenous fistulas are diagnosed more often in recent years because of the improvement in Doppler ultrasound technique. Table 5.1 provides on overview of the efficacy and most frequent complications with regard to different biopsy techniques over a period of three decades [10].

Processing of Biopsy Specimens

As important as accurate performance of the biopsy is adequate processing and interpretation of the specimen [11, 12]. The Renal Pathology Society has published practice guidelines that address specimen handling and processing [13].

Prior to fixation, each core should be examined for the presence and number of glomeruli by light microscopy with tenfold magnification. Based on sample size and location this examination should lead to a decision on whether more kidney tissue is needed. One should take into account the number of glomeruli as well as the suspected diseases process. It cannot be emphasized enough that adequacy of sample size is crucial for the validity of a biopsy specimen. In order to diagnose a focal disease process such as focal segmental glomerulosclerosis (FSGS) recognition of a single abnormal glomerulus is required.

Table 5.2 Minimum number of harvested glomeruli required to allow concluding a minimal fractional involvement (e.g. % sclerotic glomeruli in FSGS, % crescents in extracapillary GN) (from [100])

Number of harvested glomeruli	Minimal number of abnormal glomeruli (absolute and %) required to reliably estimate extent of involvement		
	≥80%	≥50%	≥20%
8	8 (100)	7 (88)	3 (38)
10	10 (100)	8 (80)	4 (40)
12	12 (100)	9 (75)	5 (42)
15	14 (93)	11 (73)	6 (40)
20	19 (95)	14 (70)	7 (35)
25	23 (92)	17 (68)	9 (36)
30	28 (93)	20 (66)	10 (33)
35	32 (91)	23 (66)	11 (31)
40	36 (90)	26 (65)	12 (30)

The probability to make this diagnosis depends on the fraction of affected glomeruli per kidney as well as on the glomeruli present in a given biopsy specimen. The same holds true for the assessment of the extent of a disease with variable pathologic involvement among glomeruli. Corwin and colleagues have published estimates on the minimum number of abnormal glomeruli that have to be present in a biopsy core that contains a certain number of glomeruli to infer with 95% confidence that a disease process involves 20%, 50% or 80% of the kidney (Table 5.2). Glomeruli within the juxtamedullary region are the ones to be involved first with FSGS, highlighting the importance that this area is represented in the sample. Overrepresentation of global sclerosis, however, may result from subcapsular cortical specimens and needs to be considered when dealing with wedge biopsy taken during an open biopsy of the native kidney or at implantation of a kidney transplant. It is also of note that the number of glomeruli that are retrieved per centimeter core length decreases with age (Fig. 5.2) [10].

Appropriate processing and potentially fixation of the biopsy should be done as soon as possible because small cores can dry out fast. The choice of fixatives should be discussed with the local nephropathologist. In pediatric kidney diseases, light microscopy (LM) alone can be insufficient to make a diagnosis. Therefore, specimens for IF and EM should be obtained. Because of the

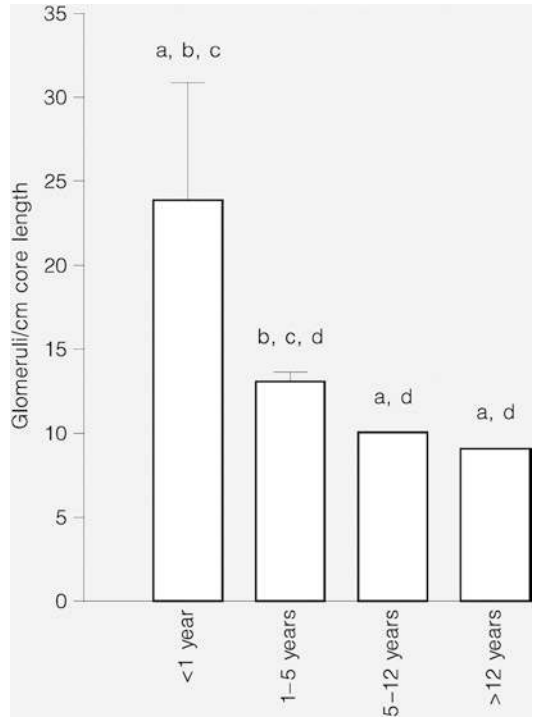

Fig. 5.2 Number of glomeruli per centimeter core length derived from native kidneys shown for different age groups. (From [10])

superior morphology, some nephropathologists prefer fixation with Bouin's alcohol picrate solution. This, however, may lead to problems if immunohistochemistry (IHC) staining needs to be performed. Fixation with paraformaldehyde or buffered formalin (4%, pH 7.2–7.4) followed by paraffin embedding is therefore common practice in most pathology departments. For IF, kidney tissue should be "snap-frozen" in liquid nitrogen or can be placed in tissue transport media or isotonic sodium chloride solution if transported to the laboratory immediately. Specimens for EM are usually fixed in a solution containing 0.1–3% glutaraldehyde.

LM specimens should be sectioned at a thickness of 2 μm or less by an experienced technician. Subtle pathologic changes are more easily detected in thinner sections and section thickness is an important issue for glomerular pathology, especially when assessing for cellularity.

A number of histochemical stains are used to evaluate kidney biopsies (Fig. 5.3). Typically,

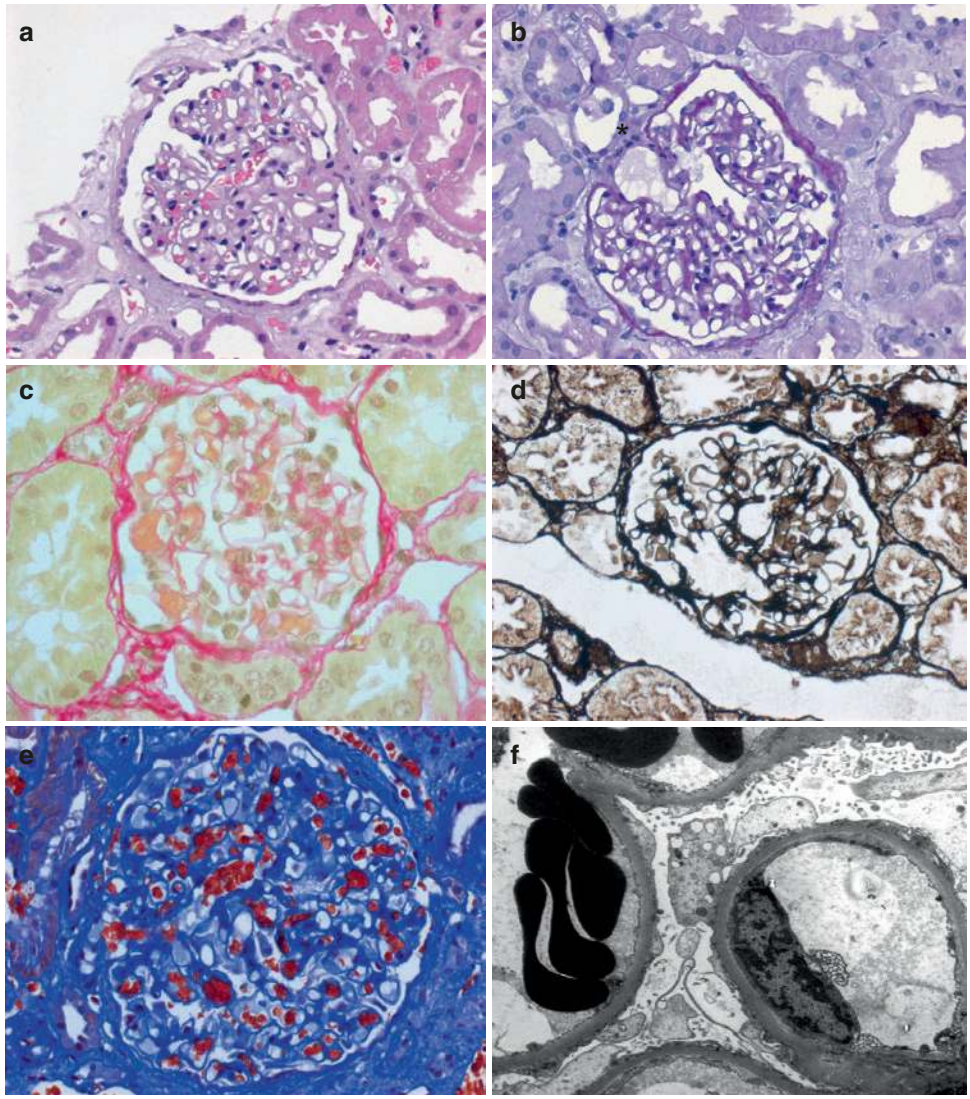

Fig. 5.3 Overview of the different stainings that are used to evaluate a kidney biopsy. Representative light (**a**–**e**) and electron microscopy (**f**) of minimal change glomerulopathy (MCGN) with mild hypercellularity. (**a**) Hematoxylin eosin stain (HE): the HE stain is the work horse of pathology; it is useful to get a first idea about glomerular changes such as proliferation and matrix deposition. In the case of MCGN the glomerulus shows a slightly increased number of mesangial cells, open capillaries, no evidence of intra- or extracapillary proliferation and normal thickness of glomerular basement membrane (GBM). (**b**) Periodic acid-Schiffs (PAS) stain: PAS staining is helpful to analyze changes in glomerular cell number and GBM in more detail. In the case of MCGN mild segmental hypercellularity (*) and normal thickness of GBM without any irregularities is seen. Some podocytes (arrows) are slightly enlarged and appear detached from the GBM. (**c**) Sirius red stain (fibrous tissue stain): this fibrous tissue stain is helpful to analyze the amount of fibrous tissue (fibrosis) of glomeruli and most importantly the interstitial tissue (interstitial fibrosis). In the case of MCGN a normal amount of fibrous tissue is found in Bowmans capsule and no increase in mesangial matrix is visible. (**d**) Silver stain: the silver stain is most useful to detect thickening and irregularities of the GBM. In the case of MCGN no thickening and spike formation is seen. (**e**) Acid fuchsin-Orange G stain (SFOG): this stain is helpful to detect protein deposition, i.e. immune complex formation, which appear in bright red within the mesangial matrix or the GBM. In the case of MCGN no immune deposits are present. (**f**) Electron microscopy of a capillary loop shows typical changes in MCGN, i.e. normal thickness of GBM with no evidence immune complex deposition, but with effacement of podocyte foot processes and loss of endothelial fenestration. (Pictures are courtesy of Dr. Amann, Erlangen)

biopsy specimens are stained with hematoxylin and eosin (H+E), periodic acid-Schiff (PAS) or periodic acid-methenamine silver (Jones silver) and Masson's trichrome. H+E is used for general morphology and reference, whereas the other three stains provide a clear distinction of extracellular matrix from cytoplasm. Depending on indication Congo red stain (amyloid), Kossa stain (calcifications), elastic tissue stain (loss of elasticity in arteries, arterial thickening) and other stains are used. IF uses fluorophore-labelled antibodies to detect and localize immunoglobulins (IgA, IgG, IgM) and their light chains (κ, λ), components of the classical or alternative complement pathways (C1q, C3c, C4), albumin and fibrinogen. In transplant biopsies, staining for C4d, a fragment within the complement pathway, has become a major diagnostic tool in antibody-mediated rejection [14]. The pattern of fluorescence positive stain should be noted, such as mesangial versus capillary staining and linear or granular staining. The granular pattern has an EM counterpart and corresponds to extracellular, electron dense masses.

EM studies do not need to be part of the routine work up of every kidney biopsy. However, EM plays an important diagnostic role in almost 50% of cases and is essential for a correct diagnosis in up to 21% [15, 16]. Even though it is sometimes possible to omit EM after evaluation of LM and IF, specimens for EM studies should always be procured. EM can localize deposits (mesangial, subendothelial, or subepithelial). EM is able to detect changes in cell structure (e.g. fusion of podocyte foot process, podocyte vacuolization) and alterations of the basement membrane (thickening, thinning, splicing, duplication and other irregularities). The definite diagnosis of e.g. minimal change nephropathy, Alport's disease or thin basement membrane disease requires EM [17, 18].

Histopathological Assessment

Abnormalities in kidney structures can occur in all four compartments of the kidney: glomeruli, tubules, interstitium and vasculature [19, 20]. Numerous consensus classifications have been developed for specific diseases [21–25] and those classifications, as well as the specific pathological changes seen with certain diseases, are discussed in the relevant chapters of this textbook. This chapter provides a general overview on the various histopathological features that can be encountered while reading a biopsy [12, 26, 27].

Glomerular changes are the primary pathological event in many kidney diseases. If glomeruli are affected it needs to be decided whether these changes are diffuse (defined as ≥50% of glomeruli involved) or whether the disease process is focal (defined as <50% of glomeruli involved). By assessing single glomeruli a decision has to be made whether the disease process involves only part of the glomerulus, i.e. is segmental, or the whole glomerulus, which is considered global. Glomerular sclerosis refers to an increase in extracellular material (e.g. hyaline) within the mesangium that leads to compression of the capillaries. The capillary basement membrane has a wrinkled appearance and adhesions to Bowman's capsule are found. Depending on the expansion of the sclerotic lesion, it can be either segmental or global. Hypercellularity is a descriptive term reflecting an increased number of cells (e.g. mesangial cells, endothelial cells, inflammatory cells) in the mesangial space, internal to the glomerular basement membrane or in the Bowman's space, which is called mesangial, endocapillary or extracapillary hypercellularity respectively. Glomerular diseases involving hypercellularity are often called "proliferative". Changes of the basement membrane that can be seen by light microscopy involve thickening of the basement membrane and basement membrane double layering. Whereas the first is caused by the accumulation of basement membrane material, the latter is meant to be caused by peripheral interposition of mesangial material. Severe glomerular diseases show the formation of crescents. Crescents are located in the urinary space of the glomerulus and consist of cells and extracellular material. The proportion of glomeruli affected by crescents is of enormous prognostic importance in acute glomerulonephritis/vasculitis. The most subtle glomerular damage is

effacement of foot process and refers to the loss of normal podocyte morphology with an undivided cytoplasmic mass covering the basement membrane. Effacement of foot processes cannot be seen by light microscopy, but is easily found by electron microscopy.

Tubular cells can show various signs of damage. This includes loss of brush border (in proximal tubules), flattening of the tubular epithelium, and detachment of tubular cells from the basement membrane, necrosis and apoptosis. Mitosis of tubular cells is often found after an episode of acute tubular necrosis as a sign of repair. Tubulitis, an important feature in acute allograft rejection, refers to the presence of inflammatory cells that have crossed the tubular basement membrane and infiltrate the tubular epithelium. Tubular changes when chronic occur as tubular atrophy. Atrophic tubules have a reduced diameter and a thickened basement membrane. Tubular atrophy is often accompanied by interstitial fibrosis. Another type of tubular pathology is the accumulation of droplets containing various substances. This for example can occur in patients with heavy proteinuria or with various storage diseases. A foamy appearance of the tubular epithelium is called vacuolization and can occur with several conditions. Intranuclear inclusions can indicate viral infection (see below), can occur non-specifically with different nephropathies, and can also reflect regeneration after acute tubular necrosis. The occurrence of coagulated proteins or formed elements in the tubular lumen is described as tubular casts (e.g. RBC casts).

Interstitial changes are edema, fibrosis and infiltration by inflammatory cells. Edema indicates acute diseases whereas fibrosis is the sequelae of chronic kidney damage. In both cases, tubules are no longer "sitting back to back" but are separated by interstitial material. The degree of interstitial fibrosis is of prognostic importance in chronic kidney diseases. In many instances, the degree of interstitial fibrosis found in a primary glomerular disease is a more powerful predictor of outcome than the glomerular changes itself. Infiltration of inflammatory cells can be the cause of kidney disease such as acute interstitial nephritis or acute transplant rejection, but an interstitial infiltrate can also be a mere accompanying phenomenon, e.g. in fibrosis.

The kidney vasculature can also show a range of pathological changes. Inflammation (vasculitis) may affect any vessel. If only the arterial subendothelial space is affected, this subtype is called endothelialitis, a finding peculiar to vascular rejection. Direct damage of endothelial cells, e.g. through *E. coli* toxins in hemolytic uremic syndrome (see Chap. 24), leads to thrombotic microangiopathy with endothelial cell swelling and intimal edema that is followed by platelet fibrin thrombi. Hypertension can lead to vascular changes affecting all parts of the arterial wall. This includes fibrous intimal thickening and medial hypertrophy. Overall, the vessel walls can be thickened and hyalinized, in extreme cases leading to complete obstruction of the vessel lumen. Very high blood pressure can result in fibrinoid necrosis, an endpoint also seen in other thrombotic microangiopathies.

Pathologists summarize the findings seen in the different kidney compartments based on their assessment using LM, IF, IHC and EM. Recently, a minimum reporting standard for nonneoplastic biopsies has been proposed to facilitate optimal communication between pathologists and nephrologists and eventually to optimize patient care [28].

Protein Analysis

Proteins in kidney tissue are classically analyzed by immunostaining, using either IF or IHC for visualization. Both techniques use antibodies or antisera directed against the protein of interest. They can be performed both in native and formalin-fixed tissues. As fixatives can mask protein epitopes, antigen retrieval steps become necessary, particularly for nuclear antigens. Detection and visualization of unlabeled primary antibody that specifically binds the target epitope is achieved by a secondary antibody, which for IF carries a fluorophore or for IHC either peroxidase or alkaline phosphatase. In order to further enhance the signal, especially if the target antigen is rarely expressed, amplification systems

such as the streptavidin-biotin-peroxidase system are used for IHC. Direct IF or IHC, for which the primary antibody is linked to a fluorophore or peroxidase, is also possible.

Both IF and IHC have advantages and disadvantages. IF is most often performed on frozen sections. It is a technically easy and fast procedure. Processing, sectioning and staining can be performed within 1–2 h. Even though the cost of the procedure itself is low, storage is difficult as the fluorophores fade over time. A broad range of suitable antibodies is available and background staining is usually not a problem. However, in case of frozen sections an additional sample for assessment of histopathological details may be required to provide good morphology. IHC can be done using the same tissue as for LM. It provides much better morphological details and causes permanent staining, in contrast to IF. IHC is highly sensitive because of the possibility to enhance the signal by certain amplifiers, but can be technically challenging (e.g. due to higher background staining) and expensive.

Some of the applications of IF and IHC in non-neoplastic kidney biopsies have already been described above as they are part of the standard work-up of biopsy specimens. Some pathology centers prefer to use IHC even for the standard workup because of the possibility to store and archive the slides for future comparisons. In addition, IHC is used to detect subtypes of type IV collagen (see Chap. 16) and viral antigens, especially in allograft biopsies, although PCR techniques are currently taking over because of their higher sensitivity. A practical example for virus detection with IHC is BK polyoma virus. Demonstration of typical smudgy tubular cells with enlarged nuclei gives direct evidence for viral tissue invasiveness [29]. A pleomorphic infiltrate with lymphocytes, plasma cells and PMNs is highly suspicious of BK virus nephropathy. Diagnostic confirmation can be achieved by IHC using a monoclonal antibody directed against simian virus 40 (SV-40) large T antigen, which is common to all known polyoma viruses [19]. In case expansile/dysplastic plasma cells are found in the interstitium of an allograft biopsy specimen, staining for Epstein-Barr virus (EBV) may be useful to make the diagnosis of post-transplant lymphoproliferative disorder (PTLD) as most but not all PTLDs are EBV positive [30].

While proteomic tools represent a major technological advancement in protein analysis, they have not been included in the routine work-up of kidney biopsies to date. Proteomics has been coined the “non-invasive kidney biopsy”, reflecting that most proteomics approaches nowadays are performed in urine. Proteomic analysis in kidney tissue has been used to identify biomarkers enabling diagnosis, disease monitoring, and treatment of kidney malignancies, especially renal cell carcinoma [31–33]. Proteomic tools may become increasingly interesting to study microdissected structures from biopsies [34, 35] as demonstrated for different glomerular diseases [34–37] and amyloidosis [38–41]. For example, mass spectrometry, by providing the molecular composition of micro-dissected deposits, is a sensitive and specific technique accurately diagnosing kidney amyloidosis [39, 40, 42]. The fact that formalin-fixed tissue even from archived tissue blocks can be used for such analyses will support future use of this approach [43, 44]. The Kidney Precision Medicine Project has recently proposed to combine traditional and digital pathology with transcriptomic, proteomic, and metabolomic analysis of the kidney tissue not only to create a reference kidney atlas, but also to characterize disease subgroups [37].

RNA Analysis

Transcriptomic analysis allows to gain insight in physiologic and pathologic processes within the kidney. RNA expression can be evaluated from as little as 10% of a biopsy core [45]. The use of RNase inhibitors stabilizes and protects the integrity of RNA in unfrozen tissue samples. Importantly, kidney tissue can be stored in these agents allowing for later micro-dissection and immunohistochemical analysis [45]. Hence, RNA expression can be evaluated from fixed and processed kidney biopsy samples, allowing for molecular analysis in combination with routine histology assessments. RNA can be isolated from

frozen sections, but also from formaldehyde-fixed, paraffin-embedded tissues [46]. This methodology enables RNA analysis even after years of storage, allowing for a correlation of expression profiles from archived materials with the subsequent clinical disease course.

Even with these sensitive methods of RNA detection, the different compartments of the kidney contribute or respond differently to diseases or injury and signals may be underestimated or even missed. Manual dissection or sieving allows to compare glomeruli with tubulointerstitium [47]. Laser-assisted microdissection allows to select a defined histological structure from a given biopsy slide, allowing direct correlation of information from histology and gene expression for the same nephron segments. While the technique has been used successfully in fixed kidney tissue [48, 49], the challenge is to retrieve sufficient high-quality material. Several technical reports have been published [46, 50–52]. Laser-assisted microdissection is often used in combination with RNA amplification protocols with 1000-fold linear amplification efficiency to generate gene profiles that are specific for a certain nephron segment. This approach has been used to generate expression profiles of single glomeruli derived from biopsies of lupus nephritis [53]. The study revealed considerable kidney-to-kidney heterogeneity, whereas glomerulus-to-glomerulus variation within a kidney was less marked.

High throughput gene expression technologies emerged in the mid 1990s and a number of different microarray platforms became available. A microarray chip assembles a number of gene-specific probes (clones or oligonucleotides) spotted on a small surface area with high density. The underlying principle of microarray is that after labeling transcripts from a specific sample and hybridizing them to an array, the amount of sample material bound to the specific complementary probe set is measured. As variation across the different platforms is an important issue, a number of studies have compared different platforms. Some claimed significant divergence across technologies, whereas others found an acceptable level of concordance [54, 55]. Nowadays chips are commercially available from different suppliers and the method is highly standardized, which allows for comparison and exchange of data between different laboratories as long as the same chips are utilized. In contrast to those high density arrays, low density arrays allow for the simultaneous evaluation of a few hundred genes and are based on a reverse transcriptase-polymerase chain reaction (RT-PCR) technique.

Gene expression profiling has been performed investigating large cohorts of patients with native kidney diseases or after transplantation [56, 57]. The major challenge of any of those expression analyses remains the extraction of biological insight from such information. Ideally, one would like to recognize specific patterns or pathways involved in certain diseases (Fig. 5.4). Approaches combining conventional histological assessment with molecular analysis for transplant biopsies, called the molecular microscope [58], have created a new understanding of transplant disease states and their outcomes [59–61]. Despite strong associations described for certain genes with specific diseases, none of those genes have made it into routine diagnostics to date.

The introduction of single cell RNA sequencing has revolutionized the field of tissue transcriptomics [62] (Fig. 5.5). While methods that measure RNA in small biopsy samples had previously been applied to analyze diseased native kidneys as well as allografts, single cell RNA sequencing allows to monitor gene expression in thousands of individual cells in a single experiment. Importantly, a combination with other Omics approaches in single-cell multi-omics analyses (mRNA plus genome, mRNA plus DNA methylation, mRNA plus chromatin accessibility, and mRNA plus protein) is often applied to gain a comprehensive understanding of cellular pathways [63–67]. The single-cell transcriptomic landscape of certain kidney structures (e.g. glomeruli [68]) or diseases [69, 70] have been described. A pre-requisite for an accurate assessment of gene expression on a single cell level is, however, the creation of a single cell suspension that preserves the viability of cells and mirrors the cellular composition in the kidney, which can be a challenge. Data from such experiments is generally made available to the public, e.g. as

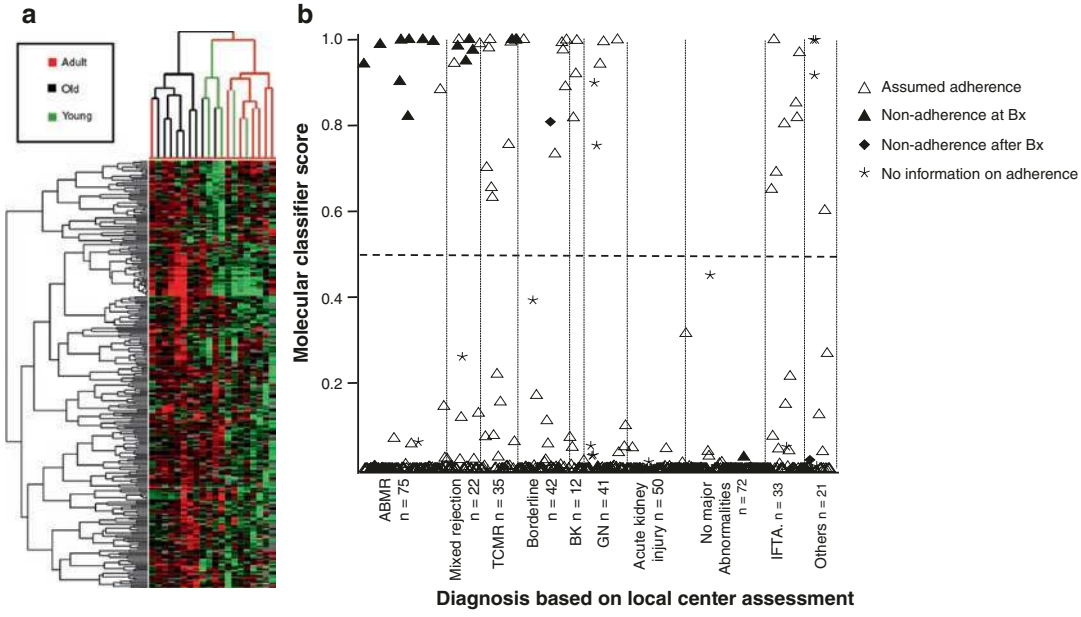

Fig. 5.4 (**a**) Dendrogram used in gene array analysis. Hierarchical cluster of genes that are differentially expressed based on kidney age (Y, young kidneys, A, adult kidneys, O, old kidneys). The color from green to red reflects increasing gene expression. Based on such gene array analysis in large cohorts, researchers have described molecular classifiers shown in (**b**) relationship between a molecular classifier score and diagnoses based on local center assessment. Molecular classifiers are able to distinguish antibody- and T-cell-mediated rejection. The order within each diagnostic category is random. Horizontal line represents arbitrary threshold of 0.5 for defining high versus low scores. Symbols indicate information about medication adherence. (Figure kindly provided by Dr. Einecke, Hannover)

single cell data sets or atlases, allowing exploration and comparison of own data against these existing data sets.

New technologies usually come along with some challenges. An important limitation of single cell RNA sequencing is the low coverage. Compared to traditional experiments using bulk RNA, the number of reads per sample is considerably lower for single cell experiments. This is especially important for genes with low expression levels, e.g. the senescence gene $p16^{INK4a}$, for which rarely any or only few corresponding reads are captured. Considerable variation in gene expression between two cells of the same type may occur as a result of the stochasticity in capturing and therefore require appropriate statistical modelling. Filtering of low-quality cells and especially of so-called doublets (libraries representing more than one cell captured in a single bead) are important quality control steps. Another important limitation is the loss of spatial information caused by the dissociation of the tissue. While techniques to overcome these limitations have been described [71–73], the need to work with fresh materials remains a major pre-analytical challenge and prevents large scale collection and analysis of human samples. Isolation protocols for archived tissues have been published; these also promise less bias between cell types [74]. Other approaches propose the use of nuclei, so-called single nucleus RNA-sequencing allowing the use of frozen tissue [75]. As further techniques are being developed, bioinformatic integration of multi-omics datasets from single-cell analyses represents a major challenge [76]. Innovative computational tools will be required that will accommodate the current limitations [77].

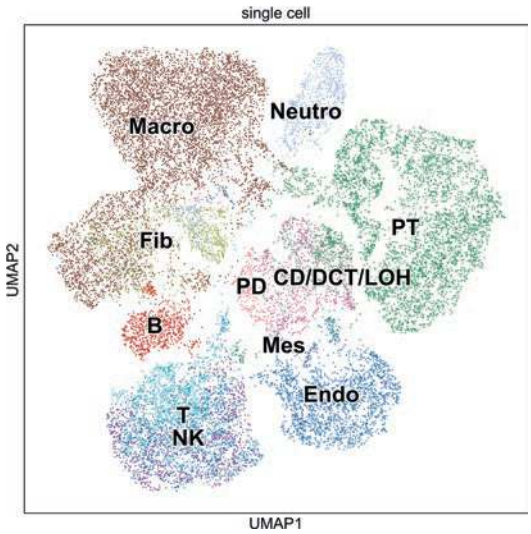

Fig. 5.5 Visualization of data from a single cell RNA-sequencing experiment using mouse kidney tissue. The high-dimensional data from such experiments is typically presented as so-called t-SNE (t-Distributed Stochastic Neighbor Embedding) plot. This technique assembles cell populations based on their expression profile. *B* B cells, *CD* collecting duct cells, *DCT* distal tubular cells, *Endo* endothelial cells, *Fib* fibroblasts, *LOH* loop of henle cells, *Macro* macrophages, *Mes* mesenchymal cells, *Neutro* neutrophils, *NK* natural killer cells, *PT* proximal tubular cells, *Podo* poocytes, *T* T cells. (Figure is retrieved from unpublished data, Drs. Melk and Schmitt)

DNA Analysis

Detection of viral DNA by PCR using sequence specific primers for a large panel of viruses such as BK virus, CMV, EBV, other herpes viruses, and hepatitis B virus is possible [78–81], but rarely used in clinical practice. Measurements of viral load to diagnose and monitor affected patients, especially after transplantation (see also Chap. 69), are preferentially performed in blood and urine [82–84]. Pathologists typically combine this information, the histopathological features and the available immunostaining methods to make the diagnosis of a virus-associated process in the kidney.

Molecular cytogenetic techniques such as chromosomal comparative genomic hybridization (CGH) are performed on tumor tissue. These techniques have improved the diagnosis of chromosomal aberrations e.g. in Wilms' tumor, but have only a limited resolution across the whole genome. The development of genomic arrays allows the assessment of the whole genome at a much higher resolution at a sub-microscopic or sub-band level [85, 86].

Indirect Measurements

Even though the complication rate with kidney biopsies is low, taking a biopsy is still an invasive procedure. Therefore, methodological progress should aim for indirect and non-invasive methods to assess the status of a kidney *in vivo* in order to minimize the need for biopsies. The kidney is well suited for such indirect measurements, as urine represents an easily accessible direct readout of the organ of interest. Indeed, proteinuria has been used for decades as a biomarker of disease activity, however it lacks disease specificity. Ideally, one would like to use urinary markers that are highly sensitive and specific for individual disease entities to screen and diagnose a kidney disease.

Urinary extracellular vesicles have become such attractive tools in biomarker development. These vesicles are secreted membrane-coated structures that allow conclusions on the cells of their origin through extraction of protein, mRNA, miRNA and lipid [87]. Urinary exosome signatures have been proposed to diagnose kidney transplant rejection [88], but also for autosomal dominant polycystic kidney disease [89]. In addition, some of the technologies discussed above have been applied to cells derived from urine. Recently single cell profiling was applied to human urine samples and shows that almost all cell types from the kidney and urinary tract can be detected and quantified in urine [90].

Transcriptome studies of urine cell extracts have identified a number of candidate biomarkers; e.g., CD3ε mRNA, IP-10 mRNA, and 18S rRNA levels in urinary cells have been postulated to detect or predict the outcome of acute rejection in kidney allograft recipients [91]. However, such measurements have not entered

routine diagnostic practice to date, highlighting the challenges in biomarker development. More advances have been made for the use of the urinary proteome [92].

Imaging methods as indirect tools to evaluate kidney tissue are also discussed elsewhere (see Chap. 3), Novel functional magnetic resonance imaging (MRI) techniques allow for detailed assessments of both kidney structure and function. While arterial spin labeling measures perfusion [93], diffusion-weighted MRI enables the assessment of fibrosis and microstructure and blood oxygen level dependent imaging detects hypoxia [94, 95]. A high cortical relaxation rate, which indicates lesser oxygenation, has been associated with faster eGFR decline [96, 97]. A longitudinal study on patients with CKD could not confirm an association between a low apparent diffusion coefficient (ADC), used as a an indicator of tissue fibrosis, and changes in eGFR over a period of 12 months after adjustment for albuminuria [98]. A much smaller study in transplant patients suggested that ADC may detect fibrotic changes and thereby disease progression earlier than through eGFR decline [99]. While it is not predictable when MRI biomarkers become available for clinical use, it is conceivable that with further technological progress applications assessing indicating oxygenation and fibrosis could replace the need for histopathological assessment in certain clinical settings.

Abbreviations

ACE	Angiotensin converting enzyme
ACEI	Angiotensin converting enzyme inhibitors
ADH	Antidiuretic hormone
ANP	Atrial natriuretic peptide
AQ2	Aquaporin-2
AT1	Angiotensin type 1 receptors
BK	Bradykinin
CA	Carbonic anhydrase
cAMP	Cyclic adenosine monophosphate
CCD	Cortical collecting duct
CD	Collecting duct
cGMP	Cyclic guanosine monophosphate
COX-2	Cyclooxygenase type-2
ENaC	Epithelial sodium channel
ET	Endothelin
FGF-23	Fibroblast growth factor 23
GA	Gestational age
GFB	Glomerular filtration barrier
GFR	Glomerular filtration rate
GH	Growth hormone
IGF-1	Insulin growth factor-1
KK	Kallikrein
NaCl	Sodium chloride
NAG	*N*-acetyl-β-D-glucosaminidase
NCC	Sodium chloride co-transporter
NHE3	Sodium-hydrogen antiporter 3
$NKCC_2$	Sodium-potassium-chloride cotransporter
NO	Nitric oxide
PGs	Prostaglandins
PTH	Parathyroid hormone
RAS	Renin–angiotensin–aldosterone system
ROMK	Renal outer medullary potassium channel
RVR	Renal vascular resistance
TALH	Thick ascending limb of loop of Henle
TRPV5	Transient receptor potential cation channel subfamily V member 5
TTKG	Transtubular potassium gradient
VMNP	Vasomotor nephropathy

General Overview of Antenatal, Perinatal, and Postnatal Fluid and Electrolyte Homeostasis

Fluid and electrolyte homeostasis in the fetus is controlled by the placenta. As a result, the placenta receives a significant proportion of the fetal cardiac output (33%), whereas the fetal kidneys receive only 2.5% even in late gestation [1]. The low fetal renal blood flow (RBF) results in a low creatinine clearance which correlates well with gestational age (GA) (Fig. 6.1a, b). Urine pro-

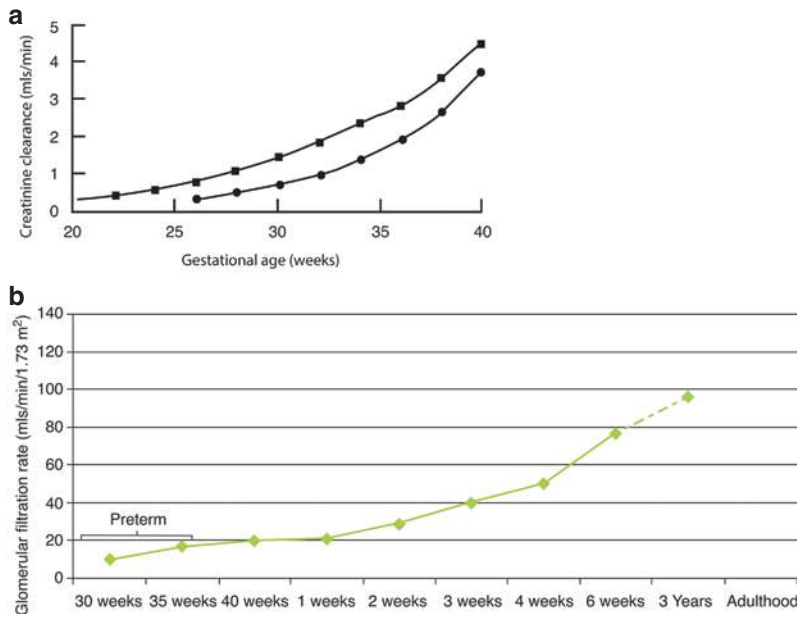

Fig. 6.1 (**a**) Creatinine clearance for human fetuses from 20 weeks. (■) and corresponding preterm neonates (●). Creatinine clearance increases with increasing gestational age (used with permission of John Wiley and Sons from Haycock [2]). (**b**) GFR doubles over the first 2 weeks of life in term infants and reaches almost 50 mL/min/1.73 m^2 between 2 and 4 weeks after birth and adult values by 2 years of age. (Used with permission of Vieux et al. [3])

duction begins at approximately 10 weeks of gestation in the human kidney. This coincides with the acquisition of the first capillary loops by the inner medullary metanephric nephrons. Subsequently, hourly fetal urine production increases from 5 mL at 20 weeks to approximately 50 mL at 40 weeks [4]. After 20 weeks, the kidneys provide over 90% of the amniotic fluid volume [5]. Severe oligohydramnios due to abnormal fetal renal function in the second trimester can result in pulmonary hypoplasia and in severe cases, Potter's syndrome [6].

At birth, the newborn consists largely of water, with total body water comprising 75% of body weight at full term and about 80–85% in preterm infants [7]. Adaptation to the extrauterine environment involves an increase in glomerular filtration with an immediate postnatal natriuresis. High circulating levels of atrial natriuretic peptide (ANP) in the newborn are responsible for the postnatal physiological natriuresis [8]. In addition, maturation of tubular function occurs postnatally [9]. Changes include an increase in resorptive surface area, transporter number and function, together with further modification of paracrine regulatory mechanisms [9]. In the following section, we will discuss the developmental changes in the neonatal kidney that are necessary for extrauterine adaptation. Regulatory mechanisms of the mature kidney will be discussed elsewhere.

Glomerular Function in the Fetal, Perinatal, and Postnatal Period

Glomerular filtration is the transudation of plasma across the glomerular filtration barrier (GFB) and is the first step in the formation of urine (Fig. 6.2). Filtration depends both on Starling's forces and an adequate RBF [10]. The total glomerular filtration rate (GFR) is the sum of the GFR of each single functioning nephron, SNGFR [where SNGFR = $(k \times S) \times (\Delta P - \Delta\pi)$]. ΔP, is the hydrostatic pressure difference between the glomerular capillary pressure (P_{GC}) and the hydrostatic pressure in Bowman's space (P_{BS}). $\Delta\pi$ is the oncotic pressure difference between the glomerular capillary pressure (π_{GC}) and the oncotic pressure in Bowman's space (π_{BS}). K_f is the product of the hydraulic permeability of glomerular capillary walls (k) and the surface area available for filtration, (S), ($K_f = k \times S$). In an adult, the rate of glomerular filtration is about 100–120 mL/min/1.73 m^2. Even though the term neonate has the full number of glomeruli, its

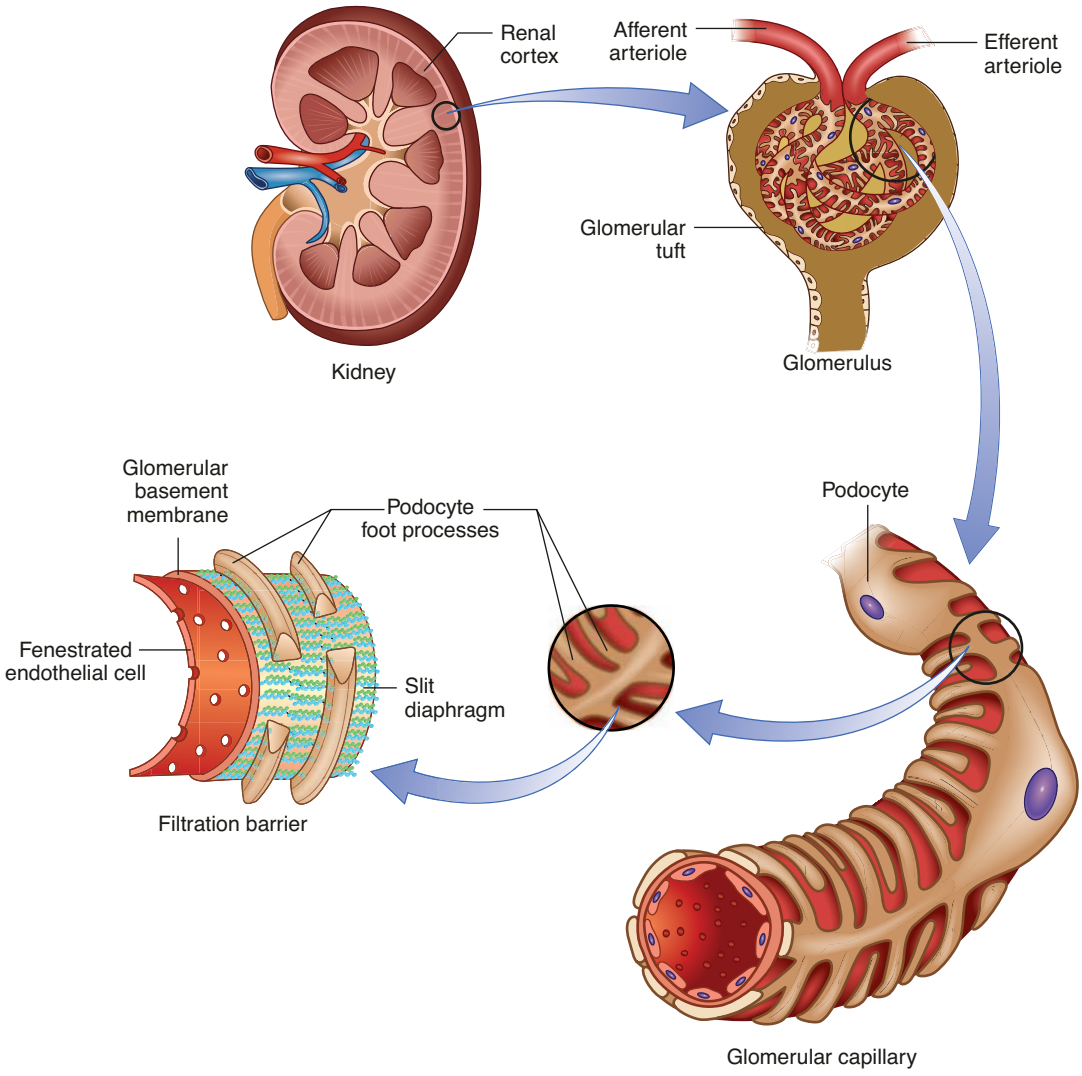

Fig. 6.2 Schematic of the structure and function of the glomerular filtration barrier. It consists of layers that block the passage of plasma macromolecules and also maintain plasma oncotic pressure. A fenestrated capillary endothelium lines each capillary loop. A porous glomerular basement membrane attached to highly dynamic epithelial cells (podocytes) is on the other side of this lining. The slit diaphragm is the prime barrier to filtration of plasma macromolecules. This slit diaphragm consists of podocytes that have interdigitating foot processes with neighbor podocytes and are connected to each other by a platform of signaling molecules

GFR is about 30 mL/min/1.73 m^2. In this section, we will discuss the functional development of glomerular filtration in the perinatal period.

Fetal GFR

During nephrogenesis, the increase in renal mass parallels an increase in fetal GFR [11]. Indeed, fetal GFR correlates well with both GA and body weight [11]. Preterm infants of 30 week GA have a creatinine clearance of less than 10 mL/min/1.73 m^2 within the first 24–40 h of birth [12], whereas creatinine clearance in term infants is higher and ranges between 10 and 40 mL/min/1.73 m^2 [13]. A study involving 275 neonates between 27 and 31 weeks GA reported GFR reference values as 3rd, 10th, 50th, 90th,

Table 6.1 Glomerular filtration rate reference values in premature infants

	Glomerular filtration rate, mL/min/1.73 m^2								
	Day 7			Day 14			Day 21

and 97th percentiles and provide useful reference ranges of the various GAs (Table 6.1) [3].

All four determinants of SNGFR contribute to the maturational increase in GFR to varying degrees [14]. Mean arterial pressure increases during fetal development and an increase in P_{GC} occurs as a result [15]. An increase in renal plasma flow leads to a further increase in SNGFR [16]. In addition, the oncotic pressure also rises with advancing GA [17]. However, the increase in P_{GC} is greater than that observed for π_{GC}, favoring ultrafiltration.

Fetal RBF can be measured by Doppler ultrasound techniques and increases from 20 mL/min at 25 weeks of gestation to more than 60 mL/min at 40 weeks [12]. Fetal RBF is low due to the high renal vascular resistance (RVR) [1, 18]. RVR depends on arteriolar tone and on the number of resistance vessels. As nephrogenesis proceeds, there is an increase in the number of glomerular vessels and in preterm infants born before 36 weeks gestation, the postnatal fall in RVR can, in part be attributable to new nephron formation [18]. Concomitantly, a re-distribution of RBF occurs from the inner medullary nephrons to the more superficial cortical nephrons. The superficial cortex is the site of more recent glomerulogenesis and the increase in SNGFR of the superficial nephrons significantly contributes to the increase in total GFR [14, 19].

Assessment of fetal glomerular function is possible by measurement of fetal serum cystatin C, α1-microglobulin and β2-microglobulin [20]. Cystatin C is a proteinase inhibitor involved in intracellular catabolism of proteins, produced by all nucleated cells, freely filtered across glomeruli and completely catabolized and reabsorbed in the proximal tubule. Fetal serum cystatin C is independent of GA and has been shown to have a high specificity (92%) for the prediction of postnatal kidney dysfunction. Reference intervals were calculated in a study of 129 cordocentesis involving 54 fetuses without renal disease [21]. Mean serum cystatin C levels were 1.6 mg/L with 2.0 mg/L being the upper limit of normal. In the same study, the authors showed that fetal serum β2-microglobulin decreased significantly with GA. In the same study, serum β2-microglobulin was demonstrated to have a higher sensitivity (87%) than cystatin C in predicting postnatal renal dysfunction. Both tests, therefore, may be used to assess fetal glomerular function in antenatally diagnosed renal malformations.

Neonatal GFR

A rapid rise in GFR occurs in term infants over the first 4 days of life. Preterm infants also experience a rise in GFR, but the rise occurs more slowly than that in term neonates [22]. Overall, a doubling of GFR is seen over the first 2 weeks of life in term infants and reaches almost 50 mL/min/1.73 m^2 between 2 and 4 weeks after birth and adult values by 2 years of age (Fig. 6.1b) [23, 24]. Postnatally, the mean arterial pressure increases and consequently an increase in glomerular hydraulic pressure occurs, resulting in an increase in GFR. A dramatic postnatal fall in RVR with redistribution of intrarenal blood flow from the juxtamedullary nephrons to the superficial cortical nephrons also contributes to the increased GFR. The fraction of cardiac output supplying the neonatal kidneys increases to

15–18% over the first 6 weeks of life [25]. In addition, an increase in the area available for glomerular filtration also contributes to the increase in GFR seen postnatally [14]. Glomerular size, glomerular basement membrane surface area and capillary permeability to macromolecules all contribute to the increase in GFR seen from the neonatal period to adulthood [26]. Maturation of glomerular filtration also occurs, as result of changes in both afferent and efferent arteriolar tone. A decrease in renal vasoconstrictors and activation of renal vasodilators occurs over the first 2 weeks of life and will be discussed in the following section.

Neonatal renal function is often assessed by measurement of serum creatinine, which is derived from creatinine and phosphocreatine of muscles and therefore reflects muscle mass. The serum creatinine concentration in the neonate is determined by maturation of the renal tubules, the total muscle mass of the body, GFR and tubular secretion. Several studies have now shown that the plasma creatinine in most infants actually increases after birth (Table 6.2) [27–30]. This is consistent with the idea that the tubules in the neonate are reabsorbing creatinine and not secreting it. Clearly, this has important implications for misinterpreting a rising creatinine in many neonatal ICU (NICU) patients as renal impairment.

Emerging evidence suggests that cystatin C is a more reliable marker of GFR in the neonatal period. A recent report involving 60 preterm (<37 weeks' GA) and 40 term infants studied from birth demonstrated that creatinine-based equations consistently underestimated GFR, whereas cystatin C and combined equations were more consistent with referenced inulin clearance studies [31].

Table 6.2 Reference values for serum creatinine levels in term neonates

	Serum creatinine, mg/dL		
Age	10th	Median	90th
Day 1	0.49	0.62	0.79
Day 3	0.37	0.48	0.61
Week 1	0.31	0.38	0.50

Vasoregulatory Mechanisms of the Neonatal Kidney

Renal Vasoconstrictors in the Developing Nephron

The Renin-Angiotensin System (RAS)

The renin-angiotensin system (RAS) plays an important role in the regulation of RBF and glomerular filtration. Angiotensin II is a potent vasoconstrictor of the efferent arteriole, causing a resultant increase in P_{GC} and, therefore, GFR. Both plasma renin activity and angiotensin II levels are high in the neonate. Renal angiotensin converting enzyme (ACE) levels are higher than adult levels during first 2 weeks of life and expression is localized to the proximal tubules and capillaries in the developing human kidney [32, 33]. Expression of angiotensinogen and ACE increases during late gestation and peaks after birth [34, 35]. In addition, the number of angiotensin type 1 receptors (AT1) are also twice that of adult levels at 2 weeks of age [35, 36]. Angiotensin II receptors, on the other hand, are more abundant in the fetal kidney with progressive downregulation during fetal maturation. In contrast, AT1 receptors undergo upregulation as the fetal kidney matures [36, 37].

Animal studies have shown that angiotensin II constricts the fetal renal arteries via the AT1 receptor and during fetal life plays an important role in controlling the resistance of the umbilical arteries and, therefore, the total fetal peripheral vascular resistance [38]. Maintenance of arterial pressure and baroreceptor control of heart rate and renal sympathetic nerve activity is controlled by circulating and endogenous angiotensin II in newborn lambs [39]. Therefore, the RAS plays a significant role in maintaining blood pressure as well as vascular resistance in the developing fetus.

Indeed, the importance of the fetal RAS is highlighted by studies reporting cases of ACE fetopathy with the use of ACE inhibitors (ACEI) in pregnancy. Maternal ACEI use can result in decreased placental perfusion, fetal hypotension, oligohydramnios and neonatal renal failure [40]. Recently, mutations in genes coding for renin,

angiotensinogen, ACE and AT1 have been described in association with autosomal recessive renal tubular dysgenesis with fetal hypotension [41]. Both inherited and acquired defects of the RAS, therefore, can alter fetal renal haemodynamics, with deleterious effects on renal development.

Renal Nerves and Catecholamines

The high RVR in the perinatal period can in part be due to increased renal sympathetic nerve activity (through α1 receptor stimulation) and rising circulating catecholamine levels [42]. The renal sympathetic nerves cause renal vasoconstriction, primarily of the afferent arteriole, which results in a decrease in P_{GC} and GFR (Fig. 6.3)

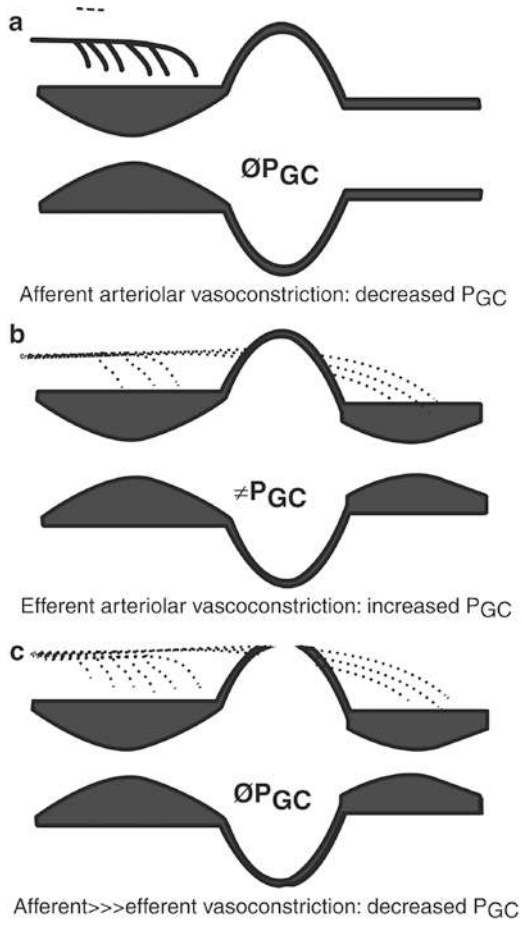

Fig. 6.3 (**a**–**c**) The renal nerves constrict the renal vasculature, causing decreases in renal blood flow and glomerular filtration. (Used with permission of John Wiley and Sons from Denton et al. [43])

[44]. Renal sympathetic nerve activity increases immediately after birth in sheep and plasma epinephrine and norepinephrine increase several fold immediately following birth [45, 46]. A fall in catecholamine levels subsequently occurs over the first few days of life [47]. Renal denervation in maturing piglets has been shown to increase RBF, demonstrating the role of renal nerves in maintaining high RVR. The sympathetic nervous system also has an important secondary role by stimulating the release of renin. Rodent studies have shown that renin-containing cells and nerve fibers are detected at 17 days of gestation, in close spatial relationship along the main branches of the renal artery [48]. Innervation of renin-containing cells follows the centrifugal pattern of renin distribution and nephrovascular development. The density and organization of nerve fibers increases with age along the arterial vascular tree [48]. Therefore, an interplay between increased sympathetic nerve activity and high plasma renin is likely necessary for the high RVR during the perinatal period.

Endothelin

Endothelin (ET) is a potent vasoconstrictor secreted by the endothelial cells of renal vessels, mesangial cells, and distal tubular cells in response to angiotensin II, bradykinin, epinephrine and shear stress [48]. Renal vasomotor tone is exquisitely sensitive to ET. An increase in RVR occurs following ET-induced contraction of glomerular arterioles (afferent > efferent) with a subsequent reduction in GFR [49]. In the first days of life, ET is elevated both in term and preterm neonates. A subsequent reduction in ET levels occur after the first week of life [50]. Newborn rat kidneys have a higher number of ET receptors than adult rat kidneys. A comparable binding affinity for ET has also been shown [51]. In addition, ET can also cause vasodilatation. Activation of ET_B receptors on the vascular endothelium evokes the release of vasodilators. The renal vasculature of fetal renal lambs reacts with vasodilatation to low doses of ET which may be due to the secondary release of nitric oxide (NO) which blunts the vasoconstrictor effects of ET [52, 53]. ET, therefore, may have both vasoconstrictor effects and vasodilatory effects on the neonatal kidney.

Renal Vasodilators in the Developing Nephron

Prostaglandins

The major prostaglandins (PGs), PGE_2, PGD_2, and PGI_2, increase RBF by stimulating afferent arteriolar vasodilatation, free water clearance, urine flow, and natriuresis. PGs are synthesized by the fetal and neonatal kidney [54]. Alterations in the synthetic and catabolic activity of renal prostaglandins occur with advancing gestational and postnatal age. Concomitant alterations in RBF, GFR, water and electrolyte excretion occur, suggesting an important role for PGs in renal functional development.

Newborns have high circulating levels of PGs that counteract the highly activated vasoconstrictor state of the neonatal microcirculation [55]. The deleterious renal vasoconstrictor effect of PG synthesis inhibitors illustrates the protective role of PGs in the immature kidney. Long-term maternal indomethacin treatment may decrease fetal urine output enough to alter amniotic fluid volume [56]. Severe renal impairment leading to fetal or neonatal death has been reported with the use of PG synthesis inhibitors which include indomethacin [57]. Neonatal indomethacin therapy may cause transient dose-related renal dysfunction characterized by a decrease in urine output. Renal dysfunction depends in part, on dosage, timing of therapy, and the cardiovascular and renal status of the infant prior to treatment [58]. In addition, recent data from studies in rodents with targeted gene disruption have shown that cyclooxygenase type-2 (COX-2) are necessary for late stages of kidney development and lack of COX-2 activity leads to pathological change in cortical architecture and eventually to renal failure [59]. Therefore, both the RAS and PGs are not only important for renal hemodynamics but are also necessary for kidney development.

Nitric Oxide

Nitric oxide (NO) plays a major role in maintaining basal renal vascular tone in the mature kidney. Through activation of its second messenger, cGMP, NO results in vasodilatation, modification of renin release and change in GFR [60]. Nitric oxide plays an important role in the maintenance of glomerular filtration in the developing kidney. Animal studies have shown that inhibition of NO synthesis by infusion with L-arginine analogues significantly decreases GFR in the developing kidney but not in the adult [61–63]. Treatment with angiotensin receptor blockers abolishes the decrease in GFR observed in the developing kidneys treated with L-arginine analogues [63]. Therefore, NO plays a critical role in the developing kidney by counter-regulating the vasoconstricting effects of angiotensin II and protecting the immature kidney.

The Kallikrein-Kinin System

Bradykinin (BK) is a vasodilator and diuretic peptide, produced by the action of kallikrein (KK), an enzyme produced by the collecting duct (CD) epithelial cells. Activation of the BK-2 receptor by BK stimulates NO and PG production, resulting in vasodilation and natriuresis. An endogenous kallikrein-kinin system is expressed in the developing kidney with higher neonatal expression than that found in adult kidneys [64, 65]. Renal expression and urinary excretion of KK rapidly rises in the postnatal period with excretion of KK correlating well with the rise in RBF [66, 67]. Blockade of the BK-2 receptor results in renal vasoconstriction in newborn rabbits, demonstrating the renal vasodilatory action of BK in the neonatal kidney [68].

Disordered Vasoregulatory Mechanisms

Vasomotor Nephropathy (VMNP)

Vasomotor nephropathy (VMNP) is defined as renal dysfunction due to reduced renal perfusion, and the preterm infant is particularly vulnerable to VMNP [69]. The main causes of neonatal acute renal failure are prerenal mechanisms and include hypotension, hypovolemia, hypoxemia and neonatal septicemia. Hypotension can stimulate vasoconstrictive mediators such as angiotensin II, causing renal vasoconstriction and hypoperfusion and thus further reduce the GFR in the newborn. The treatment of neonatal

hypotension can involve inotropic support and dopamine is usually considered as the first line agent. Dopamine has a direct effect on renal function via renal dopaminergic receptors located in the renal arteries, glomeruli, and proximal and distal tubules [70]. At low doses (0.5–2 μg/kg/min), dopamine causes renal vasodilatation and increases GFR and electrolyte excretion. In neonatal intensive care units, higher doses of dopamine (6–10 μg/kg/min) are needed to achieve systemic cardiovascular effects. Such doses have an opposite effect on renal function, causing renal vasoconstriction and reduction in sodium and water excretion [71]. Hypoxemia reduces RBF and GFR. In a study of severely asphyxiated neonates, 61% developed acute renal failure [72]. Hypoxemia stimulates ET, ANP and PG release. In addition, mechanical ventilation can reduce venous return and cardiac output and can thus cause renal hypoperfusion and impair renal function [69]. Therefore, in the neonate, VMNP can result from disturbances of glomerular hemodynamics through complex interplay of the renal vasoregulatory mechanisms.

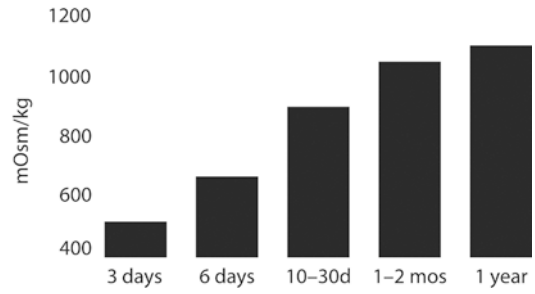

Fig. 6.4 Renal concentrating capacity increases in the postnatal period in the term infant, reaching adult values by the first month of life. (Used with permission of BMJ Publishing Group from Polacek et al. [75])

Water Transport in the Developing Kidney

Term neonates can dilute their urine to an osmolality as low 50 mOsm/L which is similar to adults [73]. However, the ability to excrete a water load is limited by the neonate's low GFR. As a result, the newborn infant is largely water, with total body water comprising 75% of body weight at full term and about 80–85% in babies between 26 and 31 weeks gestation [7]. Under normal physiological conditions, the kidneys have to excrete this water load during the first week of life [74]. Therefore, maximal concentrating abilities are not necessary at birth and, in fact, are low in the neonatal period. A progressive increase in concentrating capacity occurs postnatally and in term infants reaches adult levels by the first month of life (Fig. 6.4) [75]. In the premature neonate, maximal concentrating capacity is about 500 mOsm/L for a more prolonged period [76], which places the sick premature infant at greater risk for serious disturbances in water and electrolyte homeostasis [77]. The reasons for the limited concentrating capacity include diminished responsiveness of the CDs to antidiuretic hormone (ADH), anatomical immaturity of the renal medulla and decreased medullary concentration of sodium chloride (NaCl) and urea [78, 79]. In the following section, we will discuss each of these components in detail.

Antidiuretic Hormone in the Development of Water Transport

Normal ADH Physiology

ADH exerts its antidiuretic effect in the CD via the V_2 receptor on the basolateral membrane of the principal and inner medullary CD cells [80, 81]. Binding of ADH to the V_2 receptor results in activation of adenyl cyclase, increased cAMP and activation of protein kinase A. Subsequent phosphorylation of the cytoplasmic COOH terminus at serine 256 of the aquaporin-2 water channel (AQ2) occurs and results in the insertion of AQ2 into the apical membrane of the CD cells [82–84]. Water enters the cells via AQ2 and exits the cell via the AQ3 and AQ4 water channels located on the basolateral membrane of the CD cells [85]. Water reabsorption depends on a hypertonic medullary interstitium, which drives water from the luminal fluid across the tubular epithelium [86].

Development of Water Transport in the Collecting Duct

Neonatal low urine concentrating capacity is not attributable to low ADH levels. During labour, ADH levels are elevated, which is consistent with the raised intracranial pressure and hypoxemia acting as stimuli for ADH release [87]. Despite adequate ability to secrete ADH, no correlation exists between ADH levels and urine osmolality in the first 3 weeks of life [88]. ADH stimulation of the neonatal cortical CD (CCD) results in a lower permeability response to water than that seen in the adult [89, 90]. The response to ADH does, however, improve with age [91]. Similarly, studies have shown that the concentrating capacity is even lower in infants who have sustained neonatal asphyxia [92]. V_2 receptor mRNA expression is observed in rodents as early as day 16 of gestation in cells of the developing medullary and cortical CD [93]. During the first 2 weeks of life in rats, the number of receptors does not change. By the fifth week of life, the number of receptors reaches adult levels [94]. However, the low response of the immature kidney to ADH is more likely due to immaturity of the intracellular second messenger systems rather than inadequate receptor number. ADH binding sites precede the onset of adenyl cyclase responsiveness [95]. In addition, ADH stimulation of adenyl cyclase generation is markedly lower in the neonatal period and is only about one-third that of the cAMP response seen in the adult CCD [96]. However, even when cAMP generation is rescued using cAMP analogs, the hydraulic permeability of isolated, microperfused rabbit CCD remains low [97]. Intracellular phosphodiesterases degrade cAMP. Indeed, an increase in phosphodiesterase IV and inhibition of the production of cAMP by PGE2 acting through EP3 receptors has been shown to inhibit adenyl cyclase generation on ADH stimulation. Therefore, cAMP inhibition likely accounts for the immature kidney's reduced response to ADH [98, 99].

AQ-2 levels (mRNA and protein) are lower in early postnatal life and reach maximal expression at 10 weeks of age (Fig. 6.5) [100]. AQ2 trafficking can be appropriately stimulated by dehydration and vasopressin in the immature kidney but the urine osmolality remains low [100]. Glucocorticoids regulate the AQ2 expression in the infant and not in the adult by increasing expression of both AQ2 protein and mRNA [101]. The expression of AQ3 and AQ4 does not change significantly after birth and they do not seem to play a role in the maturation of water transport in the CD [102].

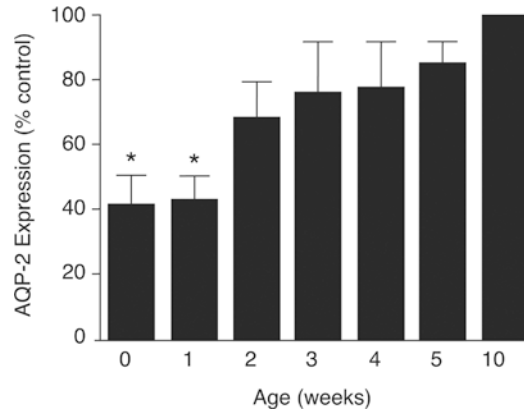

Fig. 6.5 Aquaporin-2 (AQ2) expression between 0 and 10 weeks of age. An increase in protein expression occurs in the postnatal period. (Used with permission from Bonilla-Felix [78])

Tonicity of the Developing Medullary Interstitium

In addition to low CD responsiveness to ADH, two other factors are responsible for the low concentrating capacity of the neonatal nephron. The medullary interstitium of the neonate has a low tonicity due to a low concentration of NaCl and urea [103]. Factors such as low protein intake, low sodium transport by the thick ascending limb of loop of Henle (TALH) [104], immaturity of the medullary architecture with shorter loops of Henle [105, 106] and alterations in urea transport [107] all contribute to the lower tonicity of the medullary interstitium. The activity of the Na-K-ATPase in the TALH increases after birth, with the most pronounced increase in activity between the second and third week of life, correlating well with the increase in urine concentrating capacity [108]. The loops of Henle elongate and penetrate

the medulla, forming tubulovascular units that are completed by the fourth postnatal week in rodents [109].

The medulla/cortex urea ratio increases over the first 3 weeks of life in newborn rabbits [103]. Rodent studies have shown that there is a striking increase in the number of urea transporters during the first 2 weeks of life [107]. The urea transporters prevent the loss of urea from the medulla into the circulation thereby ensuring a high concentration of urea in the medullary interstitium. Renal concentrating capacity is dependent on dietary protein intake [103] and infants fed high protein diets show a significant improvement in urinary concentrating capacity [92, 110].

In summary, the neonatal kidney's ability to concentrate urine is dependent on a number of steps involving the ADH-signal transduction pathway (Fig. 6.6), the maturation of Henle's loop and tonicity of the medullary interstitium.

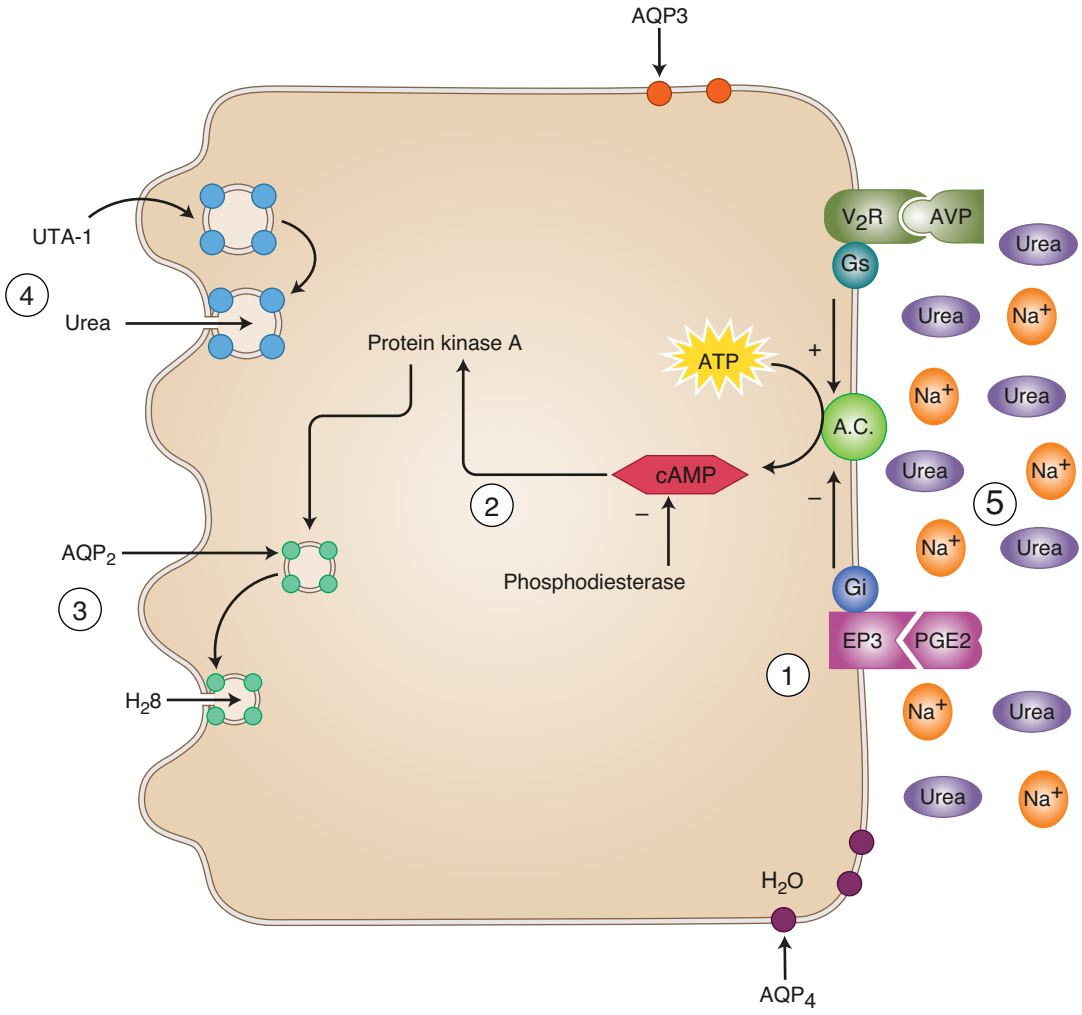

Fig. 6.6 The immature kidney's response to ADH: Responsible mechanisms are illustrated as follows: (1) Inhibition of cAMP generation by PGE_2 through EP3 receptor, (2) rapid degradation of formed cAMP resulting from increased phosphodiesterase activity, (3) low expression of AQP2 during early postnatal life, (4) low expression of UTA-1 during early postnatal life, (5) low concentration of urea and sodium in the medullary interstitium resulting from low rates of sodium transport, low dietary protein intake, and low expression of urea transporters

Postnatal Urine Flow

Oliguria is the most helpful sign of renal impairment in the neonate and a delay in the first void in a newborn may signal a renal disorder. Preterm neonates void earlier than term or post-term neonates [111] and the majority of normal newborns void within the first 24 h of life regardless of GA. Therefore, any neonate who remains anuric beyond the first day of life should be evaluated for renal insufficiency. The factors determining urine output include water balance, solute load and renal concentrating ability.

Minimum urine volume (L) = Urine solutes to be excreted/urine osmolality (max). As a result, a neonate receiving the usual renal solute load (7–15 mOsm/kg daily) with a maximal renal concentrating capacity of 500 mOsm/kg would require a minimal urine output of approximately 1 mL/kg/h to remain in solute balance. Since acute renal failure results in progressively positive solute balance, a urine flow rate less than 1 mL/kg/h has become an accepted criterion for the definition of oliguria in the neonate.

Sodium Transport in the Developing Kidney

Adaptation to the extrauterine environment involves a physiological natriuresis in the immediate postnatal period with preterm infants losing up to 16% of their birth weight in the first 3 days of life and term infants losing slightly less [112]. Human neonates remain in negative sodium balance for the first 4 days of life and then shift to a positive sodium balance by the second and third weeks of life (Fig. 6.7) [113]. Sodium conservation occurs because sodium is essential for growth in the neonate. In contrast to term neonates, preterm infants less than 35 weeks of gestation do not tolerate sodium deprivation, and hyponatremia may develop due to tubular immaturity and sodium wasting [114]. For this reason, sodium supplementation is important. Thus, the sodium requirements for a term newborn range from 1 to 1.5 mEq/kg daily, whereas the requirements for a preterm neonate range from 3 to 5 mEq/kg daily. Sodium supplementation in the preterm infant enhances the cumulative weight gain following the initial postnatal diuresis [113]. In the following section, we will discuss the mechanisms involved in the postnatal natriuresis and then the factors involved in the neonatal transition from negative to positive sodium balance.

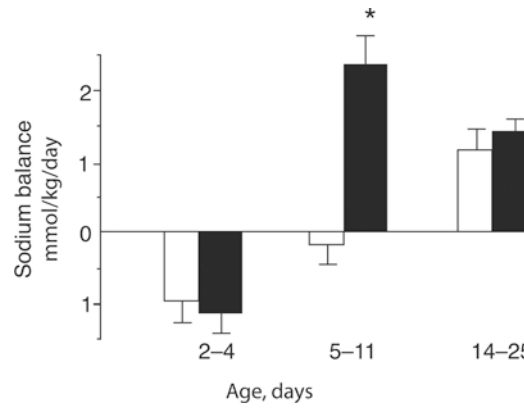

Fig. 6.7 Net external sodium balance for preterm infants in the first 3 weeks of life. Symbols are: (□) control infants; (■) sodium-supplemented infants, 4–5 mEq/kg/day; *$P < 0.0005$ vs. controls. In the first 2–4 days after birth, infants undergo natriuresis regardless of sodium intake, whereas by 1 week, supplemented infants achieve positive sodium balance sooner than controls. (Used with permission of BMJ Publishing Group from Al-Dahhan et al. [113])

Early Postnatal Natriuresis

High perinatal circulating levels of ANP have been implicated in the immediate postnatal natriuresis seen in both term and preterm infants [8]. ANP is a natriuretic hormone produced within the cardiac myocytes and released by stretch of the atrial wall. At birth, pulmonary vascular resistance falls and left atrial venous return increases, stimulating the release of ANP. ANP exerts a number of physiological effects, including an increase in GFR, natriuresis, diuresis, inhibition of renin and aldosterone release, vasorelaxation and an increase in vascular permeability [115].

ANP modulates sodium homeostasis by binding to physiologically active receptors, increasing intracellular cGMP [116]. Inhibition of sodium transport occurs through inhibition of apical sodium channels in renal tubular epithelial

cells, leading to natriuresis. Plasma ANP concentration decreases with maturation [117, 118]. A fall in right atrial volume occurs over the first 4 days of fetal life with parallel reductions in ANP concentration and urinary cGMP excretion [119]. In addition, a decrease in cGMP production per ANP binding site has been shown to occur rapidly in the suckling period in neonatal rats [120]. Therefore, sodium excretion is reduced after the first few postnatal days and the neonatal kidney subsequently aims to conserve sodium.

Neonatal Transition to Positive Sodium Balance

A reduction in the fractional excretion of sodium occurs after the first week of life, with fractions <1% in the majority of infants (Fig. 6.8) [122]. Factors contributing to the decrease in the fractional excretion of sodium include maturation of the sodium transport mechanisms in the postnatal nephron, in addition to high circulating levels of angiotensin II, catecholamines, glucocorticoids and a reduction in ANP. Each of these factors will be discussed in the following section.

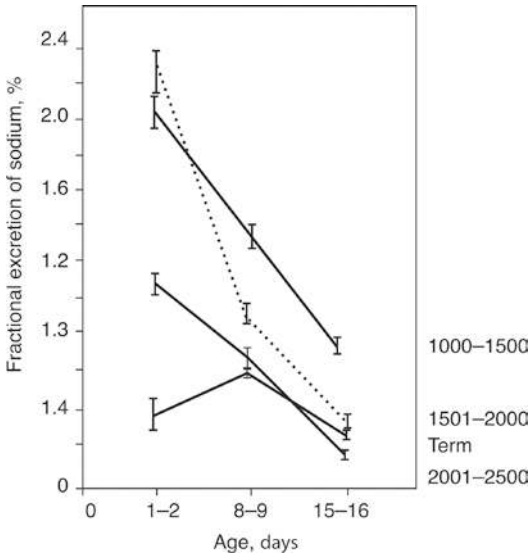

Fig. 6.8 Fractional excretion of sodium during the first 2 weeks of life in preterm and term infants. Sodium is conserved despite an increase in GFR. (Used with permission of Elsevier from Chevalier [121])

Maturation of Sodium Transport Mechanisms in the Developing Nephron

A progressive maturation of each tubular segment occurs in the postnatal kidney [123]. Each tubular segment will be discussed separately in the following section.

Proximal Tubule

Solute transport in the neonatal proximal tubule is similar to that in the adult and follows both chloride and bicarbonate reabsorption. Several animal studies have shown an increase in the activity of the Na^+/H^+ exchanger as the neonate matures [124, 125]. In addition, an increase in activity of the chloride/formate exchanger has also been shown to occur [126]. The Na-K-ATPase transporter plays a key role in sodium reabsorption in the proximal tubule and slower transport has been shown in neonates compared to adults, with a progressive maturation occurring from birth (Fig. 6.9) [127, 128]. In guinea pigs, posttranslational increase in the α1 and β1 subunits of the Na-K-ATPase transporter occurs immediately after birth [129].

Loop of Henle

NaCl transport in the TALH occurs by paracellular and transcellular pathways via the apical

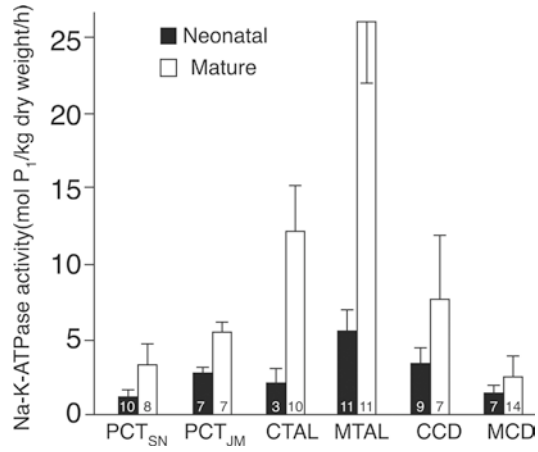

Fig. 6.9 Na^+/K^+ ATPase activity in the neonatal and adult nephron. The Na^+/K^+/ATPase activity is lower in the neonate compared to the adult. (Used with permission of Schmidt and Horster [127])

sodium-potassium-chloride cotransporter (NKCC2) and sodium-hydrogen antiporter 3 (NHE3) exchangers. The basolateral cell membrane utilizes the Na-K-ATPase to extrude sodium. Transcription of NKCC2 is observed early in development, prior to the onset of filtration in the descending loop of Henle. Physiological studies show, however, that the NKCC2 is unlikely to be functional until postnatally, as a low reabsorptive capacity has been shown for this segment in early postnatal life [109]. Compared to the adult, the expression of all of these transporters is lower in the neonate [130–133]. A postnatal five to tenfold increase in activity of the Na-K-ATPase co-transporter occurs and is greater than that seen in other tubular segments (Fig. 6.9) [127, 134]. Na-K-ATPase consists of a catalytic (α subunit) and a regulatory (β subunit). Both the α1 and β1 isoforms are present in the mature kidney. On the other hand, the α1 subunit is detected early in fetal life whereas the β1 subunit is detected only after birth. Interestingly, the β2 isoform is expressed in the fetal kidney and, in contrast to the adult, Na-K-ATPase is expressed on both the apical and basolateral cell membranes. After birth, the β2 isoform is downregulated and the α1 and β1 isoforms are upregulated [135]. Heterodimerization of the α1 and β1 isoforms is essential for the function of the Na-K-ATPase. Of note, treatment with glucocorticoids increases the synthesis of mRNA for both the catalytic and regulatory subunits of the Na-K-ATPase. During postnatal life, there is a 20% increase in the amount of sodium reabsorbed along this segment, which reflects functional maturation of transporters, an increase in the resorptive surface area and maturation mechanisms of hormonal control.

Distal Tubule

The Na^+–Cl^- co-transporter (NCC) is the major sodium influx co-transporter in the distal tubule. In the mature nephron, NCC is expressed along the entire distal tubule, starting beyond the NKCC2-expressing post-macular segment and ending at the transition into the collecting tubules [136]. During development, NCC mRNA is detected in distal tubule segments before the expression of NKCC2 mRNA and sodium-phosphate type 2 co-transporter mRNA. Later in development, NCC expression proceeds gradually into the post-macula segment of the TALH [132].

Cortical Collecting Duct

Fine-tuning of sodium reabsorption occurs in the CCD where the amiloride-sensitive epithelial sodium channel (ENaC) plays an important role. ENaC is located on the apical membrane of distal tubular, cortical and outer medullary CD cells [137]. ENaC is comprised of three subunits, α,β and γ. Rodent studies show that the amount of total renal embryonic rat ENaC subunit mRNA is low but increases from murine gestational day 16–19 [138]. A sharp rise to almost adult levels occurs in the first three postnatal days [139]. After birth, the mRNA for α ENaC increases, whereas that for β- and γ-decreases. In the immature kidney, the greatest expression is seen in the terminal CD for all three subunits. As the kidney matures, the expression in the cortical distal nephron increases and in rodents is complete by the ninth postnatal day [140]. Endogenous glucocorticoids do not appear to have any effect on the prenatal maturation of ENaC in the kidney [141]. Although this response has long been assumed to be solely the result of liganded nuclear hormone receptors transactivating αENaC, epigenetic controls of basal and aldosterone-induced transcription of αENaC in the CD were recently described [142].

The Na-K-ATPase is also present in the CCD on the basolateral cell membrane. Tracer uptake assays of individual CCDs have shown that the activity of the Na-K-ATPase increases within the same time interval as it takes for maturation of the net transepithelial reabsorption of sodium and potassium [143]. The capacity of the CCD to reabsorb sodium increases immediately after birth [144] and reflects the increase in expression of the aforementioned sodium channels.

Developmental Paracrine Regulation of Renal Sodium Excretion

Renin: Angiotensin: Aldosterone System (RAS)

Studies have shown that the RAS is involved in renal tubular sodium reabsorption in the neonate. Acute volume expansion in neonatal rat pups results in natriuresis and AT1 blockade attenuates the natriuretic response, demonstrating that angiotensin II mediates sodium reabsorption via the ATI receptor [145]. The proximal tubule is the likely site of sodium reabsorption because angiotensin II augments sodium reabsorption in the proximal tubule in adult rats during volume contraction [146]. In addition, angiotensin II stimulates aldosterone, which stimulates sodium reabsorption in the TALH as well as the distal tubule and the CD. Preterm neonates without sodium supplementation demonstrate markedly increased plasma renin and aldosterone activity compared to their sodium supplemented counterparts, indicating that the neonatal RAS is involved in sodium homeostatic mechanisms [147].

Catecholamines

Catecholamines stimulate NaCl and water reabsorption by the proximal tubule, ascending limb of Henle's loop, distal tubule and CD. Circulating plasma catecholamines are high in the neonatal period and then fall over the first few days of life as discussed earlier (see section on "Glomerular Function in the Fetal, Perinatal, and Postnatal Period"). Catecholamines stimulate an increase in renin release, which promotes sodium reabsorption. In addition, dopamine acting via the D2 receptor in preterm neonates enhances sodium reabsorption in the proximal tubule [148].

Glucocorticoids and Thyroid Hormone

Plasma cortisol levels increase markedly after birth [149]. Maturation of the Na^+/H^+ exchanger occurs under the influence of glucocorticoids, as demonstrated by the attenuated postnatal increase of Na^+/H^+ exchanger activity and protein and mRNA abundance in the brush border of proximal tubular cells of adrenalectomized newborn rodents [150]. Glucocorticoids also play a role in the maturation of transporters along the entire nephron [151, 152]. Thyroid hormone plays a role in the maturation of the paracellular pathways of sodium reabsorption [153] and in the regulation of the Na^+/K^+ ATPase activity [154].

Fractional Excretion of Sodium

In the oliguric term neonate (urine flow less than 1 mL/kg/h), fractional excretion of sodium of less than 2.5% suggests a pre-renal cause, such as volume depletion, hypoalbuminemia or reduced cardiac output [155]. The criterion of 2.5% is valid after the first 10 days of life in the low birth weight newborn after the period of postnatal natriuresis [122]. In addition, very low birth weight infants have greater fractional sodium excretion due to immaturity of the sodium reabsorptive capacity [156].

Potassium Transport in the Developing Kidney

Like sodium, potassium is critical for somatic growth and an increase in total body potassium content is associated with growth [157]. In contrast to the adult, neonates greater than 30 weeks GA must maintain a positive potassium balance [157, 158]. Premature newborns, as a result, tend to have higher plasma potassium concentrations than children [158]. In utero, the placenta transports potassium from the mother to the fetus [159]. Interestingly, potassium levels >6.5 mmol/L are observed in 30–50% of very low birth weight infants in the first 48 h in the absence of potassium intake and not after 72 h [160]. A shift from the intracellular to the extracellular fluid compartment, as a result of either Na/K ATPase pump failure and/or a limited renal potassium excretory capacity have been postulated to account for this increase [161, 162].

Renal potassium excretion is determined by the rate of potassium excretion by the principal cells of the distal tubule and CD. Net potassium secretion cannot be detected in microperfused CCD of newborn rabbits until after the third week of life (Fig. 6.10) [164] and flow-stimulated transport is not detected until after the first postnatal month [165].

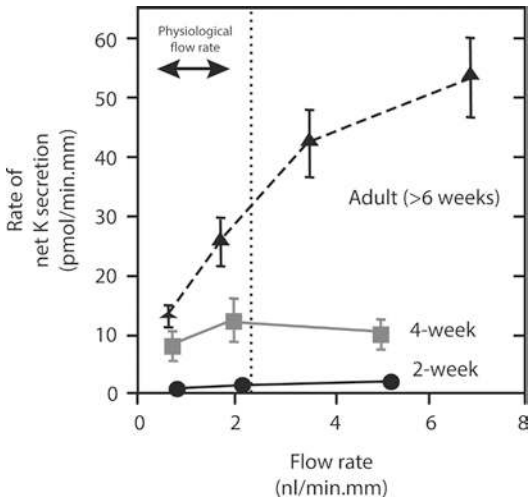

Fig. 6.10 Net potassium secretion in maturing rabbits. (Used with permission of Elsevier from Zhou and Satlin [163])

Maturation of Potassium Transport Mechanisms in the Developing Nephron

Maturation of tubular transport mechanisms will be discussed for each tubular segment in this section.

Proximal Tubule and Loop of Henle

In the mature nephron, 65% of the filtered potassium load is reabsorbed passively in the proximal tubule [166] and only 10% reaches the early distal tubule. In contrast, 35% of the filtered potassium load reaches the distal tubule of the newborn rat [167]. Therefore, postnatal maturation of the TALH is required for further potassium reabsorption. Indeed, both the diluting capacity and Na-K-ATPase activity increase after birth [108, 127]. As discussed earlier, transcription of NKCC2 is observed early in development, prior to the onset of filtration in the descending loop of Henle, but is unlikely to be functional until postnatally in view of the low reabsorptive capacity shown for this segment in early postnatal life [104]. Apical renal outer medullary potassium channel (ROMK) has been detected in the TALH at an earlier developmental stage compared to the CCD. Functional analyses on ROMK in the developing TALH have not been performed.

Cortical Collecting Duct

In the fully differentiated CCD, two types of potassium channels are involved in potassium secretion: (1) the ROMK channel mediates potassium secretion under baseline conditions [168, 169] and (2) the maxi-K^+ channel, which mediates flow-stimulated potassium secretion [170]. ROMK has only been shown in principal cells of the CCD. Maxi-K^+ exists in both the principal and intercalated cells of the CCD [170]. In isolated CCDs of neonatal rabbits, apical ROMK channels are not detected in the first 7 days of life and, subsequently, a threefold increase in the number of ROMK channels is seen in the principal cells of CCD between the third and fifth week of life [171]. The initial increase in expression follows 1 week after an increase in ENaC activity is detected [172]. Also, expression of the ROMK protein on apical cell membranes of the TALH and occasional CCD in the inner cortex and outer medulla is detected in 1-week old animals by indirect immunofluorescence studies [173]. By 3 weeks of age, expression has increased to involve the mid and outer CCDs [173]. Maxi-K^+ channels mediate flow stimulated K^+ secretion and do not appear to be functional in 4-week old rabbits subjected to a sixfold increase in tubular flow rate [165]. However, a small but significant increase in net potassium secretion after 5 weeks of age is observed. An associated increase in the mRNA and protein expression of the α subunit of the maxi-K^+ channel is seen on the apical surface of the intercalated cells of the CCD [165]. In addition to potassium excretion, potassium reabsorption also occurs in the distal nephron via the apical H^+/K^+ ATPase. Fluorescent functional assays identify significant H^+/K^+ ATPase activity on the apical cell membranes of neonatal intercalated cells [174], which suggests that neonatal CDs have a capacity to retain potassium. Indeed, a longitudinal prospective study of fractional potassium excretion in 23–31 week GA infants demonstrated that despite a threefold increase of

filtered potassium, the renal excretion fell by half between 26 and 30 weeks [157]. This study supports the idea that the developing kidney has the capacity for potassium reabsorption.

Regulation of Potassium Balance in the Neonate

Table 6.3 illustrates the factors which acutely regulate plasma potassium in the neonate. The immature kidney displays an insensitivity to aldosterone despite high circulating levels of aldosterone [158]. The number of mineralocorticoid receptors, the receptor affinity and degree of nuclear binding of hormone-receptor is similar in adult and neonatal rats [175]. Aldosterone insensitivity may result from immature intracellular signal transduction mechanisms. Aldosterone insensitivity in the immature kidney is supported by the low transtubular potassium gradients (TTKG) reported in 27 week GA infants compared to 30-week infants followed over the first 5 days of postnatal life [176]. However, the low TTKG may also reflect a low secretory ability. Glucocorticoids have a significant effect on potassium balance in extremely low birth weight infants during the first week of life. Infants whose mothers received a full course of prenatal steroids had no hyperkalemia (>6.5 mmol/L) and a less negative potassium balance at the end of the first week of life [177]. Several studies have shown that glucocorticoids upregulate the expression of the Na^+/K^+ ATPase [178], resulting in a decrease of the intracellular to extracellular potassium shift.

Table 6.3 Neonatal potassium regulation

Acid-Base Regulation in the Developing Kidney

The term neonate has a lower bicarbonate concentration than the adult (Fig. 6.11) [179, 180]. In the low birth weight newborn, total bicarbonate may be as low as 15 mmol/L during the early postnatal period and is within normal limits [179]. Bicarbonate gradually increases with increasing GFR. Misdiagnosis of renal tubular acidosis may occur if one does not take into account the physiologically low plasma bicarbonate in neonates. In addition, neonates need to excrete 2–3 mEq/kg/day of acid due to their high protein intake and formation of new bone. The neonate has a reduced ability to respond to an acid load while ammoniagenesis and titratable acidity mature after 4–6 weeks in the low birth weight newborn [181]. Renal regulation of acid-base balance undergoes complex changes during development and will be discussed in detail.

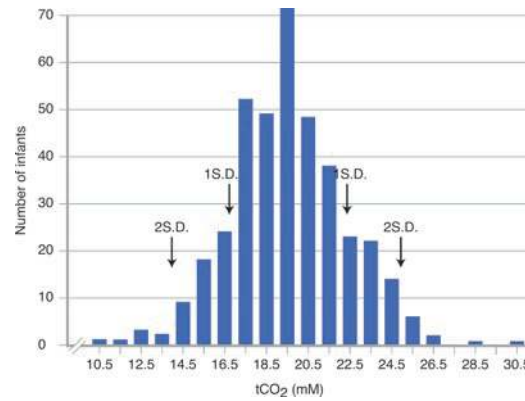

Fig. 6.11 Frequency distribution of serum total bicarbonate (tCO_2) in low birth weight neonates during first month of life. Mean is approximately 20 mM and normal range ±2 standard deviations (S.D.) is 14.5–24.5 mM. (Used with permission of Elsevier from Schwartz et al. [179])

Proximal Tubule Handling of Bicarbonate in the Neonate

Neonatal bicarbonate reabsorption in the proximal tubule is one third that of the adult [182] and is due to lower activity of the transporters present in the adult [183]. The number of apical NHE3 antiporters is lower than that in the mature nephron and has about one-third the activity [124]. The H^+/ATPase does not appear to be active in the neonate while the basolateral Na-K-ATPase has about one-half of activity compared to the adult [184]. The carbonic anhydrase (CA) type IV isoform which is expressed on the brush border of proximal tubular epithelial cells has a lower activity in the developing nephron of rabbits, but activity does increase during maturation and parallels the increase in bicarbonate reabsorption occurring in the proximal tubule [185]. Ammoniagenesis does occur in the neonatal kidney, but at a much lower rate compared to the adult [186, 187]. Glutamine and activity of the deaminating enzyme, glutaminase, is lower in the neonatal kidney while glutaminate, an inhibitor of glutaminase, is higher. Neonates, as a result, cannot generate the same amount of ammonia during an acid load and take a longer time to recover their acid-base balance.

Thick Ascending Limb of Henle's Loop

While transcription of NKCC2 is observed early in development, NKCC2 is unlikely to be functional until postnatally as a low reabsorptive capacity has been shown for this segment in early postnatal life [104]. As discussed earlier, the expression of all of the TALH transporters is lower in the neonate [130–133]. As a result, bicarbonate and ammonium reabsorption occur at a lower rate compared to the adult. A postnatal five to tenfold increase in activity of the Na-K-ATPase co-transporter has been shown and is greater than that seen in other tubular segments (Fig. 6.9) [127, 134].

Cortical Collecting Duct

Microperfusion studies of neonatal rabbit kidneys demonstrate a lower capacity to secrete acid compared to adult controls [188]. The neonatal number of intercalated cells is half that of the adult [189–191]. In addition, lower levels of the CA II isoform have been shown in neonatal rat kidneys [191, 192]. The CA II isoform is important for the function of the α-intercalated cell and may be indicative of the increase in acid secreting capability of the developing CCD.

Regulation of Maturational Acid-Base Homeostatic Mechanisms

Glucocorticoids

Glucocorticoids can stimulate bicarbonate reabsorption and a developmental increase in circulating cortisol levels precedes the increase in bicarbonate reabsorption [193]. Pregnant rabbits injected with glucocorticoids give birth to neonatal rabbits with proximal tubular bicarbonate reabsorption rates similar to that of adults [193]. An increase in NHE3 antiporters occurs with prenatal glucocorticoids [194]. Adrenalectomy prevents this maturational increase in NHE3 antiporter expression at both the level of protein and mRNA. Therefore, the maturational increase in glucocorticoids is responsible for the postnatal increase seen in proximal tubule acidification.

Renal Calcium Handling in the Developing Kidney

Higher calcium and phosphate levels are required for the growing skeleton in the fetus to ensure a positive calcium balance when bone calcium deposition rate is at its highest [195, 196]. A high geomaterial calcium ratio is maintained during pregnancy and is mediated by active transport in the placenta [197]. The elevated fetal calcium suppresses PTH release [198]. PTH is the main regulator of calcium metabolism after birth.

Circulating fetal calcium levels increase with advancing GA and at term the fetus is hypercalcemic relative to the maternal levels [199]. Serum calcium levels fall over the first 24 h in the absence of the placenta. As a result, PTH secretion is stimulated [200], but the response to the falling calcium is not sufficient such that a physiological nadir of serum calcium occurs in the first 2 days of life. This nadir is still within the adult range but represents a significant decrease compared to fetal levels [198]. Term infants typically achieve normal serum calcium levels by the second week of life, with typical circulating concentrations of ionized calcium in neonates being in the range of 1–1.5 mmol/L (2–3 mEq/L) [201].

After birth, the kidney plays an important role in calcium and phosphate homeostasis (Table 6.4). Calcium filtered by the kidney is reabsorbed along the nephron to maintain the serum concentration [202]. Only 1–2% of filtered calcium is excreted in urine by the mature nephron [203]. Most reabsorption of filtered calcium, about 70% in the proximal tubule and 20% in the thick ascending limb, is paracellular, a passive process occurring down an electrochemical gradient. Calcium diffuses across the apical cell membrane into the cell. Sodium-driven water absorption plays a significant role in this process as highlighted by a two-fold increase in the fractional excretion of calcium (FECa) in mice null for the *Nhe3* transporter, which mediates the majority of sodium reabsorption from the proximal tubule [204]. Paracellular movement of calcium is mediated by tight junction proteins called claudins (Cldn) [205]. Claudin-2 is responsible for calcium permeability in the proximal tubule. *Cldn2* deficient mice have a three-fold increase in the fractional excretion of calcium (FECa) associated with decreased proximal tubular monovalent cation permeability [206]. Little is known about the role of other claudins in paracellular calcium permeability across the proximal tubule.

Table 6.4 Summarises the developmental expression of the proteins involved in renal handling of calcium

Modified from Beggs and Alexander [202]

Claudins 16 and 19, in the TALH, form a cation permeable pore [207]. Upregulation of Claudin-14 occurs in hypercalcaemia and is associated with increased transepithelial resistance (TER) and decreased absolute calcium permeability, similar to the effect of pharmacological inhibition of Claudin-14. Activating mutations in the calcium sensing receptor (CaSR) mediate downregulation of Claudin-14 transcript, supporting the role of claudin-14 as an important negative regulator of calcium reabsorption in the TALH [202]. The regulatory role of the CaSR during postnatal development has yet to be determined. Autosomal dominant hypocalcaemia is associated with gain of function mutations, whilst loss of function mutations cause hypercalcemia, ranging from benign familial hypocalciuric hypercalcemia (autosomal dominant) to potentially fatal neonatal severe hyperparathyroidism (autosomal recessive).

Eighty percent of filtered calcium is reabsorbed by the proximal tubule whilst the remainder of calcium is reabsorbed in the distal nephron and, in particular, the distal convoluted tubule and connecting tubule via an active transcellular process. Active calcium reabsorption occurs through the highly Ca^{2+}-selective TRPV5 channel and binds to calbindin/D28K. The calbindin/D28K ferries Ca^{2+} to the basolateral $3Na^{+}/Ca^{2+}$ exchanger (NCX1) and the plasma membrane calcium ATPase 1b which extrude calcium into the blood compartment. Animal studies have shown that TRPV6, calbindin/

D9K, TRPV5 and calbindin/D28K are expressed in the kidneys of fetal mice at GA 18 days [208]. TRPV6 reaches a maximum level at 1 week of age and then decreases to <10% of TRPV5 expression, suggesting a possible role for TRPV6 during developmental regulation of calcium homeostasis. The expression of TRPV5 and calbindin/D28K peaks at the third postnatal week and then falls [208].

Renal Calcium Handling in Postnatal Period

The amount of calcium excreted increases over the first 2 weeks of life [209], and normal calcium:creatinine ratios are accordingly higher in infants. Premature and low birth weight infants have a high incidence of nephrocalcinosis on ultrasound that is most likely secondary to a three-fold higher urine calcium excretion than the upper limit of normal for term infants.

During childhood, urine calcium excretion declines by 50% between 1 month and 2 years of age. By 10 years of age, a further reduction of 30% occurs [210].

Renal Phosphate Handling in the Developing Kidney

Phosphate is of critical importance to body functions, particularly during periods of growth. Neonates excrete only 60% of intestinally absorbed phosphate and have a higher phosphate concentration than adults [211]. In neonates, the transtubular reabsorption of phosphate is high. Neonates reabsorb 99% of the filtered load of phosphate on the first day of life and 90% by the end of the first week [212]. Micropuncture studies performed on guinea pig neonatal proximal tubules demonstrated a higher phosphate reabsorption rate than adult guinea pigs [213]. Reabsorption does not occur through the $2Na^+$/Pi IIa antiporter but rather through its developmental isoform, the $2Na^+$/Pi IIc antiporter, the expression of which is higher in weaning animals and has a reduced function in adults [214].

Regulation of Renal Phosphate Handling in the Developing Kidney

The increased phosphate reabsorption in the early postnatal period is thought to be multifactorial. Parathyroidectomy in immature rats results in a greater increase in the maximal tubular phosphate reabsorption than in mature rats, suggesting a role for PTH in neonatal phosphaturia [215]. However, a decline in resorptive capacity is also observed with age in the presence of parathyroid glands, suggesting that there is an enhanced capacity of the immature tubule to reabsorb phosphate. In addition, responsiveness to PTH increases threefold during the first few weeks of life, suggesting a maturation of second messenger systems [216]. In the mature nephron, Klotho and PTH both increase the expression and activity of the $2Na^+$/Pi symporter [217] resulting in phosphaturia. Future research will provide interesting insights into the ontogeny of Klotho and fibroblast growth factor 23 (FGF-23), a phosphaturic hormone, during maturation of the renal phosphate transport systems.

Growth hormone (GH) has also been shown to upregulate $2Na^+$/Pi symporter in micropuncture studies performed on 4 week old rat proximal tubules, an effect that is independent of PTH [218, 219]. As GH levels in rodents peak in the first week of life, high serum GH in the neonate may contribute to the elevated phosphate reabsorption observed in the kidneys of neonates [220].

The mechanism enhancing the GH effect is unknown as developmental differences in the expression of GH receptors have not been shown. Both GH and IGF-1 mRNA have been localized to the apical membrane of proximal tubular epithelial cells suggesting a role of the GH/IGF-1 axis in phosphate reabsorption [221].

Magnesium Handling in the Developing Kidney

In the adult kidney, 80% of total serum magnesium is filtered and >95% is reabsorbed along the nephron [222]. The proximal tubule reabsorbs 15–20% in the adult kidney but interestingly 70%

in the developing proximal tubule [222]. A maturational decrease in the paracellular permeability at the level of the tight junction has been suggested as a reason for the decline in proximal magnesium reabsorption. From early childhood on, the majority of magnesium transport (70% of the filtered load) occurs in the loop of Henle. The distal convoluted tubule reabsorbs 5–10%. Transport in the TALH is passive and paracellular, driven by the lumen positive transepithelial voltage and involves paracellin-1, a member of the claudin family involved in tight junction formation [223]. Active and transcellular reabsorption of magnesium occurs in the distal convoluted tubule and probably through the apical TRPM6 channel [224]. Ontogeny of the TRPM6 channel and its family members and paracellin-1 requires further research.

Renal Glucose Handling in the Developing Kidney

In the mature nephron, more than 99% of the filtered glucose is reabsorbed [225]. Glucosuria is more common among neonates, with the highest levels in preterm infants [226]. The maximum tubular reabsorption of glucose is lower in preterm and term infants than in adults [227]. Age-related differences in glucose transport activity correlate with differences in sodium conductance. Changes in membrane permeability to sodium affect membrane potential, a factor which modifies glucose reabsorption. Therefore, factors such as an increase in cell membrane surface area and in basolateral Na^+/K^+-ATPase, increased density of transporter proteins and the development of new nephrons are implicated in the increase in glucose resorptive capacity observed as the fetus matures [228–230].

Renal Amino Acid Handling in the Developing Kidney

Amino acids are reabsorbed in the proximal one third of the proximal tubule in an active, sodium-dependent process [231]. Specific amino acid transport systems on the luminal cell membrane reabsorb the amino acids by secondary active transport against an uphill concentration gradient along with sodium. Aminoaciduria is frequently observed in the neonate. Factors include decreased activity of the amino acid-sodium cotransporter, increased Na^+/H^+ exchange at the luminal membrane and decreased activity of the Na^+/K^+/ATPase at the basolateral membrane [232]. Of note, not all of the amino acids are wasted to the same degree [233]. Developmental differences have been shown for the amino acid system and the glycine transporter systems [234, 235].

Assessment of Renal Functional Maturation

Renal functional maturation can be measured by either glomerular or tubular indicators. Glomerular function is assessed by serum creatinine and cystatin C levels, urinary microalbumin and immunoglobulin G and GFR. Tubular function can be assessed by the fractional excretion of sodium or urinary α1-microglobulin and urinary levels of other tubular proteins normally reabsorbed by the proximal tubule such as *N*-acetyl-β-D-glucosaminidase or β2-microglobulin [236]. All markers have been closely associated with GA. A decrease in urinary tubular proteins occurs with increasing GA [237].

Overview of Human Kidney Development

Human kidney development begins in the fifth week of gestation, with the first functioning nephrons making urine by the ninth week [1]. The formation of new nephrons continues until approximately 32–34 weeks gestation [2, 3]. Further renal growth is the result of growth and maturation of already formed nephrons, rather than the generation of new nephrons. Remarkably, there exists wide variability in the number of nephrons that occur naturally in humans, from 200,000 to 1.8 million per person [4]. In humans that suffer fetal or perinatal renal injury, the developing kidney is incapable of compensating for irreversible nephron loss by either accelerating the rate of nephron formation *ex utero* in infants born prematurely, or by *de novo* generation of nephrons once nephrogenesis is completed [2, 5]. Thus, the number of nephrons formed at birth is thought to be an important determinant of renal function later in life.

This concept is supported by the association of renal failure in humans with oligomeganephronia [6, 7], and by the demonstration of reduced glomerular number in humans with primary hypertension and chronic kidney disease [8, 9]. Quantitative analyses in humans and rodents using stereological methods of glomerular counting in renal autopsy specimens have revealed a relationship between birth weight and glomerular number [4, 10]. The latter data are consistent with the "Barker Hypothesis", which proposes that adult disease has fetal origins and is based on

epidemiological studies showing a correlation between birth weight and the incidence of cardiovascular disease [11, 12]. Equally important is the normal structural development of each nephron (or, nephron pattern), which is critical for nephron function. Abnormal nephron pattern results in renal dysplasia. Consequently, mechanisms that control congenital nephron endowment and nephron pattern are likely to be crucial factors in determining long-term as well as short-term renal function.

Our understanding of human kidney development historically began with histological descriptions of microdissected human fetal kidney autopsy specimens performed by Edith Potter and Vitoon Osathanondh [1, 13, 14]. Their seminal work was complemented by analyses of mouse kidney development performed by Lauri Saxen [15]. The mammalian kidney derives from two parts of the metanephros, its embryonic precursor. The first part is the ureteric bud, which gives rise to the collecting duct system, including the cortical and medullary collecting ducts, the renal calyces, the renal pelvis, the ureter, and the trigone of the bladder [2, 15]. The second part is the metanephric mesenchyme, which differentiates into all the epithelial cell types comprising the mature nephron, including the visceral and parietal epithelium of the glomerulus, the proximal convoluted tubule, the ascending and descending limbs of the Loops of Henle, and the distal convoluted tubule [2, 15]. Reciprocal signals between these two tissues are critical for normal kidney development.

The molecular and genetic control of kidney morphogenesis is the subject of several comprehensive reviews [16–20]. Mutational analyses in mice have yielded important insights into the molecular pathways that regulate key events during the formation of nephrons, including the specification and differentiation of the metanephric mesenchyme, ureteric bud induction, renal branching morphogenesis, nephron segmentation and glomerulogenesis. The phenotypes resulting from murine gene mutations also serve as paradigms for renal malformations (*viz.* renal agenesis, duplex kidney) that predict roles for corresponding human gene mutations in the pathogenesis of these conditions. Thus, advances in human genomics and mammalian developmental genetics have accelerated the tempo of discovery in the field of developmental nephrology, providing novel insights into the genetic, epigenetic and environmental factors that impact nephron number and pattern. In the following sections, the morphologic events and molecular underpinnings of these developmental processes will be described.

Origin of the Mammalian Kidney

The mammalian kidney is derived from the intermediate mesoderm of the urogenital ridge, which develops along the posterior abdominal wall of the developing fetus between the dorsal somites and the lateral plate mesoderm. The Wolffian (also known as the mesonephric or nephric duct) is a paired embryonic epithelial tubule extending in an anterior-posterior orientation on either side of the midline, which arises from the intermediate mesoderm. The Wolffian duct is divided into three segments—the pronephros, mesonephros, and metanephros (Fig. 7.1). At its anterior end, the pronephros forms the renal anlage in fish [21] and frogs [22], but degenerates in mammals. The mid-portion of the Wolffian duct, the mesonephros, gives rise to male reproductive organs including the rete testis, efferent ducts, epididymis, vas deferens, seminal vesicle, and prostate [23]. In females, the mesonephric portion of the Wolffian duct degenerates. The caudal portion of the Wolffian duct, the metanephros, becomes the mature mammalian kidney. The posterior segment of the Wolffian duct ultimately communicates with the cloaca to form the trigone of the bladder [23].

Several molecules have been identified as necessary in establishing the immediate precursors to the ureteric bud and metanephric mesenchyme of the developing metanephros in the intermediate mesoderm. The regional specification of metanephric mesenchyme at the posterior intermediate mesoderm next to the Wolffian duct requires the transcription factor, *Odd-skipped related 1* (*Osr1*) [24]. Cell-fate tracing studies

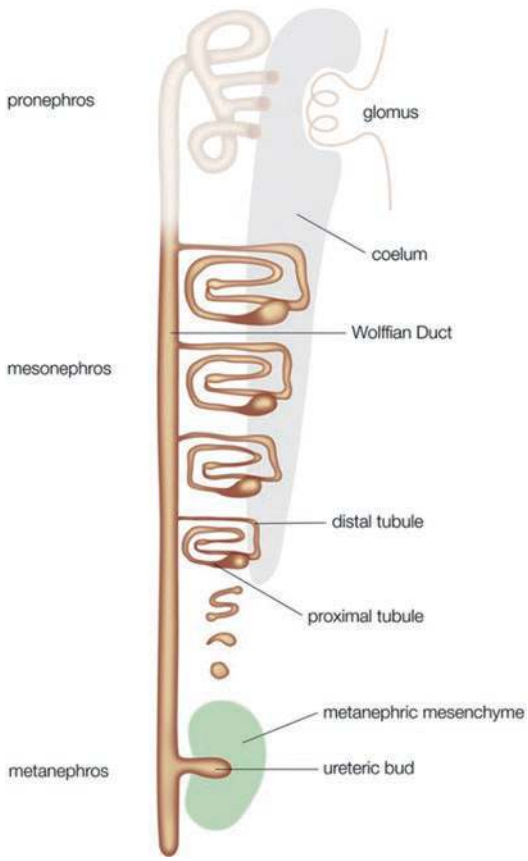

Fig. 7.1 Schematic overview of kidney development. Mammalian kidney development begins with the formation of the Wolffian duct, which is divided into three segments: pronephros, mesonephros and metanephros. The pronephros degenerates in mammals, whereas the mesonephros forms the male reproductive organs (rete testis, efferent ducts, epididymis, vas deferens, seminal vesicles and prostate). The metanephros becomes the mature mammalian kidney, and forms via inductive interactions between the metanephric mesenchyme and the ureteric bud. (Reproduced with kind permission from Springer Science+Business Media: Factors Influencing Mammalian Kidney Development: Implications for Health in Adult Life, Morphological Development of the Kidney, Advances in Anatomy and Cell Biology, Volume 196, 2008, pp. 9–16, Moritz K, et al., Figure 1)

have identified *Osr1*-expressing cells of the intermediate mesoderm as the origin of the principal cellular components of the metanephric kidney: the main body of the nephron, vascular and interstitial cell types, and the Wolffian duct [25]. The establishment and development of the Wolffian duct requires the function of the transcription factors, *Paired box gene 2* (*Pax2*) [26], *Pax8* [27], *Lim homeobox 1* (*Lhx1*) [28] and *Gata binding protein 3* (*Gata3*) [29], along with signaling through the tyrosine kinase receptor, *Ret* [30], and *β-catenin* (*Ctnnb1*) [31].

The ureteric bud forms as an outgrowth of the Wolffian duct in response to external cues provided by the surrounding metanephric mesenchyme. Signals that promote and direct ureteric bud branching morphogenesis originate from all derivative cell types of the metanephric mesenchyme, including induced and uninduced mesenchyme [32–34], stromal cells [35–39], and angioblasts [40, 41], as well as the ureteric bud itself [42]. The metanephric mesenchyme, in turn, originates from undifferentiated cells in the intermediate mesoderm adjacent to the Wolffian duct, to form nephrons and the renal stroma [25]. Similarly, the metanephric mesenchyme responds to inductive cues supplied by the ureteric bud and renal stroma to initiate nephron formation [43–47]. Subsequent patterning and differentiation of the cell types of the nephron is highly dependent on factors secreted by developing epithelial and stromal cells [38, 48, 49].

Induction of Nephrons from the Metanephric Mesenchyme

Once induced by the ureteric bud, the metanephric mesenchyme condenses around the ureteric bud tip, resulting in formation of the cap mesenchyme (Fig. 7.2). The cap mesenchyme is thought to represent a population of nephron progenitors, as these cells have the capacity to self-renew to generate an appropriate number of nephrons at the end of kidney development, and to differentiate into the multiple cell types required to form a mature nephron [50, 51]. The molecules that regulate the specification, proliferation, survival and differentiation of nephron progenitors are a focus of many studies, because an improved understanding of these processes may guide the development of novel cell-based therapies for chronic kidney disease [52].

The differentiation of the cap mesenchyme involves a process termed mesenchymal-

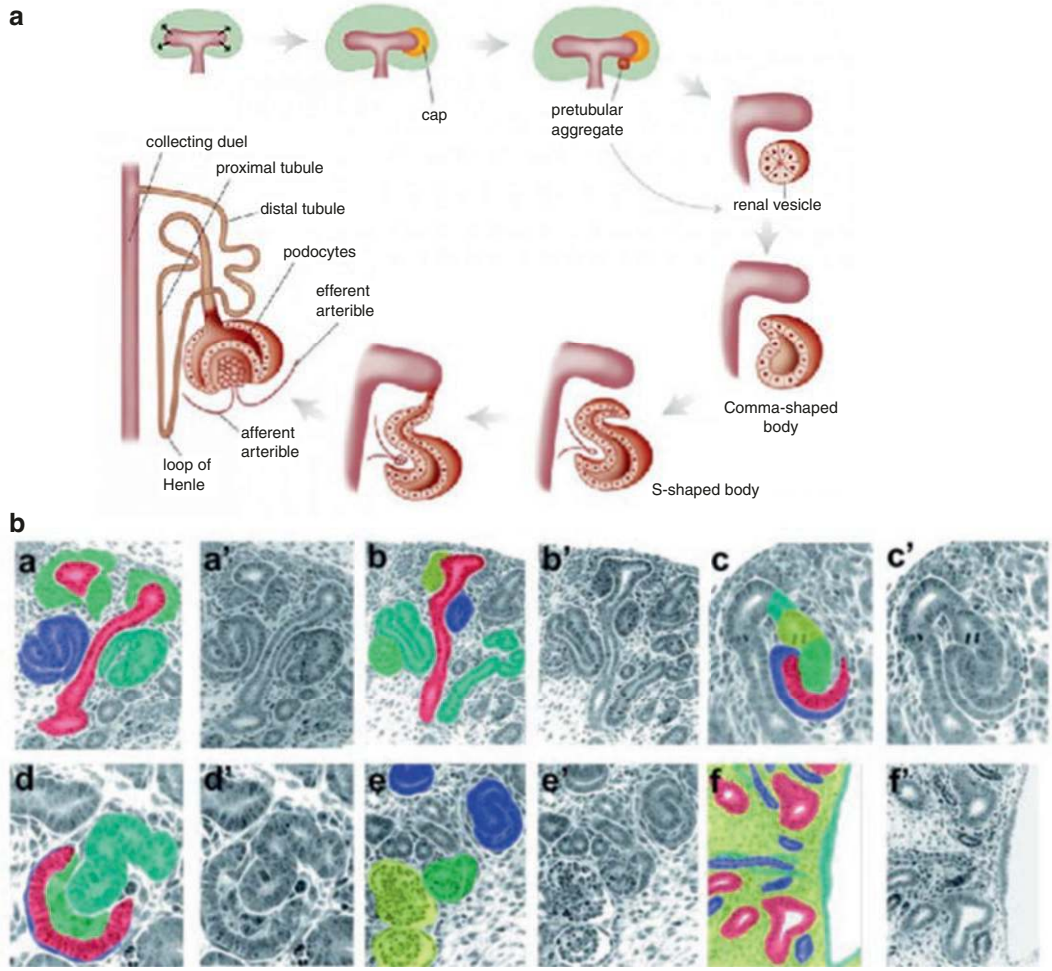

Fig. 7.2 Stages of nephrogenesis. (**A**) Induction of the metanephric mesenchyme by the ureteric bud promotes aggregation of the cap mesenchyme around the tip of the ureteric bud. The cap mesenchyme subsequently undergoes a mesenchymal to epithelial transition to form the pre-tubular aggregate, followed by a polarized renal vesicle. A cleft forms in the renal vesicle giving rise to the comma-shaped body. The development of the S-shaped body involves the formation of a proximal cleft which is subsequently invaded by angioblasts and starts the process of glomerulogenesis. Fusion of S-shaped body occurs with the collecting ducts (reproduced with kind permission from Springer Science+Business Media: Factors Influencing Mammalian Kidney Development: Implications for Health in Adult Life, Morphological Development of the Kidney, Advances in Anatomy and Cell Biology, Volume 196, 2008, pp. 9–16, Moritz, K., et al.). (**B**) Series of matched-pair histological images from a developing metanephric kidney with coloring for specific developmental stages. (a, a′) The ureteric tip and renal cortical collecting duct are in red, with the cap mesenchyme in green. Derivatives of the cap mesenchyme include the comma-shaped body in light blue and S-shaped body in dark blue. (b, b′) Next to the ureteric bud and renal cortical collecting duct (red) is a pre-tubular aggregate (yellow), a renal vesicle (dark blue), capillary loop stage developing glomerulus (green) and renal tubules (light blue). (c, c′) Segments of the S-shaped body include the visceral epithelium (red), parietal epithelium (dark blue), medial segment (green), distal segment (yellow) and renal junctional tubule (light blue). (d, d′) Segments of the capillary loop stage developing glomerulus include the visceral epithelium (red), parietal epithelium (dark blue), presumptive mesangium (green) and renal tubule (light blue). (e, e′) Image of the cortex of the metanephros showing different stages of glomerular development: an S-shaped body (dark blue), capillary loop stage (green) and maturing glomeruli (yellow). (f, f′) Image of the renal medulla and pelvis of the metanephros showing the renal medullary interstitium (yellow), medullary collecting ducts (red), immature loop of Henle (dark blue), renal medullary vasculature (green) and renal pelvic urothelial lining (blue) (reprinted from Gene Expression Patterns, Vol. 7(6), Little MH et al., A high-resolution anatomical ontology of the developing murine genitourinary tract, p. 688, 2007, Figure 3C, with permission from Elsevier)

epithelial transformation (MET). A localized cluster of cells separates from the cap mesenchyme under the ureteric bud tip, and acquires epithelial characteristics, becoming a "pre-tubular aggregate" (Fig. 7.2) [53]. Simultaneous with epithelialization, an internal cavity forms within the pre-tubular aggregate, at which point the structure is termed a renal vesicle. The renal vesicle subsequently forms a connection with its neighboring ureteric bud ampulla, permitting the ureteric bud lumen to communicate with the internal cavity of the renal vesicle. Further differentiation of the renal vesicle in a spatially organized proximal-distal pattern results in formation of the glomerular and tubular segments of the mature nephron (discussed in section "Formation of Nephrons").

Specification of the Metanephric Mesenchyme

The formation of the metanephric mesenchyme is molecularly marked by expression of the transcription factors *Wilms tumour 1* (*Wt1*) [54], *Cbp/p300-interacting transactivator, with Glu/Asp-rich carboxy-terminal domain, 1* (*Cited1*) [55], *Eyes absent homolog 1* (*Eya1*) [56, 57], *sine oculis homeobox homolog 1* (*Six1*) [58], *Six2* [59], *Sal-like 1* (*Sall1*) [60], *Pax2* [26], and *Lhx1* [61], as well as by expression of transmembrane molecules *cadherin-11* (*Cdh11*) [62] and *α8 integrin* (Fig. 7.3A, B) [63]. *Sall1* [60], *Six1* [58], *Eya1* [56, 57] and the secreted peptide growth factor, *Glial-derived neurotrophic factor* (*Gdnf*) [64], are expressed in intermediate mesoderm in the presumptive metanephric mesenchyme. Indeed, the cap mesenchyme is now understood to represent a heterologous population of nephron progenitors, which differ in their relative response to cues for self-renewal and differentiation. Molecular evidence of this is the differing expression patterns of key transcription factors. Thus, *Wt1, Cited1* and *Six2* expression is induced in the cap mesenchyme at the onset of ureteric bud outgrowth [54, 55, 59]. *Pax2* [65] and *Lhx1* [61] are also expressed in cap mesenchyme and its early epithelial derivatives. Recent single cell RNA-sequencing studies in developing mouse [66–71] and human kidneys [72–74] have contributed to our understanding of these subpopulations of nephron progenitors as well as the differences between mouse and human kidney development (Table 7.1).

Phenotypic analyses of mice with targeted gene deletions or tissue-specific inactivation of conditional alleles for these transcription factors have been informative regarding their role in specification of the cap mesenchyme, and subsequent induction of ureteric bud outgrowth. Homozygous deletion in many of these genes (including: *Eya1* [57], *Six1* [58], *Pax2* [75, 76], *Wt1* [54], *Sall1* [60], *Six2* [59] and *Lhx1* [61, 77]) causes ureteric bud outgrowth failure, and results in bilateral renal agenesis or severe renal dysgenesis with variable penetrance depending on the gene involved (Fig. 7.3E, F). However, the underlying molecular mechanism responsible for renal agenesis/severe dysgenesis in each of these mutants varies. For example, *Pax2* mutants fail to form the posterior Wolffian duct from which derives the ureteric bud [76]. In contrast, *Lhx1* [61, 78] and *Sall1* [60] mutants initiate, but do not complete, ureteric bud induction. *Wt1* mutants also exhibit failed ureteric bud induction and show apoptosis of the metanephric mesenchyme [54] (Fig. 7.3E, F). Tissue recombination experiments show that isolated metanephric mesenchyme explants from *Wt1* knock-out mice are neither competent to respond to signals from wild-type ureteric buds, nor able to induce growth and branching of isolated wild-type ureteric bud explants [54, 79]. In contrast, *Sall1*-deficient mesenchyme, which expresses *Wt1*, responds to a heterologous inducer in *ex vivo* tissue recombination experiments [60], suggesting that *Sall1* functions downstream of *Wt1* in a genetic regulatory cascade. Taken together, these data present an emerging image of intricate interplay between transcription factors that are required for the establishment of the nephric duct, subsequent specification of the cap mesenchyme, induction of *Gdnf* expression, and regulation of the differentiation capacity of the cap mesenchyme in response to inductive cues.

Indeed, insights into this interplay come from recent genome-wide studies of transcription fac-

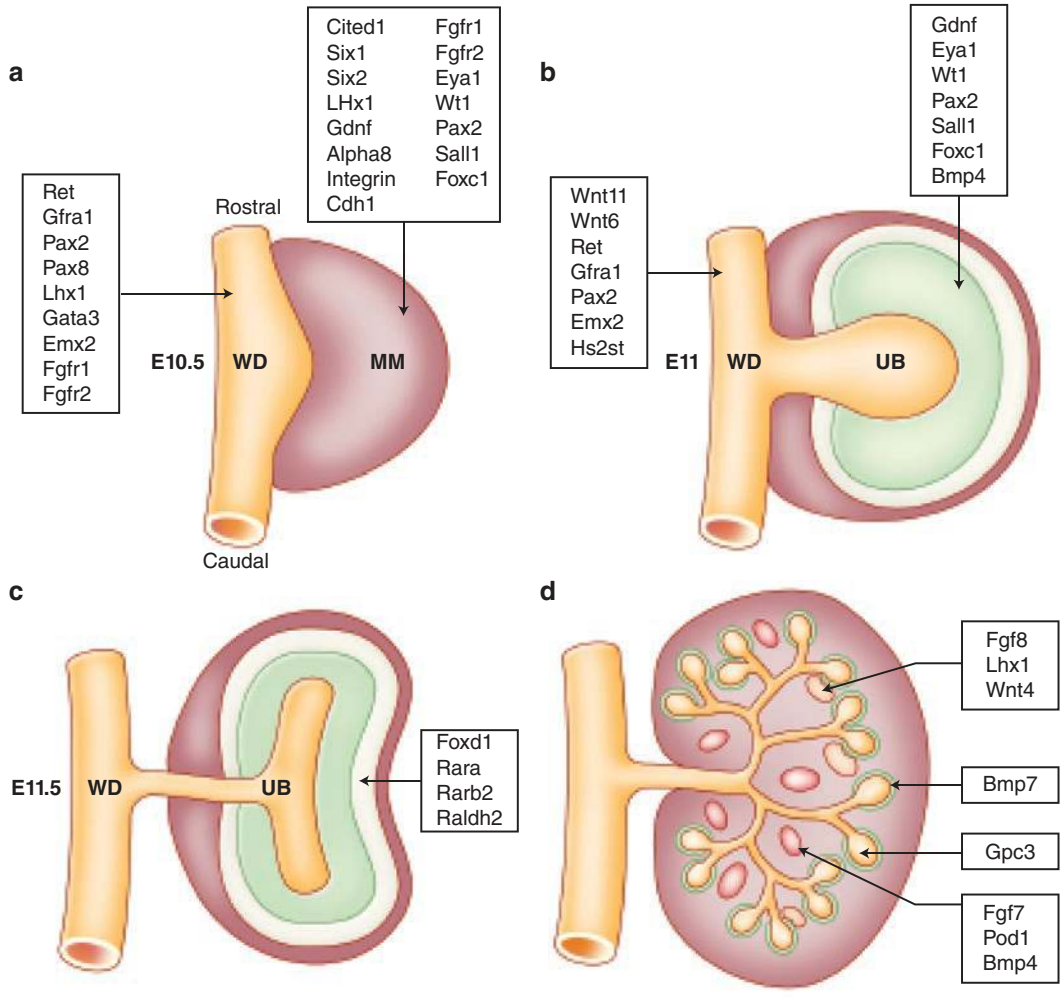

Fig. 7.3 Molecules involved in specification of the metanephric mesenchyme and nephron induction. (**A**) The mammalian kidney starts to develop when the ureteric bud forms at the caudal end of the Wolffian duct (WD) at about embryonic day (E)10.5 in mice. The ureteric bud grows into the metanephric mesenchyme (MM) and (**B**) induces the mesenchyme that is adjacent to the tips of the ureteric bud (UB) to condense to form the cap mesenchyme, as well as the stromal cells that are peripheral to the cap. (**C**) The cap mesenchyme induces the ureteric bud to branch from E11.5 onwards. (**D**) In association with ureteric branching morphogenesis, mesenchymal cells are induced at each ureteric bud tip to undergo a mesenchymal-to-epithelial transformation to form the nephron. *Bmp7* bone morphogenetic protein 7, *Emx2* empty spiracles 2, *Eya1* Eya1, eyes absent 1, *Fgf7* fibroblast growth factor 7, *Foxc1* forkhead box C1, *Foxd1* forkhead box D1, *Gdnf1* glial cell-line-derived neurotrophic factor 1, *Gfra1* glial cell-line derived neurotrophic factor receptor-α1, *Gpc3* glypican-3, *Hs2st* heparan sulfate 2-*O*-sulphotransferase 1, *Pax1* paired-box gene 1, *Rara* retinoic acid receptor-α, *Ret* Ret proto-oncogene, *Sall1* sal-like 1, *Wnt* Wingless-related, *Wt1* Wilms tumour 1 (adapted with permission from Macmillan Publishers Ltd.: Nature Reviews Genetics, Coordinating early kidney development: lessons from gene targeting, Vol. 4(7), p. 535, 2002, Vainio S and Lin Y, Figure 1). Representative kidney phenotypes of mice with targeted deletions affecting nephron progenitors and nephron induction. (**E**–**F′**) Histological transverse sections from E11.5 embryos showing a wild-type (**E**) and *Wt1* mutant embryo (**F**) with the ureteric bud (U), Wolffian duct (W) and metanephric mesenchyme (M) labeled. (**E′**–**F′**) At higher magnification, a cluster of apoptotic cells with dark nuclear fragments is visualized in the Wt1 mutant kidney, resulting in loss of nephron progenitors (arrow) (reprinted from Cell, Vol. 74(4), Kreidberg et al., WT-1 is required for early kidney development, p. 682, 1993, with permission from Elsevier). (**G**–**H′**) Loss of *Wnt4* results in renal hypoplasia and failure of nephron induction, with no epithelial to mesenchymal transition when comparing control (**G**–**G′**) to control kidneys (**H**–**H′**) (reprinted with permission from Macmillan Publishers Ltd.: Nature, Epithelial transformation of metanephric mesenchyme in the developing kidney regulated by Wnt-4, 372(6507), p. 682, 1994, Stark et al., Figure 3)

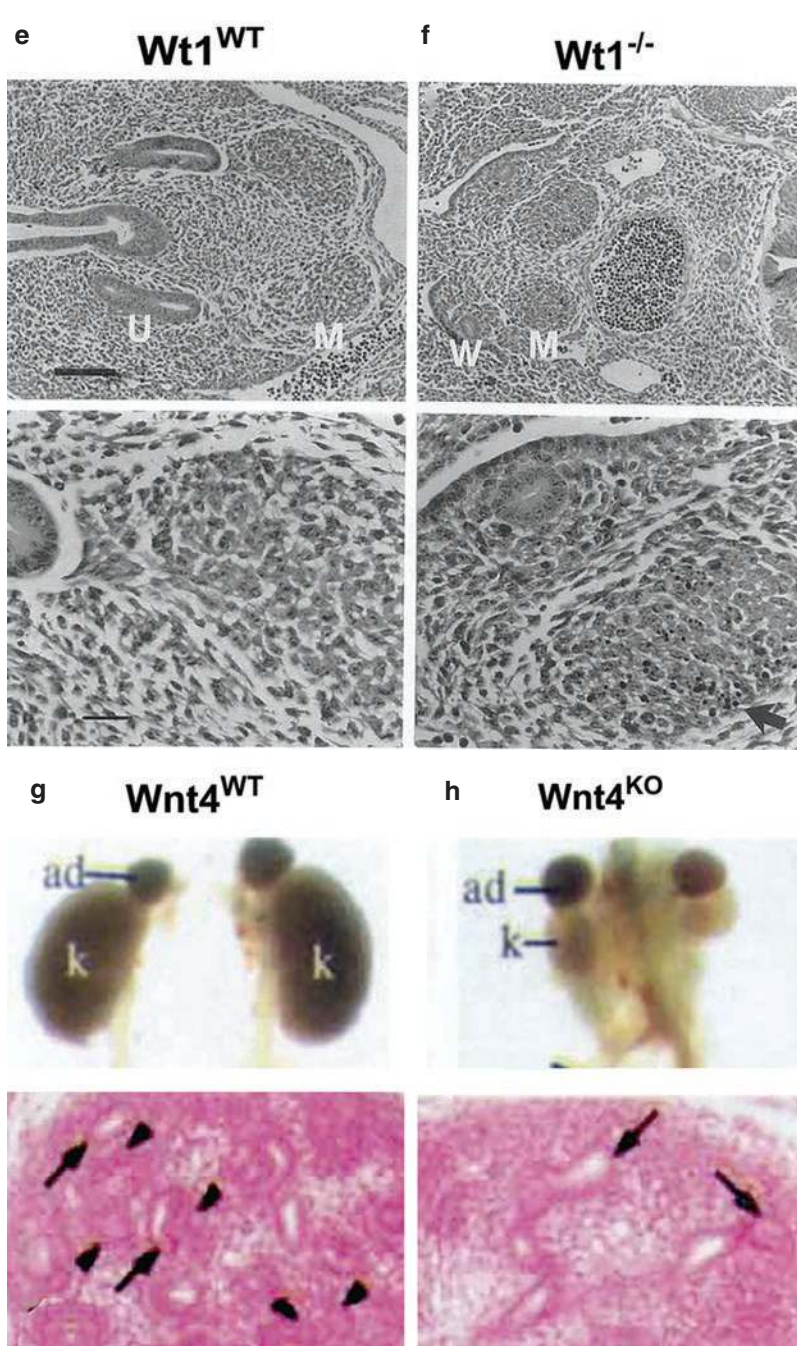

Fig.7.3 (continued)

tor binding using chromatin immunoprecipitation followed by sequencing (ChIP-seq). The transcription factors Six2, Hoxd11, Osr1, and Wt1 have been shown to bind enhancer sequences located in "regulatory hot-spots" in the genome in nephron progenitors [80]. In addition, Six2 co-binds enhancers with β-catenin to drive expression of genes associated with nephron progenitor self-renewal and differentiation [81]. These studies have also identified differences in the transcriptional regulation of mouse and human nephron progenitors mediated by Six1 and Six2 [82].

There is a growing body of work defining the signals required to induce and regulate nephron progenitors, to enable the generation of induced pluripotent stem cell (iPSC)-derived nephron progenitors and optimize the culture of kidney organoids (reviewed in [83]). Of these, the growth factor, *Wingless-type MMTV integration site family 9b* (*Wnt9b*), is required in the ureteric bud for induction of the cap mesenchyme (Fig. 7.3B). The loss of *Wnt9b* activity results in failure of the cap mesenchyme to undergo MET [84]. Moreover, *Wnt9b* plays an important role in regulating the balance between nephron progenitor differentiation and self-renewal, in cooperation with signals mediated by stromal cells [47, 85].

Fibroblast growth factor (FGF) signaling has also been shown to be critical in regulating nephron progenitors. The FGF ligands belong to a large family of secreted peptides that signal

through their cognate receptor tyrosine kinases, FGF receptors (FGFRs). Several FGFs are expressed in the developing kidney, including FGF2, FGF7, FGF8, and FGF10 [39, 86, 87] (Fig. 7.3). Two FGF ligands, *Fgf9* and *Fgf20*, have been shown to be critical in regulating

nephron progenitor survival, proliferation and competence to respond to inductive signals in mice and humans, with loss of these signals resulting in renal agenesis [88]. These *in vivo* findings were supported by *in vitro* studies showing that the addition of FGF1, 2, 9 and 20 protein results in the ability to maintain early nephron progenitor cells in culture [89]. In addition, *in vivo* data is consistent with a functionally important role for *Fgfr1* and *Fgfr2* in the metanephric mesenchyme during kidney development, with loss of *Fgr1* and *Fgfr2* function in the metanephric mesenchyme resulting in renal agenesis [90–92].

Bone morphogenetic protein (BMP) signaling interacts with FGF signaling to balance the self-renewal and differentiation of nephron progenitors. Bmp7 induces the initial exit of nephron progenitors into a state "primed" for differentiation by ureteric bud-derived Wnt 9/β-catenin signaling (Fig. 7.3). Conversely, remaining nephron progenitors are kept in an undifferentiated and self-renewing state in response to FGF9, Wnt and BMP7 signals [81, 85, 88, 89, 93–97]. Mice deficient for *Bmp7* demonstrate developmental arrest and rudimentary kidneys without the inhibition of differentiation of already induced cells, which is likely to due to failure to expand and renew the epithelial precursor population [98, 99]. Together, these data have now informed several *in vitro* protocols to propagate nephron progenitors that rely on a combination of FGF ligands and manipulation of BMP signaling, amongst other growth factors in the culture media [100–103].

The regulation of nephron progenitor survival also contributes to determining nephron number. Archetypal organ culture experiments have demonstrated that isolated metanephric mesenchyme undergoes apoptosis unless induced by co-culture with ureteric buds or a heterologous inducer (e.g. spinal cord) [15, 33]. Several soluble factors have been described to be essential to prevent mesenchymal apoptosis, e.g. epidermal growth factor (EGF), FGF2, and BMP7 [43, 104, 105]. In addition, microRNAs (miRNAs) have been implicated in regulating nephron progenitor survival [106, 107]. However, inhibition of apoptosis by pharmacologic or genetic manipulation causes defects in ureteric bud branching and nephrogenesis [108, 109], suggesting that alterations in cell survival disrupt important functional interactions between mesenchymal and epithelial cells. Possible roles for apoptosis in the metanephric mesenchyme include regulation of nephron number or establishment of tissue boundaries between cells destined to become epithelial or stromal [110, 111].

Recent studies have also shed light on the molecular mechanisms that regulate the cessation of nephrogenesis. Transcriptional changes in nephron progenitors occur as kidney development proceeds, and they are associated with genes and pathways that influence stem cell aging, in particular *Mechanistic target of rapamycin* (*mTor*) and its repressor *Hamartin* (*Tsc1*) [112, 113]. These changes are thought to desensitize nephron progenitors to signals for self-renewal, contributing to the cessation of nephrogenesis [113]. Furthermore, miRNA in the *let-7* family are thought to play an important role in the timing of cessation of nephrogenesis. Ectopic expression of *Lin28b*, a known let-7 family repressor, is sufficient to prolong nephrogenesis [114].

Nephron Induction

Seminal experiments involving isolated kidney rudiments cultured *ex vivo* established the role of ureteric bud-derived secreted factors in providing inductive cues for cap mesenchyme to undergo epithelial differentiation to initiate tubulogenesis [33]. The isolation of ureteric bud cell lines has subsequently facilitated the identification of several secreted factors that function individually or in combination to cause mesenchymal-epithelial conversion and tubulogenesis, including FGF2 [115], leukemia inhibitory factor (LIF) [44, 116, 117], transforming growth factor-β2 (TGFβ2) [117, 118], and growth/differentiation factor-11 (GDF-11) [117, 119].

Wnt genes also play a key role in epithelial conversion, as suggested by the observation that cells expressing WNT proteins are potent inducers of tubulogenesis in isolated metanephric mesenchyme [120, 121]. A genetic requirement for *Wnt4* in MET is revealed by the demonstration of the arrest of the cap mesenchyme, and the inabil-

ity to form pre-tubular aggregates in *Wnt4* mutant mice [84] (Fig. 7.3D, G, H). The effects of Wnt signals are modulated by mesenchymal-derived secreted Wnt binding proteins, including secreted Frizzled-related protein (sFrp). sFrp antagonizes the actions of Wnt4 and Wnt9b by binding secreted Wnt proteins *in vitro* and preventing them from activating membrane-bound Wnt receptors [122]. Similar to the induction of nephron progenitors, FGF signaling is also critical for MET. Mice with deletions in *Fgf8* fail to undergo tubulogenesis, and the data suggests that *Wnt4* and *Fgf8* cooperate in the conversion of mesenchymal to epithelial cells, possibly by upregulating *Lhx1* expression [123, 124]. The transcription factor, *Lhx1*, is uniformly expressed in renal vesicles [61], and conditional knockout of *Lhx1* in metanephric mesenchyme causes developmental arrest at the renal vesicle stage [61].

Ureteric Bud Induction and Branching

Ureteric bud formation begins at week 5 of human fetal gestation and at embryonic day 10.5 (E10.5) in mice. Signaling from the metanephric mesenchyme induces the ureteric bud from the Wolffian duct (Fig. 7.4A). The ureteric bud then elongates and branches into the surrounding mesenchyme, a process termed *branching morphogenesis*, to ultimately pattern the collecting ducts and pelvicaliceal system [125, 126]. Renal branching morphogenesis occurs as a sequence of tightly regulated events: (1) ureteric bud outgrowth; (2) ureteric bud branching and derivation of collecting ducts; (3) cortical and medullary patterning of the collect ducts; and (4) formation of the renal pelvises and calyces.

Ureteric Bud Induction and Outgrowth

Genes encoding *Gdnf* [127], its tyrosine kinase receptor *Ret* [128], and its co-receptor *Gfrα1* [129] are crucial regulators of ureteric bud outgrowth. Targeted *Gdnf* mutations in mice cause failure of ureteric bud induction and bilateral renal aplasia [130, 131] (Fig. 7.4B). Homozygous deletion of *Ret* or *Gfrα1* cause the same defect [128, 132–135] (Fig. 7.4C). However, initial ureteric bud outgrowth was evident in 20–40% of $Gdnf^{-/-}$ or $Ret^{-/-}$ mutants [128, 130], indicating that GDNF-RET signaling is not the only molecular pathway involved in ureteric bud induction and outgrowth. Mice with homozygous null mutations in *heparan sulfate 2-sulfotransferase* (*Hs2st*), which is involved in proteoglycan synthesis, show bilateral renal agenesis and induction of the ureteric bud, but no further outgrowth [136]. Mice with a mutation in integrin *α8* show a similar phenotype in 50% of the mutant mouse embryos [137], implicating integrin signaling as an important molecular pathway for ureteric bud outgrowth.

The downstream effect of GDNF-RET signaling is ureteric bud proliferation, cell survival, and epithelial branching. Downstream genes of GDNF-RET signaling include *ETS transcription factor 4* (*Etv4*) and *Etv5*, which are upregulated in response to RET signaling, and loss of both transcription factors results in bilateral renal agenesis due to ureteric bud formation defects [138]. Expression of several genes in the ureteric bud tip depend on *Etv4* and *Etv5*, including *Chemokine (C-X-C motif) receptor 4* (*Cxcr4*), *matrix metallopeptidase 14* (*Mmp14*), *Myb proto-oncogene* (*Myb*), *Met proto-oncogene* (*Met*), and *Wnt11* [138]. Loss of *Wnt11* in mice leads to abnormal ureteric branching with resultant renal hypoplasia and decreased levels of GDNF in the metanephric mesenchyme; conversely, *Wnt11* expression is reduced in the absence of GDNF, suggesting a feedback loop that coordinates ureteric branching [97]. Furthermore, *hepatocyte nuclear factor-1 beta* (*Hnf1β*) has been implicated as a transcriptional regulator of *Etv5*, and mice lacking *Hnf1β* also show abnormal ureteric bud outgrowth and branching [139, 140]. Thus, these studies highlight that improper ureteric bud induction and outgrowth lead to renal agenesis or renal hypoplasia.

GDNF in organ cultures induce ectopic ureteric buds along the Wolffian duct [127, 141], indicating that additional signals are required to

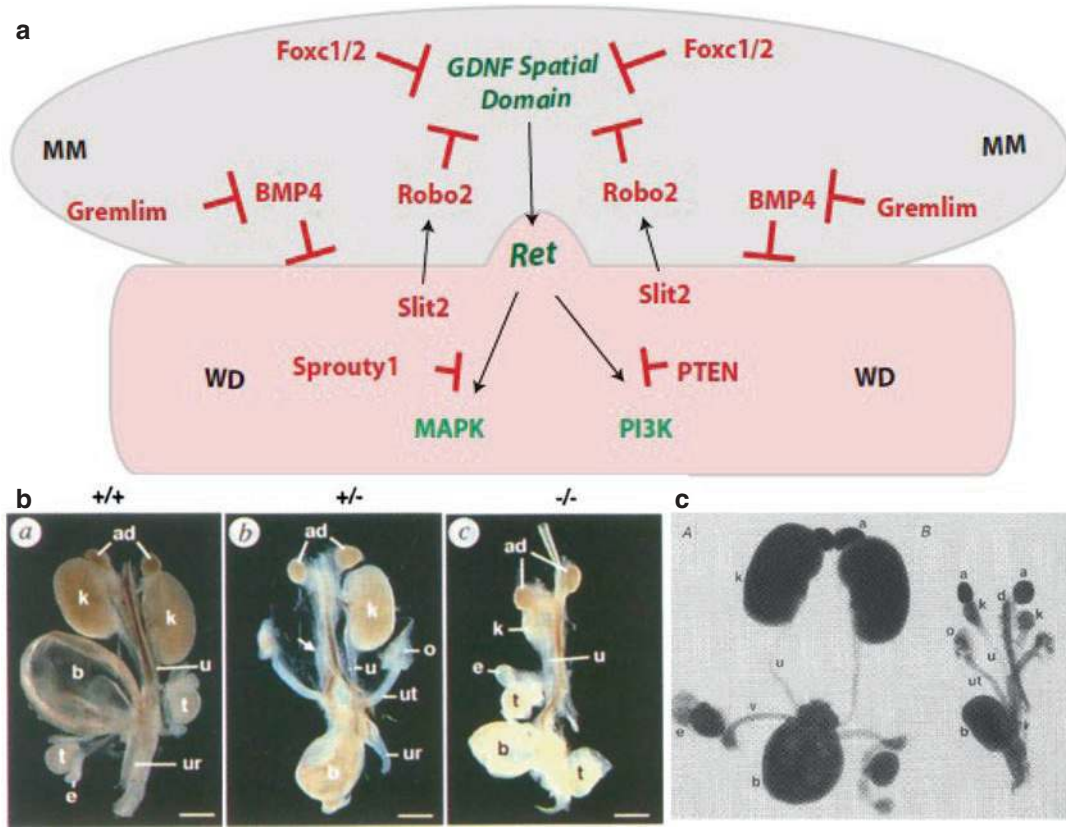

Fig. 7.4 Schematic demonstrating the molecular control of ureteric bud branching. (**A**) Glial cell-line derived neurotrophic factor (GDNF) is secreted from the mesenchyme (grey) and binds to the Ret receptor to induce a thickening of the WD (pink); the WD will then elongate to form the UB. Binding of GDNF to RET leads to activation of the MAPK and PI3K signal transduction pathways. These pathways are negatively regulated by SPROUTY1 and PTEN, respectively. SLIT2/ROBO2, FOXC1 and FOXC2 inhibit the spatial GDNF expression domain and limit UB outpouching to a single site. BMP4 inhibits branching, in a manner that is opposed by Gremlin. RED Inhibitory, Green stimulatory, Grey MM and GDNF spatial domain, Pink WD (with kind permission from Springer Science+Business Media: Pediatric Nephrology, Stimulatory and inhibitory signaling molecules that regulate renal branching morphogenesis, Vol. 24, p. 1616, 2009, Bridgewater D and Rosenblum ND, Figure 4). Representative kidney phenotypes of mice having targeted mutations affecting branching morphogenesis. (**B**) Bilateral renal agenesis in *GDNF* mutant mice (reprinted with permission from Macmillan Publishers Ltd.: Nature, Defects in enteric innervation and kidney development in mice lacking GDNF, 382(6586), p. 74, 1996, Pichel et al., Figure 2). (**C**) Severe bilateral renal hypoplasia in *Ret* null mutants. A, adrenal; K, kidney; U, ureter; B, bladder (reprinted with permission from Macmillan Publishers Ltd.: Nature, Defects in the kidney and enteric nervous system of mice lacking the tyrosine kinase receptor Ret, 367(6461), p. 382, 1994, Schuchardt et al., Figure 2)

restrict the number of ureteric buds induced, as well as the position of ureteric bud induction. When multiple ureteric buds form from a single Wolffian duct, renal and urogenital malformations occur (e.g. duplex kidney) [142]. The position of ureteric bud outgrowth from the Wolffian duct is also critical for the formation of a single ureter and competent vesicoureteral junction. Outgrowth of the ureteric bud at an ectopic site leads to ectopic insertion of the ureter into the bladder [143]. Mice with mutations in *Bmp4* [144], *Slit homologue 2* (*Slit2*) or its receptor *Roundabout guidance receptor 2* (*Robo2*) [145], components of the renin-angiotensin cascade [109], *Forkhead box C1* (*Foxc1*), *Foxc2* [146], *Fgfr2* [147, 148], *FGF receptor substrate 2α* (*Frs2α*) [149], *Dicer1* [150–152], *Ret* [153], and *Pax2* [154] exhibit abnormal ureteric bud induc-

tion sites and/or ureteric branching with subsequent ureteral duplications, abnormal ureter insertion into the bladder, and/or vesicoureteral reflux. These studies underscore the importance of tightly regulated GDNF-RET signaling activity to establish normal ureteric bud induction site and subsequent branching.

Positive Regulation of GDNF-RET Signaling

Prior to ureteric bud induction, *Gdnf* is expressed along the entire length of the intermediate mesoderm parallel to the Wolffian duct [127] and *Ret* is expressed throughout the Wolffian duct [155]. By the time of ureteric bud induction, *Gdnf* expression is restricted to the posterior intermediate mesoderm, marking the location of the presumptive metanephric mesenchyme close to the site of ureteric bud outgrowth. Once the ureteric bud enters the metanephric mesenchyme, *Ret* expression becomes restricted to the epithelial cells of the branching ureteric bud [155]. As noted above, mice that ectopically express *Gdnf* or *Ret* during ureteric bud induction and branching have renal malformations, which underscores the importance of regulation of the spatial activity of GDNF-RET signaling [156, 157].

Three transcription factor genes expressed in the intermediate mesoderm—*Eya1*, *Six1*, and *Pax2*—promote *Gdnf* expression during kidney development (Fig. 7.3A). Genetic mutations in *Eya1* or *Pax2* in mouse models both result in no *Gdnf* expression [57, 158]. *Eya1* knock-out mice fail to undergo ureteric bud induction due to loss of *Gdnf* expression and the result is renal agenesis [57]. *Eya1* mutant mice also show a loss of *Six1* expression, suggesting an Eya-Six-Gdnf signaling cascade [57, 159]. *Six1* null mice fail ureteric bud induction into the mesenchyme, which subsequently undergoes apoptosis [58]. *Eya1* expression in the *Six1* null mice is normal, further supporting that it is upstream of *Six1* [58]. *Pax2* is expressed in the intermediate mesoderm and homozygous null mice do not undergo ureteric bud outgrowth and *Gdnf* expression is absent [158]. *Gdnf* transcription is directly activated by *Pax2* [158].

Other activators of *Gdnf* expression have been identified, including the paralogous genes *Homeobox A11* (*Hoxa11*), *Hoxc11*, and *Hoxd11* [160]. Compound inactivation of at least two of these genes causes renal aplasia and loss of *Gdnf* and *Six2* expression, with normal *Eya1* and *Pax2* [160]. It has been suggested that Hox genes maintain *Gdnf* expression by cooperating with *Eya1* to induce *Six1* and *Six2* expression [159]. An additional positive regulator of *Gdnf* is *Empty spiracles homolog 2* (*Emx2*), which is expressed in the Wolffian duct [161]. Homozygous *Emx2* mutant mice exhibit renal agenesis with failure of ureteric bud branching after it is induced [161]. There is down-regulation of ureteric bud markers *Pax2*, *c-Ret*, and *Lim1* as well as reduced *Gdnf* expression in the metanephric mesenchyme [161]. In explant culture experiments, branching of the *Emx2* mutant ureteric bud was not induced by wild-type mesenchyme; whereas, mutant mesenchyme was able to induce wild-type ureteric bud branching [161]. These data suggest that *Emx2* may be important in the ureteric bud to provide cues to maintain *Gdnf* expression in the mesenchyme and sustain ureteric bud branching.

Negative Regulation of GDNF-RET Signaling

Negative regulation of Gdnf expression is equally important to control the location and number of ureteric buds induced. *Foxc1*, *Slit2*, and *Robo2* are involved in restricting *Gdnf* expression to the posterior intermediate mesoderm (Fig. 7.4A). Mice lacking either *Slit2* or its receptor *Robo2* develop supernumerary ureteric buds and multiple ureters, with *Gdnf* expression inappropriately maintained in the anterior metanephric mesenchyme [145]. The anterior expansion of *Gdnf* occurs without alterations in expression of *Foxc1*, *Eya1*, or *Pax2* [145], suggesting that SLIT2 and ROBO2 function in a parallel pathway to restrict GDNF-RET activity during ureteric bud outgrowth. The secreted protein SLIT2 and its receptor ROBO2 are encoded by genes best known for their role in axon guidance, functioning as chemorepellents that cause axons or migrating cells to move away from the source of SLIT2 [162],

which may be the mechanism by which they regulate *Gdnf* expression domain. Their expression pattern supports this: *Slit2* is primary expressed at the tips of the branching ureteric buds and *Robo2* is expressed in a complementary pattern in the metanephric mesenchyme [163]. More recently, further evaluation of *Robo2* null mice shows failure of the nephrogenic cord to separate from the Wolffian duct, leading to increased proliferation signals, which suggests a possible second mechanism by which *Gdnf* domain expands and aberrant ureteric buds form [164]. *Foxc1* homozygous null mutant mice have anterior expansion of *Gdnf* and *Eya1*, leading to ectopic anterior ureteric buds that result in ureter and renal abnormalities [146]. *Foxc1* encodes a transcription factor that overlaps in domain with *Gdnf* in the intermediate mesoderm and these data suggest that *Foxc1* regulates either *Eya1* or its upstream genes [146].

The gene *Sprouty1* (*Spry1*), a receptor tyrosine kinase agonist, is implicated in a regulatory feedback loop involving GDNF-RET signaling and downstream effector, *Wnt11*. *Spry1* is expressed along the Wolffian duct, with highest levels of expression in the posterior aspect [165] (Fig. 7.4A). Loss of *Spry1* function in mice results in ectopic ureteric bud induction and urogenital malformations such as multiple ureters and kidneys [165, 166]. Recently, tyrosine 53 of *Spry1* is implicated as essential for *Spry1* function, showing the same phenotype as *Spry1* null mice [167]. *Gdnf* and *Wnt11* expression extends more anteriorly in *Spry1* null mice [165, 166]. Metanephric cultures showed more sensitivity to GDNF in *Spry1* null mutants, inducing supernumerary ureteric buds at low concentrations compared to wildtype [165]. Further, *Ret* is required to maintain *Spry1* expression in the Wolffian duct [165]. Ectopic expression of human *SPRY2*, a related homologue to *Spry1*, in the ureteric bud in transgenic mice leads to decreased ureteric branching [168]. Together, these data suggest that *Spry1* acts as a negative regulator of a GDNF/RET/*Wnt11* feedback loop to prevent supernumerary ureteric budding and guide branching.

Another example of negative feedback in GDNF-RET signaling and branching morphogenesis involves secreted growth factors belonging to the Bone Morphogenetic Protein (BMP) family. Kidney organ culture studies reveal inhibitory roles for BMP-2, -4, and -7 in ureteric bud branching morphogenesis [169–172]. However, only *Bmp4* shows convincing evidence *in vivo* for modulating ureteric bud outgrowth [144] (Fig. 7.4A). *Bmp4* is expressed in stromal cells adjacent to the Wolffian duct and the early ureteric bud and its receptors are expressed in the Wolffian duct [144, 173]. Mice heterozygous for *Bmp4* exhibit ectopic or multiple ureteric buds, shortened ureteric trunk and first branch stem, and a spectrum of urinary tract and renal malformations [144]. The abnormal sites of ureteric bud outgrowth in *Bmp4* heterozygous mice suggests that BMP4 inhibits the local effect of GDNF-RET signaling to constrain ureteric bud induction at the appropriate site and promotes elongation at the stalk of the branching ureteric bud [144]. BMP4 can block the ability of GDNF to induce ureteric bud outgrowth from the Wolffian duct *in vitro* [158], and also inhibits further ureteric bud branching *in vitro* in an asymmetric manner [169, 170]. *Gremlin1* (*Grem1*) inhibits BMP4 activity, enabling ureteric bud outgrowth [174].

Other signaling factors have been implicated in regulating the appropriate position of the ureteric bud. For example, *Receptor tyrosine kinase like orphan receptor-1* (*Ror1*) and *-2* (*Ror2*) bind Wnt5a, and have recently been implicated in ureteric bud formation. *Ror2* and *Wnt5a* deficient mice exhibit ectopic rostral ureteric buds and abnormal *Gdnf* expression domain [175, 176].

Renal Branching Morphogenesis

Renal branching morphogenesis begins between the fifth and sixth week of gestation in humans [2], and at E11.5 in mice [177] when the ureteric bud invades the metanephric mesenchyme and forms a T-shaped, branched structure (Fig. 7.3C). The T-shaped structure then undergoes further iterative branching events to generate approximately 15 generations of branches. In human kidney development, the first 9 generations of branching are complete by approximately

15 weeks gestation [2]. During this time, new nephrons are induced through reciprocal inductive interactions between the newly formed tips of the ureteric bud and the surrounding metanephric mesenchyme. By the 20th–22nd week of gestation, ureteric bud branching is completed, and the remainder of collecting duct development occurs by extension of peripheral (or cortical) segments and remodeling of central (or medullary) segments [2]. During these final stages, new nephrons form predominantly through the induction of approximately four to seven nephrons around the tips of terminal collecting duct branches that have completed their branching program, while retaining the capacity to induce new nephron formation [2, 177].

Analysis of renal branching morphogenesis in organ culture systems employing kidneys of transgenic mice expressing the fluorescent reporter, enhanced green fluorescent protein (EGFP), in the ureteric bud lineage have been informative regarding the sequence and pattern of branching events that occur following the formation of the initial T structure [178, 179]. Throughout renal branching morphogenesis, the branching ureteric bud recapitulates a patterned, morphogenetic sequence. This sequence includes: (1) expansion of the advancing ureteric bud branch at its leading tip (called the ampulla); (2) division of the ampulla causing the formation of new ureteric bud branches; and (3) elongation of the newly formed branch segment.

Proliferation and Apoptosis in Branching Morphogenesis

During branching morphogenesis, there is a zone of high proliferation at the site of ureteric bud and then at the tips of the branching ureteric buds/collecting ducts [180]. Proliferation rates are highest at and localized to sites undergoing active branching morphogenesis [180] and as new branches form, proliferation rates are higher in branch tips than trunks [42, 180, 181], which suggests that localized cell proliferation contributes to evagination of the ureteric bud from the Wolffian duct and formation of ampullae. A time-lapse imaging study traced individual ureteric bud tip cells to find that most tip cells are self-renewing progenitors whose progeny either populate the growing ureteric bud trunk or remain at the tips [182].

Apoptotic cells are rarely seen in the ureteric branches [183], and cultured ureteric bud cells do not demonstrate apoptosis *ex vivo* [184]. This suggests that ureteric bud-derived cells may have an intrinsic survival tendency. Further evidence that cell survival is tightly regulated during branching morphogenesis is provided by several studies in which dysregulated apoptosis and cell proliferation are associated with defective collecting duct development. *Glypican-3*-(*Gpc3*) deficient mice exhibit increased cell proliferation with increased ureteric bud branching, increased cortical collecting duct proliferation, and increased medullary collecting duct system apoptosis leading to cystic and dysplastic kidneys [185, 186]. Additionally, increased apoptosis was associated with collecting duct cyst formation in mice with mutated genes associated with cell survival including *B-cell lymphoma 2* (*bcl2*) [187] and *transcription factor AP2* (*AP-2*) [188]. Also, apoptosis is prominent in dilated collecting ducts in experimental models of fetal and neonatal urinary tract obstruction [189, 190]. These data suggest a relationship between collecting duct apoptosis and two frequent features of renal dysplasia—cystogenesis and urinary tract dilation.

Signaling Molecules in Branching Morphogenesis

In addition to stimulating ureteric bud induction, GDNF is also a stimulus for subsequent ureteric bud branching [157, 191]. Transgenic mice that express *Gdnf* ectopically in the Wolffian duct and ureteric buds develop multiple, ectopic ureteric buds that branch independently of the metanephric mesenchyme [157]. However, *in vitro* studies demonstrate that GDNF is not sufficient to induce robust branching in isolated ureteric bud culture [127, 192], which suggests that other factors cooperate with GDNF-RET to control ureteric branching.

Retinoic acid (RA) signaling is also essential for ureteric bud induction and branching. Inactivation of retinoic acid receptors RARα and RARβ2 leads to decreased ureteric bud branch-

ing and downregulation of *Ret* in the ureteric bud [36]. Forced expression of *Ret* in the ureteric bud lineage in *Rarα* and *Rarβ2* double mutant mice is sufficient to restore ureteric bud outgrowth [37]. Retinoic acid activates RA-receptor signaling in the ureteric bud and regulates *Ret* expression in the ureteric bud tips and subsequent proper branching morphogenesis [37, 193]. More recently, *in vitro* studies suggest that retinoic acid-regulated *Extracellular matrix 1* (*Ecm1*) restricts *Ret* expression to the ureteric bud tip for proper branching morphogenesis [194].

WNT signaling acts in concert with GDNF-RET signaling to regulate branching morphogenesis. *Wnt11* is expressed at the tips of the ureteric bud and mice that are deficient in *Wnt11* have defects in branching morphogenesis [97, 195] (Fig. 7.3B). This data suggests that *Wnt11* functions at least in part to maintain GDNF expression; conversely, *Wnt11* expression is reduced in the absence of GDNF-RET signaling [97]. β-catenin is an effector that regulates downstream transcriptional targets of the canonical WNT pathway. Mice with β-Catenin deficiency in the ureteric bud cell lineage [196] and the Wolffian duct epithelium [31] display abnormal ureteric branching, loss of gene expression in the ureteric bud tip, and premature expression of differentiated collecting duct epithelial genes. However, β-Catenin overexpression in the metanephric mesenchyme also leads to ectopic and abnormal branching as well as overexpression of *Gdnf* [197], which highlights the complex nature of interacting compartmental signals that coordinate for proper branching. The Prorenin receptor also appears to control branching morphogenesis via the Wnt/β-Catenin pathway [198]. Together, these data suggest that WNT/β-catenin and GDNF-RET signaling pathways act to regulate branching morphogenesis.

The FGF family is also involved in growth and cell proliferation of the ureteric bud [86]. FGF family members exert unique spatial effects on ureteric bud cell proliferation *in vitro*, suggesting that they may coordinate control of three-dimensional growth. For example, FGF10 preferentially simulates cell proliferation at the ureteric bud tips, whereas FGF7 induces proliferation in a non-selective manner throughout the developing collecting duct system [86]. Displaced ureteric buds and aberrant ureteric branching occur in mice with conditional inactivation of the FGF receptor gene, *Fgfr2*, or the docking protein, fibroblast receptor substrate 2α (*Frs2α*) [91, 147, 149, 199, 200]. Increased ureteric bud apoptosis and reduced proliferation are present when *Fgfr2* is conditionally inactivated in the ureteric bud tissue or metanephric mesenchyme [91, 200]. *Fgfr2* appears to function downstream of *Eya1* and *Six1,* but upstream of *Six2*, *Sall1*, and *Pax2* [91]. FGF7 induces expression of the Sprouty gene, *Spry2*, *in vitro,* so FGF7 may also participate with *Spry2* in the feedback loop that controls ureteric bud branching by regulating *Gdnf* and *Wnt11* expression [168]. Further, *Fgf-7* null mice had smaller developing ureteric bud and collecting systems than wild-type [201].

Hepatocyte nuclear factor-1 beta (*Hnf1β*) inactivation in the ureteric bud cell lineage leads to decreased ureteric branching morphogenesis and defective collecting duct differentiation, with subsequent collecting duct system cystic dilations, renal dysplasia, hypoplasia, or agenesis [139]. Importantly, *HNF1β* mutations in humans present with various renal (and extra-renal) manifestations [202]. *Ex vivo* kidney culture studies in the *Hnf1β* null mice suggest a role in both the ureteric bud tip domain and ureteric bud stalks to organize the epithelium and cell polarity of the ureteric bud branches [139]. HNF1β is believed to directly regulate *Gfrα1* and *Etv5*, so may be involved in regulation both upstream and downstream of GDNF-RET pathway to regulate ureteric bud branching [139].

GDNF, FGF7, and TGF-β also promote expression of *Tissue inhibitors of metalloproteinases* (*TIMPs*) from cultured ureteric bud cells [203, 204]. TIMPS regulate the local activity of extracellular matrix metalloproteases (MMPs), which are implicated in altering the composition of the extracellular matrix to facilitate branch initiation. This concept is supported by demonstration that TIMPs block ureteric bud branching *in vitro* [203, 205]. Consequently, growth factors may play an important role in regulating the local

activity of matrix-degrading proteases by controlling TIMP expression.

Various other signaling factors also stimulate ureteric branching, including *Vascular endothelial growth factor* (*VEGF*) [206]. *VEGF receptor 2* (*VEGFR2*) (critical for endothelial cell development) blockade or deletion both *in vitro* and *in vivo* leads to reduced ureteric branching [40, 207], which further highlights a role for endothelial cell involvement in renal branching morphogenesis. Finally, components of the tight junction such as claudin proteins have also been implicated in branching morphogenesis [208].

Formation of Nephrons

Proximal-distal patterning of nephron epithelial cell fate, as reflected by the formation of tubular and glomerular cell fate domains, is a crucial step in nephron segmentation. Nephron segmentation begins with the sequential formation of two clefts in the renal vesicle, the earliest epithelial derivative of nephron progenitors [2] (Fig. 7.2). Creation of a lower cleft, termed the vascular cleft, heralds formation of the comma-shaped body. The comma-shaped body is a transient structure that rapidly undergoes morphogenetic conversion into an S-shaped structure (termed S-shaped body) upon generation of an upper cleft. The S-shaped body is characterized by three segments or limbs. The middle and upper limbs give rise to the tubular segments of the mature nephron. While the middle limb of the S-shaped body gives rise to the proximal convoluted tubule [2], the descending and ascending limbs of the loops of Henle and the distal convoluted tubule originate from the upper limb of the S-shaped body [2, 15] (Fig. 7.5A). As the vascular cleft broadens and deepens, the lower limb of the S-shaped body forms a cup-shaped unit (Fig. 7.5B). Epithelial cells lining the inner wall of this cup will comprise the visceral glomerular epithelium, or podocytes. Cells lining the outer wall of the cup will form parietal glomerular epithelium, or Bowman's capsule.

All parts of the developing nephron increase in size as they become mature. However, the most striking changes consist of increased tortuosity of the proximal convoluted tubule, and elongation of the loop of Henle [2]. Cellular maturation of the proximal tubule involves transition from columnar to cuboidal epithelium, elaboration of apical and basal microvilli, and gradual increase in tubular diameter and length [209]. The human kidney at birth shows marked heterogeneity in proximal tubule length as one progresses from the outer cortex to the inner cortex [210]. Uniformity in proximal tubule length is achieved by 1 month of life, and the proximal tubule subsequently lengthens at a uniform rate. Prospective cells of the loop of Henle are thought to be first positioned at the junctional region of the middle and upper limbs of the S-shaped body near the vascular pole of the glomerulus, where it will form the macula densa [211]. The descending and ascending limbs of the presumptive loop of Henle are first recognizable as a U-shaped structure in the periphery of the developing renal cortex, termed the nephrogenic zone [211, 212]. Maturation of the primitive loop involves elongation of both ascending and descending limbs through the corticomedullary boundary. Continued maturation involves differentiation of descending and ascending limb epithelia [213]. Development of the presumptive distal tubule involves elongation of the connecting segment, which joins with the ureteric bud/collecting duct.

Longitudinal growth of the medulla contributes to lengthening of the loops of Henle such that all but a small percentage of the loops of Henle extend below the corticomedullary junction in full term newborn infants [2]. As the kidney increases in size postnatally, the loops of Henle further elongate and reach the inner two-thirds of the renal medulla in the mature kidney. Functional development of the kidney's urine concentrating mechanism is dependent on elongation of the loops of Henle during nephrogenesis since longer loops favor urine concentrating capacity. In the extremely premature fetus, the loops of Henle are short owing to the relative distance between the renal capsule and the renal papilla. Consequently, the urine concentrating capacity of the premature kidney is limited by generation of a shallow medullary tonicity gradient.

(**C**) Representative kidney phenotype of mice with a conditional mutation affecting nephron segmentation. Loss of Notch2 in the metanephric mesenchyme results in loss of proximal nephron elements (glomeruli, proximal tubules and S-shaped bodies). Red arrows, glomeruli; green, proximal tubule; yellow, S-shaped bodies; turquoise, collecting duct (reprinted with permission from: Company of Biologists: Development, Notch2, but not Notch1, is required for proximal cell fate acquisition in the mammalian nephron, 134(4), p. 803, 2007, Cheng et al., Figure 1)

Nephron Segmentation

Proximal-distal patterning of nephron epithelial cell fate, as reflected by the formation of glomerular and tubular cell fate domains, is a crucial step in nephron segmentation. Recently, elegant studies have provided a high resolution view of comparative histology, RNA expression and protein localization of mouse and human developing kidneys throughout nephrogenesis [214, 215]. These studies offer insights into when proximal-distal patterning is established in renal vesicles, along with differences in marker genes in the mouse and human.

One mechanism for patterning glomerular and tubular cell fates in the S-shaped body appears to be dependent on negative feedback between *Wt1* and *Pax2* [216–218] (Fig. 7.5B). During early kidney development, the expression patterns of *Pax2* and *Wt1* become restricted in S-shaped bodies such that the expression domain of *Pax2* is complementary to the corresponding domain for *Wt1*. *Wt1* expression is restricted to glomerular epithelial precursors, which give rise to podocytes later in glomerular development [219]. In contrast, *Pax2* expression is restricted to that portion which gives rise to tubular epithelial precursors of the proximal and distal nephron segments and is later repressed in differentiated tubular epithelium [123, 220]. The precise roles for *Wt1* or *Pax2* in nephron differentiation is not evident from the analyses of renal phenotypes in mice with targeted *Wt1* or *Pax2* mutations since these mutants fail to form kidneys [54, 76]. However, evidence from transgenic mice that over-express PAX2 in all nephrogenic cell types illustrates the importance of spatially restricting *Pax2* expression during early nephrogenesis since these mice exhibit dysplastic kidneys with defective differentiation of both tubular and glomerular epithelia [221].

Two other transcription factors expressed at the renal vesicle stage, *Lhx1* and *Brn1*, also appear to be involved in initiating proximal-distal nephron epithelial cell fate patterning. While *Lhx1* is uniformly expressed in renal vesicles [61], *Brain specific homeobox 1* (*Brn1*) expression occurs in a more spatially restricted pattern in renal vesicles [212]. Conditional knockout of *Lhx1* in the metanephric mesenchyme causes developmental arrest at the renal vesicle stage, and results in loss of *Brn1* expression [61]. In contrast, targeted deletion of *Brn1* in the metanephric mesenchyme does not prevent the early stages of nephron morphogenesis, but blocks formation of the loop of Henle, and suppresses terminal differentiation of distal nephron epithelia [212]. Taken together, these data suggest that *Brn1* functions downstream of *Lhx1* in a genetic hierarchy which establishes distal cell fates. An additional role for *Lhx1* in specifying podocyte cell fate is revealed by the analysis of *Lhx1* chimeric mutant mice [61].

Genetic evidence in mice suggests that the process for selecting which nephrogenic progenitors will comprise the proximal portion of the developing nephron (i.e. the podocytes and proximal convoluted tubule) is dependent on Notch signaling [222–224]. Conditional knock-out of *Notch2* and *Recombining binding protein suppressor of hairless* (*Rbpsuh*), but not *Notch1*, in metanephric mesenchyme prior to nephron segmentation results in complete lack of both proximal tubule and glomerular epithelia [223] (Fig. 7.5C). Similar effects were observed in mutant mice when presenilin-mediated Notch activation was abrogated by mutagenesis of *Psen1* and *Psen2* [224]. Moreover, ectopic Notch activation in nephron progenitors results in premature differentiation and MET, with a preference towards proximal tubule cell fate [225].

There is limited information regarding the subsequent specification of cell types in the proximal tubule, loop of Henle and distal tubule. Mutations in the transcription factor, *Hepatic nuclear factor 4a* (*Hnf4a*), are associated with Fanconi syndrome, and *Hnf4a* has been shown to be required for the formation of differentiated proximal tubules [226].

Glomerulogenesis

During embryonic development, formation of the lower limb of the S-shaped body heralds the onset of glomerulogenesis [2, 227] (Fig. 7.6A). The vascular cleft provides an entry point to which progenitor endothelial and mesangial cells are recruited [228]. Cells residing along the inner surface of the lower S-shaped body limb represent nascent podocytes. At this stage, immature podocytes are proliferative and exhibit a columnar shape, apical cell attachments and a single-layer basement membrane [227]. Development of the glomerular capillary tuft is a dynamic process involving recruitment and proliferation of endothelial and mesangial cell precursors, formation of a capillary plexus, and concomitant assembly of podocytes and mesangial cells distributed around the newly formed capillary loops [227].

Recruitment of angioblasts and mesangial precursors into the vascular cleft results in formation of the lower S-shaped body limb into a cup-like structure [2] (Fig. 7.6A). Formation of a primitive vascular plexus occurs at this so-called capillary loop stage. Podocytes of capillary loop stage glomeruli lose mitotic capacity [229] and begin to demonstrate complex cellular architecture, including the formation of actin-based cytoplasmic extensions, or foot processes, and the formation of specialized intercellular junctions, termed slit diaphragms [230, 231] (Fig. 7.6B). Subsequent development of the glomerular capillary tuft involves extensive branching of capillaries and formation of endothelial fenestrae [2]. Mesangial cells, in turn, populate the core of the tuft and provide structural support to capillary loops through the deposition of extracellular matrix [232, 233]. The full complement of glomeruli in the fetal human kidney is attained by 32–34 weeks when nephrogenesis ceases [2]. At birth, superficial glomeruli, which are chronologically the last to be formed, are significantly smaller than juxtamedullary glomeruli, which are the earliest formed glomeruli [210]. Subsequent glomerular development involves hypertrophy, and glomeruli reach adult size by 3½ years of age [210].

Podocyte Terminal Differentiation

Functional and genetic evidence support the role of Notch signaling in the determination of podocyte cell fate early in nephron development [222, 224]. Additional roles for the Notch receptor gene, *Notch2*, and its ligand, *Jagged1*, at later stages of glomerular capillary tuft assembly are revealed by the analysis of compound mutant mice which show avascular glomeruli or aneurysmal defects and absent mesangial cells in glomerular capillary tuft formation [234].

Following podocyte cell fate determination, the transcription factors *Wt1*, *podocyte expressed 1* (*Pod1*), *Lim homeobox 1b* (*Lmx1b*), *Foxc2*, *Mafb*, and *Osr1* [235, 236] have been shown to have important roles in podocyte terminal differentiation. Loss of function mutations in *Foxc2*, *Pod1*, *Lmx1b*, and *Mafb* cause podocyte defects in mice which become evident at the capillary loop stage (in the case of *Pod1*) or later (in the case of *Foxc2*, *Lmx1b*, *Mafb*) [237–240]. Analysis of chimeric mice reveal that normal glomerular epithelial differentiation requires the function of *Pod1* in neighboring stromal cells, suggesting that *Pod1* regulates stromal factors that act to promote podocyte cell fate [49]. In humans, *LMX1b* mutations are identified in patients with Nail-Patella Syndrome, which is associated with focal segmental glomerulosclerosis [241]. A role for *Wt1* in podocyte differentiation is suggested by the identification of *WT1* mutations in humans with Denys-Drash and Frasier syndromes [242–244], which are inherited disorders associated with mesangial sclerosis, a form of glomerular disease characterized by defects in podocyte differentiation [245]. The demonstration of an identical glomerular phenotype in mice with targeted *Wt1* mutations, genetically similar to the *WT1* mutation in humans with Denys-Drash and Frasier syndromes, [246–249] serves as additional support that *Wt1* has important roles in podocyte differentiation. *TGF-β-activated kinase* (*Tak1*) targeted deletion in podocytes results in disrupted podocyte architecture associated with decreased *Wt1* expression [250].

Podocyte maturation coincides with a loss of mitotic activity and cell cycle blockade [229]. The limited capacity of mature podocytes to undergo cell proliferation has important implications on the glomerular response to injury since damaged podocytes are not capable of compensating for their loss of function by way of regeneration. Moreover, escape from cell cycle blockade in mature podocytes has been associated with severe changes in glomerular cytoarchitecture and a rapidly progressive decline in renal function, as demonstrated by the deleterious course of idiopathic collapsing and human immunodeficiency virus (HIV) nephropathies [251].

Glomerular Capillary Tuft Development

Lineage tracing studies show that the precursors of most glomerular endothelial cells (angioblasts) are Foxd1-positive stromal cells [252, 253]. Studies of autologous transplantation of embryonic kidney rudiments into adult renal cortex suggests that angioblasts originate from a unique subpopulation of induced metanephric mesenchyme that do not differentiate along epi-

thelial lineages (vasculogenesis) [228, 254, 255]. An alternate theory is provided by evidence that glomerular capillaries originate from ingrowth of primitive sprouts from external vessels through experiments involving engraftment of rodent fetal kidneys onto avian chorioallantoic membrane [256], suggesting that angiogenesis also plays a role in glomerular endothelial development.

Several signaling systems are involved in the recruitment of endothelial and mesangial precursors during the formation and assembly of the glomerular capillary tuft. Vascular endothelial growth factor (VEGF) is secreted by podocyte precursors of early S-shaped bodies [257]. VEGF promotes recruitment of VEGFR2-expressing angioblasts into the vascular cleft to initiate glomerular vasculogenesis [258] and is required to induce apoptosis for lumen capillary formation [259, 260]. This process is under tight regulatory control, as suggested by the demonstration of severe glomerular defects in mice when the gene dosage of *Vegf* is genetically manipulated [261, 262] (Fig. 7.6C). Appropriate development of the glomerular mesangial cells is also important to provide structural and functional support to the glomerular capillary network. Recruitment of mesangial cells is under the guidance of platelet-derived growth factor (PDGF)–β, expressed by endothelial cells, which binds to its receptor, PDGF receptor-β (PDGFRβ) [263]. This axis is required for proliferation and assembly of glomerular capillaries and mesangium as revealed by the absence of glomerular capillary tufts in mice deficient for either *Pdgfβ* or *Pdgfrβ* [264, 265]. Other regulators required for normal renal vasculogenesis include the renin angiotensin system genes [266–270], *Angiopoietin1* and its tyrosine receptor *Angiopoietin-1 receptor* (*Tie2*) [271–273], *Dicer* [274, 275], Notch signaling [276, 277] and TGFβ signaling [278–280]. Endothelial cells are recruited into the cup-shaped glomerular precursor region of the S-shaped body forming a primitive vascular tuft. (j, k) Wt1 in podocytes and parietal epithelium in a capillary loop stage glomerulus. Podocyte precursors contact invading endothelial cells and begin to differentiate. In turn, endothelial cells form a primitive capillary plexus (capillary loop stage). (l, m) Wt1 is strongly expressed in podocytes in maturing glomeruli. Parietal epithelial cells encapsulate the developing glomerulus. (**B**) (a) Immunohistochemistry of maturing glomeruli using antibodies to Tjp1, Wt1, Des and Aqp1. Tjp1 expression in the glomerular basement membrane (gbm) and parietal epithelium (pe); Wt1 in podocytes or visceral epithelium (ve); Desmin in the extraglomerular mesangium (egm), glomerular mesangium of Bowman's capsule (gmbc) and the glomerular mesangium (gm); and Aqp1 in endothelial cells of the glomerular capillary system (gcs) and red blood cells (rbc). (b) Schematic of a developing glomerulus showing the structures present in both the adult and embryonic kidney. The developing glomerulus is composed of a central glomerular tuft, which contains a capillary loop network arising from the afferent arteriole termed the glomerular capillary system. Forming a tight association with the endothelial cells of the capillaries is the visceral epithelium (or podocytes), a layer of highly specialized epithelial cells specific to the nephron. The fused basal lamina of the endothelial and visceral epithelial cells forms the glomerular basement membrane, an extracellular component of the renal corpuscle. In the interstitial spaces between the capillaries is the glomerular mesangium, a complex of mesangial cells and extracellular matrix. The glomerular tuft is surrounded by the Bowman's capsule, which is composed of the parietal epithelium, mesangium and the urinary space of the renal corpuscle. Extraglomerular mesangium located outside the renal corpuscle is a component of the juxtaglomerular complex and is associated with the afferent arteriole. The antibodies used to identify each of the structures are shown; Aqp1 (orange), Wt1 (red), Tjp1 (green) and Des (blue) (with kind permission from Springer Science+Business Media: Histochemistry and Cell Biology, Use of dual section mRNA in situ hybridization/immunohistochemistry to clarify gene expression patterns during the early stages of nephron development in the embryo and in the mature nephron of the adult mouse kidney, Vol. 130, p. 932 and 937, 2008, Georgas et al., Figure 2 and 5). molecules implicated in exerting attraction and repulsion guidance for glomerular capillary formation include the chemokine Stromal cell derived factor 1 (SDF1) [281], which acts on CXCR3 and CXCR7, the transmembrane protein EphrinB2 [282–284] and chemorepellent glycoprotein Semaphorin 3a [285].

During the S-shaped stage, podocyte progenitors express a primitive glomerular basement membrane which is composed predominantly of laminin-1, and α-1 and α-2 subchains of type IV collagen [286]. During glomerular development, composition of the glomerular basement membrane undergoes transition as laminin-1 is replaced by laminin-11, and α-1 and α-2 type IV collagen chains are replaced by α-3, α-4, and α-5 subchains [286]. As demonstrated in several mouse models, failure of these changes result in severe structural and functional defects [287–289].

Formation of the Collecting System

Between the 22nd–34th week of human fetal gestation [2], or E15.5-birth in mice [15], morphologic changes result in the establishment of peripheral (i.e. cortical) and central (i.e. medullary) domains in the developing kidney. The renal cortex, which represents 70% of total kidney volume at birth [290], becomes organized as a relatively compact, circumferential rim of tissue surrounding the periphery of the kidney. The renal medulla, which represents 30% of total kidney volume at birth [290], has a modified cone shape with a broad base contiguous with cortical tissue. The apex of the cone is formed by convergence of collecting ducts in the inner medulla and is termed the papilla.

Distinct morphologic differences emerge between collecting ducts located in the medulla compared to those located in the renal cortex during this stage of kidney development. Medullary collecting ducts are organized into elongated, relatively unbranched linear arrays which converge centrally in a region devoid of glomeruli. In contrast, collecting ducts located in the renal cortex continue to induce metanephric mesenchyme. The specification of cortical and medullary domains is essential to the eventual function of the mature collecting duct system. The most central segments of the collecting duct system formed from the first five generations of ureteric bud branching undergo remodeling by increased growth and dilatation of these tubules to form the pelvis and calyces (reviewed in [291]).

The developing renal cortex and medulla exhibit distinct axes of growth. The renal cortex grows along a circumferential axis, resulting in a ten-fold increase in volume while preserving compact organization of cortical tissue around the developing kidney [290]. In this manner, differentiating glomeruli and tubules maintain their relative position in the renal cortex with respect to the external surface of the kidney, or renal capsule. In contrast to the circumferential pattern of growth exhibited by the developing renal cortex, the developing renal medulla expands 4.5-fold in thickness along a longitudinal axis perpendicular to the axis of cortical growth [290]. This pattern of renal medulla growth is largely due to elongation of outer medullary collecting ducts [290]. The development of a medullary zone coincides with the appearance of stromal cells between the seventh and eighth generations of ureteric bud branches [290]. It has been suggested that stromal cells provide stimulatory cues to promote the growth of medullary collecting ducts [290]. Additional support for this hypothesis is provided by analyses of mutant mice lacking functional expression of the stromal transcription factors *Pod1* and *Forkhead box d1* (*Foxd1*) [35, 49, 292], which demonstrate defects in medullary collecting duct patterning.

In the developing collecting system, apoptosis is infrequently detected in the tips and trunks of the branching ureteric bud [110]. At later stages of embryonic and post-natal kidney development, apoptosis is prominent in the medullary regions of the rat collecting duct system that give rise to the calyces, renal pelvis and renal papilla [110]. The prominence of apoptosis in these regions suggests a potential role for apoptosis in remodeling the first 3–5 generations of the branched ureteric bud/developing collecting duct system. The extent to which apoptosis contributes to this morphogenetic process is, however,

unknown. Other suggested roles for medullary apoptosis include elimination of medullary interstitial cells as a mechanism for making room for new blood vessel ingrowth [293].

Medullary Patterning and Formation of the Pelvicaliceal System

Regional specification of cortical and medullary domains of the renal collecting duct system is a relatively late event in kidney development. At least five soluble growth factor genes (*Fgf7*, *Fgf10*, *Bmp4*, *Bmp5 and Wnt7b*), one proteoglycan gene (*Gpc3*), one cell cycle regulatory gene ($p57^{KIP2}$), and molecular components of the renin-angiotensin axis (*Angiotensinogen* (*Agt)*, *Angiotensinogen receptor* 1 and *2* (*Agtr1*, *Agtr2*)) are implicated in medullary collecting duct morphogenesis as revealed by the demonstration of defects in renal medulla development in mutant mice.

The kidneys of *Fgf7* null mice are characterized by marked underdevelopment of the papilla [39]. Similarly, *Fgf10* null kidneys exhibit modest medullary dysplasia with reduced numbers of loops of Henle and medullary collecting ducts, increased medullary stromal cells, and enlargement of the renal calyx [294]. Cellular responses to FGFs are modulated through interactions with cell surface proteoglycans [295]. Syndecans and glypicans are heparan sulfate proteoglycans expressed in developing collecting ducts [186, 296], and their expression is required for normal collecting duct growth and branching [136, 297]. Moreover, treatment of embryonic kidney explants with pharmacologic inhibitors of sulfated proteoglycan synthesis leads to loss of *Wnt11* expression at the ureteric bud branch tips [298], suggesting that sulfated proteoglycans interact with multiple mechanisms that control ureteric bud branching.

Functional and genetic evidence in humans and mice demonstrate that GPC3, a glycosylphosphatidylinositol (GPI)-linked cell surface heparan sulfate proteoglycan, is required for normal patterning of the medulla [186, 299]. Medullary dysplasia in the *Gpc3* deficient mouse arises from overgrowth of the ureteric bud and collecting ducts due to increased cell proliferation in the ureteric bud lineage [299], with subsequent destruction of these elements due to apoptosis [186]. The defect is thought to be caused by an altered cellular response of GPC3-deficient collecting duct cells to growth factors such as FGFs [186, 300, 301]. The defective renal medulla formation in *Gpc3* null mutant mice illustrates the importance of tightly regulated cell proliferation and apoptosis in this process. Other signals that promote collecting duct cell survival include Wnt7b and Egf [302, 303].

Additional support for this concept is provided by the phenotypic analysis of mice carrying a null mutation for $p57^{KIP2}$, a cell cycle regulatory gene. $p57^{KIP2}$ knock-out mice show medullary dysplasia characterized by a decreased number of inner medullary collecting ducts, in addition to abdominal, skeletal, and adrenal defects [304]. Genetic studies in humans and mice suggest a potential functional interaction between $p57^{KIP2}$ and the *Insulin-like growth factor-2* (*Igf2*) gene in the formation of the renal medulla. For example, phenotypic features of mice with $p57^{KIP2}$ null mutations are exhibited by approximately 15% of individuals with Beckwith-Wiedemann Syndrome, a heterogeneous disorder characterized by somatic overgrowth and renal dysplasia [305]. Genetic linkage studies in humans with this syndrome have mapped the disease to chromosome 11p15.5, which harbors loci for $p57^{KIP2}$ as well as for *IGF2* and *H19*. Murine *H19* mutations result in enhanced *Igf2* expression, but do not cause renal dysplasia [306]. However, $H19^{-/-}$; $p57^{KIP2-/-}$ double knock-out mice exhibit elevated serum levels of IGF2, and more severe renal dysplasia than that observed in $p57^{KIP2}$ single knock-out mice [307]. These findings support an additional mechanism for the cause of renal medullary dysplasia resulting from dysregulated stimulation of cell proliferation through the inactivation of $p57^{KIP2}$ and overexpression of IGF2.

Elaboration of the medullary collecting duct network is thought to require oriented cell divisions that permit elongation of the medullary collecting ducts through proliferation during development. One means by which this occurs is

through the activity of the secreted factor, WNT7b, in up-regulating canonical Wnt signaling in medullary collecting ducts to promote oriented cell division and cell survival [302, 308]. α3β1 integrin and the receptor tyrosine kinase c-Met (receptor for hepatocyte growth factor) appear to coordinately regulate *Wnt7b* expression in the medullary collecting duct [308]. Another member of the Wnt family, *Wnt9b*, also plays a role in elongation and appears to regulate planar cell polarity [309]. Post-transcriptional regulation by miRNAs also drives collecting duct elongation and differentiation [310, 311].

Development of the Ureteral Smooth Muscle

Urinary filtrate removal also requires coordinated ureteric contractions, which in turn is the result of development of a "pacemaker" at the base of the renal papilla and smooth muscle around the ureter. *Bmp4* heterozygous mutant mice develop both hydronephrosis and hydroureter [144], suggesting that *Bmp4* may play additional roles that involve formation of the ureter and renal pelvis. Support for this concept is provided by the finding in kidney explants that recombinant BMP4 induces smooth muscle actin, an early marker for smooth muscle differentiation, in peri-ureteric mesenchymal cells [312]. Both *Bmp4* and *Bmp5* are expressed in mesenchymal cells lining the ureter and the developing renal pelvis [144, 173, 313], and BMP receptors *Bone morphogenetic protein receptor, type 1A* (*Alk3*) and *Bone morphogenetic protein receptor, type 1B* (*Alk6*) are expressed in neighboring collecting ducts [144]. Moreover, mice mutant for *Bmp4* in the ureteric mesenchyme show similar defects in renal pelvis and ureter development with reduced ureter smooth muscle [314]. This study suggested SMAD as a downstream effector of BMP4. Indeed, mice with inactivation of *Smad4* show a similar phenotype with decreased ureteral smooth muscle and abnormal function [315, 316].

In addition to BMP signaling, the Sonic hedgehog (SHH) pathway plays a critical role in regulating ureteral mesenchymal development. SHH is secreted from the medullary collecting duct and ureteric stalk, and signals to the surrounding interstitium through its receptor, Patched1 (Ptch1) [317]. BMP4, together with SHH, induces the expression of the transcription factor, *Teashirt zinc finger homeobox 3* (*Tshz3*), which regulates the development of smooth muscle [318]. Interestingly, loss of the *Gli family zinc finger 3* (*Gli3*) repressor (resulting in inappropriate Hedgehog pathway activation) results in hydronephrosis due to ureteric dyskinesis and reduced numbers of pacemaker cells [319]. Mutations in *GLI3* are associated with Pallister-Hall syndrome in humans [320]. Loss of another zinc factor transcription factor gene, *Gata2*, in the ureteric mesenchyme also leads to abnormal smooth muscle differentiation and dilated ureters [321]. More recently, SHH was shown to use FOXF1-BMP4 signaling to program ureter elongation and differentiation [322].

Mutations in genes encoding components of the renin-angiotensin axis also cause abnormalities in the development of the renal calyces, pelvis and ureter. Mice homozygous for a null mutation in the *Agt* gene demonstrate progressive widening of the calyx and atrophy of the papillae and underlying medulla [323]. Identical defects occur in homozygous mutants for the *Agtr1* gene [324]. The underlying defect in these mutants appears to be decreased cell proliferation of the smooth muscle cell layer lining the renal pelvis, resulting in decreased thickness of this layer in the proximal ureter. Mutational inactivation of *Agtr2* results in a range of anomalies, including vesicoureteral reflux, duplex kidney, renal ectopia, uretero-pelvic or ureterovesical junction stenoses, renal dysplasia or hypoplasia, multicystic dysplastic kidney, or renal agenesis [109]. Null mice demonstrate a decreased rate of apoptosis of the cells around the ureter, suggesting that *Agtr2* also plays a role in morphogenetic remodeling of the ureter.

Other regulators of ureteral smooth muscle differentiation include *Tbx18* [325], *Tbx2* and *Tbx3* (*Tbx2* and *Tbx3*) [326], *Robo2* [327] and retinoic acid signaling [328]. Deletion of *Dicer* also led to impaired ureter morphology and function with ureteral smooth muscle abnormalities [329], suggesting that miRNAs are important in regulating ureter smooth muscle differentiation.

Renal Stroma

Stromal cells are comprised of interstitial cells that secrete extracellular matrix and growth factors that provide a supportive framework and developmental patterning signals around the developing nephrons, collecting system and vasculature. In keeping with this idea, stromal cells are found in close proximity to developing nephrons, ureteric bud branches and blood vessels (Fig. 7.3C). Developmentally, stromal cells are derived from a population of *Foxd1*-expressing stromal progenitors [330]. As the renal cortex and medulla become morphologically distinct regions, stromal cells become defined geographically into two separate populations—cortical stroma, which form interstitium between induced nephrons and express *Foxd1*, *Aldehyde dehydrogenase 1 family*, *member A2* (*Raldh2*), *Retinoic acid receptor α* (*Rarα*) and *Rarβ2*; and medullary stroma, which form interstitium between medullary collecting ducts and express *Fgf7*, *Pod1*, and *Bmp4*. Many of these stromal genes have been shown to be critical for nephrogenesis and ureteric branching morphogenesis in transgenic mouse studies [35, 36, 38, 39, 144, 239]. Further evidence of the importance of the renal stroma for kidney development comes from transgenic animal studies which result in ablation of the renal stroma with diphtheria toxin, causing an abnormally thickened cap mesenchyme and decreased ability of progenitors to differentiate [47, 331]. scRNA-seq studies have recently identified 17 molecularly distinct cell clusters of renal interstitium in the developing kidney [71]. Once nephrogenesis is complete, stromal cells differentiate into a diverse population which includes fibroblasts, lymphocyte-like cells, glomerular mesangial cells, renin-expressing cells and pericytes [330, 332, 333].

One important role for the renal stroma is regulation of *Ret* expression, and hence branching morphogenesis. RARα and RARβ2, members of the retinoic acid receptor (RAR) and retinoid X receptor (RXR) families of transcription factors, are both expressed in stromal cells and *Ret*-expressing ureteric bud branch tips [36]. *Rarα*$^{-/-}$; *Rarβ2*$^{-/-}$ double mutant mice have small kidneys characterized by a decreased number of ureteric bud branches and loss of normal cortical stromal patterning between induced nephrons [36]. In the collecting ducts of *Rarα*$^{-/-}$; *Rarβ2*$^{-/-}$ double mutant mice, *Ret* expression is down-regulated whereas *Gdnf* expression in the metanephric mesenchyme is maintained. The renal defect in these mice can be rescued by overexpressing a *Ret* transgene in the ureteric bud lineage [37]. Recent data suggests that retinoic acid derived from the renal stroma via the enzyme Raldh2 signals to the ureteric bud to up-regulate expression of *Rarα* and *Rarβ2* to induce *Ret* expression in the ureteric bud [193].

The transcription factors *Foxd1* and *Pod1* have roles in regulating the spatially restricted pattern of *Ret* expression during collecting duct development. *Foxd1* is most strongly expressed in the developing kidney in the cortical, or subcapsular, stroma [35, 38] (Fig. 7.3C). In contrast, *Pod1* is most abundant in medullary stromal cells [239, 334]. Homozygous deletion of either *Foxd1* or *Pod1* results in decreased renal branching morphogenesis and misexpression of *Ret* throughout the developing collecting system [35, 239]. These data suggest that stromal cues expressed under the control of *Foxd1* and *Pod1* are involved in inhibiting *Ret* expression in the truncal segments of the developing ureteric bud. It is not clear from the analyses of these mutants whether secreted stromal factors directly block *Ret* expression in collecting ducts. Since *Foxd1* and *Pod1* mutants show additional defects in nephron morphogenesis [35, 239], these stromal genes may indirectly control *Ret* expression through the production of nephron-derived factors that secondarily act on collecting duct cells to inhibit *Ret* expression.

Although the mechanisms by which the renal stroma regulates nephron differentiation are not entirely clear, Wnt and Hippo signaling have been implicated. With regards to Hippo signaling, loss of the protocadherin *Fat atypical cadherin 4* (*Fat4*) in the stroma results in expansion of the cap mesenchyme, and this appears to be due to binding to *Dachsous 1/2* (*Dsch1/2*) on the cap mesenchyme [47, 335]. Interestingly, activation of β-catenin in the renal stroma prevents the differentiation of nephron progenitors and results in histological and molecular features similar to Wilm's tumour [336].

Acknowledgments The authors would like to express their gratitude to Tino Piscione for his contributions to the second edition of this chapter.

Disorders of Kidney Formation

8

Norman D. Rosenblum and Indra R. Gupta

Introduction

Congenital anomalies of the kidneys and urinary tract, otherwise known as CAKUT, are classical disorders of development that are the most common cause of renal failure in children [1–3]. These disorders encompass a spectrum of entities including renal agenesis, renal hypodysplasia (RHD), multicystic kidney dysplasia, duplex renal collecting systems, ureteropelvic junction obstruction (UPJO), ureterovesical junction obstruction, megaureter, posterior urethral valves and vesicoureteral reflux (VUR). While congenital disorders like autosomal recessive and autosomal dominant polycystic kidney disease (PKD), nephronophthisis, and heritable nephrotic syndrome could also be considered as disorders of kidney formation, these generally occur later in kidney development as part of terminal cell differentiation events. However, some of the genes that cause nephronophthisis are also associated with CAKUT. In this chapter, we discuss disorders that arise during the early inductive events that lead to the formation of the kidneys and the urinary tracts. Both tissues arise from a common primordial tissue known as the mesonephric duct and thus, congenital kidney and urinary tract malformations commonly co-occur. In this chapter, we will focus on renal disorders encompassed within CAKUT and discuss their etiology, clinical manifestations and management. Other disorders within CAKUT with significant urinary tract pathology like UPJO, ureterovesical junction obstruction, megaureter, posterior urethral valves and VUR are discussed in other chapters.

Classification and Definition of Renal Malformations

Congenital malformations of the kidney can be defined at the macroscopic level by changes in size, shape, location, or number or microscopically by changes within specific lineages like the ureteric bud, the metanephric mesenchyme, or combinations of both [4]. In clinical practice, most congenital renal malformations are defined grossly using imaging methods like ultrasound and nuclear medicine scans. Sometimes renal tissue is obtained from biopsies or from nephrectomies, and in these cases, histological definitions

of renal hypoplasia, renal dysplasia, and multicystic renal dysplasia can be utilized for classification. One can group congenital malformations of the kidney as follows:

Changes in size
- Renal hypoplasia
- Renal dysplasia

Changes in shape
- Multicystic dysplastic kidney (MCDK)
- Renal fusion

Changes in location
- Renal ectopia
- Renal fusion

Changes in number
- Renal duplication
- Renal agenesis

When induction events do not occur at the right time or location during embryogenesis, the kidneys may fail to form (agenesis, hypoplasia, dysplasia), the kidneys may form, but in the wrong location (ectopia ± hypoplasia/dysplasia), the kidneys may fail to migrate to the correct location (fusion ± hypoplasia/dysplasia) or there may be multiple induction events that arise (duplication). Malformations can be either unilateral or bilateral. Importantly, from animal models and human studies, disorders of renal formation are frequently observed with concurrent lower urinary tract malformations. In these cases, it is not clear if the impairment in induction of the kidney is primary or secondary to urinary tract obstruction. Renal agenesis refers to congenital absence of the kidney and ureter. Typically, renal malformations defined as renal hypoplasia or dysplasia are grossly small in size, defined as less than 2 SD below the mean for kidney length or weight [4–6]. Usually, renal hypoplasia or dysplasia is defined based on the presence of a small hyperechogenic kidney from ultrasound imaging [7]. Simple renal hypoplasia is defined as a small kidney with a reduced number of nephrons and normal architecture. Renal dysplasia is defined by the presence of malformed kidney tissue elements. Characteristic microscopic abnormalities include abnormal differentiation of mesenchymal and epithelial elements, a decreased number of nephrons, loss of corticomedullary differentiation and the presence of dysplastic elements including cartilage and bone (Fig. 8.1). As stated, dysplastic or hypoplastic kidneys are typically small, but can range in size and appear normal or even large due to the presence of multiple cysts or coincident urinary tract obstruction with hydronephrosis. The MCDK is an extreme form of renal dysplasia and is defined grossly as a non-reniform collection of cysts.

In addition to defects in renal formation that affect size, shape, location or number, and tissue patterning, congenital anomalies of the kidneys also encompass defects in the number of nephrons formed. Nephron number in the lower range of that normally observed, but not so low that it would result in renal insufficiency during childhood and/or adolescence, typically manifests in adulthood with hypertension and/or chronic kidney disease (CKD) [8–10].

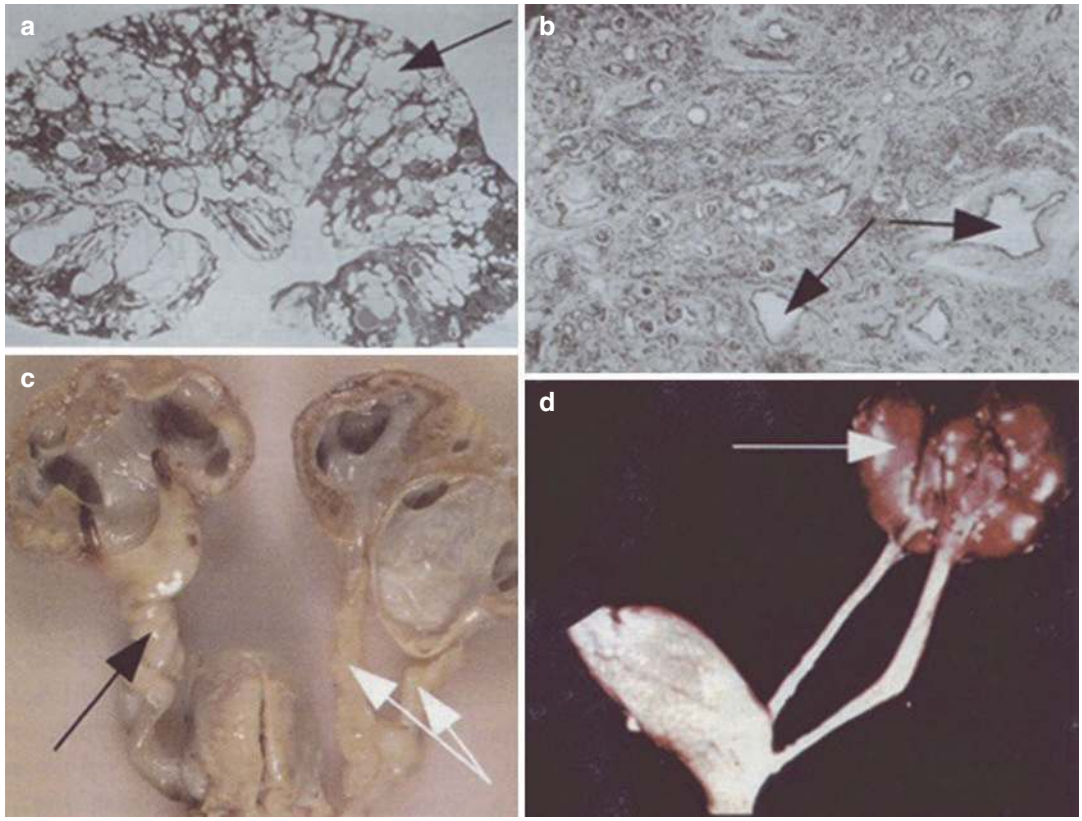

Fig. 8.1 Anatomical features of human renal and lower urinary tract malformations. (**a**) MCDK characterized by numerous cysts (arrow) distorting the renal architecture. (**b**) Dysplastic renal tissue demonstrating lack of recognizable nephron elements, dilated tubules, large amounts of stromal tissue and primitive ducts (arrows) characterized by epithelial tubules with fibromuscular collars. (**c**) Ureteral duplication (right, white arrows) and dilated ureter (left, black arrow) associated with a ureterocele. All ureters are obstructed at the level of the bladder and are associated with hydronephrosis. (**d**) Crossed fused ectopia with fused orthotopic and heterotopic kidneys (arrow)

Epidemiology and Longterm Outcomes of Renal Malformations

The prevalence of renal and urinary tract malformations is 0.3–17 per 1000 liveborn and stillborn infants [11, 12]. Due to their common embryonic origin from the mesonephric duct, lower urinary tract abnormalities are found in about 50% of patients with renal malformations and include VUR (25%), UPJO (11%), and ureterovesical junction obstruction (11%) [13, 14]. Renal malformations are commonly detected in the antenatal period and account for 20–30% of all anomalies detected [15]; upper urinary tract dilatation is the most frequent abnormality that is observed. All major organs are formed between the 4th and 8th week of gestation: the neural tube closes, the aortic arches undergo transformation, the cloacal membrane ruptures, and the kidneys begin to form. Renal malformations are therefore observed in association with non-renal malformations in about 30% of cases [12]. Indeed, there are over 100 multiorgan syndromes associated with renal and urinary tract malformations [16, 17] (Table 8.1).

Bilateral renal agenesis occurs in 1:3000–10,000 births and males are affected more often than females. Unilateral renal agenesis has been reported with a prevalence of 1:1000 autopsies. The incidence of unilateral hypoplasia/dysplasia is 1 in 3000–5000 births (1:3640 for the MCDK) compared to 1 in 10,000 for bilateral dysplasia

Glycosylation defect
Mitochondriopathy
Glutaric aciduria type II
Carnitine palmitoyl transferase II deficiency

[18]. The male to female ratio for bilateral and unilateral renal hypo/dysplasia is 1.32:1 and 1.92:1, respectively [19]. Nine percent of first degree relatives of patients with bilateral renal agenesis or bilateral renal hypoplasia/dysplasia have some type of renal malformation [20]. The incidence of renal ectopia is 1 in 1000 from autopsies, while from clinical studies it is estimated to be less frequent at 1 in 10,000 patients [21]. Males and females are equally affected. Renal ectopia is bilateral in 10% of cases; when unilateral, there is a slight predilection for the left side. The incidence of fusion anomalies is estimated to be about 1 in 600 infants [22].

While congenital renal malformations are relatively frequent birth defects, they become clinically evident at variable times during life and comprise a wide spectrum of outcomes ranging from no symptoms at all to CKD, which causes early mortality. The range in phenotypic severity makes it extremely difficult to counsel patients with certainty. Melo et al. reported a prevalence of CAKUT of 1.77 per 100 live births (524 cases of CAKUT in 29,653 newborns) in a tertiary care unit and a mortality rate of 24% in those affected (126/524) [11]. Amongst the 524 cases, risk factors for early mortality were the co-existence of non-renal and non-urinary tract organ disease, prematurity, low birth weight, oligohydramnios, and renal involvement (renal agenesis, RHD, multicystic renal dysplasia). Quirino et al. reported on the clinical course of 822 children with prenatally detected CAKUT that were followed for a median time of 43 months [23]. Their results demonstrate that most affected children do well: 29% of the children had urinary tract infection, 2.7% had hypertension, 6% had CKD, and 1.5% died during follow-up. Celedon et al. studied 176 children with chronic renal failure secondary to renal dysplasia, reflux nephropathy or urinary tract obstruction with a minimum of 5 years of follow-up [24]. They noted that patients with a urine albumin to creatinine ratio greater than 200 mg/mmol deteriorated faster compared to those with less than 50 mg/mmol (−6.5 mL/min/1.73 m^2 year vs. −1.5 mL/min/1.73 m^2 year change in estimate glomerular filtration rate [eGFR]). They also observed that those children with more than two febrile urinary tract infections deteriorated faster than those with fewer than two infections (median −3.5 mL/min/1.73 m^2 vs. −2 mL/min/1.73 m^2 year change in eGFR). Similar differences were noted for children with hypertension when compared to those without. Finally, they noted that the rate of decline in eGFR was greater during puberty (−4 mL/min/1.73 m^2/year vs. −1.9 mL/min/1.73 m^2/year change in eGFR). They noted

no differences in deterioration of eGFR when comparing children with one or two functioning kidneys. In contrast, Sanna-Cherchi et al. examined the risk of progression to end-stage kidney disease (ESKD) in patients with CAKUT. They found that by 30 years of age, 58 out of 312 patients had initiated dialysis. They also noted that the risk for dialysis was significantly higher for patients with a solitary kidney [25]. The same group reported that patients with bilateral hypodysplasia, solitary kidney, or posterior urethral valves with RHD had a higher risk of dialysis requirement at 30 years when compared to patients with unilateral RHD or horseshoe kidney, and the risk was even higher if there was coexistence of VUR. Wuhl et al. compared patients with CAKUT to age-matched patients with other causes of renal failure who were receiving some form of renal replacement therapy (RRT) and registered within the European Dialysis and Transplant Association Registry [26]. Of 212,930 patients ranging in age from 0 to 75 years who commenced RRT, only 2.2% had renal failure secondary to CAKUT. Importantly, the median age for requirement of RRT was 31 years in the CAKUT cohort versus 61 years in the non-CAKUT cohort, suggesting that most children are likely to require dialysis and/or transplantation as adults. CAKUT was the most frequent cause of need for RRT in all pediatric age groups and peaked in incidence in the 15–19-year-old group.

Low birth weight and prematurity are associated with low nephron number and have therefore been studied as surrogate markers of low nephron number. The Helsinki Study followed approximately 20,000 people born between 1924 and 1944 until death or age 86 years and established that low birth weight was a risk factor for CKD in males, whereas prematurity (birth before 34 weeks of gestation) was a risk factor for CKD in females [9]. Similarly, Crump et al. demonstrated that preterm birth, defined as <37 weeks, and extreme preterm birth, defined as <28 weeks, were strongly associated with an increased risk of CKD in childhood and in adulthood [8]. Keller et al. demonstrated that low nephron number is a risk factor for hypertension in middle-aged adults compared with age-, sex-, and race-matched controls without hypertension [10].

Taken together, many questions remain in understanding the long-term outcome of CAKUT, but clearly most children are surviving into adulthood, and thus there is a need for adult nephrologists to understand these disorders.

Abnormal Molecular Signaling in the Malformed Kidney

Human renal development is complete by 34 weeks gestation [4]. Thus, by definition, renal malformation is a problem of disordered renal embryogenesis. The morphologic, cellular, and genetic events that underlie normal renal development are reviewed in Chap. 7. During human kidney development, two primordial tissues, the ureteric bud and the metanephric mesenchyme, undergo epithelial morphogenesis to form the final metanephric kidney [27]. The kidneys and the ureters arise from two epithelial tubes that extend along the length of the embryo, the mesonephric ducts. An epithelial swelling emerges from the mesonephric duct and is known as the ureteric bud. The ureteric bud invades the adjacent undifferentiated mesenchyme and induces the formation of the metanephric mesenchyme. Reciprocal signaling between the ureteric bud and the metanephric mesenchyme induces the ureteric bud to elongate and bifurcate in a process known as branching morphogenesis that ultimately gives rise to the collecting duct system of the adult kidney. The process of ureteric bud branching morphogenesis is critical for kidney development: each ureteric bud tip induces the adjacent ventrally located metanephric mesenchyme to undergo mesenchymal-to-epithelial transition and this determines the final number of nephrons formed *in utero*. Perturbations in ureteric bud outgrowth, branching morphogenesis and mesenchymal-to-epithelial transition are thought to underlie the majority of the malformations described in humans.

Failure of ureteric bud outgrowth and invasion of the metanephric blastema are events antecedent to renal agenesis or severe renal dysplasia.

Studies in the mouse embryo, a model of human renal development, have identified genes that control ureteric bud outgrowth, ureteric bud branching morphogenesis, and mesenchymal-to-epithelial transition. Some of these genes are mutated in human renal malformations also characterized by agenesis or severe dysplasia (reviewed by [28]). If the ureteric bud fails to emerge, the ureter and the kidney do not develop, while if the ureteric bud emerges from an abnormal location, the ureter that forms will not connect to the bladder properly and potentially result in obstruction and/or VUR with a malformed kidney. Indeed, a pathogenic role for abnormal ureteric bud outgrowth from the mesonephric duct was first hypothesized based on the clinical-pathological observation that abnormal insertion of the ureter into the lower urinary tract is frequently associated with a duplex kidney. Moreover, the renal parenchyma associated with the ureter with ectopic insertion into the bladder is frequently dysplastic [29]. The local environment of transcription factors and signalling pathways is therefore critical to the successful formation of an intact kidney and urinary tract. While a large number of transcription factors and ligand-receptor signalling pathways have been identified that regulate kidney development [28, 30], we will focus on the function of a few selected molecules that have been implicated in human congenital renal malformations: *Gdnf-Ret*, *EYA1*, *Six1*, *Sall1*, *Pax2*, *HNF1b*, *Shh*, and components of the renin-angiotensin-system (RAS).

The central ligand-receptor signalling pathway that leads to the outgrowth of the ureteric bud from the mesonephric duct is the GDNF-GFRα1-RET signalling pathway. Glial cell derived neurotrophic factor (GDNF) is a ligand expressed by the metanephric blastema that interacts with the tyrosine kinase receptor, RET, and its co-receptor GFRα1, both expressed on the surface of the mesonephric duct, to initiate outgrowth of the ureteric bud. Mutational inactivation of *Gdnf*, *Gfra1*, or *Ret* in mice causes bilateral renal agenesis due to failure of ureteric bud outgrowth, demonstrating the importance of this pathway [31–34]. Similarly, when GDNF-soaked beads are positioned adjacent to cultured murine mesonephric ducts, multiple ectopic ureteric buds emerge, demonstrating the potency of this signalling pathway [35]. The expression domain of GDNF is therefore tightly regulated in the nephrogenic mesenchyme and the metanephric mesenchyme.

A network of transcription factors promotes *Gdnf* expression: *Eya1*, *Six1*, *Sall1*, and *Pax2*, while *Foxc1* restricts *Gdnf* expression [36]. Another ligand-receptor complex that limits the domain of *Gdnf* expression is the secreted factor SLIT2 and its receptor ROBO2 [37]. *Slit2* is expressed in the mesonephric duct, while *Robo2* is expressed in the nephrogenic mesenchyme Bone morphogenetic protein 4 also negatively regulates the expression domain of *Gdnf* such that the ureteric bud emerges in the correct location [38].

EYA1 is expressed in metanephric mesenchymal cells in the same spatial and temporal pattern as GDNF. Mice with EYA1 deficiency demonstrate renal agenesis and failure of GDNF expression [39]. EYA1 functions in a molecular complex that includes SIX1 and together they translocate to the nucleus to regulate GDNF expression. Therefore, mutational inactivation of *Six1* in mice also results in renal agenesis or severe dysgenesis [40]. Like GDNF, SIX1 and EYA1, SALL1 is expressed in the metanephric mesenchyme prior to and during ureteric bud invasion. Mutational inactivation of *Sall1* in mice causes renal agenesis or severe dysgenesis and a marked decrease in GDNF expression [41]. Thus, EYA1, SIX1 and SALL1 function upstream of GDNF to positively regulate its expression, thereby controlling ureteric bud outgrowth.

PAX2 is another transcription factor that is expressed in the mesonephric duct, the ureteric bud and in metanephric blastema cells induced by ureteric bud branch tips [42]. Mice with a *Pax2* mutation identical in type to that found in humans with renal coloboma syndrome (RCS) exhibit decreased ureteric bud branching and renal hypoplasia. Investigation of the mechanisms controlling abnormal ureteric bud branching in a murine model of RCS ($Pax2^{1Neu}$) revealed that increased ureteric bud cell apoptosis

decreases the number of ureteric bud branches and glomeruli formed. Remarkably, rescue of ureteric bud cell apoptosis normalizes the mutant phenotype [43]. *Pax2* appears to function upstream of *Gdnf* since in *Pax2* null mice no *Gdnf* expression is detected and the PAX2 protein can activate the *Gdnf* promoter [44].

PAX2 and HNF1β, another transcription factor, are co-expressed in the mesonephric duct and the ureteric bud lineage. Constitutive inactivation of HNF1β is embryonic-lethal in the mouse at gastrulation prior to the formation of the kidneys, but by using tetraploid and diploid embryo complementation, homozygous mutant embryos were able to proceed past gastrulation. The latter study demonstrated that HNF1β is critical for mesonephric duct integrity, ureteric bud branching morphogenesis, and early nephron formation [45]. Another group conditionally inactivated HNF1β in the proximal tubule, loop of Henle and collecting ducts and noted that null mice had cystic kidneys with cysts arising predominantly from collecting duct and loop of Henle segments [46]. The renal phenotype was severe, leading to death from renal failure in the newborn period. Importantly, cystic kidneys from null animals demonstrated downregulation of uromodulin, *Pkd2*, and *Pkhd1*, suggesting that HNF1β may regulate genes associated with cyst formation [46]. Compound heterozygous mice bearing null alleles for *Pax2* and *Hnf1β* show severe CAKUT phenotypes, including hypoplasia of the kidneys, caudal ectopic aborted ureteric buds, duplex kidneys, megaureters and hydronephrosis [47]. These phenotypes were much more severe than *Pax2* heterozygous null or *Hnf1β* heterozygous null mice, strongly suggesting that *Pax2* and *Hnf1β* genetically interact in a common kidney developmental pathway.

Sonic hedgehog (SHH) is a secreted protein that controls a variety of critical processes during embryogenesis. In mammals, SHH acts to control gene transcription via three members of the GLI family of transcription factors, GLI1, GLI2 and GLI3. A pathogenic role for truncated Gli3 was demonstrated in mice engineered such that the normal *GLI3* allele was replaced with the truncated isoform. These mice are characterized by renal agenesis or dysplasia similar to humans with Pallister Hall Syndrome (PHS) [48]. Subsequent analysis of renal embryogenesis in mice deficient in SHH suggests that the truncated form of GLI3 represses genes like *Pax2* and *Sall1* that are required for the initiation of renal development [49]. Loss of Hedgehog signalling has also been implicated in nonobstructive hydronephrosis and urinary pacemaker dysfunction in mice [50]. *Shh* is expressed in the epithelium of the ureter during embryonic development and signals to the developing ureteric mesenchyme. *Shh* deficiency results in lack of smooth muscle cell differentiation in the ureter and nonobstructive hydronephrosis [51]. Hedgehog signaling is also active in the embryonic metanephric mesenchyme; genetic deficiency of Hedgehog signaling in this spatial domain also results in nonobstructive hydronephrosis but by a different mechanism. In mice so affected, there is loss of pacemaker cell activity in the renal pelvis and ureter [50] The observation that constitutive expression of GLI3 repressor also causes nonobstructive hydronephrosis and that genetic deficiency of *Gli3* in mice with decreased Hedgehog rescues hydronephrosis demonstrates the critical role of GLI3 repressor downstream of Hedgehog signaling. Interestingly, some patients with Pallister Hall Syndrome manifest hydronephrosis, although the underlying mechanisms in these patients are unclear.

Analysis of mice with constitutive activation of Hedgehog signaling and human ureter tissues, implicates Hedgehog signaling in the pathogenesis of UPJO. Mice with deficiency of *Patched1*, a cell surface receptor that inhibits Hedgehog signaling, in renal progenitors that give rise to both nephrogenic and stromal cells are characterized by UPJO due to formation of an ectopic cluster of stromal cells that block the UPJ. Analysis of obstructing ureteric tissue in infants and children with congenital UPJO demonstrated upregulation of hedgehog signaling effectors and stromal genes, suggesting that increased hedgehog signaling may contribute to the pathogenesis of human UPJO, as well [52].

In postnatal renal physiology, the RAS plays a critical role in fluid and electrolyte homeostasis

and in the control of blood pressure. Renin cleaves angiotensinogen (AGT) to generate angiotensin (Ang) I which is cleaved by angiotensin-converting enzyme (ACE) to yield Ang II. Ang II is the main effector peptide growth factor of the RAS and acts on two major receptors: AT1R and AT2R. The role of the RAS during kidney development appears to differ somewhat in humans versus rodents, but the metanephric kidney expresses all components of the pathway in both species. Ang is expressed in the ureteric bud lineage and the stromal mesenchyme, while renin is expressed by mesenchymal cells destined to form vascular precursors in the kidney. ACE is expressed slightly later during kidney development in differentiated mesenchymal structures including glomeruli, proximal tubules and collecting ducts. The receptors AT1R and AT2R are expressed in the ureteric bud lineage and in metanephric mesenchymal cells [53]. Mutations of *AGT*, *renin*, *ACE*, or *AT1R* all result in CAKUT phenotypes in the mouse that are characterized by renal malformations with hypoplasia of the medulla and the papillae and hydronephrosis [54]. Mice with mutations in *ATR2* also exhibit CAKUT, but a wider range of phenotypes is observed that includes renal hypo/dysplasia, duplicated collecting systems, VUR, and hydronephrosis [55]. Importantly, genetic inactivation of the RAS pathway in mice does not result in renal tubular dysgenesis (RTD) as observed in humans with similar mutations. It is postulated this may be due to differences between the species: in humans, RAS activity (renin and ANG II levels) peaks during fetal life while nephrogenesis is occurring, while in rodents, RAS activity peaks postnatally from weeks 2–6, when nephrogenesis has ceased. These temporal differences likely explain the lack of concordance between genetic mouse models and affected humans [56].

Ureteric bud branching and modelling of the lower urinary tract with its insertion into the bladder is also controlled by vitamin A and its signaling effectors [57, 58]. Expression of RET, the receptor for GDNF, is controlled by members of the retinoic acid receptor family of transcription factors that function in the vitamin A signaling pathway. These members, including RAR alpha and RAR beta2, are expressed in stromal cells surrounding *Ret*-expressing ureteric bud branch tips [58, 59]. Mice deficient in these receptors exhibit fewer ureteric bud branches and diminished expression of *Ret*. These observations are consistent with the finding that vitamin A deficiency during pregnancy causes renal hypoplasia in the rat fetus [60]. A similar observation has been noted in a human study where maternal vitamin A deficiency was associated with congenital renal malformation [61].

In summary, genetic and nutritional factors like vitamin A and folic acid [61–63] interact to control ureteric bud outgrowth, ureteric bud branching, nephrogenesis, and ureter formation. The number of nephrons is likely determined by a complex combination of factors including genetic variants, environmental events and stochastic factors. This could explain the variable number of nephrons in humans, ranging from approximately 230,000 to 1,800,000 [64]. Loss-of-function mutations in developmental genes can impair nephron formation *in utero* and depending on the magnitude of this effect, renal insufficiency may present at birth, childhood, adolescence or adulthood. Despite evidence in animals that depletion of protein, total calories or micronutrients causes renal hypoplasia, their contribution to human CAKUT remains unclear and an important area of future investigation.

Human Renal Malformations with a Defined Genetic Etiology

In humans, congenital renal malformations are more frequently sporadic than familial in occurrence. This may be due to the fact that infants with severe renal malformations have only recently survived; prior to the late 1970s, chronic dialysis was not offered as a therapy for children, and this continues to be the case in much of the developing world because of a lack of resources. Therefore, it is only in the past 30 years that children with congenital renal malformations have survived and been able to reproduce and potentially transmit deleterious gene mutations.

Therefore, congenital renal malformations appear as sporadic events over time. Genetic haploinsufficiency for many of the aforementioned transcription factors (*EYA1*, *SIX1*, *PAX2*, etc.) can result in a severe renal developmental phenotype, therefore *de novo* heterozygous mutations continue to arise. However, as reported by others, incomplete penetrance with variable expressivity is frequently observed in genetic studies of CAKUT, especially in relation to many of the transcription factors described previously [65]. Congenital renal malformations can occur in isolation, as part of CAKUT, or as part of a syndrome with organ malformations. Importantly, familial cases and extra-renal symptoms are sometimes unrecognized if carefully phenotyping is not performed. A careful evaluation of family history reveals a clustering of isolated or syndromic urinary tract and renal malformations in more than 10% of the cases [66]. Knowledge of the most frequent syndromes, a careful clinical examination and appropriately selected investigations are critical to the clinical approach to these disorders.

Mutations in more than 30 genes have been identified in children with renal development anomalies, generally as part of a multiorgan syndrome (Table 8.2). Some of these syndromes and their associated genes are described here or in some recent reviews [16, 17]. The most frequent syndromes in which renal malformations are encountered are listed in Tables 8.1 and 8.2. For a

Table 8.2 Human gene mutations exhibiting defects in renal morphogenesis

Primary disease	Gene(s)	Kidney phenotype	References
Alagille syndrome	*JAGGED1, NOTCH2*	Cystic dysplasia	[177–179]
Apert syndrome (overlaps with Pfeiffer syndrome and Crouzon syndrome)	*FGFR2, FGFR1*	Hydronephrosis, VUR	[180, 181]
Beckwith-Wiedemann syndrome	*CDKN1C*($p57^{KIP2}$), *H19, LIT1, NSD1*	Medullary dysplasia, nephromegaly, collecting duct abnormalities, cysts, VUR, hydronephrosis, Wilms tumor	[182, 183]
Branchio-Oto-Renal (BOR) syndrome	*EYA1, SIX1, SIX5*	Unilateral or bilateral agenesis/dysplasia, hypoplasia, collecting system anomalies	[79, 80, 184]
Campomelic dysplasia	*SOX9*	Dysplasia, hydronephrosis	[185, 186]
Duane Radial Ray (Okihiro) syndrome	*SALL4*	UNL agenesis, VUR, malrotation, cross-fused ectopia, pelviectasis	[187]
Fraser syndrome	*FRAS1, GRIP1, FREM2, FREM1*	Agenesis, dysplasia, CAKUT	[188, 189–191]
Hypoparathyroidism, sensorineural deafness and renal anomalies (HDR) syndrome	*GATA3*	Dysplasia, VUR, CAKUT, mesangioproliferative glomerulonephritis	[192, 193]
Kallmann syndrome	*KAL1, FGFR1, FGF8, PROK2, PROK2R, CHD7, NELF, HS6ST1*	Agenesis	[133, 194]
Mammary-Ulnar syndrome	*TBX3*	Dysplasia	[195]
Pallister-Hall syndrome	*GLI3*	Dysplasia	[49, 196]
Renal-Coloboma syndrome	*PAX2*	Hypoplasia, vesicoureteral reflux	[109]
Renal tubular dysgenesis	RAS components, *REN, AGT, AGTR1, ACE*	Tubular dysplasia	[139]
Renal cysts and diabetes syndrome	*HNF1β*	Dysplasia, hypoplasia	[197]
Simpson-Golabi Behmel syndrome	*GPC3*	Medullary dysplasia	[198]
Smith Lemli Opitz syndrome	*DHCR7*	Agenesis, dysplasia	[199]
Townes-Brock syndrome	*SALL1*	Hypoplasia, dysplasia, VUR	[91]
Zellweger syndrome	*PEX1*	VUR, cystic dysplasia	[200]

complete list of syndromes featuring renal malformations, the reader is referred to McKusick's Online Mendelian Inheritance in Man.[1]

For most children with renal malformations, neither a syndrome nor a Mendelian pattern of inheritance is obvious. However, genetic studies incorporating chromosomal microarrays, targeted gene panels or whole exome sequencing (WES) have identified a genetic cause for the renal malformation in anywhere from 5% to 30% of cases [16]. One of the first such studies of 100 patients with RHD and renal insufficiency demonstrated that 15% had mutations in two transcription factors [65]: *TCF2* (HNF1β) (especially in the subset with kidney cysts) and *PAX2*. *EYA1* and *SALL1* mutations were found in single cases. Some of the mutations that were identified in these genes were *de novo* mutations explaining the sporadic appearance of RHD. Careful analysis of patients with *TCF2* and *PAX2* mutations revealed the presence of extrarenal symptoms in only half, supporting previous reports that *TCF2* and *PAX2* mutations can be responsible for isolated renal tract anomalies or at least CAKUT malformations with minimal extrarenal features [67, 68]. This study demonstrates that subtle extrarenal symptoms in syndromal RHD can easily be missed. Genetic testing in children with RHD should be preceded by a thorough clinical evaluation for extrarenal symptoms, including eye, ear, and metabolic anomalies. The presence of nonrenal anomalies increases the likelihood of detecting a specific genetic abnormality (Table 8.5). In addition, mutations in genes that are usually associated with syndromes can occur in patients with isolated RHD.

The GDNF/RET Signaling Pathway

The proto-oncogene *RET*, a tyrosine kinase receptor, and its ligand, GDNF, play a pivotal role during early nephrogenesis and enteric nervous system development. Activating *RET* mutations cause multiple endocrine neoplasia, whereas inactivating mutations lead to Hirschsprung disease. A number of human studies have demonstrated that patients with CAKUT have mutations in the RET/GDNF signaling pathway [69–72]. A study of 122 patients with CAKUT identified heterozygous deleterious sequence variants in *GDNF* or *RET* in 6/122 patients, 5%, while another group screened 749 families from all over the world and identified 3 families with heterozygous mutations in RET [69, 73]. Similar findings have been reported in studies of fetuses with bilateral or unilateral renal agenesis [70, 71].

Branchio-Oto-Renal Syndrome

The association of branchial (B), otic (O) and renal (R) anomalies was first described by Fraser and Melnick [74, 75]. Major diagnostic criteria consist of hearing loss (95%), branchial defects (49–69%), ear pits (83%) and renal anomalies (38–67%) [76, 77]. The association of these three major features defines the classical BOR syndrome (OMIM # 113650). Yet, many patients have only one or two of these major features in association with other minor features such as external ear anomalies, preauricular tags or other facial abnormalities (Table 8.3). Hearing loss can be conductive, sensorineural, or mixed.

The frequency of BOR syndrome has been estimated to be 1 in 40,000 births [78]. The transmission is autosomal dominant with incomplete penetrance and variable expressivity. Renal malformations include unilateral or bilateral renal agenesis, hypodysplasia as well as malformation of the lower urinary tract including VUR, pyeloureteral obstruction, and ureteral duplication. Different renal malformations can be observed in

Table 8.3 Major and minor criteria for the diagnosis of BOR syndrome

Major features	Minor features
Deafness	External ear anomalies
Branchial anomalies	Preauricular tags
Preauricular pits	Other facial anomalies
Renal malformations	Cataracts Lacrimal duct stenosis

[1] http://www.ncbi.nlm.nih.gov/.

the same family; moreover, some individuals have normal kidneys (BO syndrome, OMIM 120502). Other infrequent abnormalities have been described in patients with the BOR syndrome. These include aplasia of the lacrimal ducts, congenital cataracts and anterior segment anomalies [74, 75]. Characteristic temporal bone findings include cochlear hypoplasia (4/5 of normal size with only 2 turns), dilation of the vestibular aqueduct, bulbous internal auditory canals, deep posterior fossae, and acutely angled promontories [77].

Approximately 40% of patients with BOR syndrome have a mutation in *EYA1* [76]. Mutations in in *SIX1*, *SIX5*, and *SALL1* have also been identified in patients with BOR syndrome, but at lower frequencies [79–81]. Both EYA1 and SIX1 are co-expressed in the developing otic, branchial and renal tissue, where they function in a transcriptional complex that regulates cell proliferation and cell survival [82, 83]. EYA1 and SIX1 control the expression of PAX2 and GDNF in the metanephric mesenchyme [84]. The EYA1 protein contains a highly conserved region called the *eyes absent* homologous region encoded within exons 9–16, which is the site of most mutations identified to date.

A reasonable approach is to perform genetic analysis in families in which at least one member fulfils the criteria for classical BOR syndrome (Table 8.3). Investigations should include a family history, and examination of relatives to look for preauricular pits, lacrimal duct stenosis, and branchial fistulae and/or cysts. Hearing studies and renal ultrasound should be done in all first-degree relatives.

Molecular testing can confirm the diagnosis and provide genetic recurrence risk information to families. However, variability of the phenotype even with the same mutation does not permit accurate prediction of the disease severity. Within the same family, a given mutation may be associated with renal malformation in some individuals, but not in others. This discrepancy might be explained by stochastic factors that impact the formation of the kidneys or by other unlinked genetic events that may act in synergy with the EYA1 protein during nephrogenesis.

Townes-Brocks Syndrome and VATER/VACTERL Associations

Townes-Brocks syndrome (TBS) is an autosomal dominant malformation syndrome usually defined by a triad of anomalies including imperforate anus, dysplastic ears, and thumb malformations [85]. A wide spectrum of additional features includes renal malformations, congenital heart defects, hand and foot malformations, hearing loss, and eye anomalies [86, 87]. Intelligence is usually normal. REAR Syndrome (renal-ear-anal-radial) has also been used to describe this condition [88]. Its incidence is reported to be 1:250,000 live births [89]. The presentation of TBS is highly variable within and between affected families. Importantly, *SALL1*, is the only gene implicated in TBS and it encodes a C_2H_2 zinc finger transcription factor that is required for the normal development of the limbs, nervous system, ears, anus, heart and kidneys [90, 91].

The detection rate of *SALL1* mutations in patients with TBS appears to be higher when malformations of the hands, the ears, and the anus are present [92]. However genetic testing is further complicated by the fact that the phenotypic features of TBS can resemble other disorders like VACTERL association, Goldenhar syndrome, Oculo-Auriculo-Vertebral spectrum, Pallister-Hall syndrome and even BOR syndrome. TBS features overlap those seen in the VACTERL association (anal, radial and renal malformations). In contrast to VACTERL association, TBS is associated with ear anomalies and deafness and it is not characterized by tracheo-oesophageal fistula or vertebral anomalies.

VACTERL association is defined by the presence of at least three of the following congenital malformations: vertebral anomalies, anal atresia, cardiac defects, tracheo-esophageal defects, renal malformations, and limb anomalies [93]. It is reported to occur in 1:10,000–40,000 of all live births. Renal anomalies are reported in 50–80% of patients and include unilateral or bilateral renal agenesis, horseshoe kidney, cystic kidneys, and dysplastic kidneys; they can be accompanied by urinary tract and genital defects [93, 94]. Ninety percent of VACTERL cases appear to be

sporadic with little evidence of heritability [93]. In a subset of patients there is evidence of heritability [93, 95, 96], and genes that interact with the Sonic Hedgehog pathway have been implicated [97, 98]. The presence of a single umbilical artery on ultrasound has been associated with a variety of congenital birth defects, including VACTERL syndrome [99]. It has been hypothesized that the single umbilical artery is a risk factor for a placental defect that may affect nutrient supply for multiple organs simultaneously during development [100].

An important diagnosis to consider in patients suspected to have VACTERL syndrome is Fanconi's anemia. Patients with Fanconi's anemia can phenocopy VACTERL syndrome, but also exhibit bone marrow failure manifest as pancytopenia. They can also develop malignancies like acute myelogenous leukemia secondary to their propensity for chromosomal instability manifest as spontaneous cytogenetic aberrations. Patients with Fanconi's anemia also frequently demonstrate skin pigmentation (café au lait spots), microcephaly, growth retardation and microphthalmia. There are at least nine different gene mutations implicated in Fanconi's anemia and they are inherited as X-linked or recessive disorders. It has been reported that approximately 5% of patients with confirmed Fanconi's anemia have features consistent with VACTERL syndrome [101]. Therefore, the diagnosis of Fanconi's anemia needs to be carefully considered in all patients with VACTERL syndrome and confirmed if needed by performing chromosomal breakage studies [101].

Renal-Coloboma Syndrome

Renal Coloboma Syndrome (RCS) (also named papillo-renal syndrome) is an autosomal dominant disorder characterized by the association of renal hypoplasia, VUR and optic nerve coloboma from a mutation in *PAX2* [102]. The prevalence of the syndrome is unknown, but approximately 100 families have been reported [103]. A wide range of renal malformations are observed in RCS. Oligomeganephronic hypoplasia, renal dysplasia and VUR are the most frequent malformations, but multicystic dysplasia [104] and UPJO have also been described [104]. Similarly, the ocular phenotype is extremely variable. The most common finding is an optic disc pit associated with vascular abnormalities and cilio-retinal arteries, with mild visual impairment limited to blind spot enlargement, the "morning glory" anomaly [105]. In other cases, the only ocular anomaly is optic nerve dysplasia with an abnormal vessel pattern and no functional consequence (Fig. 8.2). In contrast, a large coloboma of the

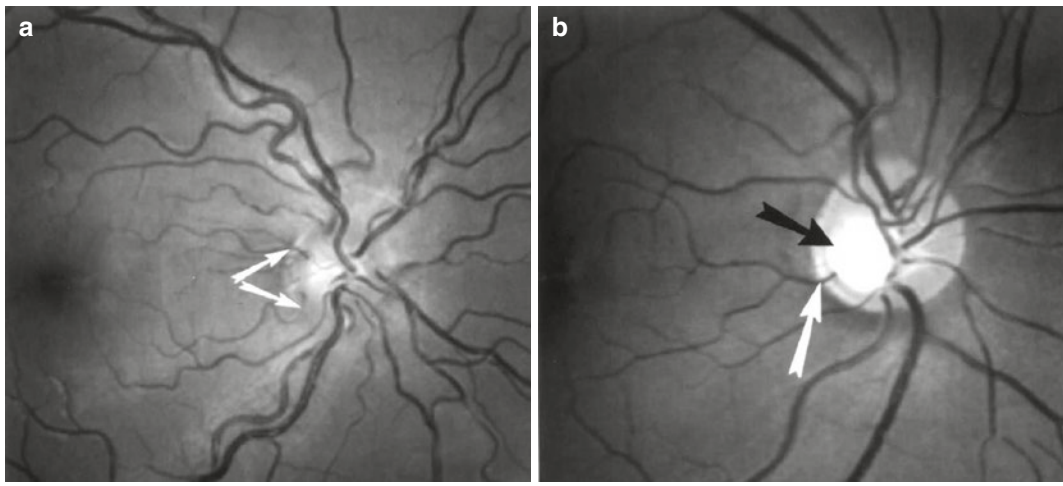

Fig. 8.2 Optic disc appearance in two patients with Renal Coloboma Syndrome and PAX2 mutations: (**a**) Characteristic features of optic disk coloboma with a deep temporal excavation (arrowheads). (**b**) The optic disk is dysplastic with thickening (arrow) and emergence of abnormal vessels ("morning glory anomaly")

optic nerve or of the choroid and retina and the morning glory anomaly can be responsible for a severe visual impairment [106]. Coloboma and the related anomalies are probably the consequence of an incomplete closure of the embryonic fissure of the optic cup. Other extrarenal manifestations can include sensorineural hearing loss, joint laxity, Arnold-Chiari malformation and seizures of unknown cause [107, 108]. In addition to its expression in the developing kidney and in the optic fissure, *PAX2* is also expressed in the hindbrain during its development. However, neurological symptoms are not usually present in RCS.

PAX2 is a transcription factor of the paired-box family of homeotic genes that is expressed in the mesonephros and in the metanephros during renal development. In 1995, Sanyanusin et al reported heterozygous mutations in two RCS families [109]. Since then, more than 30 mutations have been reported, most of them lying in exons 2–4 that encode the paired domain that binds to DNA or in exons 7–9 that encode the transactivation domain [103]. Other gene(s) are probably also responsible for this syndrome since *PAX2* mutations are not found in approximately 50% of RCS patients. Importantly the RCS phenotype is highly variable, even in patients harboring the same *PAX2* mutation, suggesting that modifier genes might be implicated.

Optic nerve coloboma occurs frequently as an isolated anomaly or as a feature of many other multiorgan syndromes such as the CHARGE association, the COACH syndrome and the acro-renal-ocular syndrome. As optic nerve coloboma and the related disorders can be easily misdiagnosed, it is likely that the prevalence of RCS is underestimated. It is wise to examine the fundus in every patient with RHD, and conversely to perform renal ultrasound and serum creatinine in every patient with optic nerve coloboma.

Even in the absence of optic nerve colobomas, mutations in *PAX2* are one of the more common genetic causes of RHD [65] and they also appear to be associated with low nephron number. Barua et al. described families diagnosed with FSGS anywhere from 7 to 68 years of age due to dominantly inherited mutations in *PAX2*. One patient had a kidney biopsy sample that exhibited glomerulomegaly, which could be secondary to low nephron endowment at birth [110]. Some of the affected individuals had imaging studies that revealed other CAKUT phenotypes including small kidneys and hydronephrosis. Vivante et al. identified heterozygous mutations in *PAX2* in three families and one child with steroid-resistant nephrotic syndrome [111]. The patients developed their steroid-resistant nephrotic syndrome or FSGS either during infancy or in adolescence. Here again, the FSGS lesion could be secondary to low nephron endowment at birth.

Renal Cyst and Diabetes Syndrome

Mutations in the *TCF2* gene encoding the transcription factor HNF1β were initially found in patients with maturity onset diabetes of the young, type 5 (MODY5), an autosomal dominant disorder [112, 113]. Diabetes mellitus is present in approximately 60% of all the cases reported, usually occurs before 25 years of age, and is often associated with pancreatic atrophy [114–116]. In some patients, a subclinical deficiency of pancreatic exocrine functions has been demonstrated. Additional features have been described, including a wide spectrum of renal phenotypes (Table 8.4). The presence of cysts is the most consistent feature of the renal phenotype, leading

Table 8.4 Renal cyst and diabetes syndrome

Main features[a]
Fetal large hyperechoic kidneys
Renal hypodysplasia with cortical microcysts
Diabetes mellitus (MODY type 5)
Occasional features
Genital malformations
Female: vaginal aplasia, rudimentary or bicornuate uterus
Male: epididymal cysts, atresia of the vas deferens, asthenospermia, hypospadias
Hyperuricemia, rarely gout (reduced uric acid fraction excretion)
Hypomagnesemia
Moderate elevation of liver enzymes
Subclinical defect of exocrine pancreatic functions

[a] Age at onset and severity of these symptoms are highly variable

to the name, "Renal Cysts and Diabetes (RCAD) Syndrome". The cysts are usually cortical, bilateral, and small [68]. Mutations in the *TCF2* gene have also been found in association with a variety of isolated renal development disorders such as RHD, MCDKs, renal agenesis, horseshoe kidneys, UPJO as well as clubbing and tiny diverticula of the calyces [117–119]. The most specific finding when histology is available is the presence of cortical glomerular cysts with dilatation of the Bowman spaces (glomerulocystic dysplasia) [120]. Other nonspecific lesions such as cystic renal dysplasia, interstitial fibrosis or oligomeganephronia have also been reported. Antenatal presentations with enlarged hyperechoic kidneys or macroscopic cysts can occur [118, 121].

Various genital tract malformations have been reported mostly in females. These include vaginal aplasia, rudimentary uterus, bicornuate uterus, uterus didelphys and double vagina. In males, hypospadias, epididymal cysts, and agenesis of the vas deferens have been reported [114]. These genital anomalies have been described in approximately 10–15% of patients with *TCF2* mutations, but these malformations might be underestimated especially in paediatric reports. Reduced fractional excretion of uric acid (<15%) and moderate hyperuricemia is observed in some cases and is usually asymptomatic. The hyperuricemia is thought to reflect altered urate transport by the kidney and impaired glomerular filtration [114]. Serum hypomagnesemia has also been reported and this may be due to the fact that HNF1b regulates FXYD2 that is needed for distal tubule reabsorption of magnesium [122]. A similar mechanism may explain the altered urate transport observed in these patients since HNF1b can activate the promoter of URAT1 that regulates urate transport in the proximal tubule [123]. Moderate elevation of liver enzymes is a common finding, but severe hepatopathy has not been reported.

HNF1β is a homeobox-containing basic helix-turn-helix transcription factor, which is involved in the development of the pancreas, the kidneys, the liver and intestine. More than 50 mutations have been reported, most of which are located in the first four exons that encode the DNA-binding domain. In more than one-third of the cases, the gene is entirely deleted [68, 115, 123]. Such alterations are not detected by conventional amplification and screening methods. Importantly, deletions are infrequently transmitted by the parents but appear *de novo* in the proband. Analysis of *TCF2* can thus be recommended not only in patients with a family history of RCAD syndrome but also in cases with renal cysts when polycystic disease or nephronophthisis are unlikely. The presence of cortical bilateral cysts is probably the most typical finding. Reduced uric acid fractional excretion, elevation of liver enzymes, hypomagnesemia, glucose intolerance and abnormalities of the genital tract should be systemically sought and *TCF2* analyzed if one of these symptoms is present. As observed in other syndromes, phenotypic variability can be observed between families and also in family members with the same mutation, suggesting a role for environmental and genetic factors.

Longitudinal follow-up of genetically proven HNF1β nephropathy has been reported in a group of 62 children and adolescents, of whom 87% were diagnosed with bilateral renal dysplasia. Among these patients, 74% and 16% had visible bilateral or unilateral cysts, respectively, at the end of an average of 4 years of follow-up [124]. During this period, 28% of patients had an increase in cyst number, which was associated with a greater decline in GFR compared to patients without an increase in cyst number. Eight percent of patients developed ESKD at a median age of 15 months. Hypomagnesemia was present in 19 of 52 patients evaluated by a median age of 1 year, while recurrent hyperglycemia was observed in 4 of 50 evaluated patients. Increased uric acid was detected in 37% of patients. HNF1β mutations were varied in type, were familial or de novo, and were not correlated with phenotype. The issue of which patients should be screened for a mutation in *HNF1β* has been investigated in a cohort of 433 pediatric patients with known *HNF1β* status and CAKUT using a 17-item weighted score inclusive of abnormalities in renal, pancreatic, genital, electrolyte, and liver function as well as family history. A score of ≥8

was reported to have a sensitivity of 98.2%, specificity of 41.1%, positive predictive value of 19.8% and a negative predictive value 99.4% [125]. The possible utility of this scoring system, particularly in predicting absence of a HNF1β mutation, needs to be validated in other cohorts with HNF1β-associated disease.

Kallmann Syndrome

Kallmann syndrome (KS) is defined by the presence of hypogonadotropic hypogonadism and deficiency of the sense of smell (anosmia or hyposmia) [126]. Some affected individuals exhibit unilateral renal agenesis, cleft lip and/or palate, selective tooth agenesis, bimanual synkinesis and hearing impairment [127]. Other CAKUT phenotypes including duplex systems, hydronephrosis, and VUR have been rarely reported. Anosmia/hyposmia is related to the absence or hypoplasia of the olfactory bulbs and tracts. Hypogonadism is due to a deficiency in gonadotropin-releasing hormone (GnRH). The GnRH-synthesizing neurons migrate during development from the olfactory epithelium to the forebrain along the olfactory nerve pathway [128]. KS is genetically heterogeneous with at least 8 genes reported including *KAL1*, an X-chromosome encoded gene that gives rise to the extracellular matrix protein anosmin-1 [129], *FGF8* (Fibroblast growth factor 8) [130], *FGFR1* (Fibroblast Growth Factor Receptor 1) [131], *PROK2* (prokinectin-2) and *PROKR2* (prokinectin-2 receptor) [132], *CHD7*, *NELF*, and *HS6ST1* [133]. Chromodomain helicase DNA-binding protein 7 (CHD7) is a transcriptional regulator that binds to enhancer elements in the nucleus. It is implicated in CHARGE syndrome, that is characterized by choanal atresia, malformations of the heart, the inner ear, and the retina, and in Kallmann syndrome. In the largest study to date of 219 patients with Kallmann syndrome, mutations were most commonly observed in the FGF pathway (either FGF8 or FGFR1), in KAL1, in the PROK2/PROKR2 pathway and in CHD7 [133]. Importantly in this study, unilateral renal agenesis was only observed in patients with KAL1 mutations (reported in 18%, 3/17), or in patients with no mutation in the above-mentioned 8 genes, where the frequency was similar at 17% (4/23). Patients with *KAL1* mutations are typically male since the disorder is X-linked and they demonstrate a much more severe reproductive phenotype compared to patients with other mutations with small testes, absent puberty, and micropenis. Females with KAL1 mutations typically present with partial pubertal development manifesting as spontaneous breast development in the absence of hormonal treatment. KAL1 is expressed in the developing human metanephric kidney at 11 weeks of gestation [134].

Renal Tubular Dysgenesis and Mutations of RAS System Elements

The differential diagnosis of oligohydramnios with neonatal renal failure includes a spectrum of diagnoses including bilateral renal dysplasia, posterior urethral valves, and PKD. All of these diagnoses are detectable and distinguishable on antenatal ultrasound imaging of the kidneys and the urinary tracts. The presence of normal kidneys on antenatal ultrasound in combination with oligo- or anhydramnios should strongly suggest the diagnosis of RTD [135]. RTD is a severe perinatal disorder characterized by absence or paucity of differentiated proximal tubules, early severe oligohydramnios, and perinatal death. The latter is usually due to pulmonary hypoplasia and skull ossification defects [136]. This condition has also been described in clinical conditions associated with renal ischemia, including the twin–twin transfusion syndrome, major cardiac malformations, severe liver diseases, fetal or infantile renal artery stenosis [137] and in fetuses that are exposed *in utero* to ACE inhibitors, Ang II receptor antagonists [138] or non-steroidal anti-inflammatory medications [135]. All of these environmental insults are postulated to lead to chronic hypoperfusion of the fetal kidneys with upregulation of the RAS. The absence or paucity of proximal tubules is believed to be secondary to chronic renal hypoperfusion [56]. Mutations in

the genes which encode components of the RAS have been identified in some families [139]. Mutations in the *ACE* gene are seen in 65.5 % of cases, while mutations in the *renin* (*REN*) are observed in 20 % of cases. Mutations in *AGT* and in the *AGT type I receptor* (*ATR1*) occur much less frequently [56]. It has been suggested that if there is no expression of the renin protein on immunohistochemistry of the kidneys, then the *renin* gene should first be assessed. Similarly, the plasma renin activity should be measured in the newborn with suspected genetic RTD and if elevated, this should prompt an analysis of genes downstream of the *REN* gene [140].

CHD1L, CHD7 and CHARGE Syndrome

Chromodomain helicase DNA binding protein 1-like protein, CHD1L, belongs to the Snf2 family of helicase-related ATP-hydrolyzing proteins and contains a helicase-like region that is similar to other family members, such as CHD7 which is the major gene that causes CHARGE syndrome. CHARGE syndrome is characterized by Colobomas, Heart defects, choanal Atresia, Retarded growth and development, Genital hypoplasia, and Ear anomalies with deafness. CHARGE syndrome is associated with CAKUT phenotypes including horseshoe kidneys, renal agenesis, VUR and renal cysts [141]. Chromatin-remodelling and -modifying enzymes like CHD1L and CHD7 are predicted to play key roles in differentiation, development and tumour pathogenesis via effects on chromatin structure and accessibility. Brockeschmidt et al. screened 85 patients with CAKUT and identified 3 patients with heterozygous missense variants in CHD1L [142]. The same paper reported that CHD1L was expressed in early ureteric bud and comma- and S-shaped structures during human kidney development. In the postnatal human kidney, CHD1L was expressed in the cytoplasm of tubular cells in all nephron segments. Similarly, Hwang et al. reported that 5 out of 650 families had heterozygous mutations in CHD1L: the affected individuals had a spectrum of CAKUT phenotypes including renal dysplasia, posterior urethral valves, UVJ obstruction and horseshoe kidneys [73]. It is not yet known if these patients will also be at greater risk for malignancies given that CHD1L is known to be an oncogene in hepatocellular carcinoma [143].

DSTYK and CAKUT

DSTYK is a dual serine-threonine and tyrosine protein kinase that is co-expressed with fibroblast growth factor receptors in the developing mouse and human kidney in both metanephric mesenchyme and ureteric bud cells. Sanna-Cherchi et al. discovered that 7/311 patients with CAKUT had heterozygous mutations in this gene [144]. The CAKUT phenotypes observed in these patients included UPJO, VUR, and RHD.

Copy Number Variants, CAKUT and Neuropsychiatric Disorders

Copy number variants are stretches of DNA that are larger than 1 kb in length with the potential to contribute to functional variation and disease. Rare CNVs have been implicated in neuropsychiatric and craniofacial syndromes, and in syndromes with CAKUT [145, 146]. Sanna-Cherchi et al. examined the burden of rare CNVs in individuals with congenital renal malformations and identified disease-causing CNVs and potentially pathogenic CNVs in 10% and 6%, respectively, of the 522 affected individuals analyzed. This burden of CNVs in CAKUT was compared to 0.2% in population controls [146]. A subsequent analysis of 2824 individuals with CAKUT highlighted an increased prevalence of large, rare, exonic CNVs compared to population-based controls [147]. In this study, genomic abnormalities were identified in 4% of patients with the majority within six pathogenic loci including chromosome 17q12 (RCAD Syndrome), 22q11.2 (DiGeorge Syndrome), 16p11.2, 1q21.1, 4p– (Wolf-Hirschhorn Syndrome), and 16p13.11. In addition, 90% of the CNVs associated with congenital renal malformations were previously reported to predispose to developmental delay or

neuropsychiatric disease, suggesting that there are shared pathways implicated in renal and central nervous system development. Similarly, Handrigan et al. demonstrated that copy number variants at chromosome 16q24.2 are associated with autism spectrum disorder, intellectual disability, and congenital renal malformations [145].

Environmental Factors and Renal Malformations

As mentioned earlier in this chapter, genetic causes of CAKUT can be identified in at most 30% of all cases, which suggests that environmental factors or epigenetic factors explain the remaining cases (Table 8.5). Epigenetics refers to changes in gene expression rather than changes in the gene sequence itself and usually arises from DNA methylation and histone modifications that can silence or enhance gene expression. Maternal obesity and diabetes are major risk factors for CAKUT. From questionnaire data of 562 parents of children with CAKUT, maternal obesity was more highly associated with duplex kidneys and VUR, while maternal diabetes was particularly associated with posterior urethral valves [148]. Dart et al. demonstrated that pregestational diabetes was significantly associated with CAKUT (odds ratio, 1.67; 95% confidence interval, 1.14–2.46), which implies a 67% increased chance of CAKUT in the children of mothers with pregestational diabetes compared to the general population (8.3 vs. 5.0 per 1000 births, respectively) [149]. These findings in humans are strongly supported by animal models in which the pregnant dam has diabetes. Animal models have also shown that maternal undernutrition and uteroplacental insufficiency are risk factors for impaired nephrogenesis and CAKUT. Maternal use of medications, alcohol and illicit drugs like cocaine are also risk factors for impaired nephrogenesis and CAKUT. Maternal use of RAS inhibitors such as ACE inhibitors, Ang II receptor blockers and direct renin inhibitors during pregnancy have been linked to an increased risk of fetopathy in humans. The majority of children manifest hyperechogenic and enlarged kidneys with proximal tubular dysplasia, thickening of arterial walls and multiple small cysts [150, 151]. Maternal supplementation with folate may also decrease the risk of CAKUT. CAKUT phenotypes have been observed in infants exposed to folic acid antagonists *in utero*, such as carbamazepine, phenytoin, primidone, phenobarbital or valproic acid, suggesting that folate is important for kidney and urinary tract development [63, 152]. Fertility treatment with in vitro fertilization or intrauterine semination are also risk factors for CAKUT, possibly through epigenetic effects on the developing zygote. Identifying the environmental risk factors that predispose to CAKUT needs to be addressed in future research.

Table 8.5 Clinical indications to search for a renal anomaly

Exposure to teratogens
ACE inhibitors and Angiotensin receptor blockers
Alcohol
Alkylating agents
Cocaine
Folic acid antagonists
Vitamin A congeners
Maternal diabetes
Findings on physical examination
High imperforate or anteriorly positioned anus
Abnormal external genitalia
Supernumerary nipples
Preauricular pits and ear tags, cervical cysts or fistula
Hearing loss
Aniridia
Coloboma or optic disc dysplasia
Hemihypertrophy
Single umbilical artery
Other
Hyperglycemia

Clinical Approach to Renal Malformation

The majority of renal malformations are now diagnosed antenatally, largely because of the widespread use and sensitivity of fetal ultrasound. The sensitivity of prenatal ultrasound screening for renal malformations is about 82% and the mean time at which these malformations

are detected is 23 weeks gestation [12]. In general, urinary tract malformations detected antenatally are isolated and present as mild hydronephrosis with no therapeutic consequences. Parents should be reassured. In contrast, bilateral forms of renal agenesis, severe dysgenesis, bilateral ureteric obstruction, or obstruction of the bladder outlet or the urethra can cause severe oligohydramnios as early as 18 weeks. Because amniotic fluid is critical to lung development, oligohydramnios as early as the second trimester can result in lung hypoplasia, a potentially fatal disorder. The oligohydramnios sequence, termed Potter's syndrome, in its most severe form consists of a typical facial appearance characterized by epicanthal folds, recessed chin, posteriorly rotated, flattened ears and flattened nose, as well as decreased fetal movement, musculoskeletal features including clubfoot and clubhand, hip dislocation, joint contractures and pulmonary hypoplasia. The renal prognosis can be evaluated antenatally. Poor outcome can be predicted when there is severe oligohydramnios, and small and hyperechogenic kidneys. Normative data on kidney dimensions including kidney length from antenatal ultrasound imaging is available from the 15th week of gestation and can be used to determine if a kidney is small, suggesting some type of renal dysplasia, or increased in size, as observed in autosomal recessive PKD (ARPKD) or autosomal dominant PKD (ADPKD) [153]. Indeed, fetal renal hyperechogenicity with renal cysts suggests the fetus may have ARPKD, ADPKD or a mutation in *HNF1B*. If there is concurrent severe oligohydramnios, then ARPKD is the most likely diagnosis. Amniotic fluid analysis may be of help in some cases if the fetus is suspected to have a trisomy. Trisomy 21, 18, and 13 are all associated with CAKUT [154–156]. Antenatal diagnosis and assessment of the renal prognosis are important for consideration of early termination in cases of fatal (or eventually severe renal disease) and to prepare parents and medical staff for the likelihood of neonatal renal insufficiency. Other organ malformations should be sought carefully and, if detected, a karyotype should be done. Some authors have suggested that fetal urine analysis may be helpful to determine fetal renal prognosis and to decide on *in utero* therapy if congenital lower urinary tract obstruction is noted. Morris et al. performed a systematic review of the literature on fetal urine analysis and concluded that none of the analytes examined had sufficient accuracy to predict poor postnatal renal function [157].

Oligo/anhydramnios from CAKUT is associated with a high incidence of fetal death *in utero*, severe pulmonary hypoplasia, umbilical cord compression and perinatal asphyxia. The earlier that renal oligohydramnios (ROH) is identified in the pregnancy, the more severe the pulmonary hypoplasia [158, 159]. Pulmonary hypoplasia is defined as deficiency in the number of lung cells, airways and alveoli, leading to a reduced surface area for gas exchange. Postnatally, pulmonary hypoplasia is suspected in cases of ROH when there is respiratory failure with the need for high ventilatory support and the chest x-ray reveals a bell-shaped chest, an elevated diaphragm, and/or pneumomediastinum or pneumothorax. Ultrasound and MRI have been used to assess lung volumes antenatally, but there is no consensus on whether they are reliable predictors of pulmonary hypoplasia postnatally. Therefore, it remains difficult to predict pulmonary prognosis postnatally.

When isolated CAKUT or CAKUT with other organ defects is diagnosed in the fetus, genetic counseling and referral to a multidisciplinary team should be offered. An individualized approach that is in accordance with the parental wishes for more information is advised [160]. A screen for gross chromosomal abnormalities can be performed using a chromosomal microarray from the amniotic fluid (if less than 25 weeks) or from fetal blood (greater than 25 weeks or severe oligohydramnios). If the chromosomal microarray is normal, then a targeted gene panel or WES on the parents and the fetus could be considered. Given the incomplete penetrance and variable expressivity of many mutations implicated in CAKUT, it remains to be demonstrated whether targeted gene panels or WES are beneficial for antenatal decision-making.

The clinical presentation of renal malformation in the postnatal period is dependent on the

amount of functioning renal mass, the presence of bilateral urinary tract obstruction and the occurrence of urinary tract infection. Bilateral renal agenesis or severe dysplasia is likely to present soon after birth with decreased renal function. This may be accompanied by oliguria. Alternatively, patients may present with a flank mass or an asymptomatic abnormality detected by renal imaging.

A detailed history and careful physical examination should be carried out on all infants with an antenatally detected renal malformation. An early (within 24 h of life) renal ultrasound is recommended for newborns with a history of oligohydramnios, progressive antenatal hydronephrosis, distended bladder on antenatal sonograms, and bilateral severe hydroureteronephrosis. In male infants, a distended bladder and bilateral hydroureteronephrosis may be secondary to posterior urethral valves, a condition which requires immediate renal imaging and clinical intervention. In general, unilateral anomalies do not require urgent investigation after birth. Renal ultrasound for unilateral hydronephrosis is not recommended within the first 72 h of life because urine output gradually increases over the first 24–48 h of life as renal plasma flow and glomerular filtration rate increase [161]. Thus, the degree of urinary tract dilatation can be underestimated during this period of transition.

A careful examination of the genitalia and the position of the anus are part of the initial assessment since CAKUT can occur in the context of cloacal malformations and with genital tract defects in females and males. The mesonephric duct gives rise to the developing kidneys, urinary tracts and the male genital tracts; therefore, a careful examination of the testes, the epididymis, and the ductus deferens is important. Congenital epididymal cysts are the most frequent anomaly noted in association with mesonephric duct anomalies and are usually asymptomatic. Other male genital duct anomalies that may occur in the context of CAKUT include an absent, ectopic or duplicated ductus deferens. Seminal vesicle cysts may also arise and typically present after puberty as pelvic pain or with urinary symptoms like dysuria, polyuria, or urinary retention [162]. Adjacent to the mesonephric ducts are the paired Müllerian or paramesonephric ducts that give rise to the fallopian tubes, the uterus, the cervix, and the upper two thirds of the vagina. Because Müllerian duct development is tightly linked to the growth and elongation of the mesonephric ducts, CAKUT is also observed with concurrent female Müllerian duct anomalies. Indeed, the Mayer-Rokitansky-Kuster-Hauser syndrome describes women with normal female external genitalia, but Müllerian duct anomalies that include aplasia of the uterus, the cervix, and the upper vagina. In a large cohort of 284 women with this syndrome, roughly 30% of them had associated CAKUT anomalies including renal agenesis, horseshoe kidney, ectopic kidney, and urinary tract defects including duplications [163]. Females with Müllerian ducts anomalies are typically discovered because of primary amenorrhea, dyspareunia, infertility, and/or obstetric complications [164]. In females with CAKUT and a suspected Müllerian duct anomaly, MRI imaging may be indicated to define the anatomical defect with better precision.

Clinical Approach to Specific Malformations

Unilateral Renal Agenesis

A diagnosis of unilateral renal agenesis depends on the certainty that a second kidney does not exist in the pelvis or some other ectopic location. Since absence of one kidney induces compensatory hypertrophy in the existing kidney, the presence of a large kidney on one side suggests the possibility of unilateral renal agenesis. Interestingly, compensatory hypertrophy has been observed to begin as early as 20 weeks of gestation: van Vuuren et al. examined 67 fetuses with a diagnosis of MCDK or unilateral renal agenesis and noted that 87% of the cases of MCDK and 100% of the cases of unilateral renal agenesis exhibited compensatory hypertrophy of the contralateral kidney with kidney length greater than the 95th percentile for gestational age [165]. Since unilateral agenesis is associated with contralateral urinary tract abnormalities

including UPJO and VUR in 20–40% of the cases [166, 167], imaging of the contralateral side is suggested. Management of affected patients involves determining the functional status of the contralateral kidney. If the contralateral kidney is normal, the long-term renal functional outcome is usually excellent, although a recent study suggests that some patients may in fact have a poor long-term outcome and require dialysis [25]. It is therefore reasonable to propose that individuals with a single functioning kidney should have their blood pressure measured, urine tested for protein, and renal function measured periodically throughout life. While some have suggested that children with single kidneys should avoid contact/collision sports, at least one study suggests that kidney injuries occur much less frequently than other organ injuries, and thus sports restriction may not be indicated solely on the basis of having a single kidney [168].

Renal Hypoplasia

Unless associated with other malformations, renal hypoplasia can be asymptomatic. Unilateral hypoplasia is often discovered as an incidental finding during an abdominal sonogram or other imaging study. In contrast, patients with bilateral renal hypoplasia are at risk for decreased renal function and CKD.

Renal Dysplasia

The dysplastic kidney is generally smaller than normal. However, cystic elements can contribute to large kidney size, the most extreme example being the MCDK (see below). During the antenatal period, unilateral disease is likely to be discovered as an incidental finding. This may also be the case for bilateral renal dysplasia unless it is associated with oligohydramnios. After birth, bilateral renal dysplasia may limit GFR, causing renal failure that is usually progressive. Postnatal ultrasonography of the dysplastic kidney is characterized by small size, increased echogenicity, loss of corticomedullary differentiation and cortical cysts. Renal dysplasia is strongly associated with dilatation of the upper and lower urinary tract from VUR, posterior urethral valves, and/or other urinary tract obstruction [169]. Accordingly, imaging of the lower urinary tract should be performed to determine whether these abnormalities are present.

Multicystic Dysplastic Kidney

The MCDK presents by ultrasonography as a large cystic non-reniform mass in the renal fossa and by palpation as a flank mass. The MCDK is nonfunctional, a condition that can be demonstrated by imaging with MAG3 or DTPA radionuclide scanning. The MCDK is usually unilateral. If bilateral, it is fatal. Complications of MCDK include hypertension (0.01–0.1%). Wilms tumour and renal cell carcinoma have also been described in MCDK, but the incidence of malignant complications is not significantly different from the general population [170]. In 25% of cases, the contralateral urinary tract is abnormal. Contralateral abnormalities can include rotational or positional anomalies, renal hypoplasia, VUR and UPJO [18]. Contralateral UPJO occurs in 5–10% of cases.

Gradual reduction in renal size and eventual resolution of the mass of the MCDK is common. At two years, an involution in size by ultrasound has been noted in up to 60% of the affected kidneys. Complete disappearance of the MCDK can occur in a minority of patients (3–4%) by the time of birth, and in 20–25% by two years. Increase in the size of MCDK can be seen in some cases. Several reports suggest that if the kidney length of the MCDK is less than 6.2 cm on the initial postnatal US, then complete resolution is likely to occur [171, 172]. The contralateral kidney usually shows compensatory hypertrophy by ultrasound evaluation. If the contralateral kidney does not show hypertrophy, it could be hypoplastic.

Management of patients with MCDK has shifted from routine nephrectomy in the past, to observation and medical therapy. Because of the risk of associated anomalies in the contralateral kidney, the possibility of VUR should be evaluated and blood pressure should be measured. For children with isolated MCDK and a contralateral kidney that is structurally normal with compensatory hypertrophy, the prognosis is excellent. While there exist no evidence-based guidelines

for long-term follow-up of these children, a review of published evidence and expert opinion supports serial investigation by ultrasound and urinalysis within the first two years of life to monitor MCDK involution and contralateral renal growth, and then very intermittent examination of renal growth, blood pressure and urine protein excretion through the end of puberty [173]. For the small number of patients with unilateral MCDK who develop hypertension, estimated to be 5.4 out of 1000 children [170], medical therapy is usually effective. Nephrectomy may be curative in resistant cases.

Renal Ectopia

Normally, the kidneys lie on either side of the spine in the lumbar region and are located in the retroperitoneal renal fossae. Rapid caudal growth during embryogenesis results in migration of the developing kidney from the pelvis to the retroperitoneal renal fossa. With ascension, comes a 90° rotation from a horizontal to a vertical position with the renal hilum finally directed medially. Migration and rotation are complete by 8 weeks of gestation.

Simple congenital ectopy refers to a low-lying kidney that failed to ascend normally. It most commonly lies over the pelvic brim or in the pelvis and is termed a pelvic kidney. Less commonly, the kidney may lie on the contralateral side of the body, a state that is termed crossed ectopy without fusion. Clinical presentation can be asymptomatic or symptomatic. Asymptomatic presentation is when the ectopic kidney has been diagnosed coincidentally such as might occur during routine antenatal sonography. Symptomatic presentation occurs with urinary tract infections. Symptoms such as abdominal pain or fever may occur. On examination, an abdominal mass may be palpable. Other presenting features include hematuria, incontinence, renal insufficiency and hypertension [21]. A high incidence of urological abnormalities has been associated with renal ectopia. VUR is the most common, occurring in 20% of crossed renal ectopia and 30% of simple renal ectopia. In bilateral simple renal ectopia, there is a higher incidence of VUR, occurring in 70% of cases. Other associated urological abnormalities include contralateral renal dysplasia (4%), cryptorchidism (5%) and hypospadias (5%) [21]. Reduced renal function is commonly observed by radionuclide scan in the ectopic kidney. Female genital anomalies such as agenesis of the uterus and vagina [174] or unicornuate uterus [175] have also been associated with ectopic kidneys. Other anomalies described include adrenal, cardiac and skeletal anomalies. Clinical assessment should therefore include a careful physical examination for other anomalies. Renal ultrasonography will help with diagnosis and defining the underlying anatomy. A VCUG should be undertaken, particularly if there is hydronephrosis, given the risk of VUR and obstruction. A DMSA scan is also recommended to assess for differential renal function.

Renal Fusion

Renal fusion is defined as the fusion of two kidneys. The most common fusion anomaly is the horseshoe kidney, in which fusion occurs at one pole of each kidney, usually the lower pole. The fused kidney may lie in the midline (symmetric horseshoe kidney) or the fused part may lie lateral to the midline (asymmetric horseshoe kidney). In a crossed fused ectopic kidney, the kidney from one side has crossed the midline to fuse with the kidney on the other side. Fusion is thought to occur before the kidneys ascend from the pelvis to their normal dorsolumbar position. This is usually between the fourth to ninth week of gestation. As a result, fusion anomalies seldom assume the high position of normal kidneys. The blood supply may therefore come from vessels such as the iliac arteries. Abnormal rotation is also associated with early fusion of the developing kidneys. The pelvis of each kidney lies anteriorly and the ureter, therefore, traverses over the isthmus of a horseshoe kidney or the anterior surface of the fused kidney. Ureteric compression may occur due to external compression by a traversing aberrant artery. The majority of patients are asymptomatic. Some, however, develop obstruction which presents with loin pain, hematuria and may be associated with urinary tract infections due to urinary stasis or VUR. Renal calculi may occur in up to 20% of cases [176].

Other associated urological anomalies include ureteral duplication, ectopic ureter and retrocaval ureter. Genital anomalies such as bicornuate and/or septate uterus, hypospadias, and undescended testis have also been described. Associated non-renal anomalies involve the gastrointestinal tract (anorectal malformations such as imperforate anus, malrotation, and Meckel diverticulum) the central nervous system (neural tube defects), and the skeleton (rib defects, clubfoot, or congenital hip dislocation). Investigations should include static imaging (renal ultrasound) and functional imaging (DMSA scan) and a VCUG.

Cilia in the Historic Context

Cilia are evolutionarily well conserved, hair-like structures projecting from the surface of most cells in vertebrates and are broadly divided into motile and non-motile cilia. While non-motile cilia can be found as single organelles on most cells in mammals, the occurrence of motile cilia in bundles of multiple (hundreds) is restricted to certain tissues in vertebrates such as the respiratory tract, the reproductive system (epididymidis and oviduct), the ependyma lining the brain ventricles and the embryonic node where they are involved in fluid movement and mucociliary clearance. Also, the flagellum of mammalian sperm has a very similar structure to motile cilia. In vertebrate photoreceptor cells within the retina, a modified ciliary structure called "connecting cilium" links inner and outer segment of those cells. See Figs. 9.1a–c and 9.2a–k for examples of cilia visualisation.

Although the existence of cilia has been described as early as the 1800s by Purkinje and Valentin [3, 4], their significance for mammalian development, organ maintenance and clinical disease has only been fully appreciated in the last two decades. Cilia were regarded as functionless cellular extensions for many years as no link between this organelle and human disease was made despite the fact that dextrocardia had already been visualised by Leonardo da Vinci in the fifteenth century and in 1793, the Scottish pathologist Matthew Baillie mentioned situs inversus in his book *The Morbid Anatomy of Some of the Most Important Parts of the Human Body*. As published by Afzelius in 1979 [5], we realise today that situs abnormalities result from (mainly motile) ciliary dysfunction in the embryonic node. The function of non-motile, so called primary cilia remained elusive for even longer; however, when "rediscovered," their role in (cystic) kidney disease was one of the initial ciliary functions acknowledged [6, 7], Since then, a large number of (inherited) human diseases have been identified to result from ciliary malfunction [8–10]. See Table 9.1 for a summary of ciliary diseases with renal involvement and their underlying genetic cause.

Table 9.1 Summary of ciliary diseases with renal involvement and their underlying genetic causes

Disease	Renal phenotype	Retinopathy	Skeletal phenotype	Obesity	Developmental delay	Situs inversus	Other	Gene
Autosomal-dominant polycystic kidney disease (ADPKD)	Always; polycystic	–	–	–	–	–	Increased risk for cerebral blood vessel aneurysma, liver involvement possible	PKD1 PKD2
Autosomal-recessive polycystic kidney disease (ARPKD)	Always; polycystic	–	–	–	–	–	Frequent liver disease, possible pancreatic cysts	Fibrocystin (PKHD1)
Medullary cystic kidney disease (MCKD1/2)	Always; cysts at the cortico-medullary junction		–	–	–	–	Extensive salt wasting	MUC1, uromodulin
Nephronophthisis (NPHP)	Always; NPHP	–	No	–	–	Rarely, especially *NPHP2*/*INVS* mutation carriers		NPHP1, NPHP2 (Inversin), NPHP3, NPHP4, NPHP5 (IQCB-1) NPHP6 (CEP290), NPHP7 (GLIS2), NPHP8 (RPGRIP1L), NPHP9 (NEK8), NPHP10 (SDCCAG8), NPHP11 (TMEM67, Meckelin), NPHP12 (TTC21B), NPHP13 (WDR19), NPHP14 (ZNF423), NPHP15 (CEP164), NPHP16 (ANKS6)
Joubert syndrome (JS) and JS related disorders, including senior-Loken syndrome, Cogan syndrome	Often; mainly NPHP-like, rarely cystic	Frequent in JSRD	Sometimes polydactyly	–	Very often	Rarely	Pathognomic "molar tooth sign" on brain MRI images; ataxia, ocular motor apraxia, hypoventilation	TMEM216, AHI1, NPHP1, CEP290, TMEM67, RPGRIP1L, ARL13B CC2D2A, CXORF5, TTC21B, KIF7 TCTN1, TMEM237, CEP41, TMEM138, C5ORF42, TCTN3, ZNF423, TMEM231, CSPP1, PDE6D

(continued)

Table 9.1 (continued)

Disease	Renal phenotype	Retinopathy	Skeletal phenotype	Obesity	Developmental delay	Situs inversus	Other	Gene
BBS	~30%, mainly NPHP-like, rarely cystic	+	Often polydactyly	Always	Very often	Rarely	Hypogonoadism	BBS1, BBS2, BBS3 (ARL6), BBS4, BBS5, BBS6 (MKKS), BBS7, BBS8 (TTC8), BBS9, BBS10, BBS11 (TRIM32), BBS13 (MKS1), BBS14 (CEP290), BBS15 (C2ORF86), BBS17 (LZTFL1), BBS18 (BBIP1), BBS19 (IFT27)
Alstrom syndrome	Often	+	–	Always	–	–	Frequent cardiomyopathy, sensorineural hearing loss, hepatic disease	Alms1
Meckel-Gruber syndrome	Often; NPHP like or cystic	na	Often orofacial clefting		na (early lethality)	Sometimes	Occipital encephalocele	MKS1, MKS2 (TMEM216), MKS3 (TMEM67), MKS4 (CEP290), MKS5 (RPGRIP1L), MKS6 (CC2D2A), MKS7 (NPHP3), MKS8 (TCTN2), MKS9 (B9D1), MKS10 (B9D2), MKS11 (TMEM231)
Orofacial digital syndrome (OFD)	Renal malformations	Usually not	Often polysyndactyly, orofacial clefting	–		Rarely	Lobulated tongue, heart defects, agenesis of the corpus callosum, conductive hearing loss, cerebellar atrophy described	OFD1 (CXORF5), TCTN3, C5orf42, DDX59

Short rib-polydactyly syndrome (SRPS)	Often; NPHP-like or cystic	Usually not evident	Often polydactyly, short ribs, shortened long bones, brachydactyly, abnormal pelvis configuration, sometimes orofacial clefting	–	na (early lethality)	Rarely	Always lethal perinatally due to cardiorespiratory insufficiency	DYNC2H1, NEK1, WDR60, WDR34, WDR35
Jeune asphyxiating thoracic dystrophy (JATD)	<30%, mainly NPHP-like, rarely cystic	Rarely	Short ribs, short long bones, rarely polydactyly, abnormal pelvis configuration, scoliosis, cone shaped epiphyses	Single cases	–	–	Sometimes retinal degeneration, mainly in cases with renal disease;	DYNC2H1, WDR34, WDR60, IFT80, IFT172, IFT140, WDR19 (IFT144), TTC21B (IFT139), CSPP1
Mainzer-Saldino-syndrome (MSS)	Always; mainly NPHP-like, rarely cystic	Always	(Mildly) shortened ribs, cone shaped epiphyses	–	Single cases	Not described	Always retinal degeneration	IFT140, IFT172
Sensenbrenner syndrome (CED)	Very often; mainly NPHP-like	Often	(Mildly) shortened ribs, brachydactyly, craniosynostosis	–	Sometimes	Usually not	Thin and sparse growing hair, nail dysplasia (ectodermal defects), heart defects	IFT122, WDR19 (IFT144) IFT43, WDR35

Ciliary Ultrastructure

The ciliary research field originates from the protozoan flagellar research undertaken since the 1950s and was therefore initially more focussed on motile cilia, possibly also because those were easier to detect due to their moving features. Electron microscopy is an essential imaging technique for visualisation these cilia also lack the central pair (9 + 0 structure). In motile cilia, so-called inner and outer dynein arms extend from the outer microtubule pairs and those outer pairs are connected to the central pair via radial spokes. This complex construction enables sliding of the microtubules generating ciliary movement. Dynein arms and radial spokes are absent from non-motile primary ciliary.

This ciliary *axoneme* is anchored to and extends from the *basal body* which itself lies within the cytosol and is derived from the mother centriole after cell division. Along its vertical axis, the primary cilium can be structurally divided into different sub-compartments: *the ciliary tip*, *the ciliary body*, *the ciliary necklace* [11], *the transition zone* [12], *the so-called inversin compartment* [13] *and the basal body* [14, 15]. The specialise cellular plasma membrane at the ciliary insertion site is referred to as the *ciliary pocket* (Fig. 9.3 for a schematic of ciliary structures). As cilia lack organelles such as endoplasmatic reticulum and Golgi and therefore no protein synthesis occurs within the cilium, all ciliary proteins are produced within the cellular cytosol, and transported to the cilium. Within the

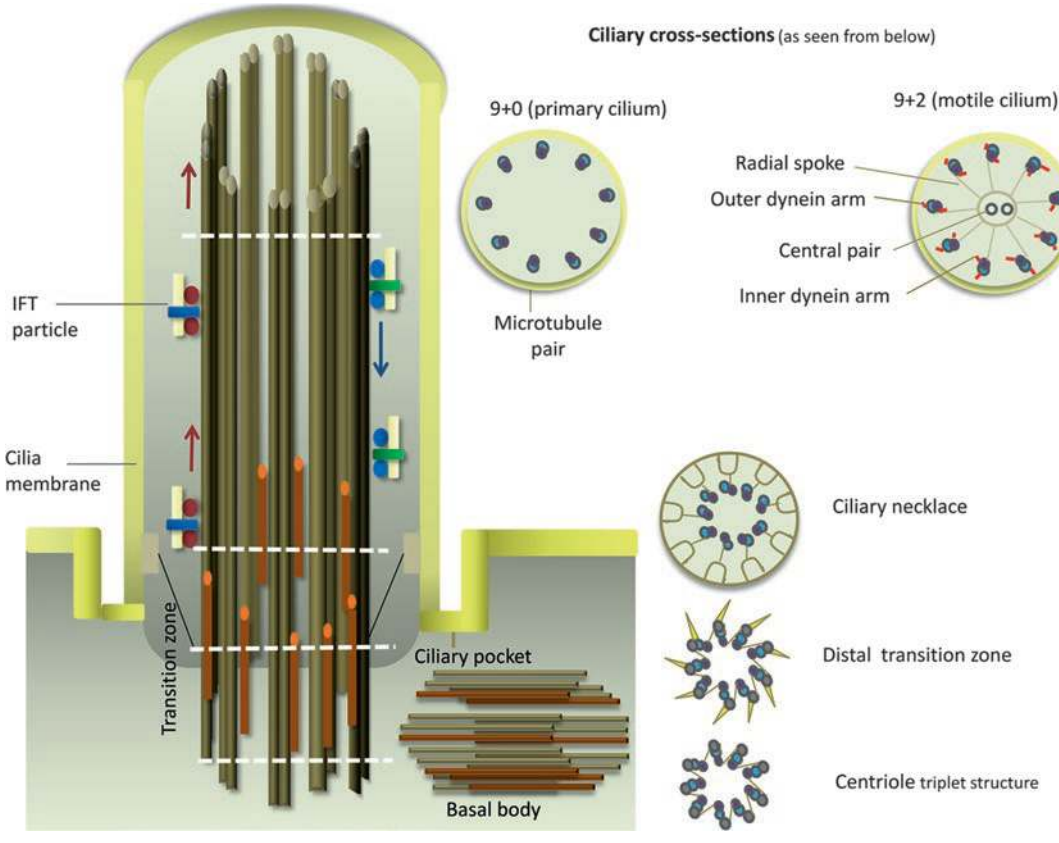

Fig. 9.3 Simplified schematic of the ciliary ultrastructure

cilium, so called **I**ntra **f**lagellar **T**ransport (**IFT**) enables protein trafficking from the ciliary base to the tip and vice versa (Fig. 9.3 for a schematic of ciliary ultrastructure and Fig. 9.4 for a schematic of IFT). Figure 9.5a–c shows a schematic of ciliary protein complex localisation and IFT defects are visualised in Fig. 9.6a, b.

Although cilia extend from the cell body and are surrounded by specialised plasma membrane forming the " *ciliary membrane*," cilia represent a distinct cellular compartment with the so called " *transition zone*" which acting as a barrier between the cilium and the rest of the cell [22, 23]. At the transition zone, the microtubule trip-

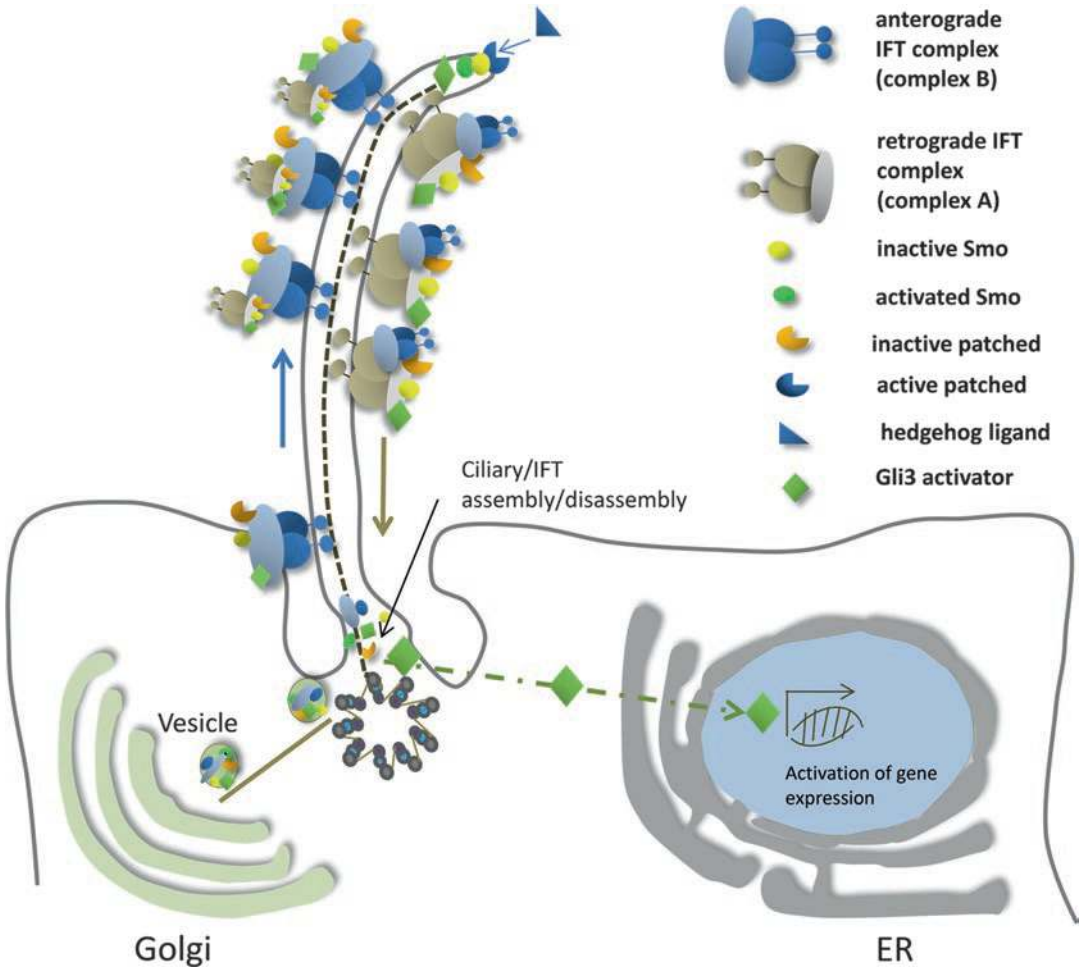

Fig. 9.4 Simplified schematic of Intraflagellar Transport (IFT) and it's relation to hedgehog signalling. Hedgehog signalling pathway components such as smoothened (smo) and patched localise to the cilium and require anterograde IFT to localise to the ciliary tip where binding of the hedgehog ligand (*blue triangle*) activates the smoothened inhibitor patched (*orange*) which in turn releases smoothened (*yellow*). Activated smoothened (*green ball*) releases GLI3 activator from its inhibitor SUFU (not shown). Gli3 activator (*green rectangle*) requires retrograde IFT to translocate to the nucleus where it activates genes involved in chondrogenic and osteogenic differentiation [16–19]

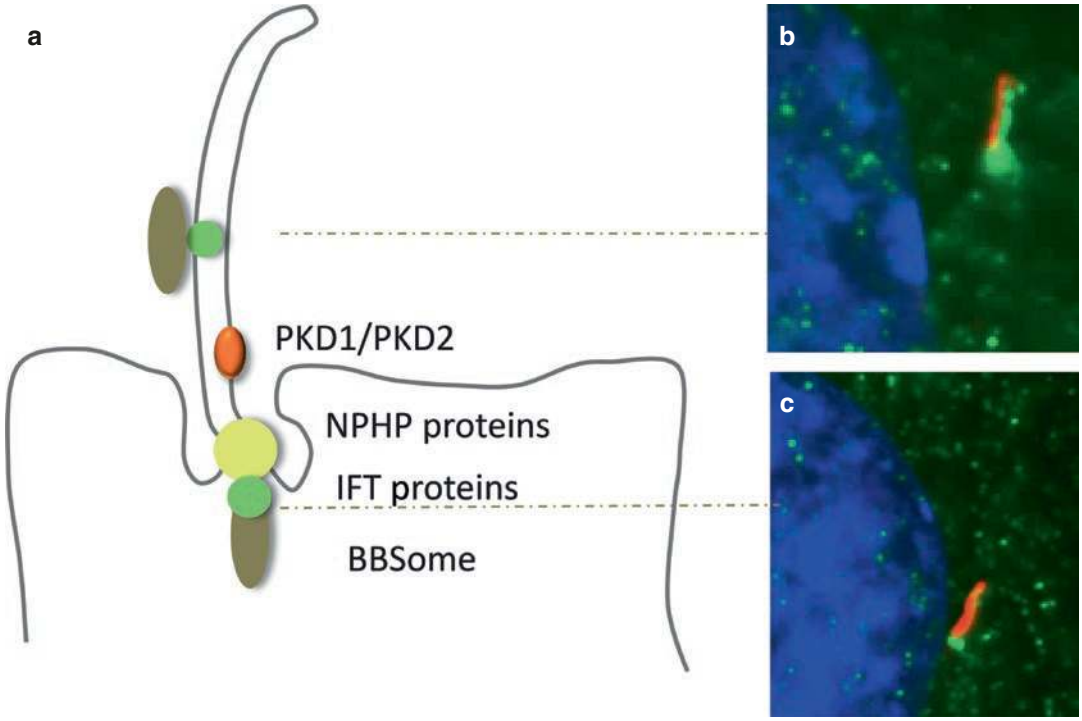

Fig. 9.5 (**a**–**c**) Localisation of major ciliary protein complexes. (**a**) Schematic of protein-complex localisation: While Bardet-Biedl-Syndrome (BBS) proteins and intraflagellar transport (IFT) proteins are detected both at the ciliary base and along the ciliary axoneme, many proteins encoded by genes mutated in nephronophthisis localise to the ciliary transition zone. (**b**) Immunofluorescence image of axonemal IFT140 localisation (*green*). (**c**) Immunofluorescence image of IFT140 localisation at the base of the cilium (*green*). The ciliary axoneme is marked in *red* using anti-acetylated tubulin antibody. ((**b**, **c**) Used with permission of John Wiley and Sons from Schmidts et al. [20])

lets of the basal body transform into the axonemal microtubule doublets. As the protein and lipid composition of the ciliary axoneme and ciliary membrane is distinct from the cell body, selective recruitment of components and transport of those components into the cilium is required. How this is precisely undertaken is still unclear, but some progress in understanding has been made in recent years. Interestingly, the connecting cilium of retinal photoreceptors is very similar in its structure to the ciliary transition zone and many proteins encoded by genes found to carry mutations leading to nephronophthisis (often with retinal degeneration) localise to the ciliary transition zone as well as the photoreceptor connecting cilium. This implicates a function of these proteins in "gate keeping" (between cytosol and ciliary axoneme as well as between inner and outer photoreceptor segment) [12, 23]. Two highly specialised areas occur within the ciliary membrane: the *ciliary necklace*, initially described by Gilula and Satir [11] where the microtubules of the basal body are connected to the plasma membrane and the base of a plasma membrane invagination around the proximal ciliary axoneme, the ciliary pocket [24]. The "*inversin compartment*" is found in the proximal ciliary region the ciliary necklace, the transitional zone and the basal body [13]. Mutations in *INVS* encoding Inversin cause nephronophthisis type 2. Please also refer to the nephronophthisis chapter of this book (Chap. 13) for details.

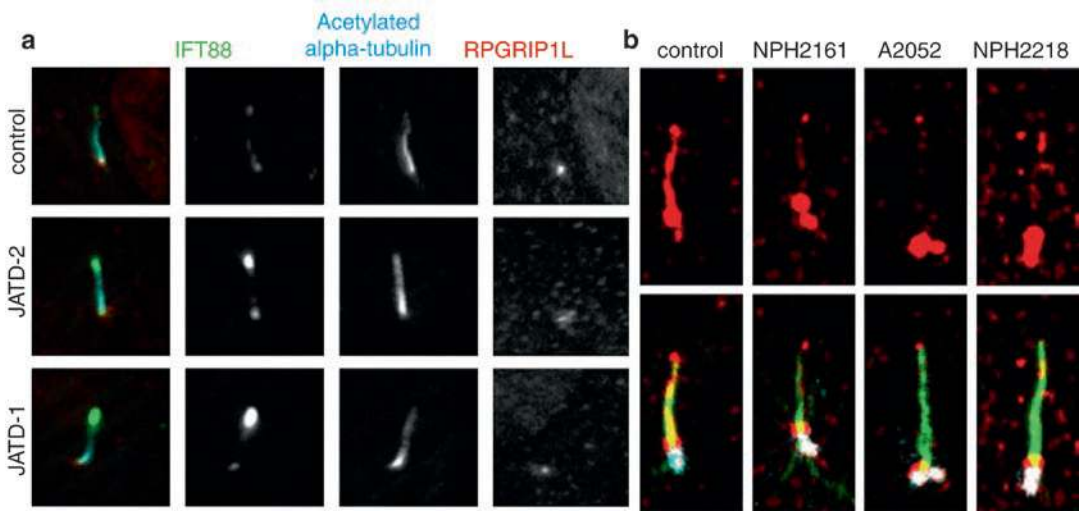

Fig. 9.6 (**a**, **b**) Visualisation of disturbed intraflagellar transport by immunofluorescence. (**a**) Compared with controls, IFT88 accumulates in distal ends of cilia in fibroblasts from Jeune Syndrome patients (JATD-1 and -2) carrying mutations in the dynein-2 complex protein dync2h1 leading to impaired retrograde intraflagellar transport (IFT). Cells were stained with anti-IFT88 (*green*); anti-acetylated α tubulin (marker for the ciliary axoneme, *cyan*); and anti-RPGRIP1L (marker for the ciliary base, *red*) (reprinted with permission from [21]). (**b**) Fibroblasts of patients with biallelic mutations in the anterograde IFT component IFT172 show decreased axonemal and increased basal body staining of IFT140 (*red*) compared to controls. The ciliary axoneme is marked with anti-acetylated-tubulin antibody (*green*), basal bodies are marked in *blue* using anti-g-tubulin antibody. (Reprinted with permission from Exome sequencing identifies DYNC2H1 mutations as a common cause of asphyxiating thoracic dystrophy (Jeune syndrome) without major polydactyly, renal or retinal involvement. (**a**) Used with permission of BMJ Publishing Group from Schmidts et al. [21]; (**b**) Halbritter et al. [1])

Ciliary Assembly

As described above, proteins necessary to build a cilium cannot be synthesized within the cilium but have to be transported to the building site. How exactly ciliary components get to the cilium and the precise process of the transformation of the mother centriole (the older of the two centrioles) into a basal body from where the cilium is assembled has not been understood in all its depth to date. Ciliogenesis is tightly linked to the cell cycle: dividing cells do not exhibit a cilium, cilia are only observed during the G1 cell cycle phase or when cells are quiescent. At least some ciliary proteins seem to reach the ciliary building site by vesicular transport: ciliary vesicles (post-Golgi vesicles) traffic close to the ciliary building site and merge there with the plasma membrane [25]. In this process of sorting membrane proteins to cilia, Bardet-Biedl syndrome proteins have been shown to be essential in assembling a coat that traffics membrane proteins to the cilium [26, 27]. Ciliogenesis is thought to start with the basal body docking to ciliary vesicles which then fuse with the plasma membrane, probably at the site of the ciliary pocket [28–32]. One of the proteins promoting this process has been identified as CEP164 and mutations in the *CEP164* gene cause nephronophthisis in humans [33, 34]. The fact that primary cilia and flagella only ever extend from the mother centriole could be due to the lack of subdistal appendages at the daughter centriole which seem to play a crucial role in anchoring the basal body to the plasma membrane [35]. Cilia stability seems to also depend on posttranslational modification of tubulin, including acetylation [36, 37], glutamylation [38, 39] and farnesylation. The latter seems of particular importance as Thomas et al. identified a homozygous *PDE6D* mutation Joubert syndrome which impaired the targeting of another known joubert protein, INPP5E to the cilium [40].

Cilia and Cell Cycle

As indicated above, ciliogenesis is interlinked with the cell cycle: dividing cells do not normally exhibit cilia, those only become visible after the cell's exit from cell cycle. When cells divide, one centrosome stays within the mother cell while the other can be found in the daughter cell. After cell division, the centrioles duplicate and the original centrioles from which duplication occurs are referred to as "mother centrioles." Once a cell has left cell cycle again, the cilium is built from this mother centriole [41]. When cells re-enter the cell cycle, cilia need to be disassembled which seems to be initiated by Percentrin-1 (PCM1) mediated recruitment of Polo-like kinase 1 (Plk1) to the pericentriolar material [42, 43]. While it has been accepted for many decades that ciliogenesis is linked to mitotic exit of the cell, the possibility that cilia themselves might influence cell cycle progression has only been recently taken into account. For example, the IFT protein Ift88 seems required for spindle orientation during mitosis [44]. Lack of Ift88 in mice leads to a polycystic kidney phenotype [7] and as for cystic renal phenotypes in humans, it remains controversial to which extent and at what time point cellular hyperproliferation contributes to the initiation and/or progression of disease [45]. The INPP5E protein (genetic mutations can cause a Joubert phenotype with renal disease) and the tumor suppressor protein VHL (mutations in the VHL gene cause Von-Hippel-Lindau syndrome which is associated with cystic renal disease) are both involved in stabilising cilia by inhibiting AURKA triggered ciliary disassembly for cell-cycle re-entry [46–48]. The question how cilia influence cell cycle, how they are influenced by cell cycle and how this contributes to ciliopathy, especially polycystic phenotypes, is difficult to resolve as proteins encoded by genes mutated in ciliopathy subjects often have multiple extra-ciliary functions which might influence cell-cycle progression independently of the cilium. For example, several genes mutated in subjects with nephronophthisis such as *ZNF423*, *CEP164* and *NEK8* have been linked to DNA damage repair and therefore directly to cell cycle progression [34, 49]. It is, however, of note that, except for VHL, no increased rate of malignancies has been demonstrated for humans affected by ciliopathies to date.

Intraflagellar Transport (IFT)

Transport of ciliary proteins along the axoneme is undertaken via IFT, an energy dependent process. Kosminski et al. were the first to notice this process in 1993 [50]. IFT is a highly conserved transport mechanism along cilia and flagellae from the green algae *Chlamydomonas* to vertebrates and mammals including humans. Building a cilium from the base to the tip is largely dependent on anterograde IFT [51]. Counter-intuitively, the anterograde IFT complex transporting proteins from the ciliary base to the tip is named "complex B" while the complex enabling retrograde transport from the ciliary tip back to the base is called "complex A." Motor for the anterograde complex is kinesin-2 while the cytoplasmic dynein-2 complex enables transport from the ciliary tip back to the base. Although named "cytoplasmic dynein," the latter complex localises to the ciliary axoneme and should not be confused with the cytoplasmic dynein-1 complex which enables transport along microtubules within the cell body and along neuronal axons. The precise composition of the dynein-2 complex has still not been completely elucidated; however, it is assumed that it resembles dynein-1 complex, a homodimer consisting of two heavy chains, two light-intermediate chains, two intermediate chains and two light chains. IFT-complex A and B are multiprotein assemblies functioning as an adaptor system between the motor complexes and cargo. As IFT-A complex proteins and the dynein-2 complex have to be brought up to the ciliary tip before they can fulfill their function in retrograde transport back from the tip to the base and vice versa, kinesin-2 and IFT complex B must be transported back to the base after they have reached the ciliary tip, it is evident that both complexes must be transported as cargo by each other [25, 52, 53]. Knockout mice for the kinesin-2 component *Kif3a*, the dynein-2 motor heavy

chain *Dync2h1* or IFT components often exhibit fewer or shorter cilia and are lethal around midgestation, indicating the fundamental role of these highly conserved proteins during development [43]. Kidney specific gene disruption or hypomorphic mutations often cause renal cysts in mice [7, 54, 55]. Human mutations in genes encoding dynein-2 complex components and IFT particles mainly cause ciliary chondrodysplasias with variable extraskeletal involvement [1, 20, 21, 56–69] and mutations in the IFT-A component *TTC21B/IFT139* and in the IFT-B component *IFT27* were recently identified in Bardet-Biedl-Syndrome [68, 70]. For more details also see the human disease section below and Fig. 9.4 for a schematic of IFT and its relation to hedgehog signalling.

Ciliary Signalling Pathways

Single non-motile (primary) cilia are considered sensory organelles involved in multiple signalling pathways transducing both signals from the cellular surroundings to the cells as well as modifying cell signalling pathways within the cell [71, 72]. As mentioned above, cilia and ciliary proteins have been highly conserved throughout evolution and mutations in genes encoding ciliary components often result in complex developmental defects in vertebrates. This can be attributed to disturbances of fundamental signalling pathways essential for embryogenesis, organogenesis and proper tissue maintenance.

Hedgehog Signalling

The best explored cilia-regulated cellular pathway is hedgehog signalling [16, 17, 73]. Hedgehog signalling crucially influences chondrogenic (and subsequently osteogenic) proliferation and differentiation [74]. Mouse models of ciliary chondrodysplasias, e.g., knockout mice for *Evc* (mutations in the EVC1 and EVC2 gene cause Ellis-van Creveld-Syndrome in humans), *Dync2h1* and *Ift80* (associated with Jeune Syndrome and Short-Rib-Polydactyly Syndrome type III in humans) indicate that IFT defects lead to imbalances in the hedgehog signalling pathway [18, 75, 76]. Lack of hedgehog signal transduction leads to decreased chondrogenic proliferation and imbalanced chondrogenic differentiation at the growth plates which impairs bone growth. As a result' mice, as well as human subjects with mutations in these genes as well as in *IFT144/WDR19*, exhibit shortened ribs and long bones. Lack of Ift80 or Ift144 also induces polydactyly in mice, a hallmark of dysregulated hedgehog signalling [18, 75–77].

The hedgehog signaling pathway operates via ciliary trafficking: the pathway components smoothened (smo) and patched move via anterograde IFT to the ciliary tip, where smo becomes activated and releases GLI3 activator. The latter is subsequently transported back to the base of the cilium via retrograde IFT and enters the cell body and nucleus where it activates genes regulating chondrogenic and osteogenic differentiation and proliferation (simplified schematic in Fig. 9.4).

Apart from altered bone growth, impaired hedgehog signalling leads to complex developmental defects in mammals including polydactyly, heart defects, midline defects such as clefting and holoprosencephaly. Renal abnormalities, especially ectopic kidneys but also cystic-dysplastic changes, can also be observed in mice [78] and human subjects affected by Smith-Lemli-Opitz syndrome, a condition thought to result from altered hedgehog signalling due to a cholesterol biosynthesis defect [79]. However, neither human subjects with *IFT80*- nor *EVC1/EVC2* mutation nor the corresponding mouse models exhibit a renal phenotype. On the other hand, human subjects with mutations in other IFT genes such as *WDR19/IFT144*, *TTC21B/IFT139*, *IFT140*, *IFT43*, *WDR35* or *IFT172* genes are affected by childhood-onset cystic or nehronopthisis-like renal disease [1, 20, 64, 65, 67–69], and in knockout mouse models for *IFT140* or *IFT172*, early onset cystic (dysplastic) kidney disease is observed [55, 80]. While it seems likely that the skeletal phenotype observed in those subjects is due to imbalances in the hedgehog pathway secondary to IFT defects,

this does not necessarily apply to the renal phenotype as no changes in the hedgehog pathway were noted in kidneys from *Ift140* knockout mice prior to the onset of cystogenesis [55].

Wnt Signalling and Planar Cell Polarity (PCP)

The role of cilia and ciliary proteins in regulating wnt signalling is subject of an ongoing discussion recently reviewed by Wallingford and Mitchell [81]. Wnt signalling can be roughly divided into a so-called "canonical" pathway branch involving wnt/beta-catenin and a so called "non-canonical" or planar cell polarity (PCP) branch. Canonical Wnt/beta-catenin dependent signalling occurs after extracellular wnt ligand binds to transmembrane Frizzled receptors which stabilize beta-catenin. Beta-catenin subsequently localises to the nucleus to activate further target genes [82]. The non-canonical or PCP pathway is mediated via Frizzled and the large transmembrane proteins Vangl2 and Celsr and involves cytoplasmic regulatory proteins such as Dishevelled (Dvl). PCP describes the process of orientation of cells and their structures along an axis in an epithelial plane in a coordinated manner [83]. Classical PCP readouts exist for all species from *drosophila* flies over *xenopus* frogs to mammals, including orientation of hair on the fly wing, convergent extension (axis elongation by cell intercalation) of the anterior-posterior body axis of frog embryos and orientation of hair cells in the inner ear of mice.

The first indication that proteins encoded by genes defective in human ciliopathies play a role in PCP came from Bardet-Biedl-Syndrome mouse models displaying typical PCP-related defects in the cochlea [84]. Further initial experiments suggested that the ciliary protein encoded by *NPHP2*, *Inversin* (*Invs*), inhibits Dvl-mediated transduction of the canonical wnt pathway while promoting a shift towards PCP signalling [85], proposing that Inversin might act as a switch between canonical and non-canonical/PCP Wnt signalling [85]. This would imply that in an inversin-deficient state such as in nephronophthisis patients with Inversin mutations, non-canonical wnt signalling might be expanded and PCP signalling reduced. In line with the assumption that cilia might act as a negative regulator of canonical wnt signalling, increased canonical wnt signalling was found in cells deficient for Bardet-Biedl-Syndrome proteins BBS1, BBS4 and MKKS and the anterograde IFT motor protein KIF3A [86], in mice mutant for *Kif3a*, *Ift88* and *Ofd1* [87] as well as in kidney-specific *Ift20* knockout mice exhibiting a cystic renal phenotype [88]. However, no abnormalities in wnt signalling were found by Ocbina et al. in the absence of cilia in mice mutant for *Kif3a*, *Ift88*, *Ift72* [89] and in *ift88* zebrafish mutants [90]. The relationship between cilia and wnt signalling therefore remains unclear.

Loss of ciliary proteins such as Ift88 and *Kif3a* in mice results in developmental defects resembling those expected for loss of PCP including mis-orientated inner ear kinocilia [91]. Also, renal tubules elongate during development using a process strongly resembling convergent extension, depending on the non-canoncial wnt ligand *Wnt9b*, where loss of Wnt9b leads to renal cyst formation [92]. Furthermore, *Ift20* disruption in mice causes cystic renal disease and in those kidneys, mitotic spindle mis-orientation has been described [88]. As mis-orientated mitotic spindles could affect **o**rientated **c**ell **d**ivision (OCD), and OCD is the basis for planar cell polarity and necessary for postnatal tubule elongation, loss of OCD might contribute to cystic phenotypes [93]. This is supported by observations in Kif3a, Pkd1, Tsc1/2 and Hnf1b-deficient mice [94–96]. Last, the wnt-regulator Dvl might also control apical docking and planar polarisation of basal bodies from which cilia extend in epithelial cells [97]. Ciliary polarity, which in turn could potentially define cellular polarity, is influenced by the anaphase promoting complex APC/C [98]. These findings, together with the suggestion that the nephronophthisis protein Inversin might act as a switch from canonical wnt towards PCP signalling [85], has led to the hypothesis that cystic and NPHP-phenotypes observed in ciliopathies might result from disturbed PCP. However, loss of OCD and/or PCP might not be the cyst-initiating event

as mice mutant for the murine homologue of PKHD1, the Fibrocystin gene causing ARPKD in humans, do not develop cysts despite disrupted OCD [99]. Moreover, cysts can be present despite normal OCD as shown in mice lacking IFT140 in the kidneys [55]. Recent work in the Xenopus model suggests nevertheless that tubular morphogenesis requires planar cell polarity (PCP) and non-canonical Wnt signalling [100].

Flow Hypothesis, Ca-Signalling/ Mechanosensation and mTOR

In 2001, Praetorius and Spring observed increased intracellular calcium levels after flow induced bending of primary cilia on canine kidney cells [101] and subsequently demonstrated that loss of cilia abolishes the flow-induced calcium influx [102]. This was subsequently confirmed in mice with ciliary defects due to *Ift88* deficiency [103]. The *Polycystin-1* and *Polycystin-2* (*PKD1* and *PKD2*) genes, mutated in subjects with ADPKD, are thought to play a role in this mechanosensation and calcium influx process [104, 105]. However, loss of mechanosensation and/or flow induced calcium influx alone is probably not sufficient to cause cystic kidney disease and Polycystin-1, although required for maintenance of tubular morphology in the long run, does not appear essential in the short or intermediate term. Possibly a second exogenous harmful event such as kidney injury is required for cyst formation in the long term [93]. How lack of flow and subsequently reduced calcium influx might lead to cystogenesis has not been clearly established. Delayed or reduced clearance of intracellular cAMP may be involved as accumulation of cAMP was noticed in cystic renal tissue [106]. This in turn might lead to increased MAP kinase signalling stimulating both cell proliferation and fluid secretion into the cyst lumen. Interestingly, fluid flow also induces phosphorylation of a key regulator of cardiac hypertrophy, histone deacetylase 5 (HDAC5) via polycystin-mediated mechanosensation. This leads to myocyte enhancer factor 2C (MEF2C)-dependent transcriptional events in the nucleus and kidney-specific knockout of *Mef2c* results in extensive renal tubule dilatation and cysts whereas *Hdac5* heterozygosity or treatment with an HDAC inhibitor reduces cyst formation in *Pkd2−/−* mouse embryos, indicating a potential treatment target [107].

Based on the observations that human subjects with tuberous sclerosis due to *TSC2* mutations develop cystic renal disease, TSC2 (Tuberin) is considered a negative regulator of mTor signalling [108], Polycystin-1 interacts with Tuberin and mTor activity is elevated in cystic tissues [109, 110], a hypothesis evolved that mTor signalling might be involved in the initiation and/or progression of cystic renal disease and that inhibition of such signalling could delay disease progression. However, while in a rodent model the mTORC1 inhibitor Rapamycin significantly delayed cyst progression [111], a clinical trial using everolimus in human PKD subjects ended with disappointing results: despite slowing down cyst expansion, renal function was not better preserved in everolimus treated subjects compared to controls. Possibly the administered dose was insufficient or more likely, the timepoint of treatment initiation was chosen too late with regards to the disease course to achieve stabilisation of renal function [112]. Nevertheless, mTor signalling seems to play a role in progression of cystic kidney disease and is potentially connected to flow-induced cilia bending: when cells are grown in a flow chamber, flow leads to Lkb1 induced mTor inhibition resulting in smaller cell size [113]. Flow might further regulate cilia length, potentially also through mTor signalling as cilia length is reduced under flow and increased within cysts where flow is absent [95]. Likewise, mTor inhibitors seem to decrease cilia length reflecting the effects of flow [93, 114].

Yap-Hippo Signalling

The hippo-signalling pathway has emerged in recent years as an important pathway controlling cell and organ growth, stem cell function, regeneration functions and tumor suppression. Dysregulation of hippo signalling was initially

noticed to lead to initiation and maintenance of cancerous growth [115]. More recently evidence for this pathway has emerged indicating its fundamental role for developmental processes, including kidney and eye development in mammals. Knockout mice for one of the main pathway components, *Yes-associated protein-1* (*Yap1*), die during early gestation with major developmental defects including yolk sack and axis elongation defects [116] while heterozygous *YAP1* loss of function mutations lead to optic fissure closure defects and possibly also cleft-lip palate, hearing loss, learning difficulties and hematuria with incomplete penetrance in humans [117]. More importantly, inactivation of another major pathway molecule, TAZ, in mice leads to polycystic kidneys (glomerulocystic disease), severe urinary concentrating defects and pulmonary emphysema [118, 119]. The renal phenotype partially resembles that of nephronophthisis patients. Further, NPHP3, NPHP4 and NPHP9/NEK8, products of genes mutated in subjects with nephronophthisis and Meckel-Gruber Syndrome, seem to be involved in Hippo-pathway regulation [120–122]. It is of note, however, that YAP1 is not only directly implicated in the hippo signalling pathway but also modulates WNT signalling via β-catenin-interaction [123], BMP signalling via interaction with Smad7 [124] as well as NOTCH signalling through up-regulation of *JAG1* [125] so that the observed developmental defects in patients with *YAP1* mutations are probably not solely effects of impaired hippo signalling. Moreover, *YAP1* itself is up-regulated by hedgehog signalling [126] raising the possibility that disturbed hedgehog signalling in ciliopathy/nephronophthisis subjects might contribute to the observed abnormalities in hippo signalling.

The substantial cross-talk between major developmental signalling pathways including wnt, hedgehog, hippo, notch and mTor [127] leaves the actual molecular basis of a developmental defect such as nephronophthisis uncertain. Nonetheless, in view of the clear renal phenotype observed in TAZ-deficient mice and well established protein-protein interactions between NPHP proteins and TAZ, dysregulated hippo signalling is one of the best candidates so far regarding the primary molecular pathomechanism leading to nephronophthisis like disorders.

Other Cilia Associated Cell Signalling Pathways

Excellent overviews of how the cilium orchestrates cellular signalling pathways during development and tissue repair have been provided by Christensen et al. [128] and Satir et al. [129]. Due to space constraints, not all pathways can be discussed here in detail so we will only scratch the surface of the relationship between cilia and TGF-beta signalling. Clathrin-dependent endocytosis governs TGF-beta signalling and interestingly, TGF-β receptors localise to endocytotic vesicles at the ciliary base and to the ciliary tip in vitro. Activation of SMAD2/3 at the ciliary base has been observed. TGF-β signalling seems to be reduced in the absence of cilia in fibroblasts lacking Ift88 suggesting that cilia might regulate TGF-β signalling and that the cilium could represent a compartment for clathrin-dependent endocytotic regulation of signal transduction [130]. Increased TGF-beta signalling has been associated with increased interstitial fibrosis in progressive renal dysfunction in ADPKD and other renal conditions. Most interestingly, the PPAR-γ agonist rosiglitazone, reversing a downstream effect of TGFß, was nephro-protective and prolonged survival in an ADPKD rodent model via inhibition of TGF-ß induced renal fibrosis [131]. If this effect is also applicable to humans remains to be established.

Cilia in Renal Disease

The clinical aspects of human ciliopathies with renal involvement are discussed in more detail in the polycystic kidney disease and nephronophthisis chapters of this book (Chaps. 12 and 13, respectively). We will here give a short introduction and overview, mainly focusing on conditions resulting from mutations in IFT and BBS genes. Please also see Table 9.1 for a summary of ciliopathies with renal involvement.

Polycystic Kidney Disease (ADPKD and ARPKD)

The classic ciliary polycystic renal diseases are represented by autosomal dominant polycystic kidney disease (ADPKD) and autosomal recessive polycystic kidney disease (ARPKD). The hallmark of both diseases is extensive cystic enlargement of both kidneys. ADPKD is one of the most common monogenetic disorders with an incidence of 1 in 600–800 live births in the western world and clinical signs of ADPKD usually become manifest in adulthood [132]. In affected subjects, heterozygous mutations in either PKD1 or PKD2, encoding for Polycystin 1 and Polycystin 2, have been identified and it is common belief that a second acquired somatic mutation is necessary for the initiation of cystogenesis ("second hit hypothesis"). Gene dosage at least of PKD1 probably plays a role for the severity of the phenotype, which rarely can mimic ARPKD [133].

With a frequency of 1:20,000 live births, ARPKD is a lot less common than ADPKD and is inherited in an autosomal-recessive manner. Two mutated germline alleles are present from the very beginning causing a very early disease onset due to loss of Fibrocystin function, the protein encoded by the *PKHD1* gene. Increased renal echogeneity and cysts are usually present prenatally and biliary dysgenesis resulting in intrahepatic bile duct dilatation and congenital hepatic fibrosis (Caroli disease) occurs frequently. Fibrocystin co-localises with PKD2 at the ciliary axoneme and the ciliary base; however, its exact function has remained elusive [134].

As outlined above, flow mediated ciliary bending might activate calcium influx and it has been suggested that PKD1 and PKD2 proteins together function as a Ca^{2+}-permeable receptor channel complex [104, 135, 136]. Further, Polycystins interact with the tuberous sclerosis protein Tuberin which is known to influence mTor signalling and the mTor pathway was found to be overactivated in cystic epithelia from Polycystin-deficient kidneys. However, despite major efforts over the past two decades, the exact pathomechanism for cystogenesis in ADPKD and ARPKD remains to be defined and to date, efficient pharmacological treatment remains to be developed. For more details on ciliary signalling pathways please refer to the above sections and the polycystic kidney disease chapter of this book, Chap. 12.

Syndromal Nephronophthisis (NPHP)

For a detailed description of Nephronophthisis, including isolated Nephronophthisis, Joubert Syndrome, Senior-Loken Syndrome and Cogan Syndrome, please refer Chap. 13. Nephronophthisis can be translated as "vanishing nephrons" or "vanishing kidney" and in contrast to ADPKD and ARPKD, where increasing numbers of cysts and increasing cyst volumes lead to larger kidneys, in subjects affected by NPHP or NPHP-like renal disease kidneys appear normal or small in size, often with increased echogenicity in ultrasound images. Many genes have been identified to date causing either isolated NPHP or NPHP combined with extrarenal symptoms which could be described as "syndromal" NPHP. These extrarenal symptoms include retinal degeneration, cerebellar malformations, skeletal dysplasia including polydactyly, situs inversus, obesity and learning difficulties. There is excessive genetic and phenotypic heterogeneity, meaning that not only the clinical symptoms overlap between different syndromes with NPHP- or NPHP-like renal phenotypes but also mutations in one and the same gene can cause different phenotypes. We will focus in this chapter on selected phenotypes of "syndromal NPHP" including Bardet-Biedl-Syndrome resulting from mutations in BBS genes and ciliary skeletal dysplasias such as Short-rib polydactyly syndrome (SRPS), Jeune Syndrome (JATD), Mainzer-Saldino Syndrome and Sensenbrenner Syndrome (CED), consequences of impaired intraflagellar transport (IFT).

Bardet-Biedl-Syndrome (LMBBS, BBS)

Among the first human ciliopathy diseases recognised as such was Bardet-Biedl-Syndrome (BBS,

Laurence-Moon-Bardet-Biedl-Syndrome, LMBBS) and therefore this condition is often referred as an example of a classical complex developmental phenotype resulting from hereditary cilia malfunction. The main features of BBS are polydactyly, developmental delay, obesity, retinal degeneration, cystic or, more commonly, NPHP-like renal disease and hypogenitalism [137]. BBS is very rare with an estimated frequency varying between 1:160,000 in northern European populations to 1:13,500 and 1:17,500 in isolated consanguineous communities such as in Kuwait and Newfoundland. Like other ciliopathies, BBS is a genetically very heterogeneous disease with mutations in 19 genes identified to date and there is considerable genetic and phenotypic overlap (especially regarding eyes and kidneys) with other ciliopathies such as Meckel-Gruber-Syndrome and Senior-Loken-syndrome. Perinatally, BBS can be difficult to distinguish from McKusick-Kaufman syndrome if polydactyly and hydrometrocolpos are present [138]. Although BBS represents an autosomal-recessive condition, in individual cases more than two mutated alleles at two different loci have been found to be necessary to cause the phenotype ("triallelic inheritance") [139, 140]. However, the vast majority of cases are inherited in the classical recessive manner [141]. Nevertheless, several "modifier" genes have been described which may influence the phenotype. While genotype-phenotype correlations have proven difficult to establish, mutations in certain genes seem to predispose for more severe kidney involvement. Mutations in *BBS6*, *BBS10* and *BBS12* are associated with renal disease at an overall frequency of 30–86%; however, this includes minor anomalies and the majority of patients do not progress to renal failure [142].

While some of the proteins encoded by genes mutated in BBS localise to the ciliary transition zone (e.g., CEP290), others localise further proximal to the basal body area and axonemal localisation has been observed as well. BBS proteins seem to form two different major protein complexes: the so-called BBSome and the BBS chaperone complex where the formation of the BBSome requires the function of the BBS chaperone complex. Data from mouse and zebrafish models indicate a role for BBS genes in intracellular and intraflagellar trafficking of ciliary components. Therefore, although the BBSome does not seem to be required for ciliary assembly itself, due to its trafficking function specific signalling receptors and transmembrane proteins no longer reach the cilium in subjects affected by BBS, leading to organ-specific signalling abnormalities and subsequently the characteristic developmental defects [26, 143, 144]. While the loss of function of BBS and IFT proteins conceivably leads to retinal degeneration due to impaired transport of molecules such as rhodopsin along the connecting cilium between the inner and outer segments of photoreceptor cells, the mechanism for (NPHP-like) renal disease in BBS and IFT-related diseases as largely remains elusive. As discussed above, imbalances in the hippo signalling pathway seem to play a role in classical nephronophthisis. To which extent this applies to BBS has not yet been investigated. While polydactyly in BBS as well as indirectly IFT-dependent disorders point towards a hedgehog-based mechanism at least for the skeletal phenotype, a contribution of misregulated hedgehog signalling to the renal phenotype has yet to be proven. Clinical hallmarks of BBS are shown in Fig. 9.7a–h.

Alström Syndrome

Alström syndrome is a very rare autosomal-recessive ciliopathy occurring with a frequency of 1:500,000–1:1,000,000 but can be more common amongst consanguineous populations. Over 100 mutations in a single large gene, *Alms1*, have been published to date. Clinical characteristics include obesity, retinal dysfunction, cardiomyopathy, hearing loss, hepatic involvement, renal disease and hypogonadism, resembling the BBS phenotype; however, with higher lethality due to cardiac complications [146]. In contrast to BBS, polydactyly and developmental delay are not common features. The Alms1 protein localises to the base of the cilium [147] and knockdown of *Alms1* in kidney epithelial cells in vitro causes

Fig. 9.7 (**a**–**h**) Clinical hallmarks of Bardet-Biedl-Syndrome (BBS). (**a**–**d**) Dysmorphic facial features including a flat nasal bridge, retrognathia, small mouth, malar hypoplasia, deep-set eyes, downward slanting palpebral fissures, hypertelorism (**e**) Brachydactyly and scars from removal of accessory digits. (**f**, **g**) High arched palate and dental crowding. (**h**) Rod-cone dystrophy in fundoscopy. (Used with permission of Nature Publishing Group from Forsythe and Beales [145])

shortened cilia and seems to abrogate calcium influx in response to mechanical stimuli. In a mouse model of Alström syndrome, loss of cilia from the kidney proximal tubules was observed [148]. *Alms1*-disrupted mice also recapitulate the neurosensory deficits observed in humans with Alström Syndrome and their cochleae display signs of disturbed planar cell polarity abnormal orientation of hair cell stereociliary bundles which seemed to be prematurely lost when the mice grow older [149]. Alms1 has further been implicated in cell cycle control, and intracellular transport as well as the recycling endosome pathway [150]. To which extent disturbance any of these processes contributes to the renal phenotype still requires further investigation.

Joubert-Syndrome Related Disorders (JSRD)

Joubert syndrome (JS) is a very rare neurodevelopmental, mostly autosomal recessive but rarely X-linked disorder characterised by the so-called molar tooth sign (MTS). MTS represents a complex midbrain-hindbrain malformation visible on brain imaging. Anatomical correlate is hypodysplasia of the cerebellar vermis, abnormally deep interpeduncular fossa at the level of the isthmus and upper pons, and horizontalized, thickened and elongated superior cerebellar peduncles [151]. The estimated incidence is 1/80,000–1/100,000 live births. Clinically, neurological features such hypotonia at birth, ataxia, developmental delay, abnormal eye movements and neonatal breathing dysregulation are predominant but multiple extra-neurological symptoms occur. JS and Joubert Syndrome related disorders (JSRD) can be classified in six phenotypic subgroups: isolated JS; JS with ocular defect; JS with renal defect; JS with oculo-renal defects; JS with hepatic defect and JS with orofaciodigital defects.

JS/JSRD are genetically heterogeneous and there is marked phenotypical variability even within families. JS with renal defect (JS-R) is characterized by additional juvenile nephronophthisis but no retinal disease and mainly caused by mutations in *NPHP* and *RPGRIP1L*. JS with oculo-renal defects (JS-OR) occurs mainly due to mutations in *CEP290*, a transition zone protein encoding gene also found defective in BBS. Mutations in *TMEM67*, a gene also found to cause Meckel-Gruber Syndrome, have

been identified in JS with hepatic defects, chorioretinal or optic nerve colobomas and NPH, indicating that Meckel-Gruber Syndrome (MKS) can be clinically regarded as the severe end of the JS spectrum. Genetically, MKS is allelic to JSRD in 7 loci. JS with oro-facio-digital defects (JS-OFD) displays a slightly different phenotype from all of the above with bifid or lobulated tongue (sometimes referred to as hamartomas in the literature), multiple oral frenulae and mesaxial polydactyly with Y-shaped metacarpals and occurs as a consequence of mutations in *TMEM216*. Mutations in this gene can also cause isolated JS as well as MKS and mutations in *C5orf42* have recently been identified in subjects with an OFDVI phenotype in addition to subjects with isolated JS [152–155].

Many of the genes involved in JS/JSRD have been found to localise to the transition zone in cilia where they might exhibit a special gatekeeping function for ciliary protein entry [156]. For more details on the renal phenotype please refer to Chap. 13.

Ciliary Chondrodysplasias

An excellent overview of skeletal chondrodysplasias is given in a recent review article by Huber and Cormier-Daire [157]. Ciliary chondrodysplasias represent a genetically and phenotypically heterogeneous group of very rare (1:20,000 to <1:1,000,000), mainly autosomal-recessively inherited conditions with the major hallmark of skeletal involvement, mainly short/hypoplastic ribs and polydactyly, but also a variable degree of extraskeletal involvement. While *Short-Rib Polydactyly Syndrome* (*SRPS*) is inevitably lethal perinatally, 20–60% lethality has been reported for *Jeune Asphyxiating Thoracic Dystrophy Syndrome* (*JATD*). Polydactyly, a ubiquitous feature in SRPS, is rarely observed in JATD. Radiologically, trident acetabulum with spurs is a pathognomic sign for JATD but can also be observed in some SRPS cases as well as Ellis-van Creveld syndrome (EVC). In SRPS, extraskeletal manifestations such as cardiac defects, orofacial clefting, cerebral, renal, liver or pancreatic abnormalities as well has situs inversus have been observed. In JATD, up to 30% of the patients develop kidney disease, often accompanied by retinal degeneration. Elevated liver enzymes are common but only a handful cases of liver failure have been reported in the literature. Clinical hallmarks of JATD are shown in Fig. 9.8a–f.

JATD also shares clinical features with *Mainzer-Saldino Syndrome*, which can be described as JATD with obligate renal and retinal disease; both conditions are summarised under "cono-renal syndromes" as cone shaped epiphyses of the phalanges are frequently observed on X-rays [157]. Clinical hallmarks of Mainzer-Saldino-Syndrome are shown in Fig. 9.9a–h.

Mutations in genes encoding several components of the retrograde IFT motor complex dynein-2 such as *DYNC2H1*, *WDR34* and *WDR60* as well as the IFT-B component *IFT80* have been identified in patients with *JATD and SRPS*, indicating that these conditions are allelic and JATD represents the milder end of the SRPS phenotypic spectrum [56, 58, 60–62, 158, 159], Mutations in genes encoding retrograde IFT (IFT-A) components such as *IFT43* [67], *IFT121/WDR35* [65], *IFT122* [63], *IFT139/TTC21B* [68], *IFT144/WDR19* [64] and *IFT140* [20, 69] have likewise been found to cause ciliary chondrodsyplasias with renal involvement such as Sensenbrenner Syndrome/Cranioectodermal Dysplasia (CED), JATD/Mainzer-Saldino Syndrome and SRPS, and isolated Nephronophthisis (*WDR19*). Interestingly, in contrast to most JATD patients with mutations in genes encoding dynein-2 components who present with a severe thorax phenotype but usually preserved kidney function if they survive, the majority of patients described with mutations in IFT-A encoding genes as well as the IFT-B component IFT172 present with a milder thoracic phenotype but experience severe renal involvement with end-stage renal disease [1, 20, 21, 56–69]. In striking contrast to other ciliopathies such as BBS where up to two thirds of affected human subjects carry two null alleles (stop- or frameshift mutations), patients with ciliary chondrodysplasias usually harbour at least 1 missense

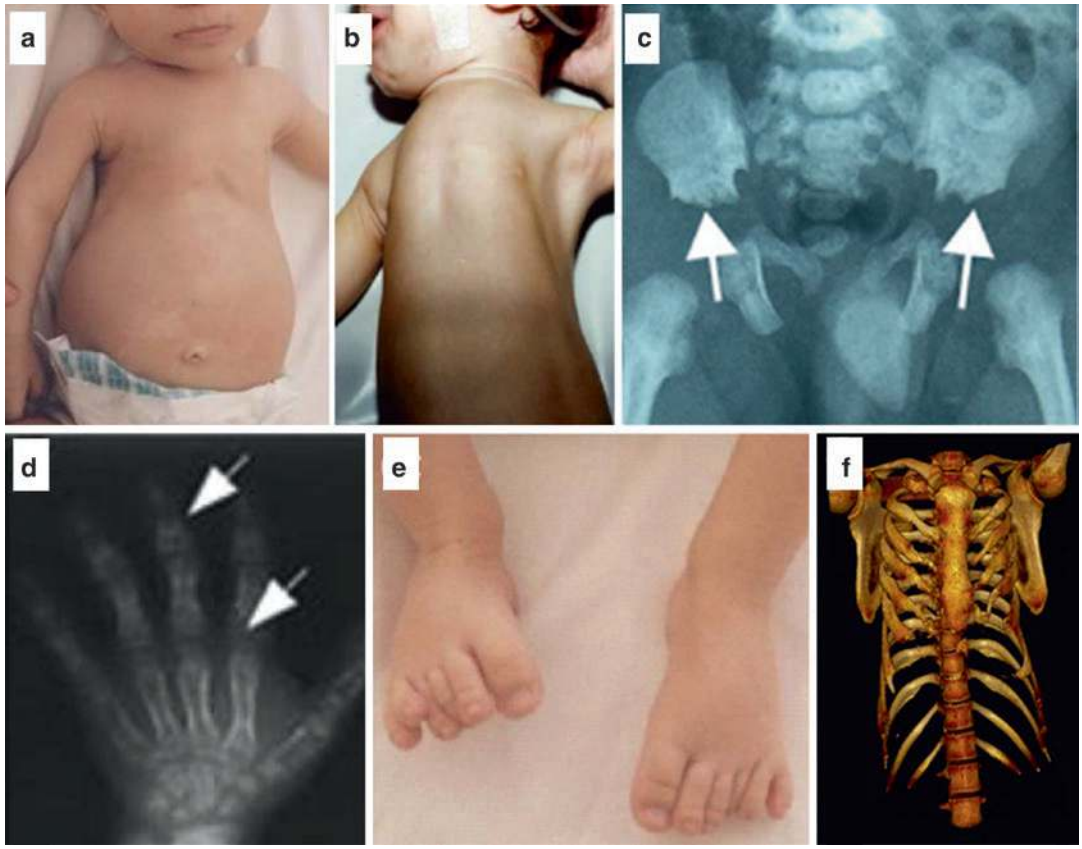

Fig. 9.8 (**a**–**f**) Clinical hallmarks of Jeune Syndrome. (**a**, **b**) Narrow thorax with short ribs. (**c**) Trident acetabulum with spurs. (**d**) Cone shaped epiphyses. (**e**) Polydactyly. (**f**) 3D-reconstruction from thoracic CT scan demonstrating long narrow thorax with short ribs. ((**a**, **e**) Used with permission from Halbritter et al. [1]; (**b**, **c**, **f**) Used with permission of BMJ Publishing Group from Schmidts et al. [21]; (**d**) Used with permission of John Wiley and Sons from Schmidts et al. [20])

allele. This is in line with findings from IFT-mutant mouse models where complete loss of IFT-protein function results in early embryonic death before midgestation (see also IFT section of this chapter) and one can assume that this also applies to humans, suggesting a more important role for IFT proteins compared to BBS proteins for ciliary function and embryonic development.

Likewise, human mutations have only been identified in two anterograde IFT (IFT-B) complex components to date: *IFT80* and *IFT172*. While *IFT80* mutations seem to cause a mild thoracic phenotype without extraskeletal involvement [57], *IFT172* mutations lead to a more complex phenotype with renal, liver and retinal involvement [1]. This might be due a more central role of IFT172 within complex-B or could also result from additional roles of IFT172 outside of IFT. The fact that in humans, mutations in more genes encoding IFT-A than IFT-B components have been identified to date again could point to a more essential role of IFT-B compared to IFT-A so that IFT-B mutations might be incompatible with embryonic development beyond very early stages. See also Fig. 9.6a, b for a visualisation of IFT defects observed in fibroblasts from ciliary chondrodysplasia patients.

SRPS can also be caused by mutations in the serine-threonine kinase *NEK1* [160] which acts within the DNA damage response pathway [161].

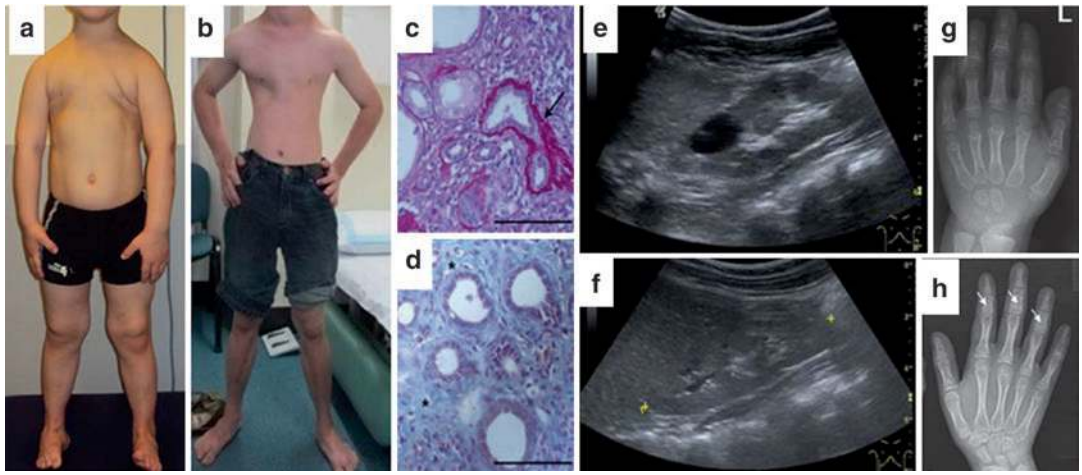

Fig. 9.9 (**a**–**h**) Clinical hallmarks of Mainzer-Saldino-Syndrome. (**a**, **b**) Mildly narrowed thorax. (**c**, **d**) Histological pictures of a renal biopsy. (**e**, **f**) Ultrasound images showing increased echogeneity and small renal cysts. (**g**, **h**) Cone shaped epiphyses. ((**b**–**h**) Used with permission of Elsevier from Perrault et al. [69]; (**a**, **e**–**g**) Used with permission of John Wiley and Sons from Schmidts et al. [20])

In humans affected by SRPS, kidney function cannot be followed due to neonatal death from respiratory failure, but mice carrying mutations in *Nek1* exhibit cystic renal disease [162]. Nek1 binds to the kinesin-2 component Kif3a [163], and kidney specific loss of Kif3a causes cystic disease [54]. Moreover, NEK1 and TAZ proteins interact physically to maintain normal levels of Polycystin 2 [164], so it seems possible that surviving patients would present with cystic or nephronophthisis-like renal involvement. Surprisingly, while impaired function of IFT proteins and Kif3a results in cystic kidney disease in mice, the combined knockout of *Kif3a* and *Pkd1* resulted in a milder rather than more severe phenotype, suggesting the existence of a cilia-dependent, as yet unidentified cyst growth promoting pathway [165]. No human mutations have been identified in *KIF3A* or other components of the kinesin-2 complex to date; presumably such mutations would lead to an early embryonic lethal phenotype.

Although mutations in some genes seem to be able to cause both JATD and *Sensenbrenner-Syndrome/CED* as mentioned above, the clinical phenotype is slightly different in CED where additional ectodermal defects such as dysplastic finger- and toe-nail, sparse and slow growing hair and teeth abnormalities are frequently observed. The thoracic phenotype is usually milder than in JATD and polydactyly not usually observed; however, craniosynostosis has been described and human subjects frequently present with renal involvement [166]. Clinical hallmarks of Sensenbrenner syndrome are shown in Fig. 9.10a–c.

While the skeletal features observed in skeletal chondrodysplasias, especially polydactyly, point towards imbalances in the hedgehog pathway as a molecular origin of disease, the molecular pathogenesis of renal disease in subjects with IFT and dynein-2 mutations has remained elusive as neither hedgehog- nor wnt signalling defects could be established as causative for the kidney phenotype in mouse models (see the IFT and Hedgehog Signalling sections of this chapter for more details). However, given the NPHP-like phenotype observed, hippo signalling might be a good candidate pathway leading to the renal phenotype in this group of ciliopathies.

Fig. 9.10 (**a**–**c**) Clinical hallmarks of Sensenbrenner Syndrome (CED). Four-year-old girl displaying short extremities, mildly shortened and narrowed thorax, thin sparse hair, dolichocephaly, prominent forehead, full, hypertelorism, small flat nose, prominent auricles (**a**). (**b**) Brachydactyly. (**c**) Small abnormally shaped teeth. (Used with permission of Elsevier from Walczak-Sztulpa et al. [63])

Summary and Conclusion

Cilia are antenna-like structures projecting from most cells and hundreds of years after their first notion, we begin to acknowledge some of their essential function in human development, including the kidney. Extensive phenotypic and genetic heterogeneity has created a slightly chaotic picture of ciliopathies in the past and many aspects of these complex inherited conditions have remained unclear. Despite linking ciliopathies to imbalances in multiple fundamental cell signalling pathways, the molecular basis of disease, especially kidney mal-development, is still largely elusive to date.

Acknowledgments We apologize to all colleagues whose findings could not be cited due to space constraints. Miriam Schmidts and Philip L. Beales acknowledge funding from the Dutch Kidney Foundation, DKF (KOUNCIl, CP11.18). Miriam Schmidts is funded by an Action Medical Research UK Clinical Training Fellowship (RTF-1411) and Philip L. Beales receives funding from the European Community's Seventh Framework Programme FP7/2009; 241955, SYSCILIA, the Wellcome Trust and is an NIHR Senior Investigator.

Polycystic Kidney Disease: ADPKD and ARPKD

10

Max Christoph Liebau, Djalila Mekahli, and Carsten Bergmann

Introduction

Polycystic kidney diseases (PKD) are among the most common causes of chronic kidney disease (CKD) and end stage kidney disease (ESKD) both in children and adults [1]. The two main forms of genetic cystic kidney disorders are Autosomal Dominant and Autosomal Recessive Polycystic Kidney Disease (ADPKD and ARPKD). ADPKD is a disorder mainly manifesting at adult ages and is oligosymptomatic in childhood, although it is nowadays accepted that cysts may be present even prenatally and early pediatric involvement raises increased attention [1, 2]. In contrast, ARPKD is usually presenting in early childhood. However, mild phenotypes with disease onset at adult age have been reported anecdotally [1, 3, 4]. Recent cell biological and clinical research approaches have considerably expanded our knowledge on both PKDs. Still, many important questions remain to be solved. This chapter aims to give an overview of the current knowledge of ADPKD and ARPKD with a special focus on pediatric clinical aspects. For genetics we focus on the main genes, but would like to emphasize that there is a growing list of genes that when mutated may mimic ADPKD or ARPKD.

Classification and Differential Diagnosis of Cystic Kidney Diseases

In their seminal studies, Osathanondh and Potter systematically classified cystic kidney diseases into four distinct types [5]. While this historical classification has had a great impact for concise pathoanatomical description, it is hard to reconcile with our current understanding of clinical and genetic entities. Accurate diagnosis is essen-

tial both in the management of patients with PKD and in counselling their families. Notably, cystic kidneys are an important feature of numerous genetic syndromes, including both dominant disorders like tuberous sclerosis complex (TSC) and recessively inherited diseases such as Joubert syndrome.

Clinical Aspects Guiding Diagnosis in Patients with Kidney Cysts

The differential diagnosis of cysts in the kidney is broad and in addition to ARPKD and ADPKD includes, e.g. single simple cysts, multicystic dysplastic kidneys and cystic dysplasia, nephronophthisis and other ciliopathies, as well as *HNF1B*-nephropathy or TSC. Six straightforward questions that can be answered by the patient and sonographic examination may be helpful to narrow down a potential clinical diagnosis [6].

In a first general consideration, it is important to differentiate a **kidney with a single or a few cysts from a cystic kidney**. Simple kidney cysts are fairly common in elderly persons [7] and usually do not impose problems or require treatment. However, simple cysts are not common in young children and even a single cyst should raise suspicion in pediatric patients**. Family history** is important. Whereas only 10–20% of ADPKD patients lack a family history [8], ARPKD and nephronophthisis (NPH) are usually inherited recessively with healthy parents and are found more frequently in offspring of consanguineous couples. Kidney ultrasound in the parents or grandparents is a useful investigation in the evaluation of a child with early-onset cystic kidney disease of unknown origin. A third important question addresses the **age of the patient** at the time of clinical presentation. ARPKD fetuses and a minor subset of ADPKD patients may be identified with oligo- or anhydramnios already during pregnancy. Juvenile nephronophthisis (NPH) classically presents with polyuria and polydipsia in school children. Most ADPKD patients are adults. While cysts in the kidney may appear during childhood or even prenatally in ADPKD and can be found by ultrasound, most children do not yet show clinical symptoms. Fourthly, the **localization of cysts** may give a hint. Cysts in NPH are found at the cortico-medullary border, whereas in ADPKD cysts localize to all parts of the kidney. **Kidney and cyst size** can also point to the correct diagnosis. Kidneys in NPH tend to be normal-sized or small, whereas ARPKD and ADPKD kidneys are large. Cysts are typically tiny in early stages of ARPKD, but may resemble large ADPKD macrocysts during the course of the disease. Finally, cystic kidney disorders may be accompanied by **extra-renal symptoms**, such as retinitis pigmentosa presenting with initial night blindness later progressing to almost complete loss of vision in case of syndromes accompanied by NPH, liver cysts in ADPKD and congenital hepatic fibrosis in ARPKD.

With these six pieces of information at hand, a potential diagnosis can be made clinically in many cases. Nonetheless, clinical diagnosis can be challenging due to overlapping syndromes and symptoms, and establishing a confirmatory genetic diagnosis can be helpful.

General Considerations on Genetic Diagnostics for Polycystic Kidney Disease

Marquardt first postulated genetic heterogeneity of polycystic kidney diseases when stating in 1935: “In surviving individuals, cystic kidneys are inherited dominantly. In non-viable individuals, cystic kidneys are recessive.” [9]. It took more than 35 years from that point of view before Blyth and Ockenden demonstrated in a systematic analysis that age at presentation alone is not a reliable criterion for defining genetic heterogeneity [10].

Indications for genetic testing and recommendations for preferred testing strategies have changed significantly over recent years. In all patients with PKD manifesting prenatally or in early childhood, genetic testing is highly recommended as a first-line diagnostic procedure as part of the initial patient evaluation [11]. Testing is not required in children with a single cyst,

absent extra-renal anomalies and a negative family history of ADPKD, but may be indicated in children with progressive disease indicated by kidney cysts increasing in size or number.

Genetic testing may be recommended due to the following aspects: The high gene detection rate in cystic kidney diseases allows to rapidly establish a definite diagnosis and avoid a "diagnostic odyssey" with unnecessary diagnostic measures for the majority of patients. To establish a definite diagnosis often is of **psychological benefit** for patients and families. Knowledge of the genotype may point to renal and **extra-renal comorbidities**, which would otherwise have taken considerably longer to diagnose and may benefit from early detection and disease monitoring (e.g. diabetes mellitus in *HNF1B* disease). Valid information on the recurrence **risk for future children** or other family members is only possible with knowledge of the genotype. The genotype can also be relevant for the inclusion of patients in clinical trials and the future choice of treatment options (see below).

Professional genetic counseling is highly recommended due to variable expressivity and the variety of extra-renal features seen in patients with cystic kidneys. It can also address the complex aspects of prenatal testing and preimplantation diagnostics in line with regional practices and regulations. Given the large clinical and genetic heterogeneity and vast pleiotropy, a **comprehensive gene testing** approach is recommended for cystic kidney diseases. A stepwise approach might only be indicated in a minority of patients in which there is clear phenotypic evidence for a specific disease, such as von Hippel-Lindau syndrome for which only one single (small) gene is known and variant detection rate is high.

Whatever primary strategy is chosen, an expanded gene panel or exome sequencing, the testing approach should be able to detect copy-number variations (CNVs) (e.g., deletions account for 50% of anomalies in *HNF1B*) and to cover complex genomic regions such as in *PKD1* [12]. Analysis of the *PKD1* gene is most complicated and needs expert knowledge due to genomic duplication of the first 33 exons at six other sites on chromosome 16p. Many of these pseudogenes are expressed as mRNA transcripts, but probably do not encode proteins. Both *PKD1* and *PKD2* variants are scattered throughout the genes' coding regions exhibiting marked allelic heterogeneity, with most variants being unique to single families ('private' variants) [1, 8, 13].

Ethical concerns exist on the question whether or not an ADPKD diagnosis should be actively sought in asymptomatic children. This includes genetic screening in addition to ultrasound examination. There is consensus on the need for early monitoring of modifiable risk factors (hypertension, proteinuria) and of early treatment of potential complications in children at risk for ADPKD [14]. As there is currently no established disease-controlling targeted treatment that would need to be started during childhood, it has, however, been argued that one should not take the right of self-determination from these children before these individuals are old enough to decide on their own what they consider best for them. Next to the last KDIGO recommendations, a recent consensus has highlighted the need of counselling these families and involving them in a process of shared decision-making between the child, parents and physicians [14, 15]. An algorithm has been proposed to facilitate the counseling of these ADPKD families in accordance to their own decision [16].

Autosomal Dominant Polycystic Kidney Disease (ADPKD)

Epidemiology and Morphology

ADPKD is the most common inherited kidney disease and one of the commonest Mendelian human disorders overall with a frequency of 1/500–1000 [1, 15, 17]. This approximates to about 12.5 million affected individuals worldwide. ADPKD is among the most common causes of ESKD; about 5–10% of all patients requiring kidney replacement therapy (KRT) as kidney transplant or dialysis are affected by ADPKD. Overall, the disease is a major health care issue of socio-economic interest.

Histopathologically, kidney cysts are fluid-filled epithelia-lined cavities. ADPKD is characterized by the formation and progressive enlargement of kidney cysts from all segments of the nephron and additional kidney fibrosis. In contrast to ARPKD in which the cysts usually remain connected with the tubular lumen, cysts in ADPKD become disconnected from the tubular space. Kidney cysts in ADPKD vary considerably in size and appearance, from a few millimeters to many centimeters (Fig. 10.1).

ADPKD is a systemic disorder with profound extra-renal cystic and non-cystic complications. Their prevalences in adults compared to children are summarized in Table 10.1.

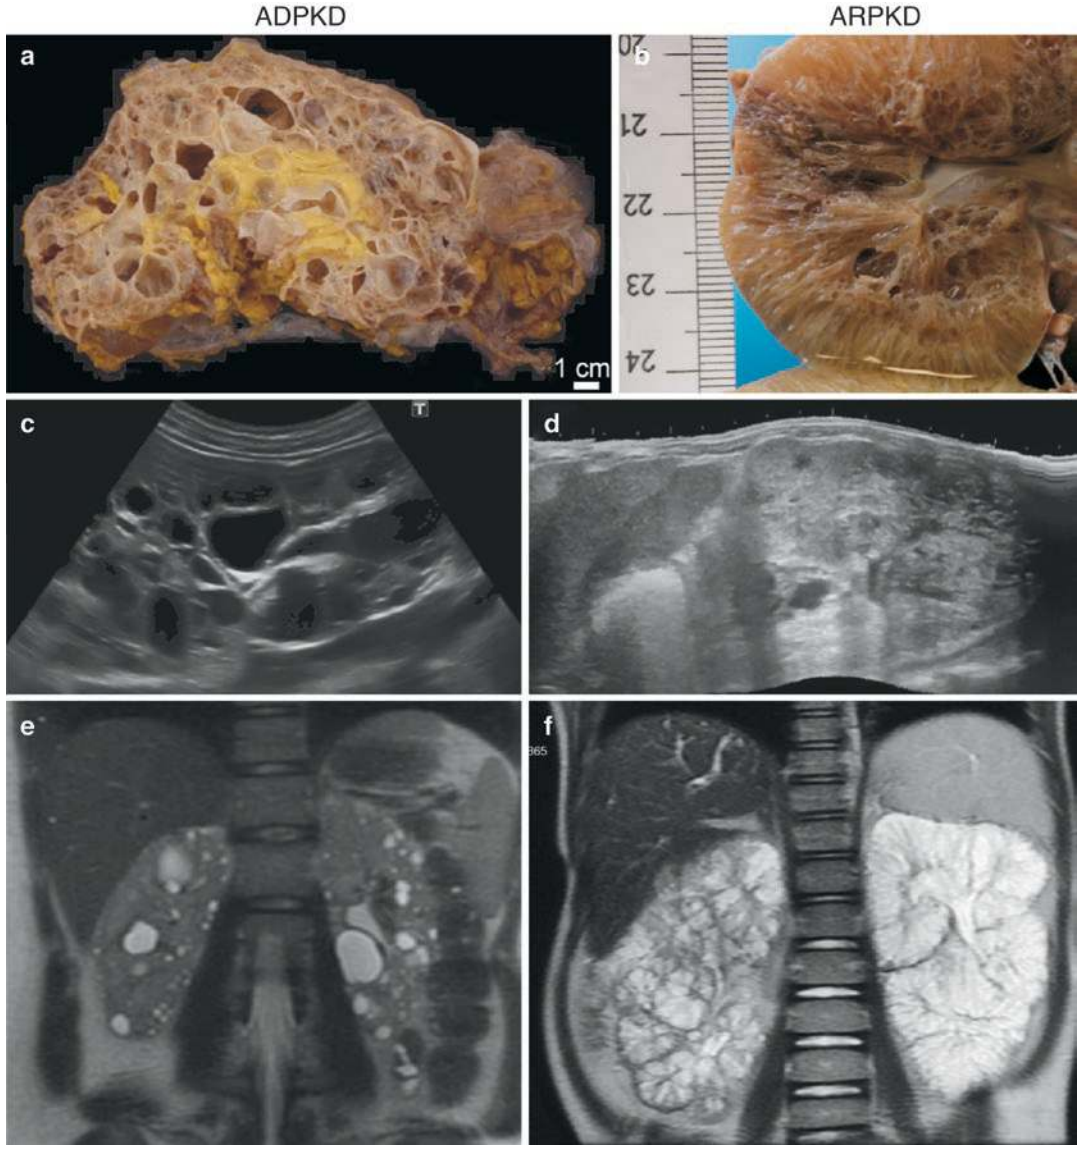

Fig. 10.1 (**a**) Macroscopic appearance of advanced-stage ADPKD (**a**) and ARPKD kidneys (**b**). On cut section, multiple cysts in the cortex and medulla can be seen that vary considerably in size and appearance, from a few millimetres to diameters of many centimeters in the ADPKD kidney, while ubiquitous small dilatations can be seen in the ARPKD kidney. These findings can also be recapitulated by ultrasound (**c**, **d**) and T2-weighted magnetic resonance imaging (MRI; **e**, **f**). (From Liebau and Serra [6] with permission)

Table 10.1 Extra-renal manifestations of ADPKD (according to [2, 198])

Manifestation	Prevalence in adults	Prevalence in children
Hepatic cysts	>90%	<5%
Arterial hypertension	Up to 70%	20–35%
Left ventricular hypertrophy	Up to 70%	
Valvular abnormalities	Up to 20%	12%
Intracranial aneurysm	6–16%	Rare
Abdominal aorta aneurysm	5–10%	
Diverticula	Up to 40%	
Hernias	Up to 45%	16%
Bronchiectasis	Up to 37%	
Genitourinary cysts	39–60%	
Depression	Up to 60%	
Pain	Up to 60%	10–20%

Clinical Course

Kidney Function

The kidneys are usually in the center of disease burden in ADPKD. A common classification differentiates a PKD1 subtype of patients with variants in the *PKD1* gene from a PKD2 subtype of patients with variants in *PKD2* [1]. ESKD presents in about 50% of ADPKD patients by the age of 60 years. On average, PKD2 is regarded to be significantly milder than PKD1 with a 20 years later median age of onset of ESKD (58.1 vs. 79.9 years) and a lower prevalence of arterial hypertension and urinary tract infections [1, 18].

Diagnosis by Imaging and Emerging Imaging Markers Predicting Clinical Courses

ADPKD diagnosis is usually established by ultrasound. Whereas 95% of patients exhibit characteristic ultrasonographic features at 20 years and almost all patients at 30 years of age, the proportion of affected children that can be identified by ultrasound is less clear. Even a single kidney cyst in a pediatric patient should raise suspicion and result in a diagnostic work-up encompassing a careful record of family and medical history, physical examination and, where required, further abdominal imaging [7, 14]. As novel treatment approaches are emerging it may become more important to identify ADPKD patients at an early stage of disease [16]. Various early markers of kidney disease are under investigation [19]. Approximately 60% of children younger than 5 years with a *PKD1* variant and 75–80% of those aged 5–18 years have kidney cysts detectable by ultrasound [20]. In the early 1990s, Bear et al. proposed a false negative diagnosis rate by ultrasound of about 35% below the age of 10 years [21]. The false positive yield of ultrasound is considered extremely low since simple cysts are extremely rare in childhood [22]. Ravine et al. found nil prevalence of cysts in healthy individuals aged 15–29 years [23].

Especially in children with a family history, ADPKD will be the most likely underlying condition for a child with kidney cysts. In adults aged ≤39 years with a family history of ADPKD, the diagnosis of ADPKD can be established by the presence of three uni- or bilateral kidney cysts [24]. Two cysts on each side for patients aged 40–59 years and four cysts on each side for patients aged >60 years make ADPKD the very likely diagnosis according to the modified Ravine criteria. The presence of less than two cysts in persons at risk aged >40 years practically excludes ADPKD. In 420 children with a family history of ADPKD, ultrasound screening detected kidney cysts in 46% of individuals at the age of 15 years [25].

Children affected by ADPKD also exhibit enlarged kidneys with an increased rate of kidney growth. ADPKD children who are hypertensive have larger kidneys than normotensive patients [26–28].

Magnetic resonance imaging (MRI) and computed tomography (CT) have higher detection rates, especially of small cysts. Given this, MRI may be a helpful tool to discover small cysts, e.g. to detect affected persons prior to living kidney donation, but unmodified application of the Ravine criteria to MRI and CT data would frequently yield false-positive results [29, 30]. Novel high-resolution ultrasound equipment may also be more sensitive in detecting small cysts. New reference datasets have therefore been

established for MRI-based cyst detection, revealing at least one cyst in about 60% of healthy adults [30]. Men appear to have more cysts than women and cysts grow with age by size and number.

A study by the CRISP (Consortium for Radiologic Imaging Studies of Polycystic Kidney Disease) consortium on ADPKD patients suggested that total kidney volume (TKV) as measured by MRI predicts kidney function decline in ADPKD. Total TKV values should be standardized to body height, especially in children. Height-adjusted TKV is considered to be a reasonably likely surrogate parameter for disease severity in ADPKD, even before kidney function declines [6].

The CRISP consortium used annual MRI as well as GFR measurements to monitor kidney and cyst volume in 232 young ADPKD patients with a GFR of >60 mL/min/1.73 m^2 over a period of 3 and 8 years [31]. The progression of cyst growth and kidney volume occurred prior to functional impairment. Rapid kidney growth was associated with faster decline in kidney function and lower kidney blood flow [31, 32]. Kidney blood flow and age as well as gender, hypertension, and kidney volume predicted the loss of kidney function [33]. In addition to height-adjusted TKV, novel radiomics approaches like image texture analysis may become an important tools to monitor the disease course and the response to interventions and to predict kidney function decline in ADPKD [34].

The applicability of MRI and CT for disease monitoring in children is limited. MRI requires sedation, and CT is associated with high radiation exposure. For daily clinical work, ultrasound remains the method of choice [6, 7], even more so as the resolution of modern ultrasound equipment is excellent. Recently, Breysem et al. validated 3D ultrasound for measuring TKV in children compared to the 2D ultrasound ellipsoid method and MRI-based volumetry in a pediatric ADPKD cohort [35]. 3D ultrasound manual contouring volumetry outperformed the 2D ellipsoid method and was comparable with MRI volumetry in children, especially for smaller kidneys. While these findings require further validation, 3D-ultrasound holds promise as a potential alternative to MRI in pediatric imaging assessment.

Early-Onset ADPKD and Clinical Spectrum of Kidney Disease in Pediatric ADPKD

Clinical symptoms of ADPKD usually do not arise before the fourth to fifth decade of life. However, there is striking phenotypic variability not only between but even within families, indicating that modifying genes, environmental factors and/or other mechanisms considerably influence the clinical course in ADPKD [36, 37]. In line with this, a small proportion of ADPKD patients presents with an early-manifesting clinical course [1]. Early manifestation in ADPKD is usually defined as clinical symptoms (e.g., arterial hypertension, proteinuria, impaired urinary concentration, impaired kidney function) occurring before the age of 15 years. Among these are cases with significant peri-/neonatal morbidity and mortality, sometimes indistinguishable from those with severe ARPKD [2]. Conflicting data exist on the precise incidence of early-manifesting ADPKD cases. While most authors propose a figure of about 2%, Sweeney and Avner suggested a prevalence of up to 5% [38, 39]. Given the prevalence rates for ADPKD (1/400–1000) and ARPKD (1/20,000), it is plausible that the total number of patients with early-onset ADPKD seen in pediatric nephrology clinics may be comparable to those of the children with ARPKD. A subset of these ADPKD patients may resemble ARPKD. Importantly, variants in *TCF2*/*HNF1B*, which initially were mainly found in children with bilateral cystic dysplasia [40], can also result in PKD-mimicking phenotypes [11, 41].

Longitudinal studies in children with ADPKD demonstrated that severe kidney enlargement at young age and hypertension are risk factors for accelerated kidney growth [14, 26, 27, 42]. Many clinical symptoms such as pain, hematuria, proteinuria, stones and hypertension are associated with large kidney size. Furthermore, a large cyst number in early childhood is a predictor for faster progression of structural anomalies.

Intriguingly, in children with ADPKD, kidney involvement is commonly asymmetric (including

asymmetric kidney enlargement) and even limited to one kidney in a small minority of cases at early stages of the disease [43]. As in ARPKD, the kidneys can present as large and hyperechoic bilateral masses with decreased corticomedullary differentiation [44, 45]. Unlike ARPKD, ADPKD kidneys are frequently characterized by greatly variable macrocysts (up to several centimeters in diameter) even in small children [6, 7].

Gross hematuria is a risk factor for the progression of kidney disease [46, 47]. Hematuria is not common in children and occurs in only about 10% of ADPKD children at a mean age of 9 years [26].

Arterial Hypertension

Arterial hypertension is common in pediatric ADPKD patients even in the presence of normal kidney function and particularly in children with very early onset ADPKD [47]. Hypertension should be diagnosed as early as possible and be treated aggressively [14, 15].

Cardiovascular disease represents the main cause of mortality in ADPKD. The onset of hypertension before age 35 years constitutes an important prognostic factor of rapid disease progression [46]. In children with ADPKD the prevalence of hypertension is between 20% and 40% [14, 48, 49]. 24-Hour ambulatory blood pressure monitoring (ABPM) represents the gold standard in evaluating hypertension in pediatric populations. ABPM in children with ADPKD revealed isolated nocturnal hypertension with normal daytime blood pressure in 16–18% of patients [11, 48].

The precise pathogenesis of hypertension in PKD still remains to be elucidated. It has been hypothesized that cyst expansion results in intrarenal activation of the renin-angiotensin-aldosterone system (RAAS) with stimulation of cyst growth, fibrosis, and hypertension [50].

Extra-Renal Manifestations

Intracerebral aneurysms (ICAs) are an important, specific cardiovascular comorbidity in ADPKD and are associated with a five-fold higher prevalence than in the general population. The risk to develop ICAs is higher in patients with a family history of ADPKD–associated ICA or subarachnoid hemorrhage (22% versus 6%) [51]. However, PKD associated intracranial aneurysms are extremely unusual in childhood and routine screening is not recommended [52].

Simple, mostly solitary hepatic cysts are common with a prevalence of 2.5–10% in the general population [53]. Women may be more often and more severely affected, especially those who used estrogens, had multiple pregnancies or both [54, 55]. Hepatic cysts can be predominant with multiple cysts throughout the liver in the presence of very few kidney cysts. Atypical or alternate disease including *GANAB*, *ALG9* variants in the case of liver cysts or *HNF1B* with significant pancreatic involvement are also to be considered [56].

Other anomalies may occur including mitral valve prolapse (usually without clinical significance), left ventricular hypertrophy, aneurysms of the abdominal aorta, diverticular disease, hernia, chronic back pain, cystic lesions in the genitourinary tract, the pancreas and the lung, hematuria, urinary tract infection, kidney stones, deregulated phosphate homeostasis, and arachnoidal cysts as well as pain and depression [18, 54] (Table 10.1). Extra-renal manifestations overall are rare in children with ADPKD.

ADPKD Genetics

As the name implies, ADPKD is transmitted in an autosomal dominant fashion, i.e., virtually all individuals who inherit a mutated *PKD1* or *PKD2* germline allele will develop kidney cysts by age 30–40. The majority of ADPKD patients are adults who carry a germline variant in the *PKD1* gene on chromosome 16p13.3 (~80%). About 10–15% harbor a variant in the *PKD2* gene on chromosome 4q21 [1, 18]. The majority of patients with ADPKD are explained by heterozygous variants in either *PKD1* or *PKD2*. However, there is a growing list of genes that when mutated either mimic ADPKD or give rise to more atypical ADPKD phenotypes (*GANAB*, *DNAJB11*, *HNF1ß*, *PKHD1*, *DZIP1L*, *TSC1/2*, *VHL*, *ALG9*, *IFT140*, *OFD1* in women, etc.).

Remarkably, ADPKD variants can occur *de novo* without a family history. This frequently results in some kind of mosaicism and the clini-

cal course may be atypical. In patients with early and severe disease manifestations (discussed in greater detail above), pathogenic *PKD1* variants can affect both disease alleles in a recessive mode of inheritance.

PKD1 and *PKD2* Genes and Their Encoded Polycystin-1 and -2 Proteins

PKD1 is a large gene with a longest open reading frame transcript of 46 exons predicted to encode a 4302 aa multidomain integral membrane glycoprotein (polycystin-1). *PKD2* has 15 exons encoding a 5.3 kb transcript that is translated into a 968 aa protein (polycystin-2). In keeping with the systemic nature of ADPKD, the two polycystins are widely expressed in tissues. The expression of polycystin-1 and -2 is developmentally regulated with highest levels during late fetal and early neonatal life. Intra-renal expression is highest in distal tubule and collecting duct epithelial cells. Notably, the majority of cysts in ADPKD originate from collecting ducts.

Although the two-hit model of tumorigenesis is too simplistic, it may still provide a reasonable basis of our understanding of ADPKD. According to this data, second-hit variant and resulting loss of heterozygosity has been proposed as the mechanism underlying cyst formation in ADPKD. The considerable intrafamilial phenotypic variation, focal cyst formation with evidence of epithelial cell clonality within individual cysts, as well as the detection of somatic variants in cells lining kidney and liver cysts are all in keeping with this theory [57–61]. However, numerous findings rule out the two-hit model of a germline variant on one allele and a somatic variant on the other as the sole cause of cystogenesis. Patients and mice have been described that carry germline variants in both *PKD1* and *PKD2* (double-heterozygotes) and, thus, are to be regarded as "homozygously" affected in every cell of the organism [62, 63]. In contradiction to a simple two-hit theory, not every renal tubular cell or nephron in these individuals may give rise to a cyst. Therefore, the second-hit variant to the other *PKD* gene may act as a modifying factor that boosts the risk of cyst development and/or drives cyst progression, rather than initiating cyst events [64]. As regards mechanisms underlying cystogenesis, it is worth noting that increased as well as decreased polycystin-1 expression may result in cyst formation [1, 65, 66]. Haploinsufficiency of *Pkd1* itself has been demonstrated to suffice to elicit a cystic phenotype [67]. Finally, the timepoint of *Pkd1* inactivation crucially determines the severity of the cystic phenotype in mice [68]. Ischemia [69–71], nephrotoxic injury [72] and immunological events involving, e.g. macrophages [73, 74] may affect cystogenesis and it has been suggested that these events might represent a required third or even further additional hit [75].

Polycystin-1 and polycystin-2 are glycosylated integral membrane proteins (Fig. 10.2). Polycystin-2 has six transmembrane passes with cytoplasmic N- and C-termini. It is believed to function as a divalent cation channel, particularly involved in cellular Ca^{2+} signalling, belonging to the transient receptor potential (TRP) protein superfamily [76].

Polycystin-1 is a huge integral membrane glycoprotein with an extensive amino-terminal extracellular region, 11 transmembrane passes, and a short 200-amino acid cytoplasmic carboxy-terminus. The intracellular C-terminus is supposed to mediate protein interactions, by, e.g., a heterotrimeric G-protein activation site and a coiled-coil domain that interacts with the C-terminus of polycystin-2. The large extracellular portion of polycystin-1 contains numerous structural motifs, which are putatively involved in protein-protein or protein-carbohydrate interactions. It has been proposed that polycystin-1 and polycystin-2 form a chemo- and mechanosensing protein complex which senses fluid flow in the renal tubule and controls cell growth and differentiation [1]. Bending of the primary cilia leads to an increase in intracellular calcium potentially via a polycystin-1-dependent mechanism [77, 78] and the ratio of polycystin-1 to polycystin-2 regulates pressure sensing [79]. However, the exact mechanisms remain unknown [80, 81]. Polycystin-1 is involved in the regulation of multiple intracellular signalling pathways [1, 82–85]. Hogan et al. found urinary exosomes with abundant expression of polycystin-1, poly-

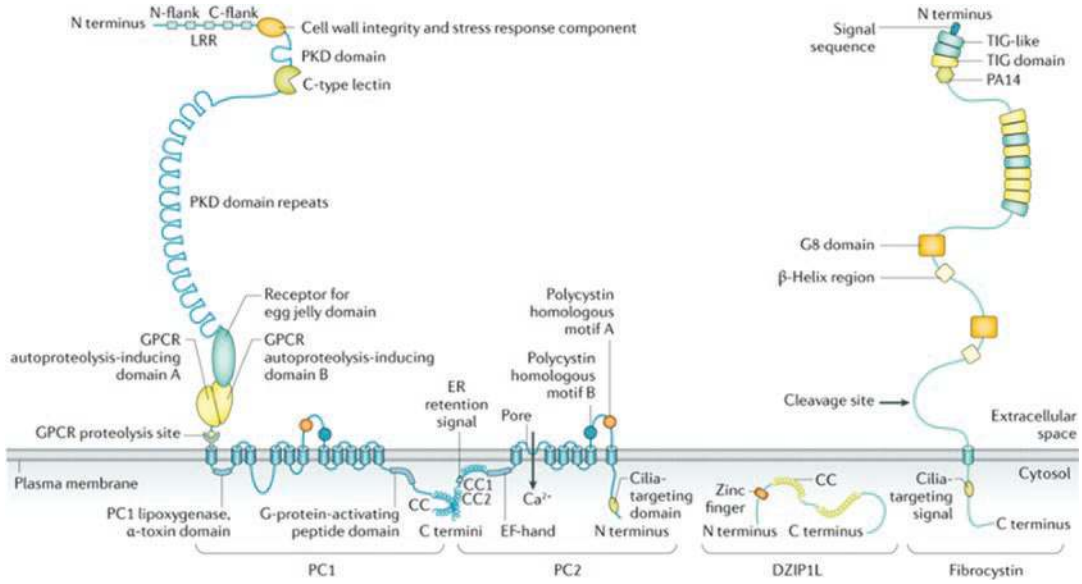

Fig. 10.2 Structures of polycystin-1, polycystin-2, polyductin/fibrocystin and DZIP1L. (From Bergmann et al. [1] with permission)

cystin-2 and the ARPKD protein fibrocystin among others, which may point to a role in paracrine signalling [86].

PKD1/*PKD2* Variant Spectrum and Routine Diagnostic Testing

Genotype-Phenotype Correlations

The wide range of age at attainment of ESKD observed within families illustrates the limitations of simple genotype-phenotype correlation analysis. There is no evidence for any sex influence in *PKD1*, however, females affected by *PKD2* were found to have a significantly longer median survival (71.0 vs. 67.3 years) than males. Another study corroborated these findings by a later mean age of onset of ESKD (76.0 vs. 68.1 years) in *PKD2* females [87, 88].

While no genotype-phenotype correlations have been identified for *PKD2* [8, 89], certain associations have been established in *PKD1*. Patients with a truncating variant have a more severe course than patients carrying a missense variant [90, 91]. *PKD1* missense variants however still go along with a more severe phenotype than *PKD2* variants. In addition, the presence of variants in multiple PKD genes can result in a more severe phenotype [92]. These patients were found to carry variants in PKD genes including *HNF1B* or a variant *in trans* affecting the other *PKD1* allele in addition to the expected germline variant [92]. However, this mechanism is unlikely to explain all cases with early-onset ADPKD. Variants 5′ to the median are associated with a slightly earlier age at onset of ESKD (53 vs. 56 years) [93]. Moreover, the median position of the *PKD1* variant was found to be located further 5′ in families with a vascular phenotype of intracranial aneurysms and subarachnoid haemorrhage [94]. At the population level phenotype findings do predict eGFR endpoints and ESKD, with genotype improving the predictive value of imaging findings and vice versa [95]. However, for genetic counselling and the prediction of the outcome of an individual patient, these genotype-phenotype correlations are only of limited value [96].

Data on families with early-manifesting offspring support a common familial modifying background for early and severe disease expression, but the underlying mechanisms are still controversial and may include anticipation, imprinting, and the segregation of modifying genes. Segregation of modifying alleles inherited

from the unaffected parent is an intriguing possibility [97] further supported by the low incidence of *in utero* presentation of ADPKD in second degree relatives. The mechanisms underlying early-onset ADPKD still require further examination [98].

Tuberous Sclerosis Complex and Contiguous TSC2–PKD1 Gene Deletion Syndrome: Important Differential Diagnoses of Cystic Kidney Disease

Tuberous sclerosis complex (TSC) is an autosomal dominant genetic syndrome characterized by marked variable expressivity and hamartomatous lesions in the brain, heart, lung, skin and kidney. Around 90% of patients suffer from epilepsy, and half exhibit cognitive impairment, autism or other behavioural disorders. Additional clinical manifestations of TSC may include sclerotic bone lesions, renal cell carcinoma (RCC) and neuroendocrine tumours [99]. Cutaneous manifestations also frequently occur with TSC and include, for example, "white spots", facial angiofibromas and peri-/subungual fibromas. About 80–90% of TSC patients have renal manifestations by adulthood, representing the second most significant cause of morbidity and mortality in all ages combined, and the most common cause of mortality after the age of 30 years. Renal lesions in TSC consist of renal cysts, angiomyolipomas (AML), fat-poor lesions, and RCC, causing CKD. There is a clear correlation between the presence of renal abnormalities (AML and renal cysts) and age. Renal lesions are observed in 38–55% of affected children at preschool age, increasing to 75–80% at school age and reaching 86–100% in adults [100]. Renal AML develop in up to 80% of individuals with TSC and appear typically first in childhood and then tend to grow during adolescence and into adulthood. The main complication of AML is retroperitoneal hemorrhage, which can be fatal due to the associated blood loss, pain, renal insufficiency, and arterial hypertension. Approximately 35–50% of patients with TSC develop multiple renal cysts [100, 101].

The incidence of TSC is 1 in 6000–10,000 live births, and its prevalence is independent of population, ethnicity and sex. TSC is caused by germline loss-of-function variants in *TSC1* (OMIM 605284; located on chromosome 9q34) or *TSC2* (OMIM 191092; located on chromosome 16p13.3), genes that encode hamartin and tuberin, respectively [101]. In the majority of patients, variants in these two genes arise *de novo*, however, the patients themselves who carry a pathogenic *de novo* variant in *TSC1* or *TSC2* bear a 50% risk to transmit the variant to their offspring. The two proteins hamartin and tuberin form a complex that negatively regulates mechanistic target of rapamycin (mTOR) complex 1 (mTORC1), a master regulator of cellular biosynthesis. Loss of the hamartin–tuberin complex results in aberrant activation of mTORC1, which promotes cell proliferation and differentiation. TSC-related cysts are thought to arise as a result of a second-hit variant in *TSC1* or *TSC2* in the renal epithelium, although genetic studies have yet to confirm this hypothesis [102].

A subset of patients carries a deletion encompassing the adjacent *TSC2* and *PKD1* genes (OMIM 600273, on chromosome 16p13) ("contiguous *TSC2–PKD1* gene deletion syndrome"). This disease was first reported by Brook–Carter et al. in 1994 with a variety of phenotypes dominated by severe, very early-onset of ADPKD and occurs in ~2–5% of TSC patients, resulting in significant kidney insufficiency already from childhood [102, 103]. Data on children diagnosed with the contiguous gene syndrome (*TSC2-PKD1*) and their long-term out-

come are scarce and currently no data on the epidemiology nor recommendations for the diagnostics, follow-up and treatment of *TSC2-PKD1* are available. The global ADPedKD initiative (www.ADPedKD.org) aims to remedy this paucity of information by collecting information on this subgroup [104].

The expansion of knowledge of the pathogenesis of TSC and the identification of the *TSC1* and *TSC2* genes and their proteins, the hamartin–tuberin complex led to the approval of mTORC1 inhibitors (also termed rapalogues), such as sirolimus and everolimus, for the treatment of the progression of subependymal giant cell astrocytomas, angiomyolipomas, skin lesions, epilepsy and lymphangioleiomyomatosis. In contrast, the efficacy of these agents in the treatment of TSC-associated renal cystic disease has not yet been fully evaluated [102].

Autosomal Recessive Polycystic Kidney Disease (ARPKD)

Epidemiology and Morphology

ARPKD is much rarer than its dominant counterpart with a proposed incidence among Caucasians of about 1 in 20,000 live births corresponding to a carrier frequency of approximately 1:70 in non-isolated populations [1, 105]. The exact incidence is unknown since published studies vary in the cohorts of patients examined (e.g., autopsied patients vs. moderately affected patients followed by pediatricians), and some severely affected babies may die perinatally without a definitive diagnosis. Isolated populations may have a higher prevalence. A recent study calculated an estimated annualized incidence of ARPKD in the USA to be 1:26,485 live births [106].

Macroscopically, the cut surface of ARPKD kidneys demonstrates the cortical extension of fusiform or cylindrical spaces arranged radially throughout the kidney parenchyma from medulla to cortex (Fig. 10.1). Histologic changes in ARPKD can vary depending on the age of presentation and the extent of cystic involvement. Invariable histological manifestations are fusiform dilations of renal collecting ducts and distal tubuli lined by columnar or cuboidal epithelium that usually remain in contact with the urinary system (unlike ADPKD), whereas glomerular cysts or dysplastic elements (e.g., cartilage, etc.) are usually not evident in ARPKD kidneys (Fig. 10.3). During early fetal development, a transient phase of proximal tubular cyst formation has been identified that can also be observed in various mouse models but is largely absent by birth [1, 107, 108]. With advancing clinical course and development of larger kidney cysts accompanied by interstitial fibrosis, ARPKD kidney structure may increasingly resemble the pattern observed in ADPKD.

Liver changes are obligatory for ARPKD and characterized by dysgenesis of the hepatic portal triad attributable to defective remodelling of the ductal plate with hyperplastic biliary ducts and congenital hepatic fibrosis (CHF) (Fig. 10.4). These hepatobiliary changes, subsumed as ductal plate malformation (DPM), are present from early embryonic development (first trimester) on and lead to progressive portal fibrosis [109]. At later stages, fibrous septa may link different portal tracts by intersecting the hepatic parenchyma often leading to portal hypertension. However, the remaining liver parenchyma usually develops normally and hepatocellular function initially often remains stable [110, 111]. As discussed for ADPKD, liver cysts usually arise from DPM and biliary ectasia, with transitions to extensive dilations of both intra- and extrahepatic bile ducts resembling Caroli's disease/syndrome.

Although ARPKD can be reliably diagnosed pathoanatomically, histology has lost relevance for daily clinical work with the increasing availability of genetic workup [11, 112, 113].

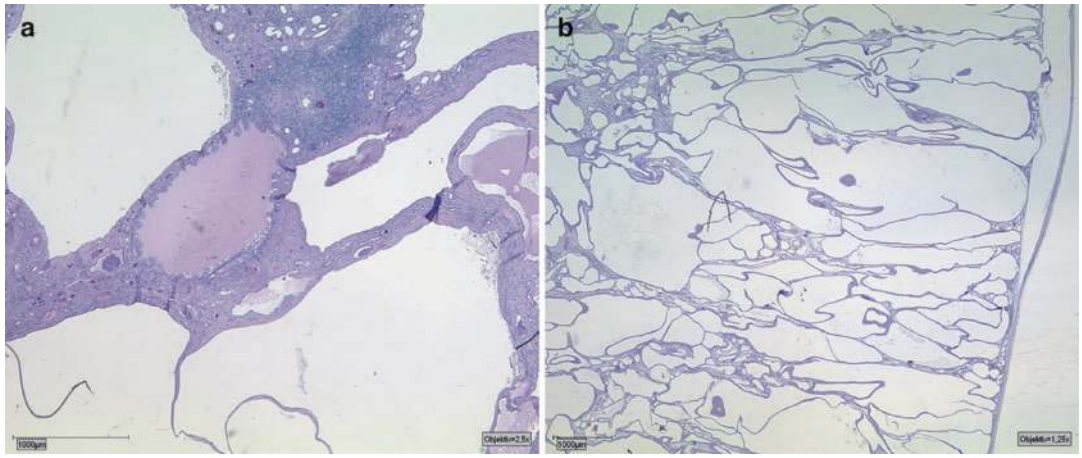

Fig. 10.3 Histological findings in ADPKD (**a**) and ARPKD (**b**) kidneys. ADPKD kidneys show a higher degree of tubuolinterstitial fibrosis. Fusiform dilations of renal collecting ducts and distal tubuli lined by columnar or cuboidal epithelium can be observed in ARPKD. These dilated collecting ducts run perpendicular to the renal capsule

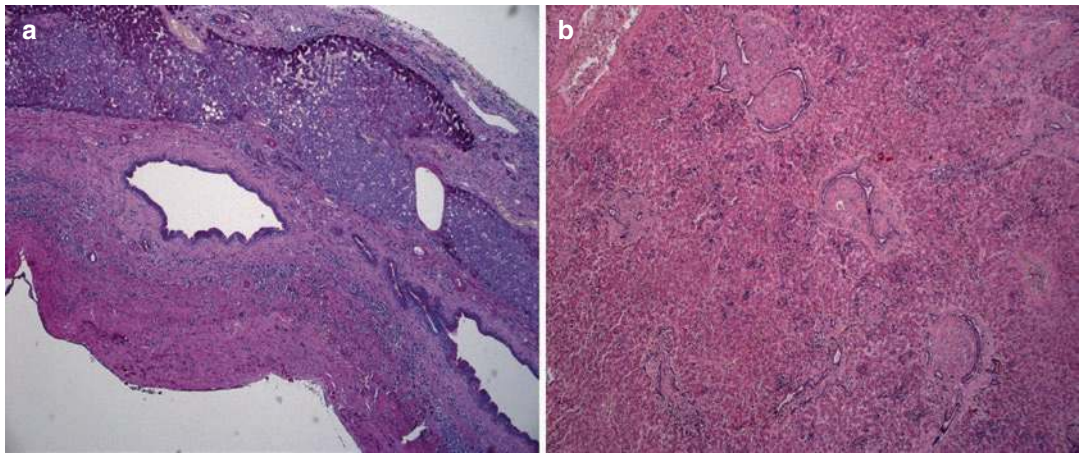

Fig. 10.4 Histological liver findings. Hepatic cysts (**a**) and the obligatory hepatobiliary changes in ARPKD subsumed as ductal plate malformation (DPM, **b**) characterized by dysgenesis of the hepatic portal triad with hyperplastic biliary ducts and congenital hepatic fibrosis (CHF)

Clinical Course and Prenatal Diagnosis

ARPKD is typically an infantile disease characterized by hepatorenal fibrocystic changes. Patients frequently present with pre- or perinatal detection of massively enlarged kidneys (Fig. 10.1, Table 10.2). Parents are typically not affected. In severely affected fetuses, oligo- or anhydramnios may develop that can result in pulmonary hypoplasia with severe perinatal respiratory disease. Despite dramatic advances in neonatal and intensive care over the past decades, the short-term mortality of ARPKD remains substantial. In less-severely affected children, progression of CKD is slow, resulting in an overall need for KRT in about 40–50% of patients in young adulthood [3, 114]. There is obligatory hepatic involvement in ARPKD resulting in portal hypertension and a risk of cholangitis.

Table 10.2 Clinical manifestations of ARPKD and ADPKD

	ARPKD	ADPKD
Incidence	1:20,000	1:500–1:1000
Macroscopic renal findings	Symmetrical, massively enlarged, reniform kidneys	Symmetrical, enlarged, reniform kidneys
Localization of renal cysts	Mainly dilated collecting ducts and distal tubuli	Cysts derived from all parts of nephron
Ultrasound and diameter of renal cysts	Increased echogenicity of renal parenchyma. "Salt-and-pepper"-pattern. Small, sometimes invisible cysts (<2 mm). More ADPKD-like pattern with avancing age	Cysts of different sizes in cortex and medulla. Usually several large cysts
Hepatic pathology	Mandatory: Ductal plate malformation/ congenital hepatic fibrosis with hyperplastic biliary ducts and portal fibrosis (may impress as Caroli syndrome)	"Liver cysts". Common in adults, rare in children. Occasionally ductal plate malformation/congenital hepatic fibrosis
Associated anomalies	Lung hypoplasia. Rarely pancreatic cysts. Single case reports of intracranial aneurysms	Pancreatic cysts and/or cysts in other epithelial organs. Familiarly clustered intracranial aneurysms, abdominal aorta aneurysms. Diverticula. Hernia. Bronchiectasis
Main clinical manifestations	Neonatal respiratory distress/failure due to pulmonary hypoplasia. Renal insufficiency. Portal hypertension. Hyponatremia. Hypertension	Arterial hypertension. Proteinuria. Hematuria. Arterial hypertension. Renal insufficiency. Pain
Risk for siblings	25%	50% (except in rare cases of spontaneous mutation with virtually no risk)
Risk for own children	<1% (unless unaffected parent is related to affected partner, or ARPKD is known in the unaffected partner's family)	50% (also for patients with spontaneous mutations)
Manifestation in affected family members	About 20% gross intrafamilial variability	Often similar within the same family
Parental kidneys	No alterations	Usually one affected parent (unless parents are <30 years or in case of spontaneous mutation)
Prognosis	Substantial mortality in patients with neonatal respiratory distress. Severe complications due to portal hypertension	Median age of end stage renal disease: 58.1 years (PKD1) vs. 79.9 years (PKD2)

Overall, the clinical spectrum is variable [115]. Notably, early studies differed widely by their selection criteria and their mode of data analysis, thus hampering direct comparison. Longitudinal registry studies with detailed characterization of patient courses have recently been established and provided important insights [106, 116]. Treatment in ARPKD remains largely symptomatic and opinion-based, although first consensus expert recommendations have been established [112].

Diagnosis by Imaging

Ultrasound remains the method of choice to diagnose children with ARPKD. Bilateral large and hyperechogenic kidneys with poor corticomedullary differentiation are the typical finding. Cysts are usually fusiform and tiny (<2 mm in diameter) and may impose as a 'pepper-salt' pattern on ultrasound. Macrocysts are uncommon in small infants, although they may be observed in advanced disease stages when ARPKD and ADPKD may become hard to differentiate by their sonographic appearance [7, 117–119]. In a large collection of ARPKD patients, 92% of ARPKD patients had a kidney length at or above the 97th centile for age [120]. In no case the kidney size was decreased and SD scores ranged from 0 to 17. In contrast to ADPKD, clear correlations were neither observed between kidney

length and kidney function nor between kidney length and duration of the disease. Various studies have found a relative decrease of kidney length during the course of the disease but numbers overall remain small and methods to quantify and standardize kidney size differed [121–124]. A recent study on 456 ARPKD patients from the international ARPKD registry study ARegPKD (www.ARegPKD.org) confirmed this finding but also revealed that height-adjusted estimated TKV remained rather stable over time [125]. Overall, there was an inverse relationship of height-adjusted estimated TKV with kidney function but with substantial variability. However, there was a clear correlation of early height-adjusted TKV (in the first 18 months) with poor kidney prognosis in childhood and adolescence (94% 10-year kidney survival for lowest quartile vs. 20% for highest quartile; Fig. 10.5) [125].

Typical ultrasound findings of the liver and portal hypertension in ARPKD include hepatomegaly, increased liver echogenicity, inhomogeneous liver parenchyma, liver cysts and dilated bile ducts, enlarged left liver lobes and splenomegaly [3, 111]. Some studies suggest that liver elastography, either by, e.g. magnet resonance techniques or by ultrasound Acoustic Radiation Force Impulse especially of the left liver lobe may be helpful in identifying liver fibrosis in patients with ARPKD [126–129]. In one cross-sectional study liver magnetic resonance elastography and ultrasound elastography measurement were strongly correlated and magnetic resonance elastography showed 78% sensitivity and 93% specificity to distinguish ARPKD and control groups at a proposed cut-off of 2.48 kPa [128]. Longitudinal data will be required to evaluate the prognostic value of these measurements for liver outcome.

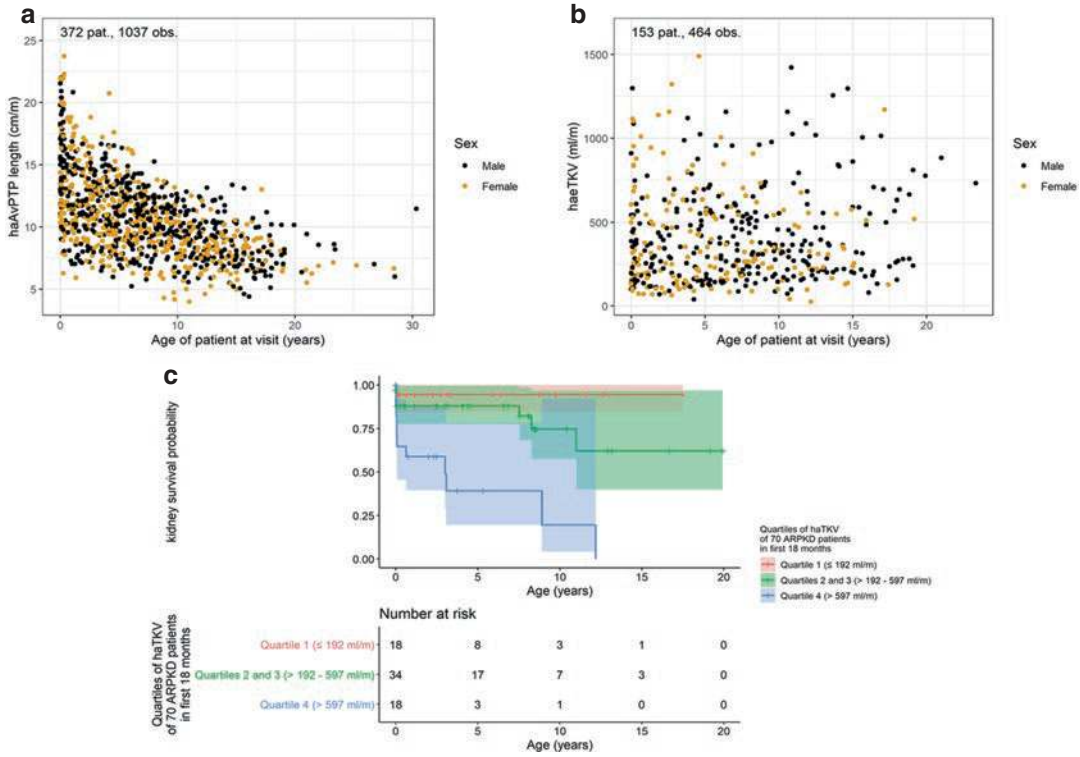

Fig. 10.5 Development of height-adjusted pole-to-pole length (**a**) and height-adjusted total kidney volume (**b**) in relation to age and kidney survival in patients in the different quartiles of height-adjusted total kidney volume (**c**). (Modified from [125])

Perinatal Disease and Mortality

Overall, the majority of cases are identified late in pregnancy or at birth. As many as 30% of affected neonates have been reported to die shortly after birth from respiratory insufficiency. Early detection of oligohydramnios seems to be associated with worse outcome [130]. In severe cases fetuses may display a "Potter" oligohydramnios phenotype with pulmonary hypoplasia (Fig. 10.6), a characteristic facies, and contracted limbs with club feet. A study performed from 2010 to 2014 in the ultrasound estimated neonatal survival to be almost 80% [106]. Advances in neonatal intensive care and improvements in kidney replacement therapies have increased the survival rates of ARPKD patients, with most of them reaching adult age. In a large study of almost 200 ARPKD patients with known *PKHD1* variant status, survival rates among those patients who survived the first month of life were 94% at 5 years and 92% at 10 years of age [120]. Kidney failure is rarely a cause of neonatal demise. In non-oliguric ARPKD neonates hyponatremia, considered to be related to defective urine concentration, is often present in the newborn period, but this complication usually resolves over time [4, 120, 131].

Kidney Disease

In a recent European study on 304 patients with ARPKD KRT was required in 25–30% of patients by the age of 15 years [114]. In another analysis 40% of young adult patients with ARPKD were on KRT [3].

Several antenatal and perinatal risk factors for dialysis dependency in early life have been identified. The presence of oligohydramnios or anhydramnios, prenatal kidney enlargement, a low Apgar score, and the need for postnatal breathing support were independently associated with an increased risk of requiring chronic dialysis [132]. The likelihood of early dialysis varied from 1.5% for patients without prenatal sonographic anomalies to 32% in patients with documented oligohydramnios or anhydramnios, kidney cysts, and enlarged kidneys (Table 10.3).

CKD with an eGFR <75% of age-adjusted normal ranges was first detected at a mean age of 4 years in a previous survey among pediatric nephrology units [120]. Infants with ARPKD may have a transient improvement in their glomerular filtration rate (GFR) due to kidney maturation in the first months of life. Subsequently, a progressive but highly variable decrease in kidney function occurs. In a small cohort of children with

Oligo/anhydramnios and enlarged kidneys and renal cysts	0.323 (0.222–0.445)			

ARPKD the annual GFR decline was 1.4 mL/min/1.73 m^2 (−6%) and rates of GFR decline in ARPKD patients were not significantly different from children with other causes of CKD [133].

In a cohort in the US, patients with perinatal presentation showed worse kidney follow-up than those with non-perinatal presentation [121]. While 25% of the perinatally symptomatic patients required kidney replacement therapy by the age of 11 years, 25% of the non-perinatal patients required kidney transplantation by age 32 years. Also, corticomedullary involvement on high resolution ultrasound was associated with worse kidney function in comparison with medullary involvement only in this specific cohort. Kidney volume correlated inversely with function, although with wide variability [121].

Liver Disease

In keeping with the generally prolonged survival in ARPKD, for many patients the hepatobiliary complications come to dominate the clinical picture [3, 124]. Interdisciplinary management by pediatric nephrologists and hepatologists is essential for optimal management of ARPKD from early life onward [4].

While hepatocellular function is usually preserved, these individuals develop sequelae of portal hypertension and may present with hematemesis or melena due to bleeding oesophageal varices and/or hypersplenism with consequent pancytopenia. Typical hepatic manifestations usually present later than classic kidney involvement [3, 110, 131], although complications of portal hypertension may occur early in life [134].

A serious, potentially lethal complication in ARPKD especially after kidney transplantation is ascending suppurative cholangitis that may cause fulminant hepatic failure [135–137]. Cholangitis always requires diligent evaluation with aggressive antimicrobial treatment. Noteworthy, ARPKD patients may not display the full picture of clinical and laboratory findings of cholangitis; thus, every patient with unexplained recurrent sepsis, particularly with gram-negative organisms, should be critically evaluated for this diagnosis [110, 138, 139].

A recent study on 49 young adults with ARPKD characterized the clinical phenotype in this age group and identified prominent liver involvement. ARPKD should also be considered as a differential diagnosis in adults with cystic kidney disease [3].

Adult ARPKD patients beyond the age of 40 years may have a slightly increased risk to develop hepatic tumors, especially cholangiocarcinoma [140, 141].

Additional Extra-Renal Manifestations

Studies have also described additional extra-renal clinical aspects. Arterial hypertension is a very common finding, affects up to 80% of children with ARPKD and usually develops in the first few months of life (Table 10.2). Arterial hypertension may be very pronounced in ARPKD. It was recently shown that children with ARPKD show high rates of abnormal left ventricular geometry with systolic mechanical dysfunction [142].

There have been various reports of patients with both intracranial and extracranial aneurysms [143].

Neurocognitive function and growth in ARPKD children appear to be comparable to children with other causes of CKD [144, 145].

Pulmonary tests in the follow-up of a subgroup were within normal references suggesting good long-term pulmonary outcome [146].

Genetics

PKHD1 is the major, but not the only gene for ARPKD. Variants in an increasing number of other genes such as *PKD1, PKD2, HNF1B, DZIP1L, CYS1* can mimic the disease and lead to an ARPKD-like phenotype [64]. *PKHD1* variant analysis is characterized by vast allelic heterogeneity and a huge number of private variants and missense changes.

PKHD1 Gene and Polyductin/ Fibrocystin Protein

The *PKHD1* gene is highly expressed in fetal and adult kidney, at lower levels in liver, and weakly in other tissues including pancreas, arterial walls and the lung [147]. *PKHD1* is amongst the largest disease genes in the human genome, extending over a genomic segment of at least 470 kb and including a minimum of 86 exons. *PKHD1* undergoes a complex and extensive pattern of alternative splicing, generating transcripts of highly variable size. The longest *PKHD1* transcript contains 67 exons encoding a protein of 4074 amino acids.

The predicted full-length protein (termed fibrocystin or polyductin) represents an integral membrane protein with a single transmembrane (TM)-spanning segment, and a short cytoplasmic C-terminal tail (Fig. 10.7). Based on the structural features of the deduced protein and on the human ARPKD phenotype, fibrocystin might be involved in cellular adhesion, repulsion and proliferation. In addition, the domain and structural analyses suggest that the potential *PKHD1* gene products may be involved in intercellular signalling and function as receptor, ligand and/or membrane-associated enzyme [1].

In common with most other cystoproteins, fibrocystin has been identified at primary cilia with concentration in the basal body area [148–151]. As part of acquisition of epithelial polarity during kidney development, fibrocystin becomes localized to the apical zone of nephron precursor cells and subsequently to the basal bodies at the origin of primary cilia in fully differentiated epithelial cells. Its peculiar subcellular localization and suggested proteins interactions point to a role of fibrocystin in centrosomal, mitochondrial or cilia-associated function. There is evidence for overlapping functions with, e.g. polycystin-1 [1, 152–154]. In addition, there is preliminary evidence of fibrocystin isoproteins which may be secreted in exosomes and undergo posttranslational processing [86, 152, 155, 156].

The number of alternative *PKHD1* transcripts that are actually translated into protein is as yet unknown. The distribution of variants over the entire *PKHD1* gene suggests that the longest transcript is necessary for proper fibrocystin function in kidney and liver. Thus, it might be proposed that a critical amount of the full-length protein is required for normal function.

Genotype-Phenotype Correlations

The analysis of genotype-phenotype correlations for *PKHD1* is hampered by multiple allelism and the high rate of different compound heterozygotes. Until recently, genotype-phenotype correlations were largely limited to the type (truncating/non-truncating) and allelic distribution (homozygous/compound heterozygous) of the variants.

Almost all patients carrying two truncating variants display a very severe phenotype although more recently it was shown that some patients may survive [114, 132, 157, 158]. Patients with at least one missense variant tend to be less severely affected and are more likely to survive the neonatal period. However, missense changes can clinically impress as severe as truncating variants. No significant clinical differences could be observed between patients with two missense variants and those patients harboring a truncating variant *in trans*; thus, the milder variant obviously defines the phenotype. Loss of function probably explains the rather uniform phenotype and early demise of many patients with two null alleles. Phenotypic diversity also reflects the variable extent to which different *PKHD1* missense variants might compromise the function and/or abundance of the mutant protein. Complex transcriptional profiles may play a further role in defining the patient's phenotype [158, 159].

Recently, the localization of a specific missense variant was shown to be of additional relevance for the phenotype. In a cohort of 304 patients, patients with two missense variants affecting amino acids 709-1837 of fibrocystin or a missense variant in this region and a null variant less frequently developed chronic kidney failure than other subgroups. Missense variants affecting amino acids 1838-2624 showed better hepatic outcome. Variants affecting amino acids 2625-4074 of fibrocystin were associated with a more severe hepatic phenotype [114].

The aspect of renal-hepatobiliary morbidity patterns in ARPKD has repetitively been discussed [111, 120, 131]. Many patients show uniform disease progression, but individual ARPKD patients present with an organ-specific phenotype. The observations that different variant localizations are associated with specific kidney and liver disease courses opens novel paths to understand the underlying pathophysiology [114].

Phenotypes cannot yet be fully explained on the basis of the *PKHD1* genotype but likely depend on mutational load for an individual patient, epigenetic factors (e.g., alternative splicing), and environmental influences [1]. Such modifiers will probably have their greatest impact on the phenotype in the setting of hypomorphic missense changes and may explain some of the clinical variability.

Phenotypic Variability Among Affected Siblings

For about 20% of pedigrees gross intrafamilial phenotypic variability with peri-/neonatal demise in one and survival into childhood or even adulthood in another affected sibling have been described [160]. An even higher proportion of 20 out of 48 sibships (42%) was observed among families with at least one neonatal survivor per family [120]. Likewise, data from the ARegPKD dataset suggest a rather limited variability of kidney function decline and hepatic symptoms in the clinical courses of patients surviving the neonatal period. With regards to genetic counselling this rate is alarming [161]. Of course, phenotype categorization into 'severe' and 'moderate' is a simplified and artificial view given the considerably better prognosis for patients surviving the most critical neonatal period. Also, the survival chance of an affected neonate might depend on available intensive care facilities and parental awareness of ARPKD risk. Hence, caution should be warranted in predicting the clinical outcome of a further affected child.

Prenatal Diagnosis

As previously pointed out the diagnosis is frequently identified antenatally. In view of the recurrence risk of 25%, the oftentimes devastating course of early manifestations of ARPKD and a usually similar clinical course among affected siblings, many parents of ARPKD children seek early and reliable prenatal diagnosis (PND) to guide future family planning. Frequently, ARPKD patients are identified by ultrasound only late in pregnancy or at birth. Therefore, an early and reliable PND for ARPKD in "at risk" families is feasible by molecular genetic analysis [147, 162, 163] as the basis for PND and genetic counselling according to local regulations.

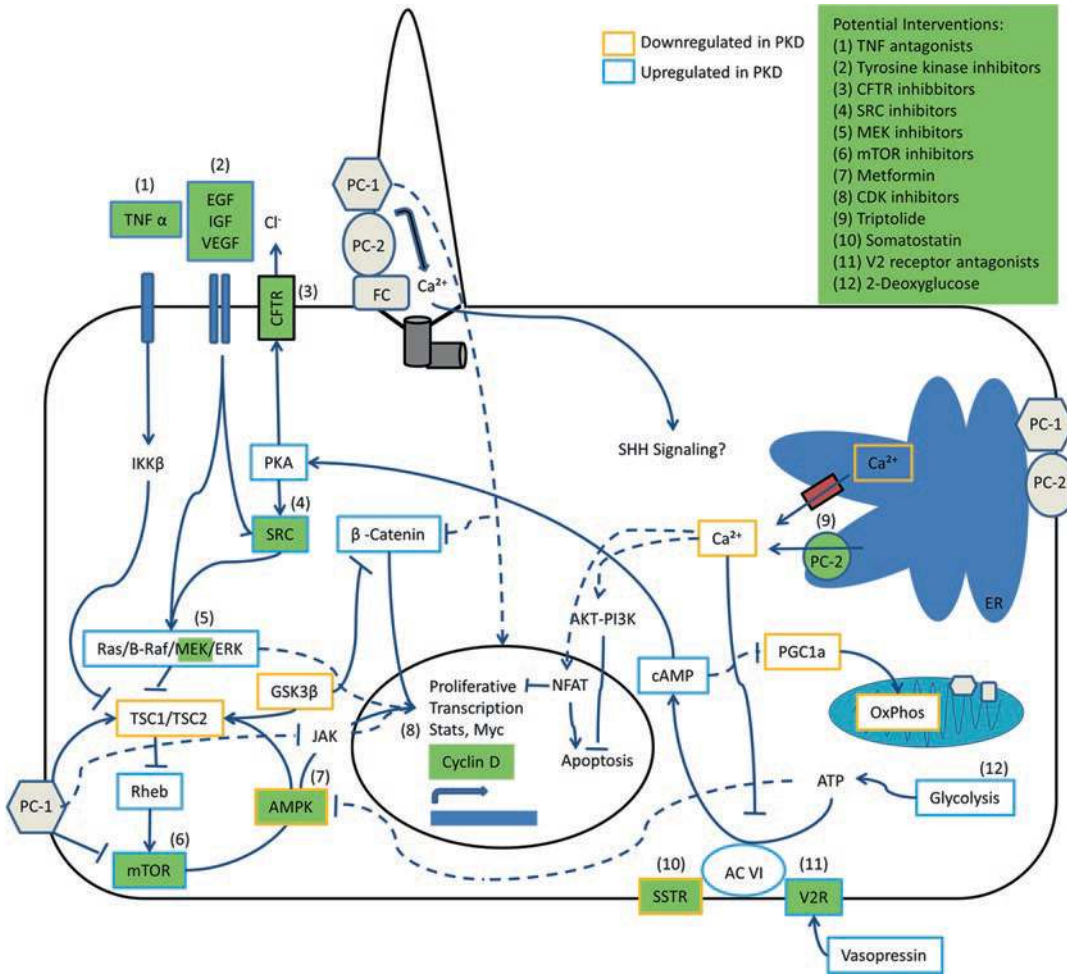

Fig. 10.7 Schematic presentation of polycystin-associated signalling pathways and potential pharmacological targets. Polycystin-1 (PC-1), polycystin-2 (PC-2), and fibrocystin/polyductin (FC) are located in primary cilia. PC2 is also located in the endoplasmic reticulum. The ciliary polycystin complex regulates ciliary calcium signals that may lead to calcium-induced calcium release from the endoplasmic reticulum. Reduction of calcium enhances cAMP accumulation, that is furthermore supported by activation of V2-receptors (V2R) but may be inhibited by activation of the somatostatin receptor (SSTR). cAMP stimulates chloride-driven fluid secretion. In PKD cAMP also stimulates cell proliferation in an src-, Ras-, and B-raf–dependent manner. Finally, Mammalian target of rapamycin (mTOR) is activated in cyst-lining PKD epithelia. *AC-VI* adenylyl cyclase type VI, *ATP* adenosine triphosphate, *CFTR* cystic fibrosis transmembrane conductance regulator, *ER* endoplasmic reticulum, *ERK* extracellular signal–regulated kinase, *MEK* mitogen-activated protein kinase kinase, *PKA* protein kinase A, *EGF* epidermal growth factor, *IGF* insulin-like growth factors, *VEGF* vascular endothelial growth factor, *CFTR* cystic fibrosis transmembrane conductance regulator, *AMPK* AMP-activated protein kinase, *SHH* sonic hedgehog signaling

Therapeutic Management

Currently, there is no curative treatment option for patients affected by PKDs to ameliorate or even regress the clinical course. However, given the insights into cell biology and dysregulated intracellular signaling pathways in different PKDs, novel treatment approaches in ADPKD have been suggested [164]. Using different rodent models, various research groups have published

promising data on treatment of PKD. Interestingly, the severity and dynamics of cystic kidney disease in orthologous mouse models varies widely. Choosing preclinical models that mimic human disease is utmost relevant when testing potential therapeutic approaches [165]. Multiple therapeutic approaches have been identified in preclinical models. As a consequence, several clinical trial programs for ADPKD have been established. Recent work summarizes the pathophysiological considerations underlying those novel treatment approaches [1] and current state-of-the-art management in adult patients with ADPKD [164]. We will therefore only provide a brief overview here, focusing on pediatric aspects of available and emerging therapeutic options.

Lifestyle Measures, Pediatric Treatment of CKD and Treatment of Co-morbidities

The basis for treatment of PKD and CKD lies in the strict application of symptomatic measures [164]. **Dietary sodium restriction, sufficient physical activity and normalization of the body mass index** should be implemented as initial approach for patients diagnosed or at-risk for ADPKD. Based on the role of vasopressin in ADPKD, **increased water intake** has been suggested in order to suppress endogenous vasopressin concentration and thereby reduce kidney cyst growth targeting a goal urine osmolality below 280 mOsm/kg H_2O [166]. Ongoing controlled trials to evaluate the impact of high water intake on TKV are in progress [167]. In addition, high fluid intake might also be generally beneficial to reduce the risk of nephrolithiasis and UTI in ADPKD. Low salt intake and maintenance of a normal body mass index would be also recommended in view of the increased risk of hypertension and cardiovascular comorbidities in children with ADPKD [14, 164]. Last but not least, **avoidance of smoking and potentially nephrotoxic drugs** including nonsteroidal anti-inflammatory drugs is also appropriate. Extra-renal co-morbidities require adequate treatment. For this chapter we will focus on aspects concerning liver disease.

Blood Pressure Control

Blood pressure control is essential in PKD patients. While blood pressure control is a critical aspect of CKD management in general in both children and adults, hypertension is a key modifiable risk factor in children with ADPKD [14]. Increased TKV and fractional cyst volume is associated with hypertension and decreased eGFR over time [27, 28]. When lifestyle measures remain insufficient, the first line pharmacologic treatment will be the inhibition of RAAS.

The HALT-PKD trials compared the combination of ACE inhibition (ACEI) with an angiotensin receptor blocker to ACEI alone in adult patients with an eGFR of either >60 or 25–60 mL/min/1.73 m^2 as well as standard blood pressure with low blood pressure targets in early-stage patients. Altogether more than 1000 ADPKD patients were enrolled [168, 169]. In these trials rigorous blood pressure control showed benefits over standard blood pressure control in early ADPKD in terms of a reduced increase in total kidney volume, a greater decline in left ventricular mass index and less albuminuria. eGFR was not different among the groups. The international consensus guidelines for pediatric ADPKD recommend at least annual blood pressure measurements for children at-risk of or diagnosed with ADPKD, with a preference for periodic 24-h ambulatory blood pressure monitoring due to the increased risk of masked hypertension. Blood pressure should be maintained below the 75th percentile (or <125/72 mmHg from age 16 years) [14]. It was suggested that lowering blood pressure even below the 50th percentile (or <120/70 mmHg from age 16 years) might provide additional long-term benefit in hypertensive children with ADPKD. Targeting the 50th–75th percentile blood pressure would be the ideal goals for hypertensive children with ADPKD [14, 16].

While formal recommendations for children with ARPKD are lacking, it is reasonable to apply the same treatment targets in the ARPKD population. Hypertension can be difficult to control in ARPKD children and may require multi-drug treatment. Hypertension needs early and aggressive treatment with careful blood pres-

sure monitoring to prevent sequelae of hypertension (e.g., cardiac hypertrophy, congestive heart failure) and deterioration of kidney function [110]. The pathophysiology of hypertension in ARPKD is not clearly understood but may involve dysregulation of renal sodium transport and activation of the RAS [170, 171] leading to increased intravascular volume [172]. It is therefore important to point out that hyponatremia in ARPKD can be considered to be an effect of excess water retention rather than sodium loss. Thus, general principles of handling hyponatremia apply. Feeding may need to be concentrated to minimize fluid intake [11, 112]. Sodium supplementation may increase hypertension. RAS antagonists (ACE inhibitors or AT1 receptor blockers) are regarded the treatment of choice [112]. Moreover, it has been proposed that the epithelial sodium channel blocker amiloride can be used to decrease intracellular cAMP concentrations that may result in Pseudo-Liddle syndrome [173].

Management of CKD and ESKD in Pediatric PKD Patients

The management of children with PKD with declining kidney function should follow the standard guidelines established for chronic kidney failure in other pediatric patients. Both peritoneal dialysis (PD) and hemodialysis are successfully used in ARPKD neonates and infants. PD has been recommended as the chronic modality of choice for infants with ESKD as nutrition can be optimized and vascular access can be preserved for later use [174]. Maintenance PD can be used in young ARPKD children with only minor modifications compared to other inborn kidney diseases [175]. Kidney transplantation is the treatment of choice for individuals with ESKD. In case of massively enlarged kidneys, native nephrectomies may be warranted to allow allograft placement.

ARPKD is one of the two major indications for combined liver and kidney transplantation (CLKTx) during childhood, next to primary hyperoxaluria that is discussed in detail elsewhere in this book [176, 177]. The best timing and strategy for combined transplantation is still a matter of debate and usually requires individualized decision-making. Recurrent cholangitis and evidence of severe portal hypertension may be indications for combined liver and kidney transplantation in ARPKD [137, 140, 176, 178]. Organ survival after CLKTx in ARPKD is good, but data from the ESPN-ERA/EDTA registry suggested higher mortality in ARPKD patients undergoing CLKTx in comparison to patients undergoing isolated kidney transplantation [137].

Functional consequences of CKD are rarely a clinical problem in children with ADPKD. In cases with VEO-ADPKD the same general principles apply as in ARPKD and other causes of pediatric CKD.

Management of Liver Disease

Liver cysts in ADPKD only rarely result in clinical problems and complications appear much less common than complications of kidney cysts. Usually, hepatic, pancreatic, or ovarian cysts are not observed before puberty [47]. Massive liver enlargement secondary to hepatic cysts may result in disabling discomfort. These individuals may benefit from percutaneous sclerotherapy when one or a few large cysts are present. Occasionally, more aggressive surgical intervention with fenestration, partial hepatectomy or even liver transplantation may be required [179]. Furthermore, as discussed below somatostatin analogues are under investigation for hepatic cysts.

Cholangitis is a prominent co-morbidity in ARPKD and always requires diligent evaluation with aggressive antimicrobial treatment.

Primary management of variceal bleeding in ARPKD may include endoscopic approaches, such as sclerotherapy or variceal banding. In some patients, portosystemic shunting or liver-kidney transplantation (sequential or combined) can be considered as a viable therapeutic option; however, since ammonia is cleared by the kidneys, impaired kidney function in ARPKD patients makes portosystemic shunting less attractive. Transjugular intrahepatic portosystemic shunt (TIPS) has been used in pediatric patients as a feasible and effective treatment alternative for surgical shunting but hepatic encephalopathy may be a problem [180, 181].

The risk of portal hypertension in ARPKD has led to concerns about the use of gastrostomy insertions in patients with ARPKD. Yet, in an international survey amongst physicians taking care of 196 ARPKD children the benefits outweighed the complications and risks of gastrostomy insertion [182].

Management of Perinatal Disease in ARPKD

During the first days of life, the pulmonary situation is the crucial factor for the overall prognosis in ARPKD [4, 11, 112]. Perinatal treatment can be highly complex and delivery in a hospital with high expertise in neonatology and pediatric nephrology has been recommended for patients with suspected ARPKD [112]. Highly sophisticated methods of ventilation and/or surfactant application have developed in neonatal intensive care, but neonatal mortality remains substantial in severely affected children. The defined use of antenatal corticosteroids to support lung maturation in late preterms may be helpful.

Nephrectomy has been proposed for pulmonary indications, to facilitate feeding and to improve blood pressure control [183–187]. However, supportive evidence for beneficial effects of nephrectomy is very limited and very careful consideration of the potential benefits against the risk of potentially accelerated loss of kidney function and subsequent kidney replacement therapy early in life are required. Furthermore, in the ARegPKD registry study bilateral nephrectomies in the first 3 months of life were associated with severe neurological sequelae (Fig. 10.8) [188]. After unilateral nephrectomy the remaining kidney may start to grow very rapidly, thus making a second nephrectomy necessary within a short time frame. Very careful indication of nephrectomies therefore seems appropriate, especially in patients with remaining kidney function.

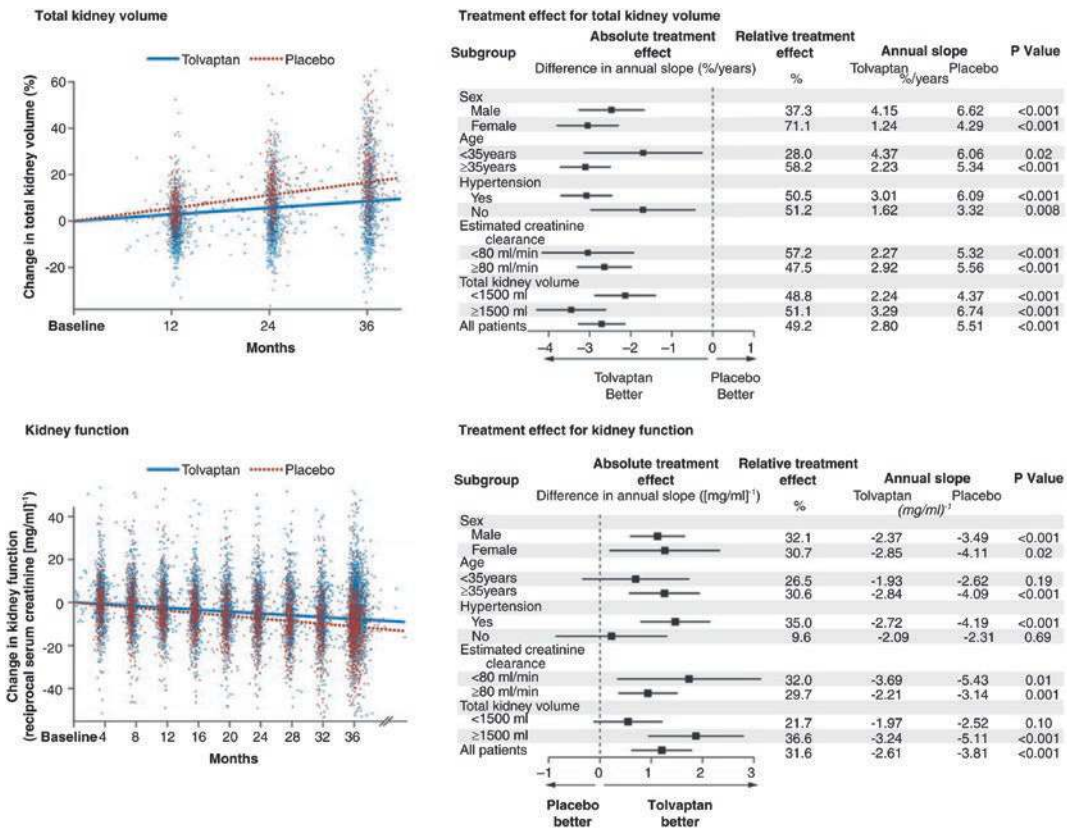

Fig. 10.8 Main results of the TEMPO 3/4 trial: Tolvaptan significantly reduced kidney growth rate and showed lower rates of renal function decline. (From Torres et al. [189], with permission)

Emerging Targeted Therapies

Vasopressin V_2 Receptor Antagonists

The rationale for the use of V2 receptor antagonists is based on the observation that tubular cells of ADPKD patients contain high cAMP concentrations and that PKD patients show high levels of circulating vasopressin. Vasopressin induces an intracellular increase of cAMP via the V2 receptor to increase fluid secretion into cysts via the CFTR channel. After promising results in preclinical studies [1], the V2 receptor antagonist tolvaptan was investigated in the TEMPO 3/4 trial (Tolvaptan Efficacy and Safety in Management of PKD and Outcomes), a large phase 3, placebo-controlled, double-blind study in 18–50-year-old patients with a GFR of >60 mL/min but very large kidneys (>750 mL) as an indicator of progressive disease. After 3 years, Tolvaptan had significantly reduced kidney growth rate (2.8%; vs. 5.5% in the control group) and shown lower rates of kidney function decline or ADPKD-related adverse events (Fig. 10.9) [189]. Later studies confirmed the long-term safety and efficacy [190] and demonstrated beneficial effects of Tolvaptan also in late-stage ADPKD [191].

A phase 3 study assessing the pharmacodynamic properties, safety and efficacy of tolvaptan over 3 years in 91 ADPKD children and adolescents has been conducted [192]. After 1 year of treatment, the mean percent increase of height-adjusted TKV from baseline in 12–17 year-old children was 2.3% for Tolvaptan and 6.1% for placebo [193]. No elevated transaminase or cases of drug-induced liver injury were reported.

The clinical overlap of ARPKD and ADPKD and ample experimental evidence suggests that Tolvaptan might also be efficacious in ARPKD. This has led to the recent initiation of a clinical trial program for Tolvaptan in children with ARPKD.

Somatostatin Analogues

Another way to decrease intracellular cAMP is the use of a long-acting analog of somatostatin. Various randomized controlled trials have been performed to evaluate somtatostatin analogues in ADPKD and ADPLD, which have recently been summarized in a systematic review and meta-analysis. The data show improvement in total liver volume but no benefit on TKV and eGFR in patients with ADPKD while there were various side effects [194]. Future work will most likely

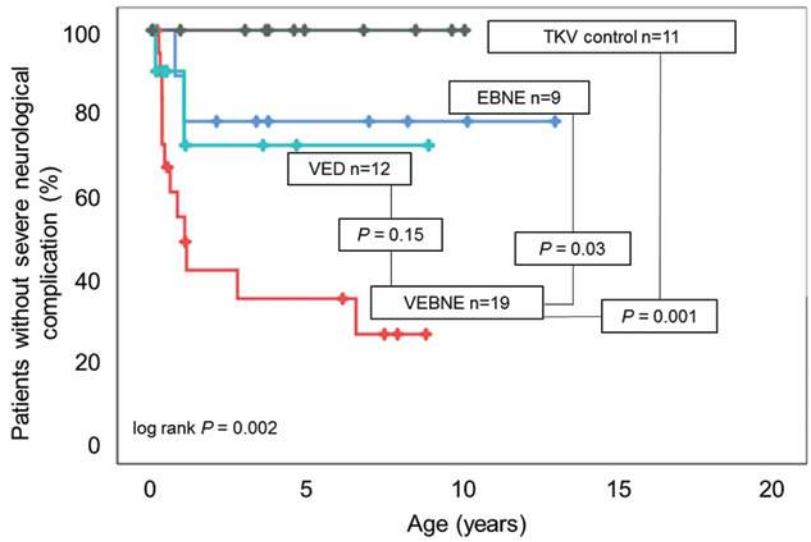

Fig. 10.9 Kaplan–Meier survival curve of ARPKD patients without severe neurological complications stratified according to nephrectomy status. Censored observations (last documented follow-up or death) are marked with a cross. P values were derived using log rank tests. EBNE early bilateral nephrectomies (second nephrectomy in months 4–15), TKV total kidney volume, VEBNE very early bilateral nephrectomies (in first 3 months), VED very early dialysis. (From [188])

focus on a potential role of somatostatin analogues for the treatment of polycystic liver disease.

mTOR Inhibition and Other Targeted Therapy of Cellular Metabolism

mTOR activation has been observed in the cyst epithelium of ADPKD kidneys. After promising results in animal models [1], different trials studied mTOR inhibition in ADPKD. The two large trials on mTOR inhibition in ADPKD did not deliver a therapeutic breakthrough [195, 196]. mTOR inhibitors might still be an option in selected patients with ADPKD or if administered in combination with other agents or in a tubule-specific way.

In addition to mTOR inhibitors, inhibition of glycolysis, activation of AMPK through Metformin, PPAR-α activation or Sirtuin inhibition are additional pharmacological strategies that are currently under investigation [85].

Dietary Intervention

Dietary interventions are an interesting emerging therapeutic strategy in addition to pharmacological approaches based on observations that PKD proteins may be involved in the regulation of cellular metabolism [85]. Moderate food or caloric restriction has shown positive effects on kidney volume in preclinical models. Importantly, obesity is a known risk factor for rapid disease progression in ADPKD. In addition to caloric restriction, time restricted feeding and ketogenic diet as well as the addition of β-hydroxybutyrate to normal chow have shown promising effects in preclinical mouse, rat and cat models of PKD [197]. Pilot clinical trials have recently been initiated.

Acknowledgments CB holds a part-time faculty appointment at the University of Freiburg in addition to his employment with the Limbach Group for which he heads and manages Limbach Genetics. His research lab receives support from the Deutsche Forschungsgemeinschaft (DFG) (BE 3910/8-1, BE 3910/9-1, and Collaborative Research Center SFB 1453—Project-ID 431984000) and the Federal Ministry of Education and Research (BMBF, 01GM1903I and 01GM1903G). 11 Nephronophthisis and Autosomal Dominant Tubulointerstitial Kidney Disease (ADTKD)

Jens König and Heymut Omran

The Nephronophthisis complex

The nephronophthisis complex comprises a clinically and genetically heterogeneous group of tubulointerstitial cystic disorders with an autosomal recessive inheritance pattern. It represents the most frequent genetic cause of end-stage kidney disease (ESKD) in children and young adults. Nephronophthisis can be accompanied by anomalies in other organs, e.g. liver, pancreas, central nervous system, eyes and bones. There are several well described complex clinical syndromes that can feature the renal picture of nephronophthisis, including Senior-Løken-syndrome, Joubert syndrome, COACH syndrome, Jeune syndrome, Sensenbrenner syndrome, Meckel-Gruber syndrome and others. Because of the extended clinical as well as genetic overlap, the term *nephronophthisis complex* has been introduced. However, phenotypic variability as well as the polygenic background complicate the timely establishment of the correct diagnosis.

Nephronophthisis

Nephronophthisis literally means "damage of the nephrons". 1951 Fanconi et al. introduced the term *familial juvenile nephronophthisis* to describe a disease characterized by autosomal recessive inheritance, a defect in urinary concentrating capacity, severe anaemia and progressive renal failure that leads to death before puberty [1, 2]. The incidence ranges from 1:1,000,000 in the US to 1:50,000 in Europe. To date, variants have been identified in 25 genes (Fig. 11.1) encoding nephrocystin proteins that localize to primary cilia, basal bodies and centrosomes. Thus, nephronophthisis (NPH) belongs to a group of rare hereditary disorders referred to as ciliopathies. Mutations in these genes lead to renal as well as extrarenal disease manifestations [3].

The clinical hallmarks of NPH are a reduced urinary concentrating capacity presenting as polyuria and polydipsia with regular fluid intake at night and slowly progressive chronic kidney failure. Other clinical manifestations comprise growth retardation, anaemia and persisting primary or secondary enuresis. However, these features are only facultative findings. Urine analyses usually do not show any characteristic abnormalities. Proteinuria and arterial hypertension are no typical findings before the onset of end-stage kidney failure. On ultrasound, patients generally show normal or small-sized kidneys with increased echogenicity and a loss of cortico-

medullary differentiation. Cysts, which are typically located at the cortico-medullary junction, often only occur late in the disease process [4] and are not an obligatory finding (Fig. 11.2). In contrast to other hereditary cystic kidney diseases such as polycystic kidney diseases (ADPKD and ARPKD), HNF1B nephropathy or Bardet-Biedl syndrome, prenatal cystic presentation is untypical and limited to infantile NPH [5]. Because of the lack of disease-specific clinical features and the slow progress, still about 15% of patients are only diagnosed when ESKD has already been reached.

In the past, kidney biopsy has been used for the diagnosis of NPH. Histology is characterized by disintegrated tubular basement membranes, tubular atrophy and cyst formation, as well as a sclerosing tubulointerstitial nephropathy accompanied by lymphocyte infiltrates [6, 7]. Since cortico-medullary cysts only occur late in the disease process [8], they are no obligatory finding and thus no hallmark of the disease. Nowadays, against the backdrop of the availability of rapid and targeted molecular genetic analysis, kidney biopsy for the diagnosis of NPH is largely obsolete and should be limited to cases in which his-

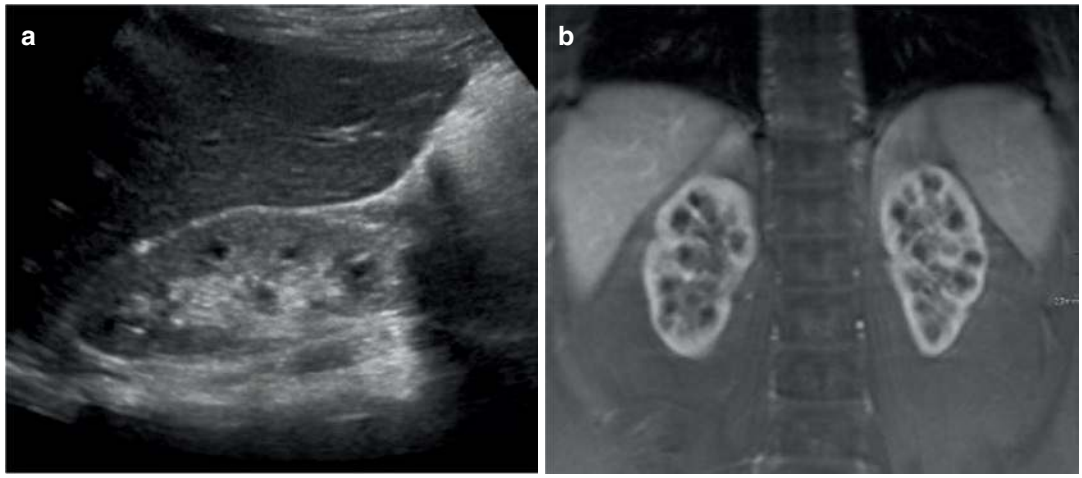

Fig. 11.2 Ultrasound (**a**) and MRI (**b**) presentation of the kidneys in a patient with classical juvenile nephronophthisis. Please note that despite the prominent cysts at the cortico-medullary junction, these are no obligatory finding

tology is needed to rule out other differential diagnoses (e.g. tubulointerstitial nephritis).

Genetics

To date, 25 genes have been identified to be associated with NPH (Fig. 11.1). Yet, about 40% of all cases still remain genetically unsolved. While *NPHP1* defects account for 20–60% of NPH cases, each of the remaining genes makes up for 1% or less of all cases [9].

Most gene products (so called nephrocystins) affected by *NPHP* gene mutations are located at the ciliary base and transition zone of primary cilia excerpting a kind of gate keeper function controlling transport processes from the cytoplasm into the cilium and vice versa [10]. Primary cilia are evolutionarily conserved, membrane-bound, microtubular projections protruding from the cell surface. They are found on virtually all cell types in the human body and play an essential role in transducing signaling information from the extracellular milieu into the cell. Only recently mutations in *NPHP1L* und *NPHP2L* have been identified, genes that encode mitochondrial rather than ciliary proteins [11].

Based on functional interaction studies, currently four distinct nephrocystin modules have been described: the NPHP 1-4-8 module, the NPHP 2-3-9-ANKS6 module, the NPHP5-6 module and the MKS module. These nephrocystin modules are related to different signaling pathways including the Wnt pathway, Hedgehog pathway, Hippo pathway, DNA damage response (DDR) pathway, mTOR pathway, the intracellular calcium and the cAMP signaling pathway [9].

Genotype-Phenotype Correlation

Depending on the onset of ESKD, three clinical subtypes of NPH have been defined: Infantile, juvenile, and adolescent NPH. The so called "classical juvenile NPH" is by far the most common entity, leading to ESKD at a median age of 13 years [4, 12]. In infantile NPH ESKD is reached very early in life (median age 8 months) whereas in adolescent forms kidney function is usually preserved until adulthood (median age 19 years).

Large homozygous deletions of approximately 290 kb involving the *NPHP1* locus on chromosome 2q12-q13 are the main genetic cause of the classical juvenile NPH accounting for up to 60% of patients. Only some patients carry point mutations or compound heterozygous variants [13, 14]. Homozygous *NPHP1* deletions have also been reported in adults who developed ESKD between 27 and 60 years of age [15].

Other genetic defects primarily associated with adolescent NPH comprise *NPHP3, NPHP4* and *NPHP9/NEK8*. While the kidney phenotype and clinical course described above is very similar for most NPH variants, this does not apply to infantile NPH, which typically already presents in utero or early infancy with enlarged cystic kidneys, arterial hypertension and ESKD before the age of 4 years. Histologically, infantile NPH differs from juvenile NPH by a cortical rather than medullary cyst location and the absence of typical tubular basement membrane changes [16]. Mutations in *NPHP2/INV* (9q22-q31) were the first molecular defects identified in infantile NPH, often associated with laterality defects like *situs inversus* and congenital heart defects [17]. Subsequently, mutations in various other genes were identified to cause infantile NPH, i.e. *NPHP3*, *NPHP12/TTC21B*, *NPHP14/ZNF423* and *NPHP18/CEP83* [9].

Detailed information about all NPH-related genes identified so far and their clinical implications is given in Table 11.1.

Life table analyses demonstrate the impact of the underlying genetic defect on renal survival. While loss-of-function mutations in *NPHP3* go along with a >50% chance of ESKD before the age of 4 years, so called hypomorphic mutations in the same gene were found to be responsible for an adolescent type of NPH. Kidney failure in the vast majority of *NPHP1* deletion carriers occurs in a narrow time slot between 7 to 16 years of age. Renal survival curves of individuals suffering from *NPHP4* variants resemble those of *NPHP1* carriers, yet with a slower progression and a fraction of 25% patients with preserved renal function at 30 years of age [4].

Extra-renal Disease Manifestations

Owing to the ubiquitous presence of primary cilia and depending on the underlying molecular defect, the clinical presentation of NPH is not necessarily limited to the kidneys but can be associated with extra-renal disease manifestations. Standardized phenotypic surveys revealed extrarenal manifestations in approx. 20–40% of affected individuals, exceeding previous incidence estimates [4]. The clinical spectrum encompasses ophthalmological abnormalities (oculomotor apraxia, retinitis pigmentosa, Leber amaurosis), hepatic fibrosis, neurologic disorders, chronic lung and upper airway infections as well as skeletal defects (Fig. 11.3). Less frequently, laterality defects, genital anomalies, congenital heart defects and endocrine dysfunctions (e.g. hypogonadism, short stature, obesity) are observed. In addition, NPH resembles the kidney phenotype of various mulivisceral ciliopathies described in detail below:

Senior-Løken Syndrome

The term Senior-Løken syndrome denotes the association of NPH and retinal degeneration [18, 19]. Two variants of retinal disorders have been described:

Leber congenital amaurosis (LCA), the most severe variant, is a clinically and genetically heterogeneous retinal disorder that occurs in infancy and is accompanied by profound visual loss, nystagmus, poor pupillary reflexes, and either a normal retina or varying degrees of atrophy and pigmentary changes [19–21]. Affected children exhibit the so-called oculodigital sign characterized by poking, rubbing and pressing of the eyes in order to mechanically stimulate the retina. The electroretinogram is extinguished or severely reduced [22]. All but one form of Leber congenital amaurosis is inherited as an autosomal recessive trait. LCA is a disorder of photoreceptors, caused by failed transport of rhodopsin and a loss of outer segments of the photoreceptor resulting in its ultimate cell death.

Although LCA is a clinical diagnosis, molecular testing is currently available for many different genes, including several genes that can be associated with NPH such as *IQCB1/NPHP5* and *CEP290/NPHP6* [23] (Fig. 11.1). So far, all reported Senior-Løken patients with underlying *IQCB1/NPHP5* mutations presented with early severe retinal degeneration (Leber congenital amaurosis) [23]. Conversely, genetic testing for *IQCB1/NPHP5* variations in patients with a late or mild ocular manifestation does not appear to be very promising. The onset of ESKD in this

cohort however ranges from 6 to 32 years with a median age of 15 years.

A milder retinopathy variant that can also be associated with NPH is referred to as **tapetoretinal degeneration**. Usually patients suffer from slowly progressive severe tube-like restriction of the visual fields and night blindness. Fundoscopy reveals various degrees of atrophic and pigmentary retinal alterations.

Mutations associated with this milder form of Senior-Løken syndrome have been identified in the following genes: *NPHP1, NPHP4, SDCC8G8, WDR19/IFT144* and *TRAF3IP1*. While *SDCC8G8* localizes to centrosomes and cell-cell-junctions in mammalian renal epithelial cell lines and shows interactions with *NPHP5* and *OFD1, WDR19/IFT144* and *TRAF3IP1* are closely linked to intraflagellar transport processes in cilia. Mutations of all three genes cause kidney cysts in zebrafish models [24].

Joubert Syndrome

Joubert syndrome (JS) is an autosomal recessive multisystem ciliopathy with a predicted incidence of 1:55,000–200,000. Clinically JS is characterized by muscular hypotonia, cerebellar ataxia, unusual eye movements, hyperpnea/apnea in infancy, variable degrees of cognitive impairment, speech ataxia and kidney cyst formation. Additionally, certain dysmorphic features have been described such as hypertelorism, broad forehead and unilateral or bilateral ptosis [25]. There is high phenotypic variability even among family members. Neuroimaging (MRI) plays an essential role in the diagnosis of JS since the "molar tooth sign" is pathognomonic and by defi-

nition an essential feature for the diagnosis of JS. It reflects a complex malformation of the midhin brain encompassing cerebellar vermis hypoplasia, increased interpeduncular distance at the pontomesencephalic junction and elongated superior cerebellar peduncles (Fig. 11.3a) [26].

Neurocognitive functioning may range from extremely impaired to almost normal with relative strengths in verbal comprehension and reasoning abilities. Diffuse background slowing in EEG can be found in about one third of patients and is associated with a poorer neurological outcome; however clinical seizures occur in less than 10% of JS patients [27]. A systemic evaluation of the MRI presentation of 110 JS patients revealed the severity of the cerebellar vermis hypoplasia to be associated with the neurodevelopmental outcome [28].

Only about 25% of the patients present an isolated neurological phenotype; the majority of cases is characterized by various phenotypic combinations of additional ocular, kidney and hepatic disease manifestations.

The **ophthalmologic** involvement comprises oculomotor apraxia (78%) with jerking head thrusting and a rotating nystagmus (67%) [29], strabismus (72%) and ptosis (31%). Retinopathy may be present in a subset of patients depending on the underlying genetic defect, with severe forms been associated with *CEP290/NPHP6* and *AHI1* mutations, while in patients with *TMEM67*, *C5orf52* and *KIAA0586* defects no retinal degeneration has been observed so far [25].

Liver disease is observed in 15–45% of JS patients, usually characterized by elevated liver enzymes, increased liver echogenicity and parenchymal stiffness on ultrasound/elastography or splenomegaly). Histopathology resembles the findings seen in ARPKD with ductal plate malformation and portal fibrosis. 15% of patients develop portal hypertension with a need for transjugular intrahepatic portosystemic shunting (TIPS; Fig. 11.3) or liver transplantation. Most patients with severe liver disease carry mutations in the *TMEM67* gene [30].

Kidney involvement is found in 25–30% of JS patients, particularly in those carrying *CEP290/NPHP6*, *TMEM67* and *AHI1* mutations. Most patients display an NPH phenotype with reduced urinary concentrating capacity and slowly progressing GFR decline. Prenatal ultrasound is usually normal and a poor predictor for kidney disease in JS. However, in some patients an ARPKD-like phenotype with enlarged cystic kidneys and early onset hypertension can be observed) [31]. The onset of ESKD ranges from 6–24 years (mean 11.3 ± 4.8 years) and is not necessarily associated with the genotype [32].

So far mutations in 35 different genes are implicated to be causative for JS, which altogether explain 62–94% of the clinical cases [31]. Almost all of these genes show a genetic overlap with other ciliopathy disorders, particularly with Senior-Løken syndrome, COACH syndrome and Meckel-Gruber syndrome. To simplify terminology, the term Joubert syndrome is now used to refer to all patients displaying a molar tooth sign including SLS and COACH syndrome.

For most genes it has proven difficult to identify clear-cut genotype-phenotype correlations. However, for individual genes, such as *CEP290/NPHP6*, the severity of the genetic defect does predict clinical disease severity, with two truncating mutations causing a severe early-onset disorder mimicking a Meckel-Gruber phenotype whereas the presence of at least one missense mutation leads to a milder, late-onset phenotype with limited organ involvement as in NPH [33]. Since *NPHP1* mutations) have also been reported to be a rare cause of JS, the *NPHP1* gene has been referred to as *JBTS4* [29]. However, screening of 117 Joubert syndrome patients revealed *NPHP1* abnormalities only in 2% of cases indicating that this gene is only a minor contributor in the pathogenesis of this disorder [34].

COACH Syndrome

The acronym COACH stands for the clinical key features **c**erebellar vermis hypoplasia, **o**ligophrenia [neurocognitive impairment], **a**taxia, **c**oloboma and congenital **h**epatic fibrosis. COACH syndrome is a rare autosomal recessive disorder that shows substantial overlap with Joubert syndrome and is almost exclusively caused by mutations in the *TMEM67* gene [35]. In contrast to Joubert syndrome, the pathognomonic feature of

this syndrome is an obligatory liver involvement caused by the malformation of the embryonic ductal plate resulting in fibrosis of the liver. Elevated liver enzymes, reduced blood flow in the portal vein and splenomegaly secondary to portal hypertension regularly develop during progression of the disease. Liver transplantation is necessary in most cases in the long run.

Chorioretinal colobomas found in the majority of *TMEM67* patients are typically located inferior to the optic nerve and do not impair vision in most patients. Retinal degeneration seems to be no problem in this particular cohort. Kidney involvement however is observed in 50% of the patients presenting with an NPH phenotype. Just recently, an impaired sense of smell (hyposmia) has been described as a so far underdiagnosed clinical feature associated with *TMEM67* mutations that can further compromise the quality of life of affected patients [36].

Meckel Gruber Syndrome

Meckel Gruber syndrome (MKS) is a neonatally lethal dysmorphic disorder affecting multiple organ systems. It follows an autosomal recessive inheritance with a global incidence of approximately 1:135.000 births. Typical clinical features comprise occipital encephalocele (Fig. 11.3e), bilateral cystic kidney dysplasia, hepatobiliary ductal plate malformation and postaxial polydactyly. Associated features might include severe cardiac anomalies, lung hypoplasia, situs inversus, severe malformations of the central nervous system, hydrocephalus, cleft palate, microphthalmia, retinal colobomas, genital disorders and skeletal deformities [37–39]. Survival beyond the neonatal period is unusual, most affected individuals die *in utero* [40]. However, owing to its allelic overlap with Joubert syndrome, rare cases have survived the first few years of life [25]. Prenatal ultrasound documenting the combination of occipital encephalocele, grossly enlarged hyperechogenic kidneys and polydactyly as well as elevated levels of alpha-fetoprotein in amniotic fluid may lead to early diagnosis. Oligohydramnios is common and often results in Potter's sequence featuring typical facial deformities and joint contractures. Prenatal MRI may be helpful to confirm typical additional malformations. Prenatal genetic testing is only useful when positive because the associated genes identified so far only account for 50–60% of cases [25].

Mutations in 13 genes responsible for MKS-like phenotypes have been reported to date: *MKS1, MKS2/TMEM216, MKS3/TMEM67, MKS4/CEP290, MKS5/RPGRIP1L, MKS6/CC2D2A, MKS7/NPHP3, MKS8/TCTN2, MKS9/B9D1, MKS10/B9D2, MKS11/TMEM231, MKS12/KIF14, MKS13/TMEM107.* Besides genetic heterogeneity, there is significant clinical overlap with NPH and Joubert syndrome (Fig. 11.4). Current data suggest that severe truncating mutations cause MKS whereas milder, non-truncating mutations cause Joubert or isolated NPH syndromes [33]. In fact, there are even some families in which one child is diagnosed with Joubert syndrome and another with MKS, indicating that genetic modifiers also influence the clinical phenotype [41].

Congenital Oculomotor Apraxia Type Cogan II

Congenital oculomotor apraxia (COMA) type Cogan II is characterized by the impairment of horizontal voluntary eye movements, ocular attraction movements, and optokinetic nystagmus [42]. Compensation for the defective horizontal eye movements is accomplished by jerky movements of the head. The disease is not progressive, and most older patients compensate the impaired eye movements by an over-shooting thrust of the eyeballs rather than by head jerks. The condition can improve with age. Some individuals with COMA type Cogan II have an increased risk to develop chronic kidney failure due to NPH. Hence, kidney function should be analysed at regular intervals in this condition.

Recently, genetic variants in the *SUFU* gene have been reported as the first disease-specific genetic cause of COMA without associated kidney disease [43]. In addition, genetic variants in different NPHP genes have been reported in association with COMA type Cogan II including *NPHP1, NPHP4, NPHP6/CEP290* and *NPHP8* [44]. Particularly, deletions in *NPHP1* have been

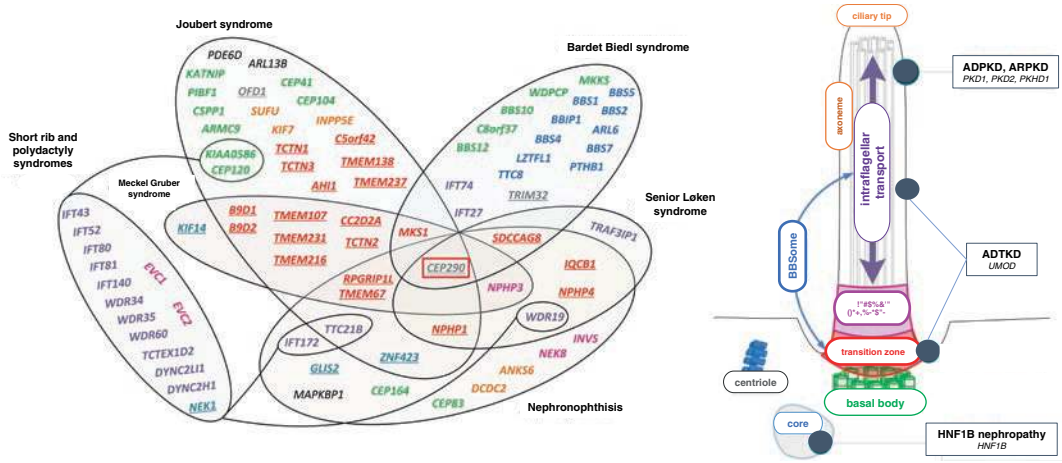

Fig. 11.4 Venn diagram illustrating the genetic and clinical overlap in hereditary renal ciliopathies. Colours indicate the ciliary location of corresponding gene products

described in quite a few affected individuals [4]. However, the vast majority of clinical cases remain genetically unsolved.

Since usually oculomotor apraxia precedes the kidney phenotype by many years but all *NPHP1* deletion carriers developed ESRD in the long run, genetic testing appears to be justified in all patients presenting COMA in early infancy, even though it will only be positive in a minority of patients.

RHYNS Syndrome

RHYNS syndrome was defined in 1997 as the combination of Retinitis pigmentosa, Hypopituitarism, Nephronophthisis and mild Skeletal dysplasia in a 17-year-old man [45]. Four years later, two brothers with a similar clinical picture were reported [46]. Just recently a whole exome sequencing approach revealed biallelic *TMEM67* variants in the index patient reported 20 years before [47].

Previously, growth hormone deficiency associated with an absent, small or ectopic pituitary gland was observed in individual JS patients and associated with variants in the ciliary genes *KIAA0753* and *CELSR2* [48, 49].

Skeletal Ciliopathies

Skeletal ciliopathies represent a distinct group of hereditary disorders clinically characterized by abnormal bone growth resulting in a long narrow chest with short ribs, short stature associated with disproportionately short limbs and polydactyly. Specific disorders in this group include the asphyxiating thoracic dystrophy (Jeune's syndrome), cranioectodermal dysplasia (Sensenbrenner syndrome), Ellis-van Creveld syndrome (EVC) and various types of short rib-polydactyly syndromes (e.g. Mainzer-Saldino syndrome) [50]. Molecular defects in 26 genes have been identified so far mostly encoding components of the ciliary transport machinery [51, 52].

Bone disorders can be accompanied by non-skeletal features including NPH leading to ESKD, cystic kidney disease, congenital hepatic fibrosis, retinal degeneration, neurological abnormalities, cardiac anomalies, cleft lip/palate and other oral defects. Other rare features include fibrocystic changes in the pancreas, ambiguous genitalia, anal atresia, polyhydramnios, malrotation, and hydrops fetalis [25]. Owing to the severity of pulmonary insufficiency associated with asphyxiating thoracic dystrophy, high levels of

perinatal lethality are observed. In cranioectodermal dysplasia (Sensenbrenner syndrome) most affected children develop early-onset NPH leading to ESKD in infancy or early childhood [51].

Respiratory Phenotype

Typically, defects of motile cilia are responsible for chronic respiratory problems subsumed under the term primary ciliary dyskinesia (PCD), a clinical entity characterized by impaired mucociliary clearance, chronic respiratory infections and distinctive low nasal nitric oxide (nNO) levels [53]. However, functional assessment of patients with renal ciliopathies revealed that molecular defects classically associated with non-motile ciliopathies can also have an impact on motile ciliary function.

Future Challenges: Genetic and Phenotypic Heterogeneity

Although the clinical characteristics of the different hereditary disease entities appear quite discriminative, there is significant genetic as well as phenotypic overlap that hampers an early diagnosis and individual management [50] (Fig. 11.4). No doubt, the tremendous progress of genetics in the last two decades had major impact on the molecular understanding of NPH-related ciliopathies. However, the new insights also further complicated the clinical situation for physicians dealing with affected individuals: It has become increasingly evident that so far well-defined clinical entities can be caused by mutations in multiple genes. Vice versa, mutations in the same gene can cause very different phenotypes that range from lethal early embryonic multivisceral manifestations to single organ involvement starting in adolescence [33] (Fig. 11.4). This complexity has been attributed to allelic heterogeneity, locus heterogeneity, reduced penetrance, variable expressivity, modifier genes, and/or environmental factors [54]. In clinical terms, this implies that the traditional approach using textbook signs and symptoms to guide diagnosis and management is no longer sufficient [56]. From the patient's perspective, the "diagnostic odyssey" does not necessarily end with the identification of a disease-causing gene defect [55]. Novel approaches are needed that should combine a deep and comprehensive clinical characterization with careful genotyping in order to discover non-obvious phenotypes and to determine precise diagnoses.

Large-scale collaborative efforts linking comprehensive clinical data collection with translational research will be fundamental to identify novel therapeutic targets and develop disease specific treatment approaches. Several national initiatives have started to address these questions, including the German NEOCYST consortium and the Dutch KOUNCIL initiative [57].

Therapy

So far, there is no specific therapy correcting the genetic or functional defects in NPH or NPH-related ciliopathies. Thus, in the early disease stage without kidney impairment, the main goal is the correction of water and electrolyte imbalances by replacing ongoing losses of water and salt due to the reduced urinary concentrating capacity.

The recent molecular insights into the pathogenesis of NPH have lead to potential novel therapeutic strategies addressing various intracellular signalling pathways. Yet, despite promising preclinical results, no clinical trials including NPH patients have been initiated to date.

Once the disease has progressed to ESKD, renal replacement therapy is required and early, if possible pre-emptive transplantation is the therapy of choice. NPH patients are not at risk of recurrence of the primary disease and the outcome of transplantation is excellent.

Autosomal Dominant Tubulointerstitial Kidney Disease (ADTKD)

Autosomal dominant tubulointerstitial kidney diseases (ADTKD) encompass a group of rare disease entities characterized by autosomal dom-

inant inheritance, tubular damage, interstitial fibrosis, the absence of glomerular lesions and a slow progression towards ESKD in late adulthood [58]. Although the clinical and histological presentation may show significant overlap with NPH [59, 60], there are two major differences: NPH refers to autosomal recessive conditions that typically present in childhood and in most cases lead to ESKD before adulthood whereas ADTKD is inherited in an autosomal dominant fashion and typically presents later in life. However, as an exception to this rule even children younger than 10 years can occasionally present clinical symptoms from ADTKD.

Recent data suggest that ADTKD qualifies to be one of the most common genetic disorders in adulthood, accounting for about 5% of genetically caused ESKD cases. So far five genes have been identified in which variants lead to ADTKD: *UMOD*; *REN*; *MUC*; *HNF1B* and *SEC61A1* [61].

Terminology and Classification

In the past, the terminology for this heterogeneous disease complex has been inconsistent and confusing. The term "medullary cystic kidney disease (MCKD)" was commonly used but fell out of fashion because the occurrence of medullary cysts is not an obligatory feature—in fact most patients with ADTKD show no cysts at all. Another term usually used by paediatric nephrologists was "familial juvenile hyperuricaemic nephropathy (FJHN)", describing a condition that is synonymous to what adult nephrologists called MCKD.

Only recently, the introduction of a gene-based, unifying terminology simplified the communication between disciplines and resulted in an increasing number of reported cases. Of note, following the KDIGO terminology, when an affected gene is identified it should be added as a suffix to the term ADTKD for further subclassification [58, 61]. To date, at least five subtypes can be distinguished (Table 11.2). Yet, about 50–60% of clinical ADTKD cases remain genetically unsolved, pointing to more causative genes to be identified in the future.

Pathophysiology

UMOD encodes uromodulin (previously known as Tamm-Horsfall protein), which is expressed

Table 11.2 Classification of ADTKD

Gene (OMIM-ID; chromosome)	KDIGO terminology	Former terminology	Protein	Protein function
UMOD (*191845; 16q12)	ADTKD-*UMOD*	MCKD2 FJHN	Uromodulin	• Regulates transport and blood pressure • Protection against urinary tract infections • Protection against kidney stones • Regulation of innate immunity
MUC1 (*158340; 1q22)	ADTKD-*MUC1*	MCKD1	Mucin 1	• Protection of epithelial mucus barrier • Immunomodulatory propertiesSignal transduction
HNF1B (*189907; 17q12)	ADTKD-*HNF1B*	–	Hepatocyte nuclear factor 1β	• Transcription factor involved in the development of neural tube, pancreas, gut, liver, lung, kidney and genital tract
REN (*179820; 1q32)	ADTKD-*REN*	–	Preprorenin	• Protease, cleavage of angiotensinogen (renin–angiotensin–aldosterone axis) • Role in nephrogenesis
*SEC61A1 (*609213; 3q21.3)*	ADTKD-*SEC61A1*	–	Alpha1 subunit of *SEC61*	• Alpha1 subunit of SEC61channel forming translocon complex that mediates transport of signal peptide-containing precursor polypeptides across the ER

Modified from Devuyst O, Olinger E, Weber S, Eckardt KU, Kmoch S, Rampoldi L, Bleyer AJ. Autosomal dominant tubulointerstitial kidney disease Nat Rev. Dis Primers. 2019 Sep 5;5(1):60

exclusively at the luminal side of renal epithelial cells of the thick ascending limb of the loop of Henle. Uromodulin is the most abundant protein in the urine of humans [62]. Studies in *UMOD*-knockout mice suggest that uromodulin has multiple physiological roles, including protection against urinary tract infections and kidney stones by direct binding of either fimbria from Escherichia coli bacteria and preventing the adhesion of these bacteria to urothelial cells or direct binding of calcium oxalate crystals [63, 64]. Furthermore, uromodulin plays an important role in maintaining the water-tight integrity of the thick ascending limb. At the same time, it appears to facilitate the transport of the NaK2Cl-Cotransporter [65] and the ROMK potassium channel to the surface of epithelial cells in the thick ascending limb [66]. Subsequently, in the scenario of defective uromodulin, restricted urinary concentration and mild volume depletion evoke an increased reabsorption of uric acid in the proximal tubule potentially explaining hyperuricemia and gout observed in 25–75% of affected patients [67]. Mutated uromodulin proteins are unable to leave the endoplasmic reticulum, resulting in accumulation of abnormal uromodulin within the epithelial cells, followed by cellular atrophy and death. This might explain the progressive chronic kidney failure of *UMOD* patients.

Mutations in the ***MUC1*** gene on chromosome 1q21 have been identified as causative of what in the past was referred to as medullary cystic kidney disease 1 (MCKD1). The majority of affected individuals show a single cytosine insertion into one variable-number tandem repeat sequence within the *MUC1* coding region. Mucin 1 is expressed intracellularly in the secretory epithelia of multiple organs, e.g. the lungs, the stomach, the intestine and the distal tubule and collecting duct of the kidneys. For so far unexplained reasons, clinical sequelae are limited to the kidneys [61]. Mutations in the *MUC1* gene result in an abnormal mucin 1 protein. The mucin 1 protein seems to play an essential role for the protection of the epithelial mucus barrier but also in signal transduction and immunomodulation. Since knockout studies in mice indicated that mucin 1 is not an essential protein, a dominant negative or gain-of function effect of *MUC1* mutations is discussed [68].

The **hepatocyte nuclear factor 1B** (HNF1B) is a ubiquitous transcription factor mainly involved in the early development of multiple organs, primarily of the neural tube, the pancreas, the gut, the liver, the lungs, the kidneys and the genital tract. Variants in the *HNF1B* gene represent the most important genetic cause of congenital anomalies of the kidney and urinary tract (CAKUT) in children. Its precise prevalence as a cause of ADTKD is hard to determine owing to a high rate of assumed undetected cases and numbers range from 5 to 31% depending on the study cohort [69].

Mutations in the ***REN*** gene leading to ADTKD are extremely rare and have been identified only in about 20 families worldwide. It appears that these mutations result in a disrupted translocation of preprorenin into the endoplasmic reticulum of renin expressing cells. Subsequently, the cleavage of pre-prorenin into prorenin and further into renin is blocked. Renin as part of the renin-angiotensin-aldosterone system (RAAS) has a high impact on nephrogenesis, blood pressure control, thirst regulation and erythropoiesis. As a consequence, ADTKD-*REN* is characterized by early onset low-erythropoietin anaemia and slowly progressive CKD accompanied by arterial hypotension and hyperkalaemia. Anaemia in ADTKD-*REN* resembles that observed in haemodialysis and patients receiving long-term angiotensin converting enzyme (ACE) inhibition, since the RAAS contributes to erythropoietin production [70]. At the same time the accumulation of preprorenin in renal tubular cells leads to apoptosis of these cells [71]. Because renin is essential for nephrogenesis, homozygous mutations of renin cause recessive renal tubular dysgenesis and are almost always incompatible with life [72]. In ADTKD-*REN* however, production of wildtype renin occurs via one allele allowing kidney development [61].

Mutations in the ***SEC61A1*** gene are even rarer and have so far only been reported in two families characterized by congenital anaemia, neutropenia and tubulointerstitial kidney disease as well

as another two families with a defect in plasma cell development, recurrent infections and an unknown kidney phenotype [73, 74]. *SEC61A* encodes the alpha 1 subunit of the heterotrimer SEC61, that is part of the ER translocon responsible for the transport of newly synthesized secretory proteins into the endoplasmatic reticulum. Mutations of *SEC61A* lead to aggregation of the altered protein in the ER and by affecting the translocon pore it appears to have a functional impact on post-translational modifications, folding and sorting of various proteins, including renin, uromodulin and mucin1. In addition, alterations in the Ca^{2+} homeostasis and energy metabolism have also been reported [75].

Clinical Presentation

Clinical symptoms are similar in all disease variants and may resemble the phenotype of NPH. Usual findings include slowly progressing chronic kidney disease, bland urine sediment, polyuria due to reduced urinary concentrating capacity and a family history compatible with an autosomal dominant inheritance pattern. If significant proteinuria or hematuria is observed, alternative causes should be ruled out. On ultrasound small cortico-medullary cysts might develop during the course of the disease but these are not a prerequisite for the diagnosis. Kidney size is normal or slightly reduced. Histological findings comprise tubular basement membrane disintegration, tubular atrophy with cyst development, and interstitial round cell infiltration associated with fibrosis resembling the findings observed in "classical" NPH. Thus, imaging and histological findings cannot confirm the diagnosis, and analysis of the clinical and pedigree data is mandatory. A definite diagnosis can be achieved by genetic testing (Table 11.3). However, for economic reasons as well as in view of the methodological difficulties associated with the genetic evaluation of *MUC1* in particular, genetic confirmation is still heavily restricted in adults.

Clinical Presentation of ADTKD-*UMOD*

Patients affected by *UMOD* mutations are typically characterized by juvenile onset of hyperuricemia, gout, and progressive kidney failure. Clinical features of both conditions vary in presence and severity. As mentioned above, the demonstration of kidney cysts is not obligatory and may differ within the same pedigree [76].

In 2004, Scolari et al. reported 205 patients from 31 families with *UMOD* mutations of whom 75% showed hyperuricemia and 65% gout, although in a subset of families neither symptom was observed. Chronic kidney disease was present in 70% of patients, leading to ESKD in 80% of these between 20 and 70 years of age [77]. Comparable findings were reported in a series of 109 patients from 45 families and in an Italian kindred with ten affected individuals, with median ages at ESKD of 54 (range 25–70) [78] and 31 (16–54) years [79], respectively. The clinical course appeared more severe in homozygotes from consanguineous families. In a large Spanish kindred with *UMOD* mutations one individual with recessive (bi-allelic) *UMOD* mutations was identified. The homozygous individual survived to adulthood and presented with an earlier onset of hyperuricemia and faster progression to ESKD than heterozygous individuals [80].

Mild urinary concentrating defects are common and may manifest by persisting enuresis [77]. MRI and ultrasound-based imaging studies on 12 individuals with *UMOD* mutations revealed small kidneys, decreased parenchyma, or cysts in all families. Kidney histology showed microcysts in 4 out of 12 cases and in the others dilated or atrophic tubules, global sclerosis, extensive tubulo-interstitial atrophy with fibrosis, and signs of chronic diffuse inflammation [62].

Clinical Presentation of ADTKD-*MUC1*

In contrast to patients with *UMOD* or *REN* gene mutations, slowly progressive chronic kidney disease is the first and main symptom in patients with *MUC1* mutations. Hyperuricemia and gout, if present at all, develop later in the course of the

Table 11.3 Clinical and laboratory findings in autosomal dominant tubulointerstitial kidney disease (ADTKD)

ADTKD type	OMIM entry	Clinical features	Age at ESRD	Laboratory findings	Renal Imaging	Other findings
ADTKD-*UMOD*	603860	• Teenage onset gout • Polyuria/polydipsia • Enuresis	16–70 years. (median 42)	• Hyperuricemia • Low urinary levels of uromodelin	Normal (50%) or small kidneys, corticomedullary cysts (40%), echogenicity ↑ (10%)	Intracellular deposits of uromodelin in thick ascending limb (TAL) of Henle
ADTKD-*MUC1*	174000	• Gout	50–76 years (median 62)	• Hyperuricemia	Normal (50%) or small kidneys, corticomedullary cysts (40%)	Intracellular deposits of MUC1fs in TAL and extra-renal tissue
ADTKD-*REN*	613092	• Childhood anaemia • Mild hypotension • Gout in adolescence	43–68 years (median 57)	• Anaemia • Mild hyperkalaemia • Hyperuricemia • Low to low-normal plasma renin levels	Normal or small echogenic kidneys, no cysts	Reduced renin-staining in juxtraglomerular apparatus
ADTKD-*HNF1B*		• CAKUT • Childhood CKD • Genital abnor-malities in girls • Syndromic features in those with 17q12 deletion	0-?	• Hypomagnesemia • Hyperuricemia • Hypokalaemia • Elevated liver enzymes • MODY	Small to normal echogenic kidneys with cortical and medullary cysts	–
ADTKD-*SEC61A1*		• Intrauterine and postnatal growth retardation • Recurrent abcess formation • Polydactyly	NA	• Congenital anaemia • Leuco−/neutropenia	Normal or small echogenic kidneys, with cortical and medullary cysts	• Cleft palate • Bifid uvula • Mild cognitive impairment

CAKUT Congintal Anomalies of the Kidney and Urinary Tract; *MODY* Maturity Onset Diabetes of the Young

disease. Other clinical manifestations are uncommon. This was illustrated by the examination of six large Cypriot families including 72 affected individuals, in whom *MUC1* was first localized as the causative gene [81]. The disease led to ESKD at a mean age of 54 years, ranging from 36 to 80 years. The annual loss of estimated GFR is comparable in ADTKD-*UMOD* and ADTKD-*MUC1*, amounting to 3–4 mL/min/1.73 m^2 on average [67]. Arterial hypertension was found in 51% of affected individuals, and strictly related to renal function. Hyperuricemia and gout were no early findings, although the prevalence of hyperuricemia increased at approximately the same rate as in other causes of chronic kidney disease. Cysts were detected sonographically in 40% of tested gene defect carriers. Mainly corticomedullary or medullary, but also cortical cysts were reported. Approximately half of the affected individuals had normal sized kidneys with no cysts, while 11% had small echogenic kidneys without cysts.

In another 23 kindreds with 128 affected individuals, ESKD was reached at a median age of 32 years [82], ranging from 5 to 76 years. Kidney biopsy revealed histological findings identical to those found in "classical" NPH. Hyperuricemia was not a consistent finding and only reported in eight families. Hypertension was present in affected individuals from 13 families.

Clinical Presentation of ADTKD-*Ren*

Patients with *REN* gene variants present a very similar phenotype as *UMOD* patients with early onset gout and development of chronic kidney disease. However, *REN* patients are somewhat older when presenting with gout for the first time (20–30 years) and kidney failure progression is slower. ESKD usually occurs after the age of 40 years. Unlike *UMOD* patients, *REN* mutations lead to additional clinical symptoms caused by the low serum levels of renin and angiotensin. A nearly universal manifestation is the presence of hypoproliferative anaemia (haemoglobin range 7–11 g/dL) in early childhood that often resolves in adolescents, likely due to the increased sex steroid and subsequent erythropoietin production [71]. Additionally, some patients present with low blood pressure, mild hyperkalemia responsive to fludrocortisone and an increased risk of acute kidney injury in a setting of volume depletion or application of non-steroidal inflammatory drugs.

Clinical Presentation of ADTKD-*HNF1B*

Variants in the *HNF1B* gene represent the most prevalent genetic cause of congenital anomalies of the kidney and urinary tract (CAKUT). Inheritance follows an autosomal dominant trait, but about 50% of patients carry *de novo* mutations with no positive family history. The clinical spectrum is highly heterogeneous and can vary significantly even between family members [83–86].

Initially, *HNF1B* variants have been described in the context of familial forms of maturity onset diabetes mellitus (MODY diabetes). Since many of the affected patients also presented malformations of the kidneys and the urinary tract, the term Renal Cyst and Diabetes Syndrome (RCDS) was introduced to refer to this clinical association [83]. The spectrum of kidney malformations observed in this context is highly variable: The majority of patients present bilateral kidney dysplasia in association with cortically located cysts. However, isolated kidney dysplasia, unilateral multicystic dysplastic kidneys, glomerulocystic changes, various urinary tract malformations and unilateral agenesis of the kidney have also been described. Prenatal ultrasound often reveals hyperechogenic kidneys with or without the evidence of cysts [84–86]. In contrast to ARPKD, kidneys usually are not enlarged, and amniotic fluid is preserved in most cases. Noteworthy, in many girls there is an association with malformations of the female genital tract [89, 90]. Thus, abdominal ultrasound should include a statement on potential genital abnormalities. Vice versa, the additional detection of such malformations increases the probability of an underlying *HNF1B* gene defect significantly.

The term HNF1B nephropathy can be misleading since many patients present a systemic disease rather than an isolated kidney phenotype [87, 88]. In addition to MODY-type diabetes and genital malformations, this primarily concerns

hypomagnesemia caused by tubular magnesium loss, hyperuricemia, pancreatic changes and concomitant hepatopathy with elevated liver enzymes. Furthermore, autism spectrum disorders have been observed in some patients [91, 92]. However, extra-renal manifestations are not obligatory findings and might only develop late in the disease process, if at all. Nevertheless, regular screening is recommended. Additionally, owing to its dominant inheritance, genetic counseling and the clinical examination of other family members might be indicated [93].

Regarding kidney function, only a minority of patients experience severe forms with the need of renal replacement therapy in infancy or early childhood. In most children a stable or only slowly declining GFR is observed for many years with preserved kidney function until adolescence at least [94]. However, HNF1B gene defects may be a relevant contributor to chronic kidney disease in adulthood, as has only recently been elucidated [94].

Clinical Presentation of ADTKD-*SEC61A1*

So far only two families with ADTKD-*SEC61A1* have been reported. The phenotype of the first family was characterized by congenital anaemia in conjunction with intrauterine and postnatal growth retardation, cleft palate, bifid uvula, preaxial polydactyly and mild cognitive impairment [73]. In the second family, congenital anaemia was accompanied by neutropenia and recurrent cutaneous abscess formation during childhood. Gout was also a common feature in affected family members; however, growth and cognitive development were normal in this family [74].

Diagnostic Work-Up and Genetic Testing

In the presence of a tubulointerstitial disease with slowly progressive CKD, the first diagnostic step is to rule out disease entities with a higher prevalence by simple measures like urinalysis and ultrasound: While the detection of haematuria and proteinuria indicate glomerular rather than tubular disease, enlarged kidney volume in combination with cystic lesions should guide the diagnosis to ADPKD in place of ADTKD. Next, family history—if positive at all—should be consistent with dominant inheritance to rule out NPH. Finally, while teenage-onset hyperuricemia and a medical history for gout hint towards underlying *UMOD* mutations, childhood anaemia and arterial hypotension may be clinical indicators for ADTKD-*REN* [61].

Yet, clinical phenotyping will only be able to provide diagnostic clues and neither extensive imaging nor a comprehensive histological work-up are sufficient to pin down a final diagnosis. Interestingly, measurement of reduced urinary uromodulin concentrations as well as negative MUC1 staining in uroepithelial bladder cells have been used to facilitate diagnosis in ADTKD-*UMOD* and ADTKD-*MUC1* individuals, respectively [95, 96]. However, both methods are not routinely accessible.

Thus, for the confirmation of the diagnosis ADTKD, the identification of the underlying genetic defect is mandatory. Although expensive, methodically difficult and so far without clear-cut therapeutic consequences, the confirmation of a molecular diagnosis helps to avoid unnecessary invasive procedures, to guide further extra-renal diagnostics, to provide personal counselling and to evaluate family members as potential kidney donors [61]. However, it should be pointed out that genetic testing of asymptomatic children for conditions in which there is no specific treatment is generally discouraged [97].

Therapy

As in NPH, there is no specific therapy correcting the genetic or functional defects in ADTKD so far. Symptomatic treatment strategies include the management of hyperuricemia, gout and progressive kidney failure. Hyperuricemia should be treated with allopurinol or other urate-lowering medication to avoid tophus development. However, whether this treatment also slows down the decline of kidney function is still under debate [98].

CKD management should include blood pressure control, correction of electrolyte abnormalities, free water supply to compensate for urinary concentration defects, cautious use of diuretics due to the associated risk of salt loss and hyperuricemia as well as a general avoidance of NSAIDs. Whether or not angiotensin receptor inhibition can be nephroprotective in this particular non-proteinuric cohort still needs to be elucidated. However, if angiotensin receptor blockers are used, losartan is the drug of choice in patients with hyperuricaemia since this compound increases urinary urate excretion [99].

Children with ADTKD-*HNF1B* and ADTKD-*REN* disease are likely to benefit from early management by neonatologists and paediatric nephrologists, including postnatal ventilation and circulation management as well as neonatal dialysis when required [58].

In ESKD, kidney transplantation is the method of choice for ADTKD patients since the disease does not recur in transplanted kidneys. Genetic testing for family members of patients with ADTKD is mandatory before a living donation.

Part IV

Glomerular Disorders

Hematuria and Proteinuria

12

Hui-Kim Yap and Perry Yew-Weng Lau

Introduction

The presence of blood or protein in the urine may be just a normal transient finding in children, usually accompanying a non-specific viral infection. More importantly, these findings may be an indicator of a kidney or urinary tract disorder. Macroscopic hematuria or the incidental finding of hematuria or proteinuria on urine dipstick examination is often an alarming occurrence to parents, bringing the child to medical attention. The etiology of hematuria and proteinuria includes a long list of conditions. Workup can be extensive, expensive and unnecessary as most children with isolated hematuria or isolated proteinuria do not have significant kidney disease and abnormal urine findings usually resolve on repeated testing. Conversely, persistent proteinuria or even persistent microscopic hematuria can be an indicator of significant glomerular disease, as well as associated with an increased risk for end-stage kidney disease (ESKD).

Hematuria

In a normal person, very few red blood cells are excreted into the urine. The passage of red blood cells (diameter 6–8 μm) through the glomerulus into the urinary space is mostly prevented by endothelial fenestrations (50–100 nm) of the glomerular filtration barrier. Increased passage of red blood cells into the urinary space can be due to glomerular diseases or conditions affecting the lower urinary tract. Glomerular hematuria can be due to structural modification of components of the glomerular filtration barrier (e.g. α-chain of type IV collagen in thin basement membrane disease and Alport syndrome) or increased inflammatory response leading to damage of capillary endothelium and glomerular basement membrane (e.g. in primary glomerulonephritis and autoimmune conditions).

Macroscopic hematuria is visible while microscopic hematuria is usually detected by a urine dipstick test during a routine examination or by microscopic examination of the urine sediment. As little as 1 mL of blood per liter of urine can produce a visible change in the urine color. If fresh blood is present in the urine, the urine will be pink or red. If left standing, even in the bladder, the urine will develop a hazy smoky or brown color. The brown color comes from the metheme derivative of the oxidized heme pigment. Some pigments and crystals, when present at a significant concentration, will cause color changes in

Table 12.1 Causes of discoloration of urine

Dark yellow or orange urine	Normal concentrated urine Rifampicin Carotene Pyridium Warfarin
Dark brown or black urine	Bile pigments Methemoglobinemia Alanine, resorcinol Laxatives containing cascara or senna Alkaptonuria, homogentisic acid, melanin, Tyrosinosis Thymol Methyldopa metabolite Copper Phenol poisoning
Red or pink urine	Red blood cells (hematuria) Free hemoglobin (hemoglobinuria) Myoglobin (myoglobinuria) Porphyrins Urates in high concentration (may produce a pinkish tinge) Foods (e.g. beetroot, rhubarb, blackberries, red dyes) Drugs (e.g. benzene, chloroquine, desferoxamine, phenazopyridine, phenolphthalein)

the urine that can be misinterpreted as hematuria. Discoloration of urine can be due to intravascular hemolysis, rhabdomyolysis, metabolic disorders and a number of foods and drugs (Table 12.1).

Definition

The definition of hematuria is based on urine microscopic examination findings of red blood cells and it varies according to the method of quantification. The most commonly accepted upper limits of normal for urinary red blood cells are three red blood cells per high power field in fresh centrifuged urine [1]. There is some controversy as to the amount of red blood cells required for the diagnosis of microscopic hematuria. A population-based study of over 12,000 children in Texas by Dodge et al. [2] recommended five or more red blood cells per high power field in at least two of three consecutive fresh centrifuged urine obtained at least 1 week apart, as the definition of hematuria to capture children with significant disease. A study of 8954 Finnish school children by Vehaskari et al. [3] defined hematuria as more than 5 red blood cells/0.9 mm^3 in a fresh uncentrifuged midstream urine specimen and this identified all children with kidney disease if the urine sample was positive twice in a 6-month period. A study using more stringent criteria has greater positive predictive value with regard to presence of disease, but loses some negative predictive value. Regardless of the criterion used, important cofactors to consider when a child has microscopic hematuria include the presence of proteinuria, urinary casts, hypertension, a family history of kidney disease and other clinical or laboratory findings suggestive of kidney or urinary tract disease.

Urine Dipstick

The urine dipstick utilizes the peroxidase-like activity of hemoglobin present in the urine. Hemoglobin peroxidase activity converts the chromogen tetramethyl benzidine incorporated in the dipstick into an oxidized form, resulting in a green-blue color. The test depends on the presence of free hemoglobin, which comes from hemolysis of the red blood cells in the urine. It is assumed that when there is significant hematuria, some of the red blood cells will always lyse and there will be sufficient free hemoglobin released to cause a positive test. The test is very sensitive, capable of detecting as little as 150 μg/L of free hemoglobin. As few as two to three red blood cells per high power field can make the urine dipstick positive.

It is important to follow the manufacturer's instructions of the dipstick. Delayed reading may produce false positive results. Positive results can also occur in hemoglobinuria following intravascular hemolysis or in myoglobinuria after rhabdomyolysis. Positive results can also be due to the presence of oxidizing agents in the urine such as hypochlorite (cleaning solution) and microbial peroxidases associated with microbial contamination, including urinary tract infection (UTI).

Conversely, false negative results can be due to the presence of large amounts of reducing

agents such as ascorbic acid or urine with high specific gravity, in which the dipstick test is less sensitive.

Due to the very sensitive nature of the urine dipstick test, it is unwise to investigate based on a "trace" reading on the dipstick. Similarly, a child with dipstick reading of "1+" on one occasion and negative readings on subsequent dipstick testing is unlikely to benefit from further investigations. Only if the urine dipstick reading for blood is persistently greater than "trace" is further evaluation warranted. In clinical practice, it is important to confirm hematuria with urine microscopic examination. An absence of red blood cells in the urine with a positive dipstick reaction in a child with red or brown urine may suggest hemoglobinuria or myoglobinuria.

Urine Microscopy

Microscopic examination of the urine sediment is important in diagnosing and evaluating hematuria. When abundant, red blood cells are easy to identify by their characteristic biconcave disc appearance under microscopy. When scanty, red blood cells become distorted in the urine and it is difficult to differentiate them from other unidentified small objects.

Urine centrifugation is one way to solve this problem. After centrifugation and removal of supernatant, the deposit is resuspended in the remaining urine and examined under the microscope. Urine microscopic examination can have false negative results when the urine is of low specific gravity or has an alkaline pH. These conditions result in red blood cells hemolysing rapidly in standing urine, resulting in a positive urine dipstick test due to the free hemoglobin, but without the characteristic red blood cells seen by microscopy.

The morphology of the red blood cells may help identify the origin of the bleeding [4, 5]. Red blood cells from the lower urinary tract maintain their morphology whereas red blood cells from the glomeruli show great variation in shape, size and hemoglobin content due to sheering stresses on their surface in their passage from the capillary lumen through gaps in the glomerular filtration barrier into the urinary space [6]. Phase-contrast microscopy on freshly voided urine allows this differentiation. Red blood cells that are more than 90–95% isomorphic (i.e., of normal size and shape) are most commonly from the lower urinary tract. If more than 30% of dysmorphic red blood cells (blebs, budding and segmental loss of membrane with reduction in red cell volume) are present, the hematuria is more likely to be of glomerular origin [7].

The presence of casts, other cells and crystals in the urine can be helpful. Red blood cell casts are always pathological and usually suggest glomerulonephritis. Identification of red blood cell casts should be done on fresh urine or acidic urine stored at 4 °C, as red blood cell casts disintegrate readily in alkaline urine, taking on a granular appearance. Hence the finding of granular casts in association with hematuria may indicate that the blood has originated from the kidneys. The low rate of red blood cell cast identification using conventional microscopy is probably related to centrifugation of the urine specimen at a low speed of 400 g. A study using high speed centrifugation at 2000 g for microscopy was able to increase the red blood cell cast yield in the urine [8]. Hyaline casts are associated with proteinuria, and a few such casts may be found in concentrated early morning samples from healthy people. When white blood cells are also present in the urine, infection and interstitial or glomerular inflammatory disorders should be considered. Interstitial nephritis is even more likely if Wright stain of the urine shows the presence of eosinophils. Infections and poststreptococcal nephritis often have neutrophils on urinalysis. If the child has other findings suggestive of nephrolithiasis, the shape of the crystals may help to identify the chemical nature of the calculi. Calcium oxalate crystals may point to hypercalciuria.

Etiology

A practical approach is to determine whether the hematuria is of glomerular or non-glomerular origin. Non-glomerular bleeding occurs from the urinary tract, which includes the collecting sys-

Table 12.2 Causes of hematuria in children

tems, ureters, bladder and urethra. The various causes of hematuria in children are listed in Table 12.2. In children, the source of bleeding is more often from the glomeruli than from the urinary tract.

There are four different clinical presentations of hematuria:

1. Child with red or dark-colored urine
2. Child with lower urinary tract symptoms
3. Child with clinical features of acute glomerulonephritis
4. Asymptomatic child with incidental finding of microscopic hematuria on urine dipstick

These four clinical presentations will be considered separately as the approach is different in each of these scenarios, though there is an overlap in the causes.

Child with Red or Dark-Colored Urine

The first step in the evaluation is to exclude red discoloration of urine due to certain foods, drugs, hemoglobinuria or myoglobinuria (Table 12.1). A urine microscopic examination is essential to confirm that the discoloration is due to red blood cells.

The causes of gross hematuria in children include:

1. Acute glomerulonephritis, especially if edema and hypertension are also present.
2. UTI, adenovirus hemorrhagic cystitis, schistosomiasis, urethritis, perineal irritation, urolithiasis, or hypercalciuria. These conditions are usually accompanied by voiding symptoms such as dysuria, frequency and urgency.
3. Exercise-induced hematuria
4. Trauma
5. Coagulopathy
6. Renal vein thrombosis
7. Urinary tract tumors
8. Recurrent gross hematuria which is seen in IgA nephropathy, nutcracker syndrome, Alport syndrome, CFHR5 nephropathy.

Exercise-induced hematuria is a transient hematuria that appears immediately after pro-

longed, vigorous exercise such as long-distance running, and usually disappears within 48 h. This is benign and results from relative higher vasoconstriction of the efferent glomerular arterioles compared with the afferent vessels, resulting in increased filtration pressure and excessive increase in red cell excretion into the urine [9].

Trauma sufficient to cause hematuria is usually associated with an obvious history such as urethral catheterization or abdominal injury. Mild trauma may cause hematuria in a patient with a previously unsuspected obstructed urinary tract, such as ureteropelvic junction stenosis.

Children with bleeding disorders such as hemophilia or thrombocytopenia commonly have microscopic hematuria, but may also develop gross hematuria following minor trauma. Sickle cell hemoglobinopathy can cause hematuria by causing infarction of the renal collecting systems [10]. Renal vein thrombosis is rare, but should be strongly considered when gross hematuria presents in nephrotic children, neonates with umbilical lines, severe dehydration, polycythemia or prothrombotic conditions.

Urinary tract tumors are rare in children. Children with Wilms tumor can have microscopic hematuria (rarely macroscopic hematuria), but are more commonly discovered following evaluation of abdominal distension or abdominal masses. Rhabdomyosarcoma of the bladder is extremely rare, and usually presents with voiding symptoms in addition to macroscopic hematuria.

The nutcracker phenomenon refers to compression of the left renal vein between the aorta and superior mesenteric artery before the left renal vein joins the inferior vena cava. This leads to left renal vein hypertension, which may result in rupture of the thin-walled vein into the renal calyceal fornix, with the clinical presentation of intermittent gross or microscopic hematuria. In addition, the increased venous pressure within the renal circulation can promote the development of varices of the renal pelvis and ureter. This phenomenon, with its associated symptoms of unilateral hematuria and left flank pain, is defined as the nutcracker syndrome. It occasionally presents as a varicocele in boys or abnormal menstruation in pubertal girls, as a result of the development of venous varicosities of the gonadal vein [11]. Orthostatic proteinuria has also been reported in nutcracker syndrome, although the exact mechanism is unknown [12]. Possible mechanisms include subtle glomerular lesions associated with hemodynamic abnormality, and an increased release in norepinephrine and angiotensin II on standing up [12]. Nutcracker syndrome appears more commonly in Asian communities. It may be one of the important causes of gross or microscopic hematuria in relatively young and previously healthy patients with a thin habitus [13].

Diagnosis of nutcracker syndrome can be made by renal ultrasound demonstrating compression of a pre-aortic left renal vein in the fork between the abdominal aorta and the proximal superior mesenteric artery, and Doppler flow scanning measuring the peak flow velocity ratio between the aorto-mesenteric portion and the hilar portion of the renal vein. The most accurate method for diagnosing the nutcracker syndrome is left renal venography, with measurement of the pressure gradient between the left renal vein and the inferior vena cava. Such invasive examination is difficult to perform in children. Magnetic resonance angiography can be used to demonstrate the dilated left renal vein after passing between the aorta and superior mesenteric artery. An alternative is multidetector computed tomography, which can detect the decrease in velocity of contrast enhancement to the parenchyma of the left kidney due to compression of left renal vein; however, the radiation risk in childhood is not negligible [14].

Controversy exists as to the treatment of nutcracker syndrome. Spontaneous resolution of hematuria in 75% of children with nutcracker syndrome followed up for 2 or more years has been reported following an increase in the body mass index (BMI) [13, 15, 16]. Surgical or radiological intervention are indicated for severe pain, significant hematuria and renal impairment, with percutaneous endovascular stent insertion being the preferred mode of therapy [17].

Children with IgA nephropathy and some of the familial hematuria syndromes (Table 12.3) can have macroscopic hematuria at the time of, or

Table 12.3 Familial hematuric disorders

Disorder	Gene(s)	Protein	Estimated risk of ESKD
X-linked Alport syndrome	*COL4A5*	α5(IV)	
	Hemizygous (male)		100%
	Heterozygous (female)		Up to 25%
Autosomal Alport syndrome	*COL4A3* or *COL4A4*	α3(IV) or α4(IV)	
	Recessive (homozygous or compound heterozygous)		100%
	Dominant		<1% if no risk factors (TBMN); ≥20% if risk factors present
Digenic Alport syndrome	*COL4A3* and *COL4A4*	α3(IV) and α4(IV)	
	Mutations in trans		Up to 100%
	Mutations in cis		Up to 20%
	Mutations in *COL4A5* and in *COL4A3* or *COL4A4*		Up to 100% (affected males)
Autosomal dominant HANAC syndrome	*COL4A1*	α1(IV)	
	Heterozygous		Unknown
Autosomal dominant MYH9 associated nephropathy	*MYH9*	Nonmuscle myosin heavy chain IIA	
	Heterozygous		30%
CFHR5 nephropathy	*CFHR5*	Complement factor H-related protein 5	
	Heterozygous (males)		80%
	Heterozygous (females)		20%
Glomerulopathy associated with fibronectin deposition	*FN1*	Fibronectin 1	>90% between second to sixth decade

ESKD end-stage kidney disease; *TBMN* thin basement membrane nephropathy

1 or 2 days following, an upper respiratory tract infection, a phenomenon known as synpharyngitic hematuria. Some degree of accompanying proteinuria, at least at the time of intercurrent illness, is common. The urine can be normal between the bouts of gross hematuria but a considerable proportion has persistent microscopic hematuria between the attacks of gross hematuria.

Alport syndrome is a genetic disease with both gross and microscopic hematuria that is associated with high risk of progression to kidney failure before the fourth decade of life. The rate of progression to kidney failure is influenced by the type of *COL4A* mutations (*COL4A5*, *COL4A3*, *COL4A4*) affecting the α-chains of type IV collagen in the glomerular basement membrane. The inheritance pattern is most commonly X-linked, but may also be autosomal recessive or dominant. A family history of relatives with hematuria, renal failure or deafness may suggest Alport syndrome, but it must be remembered that a negative family history does not exclude Alport syndrome.

A syndrome in which hereditary angiopathy, nephropathy, aneurysms and muscle cramps (HANAC) linked to heterozygous mutations of *COL4A1* gene has been described [18]. HANAC syndrome is autosomal dominant and extremely rare. The kidney disease presents with microscopic or macroscopic hematuria. Cortical cysts and mild chronic kidney disease (CKD) have been described in adults. *COL4A1* gene mutation detection should be considered if there is hematuria in a patient with cerebral abnormalities (intracerebral aneurysm, stroke), cataracts and retinal arteriolar tortuosity.

Complement Factor H-Related 5 (CFHR5) nephropathy is endemic in the Greek Cypriot population and is extremely rare in the non-Cypriot population. It is one of the group of disorders known as C3 glomerulopathy. It is caused by a mutation of the *CFHR5* gene. Which encodes proteins that regulate the alternative complement pathway. It is characterized by low serum C3 levels but normal C4 levels, and kidney biopsy invariably shows mesangial C3 deposition. Genetic testing is required for the diagnosis.

Studies from families of Cypriot descent have shown that patients with duplication of exons two to three of the *CFHR5* gene present with hematuria, proteinuria and hypertension, with up to 50% progressing to kidney failure within 10 years of diagnosis [19].

Child with Associated Lower Urinary Tract Symptoms

Hematuria with accompanying dysuria, frequency, urgency, flank or abdominal pain may suggest a diagnosis of UTI, hypercalciuria or nephrolithiasis.

One third of UTIs have associated hematuria, though this is usually microscopic. UTIs are usually caused by bacteria, but viruses, fungi and parasites are potential etiological agents. Acute hemorrhagic cystitis is characterized by gross hematuria and symptoms of bladder inflammation. It is associated with adenovirus types 11 and 21. The macroscopic hematuria usually lasts 5 days and microscopic hematuria may persist for an additional 2–3 days [20]. Schistosomiasis is an important cause of hematuria in tropical Africa, Middle Eastern countries, Turkey, India, South-East Asia and in immigrants from these areas [21]. It is caused by swimming in lakes and ponds infested with snails infected by the flatworm *Schistosoma haematobium*. The trapped eggs of the flatworm in the bladder and lower urinary tract cause an intense granulomatous inflammatory reaction resulting in hematuria. In developing countries, tuberculosis of the urinary tract is another cause of hematuria, both microscopic and macroscopic, especially in the context of a child with prolonged ill health [22].

Nephrolithiasis is rare in children. The incidence of stone disease in children has been reported to account for between 0.13 and 0.94 cases per 1000 hospital admissions [23]. It can present with hematuria alone or hematuria with colic. Pain can be due to the presence of the stone or clots of blood passing down the ureter. An association between hematuria and hypercalciuria has been reported in children with asymptomatic macroscopic or microscopic hematuria without signs of renal stones [24]. Children with hypercalciuria can also have accompanying irritative urinary symptoms such as dysuria, frequency and urgency. These children have increased urinary excretion of calcium despite normal serum calcium levels. The urinary calcium to creatinine ratio in a single urine specimen is a useful index of calcium excretion for screening and monitoring purposes. In a large study, the 97th percentile level of urinary calcium to creatinine ratio in children eating an unrestricted diet was 0.69 mmol/mmol, whereas in infancy, it can reach as high as 2.2 mmol/mmol [25].

Child with Clinical Features of Acute Glomerulonephritis

Acute glomerulonephritis is characterized by sudden onset of macroscopic hematuria, accompanied by hypertension, oliguria, edema and varying degrees of abnormal kidney function. In children, the majority of cases of acute glomerulonephritis have a post-infectious etiology, most commonly following infection with group A β-hemolytic streptococcal infection of the throat or skin. It is important to identify acute glomerulonephritis in a child with hematuria because urgent appropriate management can prevent morbidity and mortality due to uncontrolled hypertension, fluid overload and abnormal kidney function.

Asymptomatic Child with Incidental Finding of Microscopic Hematuria on Urine Dipstick

Use of urine dipstick testing to screen for UTI in a febrile child or during routine school health examination in many countries detects asymptomatic microscopic hematuria. Mass urine screening programs of school-aged children suggest that approximately 1% will have two or more urine dipsticks positive for microscopic hematuria, but this only persists at 6 months in a third of the population [2, 3, 26]. Of those chil-

dren who were subsequently referred for evaluation of persistent microscopic hematuria, a glomerular pathology was the most likely cause, occurring in between 22.2% and 52.3% based on either phase-contrast microscopy or kidney biopsy findings [27–30].

Isolated hematuria (without accompanying hypertension, significant proteinuria or abnormal kidney function) in children is traditionally regarded as benign. However, publications describing the long-term follow-up of patients who presented initially with microscopic hematuria has challenged this view. An adjusted hazard ratio of 18.5 for the development of ESKD was observed in Israeli adolescents and young adults with persistent asymptomatic isolated microscopic hematuria over a period of 22 years in a population-based retrospective cohort study [31]. A study in China involving 351 children who had undergone kidney biopsy secondary to persistent asymptomatic isolated hematuria reported increased adverse kidney events (i.e. development of proteinuria, hypertension, or abnormal kidney function) after 2–10 years of follow-up in those children with recurrent macroscopic hematuria and/or proteinuria as compared with patients with asymptomatic isolated microscopic hematuria (22.8% versus 6.0% respectively, $p < 0.001$) [32]. This finding suggests that microscopic hematuria, especially when accompanied by macroscopic hematuria and/or proteinuria, may be associated with unfavorable kidney outcome. While the clinical outcome for many children presenting with isolated hematuria is good, the lifetime risk of kidney disease is not insignificant and is dependent on the underlying pathology.

As microscopic hematuria and mild proteinuria may appear transiently during fever, illness or extreme exertion, it is therefore not cost-effective to subject every child to extensive investigations to elucidate the cause of microscopic hematuria. One practical approach is to repeat the urine dipstick and microscopic urinalysis twice within 2 weeks after the initial result. If the hematuria resolves, no further tests are required. If microscopic hematuria persists on at least two of the three consecutive samples, then further evaluation is required [33].

The common diagnoses in children with persistent microscopic hematuria without proteinuria are familial benign hematuria, idiopathic hypercalciuria, and IgA nephropathy. In addition, there is a group of genetically heterogenous monogenic conditions causing microscopic hematuria that may progress to ESKD, typically during adulthood. This group of familial hematuric disorders is caused by mutations in several genes (Table 12.3).

Benign familial hematuria, also known as thin basement membrane nephropathy (TBMN), is the most common cause of persistent microscopic hematuria in children, occurring in at least 1% of children worldwide [34]. It is autosomal dominant, and is frequently associated with heterozygous mutations of *COL4A3* or *COL4A4* genes. Absence of a family history does not exclude the diagnosis of TBMN because there may be a de novo mutation, the penetrance may not be complete, or family members may not be aware that they have microscopic hematuria [35]. The red blood cells in the urine are mainly dysmorphic and there may be red blood cell casts. Hearing deficits or eye abnormalities almost never occur in patients with TBMN or their family members. Universal thinning of glomerular basement membrane is seen on electron microscopy. A kidney biopsy is usually not indicated if TBMN is suspected, unless there are atypical features to suggest IgA nephropathy or Alport syndrome. The prognosis of TBMN was traditionally regarded as benign. However, it is now recognized that TBMN can be associated with an increased risk of kidney failure in adulthood, with up to 50% of patients developing various degrees of CKD after the age of 50 years [36]. TBMN is thought to be a spectrum of autosomal Alport syndrome, where the risk of progressive glomerulopathy is up to 20% in the presence of factors such as proteinuria, sensorineural deafness, family history of kidney failure and histological findings of focal segmental glomerulosclerosis, or glomerular basement membrane thickening and lamellation [37]. Hence, lifelong follow-up is recommended for children with persistent isolated microscopic hematuria due to suspected TBMN.

The better understanding of the genetic basis of diseases in recent years has prompted a better classification of familial hematuria into a number of rare glomerulopathies, such as CFHR5 nephropathy, MYH9-related disease and glomerulopathy with fibronectin deposition. The kidney outcome of these conditions is worse than was initially described for benign familial hematuria. Hence, genetic analysis in those children with family histories of hematuria and/or proteinuria or kidney failure may be considered for the early detection of these progressive, familial, hematuric disorders (Table 12.3).

One rare familial hematuric disorder is autosomal dominant MYH9-related disease, which includes Fechtner and Epstein syndromes [34, 38, 39]. Besides nephritis, these syndromes are associated with giant platelets, cytoplasmic leukocyte inclusions (Döhle-like bodies), sensorineural deafness and cataracts. The associated nephritis seen in 30–70% of patients presents initially with microscopic hematuria, with proteinuria developing as the disease progresses, and reaching ESKD in young adulthood.

Glomerulopathy with fibronectin deposition (GFND) is another rare autosomal dominant glomerulopathy characterized by microscopic hematuria, proteinuria, hypertension and massive fibronectin deposits in the mesangium and subendothelial space. GFND presents at different ages. The urinary abnormalities usually occur during the first decade of life, with progression to ESKD typically occurring in the second to sixth decade [40–42].

Clinical Approach

In approaching a child with hematuria, we should ensure that serious conditions are not missed, avoid unnecessary and expensive laboratory tests, reassure the family and provide guidelines for further studies if there is a change in the child's course. Obtaining a careful history and physical examination is the crucial first step in the evaluation.

History

It is helpful to determine the color of the urine and timing of color change related to the urinary stream. Macroscopic hematuria of glomerular origin is usually described as dark brown or cola-colored. In contrast, visible hematuria of lower urinary tract origin (bladder and urethra) is usually pink or red, there may be clots, and the blood may be only be visible at the beginning or end of the urinary stream. Hematuria at voiding onset is seen in urethral causes such as urethritis, whereas terminal hematuria is indicative of a bladder cause such as a bladder stone or tumor and schistosomiasis. Patients should be asked regarding history of recurrent gross hematuria, recent trauma or exercise, passage of urinary stones, recent or concurrent respiratory or skin infections, and intake of medications (including over-the-counter medications, calcium or vitamin D supplementation) or herbal compounds. In girls at peripubertal age, menarche as the cause of hematuria should be considered.

Associated symptoms may include fever, dysuria, urinary frequency and urgency, back pain, skin rashes, joint symptoms, and face and leg swelling. Predisposing illnesses such as sickle cell disease or trait should also be noted. The family history should search for documented hematuria, hypertension, intracerebral bleed, kidney stones, kidney failure, deafness, coagulopathy and polycystic kidney disease. In a sexually active teenager, the social history should consider any recent sexual activity and any known exposure to sexually transmitted diseases since cystitis and urethritis can present with hematuria.

Physical Examination

The presence of hypertension and edema, suggestive of acute glomerulonephritis, requires a more urgent and extensive evaluation. Associated rashes or arthritis may indicate hematuria due to systemic lupus erythematosus or nephritis due to IgA vasculitis. The presence of fever or loin pain

may point to pyelonephritis. A palpable and ballotable kidney mass will require radiological investigations to exclude hydronephrosis, polycystic kidney or kidney tumor. Screening for eye and hearing abnormalities may be useful if there is a suggestive family history of familial hematuric disorders associated with progression to ESKD.

Investigations

Investigations to look for the cause of hematuria can be extensive. Tailoring the evaluation according to the type of clinical presentation reduces unnecessary laboratory and radiological investigations (Fig. 12.1). The first step is to confirm hematuria with urine microscopic examination. If the child has associated edema, hypertension, oliguria or proteinuria with hematuria, evaluation for glomerular causes such as acute glomerulonephritis or hemolytic uremic syndrome is required. If the child has associated irritative urinary symptoms, evaluation for UTI and nephrolithiasis should be considered. For children with an incidental finding of microscopic hematuria during illness or after exertion, further evaluation is required only if there is persistent microscopic hematuria on at least two of three consecutive samples. If the subsequent two urine samples do not show microscopic hematuria, the hematuria is transient and further evaluation is not required.

The next step in the evaluation of persistent hematuria is to determine the site of bleeding. Two investigations that should be done once hematuria is confirmed are urine tests for protein and urine phase contrast microscopic examination to look at the red blood cell morphology. Hematuria (gross or microscopic) associated with greater than 30% dysmorphic red blood cells, in particular acanthocytes (ring forms with vesicle-shaped protrusions) [43], and proteinuria indicate glomerular bleeding. It is important to remember that some proteinuria may also be present in non-glomerular causes of macroscopic hematuria. However, the proteinuria usually does not exceed 2+ (1 g/L) on dipstick examination if the only source of protein is from bleeding due to a non-glomerular etiology. Therefore, a child with proteinuria 2+ or more should be investigated for glomerulonephritis. Similarly, red blood cell casts, if present, are highly specific for glomerulonephritis.

A serum creatinine to estimate kidney function needs to be determined in children with glomerular pathology. If there is significant proteinuria, the serum albumin should be measured. In addition, laboratory investigations to look for the cause of glomerular disease should be performed. These investigations may include serum complements C3 and C4, anti-streptolysin O titer (ASOT) or anti-DNase B, anti-factor B antibody, anti-nuclear antibodies (ANA), anti-double-stranded DNA (dsDNA) antibody, anti-neutrophil cytoplasmic antibodies (ANCA), IgA level, hepatitis B surface antigen and viral titers if appropriate. Anti-factor B antibody levels, an autoantibody targeting factor B (a component of the alternative pathway C3 convertase), is highly specific for post-infectious glomerulonephritis [44]. Serum IgA levels are increased in 30–50% of adult patients, but in only 8–16% of children with IgA nephropathy [45]. In countries where IgA nephropathy is an important cause of glomerulonephritis, 10–35% of children undergoing kidney biopsy for isolated hematuria were found to have IgA nephropathy [45, 46].

The clinical presentation is important in deciding the type of investigations required. For example, a preceding sore throat, pyoderma or impetigo and the presence of edema, hypertension and proteinuria are suggestive of post-streptococcal glomerulonephritis. Serum ASOT, anti-DNase B and complement C3 levels would suffice in this case. If these tests are not informative, then further investigations are warranted to rule out other causes of glomerulonephritis. If a familial hematuric disorder is suspected, an audiological examination may be useful to detect high frequency sensorineural hearing deficit associated with Alport syndrome. If suspicion of X-linked Alport syndrome is high, skin biopsy with immunostaining for the α5(IV) chain can be useful. The presence of macrothrombocytopenia with or without basophilic cytoplasmic leukocyte inclusion bodies (Döhle-like bodies) suggests

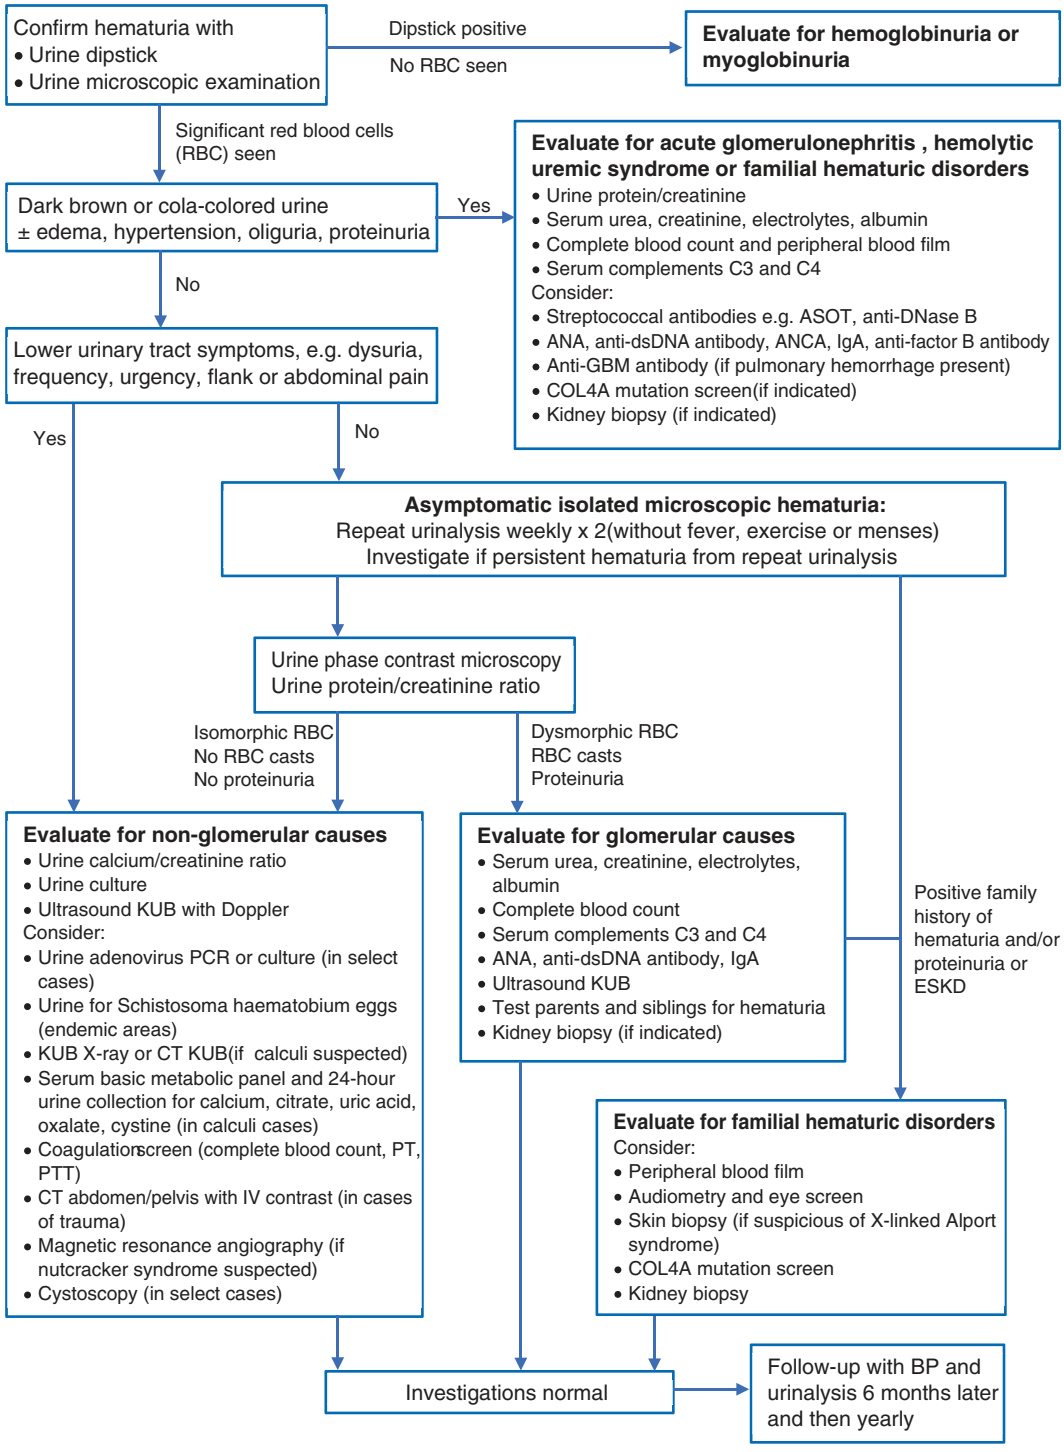

Fig. 12.1 Algorithm for investigating hematuria

MYH9-related diseases [39]. The utility of kidney ultrasonography for evaluation of the asymptomatic child with microscopic hematuria of glomerular origin remains unproven [47]. However, it may be useful to determine the size of the kidneys as a guide to chronicity in patients with evidence of progressive kidney disease, and to diagnose polycystic kidneys in the presence of a suggestive family history.

Hematuria associated with mainly isomorphic red blood cells, together with absence of red blood cell casts and proteinuria, indicate a nonglomerular cause. Urine calcium to creatinine ratio is performed to rule out hypercalciuria. In endemic areas, urine should be examined after sedimentation for *Schistosoma haematobium* eggs, especially during the day when excretion is highest. Ultrasound of the kidneys and bladder is indicated to exclude hydronephrosis, kidney calculi, tumor or cystic kidney disease. A plain abdominal x-ray may be necessary to exclude ureteric stones. If a urinary tract calculus is identified, a complete assessment of the urinary constituents associated with stone risk is needed. If the investigations reveal the presence of tumor, structural urogenital abnormality or urinary calculus, a urological referral is required. A coagulation screen may be necessary when there is a family history of bleeding diathesis. Computed tomography scan of the abdomen and pelvis may be required if there is a history of abdominal trauma followed by gross hematuria. If the nutcracker syndrome is suspected in a thin child with recurrent gross hematuria, Doppler sonography assessing the left renal vein diameter and peak velocity is a useful diagnostic tool. When Doppler renal vein ultrasonography is not diagnostic, axial imaging by computed tomography or magnetic resonance imaging may be required.

Cystoscopy may also be required in cases of children with recurrent nonglomerular macroscopic hematuria of unknown cause. Cystoscopy in children seldom reveals the cause of hematuria, but should be done when preliminary investigations have failed to find a cause, and bladder or urethral pathology is a consideration because of accompanying voiding symptoms. Vascular malformations in the bladder have been detected via cystoscopy. In the rare instance when a bladder mass is noted on ultrasound, cystoscopy is also indicated. Cystoscopy to lateralize the source of bleeding is best performed during active bleeding.

An asymptomatic child with an incidental finding of persistent microscopic hematuria often poses the greatest dilemma regarding the extent of investigations and subsequent follow-up. The most common diagnoses in children with persistent microscopic hematuria without proteinuria and hypertension are TBMN, idiopathic hypercalciuria, IgA nephropathy and Alport syndrome. It is therefore worthwhile to screen family members for microscopic hematuria. If the parents are found to have incidental asymptomatic microscopic hematuria without proteinuria and kidney failure, TBMN is the most likely cause. More extensive evaluation is then not necessary. However, it is important that these patients are followed up yearly to detect proteinuria, which is an indication of progressive kidney disease. When proteinuria is present, these patients need to undergo further evaluation, including genetic analysis for the relevant mutations associated with the familial hematuric disorders. In communities where post-infectious glomerulonephritis is common, subclinical disease is also a common cause of persistent microscopic hematuria.

Indications for Kidney Biopsy

Kidney biopsy is usually not indicated in isolated glomerular hematuria. Kidney biopsy should be considered in the following cases of hematuria associated with:

- Significant proteinuria, except in poststreptococcal glomerulonephritis
- Persistent low serum complement C3
- Unexplained azotemia
- Systemic diseases such as systemic lupus erythematosus or ANCA-associated vasculitis
- Family history of significant kidney disease suggestive of progressive forms of familial hematuric disorders including Alport syndrome

- Recurrent gross hematuria of unknown etiology where investigations are suggestive of a glomerular pathology
- Persistent glomerular hematuria where the parents are anxious about the diagnosis and prognosis.

With recent improvements in understanding the molecular genetics of the familial hematuric disorders, genetic testing, if available and affordable, can sometimes contribute useful diagnostic and prognostic information and may even obviate the need for a kidney biopsy [48].

Proteinuria

It is well-established that proteinuria is a mediator of progressive kidney insufficiency in both adults and children [49–51], as well as a risk factor for cardiovascular disease [52, 53]. Conversely, proteinuria can also be a transient finding in children, occurring during times of stress, including exercise, fever and dehydration, and does not denote kidney disease.

Renal Handling of Proteins

Plasma proteins can cross the normal glomerular filtration barrier. The ability of these proteins to cross the glomerular filtration barrier is related primarily to the molecular size and charge. The larger plasma proteins, such as globulins, are virtually excluded from the normal glomerular filtrate. Smaller proteins, mostly of low molecular weight (LMW; <40,000 Dalton), are filtered across the glomerular filtration barrier. Molecular charge plays an important role in determining glomerular permeability to macromolecules. This is due to the presence of negatively charged sialoproteins that line the surfaces of both the glomerular endothelial and epithelial cells, and glycosaminoglycans present in the glomerular basement membrane. Hence, negatively charged molecules are less able to cross the glomerulus than neutral molecules of identical size. On the other hand, positively charged molecules have enhanced clearances.

In health, albumin is the most abundant protein in serum and constitutes about 40% of the filtered urinary protein despite being anionic and molecular weight of 67,000 Dalton. The rest of the urinary proteins are immunoglobulins, peptides, enzymes, hormones and partially degraded plasma proteins. After crossing the glomerular barrier, 71% of the filtered proteins are reabsorbed by the proximal tubule, 23% by the loop of Henle and 3% by the collecting duct. The quantity of urinary proteins excreted results from a balance between the amount of these proteins filtered and the amount reabsorbed.

Under normal conditions, approximately 60% of protein in urine is filtrate of plasma protein and 40% is of kidney origin. This is a heterogeneous group of proteins, many of which are glycoproteins. Some are derived from cells lining the urinary tract and have the potential of being important diagnostic indicators. The major protein in this group is Tamm-Horsfall protein or uromodulin, which is a major constituent of urinary casts [54]. Adults excrete 30–60 mg/day. It is secreted mainly in the thick ascending limb of the loop of Henle.

Excessive urinary protein losses can be due to the following mechanisms:

- **Glomerular proteinuria:** Increased permeability of the glomerular basement membrane due to structural defects of the membrane, loss of its negative charges or damage by immune complexes or other mediators. This leads to increased filtration of macromolecules, especially albumin, across the glomerular filtration barrier
- **Tubular proteinuria:** Impaired reabsorption of normally filtered LMW proteins (e.g. α-1 microglobulin, β-2 microglobulin, retinol binding protein) by the proximal tubule
- **Secretory proteinuria:** Increased secretion of tissue proteins into the tubules, most notably Tamm-Horsfall protein in interstitial nephritis
- **Overflow proteinuria:** Marked overproduction of LMW proteins (e.g. myoglobin),

resulting in the filtered load exceeding the normal proximal reabsorptive capacity

Hence, the specific type of protein excreted in the urine, such as albumin or LMW proteins, depends on the type of kidney disease. Albuminuria is a marker of glomerular disease while urinary loss of LMW proteins suggests tubulointerstitial disease.

Albuminuria

Albuminuria refers to abnormal loss of albumin in the urine. Albumin is found in the urine in normal subjects and in larger quantities in patients with kidney disease. Recommendations for measurement of urine protein emphasize quantification of albuminuria rather than total protein, as epidemiologic data worldwide have demonstrated a strong graded relationship between the quantity of urine albumin with both kidney and cardiovascular disease risk in adults. The Kidney Disease Improving Global Outcomes (KDIGO) 2012 Clinical Practice Guideline for the Evaluation and Management of Chronic Kidney Disease incorporated albuminuria in the criteria and classification of CKD in adults [55]. A urinary albumin excretion rate of 30 mg/24 h or more sustained for longer than 3 months is used to indicate CKD in adults. This value is considered to be approximately equivalent to an albumin-to-creatinine ratio in a random urine sample of greater than 30 mg/g or 3 mg/mmol. On the other hand, urinary albumin excretion rates in children and adolescents vary with age. Urinary albumin excretion is lowest in children age less than 6 years, followed by an increase through the adolescent years, with a peak at age 15–16 years [56].

Microalbuminuria is below the detection threshold of a standard urine dipstick test. Albuminuria in children and adolescents has been defined as urinary albumin excretion of 30–300 mg/24 h urine collection, 20–200 μg/min in a nighttime collection and 3–30 mg/mmol creatinine (30–300 mg/g creatinine) in a first morning urine sample [57]. This range of urinary albumin excretion, although used in the pediatric population, is derived from population studies in adults.

The prevalence of albuminuria in children and adolescents is estimated to be about 5.7–7.3% in boys and 12.7–15.1% in girls from the National Health and Nutrition Examination Survey III (NHANES III) in the United States [57]. The higher prevalence of albuminuria in girls than in boys could be due to the larger muscle mass and urinary creatinine excretion of boys, resulting in a lower albumin:creatinine ratio. There is a positive association between albumin:creatinine ratio and pubertal development stage [58]. Girls a have a peak albumin:creatinine ratio at Tanner stage 4 (14 years old), whereas in boys there is no increase in albumin:creatinine ratio until Tanner stage 5 (18 years old) [58]. Estimation of the prevalence of albuminuria in children and adolescents can be difficult because a great percentage of children (30–50%) have transient albuminuria because of strenuous exercise [59] or during febrile illnesses.

The significance of albuminuria in diabetic children and adolescents is well established and urinary albumin excretion rate has been used as a screening test for the presence of diabetic nephropathy [60]. The significance of using albuminuria for other conditions in the pediatric population is less well-defined. A cross-sectional study analyzing the NHANES data for 12–19 year old adolescents [61] showed that, despite the presence of cardiovascular risk factors, overweight teenagers had a lower prevalence rate of albuminuria compared to healthy controls. The reason for this lower prevalence of albuminuria in overweight teenagers is uncertain, but one explanation is that lower exercise levels in overweight teenagers leads to less confounding influence by orthostatic proteinuria. Conversely, another study has shown that obese children (BMI 30.4 kg/m^2) compared to normal weight children (BMI 18.2 kg/m^2) were found to have a significantly higher albumin:creatinine ratio determined in a random spot urine sample [62], indicating early kidney dysfunction as a consequence of obesity. The elevated albumin:creatinine ratio in these obese children was also associated

with impaired glucose tolerance and hypercholesterolemia, two of the most important features of the metabolic syndrome [62]. The relationship between albuminuria and cardiovascular outcome in the pediatric population is not as well-studied as in adults [56]. Further longitudinal research is required to evaluate the significance of increased urinary albumin excretion rate in obese children with regards to the future development of cardiovascular morbidity in adulthood.

Definition of Abnormal Urinary Protein Excretion in Children

Normal urinary protein excretion varies across age, gender, puberty and body size. Neonates and young infants have higher urinary losses of both glomerular and tubular proteinuria due to lack of maturation in the proximal tubular reabsorption of proteins. In infants less than 6 months of age, at least one study has suggested that as much as 6–8 mg/m^2/h or up to 300 mg/1.73 m^2/day of proteinuria is normal [63]. The normal rate of protein excretion in the urine for children 6–24 months of age is less than 4 mg/m^2/h or 150 mg/1.73 m^2/day [64]. The first morning spot urine protein-to-creatinine ratio is normal when it is less than 50 mg/mmol (500 mg/g).

Children older than 24 months of age are expected to achieve normal adult urinary protein values, with the caveat of an exaggerated postural loss of glomerular protein (albumin), which can be seen in 2–5% of the adolescent population (i.e. orthostatic proteinuria) [59]. Hence, in children older than 24 months, the normal rate of protein excretion in the urine is still less than 4 mg/m^2/h or less than 150 mg/1.73 m^2/day. However, the first morning spot urine protein-to-creatinine ratio is defined as normal at less than 20 mg/mmol (200 mg/g) and the spot urine albumin-to-creatinine ratio is normal at less than 3 mg/mmol (30 mg/g) [64].

At all ages, urinary protein excretion of greater than 40 mg/m^2/h or 3 g/1.73 m^2/day is defined as nephrotic range proteinuria (Table 12.4) [64]. If albumin excretion is measured, nephrotic range proteinuria is defined as urine albumin greater

Table 12.4 Quantification of urinary protein excretion in children

Method	Abnormal proteinuria	Precautions
Urine dipstick	≥1+ in a urine specimen of specific gravity ≥1.002	False-positive if urine pH >8.0 or specific gravity >1.025 or tested within 24 h of radiocontrast study
Sulfosalicylic acid test	≥1+	False-positive with iodinated radiocontrast agents
Urine protein:creatinine ratio in spot urine	>20 mg/mmol (>0.02 g/mmol) or >200 mg/g *in children >2 years old* [51] >50 mg/mmol (>0.05 g/mmol) or >500 mg/g *in children 6 months to 2 years old* Nephrotic range: >220 mg/mmol (>0.22 g/mmol) or >2200 mg/g [55]	Protein excretion varies with child's age
Timed urine protein excretion rate [49]	>4 mg/m^2/h or >150 mg/1.73m^2/24 h *in children >6 months old* >8 mg/m^2/h or >300 mg/1.73m^2/24 h *in children <6 months old* Nephrotic range: >40 mg/m^2/h or >3 g/1.73m^2/24 h [59]	In an accurately collected 24-h urine specimen, the urine creatinine should be in the range of 0.13–0.20 mmol/kg or 16–24 mg/kg ideal body weight for females, and 0.18–0.23 mmol/kg or 21–27 mg/kg ideal body weight for males
Urine albumin:creatinine ratio in spot urine	>3 mg/mmol (>0.003 g/mmol) or >30 mg/g in children >2 years	
Timed urine albumin excretion rate [57]	>30 mg/1.73m^2/24 h	

than 2200 mg/1.73 m^2/day or albumin-to-creatinine ratio greater than 220 mg/mmol or 2200 mg/g [55].

With regards to using urinary albumin or protein excretion in the classification of children with CKD, variations in the definition of abnormal urinary albumin or protein excretion based on age must be taken into account. Abnormal urinary protein excretion in children should also consider the possibility of tubular versus glomerular proteinuria, depending on the underlying disease. Urinary albumin excretion rate may be normal in tubular proteinuria. Hence, in children, the quantification of total protein, as compared to the albumin only fraction, may be the preferred method of assigning risk in relation to the presence of urinary protein.

The KDIGO 2012 guidelines recommended a urinary total protein or albumin excretion rate above the normal value for age be used for children and adolescents [55]. Table 12.5 shows the categories of persistent albuminuria and proteinuria to be used in the classification of CKD. Albuminuria is classified into normal to mildly increased, moderately increased and severely increased. However, in children, urine protein-to-creatinine ratio is the preferred test, followed by albuminuria, and lastly by automated reagent strips for detection of proteinuria. This is because the vast majority of children have underlying congenital anomalies of the kidney and urinary tract, unlike in adults, where the etiology of CKD is more commonly an underlying glomerular disease such as diabetic nephropathy or hypertensive damage. The use of albumin excretion may therefore be less sensitive for diagnostic purposes in children, as those with underlying tubular conditions will tend to excrete more Tamm-Horsfall protein and other LMW proteins.

Urine Dipstick

The urine dipstick is an excellent screening test for the presence of proteinuria [64]. The dipstick is impregnated with the dye tetrabromophenol blue buffered to pH 3.5. At a constant pH, binding of protein to this dye results in the development of a blue color in proportion to the amount of protein present. If urine is protein-free, the dipstick is yellow. The color of the dipstick changes through yellow-green, to green, to a green-blue with increasing concentrations of protein. The dipstick can be read as negative, trace, 1+, 2+, 3+ and 4+, which corresponds to insignificant, less than 0.2 g/L, 0.3 g/L, 1 g/L, 3 g/L and greater than 20 g/L concentrations, respectively.

The dipstick test has a few limitations. Observer error can occur during interpretation of the color of the dipstick. False positive and false negative tests can occur. If the dipstick is kept in

Table 12.5 Categories of albuminuria in chronic kidney disease [55]

	Categories		
Investigation	Normal to mildly increased (A1)	Moderately increased (A2)	Severely increased (A3)
Albumin excretion rate (mg/1.73 m^2/24 h)	<30	30–300	>300
Protein excretion rate (mg/1.73 m^2/24 h)	<150	150–500	>500
Albumin:creatinine ratio (ACR)			
(g/mmol)	<0.003	0.003–0.030	>0.030
(mg/mmol)	<3	3–30	>30
(mg/g)	<30	30–300	>300
Protein:creatinine ratio (PCR)			
(g/mmol)	<0.015	0.015–0.050	>0.050
(mg/mmol)	<15	15–50	>50
(mg/g)	<150	150–500	>500
Protein reagent strip	Negative to trace	Trace to +	+ or greater

the urine too long, the buffer may leach out and a false positive test may result. False positive tests for protein can also occur in the presence of gross hematuria, pyuria and bacteriuria or if the urine is contaminated with antiseptics such as chlorhexidine or benzalkonium, which are often used for skin cleansing prior to clean catch of the urine. False positive results may occur with urine specimens after the administration of radiographic contrast or with ingestion of certain medications, including penicillins, cephalosporins, tolbutamide or sulfonamides.

The result of the dipstick test can be affected by the concentration of the urine. If the urine is very dilute, the urinary protein concentration may be reduced to a level below the sensitivity of the dipstick (0.1–0.15 g/L), even in patients excreting up to 1 g of protein per day. Hence, a negative dipstick should be interpreted with caution if the urine specific gravity is less than 1.002. In contrast, if the urine specific gravity is greater than 1.025, a healthy child can register trace of protein on the dipstick, resulting in a false positive result. The dipstick test for protein can also be affected by the pH of the urine. Very alkaline urine (pH greater than 8.0) can cause a false positive result while very acid urine (pH less than 4.5) can cause a false negative result.

False negative results occur in non-albumin proteinuria. Albumin binds better to the dye than other proteins. Hence, the urine dipstick primarily detects albumin, leaving LMW proteins undetected. The dipstick results correlate better with albuminuria than with proteinuria. However, though the dipstick is more specific for albumin, it lacks the sensitivity to detect microalbuminuria associated with early glomerular injury seen in diabetic nephropathy or cardiovascular disease. A negative dipstick test for protein does not exclude the presence in the urine of low concentrations of globulins, mucoproteins or Bence-Jones protein.

Sulfosalicylic Acid Test

An alternative method to measure urine protein in patients with questionable proteinuria by dipstick in the office is the sulfosalicylic acid precipitation of protein in urine. This technique provides a more quantitative estimate of all the proteins present in the urine, including both albumin and the LMW proteins. This test is performed by mixing one part urine supernatant with three parts 3% sulfosalicylic acid, and the resultant turbidity is then graded, as shown in Table 12.6 [65]. As with the urine dipstick, iodinated radiocontrast agents can cause a false positive result; hence, the urine should not be tested for at least 24 h after a contrast study.

Table 12.6 Sulfosalicylic acid test

Grade	Appearance	Protein concentration (g/L)
0	No turbidity	0
Trace	Slight turbidity	0.01–0.1
1+	Turbidity through which print can be read	0.15–0.3
2+	White cloud without precipitate through which heavy black lines on a white background can be seen	0.4–1
3+	White cloud with precipitate through which heavy black lines cannot be seen	1.5–3.5
4+	Flocculent precipitate	>5

Quantification of Proteinuria: 24-h Urine Specimen Versus Spot Urine Specimen

The results obtained with urine dipstick and with quantitative 24-h protein excretion methods correlate fairly well in most situations. As mentioned earlier, the dipstick is more sensitive to albumin, whereas quantitative methods detect all proteins, including globulin and LMW protein. For example, in multiple myeloma, large amounts of protein are excreted and yet the urine dipstick for protein is negative. Hence, quantitative urinary protein measurement is necessary in this case. A more important reason why quantitative measurement of protein loss in the urine should be done is to determine whether the patient requires a more extensive evaluation. For example, many patients with a dipstick reading of 1+ protein

have a normal quantitative result and additional evaluation is not indicated.

Quantification of proteinuria has traditionally demanded timed urine collection. Urinary protein excretion in adults is usually measured in a 24-h urine collection. This is more accurate than a spot urine protein analysis. However, 24-h urine collection poses logistical problems with timing and volume measurements, especially in young children who have yet to achieve continence at night. In this case, a 12-h urine collection can be done, and the protein excretion rate is then extrapolated to a 24-h value by using the appropriate correction factor.

The other method is to obtain a single voided urine sample. The concentrations of both protein and creatinine are measured in the urine sample and protein levels are expressed per unit of creatinine. The advantages of this method include not requiring timed urine samples and not having to correct for body size. The assumption is creatinine excretion is directly related to body mass and is relatively constant throughout the day. Many studies have found that the amount of protein excreted in a 24-h urine correlates extremely well with the protein-to-creatinine ratio measured in random urine samples [66, 67].

What remains debatable is whether early morning urine samples or random urine samples obtained during normal activities during the day are better indicators of kidney disease. The urine protein-to-creatinine ratio is higher in urine samples obtained in a person in an upright position than in a recumbent position, a phenomenon known as orthostatic proteinuria [59]. Studies that included subjects with normal kidney function as well as those with kidney failure have shown that urine protein-to-creatinine ratios from daytime samples correlated better with 24-h urine protein excretion values than did values from early morning samples [59]. Conversely, early morning samples had better correlation when data were evaluated from normal subjects and from those with kidney disease but normal glomerular filtration rates [68]. In subjects with kidney disease and orthostatic proteinuria, daytime urine protein-to-creatinine ratios can be misleading. Hence, in the evaluation of children with possible kidney disease, the first morning urine specimen is recommended for urine protein-to-creatinine ratio quantification to eliminate the effect of posture. In general, the 24-h urine collection for protein excretion is ideal as the initial diagnostic investigation, with the exception of children who have yet to achieve continence; whereas, the first morning spot urine protein-to-creatinine ratio is useful to monitor progress of proteinuria.

An important consideration when interpreting spot urine protein-to-creatinine ratio is a falsely elevated urine protein-to-creatinine ratio, which can occur when there is low creatinine excretion in children with very low muscle mass (e.g. neuromuscular disorders). The spot urine protein-to-creatinine ratio can be underestimated when there is a very concentrated urine sample with high creatinine level in the urine. One method to avoid overestimation or underestimation is to send spot urine sample for both protein-to-creatinine ratio as well as urinalysis, with the expectation that significant proteinuria will be present in both examinations.

The spot urine protein-to-osmolality ratio has been suggested as another convenient method for estimating urine protein excretion without a 24-h urine collection and to overcome the problem of low creatinine excretion in children with very low muscle mass. Compared to urine creatinine concentration, urine osmolality, which is a direct measure of degree of urine concentration, may thus have advantages of a methodology to standardize normal protein excretion on a random sample. Data describing the normal range of urine protein-to-osmolality ratios have been published for adults [69]. However, the results in the pediatric population differ from the adult population. In the pediatric population, urine protein-to-creatinine ratio was superior to urine protein-to-osmolality ratio for predicting abnormal amounts of proteinuria in children and adolescents [70]. Dilanthi et al. reported that urine protein-to-creatinine ratio (sensitivity 100%, specificity 94%) was more sensitive than urine protein-to-osmolality ratio (sensitivity 85.7%, specificity 100%) in detecting children with mild proteinuria [71]. Hence, using spot urine protein-

to-osmolality as an alternative method to estimate 24-h urine protein excretion in children is not widely practiced. If spot urine protein-to-osmolality ratio is used, it is important to remember that high urine osmolality due to glycosuria can cause an underestimation of the protein-to-osmolality ratio. Glycosuria should be excluded prior to assessment of protein-to-osmolality ratio in a spot urine sample.

The dipstick, Multistix® PRO (Bayer, Elkhart, Ind., USA), is able to analyze concentrations of both urinary protein and creatinine semi-quantitatively in only 60 s and is commercially available. The semi-quantitative urine protein-to-creatinine ratio by Multistix® PRO correlated well with both quantitative urine protein-to-creatinine ratio and daily urinary protein excretion [72, 73], and use of the Multistix® PRO would avoid errors and difficulties associated with timed urine collection. It may become a useful tool to monitor the urinary protein excretion in children with kidney diseases in the outpatient setting.

Clinical Scenarios

Proteinuria can be symptomatic (presenting with edema) or asymptomatic, which can be intermittent or persistent.

Child with Edema

Proteinuria associated with edema can be due to nephrotic syndrome, nephritic syndrome or kidney failure. Nephrotic syndrome is defined as heavy proteinuria that is severe enough to cause hypoalbuminemia, edema and hypercholesterolemia. Nephrotic range proteinuria is defined as greater than 40 mg/m^2/h or greater than 3 g/1.73 m^2/day for timed urine collection, or random urine protein-to-creatinine ratio of greater than 0.22 g/mmol (220 mg/mmol or 2200 mg/g) [64]. The evaluation and management of a child presenting with nephrotic syndrome, nephritic syndrome or kidney failure is different from that of a child with intermittent or persistent proteinuria without edema. Nephrotic syndrome, nephritic syndrome and kidney failure are discussed elsewhere in the book.

Child with Intermittent Proteinuria

In intermittent proteinuria, protein is detectable in only some of the urine samples collected. This may be related to posture or occur at random.

Frequently, intermittent proteinuria is not related to posture. It may be found after exercise or in association with stress, seizures, dehydration or fever. It may occur on a random basis for which there is no obvious cause. This is also known as transient proteinuria, which is defined as proteinuria noted on 1 or 2 occasions, but not present on subsequent testing, especially when the inciting factor remits or is removed. A large proportion of healthy children may have an occasional urine sample with proteinuria. This is rarely associated with significant kidney disease.

Orthostatic (postural) proteinuria is defined as elevated protein excretion when the subject is upright, but normal protein excretion during recumbency. This occurs commonly in adolescents, with a prevalence of 2–5% [74]. The diagnosis is suggested by a normal protein-to-creatinine ratio in a first morning spot urine sample after the subject has been supine for the entire night, but an elevated protein-to-creatinine ratio after the subject has been upright for at least 4–6 h. Total urine protein excretion rarely exceeds 1 g/1.73 m^2/day in orthostatic proteinuria. A study of healthy Turkish children aged 6–15 years old found that the prevalence of orthostatic proteinuria was lower than previous literature if at least three random urine samples at least 2 weeks apart were taken to exclude transient proteinuria [75]. For continuing assessment of proteinuria after the third sample, the first morning urine sample was collected. In this study, the prevalence of proteinuria was 3.7%, 1.3% and 0.94% on the first, second and third samples, respectively and the prevalence of orthostatic proteinuria was 0.65% after the first morning urine collection. This study also suggested that underweight children had a tendency for orthostatic

proteinuria compared with overweight and obese children [75].

The postulated causes of orthostatic proteinuria are alterations in kidney or glomerular hemodynamics, circulating immune complexes and partial left renal vein entrapment, as may be seen in thin individuals [76]. The incidence of orthostatic proteinuria decreases with advancing age, possibly due to the gradual accumulation of retroperitoneal fat. Long-term studies where patients have been followed for up to 50 years have documented the benign nature of orthostatic proteinuria, although rare cases of glomerulosclerosis have been identified later in life in patients who were initially diagnosed to have orthostatic proteinuria [77, 78]. No treatment is required for children with orthostatic proteinuria. It has been recommended that children with orthostatic proteinuria should be followed up annually [79].

It is important to remember that patients with glomerular disease may have an orthostatic component to their proteinuria. Protein excretion in these patients is greater when they are active or upright than when they are resting. Hence, orthostatic proteinuria should not be diagnosed unless the recumbent urine sample is normal.

Child with Persistent Proteinuria

Persistent proteinuria is defined as proteinuria of 1+ or more by dipstick on multiple occasions. This should be further investigated. Subjects who have persistent proteinuria, especially if this is associated with additional evidence of kidney disease such as microscopic hematuria, are more likely to have significant pathology in the urinary tract. In the Japanese school screening study, which looked at almost five million children, the prevalence of persistent isolated proteinuria was 0.07% in the 6–11-year age group, and this rose to 0.37% in the 12–14 year age group [27].

The majority of cases of persistent proteinuria are of glomerular origin, though non-glomerular mechanisms can also cause marked proteinuria (Table 12.7).

Glomerular proteinuria may be due to the following factors:

Table 12.7 Causes of proteinuria in children

Intermittent proteinuria	Persistent proteinuria	
	Glomerular	Tubular
Non-postural Fever Exercise Seizures Emotional stress Dehydration No known cause Postural (Orthostatic)	Primary glomerulopathies Minimal change disease Focal segmental glomerulosclerosis Membranoproliferative glomerulonephritis Membranous nephropathy Rapidly progressive glomerulonephritis Congenital nephrotic syndrome Secondary glomerulopathies Post-infectious glomerulonephritis Lupus nephritis IgA nephropathy IgA vasculitis nephritis Alport syndrome Hepatitis B nephropathy Hepatitis C nephropathy Human immunodeficiency virus (HIV) nephropathy Amyloidosis Hemolytic uremic syndrome Diabetes mellitus Hypertension Hyperfiltration following nephron loss Reflux nephropathy	Hereditary Cystinosis Galactosemia Tyrosinemia Hereditary fructose intolerance Wilson disease Lowe syndrome Mitochondrial cytopathies Dent's disease Polycystic kidney disease Acquired Pyelonephritis Tubulointerstitial nephritis Acute tubular necrosis Analgesic abuse Drugs such as penicillamine Heavy metal poisoning (e.g., lead, cadmium, gold, mercury) Vitamin D intoxication

- Increase in glomerular permeability to plasma proteins in residual nephrons in cases where there is reduction in nephron mass. This mechanism probably explains the increased proteinuria seen in patients with reflux nephropathy, progressive kidney disease reaching end-stage and the increased proteinuria observed in kidney transplant donors [80].
- Loss of negative charge in the glomerular filtration barrier [81, 82]. This results in mostly albuminuria. There is little increase in glomerular permeability to globulins;hence, the proteinuria is highly selective. A typical example is minimal change disease.
- Direct injury to the glomerular filtration barrier. The glomerular capillary wall consists of three structural components that form the permselectivity barrier: the endothelial cells, glomerular basement membrane and podocytes. The podocyte is crucial for maintenance of the glomerular filter, and disruption of the epithelial slit diaphragm leads to proteinuria [83]. These changes have been demonstrated in patients with nephrotic syndrome irrespective of the primary disease. Such injury increases the "effective pore size" in the glomeruli, causing an increase in the permeability of the mechanical barriers to the filtration of proteins. Hence, there is an increase in filtration of albumin and also larger proteins such as globulins. The clearance of globulins is relatively high and the proteinuria is described as non-selective.
- Mutations of key podocyte genes. Mutations of genes involved in regulation of the slit diaphragm proteins and their interaction with the actin cytoskeleton also result in proteinuria.
- Changes in glomerular capillary pressure due to disease and resulting in increased filtration fraction [49, 50, 84]. Examples are increased filtration fraction in hyperreninemia and hyperfiltration in the early stages of diabetic nephropathy.

The increased filtered load of protein overwhelms the tubular reabsorptive mechanisms; hence, the excess protein appears in the urine. Glomerular proteinuria can be classified as selective or nonselective. In selective proteinuria, there is a predominance of LMW proteins such as albumin or transferrin, as compared to higher molecular weight proteins such as IgG. The selectivity index is expressed as the clearance ratio of IgG over albumin or transferrin. An index less than 0.1 is indicative of highly selective proteinuria [85, 86], and this is seen in steroid-sensitive nephrotic syndrome and Finnish-type congenital nephrotic syndrome. More recent studies have shown that there is a significant relationship between selectivity of proteinuria and tubulointerstitial damage in kidney disease [87]. When proteinuria is highly selective, tubulointerstitial damage is less common.

Non-glomerular mechanisms include tubular proteinuria, overflow proteinuria and secretory proteinuria. Tubular proteinuria results when there is damage to the proximal convoluted tubule, which normally reabsorbs most of the filtered protein. The amount of protein in the urine due to tubular damage is usually not large and does not exceed more than 1 g/1.73 m^2/day. Glomerular and tubular proteinuria can be distinguished by protein electrophoresis of the urine. The primary protein in glomerular proteinuria is albumin, whereas in tubular proteinuria the LMW proteins migrate primarily in the α and β regions. β2-microglobulin, α1-microglobulin and retinol-binding protein are the markers commonly used for identification of tubular proteinuria [88]. Children with proximal tubulopathies such as Lowe syndrome and Dent's disease have tubular proteinuria. Albuminuria may eventually be detected in many tubulopathies as a marker of late glomerular involvement.

Overflow proteinuria results when the concentration of filterable proteins in the glomerular filtrate exceeds the maximal tubular reabsorption capability for that protein. This can occur even with normal renal function. Examples include monoclonal gammopathy of undetermined significance or multiple myeloma in adults (immunoglobulin light chains or Bence-Jones protein), hemoglobinuria, myoglobinuria, β2-microglobulinemia, myelomonocytic leukemia and even following transfusions. After multi-

ple transfusions of either albumin or whole blood, plasma albumin concentration may increase sufficiently to cause albuminuria.

In secretory proteinuria, the increased excretion of tissue proteins into the urine may result in proteinuria. The typical example is excretion of Tamm-Horsfall protein in the neonatal period, accounting for the higher levels of protein excretion typically seen at this age. In UTIs, mild proteinuria may be detected due to irritation of the urinary tract and increased secretion of tissue proteins into the urine. Secretory proteinuria also occurs in analgesic nephropathy and inflammation of the accessory sex glands.

Clinical Approach to Proteinuria

The finding of proteinuria in a single urine specimen in children and adolescents is relatively common. In large school screening programs, the prevalence of isolated proteinuria on a single urine ranged from 1.2 to 15% [2, 28, 89]. Persistent proteinuria on repeated urine testing is much less common [75]. When proteinuria is detected, it is important to determine whether it is intermittent, especially orthostatic, or persistent. It is also important to exclude kidney failure and acute nephritic or nephrotic syndrome because these conditions demand urgent investigations and treatment.

History

It is important to ask about any recent illness. Inquire about symptoms of CKD (e.g. polyuria, nocturia, pruritus, lethargy) or glomerulonephritis (e.g. edema, hematuria, oliguria), and connective tissue disorders (e.g. rashes, joint pain). A history of recurrent UTIs may suggest reflux nephropathy. Medications that are associated with proteinuria include non-steroidal anti-inflammatory medications, antibiotics (e.g. penicillin, sulfonamides, cephalosporins, quinolones, aminoglycosides), amphotericin B, cisplatin, allopurinol, and herbal medicines. A family history of polycystic kidney disease, hematuria, proteinuria, nephrotic syndrome, kidney failure or deafness should be obtained.

Physical Examination

Examination may reveal evidence of CKD such as growth failure, pallor from anemia, and rickets from metabolic bone disease. Hypertension is common in CKD. The presence of raised jugular venous pressure, hepatomegaly and edema suggest the child may be fluid overloaded due to acute nephritic syndrome or severe kidney functional impairment, and thus require urgent diuresis. Nephrotic syndrome may cause generalized edema, ascites, pleural effusion and scrotal edema. Associated signs of systemic illnesses, such as palpable purpuric rash on the lower limbs suggesting IgA vasculitis nephritis (Henoch Schönlein purpura) and joint swelling suggesting connective tissue disorders, should be sought. Palpable flank masses may suggest hydronephrosis or polycystic kidney disease.

Investigations

Isolated proteinuria is benign in the vast majority of children and can be transient and postural; hence, it is inappropriate to extensively investigate all children found to have proteinuria. A step-by-step approach is recommended to evaluate isolated proteinuria in an asymptomatic child or a child with an incidental finding of urine dipstick protein 1+ or 2+ during an acute illness. However, if the child has signs and symptoms suggestive of kidney disease, a detailed investigation should start promptly. Similarly, if the initial urine dipstick shows the presence of hematuria and proteinuria, detailed evaluation for kidney disease should be performed. Microscopic hematuria is the most common indicator of a glomerular lesion in a proteinuric patient. The existence of hematuria with proteinuria carries a more serious connotation than isolated proteinuria. Investigations including kidney biopsy of school children with persistent hematuria and proteinuria have found that 25–60% had evidence of a

glomerulopathy [29, 90], especially in those with proteinuria greater than 1 g/L. [29]

The first step in the evaluation of a child with isolated proteinuria is to determine whether the proteinuria is persistent (Fig. 12.2). Most children who have proteinuria on screening urine dipstick do not have kidney disease, and the proteinuria will resolve on repeat testing [27]. If proteinuria of 1+ or more persists on two subsequent dipstick tests at weekly intervals, further investigations are required. If proteinuria is absent on subsequent testing, the initial proteinuria may be transient and related to fever, vigorous exercise or emotional stress, and no further investigations are required. The parents and patient should be reassured and, as a precaution, a urine dipstick test for protein can be repeated in 3–6 months. If proteinuria on dipstick recurs or is persistent, the next step is to quantify the amount of proteinuria.

There are two methods to quantify proteinuria, spot urine protein-to-creatinine ratio and 24-h urinary total protein collection. An early morning spot urine protein-to-creatinine ratio is recommended to exclude orthostatic proteinuria. In orthostatic proteinuria, the first morning urine sample is negative for protein and the later urine samples may contain varying concentrations of protein, whereas the 24-h urinary total protein is normal or mildly elevated. If orthostatic proteinuria is strongly suspected, one way to prove this is to provide the family with urine dipsticks. The child's urine is tested twice daily for 1 week. The family should test the first urine sample voided in the morning and the last urine sample voided in the evening before the child sleeps. It is important that the bladder is completely emptied before going to sleep, and the child remains supine in bed throughout the night so that the early morning urine sample on awakening consists of urine formed in the recumbent position. The evening urine sample consists of urine formed in the upright position. If the urine dipstick is persistently negative in the morning and positive in the evening, orthostatic proteinuria is likely. No further investigations are required, and the urine should be rechecked for proteinuria yearly as a precaution.

If spot urine protein-to-creatinine ratio is more than 0.02 g/mmol (20 mg/mmol or 0.2 mg/mg), it is advisable to confirm the presence of significant proteinuria with a 24-h urinary total protein collection. After excluding transient and orthostatic proteinuria, and if the 24-h urinary total protein is greater than 0.3 g/1.73 m^2/day, it is useful to evaluate for kidney disease. Urinary protein excretion less than 0.3 g/1.73 m^2/day is associated with regression of proteinuric chronic nephropathies [91], suggesting that investigations are only necessary above this level. The suggested work-up includes the following:

Urine Examination

Microscopic examination of the fresh urine sample for blood, casts and crystals is required. A clean catch urine sample for culture may be necessary to rule out occult UTI, especially if there is a history of recurrent fevers in infancy. If a tubular disorder or interstitial nephritis is suggested from the history or urinary findings of eosinophils, measurement of the urinary excretion of β2-microglobulin, α1-microglobulin and retinol-binding protein, markers of tubular proteinuria, can be helpful. Tubular proteinuria is suspected if the urinary excretion of β2-microglobulin, α1-microglobulin and retinol-binding protein exceeds 0.04, 2.2 and 0.024 mg/mmol creatinine or 4×10^{-4}, 0.022 and 2.4×10^{-4} mg/mg creatinine, respectively [88].

Blood Examination

Assess the kidney function with serum urea, creatinine and electrolytes. Creatinine clearance or application of an estimating formula such as the revised Schwartz formula [92] gives a more accurate assessment of kidney function than serum creatinine alone. A reduction in kidney function is one of the most important indications for a kidney biopsy. Serum total protein and albumin should be checked. Most proteinuric patients do not have decreased serum levels of protein or albumin unless they have nephrotic syndrome or they have heavy proteinuria for a significant period. Hypoproteinemia may be an indication for kidney biopsy. In addition, serum cholesterol

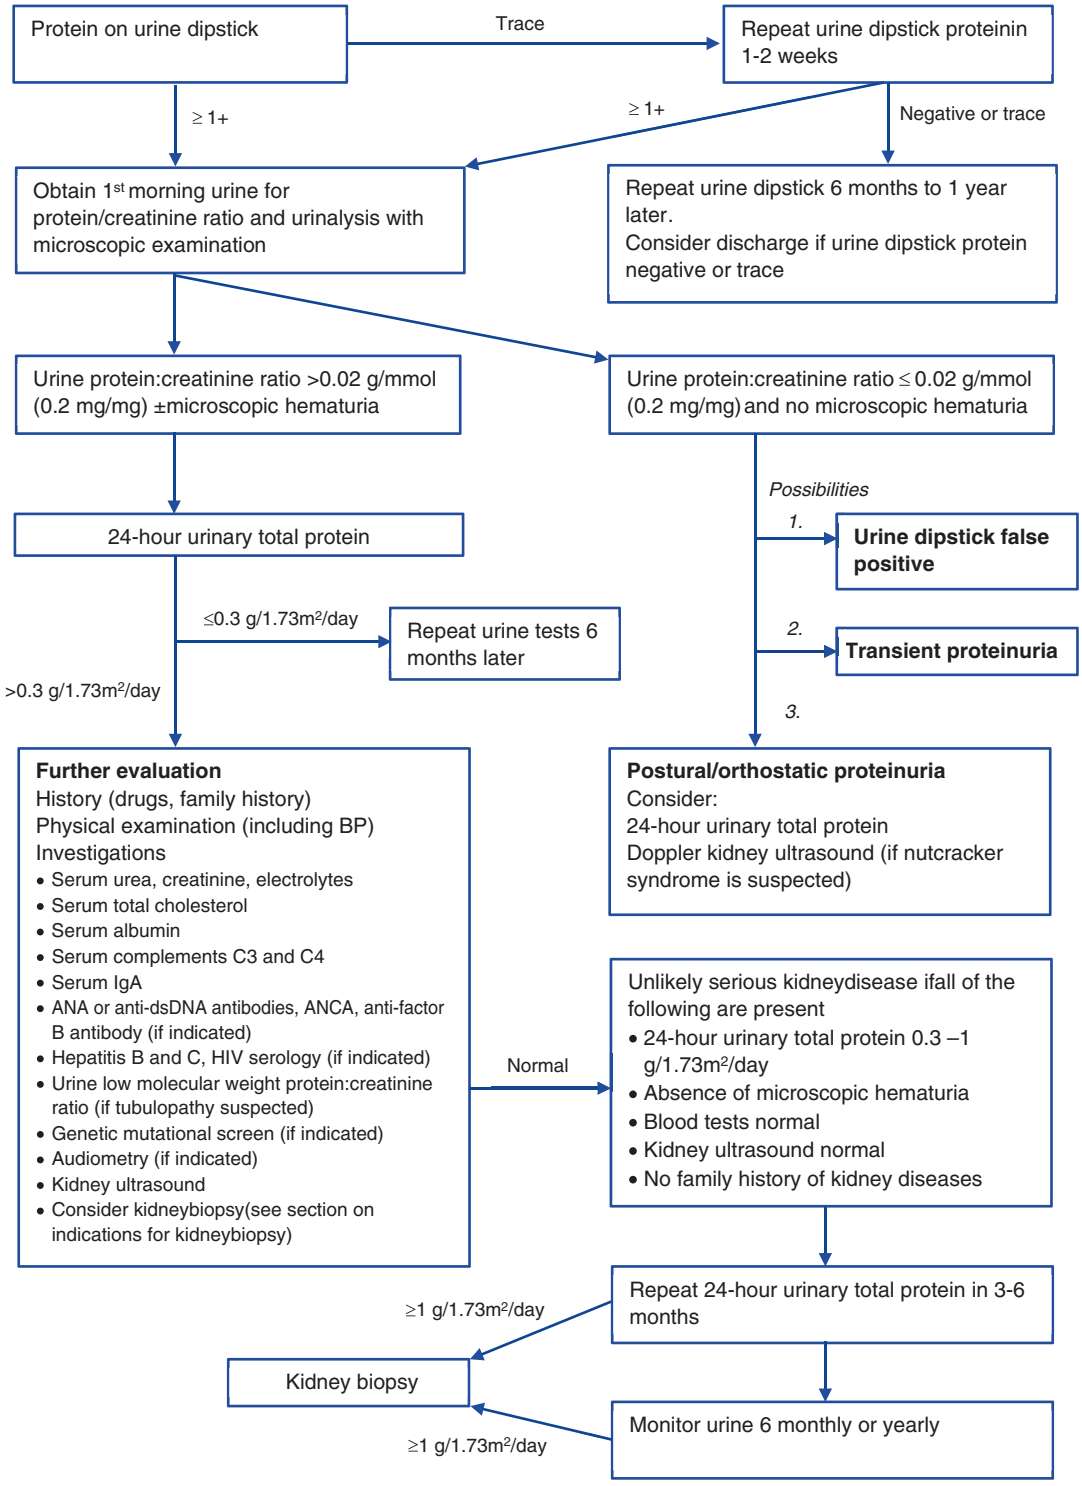

Fig. 12.2 Algorithm for investigating proteinuria

is measured as an indicator of the presence hyperlipidemia, which is suggestive of nephrotic syndrome.

Serum levels of C3 and C4 should be checked routinely as this may provide evidence of glomerulonephritis. Decreased C3 and C4 levels are seen in systemic lupus erythematosus, while decreased C3 with normal C4 levels occurs in post-infectious glomerulonephritis or C3 glomerulopathies, including membranoproliferative glomerulonephritis. Anti-factor B antibody levels, an autoantibody targeting factor B (a component of the alternative pathway C3 convertase), is highly specific for post-infectious glomerulonephritis, distinguishing it from C3 glomerulopathy [44]. ANA, anti-dsDNA antibodies, IgA levels, antistreptolysin O titers (ASOT) or anti-DNase B titers, ANCA, hepatitis B, hepatitis C and human immunodeficiency virus (HIV) serology should be considered if the clinical setting and preliminary investigations are suggestive, as these may give a clue to the underlying etiology of the proteinuria. In addition, appropriate mutational screening should be considered if a hereditary disorder for the proteinuria or nephrotic syndrome is suspected.

Kidney Imaging

Kidney ultrasonography is done routinely in the evaluation of isolated proteinuria to identify anatomical abnormalities of the kidneys or urinary tract as these can result in reduction of nephron mass. A significant difference in the sizes of the kidneys may suggest underlying reflux nephropathy or renal dysplasia. If reflux nephropathy is suspected, a DMSA scan is useful to demonstrate the existence of renal scars. Doppler kidney ultrasonography is helpful if the patient has coexisting hypertension as proteinuria can occur in hypertensive nephropathy due to renal artery stenosis. In patients with orthostatic proteinuria, Doppler sonography of the left renal vein may be a useful screening tool to exclude the nutcracker syndrome [93].

Audiometry

Audiometry is indicated when there is a family history of nephritis, kidney failure or deafness. Deafness may be detected during later childhood in Alport syndrome, and is generally associated with progressive kidney disease.

If these urine and blood tests as well as the initial kidney ultrasound are normal, and if the proteinuria is less than 1 g/1.73 m^2/day, it is unlikely that the child has a serious kidney disease. The family should therefore be reassured that the proteinuria may disappear or it may persist without any evidence of progressive kidney failure developing. As the level of proteinuria is associated with outcome in chronic nephropathies [49, 91, 94], it is also important to emphasize to the family that follow-up urine tests are necessary. The child should be reviewed in 3–6 months. If the repeat test shows that the proteinuria is not marked (i.e., less than 1 g/1.73 m^2/day), the child's urine is then monitored twice during the subsequent year and yearly thereafter. If there is persistent significant proteinuria on follow-up, a kidney biopsy may be indicated.

Indications for Kidney Biopsy

Kidney biopsy is indicated in the following situations:

- Persistent significant proteinuria of more than 1 g/1.73 m^2/day [95] or random urine protein-to-creatinine ratio of >0.05 g/mmol (>50 mg/mmol, >0.5 g/g) [96]. The heavier the proteinuria, the more likely a tissue diagnosis will be obtained from the kidney biopsy. A study on kidney biopsies in Japanese children with asymptomatic, persistent, isolated proteinuria showed that a 41.4% probability of significant glomerular changes, such as focal segmental glomerulosclerosis, when using a urine protein-to-creatinine ratio > 50 mg/mmol (0.5 g/g) as a biopsy criterion [96]. The exception is the child with typical steroid sensitive nephrotic syndrome suggestive of minimal change disease, where kidney biopsy is not indicated at presentation.
- Proteinuria associated with urinary sediment abnormalities (e.g. hematuria). Kidney biopsy is more likely to be diagnostic when proteinuria is associated with urinary sediment abnor-

malities than when there is either isolated proteinuria or isolated hematuria.
- Decreased glomerular filtration rate (GFR). A GFR less than 60 ml/1.73 m^2/min is an indication for kidney biopsy. The exception is a child who is recovering from an acute glomerulonephritis (e.g. post-infectious glomerulonephritis). In this case, the GFR should be remeasured in a month, and if the GFR remains low, a kidney biopsy is required.
- Low C3 levels for more than 3 months. A low C3 level during the acute phase of post-infectious glomerulonephritis is not an indication for biopsy. If the C3 level remains low after 3 months, a kidney biopsy is indicated.
- Evidence of a vasculitis (e.g. systemic lupus erythematosus, IgA vasculitis nephritis, ANCA-positive vasculitis), either clinically or serologically.

Potential Role of Genetic Testing in Evaluation of Proteinuria in Children

Historically, the diagnostic workup of children with persistent isolated proteinuria included urinalysis, blood examination, and radiological imaging before proceeding to histological diagnosis via kidney biopsy. The role of kidney biopsy in the investigation of asymptomatic, isolated proteinuria is controversial in children due to its invasiveness and requirement for sedation. Advances in technology has resulted in increased availability of genetic testing to establish a diagnosis. Genetic testing may be considered early in the diagnostic workup in order to reduce the need for kidney biopsy.

ADCK4-related glomerulopathy is an example of a genetic disorder presenting with proteinuria where effective intervention is possible. The PodoNet consortium found biallelic ADCK4 pathogenic variants in 1.9% of 534 patients with steroid resistant nephrotic syndrome. Most patients with ADCK4 mutations had a renal-limited phenotype with nephrotic range proteinuria or advanced CKD during adolescence [97]. Renal biopsy uniformly showed FSGS. These patients did not respond to corticosteroids or other immunosuppressive therapy and progressed to ESKD in the second decade of life. A Korean study showed that all patients with ADCK4 mutations also had medullary nephrocalcinosis [98].

Coenzyme Q10 supplementation (dose of 20–30 mg/kg/day) reduces proteinuria and preserves GFR in young patients with ADCK4 mutations when initiated in the early stage of the disease when patients have asymptomatic proteinuria and before the development of irreversible kidney damage [99–101]. Hence, there is a role of genetic testing in the diagnostic workup of patients with proteinuria. Early detection and early intervention of potentially treatable genetic kidney diseases such as ADCK4-related glomerulopathy may slow or prevent progression to kidney failure.

Treatment Options for Significant Proteinuria in the Non-nephrotic Range

It is well-recognized that glomerular proteinuria may play a role in the progression of kidney disease [102]. Proteinuria has also been identified as a risk factor for cardiovascular disease in adults and children [52, 53]. Moreover, as the severity of proteinuria increases, it is associated with metabolic disturbances such as hypercholesterolemia, hypertriglyceridemia and hypercoagulability that contribute to cardiovascular disease.

The following are postulated mechanisms whereby proteinuria may induce kidney injury: [64].

- Filtration of lipoproteins and absorption by proximal tubules may activate inflammatory pathways causing cell injury.
- Filtration of cytokines or chemokines may provoke cell proliferation, inflammatory cell infiltration, and activation of infiltrating cells.
- Filtration or generation of novel antigens may function as antigen-presenting cells and initiate a cellular immune response.
- Iron that is filtered into tubular fluid and bound to transferrin may be directly toxic or may

have indirect effects due to iron-catalyzed synthesis of reactive oxygen metabolites.
- Activation of the alternative complement pathway by proximal tubules may be harmful.
- The release of lysosomal enzymes into the cytoplasm of protein-reabsorbing tubules may cause damage.
- The release of vasoconstricting molecules may cause ischemic tubular injury.
- Interstitial fibrosis may result from the release of fibrosis-promoting factors from kidney cells activated or injured by proteinuria.
- The proteinaceous casts can obstruct kidney tubules.

Persistent significant proteinuria should be addressed. Besides determining the cause and initiating specific therapy if possible, other treatment options include dietary protein recommendations and use of anti-proteinuric medications.

Dietary Protein Recommendations

Dietary protein restriction has been proposed in adults with CKD to stabilize kidney function [91, 103]. In a small series of children with CKD, there was some benefit from dietary protein restriction [104]. However, another controlled study did not demonstrate a significant impact of protein restriction on the rate of progression of CKD [51]. High dietary protein intake may worsen proteinuria in some patients with nephrotic syndrome. Moreover, it does not result in a higher serum albumin. Hence, it is best to avoid an excess of dietary protein in children with proteinuric kidney diseases. It is recommended that children with proteinuria receive the suggested dietary intake of protein for age; they should not be protein-restricted [105].

Drugs with Anti-proteinuric Effects

The angiotensin converting enzyme inhibitors (ACEI) and the angiotensin II receptor blockers (ARBs) can reduce systemic blood pressure (BP) and exert other beneficial effects, such as decreasing urinary protein excretion and decreasing the risk of kidney fibrosis. In addition, kidney function is better preserved in children with CKD when lower systolic BPs are achieved [106]. However, the long-term benefit of ACEIs and ARBs in children and adolescents with proteinuria remains to be established. Intensive BP control with ACEI effectively delays the progression of kidney disease among children with an underlying glomerulopathy or renal hypoplasia or dysplasia, but not among children with other congenital or hereditary nephropathies. In the ESCAPE trial, ACEI was shown to reduce proteinuria by approximately 50% within the first 6 months. However, proteinuria gradually increased during ongoing ACEI therapy to levels that were no different after the third year, despite persistently good BP control [107]. A post hoc analysis of the ESCAPE trial showed that a higher degree of proteinuria reduction during the first months of ACEI treatment was independently associated with a lower risk of CKD progression [108]. Both a higher residual proteinuria level after attaining the full dose of ACEI and the total exposure to proteinuria during follow-up was associated a higher risk of CKD progression in children. These findings were independent of the underlying kidney disease, baseline proteinuria and BP control.

There are reports of infants born to mothers taking ACEI during the second and third trimesters of pregnancy who developed oligohydramnios, pulmonary hypoplasia and postnatal hypertension. Postmortem examination of these neonates who died showed severe glomerular and tubular malformations in the kidneys. Hence, ACEI are contraindicated during pregnancy [109]. The safety of ACEI and angiotensin II receptor blockers in young infants is still unknown. Cases of ACEI-induced nephrotoxicity had been reported in premature infants with cardiac failure due to congenital heart disease [110] and young infants after cardiac surgery [111]. There was no underlying kidney disease found in these infants and acute kidney injury was reversible upon discontinuation of the ACEI. Another concern of ACEIs in premature infants is that

they may impair the final stages of kidney maturation, and therefore should be avoided before a corrected post-conceptual age of 44 weeks [112].

Aliskiren, the first orally active direct renin inhibitor, has shown promising results in proteinuria reduction in adult patients with CKD [113]. In a case series of four children treated with aliskiren for refractory proteinuria, three children experienced clinically significant adverse effects, including symptomatic hypotension, hyperkalemia and accelerated loss of kidney function [114]. Hence, clinicians should exercise caution when prescribing aliskiren until appropriate pediatric trials establish dosing, efficacy and safety.

Conclusion

Hematuria or proteinuria in children is frequently encountered. Many investigations have been recommended in the workup for a child presenting with hematuria or proteinuria. Many of the cases of hematuria or proteinuria are normal transient findings. Hence, a stepwise evaluation is recommended to avoid unnecessary and expensive investigations, but identify children with serious conditions. There is an increasing role of genetic testing to establish a clinical diagnosis of hereditary causes of kidney disease. Early detection and treatment of serious conditions should hopefully delay or prevent the onset of kidney functional abnormalities. Screening programs for hematuria and proteinuria may be able to identify children at an earlier stage; however, the major disadvantage is the cost effectiveness, as well as the anxiety in parents and children when the finding is spurious or transient.

SSNS	Steroid sensitive nephrotic syndrome
VEGF	Vascular endothelial growth factor
VPF	Vascular permeability factor

Introduction

Nephrotic syndrome is characterized by massive proteinuria, hypoalbuminaemia and generalized oedema. Clinically childhood nephrotic syndrome has been classified into steroid sensitive nephrotic syndrome (SSNS), steroid resistant nephrotic syndrome (SRNS), congenital and infantile nephrotic syndrome (0–12 months) and nephrotic syndrome secondary to other diseases including IgA vasculitis, systemic lupus erythematosus (SLE) and hepatitis B nephropathy. Between 1967 and 1974, the International Study of Kidney Disease in Childhood (ISKDC) enrolled 521 children aged 12 weeks to 16 years with idiopathic nephrotic syndrome to evaluate the histopathological, clinical and laboratory characteristics of nephrotic syndrome in children. The kidney biopsy studies demonstrated that about 80% of children had either minimal change disease (MCD; 76.4%), focal and segmental glomerulosclerosis (FSGS; 6.9%) or mesangioproliferative glomerulonephritis (MesPGN: 2.3%) [1]. Subsequently the ISKDC demonstrated that the response to corticosteroids was highly predictive of kidney histology with 93% of children with MCD achieving complete remission following an 8 week course of prednisone [2]. However between 25–50% of children with MesPGN or FSGS on biopsy also responded to prednisone [2]. Since most children presenting with nephrotic syndrome now do not undergo kidney biopsy at diagnosis, children with idiopathic nephrotic syndrome are now classified according to their initial response to corticosteroids into SSNS or SRNS. Although many children with SSNS have one or more relapses, the majority continues to respond to corticosteroids throughout their subsequent course [3–5] and the long term prognosis for complete resolution with normal kidney function is good. This chapter is devoted to SSNS. Commonly used definitions for SSNS and SRNS are shown in Table 13.1.

Table 13.1 Definitions used in idiopathic nephrotic syndrome [125, 166, 311–313]

Classification	Definition
Nephrotic syndrome	Oedema, uPCR ≥200 mg/mmol (≥2000 mg/g) or ≥50 mg/kg/day or ≥3+ on urine dipstick, hypoalbuminaemia ≤25 g/L (≤2.5 mg/dL)
Complete remission	uPCR ≤20 mg/mmol (≤200 mg/g) or ≤1+ protein on urine dipstick for 3 consecutive days
Initial responder	Attainment of complete remission within initial 4 weeks of corticosteroid therapy
Initial non-responder/steroid resistance	Failure to achieve remission during initial 4 weeks of corticosteroid therapy
Relapse	uPCR ≥200 mg/mmol (≥2000 mg/g) or ≥3+ protein or more on urine dipstick for 3 consecutive days
Infrequent relapse	One relapse within 6 months of initial response or 1–3 relapses in any 12 month period
Frequent relapse	Two or more relapses within 6 months of initial response or 4 or more relapses in any 12 month period
Steroid dependence	Two consecutive relapses during corticosteroid therapy or within 14 days of ceasing therapy
Late non-responder	Persistent proteinuria after 4 weeks or more of corticosteroids following one or more remissions

uPCR urine protein-creatinine ratio

Epidemiology

Prospective studies of children with newly diagnosed idiopathic nephrotic syndrome identified through Pediatric Surveillance Units in the Netherlands, Australia and New Zealand reported incidences of idiopathic nephrotic syndrome of 1.12–1.9 per 100,000 children aged below 16 years [6–8]. However the reported incidence of idiopathic nephrotic syndrome from other countries varied between 1.8 and 16.9 per 100,000 children aged below 16 years [9]. The

incidence is highest in children of south Asian ancestry as demonstrated in studies from Canada and the United Kingdom [9].

Most children with nephrotic syndrome have SSNS [9]. The incidence of SRNS ranges from 2.1 to 27.3% and varies with country of origin with the highest rates seen in African and African-American children and the lowest rates seen in children of South Asian ancestry [9]. SSNS is more common in boys than girls with a male: female ratio of around 2:1 and a peak incidence between 1–4 years [1]. In 2007, a review of retrospective studies from tertiary services comparing the prevalence of FSGS over two time periods found that the odds of FSGS in children with nephrotic syndrome had increased twofold suggesting an increase in the number of children with FSGS [10]. However, the analyses involved fewer than 1000 children, there was significant heterogeneity in the results and bias related to selective referral to tertiary centres could not be excluded.

Aetiology and Pathogenesis

A T Cell Disease but New Thoughts on B Cells

A series of clinical observations led Dr. Shaloub in 1974 to propose that SSNS was due to an abnormality of function in T cells [11]. Nephrotic syndrome had been observed in patients with Hodgkins lymphoma, and cases of thymoma [12, 13]. The disease was noted to remit in children who had measles, which led some people to propose using measles as a therapeutic strategy [14–16]. A major effect of measles is to inhibit cell mediated immunity thereby shutting down T cell function. Further the response of nephrotic syndrome to T cell suppressive agents such as steroids or calcineurin inhibitors (CNI) also supported their role in nephrotic syndrome [11]. These features all suggested that lymphocytes are key cells in SSNS. Recent success in treating recurrent FSGS and SSNS with the CD20 B cell depleting antibody rituximab raises the possibility of either B cells influencing T cells or B cells themselves being primary players in nephrotic syndrome. It is unclear if this a function of the role of B cells as antigen presenting cells or because of antibody production.

A Circulating Factor

MCD appears to exist in a spectrum with FSGS. A proportion of children with MCD on clinical and histological grounds evolve into FSGS [17]. In both there appears to be a circulating factor with the children with FSGS being less responsive to therapeutic agents. Within this group is a subset of children where the disease resides in structural changes in the glomeruli with genetic mutations in key glomerular slit process proteins including nephrin, podocin, Actinin4 and WT-1. These are described elsewhere but in brief are associated with no response to steroids and progression to end-stage kidney disease (ESKD), and do not show evidence of a circulating factor as demonstrated by rapid recurrence of disease in a transplanted kidney. The timing of response with the return to normal function taking days to weeks is also supportive of slow podocyte recovery from an injurious cytokine. The higher rates of recurrence in children with FSGS receiving living related kidneys suggests that there may be a degree of HLA restriction of response and this is also supported by HLA linkage studies showing that increased incidence of disease is tied to certain alleles such as HLA B8, B13, DWQ2, DQB10301 and DR7 [18–21].

Various growth factors and cytokines have been proposed as pathogenic in SSNS over the years. The initial identification of the factor, vascular permeability factor (VPF) now called vascular endothelial growth factor (VEGF), was thought to have identified the key protein leading to nephrotic syndrome [22–24]. However, the identification of this protein in normal urine delayed further investigation of its role. More recently it has been noted to be increased in urine during relapses of nephrotic syndrome though circulating levels are unchanged suggesting that VEGF levels reflect the concomitant proteinuria [25, 26]. Recent tissue-specific knock-outs of VEGF in mice restricted to podocytes have dem-

onstrated a key role for local VEGF in maintaining glomerular endothelial integrity and again reinforced its importance though perhaps more locally in maintaining permeability [27, 28]. Soluble immune response suppressor (SIRS) was also identified as a potential protein mediating nephrotic syndrome but again the inability to characterize this protein despite many mechanistic observations led to its exclusion as the likely factor [23, 24, 29]. Other circulating factors have been proposed and the development of a functional assay of glomerular permeability by Dr. Savin in the late 1990s identified a proteinuric factor that was small, highly glycosylated, and hydrophobic [30]. This appeared to be likely to allow fractionation of nephrotic sera and identification of the factor. Other observations that protein A columns could remove the nephrotic factor post-transplant also seemed to point to identifying features [31]. More recently induction of proteinuria in rats with transfer of serum may allow models that can identify this factor as has the demonstration that overexpression of the Th2 cytokine IL-13 induces proteinuria in rats [32]. Recently podocyte-secreted angiopoietin-like-4 was found to mediate proteinuria in SSNS using overexpression in the podocyte in rat models though further confirmatory studies are awaited [33].

The central role of T cells in disease has led to a number of strategies to identify the underlying defect. The thought that the disease was caused by a low frequency pathogenic clone has given way to a view that there is a generalized alteration in the lymphocytes that is triggered in these individuals and then can be switched off by treatment. This has been studied in several ways including assessment of T cell derived cytokine responses either directly in plasma or by measurement of supernatants from activated mononuclear cells or measurement of RNA, assessment of T cell subsets by immuno-phenotyping or finally by functional assays of cell mediated immunity. More recently the identification of a role for microRNAs in FSGS affecting WT1 or more recently CD2AP in nephrotic syndrome suggested this may be a fruitful area of research [34, 35].

Phenotypes of Cytokine Secreting T Cells: Th1, Th2, Treg, Th17

Naïve T cells on activation become polarized into different subsets defined by their cytokine production and driven by the cytokine milieu in which they are activated. The initial division of T cells was into CD4 (originally helper) T cells, that respond to exogenous antigen presented by antigen presenting cells in the context of MHC Class II, and CD8 (originally effector) T cells that respond to internal antigens presented by all cells. CD4 T cells were further divided into Th1 and Th2 cells based on the cytokines they produced [36]. This was initially observed in mice but human Th1 cells also produce cytokines such as IFN-gamma and TNF, which are used in cell mediated immune responses. Th2 cells produce IL-4, IL-5 and IL-13 which are key to humoral immunity and are used by B cells to class switch and act as growth factors for eosinophils [37, 38]. It is now apparent that CD8 T cells can produce cytokines and can be polarized to Tc1 and Tc2 expressing similar cytokines to those in CD4 Th cell subsets [39]. The observation that allergy is more common in children with nephrotic syndrome suggested that this might be a Th2 disease [18]. A subset of T cells thought to suppress activity in other T cells was originally described as suppressor T cells and these have recently been reclassified as regulatory T cells. These are thymically derived and express regulatory cytokines such as TGF-β and IL-10 and express regulatory molecules such as CTLA-4. A key marker of these cells is the expression of the transcription factor foxp3 [40–42]. Interestingly there is now another T cell subset that is an alternative to regulatory T cells called the Th17 cell because it expresses the cytokine IL-17. Th17 cells are induced by IL-23 but can be generated by IL-6 and TGF-ß thus acting as an alternate pathway of development to regulatory T cells [42, 43]. There are now data linking Th17 cells to nephrotic syndrome and the biological effect of these cells on podocytes [44, 45].

In general, studies of cytokines have been disappointing. No clear up-regulation of Th2 type

cytokines has been demonstrated. Studies of serum of patients in remission show IL-1 unchanged, IL-2 normal or undetected in four of five studies, sIL-2R increased in four of six studies, IFN-gamma normal or not detected in three and increased in two studies, IL-4 normal or decreased, IL-8 normal, increased and decreased in four studies, IL-10, IL-12 and IL-13 either normal or not detected and TNF-β normal in three of four studies [46]. Studies of culture supernatants of stimulated mononuclear cells from children with active SSNS are also highly variable though four studies suggest elevated IL-4, two studies elevated IL-12, and five studies elevated TNF-α. RNA measurements for specific cytokines in blood have been equally unrewarding as have those using intracellular cytokine staining [46]. Urinary reports are confounded by concurrent proteinuria but there has been a recent report of IL-17 increased in the urine of patients with SSNS [22, 47]. Other non-T cell inflammatory proteins associated with SSNS include neopterin which is produced by activated macrophages and is increased in SSNS [48].

Genetic Influence in the Aetiology of SSNS

Significant research effort over recent years has identified over 50 genes linked to SRNS [49] with the majority coding for proteins in the podocytes which control function and stability of the actin cytoskeleton. In stark contrast, almost no genes have been identified that have a Mendelian influence on the development of SSNS. This is despite the known ethnic variation in prevalence, familial clustering and a history of affected first degree relatives previously reported at 3% [50, 51]. Similarly to IgA Nephropathy, any genetic influence is likely mediated through complex inheritance of risk alleles in multiple genes.

Initial investigation of complex inheritance focused solely on HLA genes and identified possible association with HLA-DQ/DR. Further studies using exome wide association [52] and then genome wide association studies (GWAS) [53–56] confirmed that association across European, African, South Asian and Japanese cohorts. Through the use of HLA imputation, HLA haplotypes that confer maximum risk and also those that confer protection can be derived. Interestingly, while these were reproducible across the European and South Asian cohorts, Japanese cohorts had differing haplotypes [53–56]. The use of GWAS to study Membranous Nephropathy enabled identification of a non-HLA locus at PLA2R1 which has been incredibly informative in understanding disease pathology. In SSNS non-HLA loci have been identified (BTNL2, CALHM6/DSE, PARM1, TNFSF15 and NPHS1) but the signals are not as strong and to date are not clearly reproducible across all ethnic groups but cohort size has been relatively small [53, 55, 56]. The pathological mechanism by which an HLA haplotype may confer risk in SSNS has not yet been clearly elucidated and while it is likely to be related to the association with CD4 positive T cells, further work utilising new molecular tools may prove highly valuable [57].

Role of the Thymus

The information above, the association of nephrotic syndrome with T cell lymphomas and thymomas, the timing of thymic involution occurring around puberty at the same time as the resolution of relapses for the majority of children with uncomplicated SSNS, and the exquisite sensitivity of thymocytes to steroids all suggest a role for early T cells or other thymically derived cells in SSNS. Further evidence of early thymic emigrants in single cell analysis of CD2 positive cells from children with FSGS also supports a role for T cells, which are early emigrants from the thymus.

Role of Infection

While there has been no clear infectious agent identified as inducing nephrotic syndrome, there is an identifiable viral prodrome in around 50% of cases of relapse. Whether this merely

reflects cytokine release with the initiation of nephrotic syndrome or whether this is initiation of the disease by a viral trigger is not clear. Some groups have postulated that inflammation through TLRs may upregulate CD80 on podocytes leading to activation though CD80 and nephrosis [58]. There has also been interest in CD80 as a therapeutic target in resistant nephrotic syndrome [59].

Summary

While the evidence supports a role for T cells activated to secrete a permeability factor, identifying the specific T cell changes or characterization of the factor remains a major challenge in SSNS. The clinical results with rituximab in depleting B cells, and the data on CD80 expression on podocytes raises other alternatives as potential causes of SSNS including circulating cells other than T cells and specific podocyte responses, but there are limited data so far on these pathways.

Histopathology

Steroid sensitive nephrotic syndrome comprises a spectrum of disease that includes MCD, MesPGN (also known as "diffuse mesangial hypercellularity"), IgM nephropathy and FSGS. Although these are readily distinguished on biopsy, the clinical significance of this distinction remains controversial with significant overlap in behaviour and variation in morphological diagnosis over time in a small proportion of cases. This confusion is reflected in the literature. Some studies suggest a difference in behaviour between those with and without mesangial hypercellularity in the absence of immune deposits [60]. Some studies suggest an increased risk of steroid resistance and/or development of focal sclerosing lesions with MesPGN/IgM nephropathy [61, 62] with some studies documenting transition of MCD, MesPGN and IgM nephropathy to FSGS in frequently relapsing patients over time [17, 63]. In addition some studies suggest that the response to therapy in cases with immune deposition is "unpredictable" [64] or variable [65], and finally a number of studies have failed to find any significant difference in outcomes between these categories [66, 67]. Histological overlap also exists with MCD, MesPGN and FSGS in patients with predominant mesangial deposition of C1q (C1q nephropathy), although representing a small minority of patients with initial presentation of clinical nephrotic syndrome [68–70]. Similarly, mesangial IgA deposition in association with nephrotic syndrome has also been described in a defined subset of IgA nephropathy patients, with either MCD like changes or MesPGN on biopsy. IgA with MCD-like changes is generally responsive to steroid therapy, although with a significant rate of relapse [71]. Regardless of histopathology, children with disease resistant to steroids generally have a poorer outcome compared with those with responsive disease [72]. The ultimate prognosis for children with primary nephrotic syndrome and frequently relapsing disease associated with mesangial hypercellularity and/or positive immunofluorescence remains difficult to predict.

Minimal Change Disease (MCD)

The defining histological feature of minimal change disease (MCD) is normal appearing glomeruli on light microscopic examination (Fig. 13.1). This assumes that the specimen has an adequate sample of glomeruli, including deep glomeruli from the juxtamedullary region of the renal cortex. Glomeruli of normal young children are generally smaller compared with adults so appear relatively hypercellular. There is no significant expansion of mesangial matrix, and no increase in mesangial cellularity (either by increased numbers of mesangial cells or infiltration by inflammatory cells). The cytoplasm of the podocytes may appear to be mildly swollen or vacuolated. Glomerular capillary loops remain patent, and in many cases may appear mildly dilated. The glomerular capillary walls are thin with no evidence of basement membrane thickening. No basement membrane reduplication or

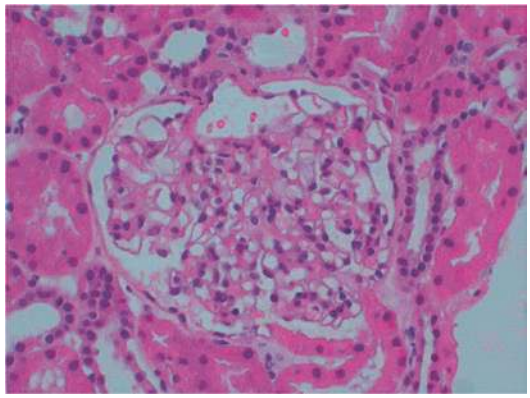

Fig. 13.1 The glomerulus appears normal to light microscopic examination, with normal mesangial matrix and cellularity. Capillary loops are dilated with normal thin capillary walls. (H&E stain, ×400)

Fig. 13.2 Low power electron photomicrograph includes a capillary loop with extensive effacement of foot processes accompanied by swelling and microvillarisation of podocytes. Glomerular basement membranes are of normal appearance and no dense deposits are seen. (Courtesy of Paul Kirwan, Electron Microscopy Unit, Department of Anatomical Pathology, CRGH, Concord, Sydney, Australia)

epithelial spike formation are evident on examination of silver stained sections. The presence of an occasional glomerular "tip" lesion, defined as adhesion of the tuft to the Bowman's capsule at the site of opening of the proximal convoluted tubule, may be seen in MCD provided the glomerulus is otherwise normal in size and cellularity [73, 74]. The interstitium is normal without significant inflammation, fibrosis or tubular atrophy. Proximal tubule epithelial cells may contain hyaline droplets consistent with protein loss.

The immunofluoresence in MCD is negative. Very small amounts of IgM or C3 are considered by some to be compatible with MCD; however any significant immune reactant even in the setting of histologically normal glomeruli effectively excludes this diagnosis [64, 67, 72]. However, the clinical significance of these immune positive cases with normal histology is still controversial, and many now consider that these cases represent a spectrum of disease rather than distinct entities. Electron microscopic examination of untreated MCD shows uniform abnormality of the podocytes, with marked effacement of the foot processes over at least 50% of the glomerular capillary surface resulting in a smooth homogenous layer of epithelial cell cytoplasm which lacks the normal interdigitation. The cytoplasm of the cells may be enlarged with clear vacuoles and prominence of organelles. This is accompanied by microvillus transformation along the urinary surface of the podocytes (Fig. 13.2). The glomerular basement membrane otherwise appears normal, as do the mesangial cells and matrix. Immune deposits are absent. These changes are commonly modified with steroid treatment, and the degree of foot process effacement may be incomplete if the biopsy is taken from a partially treated patient.

Mesangial Proliferative Glomerulopathy (MesPGN)

Light microscopic examination of MesPGN shows generalized, diffuse mesangial cell hyperplasia, involving over 80% of the glomeruli. Increased numbers of mesangial cell nuclei are clearly present within mesangial matrix which is either normal or only mildly increased in amount (Fig. 13.3). There is generally no obvious lobulation of the glomerulus, and segmental sclerosis is absent. As in MCD, glomerular basement membranes remain thin and capillary loops clearly patent. By definition, spikes are not seen in silver stained sections. There is no significant intersti-

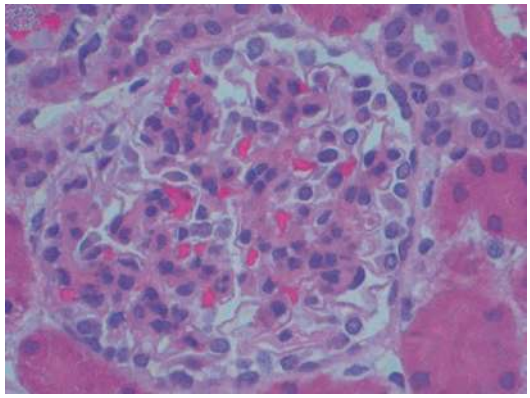

Fig. 13.3 The glomerulus shows increased numbers of mesangial cells with mildly increased matrix. The capillary loops appear normal. (H&E stain, ×400)

tial change (either tubular atrophy or fibrosis) to suggest glomerular loss. Glomerular immaturity, characterized by hypercellularity and a layer of cuboidal epithelium along the surface of the glomerular tuft, may be seen in some cases, particularly in younger children. Recent studies have suggested that these cases may have a less favourable clinical course [75].

Many cases of MesPGN show positive granular mesangial IgM ± C3 and very occasionally small amounts of C1q or IgG, although a proportion of cases have negative immunofluorescence. Some have considered these immune-positive cases as MesPGN, while others separate the positive cases into further distinct categories, most commonly IgM nephropathy. As noted earlier, these three "entities" (MCD, MesPGN, IgM Nephropathy) probably represent a spectrum rather than separate diseases. On electron microscopy there is mesangial cell hyperplasia with effacement of epithelial cell foot processes and microvillus transformation of epithelial cells. Dense deposits are not typically found, and the glomerular capillary basement membrane is normal.

IgM Nephropathy

IgM Nephropathy shows light microscopic features that may mimic those of either MCD or MesPGN. The sampled glomeruli may appear completely normal on routine stains, or may show diffuse mesangial hypercellularity. Some cases will show a combination of features, with some but not all glomeruli appearing hypercellular. As with MCD and MesPGN, segmental sclerosing lesions are not seen in an adequately sampled specimen, glomerular capillary loops remain thin walled and patent, and there is no basement membrane thickening or evidence of spike formation. Interstitial changes are absent. Granular deposits of IgM are confined to the mesangium and are generally seen in all glomeruli regardless of their histological appearance. Lesser amounts of C3 are common, and some cases may also show small amounts of C1q or IgG. In these cases, the IgM should remain as the dominant reactant. On electron microscopy there may be a mild increase in mesangial matrix. Immune deposits are often absent though some cases will show occasional small dense deposits that are located in paramesangial regions. Effacement of epithelial cell foot processes is usually seen to a varying degree, usually with microvillus transformation.

IgA Nephropathy with Nephrotic Syndrome

IgA nephropathy may present with clinical nephrotic syndrome indistinguishable from MCD in approximately 8–10% of cases. Nephrotic IgA nephropathy may show light microscopic features of MCD, MesPGN, or a focal GN (proliferative or sclerosing), however it is defined by the presence of dominant mesangial IgA deposition (frequently with some associated C3, and in approximately 50% of cases with lesser amounts of IgG and/or IgM), usually with electron microscopic evidence of immune deposits.

C1q Nephropathy

C1q nephropathy is an uncommon disorder that may also present with clinical nephrotic syndrome. Histology of these cases most commonly

shows an MCD-like picture (70–75% of cases), with MesPGN (20%) and FSGS (7–13%) seen in some cases. Distinction is made with immunofluorescence finding of predominant C1q deposition in the mesangium and electron dense deposits on electron microscopic examination. Although many of these cases are clinically steroid resistant or steroid dependent, being more likely to require chronic immunosuppression and combined therapy, overall prognosis is good in particular for those with minimal changes on light microscopy. Of note, a number of studies have shown disappearance of the C1q deposits following therapy [68, 70].

Focal Segmental Glomerulosclerosis

Although FSGS more commonly results in steroid resistant disease, a proportion of cases will respond, at least initially, to steroid therapy [76, 77], and thus brief mention of the pathological features is made here. In FSGS, segmental (involving only a portion of the tuft) and focal (involving some but not all glomeruli) sclerosis of glomeruli is present. The light microscopic changes are not specific for primary idiopathic FSGS and other causes of segmental sclerosing lesions need to be excluded [78]. The sclerosed segments show collapse of the glomerular capillary with increase in matrix material though with variable patterns of glomerular involvement [79]. The uninvolved portion of the glomerular tuft should appear essentially normal. Idiopathic FSGS typically shows early preferential involvement of the deep juxtamedullary glomeruli so that adequate sampling of this region is needed to reduce the risk of missing a focal lesion. (This risk is estimated at 35% if only 10 glomeruli are examined, falling to a 12% risk if 20 glomeruli are examined [76]). Even a single segmental sclerosing lesion away from the glomerular tip is sufficient to exclude a diagnosis of MCD. Clues to the presence of possible FSGS without diagnostic sclerosing lesions include abnormal glomerular enlargement, which appears to be an early indicator of the sclerotic process, and focal interstitial fibrosis and tubular atrophy (above that expected for age), which suggest glomerular loss [76]. Typically idiopathic primary FSGS shows negative immunofluorescence though non-specific uptake of IgM may be seen, commonly within sclerosed segments. Deposits similar to that of IgM nephropathy may also be present. On electron microscopy non-sclerosed glomeruli show epithelial cell foot process fusion though this may not be complete or as widespread as in typical untreated MCD. However, this is often not helpful in making this distinction as steroid therapy may partially restore foot processes in MCD.

Clinico-pathological Correlations at Presentation of Nephrotic Syndrome

Children with MCD cannot be separated on clinical features from those with FSGS or MesPGN though children with MCD are generally younger and less likely to have haematuria, hypertension and kidney dysfunction at presentation [1]. The ISKDC found that 80% of children with MCD were aged 6 years and under compared with 50% of children with FSGS. Systolic and diastolic blood pressures were elevated at presentation in 21% and 14% of children with MCD and 49% and 33% of children with FSGS. Haematuria occurred in 23% of children with MCD and 48% of children with FSGS.

Clinical and Laboratory Features at Onset of Nephrotic Syndrome

In 30–50% cases the onset of SSNS is preceded by an upper respiratory tract infection [80, 81]. Atopy is more common in children with SSNS compared with children without SSNS [81] and more common in SSNS than SRNS [82] but an acute allergic reaction rarely precipitates a relapse. The most common initial symptom in SSNS is periorbital oedema though the significance of this finding may not be realized till the child develops generalized oedema and ascites [83]. Frequently the periorbital oedema

is misdiagnosed as an allergy or as conjunctivitis particularly if the child is assessed initially in primary care rather than in emergency or paediatric care settings [84]. Symptoms may be present for longer than a year before diagnosis though 78% present within a month of the first symptom [84]. The degree of oedema is variable with some children having only mild periorbital and ankle oedema while others have pleural effusions and gross ascites with scrotal and penile oedema in boys and labial oedema in girls. The rapid formation of oedema with reduction in plasma volume may be associated with abdominal pain and malaise. Some children have serious infections at presentation including peritonitis [85]. Elevated systolic and diastolic blood pressures are present in 5–20% at presentation in children but generally hypertension does not persist [1, 80]. Urinalysis shows ≥3–4+ protein on urinalysis with a urine protein-creatinine ratio (uPCR) ≥ 200 mg/mmol (≥2000 mg/g). Microscopic haematuria is present at diagnosis in 20–30% of children but rarely persists and macroscopic haematuria is rare occurring in less than 1% of children with SSNS [1, 80]. Serum albumin levels usually fall below 20 g/L and may be less than 10 g/L with a concomitant reduction in total protein levels. Kidney function is generally normal though serum creatinine may be elevated at presentation in association with intravascular volume depletion and rarely acute kidney failure. Children have elevated cholesterol and triglycerides and these continue to be abnormal while the child remains nephrotic. However it is unknown whether the intermittent lipid abnormalities seen in children with SSNS during relapses increase the risk of cardiovascular disease in adult life [86]. Serum electrolytes are usually within the normal range. Total serum calcium levels are low associated with hypoalbuminaemia but ionized calcium is usually normal. Haemoglobin and haematocrit levels may be elevated at presentation in patients with reduced plasma volumes.

Outcome of Children with SSNS

Relapse

Despite a relapsing course, the long-term prognosis for most children with SSNS is for resolution of their disease and maintenance of normal kidney function. Early follow up studies of children with SSNS and MCD [3, 5] indicated that 80–90% children relapsed one or more times. Among children who relapsed, 35–50% relapsed frequently or became steroid dependent [3, 5]. A recent retrospective observational study of 631 children diagnosed with idiopathic nephrotic syndrome (589 with SSNS) between 1993 and 2006 with a median follow up of 3.9 years (IQR 2.1–6.66 years) found that 24% children had a single episode of SSNS, 43% relapsed infrequently and 33% relapsed frequently or had SDNS [87]. In the NEPHROVIR study (a prospective population-based observational study), the 5-year relapse-free rate was 22% (36/174) [88]. The first relapse in 138 children occurred at a median of 8.3 months (IQR 3.4–11.3). Forty three children (24%) relapsed frequently and 83% of these still required treatment with prednisone and/or immunosuppressive agents at 96 months.

Although numerous predictors for a frequently relapsing or steroid dependent course have been identified, there is considerable variation in significant predictors between studies. Most studies of predictors have been retrospective studies from tertiary paediatric nephrology services. Predictors include young age at presentation [8, 88, 89], male sex [8, 89, 90], a longer time to first remission after commencing prednisone [91–95], a shorter time between first remission and first relapse [5, 94, 96], the number of relapses in the first 6 months after presentation [91, 93, 96], infection at presentation or relapse [91, 95, 96] and low birth weight [97].

Most children with SSNS cease having relapses before adulthood. The International Study of Kidney Disease in Children of 344 children with SSNS with MCD on kidney biopsy found that the proportion of children without

relapses increased from 40% at 5 years to 80% at 8 years with very few children continuing to relapse at 18 years [5]. However, relapses may continue into adult life. In ten series of 705 participants with SSNS followed for 10–44 years, the proportion of people with continuing relapses varied between 9 and 50% [4, 90, 98–105]. The same series reported that the overall risk of reduced glomerular filtration rate was 0–2%. Higher numbers of relapses were reported in series with higher proportions of participants with FRNS or SDNS [4, 102]. Studies have also assessed the risk of treatment related complications in adults with childhood nephrotic syndrome. Hypertension was reported in between 0 and 32% of 569 adults (eight studies) with previous or continuing SSNS [4, 90, 100–105]. Overweight and obesity were reported in 13–46% of adults [99, 101, 102, 104, 105] though several authors pointed out that the prevalence of obesity may not differ from that in the local population [104, 105]. Short stature was reported in 2–20% of adults [99, 100, 102, 104]. Myocardial infarctions were reported in 2 of 66 participants with continuing relapses [4, 105] while a follow up study of 40 participants who had had SSNS during childhood but had no relapse for 23 years or more, identified three males who had had myocardial infarctions but all had other risk factors for cardiac disease [106]. Also the frequency of events in this group did not differ from that in the general population of the same age. No studies reported any malignancies in adults with previous nephrotic syndrome.

Kidney Function and the Development of Late Steroid Resistance

Most children with SSNS maintain normal kidney function. In a retrospective Canadian study of 78 children with SSNS followed for a median of 4.4 years (IQR 5.6), eGFR remained unchanged during follow up [107]. Development of late steroid resistance is well recognised. In European studies, most children with SSNS and biopsy proven or presumed MCD do not develop late steroid resistance and have a good prognosis for kidney function. In the ISKDC series of 334 children with SSNS and MCD, 15 (4.5%) children became transiently non-responsive to steroids but only one child (0.3%) became persistently non-responsive to therapy and developed ESKD [5]. Similarly in five series of 463 patients [4, 90, 98–100], only one patient (0.2%) developed late steroid resistance and progressed to ESKD [4]. A recent Canadian study of 589 children with initial SSNS reported that 10 (1%) children progressed to ESKD during a follow up period of up to 6.6 years [87]. Studies from the USA have identified higher risks of late steroid resistance and ESKD [108, 109]. In a retrospective analysis of 115 children with SSNS, 19 (17%) developed late steroid resistance with its development being associated with a shorter interval to first relapse and with relapse during the initial steroid therapy [109]. Although more African American children had initial steroid resistance, ethnicity did not predict for late steroid resistance [109]. A retrospective study from the USA Midwest Pediatric Nephrology Consortium investigated the outcomes in 29 children with late steroid resistance [110]. The median time to late steroid resistance was 19 months (range 2–170 months). After a mean follow up of 85 ± 47 months, 20 (70%) children were in complete or partial remission following treatment with CNI, mycophenolate mofetil (MMF) or alkylating agents. Six (21%) had persistent nephrotic range proteinuria and three (10%) had reached ESKD. Fewer African-American children responded to treatment compared with other children. These data suggest that children with late steroid resistance are more likely to respond to non-corticosteroid immunosuppressive agents and to have a better prognosis for kidney function compared with children with initial steroid resistance. Although initial steroid resistance is commonly associated with FSGS on kidney biopsy, the authors found no consistent relationship between initial or later kidney histology and late steroid resistance. Children with late steroid resistance are more likely to have recur-

rences of nephrotic syndrome following kidney transplantation [111]. Previous studies [112–115] have emphasized that progression to chronic kidney failure is not seen or is uncommon in children with FSGS if they continue to be steroid sensitive during follow up periods averaging about 10 years.

Other Complications of Steroid Sensitive Nephrotic Syndrome

Compared with earlier data, death is now uncommon in children with nephrotic syndrome. One study reported only one death (0.7%) associated with disease among 138 children with SSNS presenting between 1970 and 2003 [99] and no deaths were reported among 631 children presenting between 1993 and 2016 [87]. The death rate before corticosteroids and antibiotics were available was 40%, of whom half died from infection [83]. In the 1960s, 70s and 80s death rates of around 7% were reported among children with SSNS [80, 100, 116]. While upper respiratory tract infections are the most common infections, pneumonia, urinary tract infections, cellulitis, septicaemia and peritonitis are important causes of hospital admissions in children with nephrotic syndrome [117, 118]. Infections are more common in children receiving higher cumulative doses of corticosteroids and in those receiving non-corticosteroid immunosuppressive agents [119]. Routine screening for latent tuberculosis infection before treatment is indicated in areas with a high prevalence of tuberculosis but this is not cost effective in areas with a low prevalence [120]. Thromboembolism, most commonly venous, is a rare but potentially life threatening complication of SSNS though it is more common in children with congenital nephrotic syndrome or SRNS and in children aged over 12 years [121]. The majority of clinically evident venous thromboembolic episodes present in the first 3 months after nephrotic syndrome diagnosis [122]. Admissions for nephrotic syndrome complicated by acute kidney injury (AKI) increased significantly between 2000 and 2009 while admission rates for infection and thromboembolism were unchanged [117]. AKI developed in 59% of 336 children with nephrotic syndrome admitted to 27 paediatric nephrology services in USA; 237 children had SSNS. The risk of AKI was associated with infection, nephrotoxic drug exposure and duration of that exposure as well as steroid resistant disease [123]. Admissions complicated by infection, hypertension, thromboembolism and acute kidney injury result in longer hospital stays and increased costs [117, 118, 124].

Indications for Kidney Biopsy

Following the studies of the ISKDC, routine kidney biopsy at presentation and before corticosteroid administration has been abandoned. Biopsy is reserved for nephrotic children with unusual clinical and laboratory features (macroscopic haematuria, hypertension, persistent kidney insufficiency and low C3 component of complement) and for those with initial or secondary steroid resistance [125]. Rarely SSNS presents in the first year of life though more commonly nephrotic syndrome in this age group is resistant to corticosteroids and associated with monogenic podocyte disorders [126]. Where available, genetic studies should be carried out in children aged below 1 year before considering a kidney biopsy [127]. Originally biopsies at presentation were recommended for children aged above 8–10 years based on the ISKDC studies [128]. Now many paediatric nephrologists do not have a rigid upper age limit for treating children with idiopathic nephrotic syndrome without prior kidney biopsy and will give corticosteroids to children and adolescents if kidney function and complements are normal, persistent hypertension absent and microscopic haematuria transitory. This management is supported by retrospective studies of clinicopathological correlations in Indian children and adolescents, in which children without two or more abnormal clinical features generally demonstrated steroid sensitivity regardless of histology [129, 130]. However these data may not apply to African-American adolescent populations where the incidence of MCD at 20–30% [131] is much lower than the 40–50% seen in Indian or Northern European

adolescents [129, 132]; kidney biopsy is recommended for children aged 12 years or above in the USA [133].

Opinions differ as to whether children with SSNS should have kidney biopsies before commencing corticosteroid sparing therapies. In some centres particularly in North America, kidney biopsies have been commonly carried out before using alternative therapy while this practice has been largely abandoned in Europe and India. Respondents to surveys in North America reported that biopsies before commencing alternative therapy provided them with prognostic information or would influence therapy with the choice of steroid sparing agent varying according to histology [134–136]. Studies from North America have demonstrated that kidney pathology (FSGS, MesPGN and IgM nephropathy) with less favourable prognoses are common in children with FRNS or SDNS [137, 138], that steroid dependent patients with MesPGN, IgM nephropathy or FSGS are more likely to have one or more relapses after cyclophosphamide therapy compared with children with MCD [63, 112] and that African American children with FSGS are more likely to progress to chronic kidney failure [139]. In contrast studies from Europe and India [113, 130, 140] have demonstrated no relationship between kidney histology and the pre-biopsy or post cyclophosphamide course even though MesPGN and FSGS are more common in selected series of children with FRNS or SDNS compared with ISKDC data. Some clinicians have argued that kidney biopsies should be obtained before commencing treatment with CNIs to provide a baseline for interstitial and tubular damage due to the underlying disease particularly in children with FSGS, where CNIs are considered the treatment of choice [134, 136]. Guidelines from KDIGO recommend that kidney biopsies are not required before commencing CNIs or other non-corticosteroid agents [125]. However kidney biopsies should be considered in children who have received prolonged treatment (2–3 years) with a CNI and are indicated in children with late resistance to corticosteroids [125, 141, 142].

Before the clinician biopsies a child with FRNS or SDNS, he or she needs to consider whether the benefits of this procedure outweigh the 1% risk of significant haemorrhage requiring blood transfusion [143, 144]. In particular, the clinician needs to know whether the kidney pathology will influence the specific therapy administered and/or whether it will provide information on the likelihood of the child progressing to ESKD. Studies show that, even if the kidney biopsy shows FSGS, the most important predictor for ESKD in idiopathic nephrotic syndrome is not the kidney pathology but the achievement and maintenance of remission following any therapy [145].

Management of Steroid Sensitive Nephrotic Syndrome

Treatment of the First Episode of Nephrotic Syndrome with Corticosteroids

Corticosteroids have been used to treat idiopathic nephrotic syndrome since the early 1950s [146]. Because of the clear net benefits of corticosteroids, no placebo-controlled trials were performed in children with nephrotic syndrome. The ISKDC agreed on a standard corticosteroid regimen for the first episode of SSNS [147] and this has provided the control group against which to test other regimens of prednisone or prednisolone therapy. At presentation children received prednisone 60 mg/m^2/day in divided doses for 4 weeks followed by 40 mg/m^2/day in divided doses on 3 consecutive days out of 7 days for 4 weeks. Subsequently a randomised controlled trial (RCT) carried out by the Arbeitsgemeinschaft für Pädiatrische Nephrologie (APN) [148] demonstrated that alternate day prednisone was more effective in maintaining remission than prednisone given on 3 consecutive days out of 7 days so alternate day prednisone dosing is generally used now in the second 4 week period. Since no significant differences in the time to remission or risk for subsequent relapse between single and divided doses of prednisone have been demonstrated [149], a single daily dose may be preferred during daily therapy to achieve greater compliance. For ease of clinical use, a dose of 2 mg/kg has commonly been substituted for

60 mg/m^2/day. Dosing per kilogram results in lower dosing for patients with weights below 30 kg [150] and two retrospective studies suggested that relative underdosing may increase the likelihood of FRNS [151, 152]. However two recent RCTs comparing dosing per kilogram with dosing by surface area in children weighing under 30 kg found no differences between dosing regimens in the time to remission and the number of relapses by 6 months with some increase in corticosteroid related adverse effects in children dosed by surface area [153, 154].

Though demonstrated to be more effective than shorter durations of treatment [155], the 8 week ISDKC/APN regimen was associated with a high relapse rate so RCTs investigated longer durations of prednisone compared with the ISKDC/APN regimen to determine if longer durations of prednisone reduced the risk of relapse and reduced the number of children, who developed FRNS or SDNS. Recently four well-designed RCTs (three placebo-controlled) involving 775 children have shown no benefit of extending the duration of treatment beyond eight (4 weeks daily and 4 weeks of alternate day prednisone) or 12 weeks (6 weeks daily and 6 weeks alternate day prednisone) on reducing the number of children with relapse or with frequent relapses (Table 13.2). Therefore children presenting with their first episode of SSNS should be

treated with 8 weeks [156, 157] or 12 weeks of prednisone [158, 159]. Currently there are no adequately powered well designed RCTs comparing 8 with 12 weeks of prednisone treatment. Children under 6 years may be at higher risk of developing frequently relapsing or steroid dependent nephrotic syndrome [159]. It is uncertain whether prolonging the treatment period in young children would reduce the their risk of relapse and an RCT is underway to investigate this [160]. Meta-analyses of earlier trials had previously suggested that increasing the duration of prednisone beyond 8 to 12 weeks was associated with a reduced risk of relapse [161]. However poorly designed RCTs with inadequate allocation concealment and lack of blinding can exaggerate the efficacy of therapy [162, 163]. Therefore the 21 RCTs published between 1988 and 2018, which evaluated prednisone duration in the first episode of SSNS, were stratified in meta-analyses according to risk of bias for allocation concealment or for performance/detection bias. RCTs at low risk of bias showed no benefit of increasing the duration of prednisone while studies at high risk of bias showed a benefit of increased duration of prednisone [164].

Current international and national guidelines suggest 8–12 weeks of prednisone in the initial episode of SSNS [125, 133, 165, 166] with some guidelines including tapering of prednisone dose after 12 weeks though the recent PROPINE study found no benefit in terms of efficacy and safety of tapering prednisone dose [167]. The French protocol for the initial episode of SSNS includes the administration of three doses of intravenous methylprednisolone (1 g/1.73m^2) for those children who have not achieved remission by 30 days [165] and this protocol is used in other European centres [168]. Children who require intravenous methylprednisolone to achieve their first remission are more likely to become steroid dependent, to require ciclosporin and to develop late steroid resistance with reduced kidney function [169, 170]. Surveys of pediatric nephrologists in North America and Europe have demonstrated considerable variation among respondents in their approach to the first episode of idiopathic nephrotic syndrome [134, 136, 168, 171, 172]. A survey on SSNS management in all 12 Canadian pediatric nephrology centres indicated both within-centre and between-centre variability in prescribed doses and duration of prednisone for the first presentations and relapses of SSNS irrespective of whether or not the Centre had standard protocols [173].

Treatment of Relapsing SSNS with Corticosteroids

The ISKDC defined relapse as recurrence of proteinuria for 3 consecutive days after previously achieving remission (Table 13.1). Proteinuria may remit spontaneously in 15–30% of relapses without commencing prednisone or increasing the dose [174, 175]. Therefore it is reasonable to wait for some days of mild proteinuria (≤2+ on dipstick) before commencing corticosteroids provided the child remains well and without significant oedema because spontaneous remissions may occur after several days of low grade proteinuria particularly if the child has an intercurrent viral infection. Compliance with prednisone therapy should be considered in children with multiple relapses since poor compliance could be misinterpreted as steroid dependence. If available, triamcinolone acetonide, a long acting steroid for intramuscular injection, may be used instead of oral prednisone treatment if non-compliance is suspected [176].

Paediatric nephrologists have generally treated relapses with daily prednisone (60 mg/m^2/day) till the child achieved remission and then continued alternate day therapy (40 mg/m^2) for 4 weeks or more [177]. Two observational studies and a small RCT have demonstrated that most children with relapsing SSNS achieve and maintain remission with prednisone given at a dose of 30 mg/m^2/day [178–180]. These data need confirmation in an adequately powered RCT.

In children with FRNS, observational studies have demonstrated that low-dose alternate-day prednisone (mean dose 0.48 mg/kg on alternate days) or low-dose daily prednisone (0.25 mg/kg/day) reduced the risk of relapse compared with historical controls with maintenance of growth

rates [181, 182]. Guidelines recommend low-dose alternate-day prednisone in children with FRNS and SDNS [183]. However a recent RCT [184] in 61 children with FRNS or SDNS found that children receiving daily prednisone (0.2–0.3 mg/kg/day) had significantly fewer relapses than children receiving alternate day prednisone (0.5–0.7 mg/kg/day) with no increase in adverse effects. Four small RCTs have demonstrated that, in children with FRNS, increasing the frequency to daily administration at the onset of an intercurrent infection significantly reduces the risk of relapse [185–188]. However results from a large RCT with 271 children evaluated found that giving 6 days of daily low-dose prednisolone at the time of an URTI did not reduce the risk of relapse of nephrotic syndrome in children in the United Kingdom [189].

Adverse Effects of Corticosteroids

A study from the Kidney Research Network Registry [190] provides an overview of the frequency of corticosteroid adverse effects in patients with primary proteinuric kidney disease. Among a cohort of 884 patients (393 children) with primary proteinuric kidney disease, 534 received corticosteroids. At least one steroid associated adverse event was seen in 333 (62%) of those who received corticosteroids with hypertension, diabetes, overweight and obesity, infections and short stature being the most common. There was no difference in risk of steroid associated adverse effects between children and adults. The adjusted relative risk increased overall 2.5-fold for each 1 mg/kg increase in corticosteroid dose; hypertension increased 4.5-fold, obesity increased 2.9-fold and diabetes increased 1.9-fold.

Behavioural changes are common and include anxiety, depression, emotional lability, aggressive behaviour, inattention, hyperactivity and sleep disturbance [191, 192]. The adverse effects seen in the four large RCTs evaluating the initial episode of SSNS are shown in Table 13.2. Health related quality of life over time is reduced in children with nephrotic syndrome on prednisone or steroid sparing agents, compared with children not on medications [193]. In addition, nephrotic syndrome causes significant mental and economic stress on families [194].

The current practice of using alternate day rather than daily prednisone to maintain remission results from early reports that growth was less affected by alternate day prednisone. An RCT demonstrated that children given alternate day prednisone after kidney transplantation grew better than those given daily prednisone [195]. Studies of children with FRNS or SDNS, which have evaluated the adverse effects of corticosteroids on linear growth, have shown variable results. In a study of 56 children with FRNS or SDNS, children lost 0.49 ± 0.6 of height standard deviation score (SDS) during pre-pubertal growth [196]. Prednisone therapy was the only significant variable associated with the negative delta SDS. In a second study, growth rates remained normal if prednisone doses were maintained below 1.5 mg/kg on alternate days in 41 prepubertal children [197]. A third study of 64 boys found that growth rates remained stable from diagnosis for 5 years and then deteriorated [198]. In two studies final height was significantly below target in children, who required prednisone during puberty [196, 198] though partial catch up growth occurred in pubertal children permanently withdrawn from prednisone [196]. However a third study of 60 children with SSNS found that final height SDS did not differ significantly from initial height SDS (−0.60 ± 1.0 versus −0.64 ± 0.92) though the mean final height SDS differed significantly from that expected in healthy children [199].

Derangements of bone mineral metabolism may occur in patients with nephrotic syndrome and normal kidney function. Vitamin D-binding protein and 25-hydroxyvitamin D levels are reduced in nephrotic children [200] while generally levels of calcium, 1,25-dihydroxyvitamin D and parathyroid hormone levels are normal [200–202]. 25-hydroxyvitamin D levels increase in remission but remain low compared with healthy children [202] and may be associated with continuing reduction in bone mineral density [203]. Abnormalities of bone mineral metabolism are

aggravated by treatment with corticosteroids. Corticosteroids reduce bone formation by inhibiting osteoblast activity and inhibiting bone matrix formation. In addition they increase bone resorption directly and by reducing calcium absorption via inhibition of Vitamin D activity with a secondary increased release of parathyroid hormone [204, 205]. Low bone area and trabecular thickness with focal areas of osteoid accumulation consistent with osteopenia and abnormal mineralisation have been found in children with steroid dependent SSNS [205]; bone formation rate correlated inversely with the daily prednisone dose. Serum osteocalcin and alkaline phosphatase levels fall during corticosteroid therapy consistent with reduced bone formation [202].

Corticosteroid therapy is associated with osteopenia (decrease in quantity of bone tissue) and osteoporosis (osteopenia with bone fragility). Trabecular bone is affected more severely than cortical bone. Dual energy x-ray absorptiometry (DXA) is widely used to assess bone mass in children with SSNS. DXA measures the mass of bone mineral per projection area (g/cm^2), which is a size dependent measure [206]. Thus results must be corrected for height in short children to prevent underestimation of bone mineral density (BMD) in comparison with age matched controls. A North American cross-sectional study of 60 children with SSNS, who had received an average of 23 g of prednisone, demonstrated that whole body bone mineral content (BMC) was increased and lumbar spine BMC was normal in children with SSNS compared with age matched local controls when adjusted for bone area, height, age, sex, pubertal stage and race [207]. Nephrotic children had significantly lower z-scores for height and higher z-scores for weight and body mass index (BMI) compared with controls. The authors concluded that corticosteroid induced increases in BMI were associated with increased whole body BMC and maintenance of BMC of spine. In contrast in 100 non obese Indian children with SSNS, who had received 5.6–18 g of prednisone, 61% had low BMD levels compared to normal values from North American controls [201]. No children developed fractures. These data indicate that differences in growth and body composition in different study populations need to be considered when interpreting studies of bone mass in children with SSNS. In a prospective Canadian study, lumbar spine BMD was studied at baseline (median 18 days from prednisone initiation), 3, 6, 9 and 12 months after the onset of nephrotic syndrome [208]. Only 51% of children were receiving prednisone by 12 months. Mean lumbar spine BMD was significantly reduced at baseline and 3 months but subsequently mean values did not differ significantly from values in healthy children. Cross sectional and longitudinal studies using peripheral quantitative computed tomography (pQCT) in children with nephrotic syndrome have confirmed differential effects of corticosteroids on cortical and trabecular bone mineral densities with evidence of reduced bone formation [209, 210].

Corticosteroid associated fractures are rare in children with SSNS unlike children with chronic inflammatory disorders such as juvenile rheumatoid arthritis. In the Canadian study, only three children (6%) of 65 children had asymptomatic vertebral fractures by 12 months after commencing prednisone [208]. Children with SSNS appear to be at a low risk of osteoporosis [206]. Bone mineral density improves in children with SSNS, who are given vitamin D and calcium supplements during prednisone therapy [211–213]. The Committee on Nutrition of the French Society of Paediatrics recommend that children with nephrotic syndrome should receive daily vitamin D supplements particularly in winter months [214].

Long term corticosteroid therapy results in suppression of the hypothalamic-pituitary-adrenal (HPA) axis in 35–60% of children with nephrotic syndrome particularly in younger children and children with FRNS or SDNS [215–218]. In the most recent study, the mean duration of prednisone in 13 children with HPA suppression was 66 months compared with 30 months in 24 children without HPA suppression with mean daily doses of 22 mg/kg and 26 mg/kg in the two groups [217]. Families with children receiving long term prednisone therapy should be educated about the possible need for hydrocortisone

replacement at times of illness or stress including surgical procedures. To avoid HPA suppression, long periods of high dose prednisone therapy should be avoided by introducing non-corticosteroid sparing agents.

Corticosteroid Sparing Agents in Frequently Relapsing and Steroid Dependent SSNS

Corticosteroid sparing agents are indicated in children, who have frequent relapses despite low dose alternate day prednisone and/or who have significant adverse effects of prednisone therapy. Corticosteroid sparing agents used in children with FRNS or SDNS include alkylating agents (cyclophosphamide, chlorambucil), levamisole, calcineurin inhibitors (cyclosporin, tacrolimus), mycophenolate mofetil or mycophenolate sodium and rituximab. In addition mizoribine is used in Japan.

Alkylating Agents

Cyclophosphamide remains an important medication to treat FRNS in low and middle income countries where it is be cheaper than other non-corticosteroid immunosuppressive agents [219] while chlorambucil is less commonly used. In six RCTs combined in meta-analysis, oral cyclophosphamide 2–3 mg/kg/day for 8–12 weeks or chlorambucil 0.2 mg/kg/day administered for 8 weeks reduced the risk of relapse by 60% in frequently relapsing SSNS at 6–12 months after treatment compared with prednisone alone [220]. Two studies have shown that intravenous cyclophosphamide (500 mg/m^2/dose for 6 monthly doses) was more effective than oral cyclophosphamide (2 mg/kg/day for 12 weeks) in reducing the risk for relapse at 6 months (RR 0.56; 95% CI 0.33–0.92) but not at 2 years [220–222]; in both studies the cumulative dose of cyclophosphamide was lower in the intravenously treated groups. In a systematic review of 26 observational studies of cyclophosphamide and chlorambucil usage in SSNS. relapse-free survivals after 2–5 years were 72% and 36% in children with FRNS and 40% and 24% in children with SDNS. More recent single centre studies have found similar results [223–227].

Adverse effects with alkylating agents are frequent and may be severe. A third of children will experience leucopenia so white blood counts need to be checked regularly during treatment. If leucopenia occurs, the treatment dose should be reduced or ceased temporarily to reduce the risk of infection. Latta and co-workers identified adverse effects from 38 reports involving 866 children with FRNS or SDNS, who received 906 courses of cyclophosphamide and 638 children, who received 671 courses of chlorambucil (Table 13.3) [228]. They concluded that chlorambucil in the recommended dosage was potentially more toxic than cyclophosphamide based on a higher risk of infections, malignancies and seizures so chlorambucil is rarely used now. Cyclophosphamide may reduce male fertility and cause abnormal gonadal function in men and should not be used in peripubertal male children. In SSNS there is a dose dependent relationship

Table 13.3 Adverse effects of alkylating agents in children with steroid sensitive nephrotic syndrome

		Cyclophosphamide		Chlorambucil	
Adverse effect		Total assessed	N (%) with outcome	Total assessed	N (%) with outcome
Deaths	Patients	866	7 (0.8%)	625	7 (1.1%)
Malignancies	Patients	866	2 (0.2%)	534	3 (0.6%)
Seizures	Patients	866	0 (0%)	266	9 (3.4%)

Reproduced with permission from Latta K, von Schnakenburg C, Ehrich JH. A meta-analysis of cytotoxic treatment for frequently relapsing nephrotic syndrome in children. Pediatric Nephrology. 16(3):271–82, 2001 [228]

between the number of patients with sperm counts below 10^6/mL and the cumulative dose of cyclophosphamide [228]. The threshold cumulative dose for safe use of cyclophosphamide remains uncertain because of individual reports of oligospermia in boys receiving less than 200 mg/kg. These data suggest that single courses of cyclophosphamide at a dose of 2 mg/kg/day should not exceed 12 weeks (cumulative dose 168 mg/kg). There are few data on gonadal toxicity with chlorambucil in SSNS. In male patients treated for lymphoma, total doses of 10–17 mg/kg led to azoospermia [229]; similar total doses are used in SSNS. Gonadal toxicity is less severe in women with most reports observing little or no toxicity with alkylating agents in SSNS [228]. The 2012 KDIGO guidelines advise that second courses of alkylating agents should not be given because of their potential long term toxicity [125].

In many countries, cyclophosphamide has been largely replaced by other non-corticosteroid medications because of its adverse effects. The main advantage of cyclophosphamide over levamisole, MMF and CNIs is that it often results in a prolonged period of remission after the medication is ceased. Rituximab also leads to a prolonged period of remission off treatment. Two recent observational studies [230, 231], which compared outcomes of children treated with cyclophosphamide with those treated with rituximab, found that 1 and 2 year relapse-free survivals were similar between treatments but adverse effects were more common with cyclophosphamide. Importantly more children treated with rituximab were able to cease steroids completely [231]. However rituximab is expensive and may not be available in resource limited countries.

Calcineurin Inhibitors

Cyclosporin has been used to treat children with frequently relapsing or steroid dependent SSNS since 1985 [232]. Two small trials enrolling 95 children demonstrated no significant difference in the risk of relapse during treatment between alkylating agents given for 6 or 8 weeks and cyclosporin given for 6 or 9 months [233–235]. However most children treated with cyclosporin relapsed when therapy was ceased so the risk of relapse with alkylating agents was lower than with cyclosporin after cyclosporin had been ceased for 12–15 months. In a prospective 2 year follow up of 44 children, in whom cyclosporin was discontinued after completion of an RCT, 37 (84%) experienced a relapse [236]. Relapses occurred in 81% (26/32), without relapse during cyclosporin therapy, and in 92% (11/12) children, who had one or more relapses during cyclosporin therapy. The probability that children would re-develop FRNS or SDNS by 2 years was 75% and 53% respectively in children with or without relapse during their previous cyclosporin therapy. Adverse effects of cyclosporin reported in four trials were common with 13% of children developing hypertension, 10% reduced kidney function, 23% gum hypertrophy and 27% hirsutism [235]. A potentially serious adverse effect of CNI is posterior reversible encephalopathy syndrome (PRES) [237]. Nephrotic syndrome per se and hypertension also are predisposing factors for PRES.

Cyclosporin (microemulsified) is usually commenced at 4–5 mg/kg/day in two divided doses with subsequent dosing altered to achieve 12 h trough whole blood levels (C_0) of 80–150 ng/mL (67–125 nmol/L) initially. In an RCT the sustained remission rate at 2 years was significantly higher in children with C_0 levels maintained between 80–100 ng/mL (50–67 nmol/L) [mean dose 4.8 mg/kg/day] compared with children treated with a fixed dose of 2.5 mg/kg/day (sustained remission rates 50% versus 15%) [238]. Hypertension and mild arteriolar hyalinosis were less common in the fixed dose group. The cyclosporin dose, required to maintain trough levels, may be reduced by one third by administering ketoconazole as a cyclosporin sparing agent with reduction in drug costs [239]. Studies in children with SSNS have demonstrated better correlations between area under the curve concentrations of cyclosporin and 2 h post dose levels (C_2) than with trough levels [240]. A Japanese RCT compared the effect of two different C_2 levels on the relapse rate in children with FRNS or SDNS [241]. Children were randomised to receive cyclosporin to achieve whole blood C_2 levels of

600–700 ng/mL (499–582 nmol/L) for 6 months followed by 450–550 ng/mL (374–457 nmol/L) for 18 months or to achieve C_2 levels of 450–550 ng/mL (374–457 nmol/L) for 6 months and then 300–400 ng/mL (250–333 nmol/L). The sustained remission rate was slightly but not significantly higher in the high C_2 level group compared with the lower C_2 level group but the relapse rate was significantly lower in the high level group; adverse effects did not differ between groups.

Tacrolimus is now the preferred CNI agent for SSNS where available largely because of the cosmetic effects of cyclosporin though it is also nephrotoxic and may be associated with diabetes mellitus. No RCTs have compared tacrolimus with cyclosporin in children with SSNS. In a prospective uncontrolled study of 74 children (50 on tacrolimus; 24 on cyclosporin), relapse frequency during 2 years follow-up did not differ significantly between treatments [242]. Nephrotoxicity defined as an increase in serum creatinine >25% above baseline was less common in tacrolimus treated children and diabetes mellitus was not reported. The starting dose of tacrolimus was 0.5–1.5 mg/kg/day in two divided doses; subsequently the dose was adjusted to 12 h trough levels of 5–12 ng/mL (6–14 nmol/L). There are also some observational data in children with SDNS suggesting that tacrolimus may be associated with less CNI nephrotoxicity than cyclosporin [243]. In a retrospective cohort study of 340 children with FRNS or SDNS examining the relative efficacy and safety of tacrolimus, MMF and levamisole as the first non-corticosteroid agent, the 30-month relapse free survival was 62% with tacrolimus, 39% with MMF and 24% with levamisole [219]. Fewer adverse effects were seen with levamisole (three reports) compared with tacrolimus (33 reports). Serious adverse effects mainly related to infection were only seen with tacrolimus.

CNI toxicity is well documented in children receiving this therapy outside the transplant setting [244] though few studies have correlated clinical toxicity with morphologic features [245, 246]. The toxic effects are essentially the same in transplant and non-transplant settings. CNI toxicity may be characterized by reduction in glomerular filtration rate with no discernible histological abnormality or by acute and chronic tubular and/or vascular changes in the kidney. Acute changes of toxic tubulopathy are classically described as "isometric" vacuolation of proximal tubular epithelial cells. However this is often a focal phenomenon and may only be seen in a small number of tubules in a biopsy sample. The vacuoles are of similar size (hence "isometric") and occur on the basis of dilatation of the smooth endoplasmic reticulum of the cells. Non-specific changes of acute tubular necrosis may be seen in some cases, with intraluminal desquamation of epithelial cells, dilatation of the tubules and regenerative nuclear changes. Acute vascular changes may result in microvascular thrombosis, endothelial and myocyte necrosis. Chronic vascular changes include nodular hyaline arteriopathy, which arises on the basis of individual myocyte necrosis of arteriolar smooth muscle, and "striped" interstitial fibrosis and tubular atrophy that reflect focal ischaemic damage. Ultimately, chronic CNI nephrotoxicity can result in glomerular changes of chronic ischaemia and/or focal and segmental glomerulosclerosis. The morphological nephrotoxic effects of tacrolimus are essentially the same as those seen with cyclosporin and include acute tubular necrosis, acute and chronic vascular changes, and interstitial fibrosis.

Cyclosporin-induced tubulointerstitial lesions on kidney biopsy are reported in 30–40% of children who have received cyclosporin for 12 months or more [247–249]. Cyclosporin associated arteriopathy is uncommon. Risk factors for fibrosis are total duration of cyclosporin therapy, having heavy proteinuria for more than 30 days during therapy [247] and higher trough cyclosporin levels [250], higher 2 h peak cyclosporin levels and concurrent use of angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers [249]. Arteriopathy but not interstitial fibrosis improves after cyclosporin has been ceased for 12 months or more [251].

The duration of administration of CNIs is controversial with some authors suggesting that

duration should not exceed 2 years [247]. However other authors have suggested that longer periods of CNIs may be well tolerated [252]. There are few data on kidney histology in children with SSNS who have received tacrolimus but increases in interstitial fibrosis correlated with trough tacrolimus levels [253]. These few data suggest that as with cyclosporin, the lowest possible dose of tacrolimus should be used to maintain remission.

Levamisole

Levamisole is a synthetic antihelminthic agent with immunomodulatory properties [254]. Its use in childhood nephrotic syndrome was first described by Tanphaichitr and co-workers in 1980 [255] and since then many studies have described its benefits [254]. Levamisole is usually administered in a dose of 2.5 mg/kg on alternate days. Levamisole given for 4 months to 1 year reduced the risk of relapse by 50% in comparison with prednisone alone in 6 trials (474 patients; RR 0.41, 95% CI 0.27–0.61) [220, 256–261] but was ineffective in a seventh trial, in which a lower total dose of levamisole was given [220, 262]. However several of these RCTs were at high risk of bias because of methodological problems, which may lead to an overestimation of treatment effects [163]. Recently a multicentre, double-blind RCT evaluating levamisole compared with placebo in 99 children with FRNS or SDNS confirmed the efficacy of levamisole [263]. Between 100 days and 12 months from the start of the medications, the time to relapse was significantly increased in the levamisole group compared with the placebo group (HR 0.22; 95% CI 0.11–0.43). After 12 months, 26% of levamisole treated participants remained in remission compared with 6% of placebo-treated participants. Four of 50 children treated with levamisole suffered moderate leucopenia. Adverse effects of levamisole are uncommon but include leucopenia, gastrointestinal effects and occasionally vasculitis [264, 265]. Although levamisole is a valuable corticosteroid sparing agent, it is currently unavailable in many countries.

Mycophenolate Mofetil/ Mycophenolate Sodium

Mycophenolate mofetil (MMF) and mycophenolate sodium (MPS) are converted to mycophenolic acid (MPA), which is an inhibitor of the *de novo* purine pathway with inhibitory effects on T and B lymphocyte proliferation [266]. MMF has become an important corticosteroid sparing agent in children with FRNS or SDNS and is often used as the initial non-corticosteroid immunosuppressive agent [267]. MPS is used in adults with nephrotic syndrome and minimal change disease [268] but has rarely been used in children though its efficacy can be expected to be similar to MMF [269]. Numerous observational studies have demonstrated a reduction in relapse rate during MMF treatment compared with prednisone treatment [270] though no RCT has compared MMF with prednisone alone. Its efficacy in SSNS has been evaluated in three RCTs (144 children) comparing MMF (800–1200 mg/m^2/day in two divided doses) with cyclosporin (4–5 mg/kg/day) [271, 272] and in one RCT (149 children) comparing MMF (1200 mg/m^2/day) with levamisole (2.5 mg/kg on alternate days) [273]. When combined in a meta-analysis, the relapse rate was lower with cyclosporin compared with MMF (142 children. Mean difference 0.83; 95% CI 0.33–1.33) but adverse effects of hypertension, hypertrichosis and gum hypertrophy were lower and GFR higher in MMF treated children [220]. The main adverse effects of MMF are abdominal pain, diarrhoea, anaemia, leucopenia and thrombocytopenia although MMF has been well tolerated in children with SSNS with gastrointestinal disorders reported in only 4% of 130 children in a large observational study [219]. *In utero* exposure to MMF has been associated with prenatal defects so women should be counselled that they will need to cease MMF before becoming pregnant [270].

Higher MPA exposure is required in children with nephrotic syndrome compared with levels in kidney transplant recipients [270]. Studies of therapeutic drug monitoring show that the target MPA area under the curve (AUC) needs to be

above 45–50 μg h/mL to maintain remission though there is large between-patient variability [271, 274, 275]. *Post hoc* analysis of the Gellermann study revealed that the relapse rate in children with higher MPA exposure (mean MPA-AUC 74.0 mg h/mL) did not differ from that seen in cyclosporin treated children [271]. None of the RCTs reported to date have used therapeutic drug monitoring to determine the correct dose of MMF for individual patients so it remains possible that results of these RCTs would differ if drug monitoring had been included. Currently therapeutic drug monitoring of MMF in children with nephrotic syndrome is not widely available. No consistent single time point for measurement has been identified that correlates with AUC data and can be used to monitor children with FRNS or SDNS receiving MMF.

Rituximab

Rituximab is a mouse-human chimeric monoclonal antibody which binds to the CD20 antigen expressed on B cells. Treatment leads to a suppression of CD19 cells to below 1% and relapse generally occurs when levels of CD19 cells recover. Rituximab has now been evaluated in seven RCTs using one [276–278] (Fig. 13.4), two [279–281] or four doses [282] of rituximab (375 mg/m^2 per dose). In five studies including 296 children with difficult to treat SDNS, the risk for relapse was reduced by 63% at 6 months (4 studies, 239 children; RR 0.27; 95% CI 0.15–0.47) and 36% at 12 months (2 studies, 168 children; RR 0.74; 95% CI 0.58–0.94) [220]. In two studies (60 participants), which assessed RTX in children with SSNS treated with high (≥0.7 mg/kg/day) or low doses (≤0.4 mg/kg/day) of prednisone without other immunosuppressive agents, the risk of relapse was reduced by 94% and 74% at 6 and 12 months compared with prednisone alone [277, 278].

To gain further information about the optimum dosing regimen of rituximab, a study evaluated retrospectively the different dose regimens used in 11 tertiary centres in Asia, Europe and North America [283]. Among 511 children with complicated relapsing SSNS (defined as relapsing despite ongoing treatment with prednisone and at least one additional agent), 191 received low dose rituximab (375 mg/m^2), 208 received medium dose rituximab (750 mg/m^2) and 112 received high dose rituximab (1125–1500 mg/m^2). Fifty five percent [283] of children received concurrent immunosuppressive treatment (CNI, MMF, prednisone). Children who received low dose rituximab had shorter relapse-free periods (8.5 months) compared with those receiving medium dose (12.7 months) or high dose (14.3 months) rituximab. However when rituximab was combined with immunosuppressive therapy, relapse-free survival did not differ between different dosage groups. Two RCTs is underway to determine whether MMF compared with placebo maintains remission in children with SSNS after successful treatment with rituximab [284, 285].

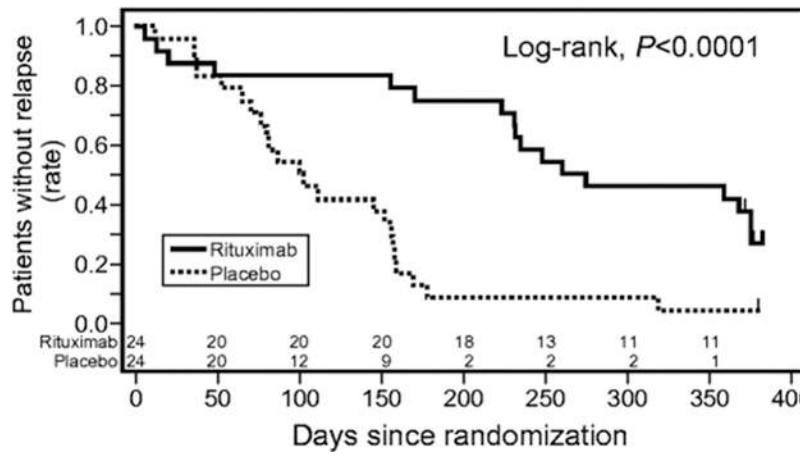

Fig. 13.4 Relapse-free survival probability in participants with relapsing nephrotic syndrome treated with rituximab. Reproduced with permission from Iijima K, Sako M, Kamei K, Nozu K. Rituximab in steroid-sensitive nephrotic syndrome: lessons from clinical trials. Pediatric Nephrology (2018) 33:1449–1455

The main adverse effects reported with rituximab have been acute episodes of bronchospasm, hypotension, fever and arthralgias occurring during or immediately after intravenous infusion. Premedication with anti-histamine and anti-pyretic agents is recommended. Adverse effects are generally mild with infusion reactions (13%) and infections (4%) being most common [283]. Mild to moderately serious infections are reported to be less commonly seen with rituximab compared with tacrolimus [280]. However rare but serious adverse effects reported in children with nephrotic syndrome treated with rituximab include fatal pulmonary fibrosis [286], *Pneumocystis jiroveci* pneumonia with respiratory failure [287, 288], bacterial pneumonia including *Pseuodomonas aeroginosa* pneumonia [289] and severe myocarditis requiring heart transplantation [290]. Though not yet reported in children with SSNS, a survey of patients with SLE treated with rituximab identified 57 patients with multifocal leucoencephalopathy caused by JC polyomavirus [291]. Fifty six children (14%) of 400 children in whom IgG levels were measured had persistent hypogammaglobulinaemia at 1 year following rituximab infusion [283]. Among 27 children who had received rituximab more than 2 years previously, most had a sustained reduction in total and switched memory B cells while 11 children had hypogammaglobulinaemia [292]. Younger patients appear to be at increased risk of hypogammaglobulinaemia [293]. More information is required to determine the longer term impact of these immunological abnormalities.

Because of the uncertainty about long term adverse effects and its cost, rituximab use was previously restricted to children with steroid and CNI dependent SSNS. However a study from the USA has demonstrated that the 1 year overall treatment costs of using rituximab compared with CNIs may not differ significantly [294]. Increasingly rituximab is being used in children with FRNS or SDNS because it can achieve long periods of remission off treatment [278] though the long term effects of prolonged B cell depression and hypogammaglobulinaema remain to be elucidated.

Choice of First Corticosteroid Sparing Agent for Children with FRNS or SDNS

RCTs to date have not provided sufficient data on the comparative efficacy and adverse effects of corticosteroid sparing agents to allow definitive recommendations on which medication should be the first agent used in FRNS or SDNS. Most international [125] and national guidelines [133, 165, 166] have not provided recommendations on which medication should be preferred as the first corticosteroid sparing agent. New guidelines from KDIGO and the International Pediatric Nephrology Association are awaited. Table 13.4 lists the advantages and disadvantages of each corticosteroid sparing medication. The choice of first agent will depend on clinician and family preferences based on an assessment of the benefits and harms as well as the cost and availability of medications.

Other Agents

In RCTs, no significant reduction in the risk of relapse has been demonstrated with azathioprine [235]. Mizoribine blocks purine biosynthesis pathways and is used in Japan for children with SSNS. In an RCT involving 197 children, who received 4 mg/kg/day of mizoribine or placebo, there was no significant difference in relapse rates and 16% of treated patients developed hyperuricaemia [295]. Recent studies suggest that some children with SSNS respond well to mizoribine and that differences in the pharmacokinetics in responders and non-reponders may explain differences in response. Mizoribine has a lower frequency of adverse effects compared with cyclophosphamide and cyclosporin so in Japan it may be used before other second line agents [296]. Two RCTs [297, 298] compared azithromycin (a macrolide antibiotic with immunomodulatory properties) and prednisone with prednisone alone and found a lower risk of relapse at 6 months in children treated with azithromycin. Adrenocorticotrophic hormone (ACTH) was widely used to try nephrotic syndrome in the 1950s but was subsequently replaced by prednisone. More recently there have been case reports of its efficacy in SSNS. However a

Table 13.4 Advantages and disadvantages of corticosteroid-sparing agents as first agent for use in frequently relapsing or steroid dependent steroid sensitive nephrotic syndrome

Medication	Advantages	Disadvantages
Cyclophosphamide	Prolonged remission off therapy Inexpensive	Less effective in SDNS Monitoring of blood count during therapy Potential serious short- and long-term adverse effects Only one course should be given
Chlorambucil	Prolonged remission off therapy Inexpensive	Less effective in SDNS Monitoring of blood count during therapy Potential serious short- and long-term adverse effects Only one course should be given
Levamisole	Prolonged remissions in some children with FRNS Generally inexpensive Few adverse effects	Continued treatment required to maintain remission Limited availability Not approved for SSNS in some countries
Mycophenolate mofetil/ Mycophenolate sodium	Prolonged remissions in some children with FRNS and SDNS Few adverse effects	Continued treatment required to maintain remission Less effective than CNIs Limited availability Expensive Risk of birth defects & pregnancy loss in first trimester of pregnancy Little data on use of mycophenolate sodium in children with SSNS
Cyclosporine	Prolonged remissions in some children with FRNS/SDNS	Continued treatment required to maintain remission Expensive Nephrotoxic Cosmetic side-effects
Tacrolimus	Prolonged remissions in some children with FRNS/SDNS	Continued treatment required to maintain remission Expensive Nephrotoxic Risk of diabetes mellitus Not approved for SSNS in some countries
Rituximab	Prolonged remissions off treatment in many children with FRNS/SDNS	Risk of prolonged B cell depression and hypogammaglobulinaemia Expensive Usually well tolerated but small risk of very serious adverse effects

FRNS frequently relapsing steroid-sensitive nephrotic syndrome; *SDNS* steroid dependent steroid-sensitive nephrotic syndrome

recent RCT found that ACTH at 80 U/1.73 m^2 administered twice weekly was ineffective at preventing disease relapses in children with steroid dependent SSNS [299].

Vaccinations in Children with SSNS

Physicians should encourage families to complete routine childhood vaccination programmes though the timing of administration of live vaccines (measles, mumps, rubella, varicella [MMRV]) may need to be altered if the child is receiving high dose corticosteroids or corticosteroid sparing agents. *Steptococcus pneumonia*e and *Haemophilis influenza* are important causes of invasive infections in children with SSNS. Vaccines against both organisms are included in the routine vaccination schedules of many countries. The safety and efficacy of the 13-valent pneumococcal conjugate vaccine (PCV13) and the 23-valent pneumococcal poly-

saccharide vaccine (PPSV23) have been demonstrated in children with SSNS [300–302]. In 42 children with nephrotic syndrome who received PCV13, serotype specific antibodies increased in all children and remained elevated for 12 months [302]. However serological responses were lower in children receiving both prednisone and non-corticosteroid immunosuppressive agents (tacrolimus, cyclosporin, MMF). Response to PPSV23 was similar in 30 nephrotic children who received PPSV23 while on prednisone 60 mg/m^2/day to that seen in 13 children on low dose alternate day prednisone [300]. Similar rises in anti-pneumococcal antibody levels were detected in both groups for up to 36 months. Response was not affected by non-corticosteroid immunosuppressive agents. Relapse rates did not increase following vaccination compared with the pre-vaccination period or compared with historical controls [300]. The Centre for Disease Control and Prevention's Advisory Committee on Immunization Practices recommends that the 13-valent pneumococcal conjugate vaccine (PCV13) be given routinely to all children aged below 60 months and to children with immunocompromising conditions including nephrotic syndrome to 18 years [303]. The Committee advises that PCV13 should be administered whether or not the child has previously received PCV7 and/or PPSV23. To broaden protection against serotypes not in PCV13, PPSV23 is also recommended for all children aged 2 years and over with immunocompromising conditions. Influenza vaccine should be given annually to children with nephrotic syndrome who are receiving corticosteroids and/or other immunosuppressive agents. Contacts of these children should also receive influenza vaccine. Hepatitis B vaccination should be administered to at risk children. Seroprotection rates were higher in SSNS than SRNS and higher in those who had received prednisone compared with those receiving prednisone with corticosteroid sparing agents [304].

Live vaccines are generally contraindicated in children on high dose prednisone or on other immunosuppressive agents. Most national recommendations on the administration of live vaccines in children do not specifically address children with SSNS. Based on a study of the South West Pediatric Nephrology Group [305], the 2012 KDIGO guidelines suggest that children not be given varicella vaccines until their prednisone dose is below 1 mg/kg/day (maximum 20 mg daily) or below 2 mg/kg on alternate days (maximum 40 mg on alternate days) and that live vaccines should not be given until children have been off cytotoxic agents for more than 3 months and off other immunosuppressive agents (CNIs, levamisole, MMF) for at least 1 month [125]. Varicella vaccination of household contacts is recommended [306]. A recent study from Japan has questioned the 2012 KDIGO guidelines [307]. The study reported no vaccine-related infections with satisfactory seroconversion rates to measles, rubella, varicella and mumps in 60 children with SSNS who were receiving immunosuppressive agent (CNI, MMF, mizoribine) with low dose prednisone when the vaccines were administered and had negative titres against one or more of these infections. Most children maintained seropositivity for these viruses at 1 year. No serious adverse reactions including vaccine-related infections were seen.

Of importance now to children with steroid sensitive nephrotic syndrome and their families is coronavirus disease 19 (COVID-19). In the United States, the Centers for Disease Control recommend COVID-19 vaccination for everyone aged 12 years and older for the prevention of COVID-19 disease [308] and their interim guidance states that immunocompromised individuals may receive COVID-19 vaccination if they have no contraindications to vaccination. There is limited information on the risk for and outcomes of COVID 19 in people with any immune related kidney disease though preliminary findings suggest that COVID 19 illnesses may be more severe than in people without such kidney disease particularly in people on high dose prednisolone [309]. The Immunonephrology Working Group of the ERA—EDTA (European Renal Association—European Dialysis and Transplant Association) recommend that all eligible people should receive vaccination against COVID-19 (except for those with known allergic reactions to any of the vaccine components) since the poten-

tial of COVID-19 vaccines to induce immunity protecting from severe COVID 19 should outweigh potential risks in most cases [310].

Conclusions

Though the long-term outlook in most children with SSNS is for resolution of nephrotic syndrome and continuing normal kidney function, approximately half of these children will suffer multiple relapses requiring corticosteroids and one or more corticosteroid sparing agents during the course of their disease and are at risk of multiple disease and treatment related complications. In summary:-

- SSNS is more common in Asian but less common in African and African-American children compared with Caucasian children.
- The aetiology and pathogenesis of SSNS remains largely uncertain.
- The outcome of SSNS is for resolution of disease and normal kidney function in the majority of patients.
- The prognosis for long-term kidney function in SSNS depends on complete remission of proteinuria rather than histology so that kidney biopsies are usually not required at presentation or before commencing corticosteroid sparing therapy in children with SSNS.
- Four large well-designed RCTs have demonstrated that there is no benefit of continuing prednisone therapy in the initial episode of SSNS beyond 2 or 3 months to reduce the risk of relapse or FRNS.
- Small studies suggest that relapses of SSNS can be treated successfully with smaller doses of prednisone (1 mg/kg/day) compared with 2 mg/kg/day but adequately powered RCTs are required to confirm this.
- RCTs and large observational studies have evaluated the relative efficacies of alkylating agents, levamisole, mycophenolate mofetil and CNIs. However these data remain insufficient to provide definitive recommendations on which corticosteroid sparing agent should be preferred as the first agent in a child with FRNS or SDNS so the choice of agent depends on patient and physician preferences based on adverse effects, availability and costs.
- In RCTs, rituximab reduces the risk of relapse compared with other therapies. However many children relapse within 6–12 months and uncertainties remain about the risk of serious adverse effects and the significance of persistent hypogammaglobulinaemia.

Further information on the underlying cause of SSNS is needed to guide therapy. New randomised controlled trials are required both to compare new therapies with existing therapies and to determine the optimal regimens for using corticosteroid therapy in SSNS. In particular further studies are required to determine the optimum dose and duration of corticosteroid therapy required in the initial episode of SSNS and in relapsing disease. Further studies on the safety of rituximab are required to determine whether it should be used ahead of other non-corticosteroid agents in children with FRNS and SDNS.

Steroid Resistant Nephrotic Syndrome

14

Rasheed Gbadegesin, Keisha Gibson, and Kimberly Reidy

Introduction

Idiopathic nephrotic syndrome is characterized by severe proteinuria, hypoalbuminemia, and/or presence of edema. Whereas approximately 85% of affected children achieve complete remission of proteinuria upon corticosteroid treatment, those who do not achieve remission are labeled as having "steroid resistant nephrotic syndrome" (SRNS). While details related to steroid sensitive forms of nephrotic syndrome are discussed in Chap. 14 of this book, our chapter will focus on the epidemiology, diagnosis, treatment and clinical outcomes of those children who fail to enter clinical remission after treatment with glucocorticoids.

Definitions

The most important implication for a child given the label of SRNS is that he or she is at increased risk for both the development of disease complications as well as progression to chronic kidney disease (CKD) and eventually end stage kidney disease (ESKD). A major challenge of discussing the multiple issues related to children with SRNS is that its very definition has been standardized within the pediatric nephrology community only recently. In 2020, an IPNA expert committee launched a set of clinical practice recommendations for SRNS in children and in 2021, KDIGO published a clinical practice guideline for the management of glomerular diseases including a pediatric section [1, 2]. The two guidance documents provide the same uniform definitions of SRNS and its subsets:

Steroid Resistant Nephrotic Syndrome (SRNS): Children who fail to enter complete clinical remission within 4 weeks of treatment with prednisone or prednisolone at standard dose [3, 4].

It should be noted that several alternative definitions of SRNS have been used in the past, such as failure to enter remission after 6 weeks of daily oral prednisone, 4 weeks of daily followed by 4 weeks of alternate day oral prednisone, or 4 weeks of daily oral prednisone followed by three intravenous pulses of methylprednisolone [5, 6]. It is hoped that the new definition will be

followed both in research settings and in routine clinical practice. This will be a prerequisite to compare the efficacy of established and novel treatments for nephrotic syndrome.

Calcineurin inhibitor responsive SRNS: Partial remission after 6 months of treatment and/or complete remission after 12 months of treatment with a CNI at adequate doses and/or levels.

Calcineurin inhibitor resistant SRNS: Absence of at least partial remission after 6 months of treatment with a CNI at adequate doses and/or levels.

Multidrug resistant SRNS: Absence of complete remission after 12 months of treatment with two mechanistically distinct steroid-sparing agents at standard doses.

Secondary SRNS: A steroid sensitive nephrotic syndrome patient at disease onset who at subsequent relapse fails to achieve remission after 4 weeks of therapy with daily prednisone or prednisolone at standard dose. Emerging data in the literature has drawn attention to this subgroup of patients with NS [7]. A unique characteristic of this group is that up to 80% of patients in this subgroup who progress to ESKD will develop recurrence of disease following kidney transplantation [8, 9].

Epidemiology

The annual incidence of nephrotic syndrome in most countries studied to date is ~1.2–17.0 new cases per 100,000 children [4, 10–14], and the prevalence is ~16 cases per 100,000 children [4]. The incidence varies widely between countries and different ethnicities [14]. In young children there is a male preponderance, with a male to female ratio of 2:1, although this gender disparity completely disappears by adolescence [11, 15–18]. Steroid resistant nephrotic syndrome (SRNS) is seen in about 15–20% of all cases of childhood nephrotic syndrome. Monogenic SRNS is responsible for 10–30% of all SRNS. The higher percentage is seen in the regions of the World here in breeding is very high and also in population where there are founder mutations. The most common causes of monogenic autosomal SRNS are mutations in nephrin (*NPHS1*), podocin (*NPHS2*), phospholipase c epsilon 1 (*PLCE1*) and *nucleoporin* genes. Majority of all cases of autosomal dominant monogenic SRNS are due to mutations in inverted formin2 (*INF2*), transient receptor potential cation channel, subfamily C, member 6 (*TRPC6*) actinin4 alpha (*ACTN4*), and wilms tumor type 1 (*WT1*) genes.

The incidence of nephrotic syndrome has been largely unchanged over the last 35 years, but the histopathologic lesions associated with nephrotic syndrome appear to be evolving. Some reports from various countries suggest that the incidence of focal segmental glomerulosclerosis (FSGS) is increasing, even after correction for variations in renal biopsy practices, and also assuming that children who did not undergo a renal biopsy had minimal change nephrotic syndrome (MCNS) [9, 15–18].

The histologic patterns and incidence of nephrotic syndrome are also affected by **ethnicity and geographic location**. For instance, idiopathic nephrotic syndrome in the United Kingdom was found to be more common among Asian children living in the UK and Canada compared to European children [19, 20]. In contrast, in Sub-Saharan Africa, idiopathic nephrotic syndrome occurs less commonly and disease is more commonly due to infection-associated glomerular lesions [21–23]. In the US, nephrotic syndrome has a relatively higher incidence among children of various ethnic backgrounds. A review of children with nephrotic syndrome in Texas reported that the distribution of children closely resembled the ethnic composition of the surrounding community [15]. These data in conjunction with the data from African countries suggests that the interaction of environmental and genetic factors plays an important role in the pathogenesis of nephrotic syndrome. Despite this, race alone seems to have a clear correlation with the histologic lesion associated with nephrotic syndrome. Indeed, 47% of African American children with nephrotic syndrome in the above study were found to have FSGS, while only 11% of Hispanic and 18% of Caucasian children had this unfavorable pattern of injury [15]. The genetic basis for the high prevalence of

FSGS in people of African ancestry was established in 2010 when homozygous or compound heterozygous G1 and G2 genotype in the gene encoding apolipoprotein 1 (*APOL1*) were shown to confer ten times the odds of developing FSGS in African Americans [24].

The age at presentation with nephrotic syndrome also has strong correlations with the frequency of presentation, as well as the associated renal histology. The most common age for presentation with nephrotic syndrome is 2 years, and 70–80% of all cases of nephrotic syndrome develop in children <6 years of age [4, 10]. In addition, children diagnosed prior to 6 years of age comprised 80% of those with MCNS, compared to 50% of those with FSGS, and only 2.6% of those with MPGN [25]. When analyzed based on renal histology, the median age at presentation was 3 years for MCNS, 6 years for FSGS, and 10 years for MPGN [25]. Therefore, excluding presentation in the first 12 months of life, these data suggest that the likelihood of having MCNS as a cause for nephrotic syndrome decreases with increasing age, while the likelihood for having the less favorable diagnoses of FSGS or MPGN increases [25, 26].

The most common renal histologies seen in children with SRNS are FSGS, MCNS, MPGN and membranous nephropathy.

Additional variables associated with clinical steroid responsiveness include ethnicity and geographic location. While 20% of children in Western countries have steroid resistant nephrotic syndrome, studies from Africa reported steroid resistance in 50–90% of children with nephrotic syndrome, with higher proportions of children with steroid responsive disease in more affluent and diverse urban centers [23, 27–29].

Histopathological Findings

SRNS is a heterogeneous clinical condition with multiple etiologies. The histopathologic entities that may cause SRNS vary in different series depending on the age group and the population being studied. However, in different series focusing on children presenting after the first year of life, the common pathologic variants associated with SRNS include focal segmental glomerulosclerosis (FSGS), membranous glomerulopathy, membranoproliferative glomerulopathy (MPGN), and minimal change disease (MCD) [11, 15, 31–34]. The majority of cases are due to disease on the continuum between MCD and FSGS (Table 14.1). Since the MCD/FSGS spectrum represents the most common pathologic variants of SRNS, and since other chapters are devoted to each of the other histologic variants, the rest of this chapter will focus mainly on FSGS.

Table 14.1 Pathologic findings in steroid resistant nephrotic syndrome

Histology	South-Asia[a] [25, 26] n = 326	South-Africa [28] n = 183	Poland [27] n = 34	USA[b] [9, 12] n = 253

Focal Segmental Glomerulosclerosis (FSGS)

FSGS is a pathologic finding that is characterized by focal glomerulosclerosis or tuft collapse, segmental hyalinosis, IgM deposits on immunofluorescence staining, and podocyte foot process effacement on electron microscopy [35]. In the majority of children, it is characterized by SRNS and progression to end-stage kidney disease (ESKD) within 5–10 years of diagnosis [30]. It was first described in kidney biopsies of adults with nephrotic syndrome by Fahr in 1925, although it was Rich who later made the observation that the lesion of FSGS in children with nephrotic syndrome classically starts from the corticomedullary junction before involving other parts of the renal cortex [36, 37]. The observation of Rich is probably the explanation for why many cases of FSGS

are initially misdiagnosed as MCD since early disease may be confined to the corticomedullary junction. The incidence of FSGS is estimated at seven per million people, and the incidence is higher in blacks than whites and the rate of decline in kidney function is also worse in blacks [38]. The incidence of FSGS is increasing in all populations. In a predominantly adult cohort, Kitiyakara et al. reported an 11-fold increase among dialysis patients over a 21 year period, and a similar pattern was reported in a population-based study in the USA [39, 40]. The most compelling pediatric data to date is a metanalysis that examined over 1100 nephrotic patients over two time points. This study demonstrated a twofold increase in the incidence of FSGS in children [41]. The reason for the increasing incidence is unknown, but possible explanations include changing criteria in the selection of patients for kidney biopsy, better diagnostic instruments, or changing environmental factors such as infection-driven disease. For example, patients with severe acute respiratory syndrome due to coronavirus 2 (SARS-CoV-2) can develop nephrotic syndrome with renal histology findings of FSGS due to direct podocyte infection and or cytokine production [42].

Aging
Ischemia
Renal artery stenosis
Hypertensive kidney disease
Calcineurin inhibitor nephrotoxicity
Acute and chronic renal allograft rejection
Cholesterol crystal embolism
Cyanotic congenital heart disease

Clinical and Pathologic Classification of FSGS

Until recently, FSGS was classified based on presumed causes. The etiology was unknown in more than 80% of cases (primary or idiopathic FSGS) and the remainder secondary to other disease processes such as infectious agents like hepatitis, HIV, toxic agents, ischemia, obesity and other glomerulonephritides. A list of causes of FSGS is shown in Table 14.2.

With the recent advances in genomic science, hereditary causes of FSGS are increasingly being recognized. Although this group is estimated to be responsible for not more than 30% of all cases, detailed studies of hereditary FSGS have shed more light on the molecular pathogenesis of the disease [43].

The morphological changes in kidney biopsies of patients with FSGS are heterogeneous. In order to standardize the pathological diagnosis of FSGS and relate histologic findings to clinical course, the Columbia classification of FSGS was proposed [44]. In this classification schema, five patterns of FSGS have been proposed including: (1) FSGS not otherwise specified (NOS), (2) Perihilar variant, (3) Cellular variant, (4) Tip variant, and (5) Collapsing variant (Table 14.3 and Fig. 14.1). The clinical significance of the

Table 14.3 Outcome of FSGS histologic subtypes in the NIH-sponsored FSGS trial [21]

FSGS subtypes	Frequency (%) n = 138	% with ESKD at 3 years
NOS	68	20
Collapsing	12	47
Tip	10	7
Perihilar	7	Number too small
Cellular	3	Number too small

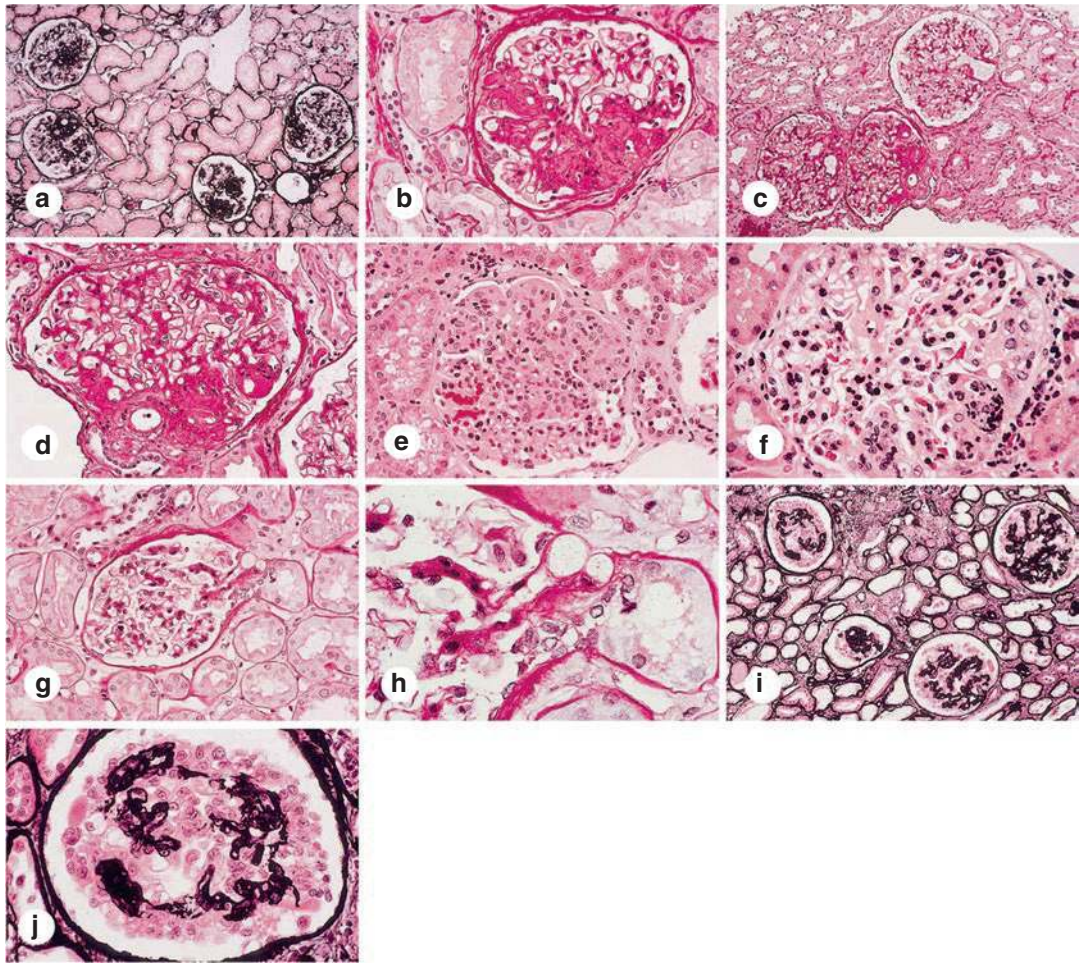

Fig. 14.1 Columbia classification of FSGS: *FSGS NOS:* (**a**) Low power magnification showing segmental sclerosis in two glomeruli. Lesions are characterized by increased matrix and obliteration of the capillary lumen. Distribution of lesions within the tuft is variable. (**b**) PAS staining at higher magnification showing obliteration of glomerular tuft by increased matrix and hyaline deposit. Sclerosed segments form adhesions to Bowman's capsule, note that there is no podocyte hypertrophy or hyperplasia. *FSGS perihilar variant:* (**c**) Low power examination showing segmental sclerosis affecting the vascular pole in one of three glomeruli. The lesion shows increased sclerosis and hyalinosis and there is adhesion of the sclerotic segment to the Bowman's capsule in the vascular pole region. (**d**) Higher magnification of C showing increased sclerosis and glassy hyalinosis deposited in the vascular pole segment of the tuft. *FSGS cellular variant:* (**e**) The glomerulus in this image shows endocapillary hypercellularity. The involved segments are engorged with endocapillary cells including mononuclear leukocytes. (**f**) Further demonstration of numerous endocapillary leukocytes mimicking endocapillary glomerulonephritis. In addition there is hypertrophy and hyperplasia of overlying podocytes. *FSGS tip variant:* (**g**) Low power view shows a segmental lesion involving the tip domain at the origin of the tubular pole. (**h**) Higher magnification of the lesion in G showing endocapillary foam cells and adhesion of the sclerotic segment to Bowman's capsule at the mouth of the proximal tubule. *FSGS collapsing variant*: (**i**) Low power magnification shows four glomeruli with global collapse of the tuft and podocyte hypertrophy and hyperplasia with tubular degenerative changes. (**j**) High power magnification shows global occlusion of capillary lumina by implosive collapse of the glomerular basement membranes. There is no significant increase in intracapillary cells or matrix. Overlying podocytes form a cellular corona over the collapsed tuft. Some of the enlarged podocytes appear binucleated and have lost their cohesion to the tuft. (Adapted with permission from reference [44])

variants is still being studied. In a cohort of adults with FSGS, it was reported that collapsing FSGS had the highest rate of renal insufficiency at presentation and worst long term outcome [45]. The most comprehensive prospective report of the clinical significance of the classification in children comes from the analysis of the kidney biopsies from the patient cohort in the NIH sponsored FSGS trial [46]. In this study FSGS NOS was the most common variant, being responsible for 68% of all cases, with collapsing, tip, perihilar and cellular variants responsible for 12%, 10%, 7% and 3%, respectively. Patients with collapsing FSGS were more likely to be black and to have nephrotic syndrome with renal impairment at presentation, compared to patients with NOS and tip variants [46]. Furthermore, globally sclerotic changes were found more commonly in the NOS variant while segmental sclerosis, tubular atrophy and interstitial fibrosis were found more commonly in collapsing FSGS [46]. At the end of 3 years follow up, 47% of patients with collapsing FSGS were in ESKD compared with 20% and 7% for the NOS and tip variants, respectively [46] (Table 14.3). These findings were confirmed in a study of 201 Japanese FSGS patients [47].

Integrated molecular and morphologic classification: Emerging data is recognizing the fact that FSGS and related morphologic descriptions such as diffuse mesangial sclerosis and minimal change disease are non-specific diagnoses but morphologic changes resulting from multiple injuries to the podocyte [48]. It is now proposed that these morphologic entities should be called **podocytopathies** [49]. The advantages of looking at FSGS and the other morphologic patterns as podocytopathies are (1) focusing on a cell that is central to pathogenesis and therefore a target for biochemical analysis and cellular therapy, (2) facilitating identification of other cellular lineage that may be working in concert with the podocyte to preserve the function and the integrity of the GFB, and (3) enabling clinical work-up focusing on identifying causes or risk factors for podocyte injury and therefore more informed prognosis and personalized therapy [48].

Pathogenesis

The hallmark of nephrotic syndrome is glomerular proteinuria [48]. While there are other causes of proteinuria, proteinuria in nephrotic syndrome results from leakage of protein through the glomerular filtration barrier (GFB). The GFB is composed of three layers: podocyte (glomerular epithelial cell), glomerular basement membrane, and fenestrated endothelium (Fig. 14.2) [24, 48–108]. Defects in any of the three layers can result in proteinuria [107, 108].

Hereditary and Monogenic Forms of SRNS

Over the past 20 years, investigations of inherited forms of nephrotic syndrome led to recognition of the importance of the podocyte in the pathogenesis of SRNS [24, 48–110]. The majority of

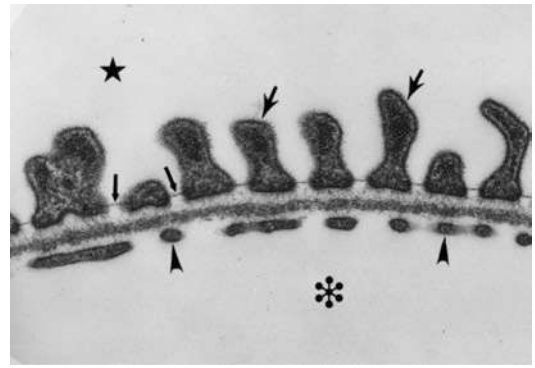

Fig. 14.2 Electron micrograph of the components of the glomerular filtration barrier. During normal glomerular filtration, plasma water is filtered from the glomerular capillary lumen (asterisk) through the fenestrated endothelial cell layer (arrowheads), then across the glomerular basement membrane (GBM) and through the slit diaphragms (small arrows) which bridge the filtration slits between adjacent podocyte foot processes (large arrows) and finally into the urinary space (star) where it enters the lumen of the proximal tubule. These podocyte foot processes are normally tall and evenly-spaced along the GBM, but during nephrotic syndrome they become spread out along the GBM, with apical displacement of the slit diaphragms. The layer of negatively-charged glycocalyx can be seen in this image as a blurry coating on the apical surfaces of the podocyte foot processes. (Adapted with permission from reference [50])

monogenic causes of SRNS affect the structure and function of the podocyte [24, 48–110]. The podocyte is a terminally differentiated epithelial cell with limited ability to regenerate [111]. The prominence of the podocyte in the pathophysiology of SRNS is highlighted by the fact that most common causes of monogenic NS are genes with preferential or selective expression in the podocyte.

In a large cohort of patients with SRNS, the top six monogenic causes of SRNS were *NPHS2* (encodes podocin), *NPHS1* (encodes nephrin), *PLCE1* (encodes phospholipase C epsilon 1), *WT-1* (encodes Wilms tumor 1), *LAMB2* (encodes laminin beta 2) and *SMARCAL* (encodes SW/SNF2 related, matrix associated, actin dependent regulator of chromatin, subfamily a-like 1) (Fig. 14.4 and Table 14.4) [112, 113]. Beyond

Table 14.4 Genetic causes of FSGS and SRNS

Gene	Protein	Mode of Inheritance
Slit diaphragm genes		
NPHS1	Nephrin	AR
NPHS2	Podocin	AR
PLCE1	Phospholipase C epsilon 1	AR
CD2AP	CD2-associated protein	AD, AR
TRPC6	Transient receptor potential channel C6	AD
CRB2	Crumbs family member 2	AR
FAT1	FAT atypical cadherin	AR
KIRREL1	kirre like nephrin family adhesion molecule 1	AR
Transcription factors and nuclear genes		
WT1	Wilm's tumor protein 1	AD
LMX1B	LIM homeobox transcription factor 1-beta	AD
SMARCL1	SMARCA-like protein	AR
NUP93	Nuclear pore complex protein 93	AR
NUP107	Nuclear pore complex protein 107	AR
NUP205	Nuclear pore complex protein 205	AR
NUP160	Nuclear pore complex protein 160	AR
NUP85	Nuclear pore complex protein 85	AR
NUP133	Nuclear pore complex protein 133	AR
XPO5	Exportin 5	AR
E2F3	E2F transcription factor	AD
NXF5	Nuclear RNA export Factor 5	X-linked recessive
PAX2	Paired box protein 2	AD
LMNA	Lamin A and C	AD
WDR73	WD repeat domain 73	AR
Cytoskeletal and membrane genes		
ACTN4	Alpha-actinin 4	AD
INF2	Inverted formin 2	AD
MYO1E	Myosin 1E	AR
MAGI2	Membrane Associated Guanylate kinase, inverted 2	AR
ANLN	Anillin actin binding protein	AD
PTPRO	Protein-tyrosine phosphatase-R O	AR
EMP2	Epithelial membrane protein 2	AR
CUBN	Cubilin	AR
PODXL	Podocalyxin	AR, AD
ARHGAP24	Rho GTPase-activating protein 24	AD
ARHGDIA	Rho GDP dissociation inhibitor alpha	AR

Endosomal regulator genes		
GAPVD1	GTPase Activating Protein And VPS9 Domains 1	AR
ANKFY1	Ankyrin Repeat And FYVE Domain Containing 1	AR

these top six monogenic causes of SRNS, pathogenic variants have been identified in over 60 genes in patients with SRNS (Table 14.4). Recent large cohort studies revealed that altogether 20–30% of sporadic childhood onset SRNS may be due to single gene defects [112–115]. In animal models, including transgenic mice and zebrafish, most identified single gene causes of SRNS result in podocyte dysfunction. Mechanisms of podocyte dysfunction include: (1) slit diaphragm abnormalities (*CD2AP, NPHS1, NPHS2*, and *FAT1*) (2) impaired podocyte actin cytoskeleton regulation and/or adhesion to the glomerular basement membrane (*ACTN4, ANLN, ARHGAP24, INF2, SMARCAL and TRPC6*); (3) defective podocyte differentiation (*PLCE1* and *WT1*), (4) mitochondrial dysfunction (*ADCK4*, *COQ2*, *COQ6, COQ8B* and *tRNA (Leu))* and (5) nuclear pore dysfunction (*NUP94, NUP107, NUP160*), Table 14.4 [48, 116–118].

Beyond the podocyte, pathogenic variants in genes encoding for key molecular components of the glomerular basement membrane are increasingly being recognized as monogenic causes of SRNS. These include *COL4A3* and *COL4A4*, which encode for type 4 collagen of the GBM, and *LAMA5* and *LAMB2*, forming laminin LM-521; α5β2γ1 that is a key component of the glomerular basement membrane. While *COL4A3* and *COL4A4* mutations typically present with the more classic phenotype of Alport syndrome (see Chap. 16), they may also phenocopy FSGS and present with SRNS [119, 120]. Further discussion of monogenic SRNS can be found in Chap. 15.

Common Gene Variants Associated with SRNS/FSGS

In addition to monogenic causes of SRNS, common variants in the gene encoding for apolipoprotein L1 (*APOL1*) are associated with FSGS [24, 122]. *APOL1* contributes to innate immunity and protection against *Trypanosoma*, the cause of African sleeping sickness. The APOL1 protein forms a channel that contributes to *Trypansomal* lysis. Two common variants (known as G1 [2 single nucleotide polymorphisms S342G and I384M] and G2 [a 6 base pair deletion (p.NYK388K] are common in people of West African descent and are associated with protection against resistant *Trypanosoma brucei rhodesiense* and *gambiense*. However, carriage of any combination of *APOL1* high risk genotype defined as homozygous or compound heterozygous G1/G2 genotypes: (G1/G1; G1/G2; or G2/G2) are associated with increased risk for kidney disease [123]. In children of African descent with SRNS, prevalence of *APOL1* high risk genotype may be as high as 40% [124, 125]. The mechanisms of *APOL1* related kidney disease continue to be a focus of ongoing investigations. The prevalence of high risk genotype is about 14% in African Americans, however less than 25% of individuals with these high risk genotypes will develop kidney disease suggesting that genetic and environmental second hits may be needed for phenotypic manifestations. Increased podocyte APOL1 expression with enhanced inflammatory signaling may be one such second hit [126, 127]. Other pathways implicated in APOL1 related kidney disease include podocyte lipid and mitochondrial dysfunction and alterations in ion channel functions [126, 128, 129]. Interestingly *APOL1* high risk genotype is also associated with increased susceptibility to infection related nephropathy, including HIV and COVID-19 nephropathy [130, 131].

Circulating Factors

Beyond genetic factors, a major mechanism of idiopathic SRNS is the presence of a circulating pathogenic factor or absence of factors that prevent proteinuria [132]. Evidence supporting the role of circulating factors includes the recurrence of FSGS post-transplant that is amenable to treatment with plasmapheresis and immunosuppression in some patients [133]. In addition, administration of plasma from FSGS patients alters glomerular and podocyte morphology *in vitro* [134]. Despite extensive efforts, a single circulating factor has not been identified to date. Several candidate factors have been proposed; one of these is sUPAR, the soluble urokinase receptor, which was shown to be elevated post FSGS recurrence and induced proteinuria in a mouse model of FSGS [135]. However, additional studies failed to confirm sUPAR as the circulating factor, although its role in disease progression remains the subject of ongoing investigations [133]. Other circulating factors that have been implicated include cardiotrophin-like cytokine factor-1 (CLCF-1), CD40 antibodies, and apolipoprotein A-Ib (ApoA-Ib) [133]. CLCF-1 is a cytokine that functions in B-cell stimulation. CD40 is a costimulatory protein expressed on immune cells. Elevated CLCF1 levels and anti-CD40 antibodies were identified in sera from patients with recurrent FSGS [136]. Application of CLCF1 or anti-CD40 antibodies to cultured podocytes induced actin cytoskeleton alterations [136]. ApoA-1 is a circulating component of the HDL complex; The ApolA-1b variant was identified by urine proteomics studies as increased in patients with recurrent FSGS [137].

Podocyte Endowment, Loss, Regeneration and Glomerulosclerosis

Glomerulosclerosis is the most common pathologic finding underlying SRNS. Regardless of the initial factor, podocyte damage and loss is key to development of the lesions of glomerulosclerosis [138]. The mechanisms by which podocyte damage evolves into the pathological appearance seen in FSGS have been studied extensively in murine models of FSGS [73]. The initial defect appears to be a reduction in podocyte number and the inability of podocytes to completely cover the glomerular tufts. The reduction in podocyte density causes the loss of separation between the glomerular tuft and Bowman's capsule, leading to the formation

of synechiae or adhesions between the tuft and the Bowman's capsule [73]. The perfused capillaries lacking podocytes at the site of tuft adhesion then deliver their filtrate into the interstitium instead of Bowman's space (Fig. 14.3) [73]. This misdirected filtration through capillaries lacking podocytes leads to progression of segmental injury, tubular degeneration and interstitial fibrosis [73]. Further evidence for the role of podocytopenia in the pathogenesis of FSGS was shown using a rat model of diphtheria toxin-induced podocyte depletion in which the extent of podocyte loss is regulated [74]. In this model, mild podocyte loss resulted in hypertrophy of the remaining podocytes to cover the glomerular basement membrane. However, with moderate to severe depletion FSGS and global sclerosis developed; 30–40% of podocyte loss appear to be sufficient to drive progressive glomerulosclerosis [74].

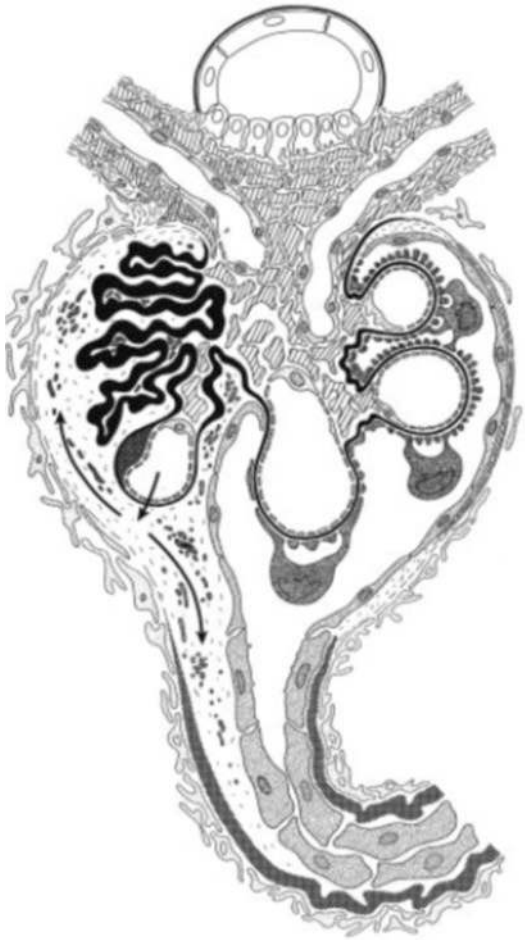

Fig. 14.3 Kriz's misdirected filtration hypothesis of evolving FSGS lesion: The glomerular basement membrane (GBM) is shown in black, podocytes are densely stippled, parietal epithelial cells are less densely stippled and interstitial as well as endothelial cells are loosely stippled, mesangial cells are hatched. The tuft adhesion contains several collapsed capillary loops. It also contains a perfused loop, which is partially hyalinized. The filtrate of this loop is delivered into a paraglomerular space that is separated from the interstitium by a layer of fibroblasts. This newly created space extends onto the outer aspect of the tubule by expanding and/or separating the tubular basement membrane from its epithelium. (Reproduced with permission from reference [73])

Diagnostic Evaluation

Patient and Family History

In patients diagnosed with SRNS, the medical history should be explored for potential secondary causes of the disease such as sickle cell disease, HIV, SLE, as well as recent hepatitis B, malaria or parvovirus B19 infections. Family history should be assessed for other family members affected by nephrotic syndrome and/or chronic kidney disease, and parental consanguinity should be checked.

Clinical Assessment

The clinical evaluation of children with SRNS should include an assessment of fluid status, as well as careful exploration of extrarenal disease features such as dysmorphic features, ambiguous genitalia, skeletal, skin, ocular, hearing and neurological abnormalities. Any abnormalities should prompt further diagnostic evaluation.

Laboratory Workup

Proteinuria should be quantitated by measuring the urinary protein:creatinine ratio (uPCR) in spot urine or 24-h protein excretion. Urine dipstick is not considered sufficient to make the diagnosis or monitor treatment responsiveness in

SRNS. Basic chemistries including serum creatinine, serum albumin, a complete blood count, a lipid profile and coagulation testing are important for estimating renal function, confirming the presence or absence of overt nephrosis, and evaluating the risk for disease complications.

SRNS patients require a diligent effort to rule out secondary disease processes. Tests for systemic autoimmune disorders, including antinuclear antibody (ANA), anti–double stranded DNA (anti-dsDNA) antibodies, ANCA, and complement C3 levels should be performed and testing for hepatitis B and C, HIV, malaria, parvovirus B19 and depending on geographic area and ethnicity, sickle cell disease, tuberculosis, and even syphilis may be indicated.

Genetic Testing

Genetic screening is emerging as a critically important clinical tool in the management of children with SRNS. Identification or exclusion of pathogenic gene variants potentially allows for (1) a rational approach to the use of immunosuppressive agents and avoidance of side effects; (2) selection of targeted therapies that may induce remission and/or delay progression to ESKD (e.g., COQ10 supplementation in patients with hereditary COQ10 deficiency; (3) prediction of clinical course and risk of post-transplant disease recurrence; (4) avoidance of kidney biopsy; and (5) genetic counseling and possible prenatal screening [139]. In view of these considerations, the IPNA SRNS guideline recommends genetic testing for all children as soon as the diagnosis of primary SRNS is established [1]. When considered later in the course of the disease, genetic screening is not indicated in patients who have responded to intensified immunosuppressive therapy and in patients with secondary SRNS.

Kidney Biopsy

Kidney biopsy allows the confirmation of a primary podocytopathy (MCD, FSGS, or DMS) and the exclusion of other differential diagnoses such as membranous nephropathy or MPGN. Biopsy is therefore indicated in all children with SRNS except in those with an established monogenic cause of SRNS, potentially in familial and/or syndromic cases, and in patients with known secondary SRNS due to infection or malignancy. Even in suspected or confirmed hereditary forms of SRNS, kidney biopsy may sometimes be indicated, particularly in patients with CKD stage 2 and higher, to grade the amount of tubular atrophy, interstitial fibrosis and glomerulosclerosis as prognostic markers [32, 33].

Management

The IPNA SRNS Clinical Practice Recommendation contains a refined algorithm for the management of SRNS in children (Fig. 14.4). We will describe and explain the rationale for the preferred therapeutic approaches along the lines of this recommendation.

Confirmation Period

When the diagnosis of SRNS is established after 4 weeks of standardized oral corticosteroid therapy, it is suggested to utilize a 2- to 3-week period to further confirm and elaborate the diagnosis before starting new immunosuppressive therapies other than steroids. During this period, genetic testing should be initiated and a kidney biopsy performed, oral prednisone therapy continued and/or three intravenous steroid pulses may be optionally performed. Importantly, renin-angiotensin system (RAS) blockade should be implemented by up-titrating an angiotensin converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB) to full antiproteinuric efficacy. It is essential to measure proteinuria at the end of this period to avoid confounding the antiproteinuric effect of RAS blockade with that of any subsequent immunomodulatory therapies. If genetic screening reveals a monogenic form of SRNS, RAS blockade should be continued at the maximally effective dose, steroid therapy discontinued and no alternative immunosuppressive

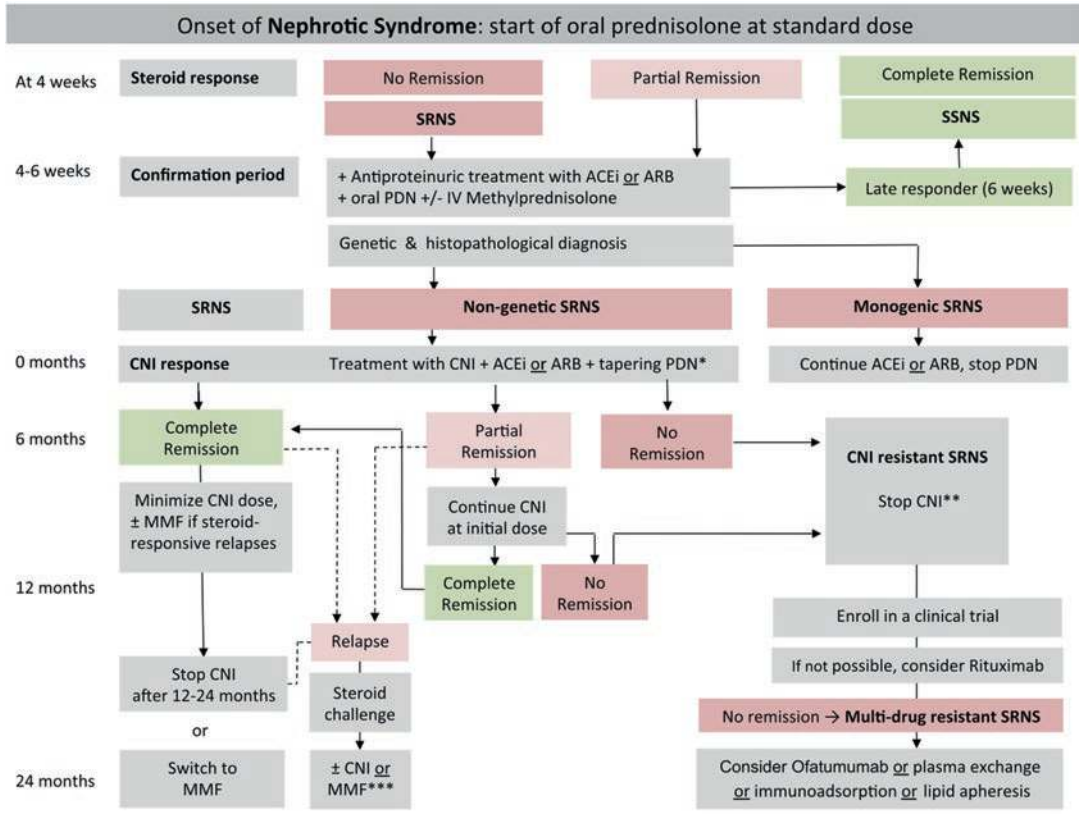

Fig. 14.4 IPNA clinical practice recommendation for management of SRNS in children (Reproduced from [1] with permission)

therapies should be started (or stopped if already started) in order to avoid a futile, potentially toxic treatment.

Therapeutic Pathway

If no genetic disorder is identified, a calcineurin inhibitor (CNI, tacrolimus or cyclosporin A) should be started, the RAS blocker continued at unchanged dose, and oral prednisone weaned over 4–5 months. The response to calcineurin inhibition should be evaluated after 6 months of treatment. If complete remission has been achieved, the patient can be classified as **CNI-responsive SRNS**. In this case, the CNI dose should be minimized and optionally supplemented by MMF. In case of persistent remission, the CNI should be stopped after 12–24 months, optionally continuing or switching to MMF monotherapy. If partial remission is achieved at 6 months, treatment should be continued for a total of 12 months. If complete remission does not occur, the CNI should be discontinued and the patient should receive the diagnosis **CNI-resistant SRNS**. In these patients, a B-cell depleting monoclonal antibody (e.g. Rituximab) can be tried. If this treatment does not yield full remission, the patient should receive the diagnosis **multidrug-resistant SRNS**. Children with CNI-resistant or multidrug-resistant SRNS are candidates for clinical trials and experimental extracorporeal rescue therapies, such as plasma exchange, immunoadsorption and lipid apheresis.

Pharmacotherapies

In the following, we describe the evidence base supporting the use of antiproteinuric and immunosuppressive pharmacotherapies in the therapeutic pathway above. It should be emphasized that due to the rarity of the disease, randomized trial evidence for any of the drugs is scarce or absent. Generally, the apparent efficacy of all of the immunosuppressive agents is lower in SRNS compared to those with frequently relapsing or steroid sensitive nephrotic syndrome [140, 141]. However, most previous treatment studies did not identify and exclude patients with genetic forms of SRNS who are highly unlikely to respond to immunosuppressive treatment. Since these cases comprise up to 30% of SRNS cases, most trial results must be considered substantially confounded. Finally, spontaneous remission of SRNS can occur and may explain some occasional responses of largely ineffective therapies.

RAS Blockade

Several controlled and non-controlled clinical studies have demonstrated the antiproteinuric efficacy of ACE inhibitors and angiotensin-receptor blockers (ARBs) in adults and children with glomerular diseases [142–148]. The antiproteinuric effects of ACEIs and ARBs are due to their ability to reduce glomerular capillary plasma flow rate, decrease transcapillary hydraulic pressure, and alter the permselectivity of the glomerular filtration barrier. On average, RAS blockers reduce proteinuria by approximately 30% in children with SRNS [149], although even complete remissions have been reported [150]. ACEIs and ARBS should be administered at the maximum approved and tolerated dosages since proteinuria reduction is dose dependent. However, the use of RAS blockers may increase the risk for AKI in patients with intravascular volume depletion [151]. Combined treatment with ACEi and ARBs is not recommended as it increases the risk for adverse events [152]. ACE inhibitor therapy may lead to a phenomenon known as 'aldosterone escape' with a long-term increase in plasma aldosterone levels. The addition of aldosterone blockade with ACE inhibition reduces urine protein excretion by 30–58% in patients with both diabetic and non-diabetic proteinuria [153]. The long-term safety of this form of combined RAS blockade remains to be elucidated.

Calcineurin Inhibition

Several randomized trials have suggested improved complete or partial remission rates in patients with SRNS when treated with cyclosporine compared with placebo, no treatment, or intravenous methylprednisolone pulses (~75% vs. 22%) [154–158].

Out of 433 children with primary SRNS in the PodoNet registry treated with CsA or Tacrolimus in the year following diagnosis, 30% achieved complete and 19% partial remission [159]. CsA and tacrolimus show similar efficacy in inducing remission [160].

In addition to immunomodulation, antiproteinuric effects of the calcineurin inhibitors may in part be mediated by hemodynamic effects that reduce renal blood flow [161]. In addition, calcineurin inhibitors may reduce proteinuria by inhibition of calcineurin-mediated degradation of synaptopodin and stabilization of the podocyte actin cytoskeleton [162, 163].

While CNIs are generally not recommended in patients with reduced eGFR due to their nephrotoxic effects, their use may be justified in SRNS patients with CKD and no other option for disease control [162]. CsA and tacrolimus have similar nephrotoxicity, but gingival hyperplasia and hypertrichosis are more prevalent with CSA and glucose intolerance occurs more frequently with tacrolimus (Table 14.5).

Mycophenolate-Mofetil (MMF)

The efficacy of MMF in inducing or maintaining remission in children with SRNS has not been demonstrated against placebo or no treatment in randomized clinical trials.

Table 14.5 Treatment options for steroid resistant nephrotic syndrome

Drug	Efficacy Evidence	Toxicity	Benefit
ACE Inhibitors/ ARBs	Good	May lower eGFR Teratogenicity	Slowed progression of CKD
IV Corticosteroids	Good	Weight gain Hypertension Glucose intolerance Hyperlipidemia Striae	May ensure achieving therapeutic drug levels.
Cyclosporine	Good	Nephrotoxicity Hypertension Gingival hyperplasia	May only require low dose
Tacrolimus	Good	Nephrotoxicity Hypertension Glucose Intolerance	May only require low dose
Mycophenolate Mofetil	Mixed	GI intolerance Teratogenicity	No nephrotoxicity
Rituximab	Mixed	Infections Hypogammaglobulinemia Long-term effects unknown	May enable discontinuation of daily immunosuppressive medications

In a multicenter randomized trial of 192 children and young adults with steroid resistant FSGS, MMF in combination with dexamethasone was similarly effective as CsA (33% vs. 46%] and the rates of adverse events were similar [163]. MMF was less effective than tacrolimus in maintaining remission (45% vs. 90%) [164]. In the PodoNet registry, MMF therapy was associated with complete or partial remission in only 4 of 24 cases (17%) [159]. CNI/MMF co-treatment yielded full remission in four and partial remission in 10 of 34 patients, i.e. not different from CNI monotherapy [159].

B-Cell Depleting Agents

Rituximab is a chimeric monoclonal antibody directed against CD20. Rituximab-induced B-lymphocyte depletion may act on proteinuria in nephrotic syndrome by inducing regulatory T lymphocytes, as has been observed in patients with lupus nephritis [164]. Experimental findings suggest that Rituximab may also directly protect podocytes by stabilizing the podocyte cytoskeleton and preventing apoptosis through an interaction with the sphingomyelin phosphodiesterase acid-like 3b protein that is expressed in podocytes [165].

In a retrospective review of 33 patients with SRNS treated with two to four doses of intravenous rituximab, and followed for ≥12 months, 9 (27%) patients with SRNS showed complete remission, 7 (21%) had partial remission, and 17 (52%) had no response after 6 months of observation [166]. A similar response pattern was reported from a randomized trial in Korean children and in 66 children followed in the PodoNet registry [159, 167]. However, in an open-label, controlled trial that randomized 31 children with SRNS to either receive rituximab or continue prednisone and calcineurin inhibitors, no subjects in either arm achieved significant reduction of proteinuria. Hence, the efficacy of rituximab in the treatment of SRNS is unclear and there is a need for a randomized control trial [168].

More recently, case reports suggested that Ofatumumab (OFA), a fully humanized anti-CD20 monoclonal antibody, may be useful in inducing remission in patients with hypersensitivity reaction to rituximab or in children who are resistant to multiple immunomodulators including rituximab [169, 170]. However, a recent low-dose ofatumumab randomized placebo-controlled trial was prematurely terminated because the first 13 patients (25% of targeted

enrollment) did not respond to the treatment [171]. Meanwhile, Ofatumumab has been withdrawn from the market.

Newer Therapies and Ongoing Clinical Trials

For children with CNI-resistant SRNS, consideration for entry into clinical trials evaluating novel therapies on the horizon should be strongly considered.

The FONT2 study (Novel Therapies in the Treatment of Resistant FSGS) aimed to compare novel therapies in patients with FSGS that have failed standard immunosuppressive therapies with conservative management [172]. In vitro studies have documented decreases in glomerular permeability when isolated glomeruli were incubated with galactose-containing sera [173]. The proposed mechanism suggests galactose may bind a glomerular permeability factor thus rendering it ineffective. Another proposed mechanism for proteinuria in patients with SRNS implicate Tumor Necrosis Factor-alpha (TNF-α), a pro-inflammatory cytokine that is important in the recruitment of leukocytes to the site of glomerular injury, induction of cytokines and growth factors, generation of oxygen radicals with increased glomerular endothelial cell permeability, cytotoxicity, and induction of apoptosis. In the FONT2 trial, 21 patients were randomized to one of the three study arms to receive the TNF-α antibody **adalimumab, galactose,** or standard medical therapy for 26 weeks. None of the adalimumab-treated subjects achieved the primary outcome of ≥50% reduction in proteinuria, whereas two subjects in the galactose and two in the standard medical therapy arm had a 50% reduction in proteinuria without a decline in eGFR, suggesting that some patients may benefit from treatment with oral galactose [173].

ACTH (Adrenocorticotropic Hormone) was the therapy of choice for children with nephrotic syndrome in the 1950s before corticosteroids became widely available [174, 175]. The development of an ACTH analog has made this therapy available once again as a second line agent in the treatment of SRNS. The largest published series to date by Hogan et.al reports a cumulative remission rate of 29% in 24 patients with SRNS and SDNS treated with subcutaneous ACTH [176]. In a recent systematic review that included 98 patients with FSGS, 42% achieved remission following treatment with ACTH. However, it should be noted that the population comprised frequently relapsing, steroid dependent, and steroid resistant patients [177].

Sparsentan, a dual endothelin and ARB was found to decrease proteinuria by 45% vs. 19% in a phase 2 randomized double-blind trial of those treated only with irbesartan with no differences in serious adverse events between the groups [178]. A phase-3 multicenter trial is in progress.

A small post-approval study for **low-density lipoprotein (LDL) apheresis** for children with CNI-resistant SRNS has shown increased treatment responsiveness and improved or stable eGFR over the follow-up period, it should be noted that this was not a randomized control trial [179].

Common variants in APOL1 gene termed G1 and G2 account for a significant proportion of the excess risk of progressive kidney disease in individuals of recent African ancestry with an estimated lifetime risk of kidney disease in 15% in those with a high-risk genotype [180, 181]. Novel **APOL1 inhibitors** are currently in clinical development. A Phase II trial investigating the APOL1 inhibitor VX-147 has started recruitment [182]. Antisense oligonucleotides are short, synthetic, modified chains of nucleotides that bind to the target mRNA, inducing its degradation and preventing the mRNA from being translated into a detrimental protein product. Preclinical studies with antisense oligonucleotides are showing promise as a novel therapeutic approach for APOL1 associated nephropathy [183, 184].

Treatment of Monogenic SRNS

Increased availability of genetic testing for children with SRNS has enabled the development of more personalized treatment decisions. The clinical value of genetic testing in SRNS is illustrated by our ability to make decisions on the intensity and duration of immunosuppression, as well as pre- and post-transplant management based on genomic findings [8, 9, 185, 186]. Generally, >95% of patients with monogenic SRNS will not respond to treatment with immunomodulatory agents [121, 159], and hence it is recommended to withdraw immunosuppressive therapy. RAS inhibitors should be administered at maximally effective and tolerated doses. There are anecdotal reports of individuals with mutations in *WT1, PLCE1, and MYO1E* who achieved partial or complete remission when exposed to immunosuppressive treatments, in particular calcineurin inhibitors [64, 69, 121, 187]. It is unclear if these responses, which are usually transient, are due to immunomodulatory effects or rather to their effects on stabilizing the podocyte cytoskeleton.

One of the promises of the genomic revolution is that identification of genetic causes of SRNS will lead to identification of specific and non-toxic therapeutic agents. Along this line, some monogenic causes of SRNS have given clue to novel therapeutic agents. An intriguing example is Coenzyme Q10 (CoQ10) supplementation in patients with mutations in genes encoding for components of the CoQ10 synthase complex (COQ6, COQ2, COQ8B) [67, 139, 188]. Other examples are Vitamin B12 supplementation in patients with mutations in the cubilin (CUBN) gene, and targeting of *TRPC6*, *TRPC5*, and RhoGTPases for potential treatment of some form of monogenic SRNS [62, 189, 190].

Long-Term Prognosis of SRNS

Most studies examining the long-term prognostic factors for kidney survival in patients with SRNS were from small cohorts, frequently single-center studies, with short term follow up, and often incomplete datasets [191, 192]. A multi-center study of 75 children with FSGS reported that within 5 years from the diagnosis of FSGS, 21% of children had developed ESKD, 23% had developed CKD, and 37% had developed persistent proteinuria, while only 11% remained in remission [30]. The most comprehensive study to date has been performed by the PodoNet consortium [159]. In this study, clinical, treatment-related, genetic, and laboratory data including kidney biopsy findings were collected from >1300 patients with SRNS with an average follow up time of about 4 years but extending up to 15 years. The overall proportion of SRNS patients with preserved kidney function was 74%, 58%, and 48% at 5, 10, and 15 years respectively. Risk factors for disease progression included lacking responsiveness to intensified immunosuppression (IIS) protocols, genetic disease, and FSGS on biopsy. Ten-year ESKD-free survival rates were 94%, 72%, and 43% in patients with complete remission, partial remission, and IIS resistance respectively (Fig. 14.5). After 15 years, kidney function was preserved in 96% of IIS-responsive, 53% of multidrug resistant and 17% of genetic SRNS patients. The histopathological findings at time of diagnosis were also predictive of outcome but less so than IIS responsiveness and genetic disease status, with 37% 15-year ESKD-free survival in patients with FSGS as compared to 79% in those with minimal change disease. The predictive value of IIS responsiveness and genetic status was independent of the histopathological diagnosis.

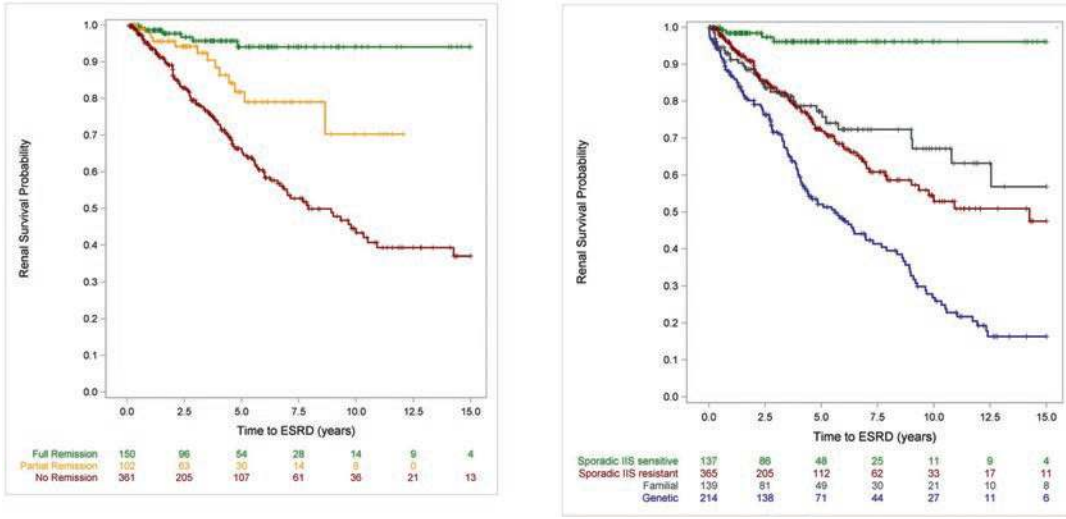

Fig. 14.5 ESKD-free survival in children with SRNS followed in PodoNet Registry. *Left panel:* Survival according to responsiveness to calcineurin inhibitor therapy (green; full remission, yellow; partial remission, red; no remission). *Right panel*: ESKD-free survival according to responsiveness to intensified immunosuppression (IIS) and genetic familial disease status (green: IIS responsive sporadic SRNS, red: multidrug resistant SRNS; grey: familial SRNS without identified genetic cause; blue: genetic SRNS). Complications of Nephrotic Syndrome

Hyperlipidemia

Hyperlipidemia is a common clinical finding in children with nephrotic syndrome. The characteristic lipid profile includes elevations in total plasma cholesterol, very low-density lipoprotein (VLDL), and low-density lipoprotein (LDL) cholesterol, triglyceride, lipoprotein A, as well as variable alterations (more typically decreased) in high-density lipoprotein (HDL) cholesterol [193, 194]. While the hyperlipidemia in children with SSNS is often transient and usually returns to normal after remission, children with SRNS refractory to therapy often have sustained hyperlipidemia. Such chronic hyperlipidemia has been associated with an increased risk for cardiovascular complications and progressive glomerular damage in adults [195–199]. Based on this, pharmacologic treatment of hyperlipidemia in children with refractory nephrotic syndrome may both reduce the risk for cardiovascular complications later in life and reduce the risk of disease progression.

The potential usefulness of hydroxymethylglutaryl CoA (HMG CoA) reductase inhibitors (statins) in children with SRNS has been reported in a few uncontrolled trials. One study reported a 41% reduction in cholesterol and 44% reduction in triglyceride levels within 6 months of treatment [200]. A second study found significant reductions within 2–4 months in total cholesterol (40%), LDL cholesterol (44%), and triglyceride (33%) levels, but no significant changes in HDL cholesterol levels [201]. Treatment was found to be very safe in these studies, with no associated adverse clinical or laboratory events. Although the long-term safety of statins in children has not yet been established, these medications appear to be generally well tolerated in adults with nephrotic syndrome, with only minor side effects such as asymptomatic increases in liver enzymes, creatine kinase, and rarely diarrhea [202].

Thrombosis

The risk of thromboembolic events in children with nephrotic syndrome is estimated to be 1.8–5% with a higher risk reported in children with SRNS compared with those with SSNS [203, 204]. Factors contributing to an increased risk of thrombosis during nephrotic syndrome include abnormalities of the coagulation cascade, such as increased clotting factor synthesis in the liver (factors I, II, V, VII, VIII, X, and XIII) and loss of coagulation inhibitors such as anti-thrombin III in the urine. Other prothrombotic risks present in these children include increased platelet aggregability (and sometimes thrombocytosis), hyperviscosity resulting from increased fibrinogen levels, hyperlipidemia, prolonged immobilization, and the use of diuretics. In one series, the use of diuretics was the major iatrogenic risk factor for thrombosis [204].

The majority of episodes of thrombosis are venous in origin. The most common sites for thrombosis are the deep leg veins, ileofemoral veins, and the inferior vena cava. In addition, use of central venous catheters can further increase the risk of thrombosis. Renal vein thrombosis (RVT) can also occur and may manifest as gross hematuria with or without acute renal failure. Development of these features should prompt either renal Doppler ultrasonography or magnetic resonance angiography to rule out RVT. Pulmonary embolism is another important complication that may be fatal if not recognized early. Rarely, cerebral venous thrombosis, most commonly in the sagittal sinus, has also been reported [205]. In addition to imaging studies, development of thrombosis should prompt an evaluation for possible inherited hypercoagulable states.

The typical acute management of thrombosis in children with nephrotic syndrome includes initial heparin infusion or low molecular weight heparin, followed by transition to warfarin for 6 months. Children with a history of prior thrombosis and patients with severe proteinuria should also receive prophylactic anticoagulation therapy during future relapses.

Nutrition

Several recommendations supported by observational data exist regarding nutrition in pediatric patients with nephrotic syndrome. Specifically, children with nephrotic syndrome and edema should be evaluated for malabsorption and subsequent malnutrition due to bowel wall edema. In edematous patients, long-term sodium restriction is appropriate with a maximum goal of approximately 2500 mg/day. In patients with persistent hyperlipidemia due to inability to control nephrosis, a low saturated fat diet should be instituted with their HMG CoA-reductase inhibitor. Protein intake should only be supplemented at the Recommended Daily Allowance (RDA) [206]. Although it would appear intuitive that states of excess urinary protein loss should warrant increase dietary protein intake, several studies have successfully challenged this notion. In nephrotic rats, augmentation of dietary protein was found to stimulate albumin synthesis by increasing albumin mRNA content in the liver, but there was also a notable increase in glomerular permeability and subsequently increased albuminuria [207]. No change in albumin synthesis was noted with dietary protein restriction in this model or in nephrotic patients.

Immunization

Children with nephrotic syndrome are at increased risk for infections, including but not limited to streptococcus and staphylococcal species due to urinary losses of IgG, loss of factors crucial for regulation of the alternative complement pathway, and large fluid collections prone to breeding bacteria. Live-viral vaccines (rotavirus vaccine, varicella vaccine, measles, mumps, and rubella vaccine, and the live-attenuated influenza vaccine) are generally recommended to be avoided in CKD patients who are immunosuppressed and therefore should be avoided in patients that are frankly nephrotic and/or currently receiving immunosuppressive therapy. Anti-pneumococcal vacci-

nation using the 23-valent polysaccharide vaccine (PPSV23) is recommended for children with nephrotic syndrome [208]. Due to the low immunogenicity of this vaccine in children less than 2 years of age, the 13-valent polysaccharide pneumococcal vaccine (PCV13) is recommended in this age group, followed by supplemental immunization with PPSV23 over the age of 2 years at least 8 weeks after the final dose of PCV13. A second dose of PPSV23 should be repeated in 5 years.

Kidney Transplantation

Recurrence of nephrotic syndrome may occur in up to 30% in the first kidney allograft of patients with ESKD due to FSGS and approach 100% in those who have a history of prior allograft loss due to FSGS. The risk post-transplant recurrence appears to be mainly determined by the underlying disease etiology, i.e. immune-mediated vs. genetic. Whereas patients with secondary steroid resistance have about 80% risk of recurrence, the risk appears to be close to zero in patients with genetic forms of SRNS [7–9, 139]. Hence, genetic testing should be considered mandatory in all children with SRNS considered for kidney transplantation.

In addition, young age, mesangial proliferation in the native kidneys, rapid progression to ESKD, pre-transplant bilateral nephrectomy, and white ethnicity have been associated with increased risk of recurrence post-transplant [209, 210]. The histologic variant type of FSGS does not appear to be predictive of disease recurrence. There is a higher risk of recurrence in living donor transplant pediatric recipients; however, the reduced risk of rejection and a lower immunosuppression in living-related transplants may overcome the deleterious effect of recurrent glomerulonephritis [211].

The management of recurrent FSGS disease remains controversial and results from observational reports vary. The implementation of plasma exchange is supported in part by the idea of a circulating permeability factor. Up to 70% of children with recurrent FSGS treated with repeated plasma exchanges and/or rituximab may achieve at least a partial remission.

Hereditary Nephrotic Syndrome

15

Stefanie Weber

Introduction

During the past two decades defects in various genes have been associated with the development of steroid resistant nephrotic syndrome (SRNS) in children and adults. These genes encode for proteins that participate in the development and structural architecture of glomerular visceral epithelial cells (podocytes). These insights moved the podocyte with its interdigitating foot processes and slit diaphragm (SD) into the center of interest regarding the pathophysiology of proteinuria.

While light microscopy shows variable aspects ranging from minimal change nephropathy to diffuse mesangial sclerosis or focal-segmental glomerulosclerosis (Fig. 15.1a, b), all hereditary proteinuria syndromes share a common phenotype when evaluated by electron microscopy, which uniformly demonstrates the typical flattening of the foot processes and loss of the SD. With respect to the clinical course, different entities can be distinguished, especially referring to the onset of the disease and modi of inheritance. Disorders of early glomerular development most often manifest prenatally, directly after birth or in early infancy. Disorders with late-onset nephrotic syndrome typically manifest as FSGS in adolescence or adulthood, frequently following an autosomal-dominant mode of inheritance with incomplete penetrance and variable expression. In rare cases, extrarenal symptoms are associated with hereditary nephrotic syndrome, e.g., in Denys-Drash, Frasier, Schimke and Pierson syndrome as well as in mitochondrial disorders. In the following, important genes involved in hereditary nephrotic syndrome will be discussed. Given the rapid development in the field, this list is comprehensive, though may not be complete.

Hereditary Disorders of Early Glomerular Development

Podocytes develop from the nephrogenic blastema in a chain of events in conjunction with the development of the renal glomeruli. First, local condensation of the mesenchyme leads to the formation of the nephron anlage, i.e., the comma-shaped and the S-shaped bodies and eventually the formation of the mature glomerulus. Podocytes are the first cells that can clearly be distinguished in this process, forming a disk-like layer of epithelial cells. The subsequent differentiation to mature podocytes with interdigitating primary and secondary foot processes is associated with a general loss of the ability for further proliferation. At this stage, early cell-cell contacts (adherens junctions) have developed into a specialized structure, the SD, spanning the intercellular space. The final glomerular filtration barrier is constituted by the fenestrated endothelium, the glomerular basement membrane (GBM) and interdigitating podocytes.

A number of genes are involved in these processes (Table 15.1 and Fig. 15.2), and *WT1* is one of the major mediators of podocyte differentation. *NPHS1* and *NPHS2* code for nephrin and podocin, respectively, two proteins that have important roles for the organization of the SD. *LAMB2* encodes laminin ß2, one component of the heterotrimeric laminins that link the podocyte to the GBM. *LMX1b* encodes the transcription factor Lmx1b that in the kidney is exclusively expressed in podocytes. It is one of the crucial genes regulating gene expression during early steps of podocyte development. Another group of genes involved in early-onset nephrotic syndrome, e.g. *PLCE1*, encoding for phospholipase C epsilon-1, are involved in podocyte signaling processes.

WT1 Gene Mutations

The *Wilms tumor* is one of the most common solid tumors of childhood, occurring in 1 of 10,000 children and accounting for 8% of childhood cancers. The Wilms' tumor suppressor gene (*WT1*) was first identified in 1990 [1]. *WT1* locates on chromosome 11p13 and encodes a zinc finger transcription factor that regulates the expression of many genes during kidney and urogenital development. Mutations in *WT1* were first identified in pediatric patients affected by Wilms'

Table 15.1 Overview on important disorders causing hereditary nephrotic syndromes

	Inheritance	Locus	Gene	Protein	OMIM accession no.
Early-onset nephrotic syndrome					
Isolated DMS	AR	11p13	*WT1*	WT1	256370
Denys-Drash syndrome (typically DMS)	AD	11p13	*WT1*	WT1	194080

tumor, aniridia, genitourinary malformations and mental retardation (WAGR syndrome), a contiguous gene deletion syndrome including *WT1* and *PAX6* [2]. *WT1* mutations were also identified in patients with isolated Wilms' tumor [3]. These are classically truncating mutations, associated with a complete loss-of-function of WT1. In tumor material of isolated cases both germline and somatic mutations have been detected. Familial Wilms tumor forms seem to follow a dominant pattern of inheritance, with dominant germline mutations. However, in a number of these cases the classical two-hit inactivation model, with loss of heterozygosity due to a second somatic event, has been described as the underlying cause of tumor development [4]. Alternative genes involved in familiar Wilms tumors are *CTR9*, *REST* and multiple others.

Subsequently, *WT1* mutations were also associated with Denys-Drash syndrome (DDS) [5], Frasier syndrome (FS) [6], and diffuse mesangial sclerosis (DMS) with isolated nephrotic syndrome (NS) [7]. The full picture of autosomal dominant *Denys-Drash syndrome* is characterized by early onset NS, male pseudohermaphroditism, gonadal dysgenesis and the development of Wilms tumor (in more than 90% of patients). The Wilms tumor may precede or develop after the manifestation of NS.

Of note, besides the Wilms tumor risk, individuals with 46,XY and associated disorders of sexual development (DSD) or complete gonadal dysgenesis (CGD) are at an increased risk for germ cell tumors, particularly gonadoblastoma with an observed incidence of one per 30 years at risk.

Age at onset of NS is generally within the first months of life [8]. In rare cases enlarged and hyperechogenic kidneys were already demonstrated by prenatal ultrasound [9]. Renal histology typically presents with DMS [10] and electron microscopy reveals foot process effacement. In rare cases, a histology reminiscent of MPGN may be observed. The NS is resistant to steroid treatment and renal function is deteriorating rapidly to end-stage renal disease (ESRD) already during infancy. Bilateral nephrectomy is generally advised in ESRD in order to prevent the development of Wilms tumor [11]. Recurrence of NS after kidney transplantation has not been observed so far [12].

Dominant *WT1* mutations are identified in the vast majority of DDS patients. These mutations predominantly affect exons 8 and 9 of the *WT1* gene and most of them are de novo mutations not observed in the parents. Most *WT1* mutations associated with DDS are missense mutations affecting conserved amino acids of the zinc finger domains, with p.R394W being the most frequent mutation observed. These alterations of the zinc finger structure reduce the DNA binding capacity of the *WT1* protein [13]. A heterozygous knock-in mouse model has been created for the p.R394W missense mutation, presenting with DMS and male genital anomalies [14] supporting the dominant nature of the disease.

Of note, some of the patients affected by *WT1* mutations in exons 8 and 9 do not present with the full picture of DDS but with isolated DMS or isolated (steroid-resistant) proteinuria. *WT1* analysis should therefore be performed in all children with isolated DMS and early-onset NS because of the risk of Wilms tumor development in case of a positive mutation analysis result. Close monitoring by renal ultrasound (e.g., every 6 months) is important in all children with *WT1* mutation and early-onset NS. In addition, karyotype analysis is recommended in all girls with isolated DMS to detect a possible male pseudohermaphrodit-

ism. Some patients with isolated DMS present with recessive mutations in *WT1* with both the maternal and paternal allele being affected [7].

Frasier syndrome is also characterized by a progressive glomerulopathy and male pseudohermaphroditism [15]; however, there are specific differences to DDS: the onset of proteinuria occurs later in childhood and the deterioration of renal function is slower. ESRD develops only in the second or third decade of life. As in DDS, proteinuria and NS are steroidresistant. Renal histology in FS patients typically shows focal and segmental glomerulosclerosis (FSGS) [16]; in a minority of patients only minimal change lesions are observed. In female patients, the genitourinary tract is normally developed, whereas a complete sex reversal with gonadal dysgenesis is observed in 46,XY patients. Primary amenorrhoea in conjunction with NS is a typical feature of these 46,XY patients and should prompt molecular analysis of *WT1*. While the risk to develop a Wilms tumor is low in patients with FS, gonadoblastomata, developing from gonadal dysgenesis, are frequently observed (in up to 40% of FS patients). After the diagnosis of FS, gonadectomy is highly recommended in 46,XY patients.

In 1997, it was first demonstrated that mutations in the *WT1* gene also underly the pathogenesis of FS [6]. Notably, the class of mutations in FS classically differs from DDS: whereas mutations affecting the coding sequence of exons 8 and 9 cause typical DDS, mutations associated with FS represent donor splice-site mutations located in intron 9. Similar to DDS, these mutations occur in a heterozygous state and, frequently, they are de novo mutations not observed in the parents. The donor splice-site of intron 9 plays an important role for the generation of the KTS isoform of the WT1 protein. This isoform contains three additional amino acids (lysine-threonine-serine; KTS). It has been demonstrated that the (+) KTS/(−) KTS protein dose ratio is of high relevance for WT1 action during genitourinary and kidney development. In FS patients, this ratio is markedly reduced due to the splice-site mutations [6].

Large genotype-phenotype studies confirm these associations based on the nature of the underlying mutation [17]. Still, there is some overlap and phenotypic heterogeneity in selected cases: splice-site mutations typical for FS may in some cases be found in patients with DDS [5] or isolated DMS [18], and patients with typical DDS mutations may display with isolated FSGS [19] or Wilms' tumor without NS [20]. Since the histologic findings often do not correlate with clinical findings and remarkable histopathologic heterogeneity is observed even among individuals with the same *WT1* pathogenic variant, kidney biopsy is no longer considered a first-tier diagnostic measure for patients of any age in the view of some authors. Instead, analysis of *WT1* should be included in routine genetic screening in all patients with SRNS or unexplained proteinuria. Owing to the experience of phenotypic heterogeneity, the group of clinical pictures is now entitled **WT1 disorder**s.

NPHS1 Gene Mutations Associated with Autosomal Recessive CNS of the Finnish Type (CNF)

CNS of the Finnish type is characterized by autosomal recessive inheritance and the development of proteinuria in utero [21]. The responsible gene was mapped in 1994 to chromosome 19q13 [22] and mutations in *NPHS1* have been subsequently identified in affected children [23]. *NPHS1* encodes for nephrin, a zipper-like protein of the glomerular SD. Typically, severe NS manifests before 3 months of age and renal biopsy specimens show immature glomeruli, mesangial cell hypercellularity, glomerular foot process effacement and microcystic dilatations of the proximal tubules. NS is steroid-resistant in these patients and treatment options comprise albumin infusions, pharmacological interventions with ACE inhibitors and indomethacin and ultimately uni- or bilateral nephrectomy [24–27].

Nephrin is exclusively expressed in podocytes, at the level of the SD once full differentiation has occurred [28]. Nephrin belongs to the immunoglobulin superfamily with a single putative transmembrane domain, a short intracellular N-terminus and long extracellular C-terminus

[23]. The extracellular C-terminus is predicted to bridge the intercellular space between the interdigitating foot processes, rendering nephrin a key component of the SD. Nephrin strands contribute to the porous structure of the SD, forming pores of approximately 40 nm in size [29]. These pores are currently believed to be in part responsible for the size selectivity of the SD and the glomerular filtration barrier.

Apart from its role as a structural protein, nephrin also appears to participate in intracellular signaling pathways maintaining the functional integrity of the podocyte [30–32]. The SD is discussed to constitute a highly dynamic protein complex that recruits signal transduction components and initiates signaling to regulate complex biologic programs in the podocyte. A number of proteins within this signaling platform were identified to interact with nephrin, among these podocin, CD2AP and TRPC6, all of which are also associated with the development of NS when altered by gene mutations (see below). It is suggested that the plasma membrane of the filtration slit has a special lipid composition comparable to lipid rafts [33]. Lipid rafts are specialized microdomains of the plasma membrane with a unique lipid content and a concentrated assembly of signal transduction molecules [34]. It was shown that nephrin is a lipid raft-associated protein at the SD and that podocin serves to recruit nephrin into these microdomains. Disease-causing podocin mutations fail to target nephrin into rafts, altering nephrin-induced signal transduction [32]. In summary, these studies confirm the extraordinary role of SD proteins for the maintenance of the glomerular filtration barrier.

Mutations in *NPHS1* were first identified in the Finnish population, leading to the classification of "Finnish type" CNS. Two truncating mutations were found with high frequency in affected Finnish children suggesting an underlying founder effect in the Finnish population: p.L41fsX90 (Fin major, truncating the majority of the protein) and p.R1109X (Fin minor, truncating only a short C-terminal part). In subsequent studies, *NPHS1* mutations were also identified in non-Finnish patients throughout the world. The Fin major and Fin minor mutations are only rarely observed in non-Finnish patients. Several mutational hot spots were identified affecting the immunoglobulin domains of the nephrin protein [35]. The immunoglobulin domains 2, 4 and 7 appear particularly important for gene function. In addition to the high prevalence in Finland, *NPHS1* mutations are also common among Mennonites in Pennsylvania, 8% of this population is carrier of a heterozygous mutant allele [36].

Recent studies pointed out that congenital nephrotic syndrome can also be caused by recessive mutations in *NPHS2* (see below), particularly involving nonsense-, frameshift or the homozygous missense mutation p.R138Q [37–39]. In rare cases a triallelic digenic mode of inheritance was observed in patients with CNS/SRNS: in these patients, sequence variations in both *NPHS1* and *NPHS2* were identified with a total of three affected alleles (two *NPHS1* mutations and one *NPHS2* sequence variation or vice versa) [35]. It is speculated that the additional sequence variation of the second gene plays a role as a genetic modifier, possibly aggravating the clinical phenotype.

NPHS2 Gene Mutations Associated with Autosomal Recessive Steroid-Resistant Nephrotic Syndrome

The *NPHS2* gene was mapped by linkage analysis in eight families with autosomal recessive SRNS to chromosome 1q25-q31 [40] and recessive mutations in *NPHS2* were identified subsequently [41]. NS in these families was characterized by steroid-resistance, age at onset between 3 and 5 years and no recurrence of proteinuria after renal transplantation. *NPHS2* mutations have never been reported in patients with SSNS. Renal histology typically shows FSGS; however, some patients present with only minimal change lesions. In some cases, progression from minimal change lesions to FSGS has been demonstrated in repeat biopsies.

NPHS2 encodes for podocin, a 42 kD integral membrane protein expressed in both fetal and mature glomeruli [41]. By electron microscopy

and immunogold labeling it was demonstrated that the site of expression is the SD of the podocytes. As both protein termini are located in the cytosol and podocin is predicted to have only one membrane domain, a hair-pin like structure of the protein was proposed. Interacting with both nephrin and CD2AP, podocin appears to link nephrin to the podocyte cytoskeleton. In patients affected by recessive mutations in *NPHS2*, SD formation is impaired and the typical foot process effacement is visible. These observations suggest that podocin has an important function for maintaining the glomerular filtration barrier. The knock-out of *Nphs2* in mice is associated with a phenotype highly reminiscent of the human disease with podocyte foot process effacement, nephrotic range proteinuria and chronic renal insufficiency [42]. As nephrin, podocin is localized in lipid rafts [33] and is important for recruiting nephrin to these microdomains of the plasma membrane [32]. Some mutations in *NPHS2* impair the ability of podocin to target nephrin to the rafts, especially the most frequent mutation identified in European patients (p.R138Q) [32].

Up to now, more than 125 pathogenic mutations have been described in *NPHS2* [43]; most mutations affect the stomatin domain located in the C-terminal part of the protein [37, 44]. Mutations in *NPHS2* were first identified in infants with SRNS and rapid progression to ESRD [41]. Subsequently, however, it became evident that defects in podocin can be responsible for SRNS manifesting at any age from birth to adulthood [45–47]. A partial genotype-phenotype correlation is apparent: while frameshift-, nonsense- and the p.R138Q mutation in homozygosity are typically associated with early-onset NS, other missense mutations (e.g., p.V180M, p.R238S) are predominantly found in patients with a later onset of SRNS [37]. A single nucleotide polymorphism in *NPHS2* (p.R229Q) has been identified to be a common cause of adulthood-onset of hereditary nephrotic syndrome when present in compound heterozygosity with specific pathogenic *NPHS2* mutations [48–50]. In the study of Machuca et al., among 119 patients diagnosed with NS presenting after 18 years of age, 18 patients were found to have one pathogenic mutation and p.R229Q, but none with two pathogenic mutations in *NPHS2* [50]. Screening for the p.R229Q variant seems therefore recommended in adolescent or adult patients. Recent data demonstrated that the pathogenicity of p.R229Q depends on the *trans*-associated mutation. It was shown that the association of *NPHS2*-p.R229Q with specific exon 7 or exon 8 mutations in *NPHS2* altered heterodimerization and mislocalisation of the encoded p.Arg229Gln podocin protein [51]. Following this study, homozygosity of *NPHS2*-p.R229Q alone is not disease causing. This observation is important as the p.R229Q variant is prevalent in heterozygous state in approximately 3% of the normal population (range 0.5–7%, depending on the genetic background) [51], resulting in a frequency of homozygous carriers of up to 1%.

Still, the p.R229Q variant is discussed to be a non-neutral PM with an enhanced frequency in FSGS patient cohorts of different ethnical origins [52]. In vitro studies have demonstrated that p.R229Q podocin shows decreased binding to its interacting protein partner nephrin [48] and in a large study of more than 1500 individuals of the general population p.R229Q was significantly associated with the prevalence of microalbuminuria, a risk factor for developing chronic renal insufficiency and cardiovascular events [53].

LAMB2 Gene Mutations Associated with Pierson Syndrome

Pierson syndrome is characterized by CNS and peculiar eye abnormalities including a typical nonreactive narrowing of the pupils (microcoria, Fig. 15.3) but also additional lens and corneal abnormalities [54]. Recessive mutations in *LAMB2* on chromosome 3p21 were identified as underlying genetic defect [55]. *LAMB2* encodes for the protein laminin β2, one component of the trimeric laminins in the kidney that crosslink the basolateral membrane of the podocyte to the GBM. Most disease-associated alleles identified in Pierson patients were truncating mutations leading to loss of laminin β2 expression in the

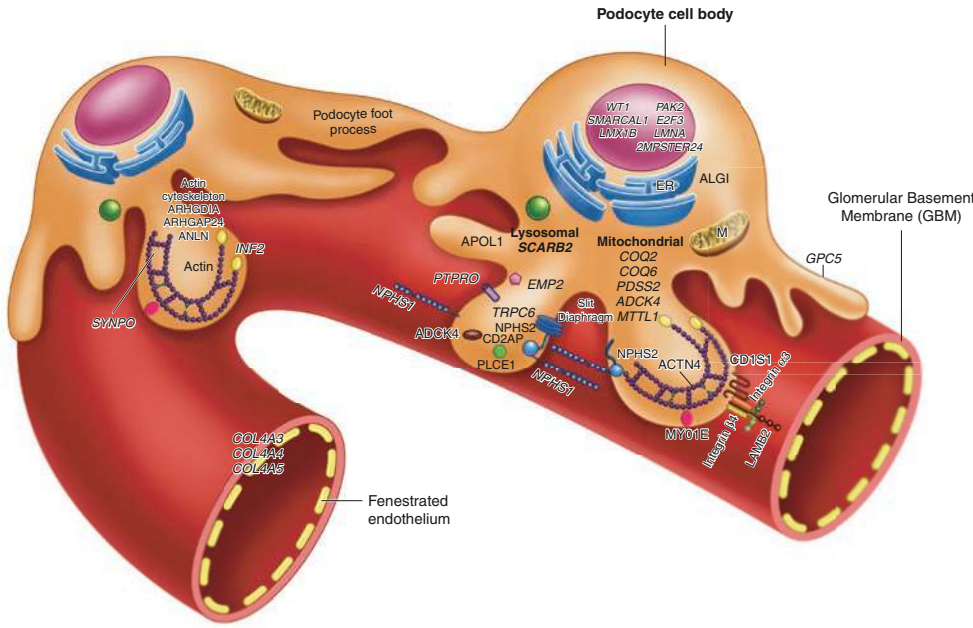

Fig. 15.3 Schema of a podocyte foot process cross-section, depicting important components involved in hereditary nephrotic syndrome

kidney [55]. Ocular laminin β2 expression in unaffected controls was strongest in the intraocular muscles, corresponding well to the characteristic hypoplasia of ciliary and pupillary muscles observed in affected patients. Subsequent genotype-phenotype studies revealed that some mutations in *LAMB2*, especially hypomorphic missense mutations, can be associated with a phenotypic spectrum that is much broader than previously anticipated including isolated CNS or CNS with minor ocular changes different from those observed in Pierson syndrome [56]. Fetal ultrasound in four consecutive fetuses of a family with Pierson syndrome and positive *LAMB2* mutation analysis consistently revealed marked hyperechogenicity of the kidneys and variable degrees of pyelectasia by 15 weeks of gestation [57]. Placentas were significantly enlarged. Hydrops fetalis due to severe hypalbuminemia demonstrated by chordocentesis occurred in one fetus and anencephaly was detected in another fetus. Development of oligohydramnios indicated a prenatal decline of renal excretory function. From these studies it can be concluded that mutational analysis in *LAMB2* should also be considered in isolated CNS if no mutations were found in *NPHS1*, *NPHS2*, or *WT1*, and in cases with prenatal onset of nephrotic disease with typical sonomorphologic findings of the kidneys and the development of oligohydramnios.

The *LAMB2* missense mutation p.C321R, for example, has been identified in congenital nephrotic syndrome with only mild extrarenal symptoms. Functional studies in cell culture and mice suggested defective intracellular trafficking of the mutant protein, associated with endoplasmatic reticulum stress [58]. Another missense mutation (p.S80R) has been identified in homozygous state a teenage girl with severe myopia since early infancy and nephrotic range proteinuria first detected at the age of 6 but normal renal function. Renal biopsy revealed mild DMS and a residual expression of laminin β2 [59].

Summarizing these reports, it becomes obvious that the phenotype associated with pathogenic *LAMB2* mutations can be very variable and that genetic testing for *LAMB2* mutations should be considered in all patients with either early-onset proteinuria or glomerular proteinuria with an abnormal ocular phenotype.

LMX1b Gene Mutations Associated with Autosomal Dominant Nail-Patella Syndrome

Nail-patella syndrome (NPS) or onychoosteodysplasia is caused by dominant mutations in the *LMX1b* gene, located on chromosome 9q34.1 and encoding the LIM-homeodomain protein Lmx1b. Lmx1b plays a central role in dorsal/ventral patterning of the vertebrate limb and targeted disruption of Lmx1b results in skeletal defects, including hypoplastic nails, absent patellae, and a unique form of renal dysplasia [60]. Prominent features of affected children are dysplasia of nails and absent or hypodysplastic patellae. In many patients, also iliac horns, dysplasia of the elbows, glaucoma and/or hearing impairment are detected. *LMX1b* is highly expressed in podocytes and patients can also present with an involvement of the kidney comprising proteinuria, nephrotic syndrome or renal insufficiency. Overall, nephropathy is reported in approximately 40% of affected patients (microalbuminuria or overt proteinuria) [61] but ESRD in less than 10% [62]. Interestingly, renal involvement appears significantly more frequent in females and in patients with a positive family history of NPS nephropathy [61]. In NPS patients with renal involvement, electron microscopy shows collagen fibril-like deposition in the GBM with typical lucent areas [63]. These characteristic ultrastructural changes can even be present in patients without apparent nephropathy [64]. Large genotype-phenotype studies demonstrated that individuals with an *LMX1B* mutation located in the homeodomain showed a significantly higher frequency of renal protein loss and higher values of proteinuria than subjects with mutations in the LIM domains [61]. Recent studies identified *LMX1B* missense mutations affecting residue p.R246 also in a subset of patients with isolated FSGS without extrarenal symptoms, expending the spectrum of FGSG-related genes to *LMX1B* [65, 66]. Insight into Lmx1b function was further obtained by the generation of *Lmx1b* knockout animals [67]. In *Lmx1b*(−/−) mice the expression of GBM collagens is reduced and podocytes have a reduced number of foot processes, are dysplastic, and lack typical SD structures. Interestingly, mRNA and protein levels for CD2AP and podocin are greatly reduced in these kidneys and several *LMX1B* binding sites were identified in the putative regulatory regions of both *CD2AP* and *NPHS2* (encoding podocin) [67]. These observations support a cooperative role for Lmx1b, CD2AP and podocin in foot process and slit diaphragm formation.

PLCE1 Gene Mutations Associated with Autosomal Recessive Nephrotic Syndrome

Following positional cloning, a gene locus for nephrotic syndrome (*NPHS3*) was mapped to chromosome 10q23-q24 and homozygous truncating mutations were identified in the gene *PLCE1*, encoding the enzyme phospholipase C-ε1 which is involved in intracellular signal transduction [68]. Onset of nephrotic syndrome was generally early in affected children and renal histology revealed DMS in most cases. In subsequent studies, mutations in *PLCE1* were identified in a relevant percentage of patients with DMS (28–33%) [69, 70] and with a lower frequency in hereditary FSGS (8%) [70]. Interestingly, two of the individuals with truncating *PLCE1* mutations entered sustained remis-

sion following steroid or cyclosporin A treatment [69]. The observation of a possible responsiveness to immunosuppression in *PLCE1* mutation carriers awaits confirmation in a larger number of affected patients.

PLCE1 is widely expressed in many tissues including also the podocytes. The knock-down of *pcle1* in zebrafish is associated with the development of podocyte foot process effacement and edematous outer appearance of the fish [68] confirming a specific role of phospholipase C epsilon-1 for the maintenance of the glomerular filtration barrier. Still, the pathogenesis of isolated podocyte damage and the development of proteinuria in patients lacking phospholipase C epsilon-1 remains to be elucidated.

PTPRO Gene Mutations Associated with Autosomal Recessive Nephrotic Syndrome

Homozygous *PTPRO* splice-site mutations were identified in two families of Turkish origin with childhood-onset nephrotic syndrome and minimal change nephropathy or FSGS on renal biopsy [71]. Nephrotic syndrome was resistant to oral prednisone therapy but a partial response to an intensified immunosuppressive regimen including pulse methylprednisolone and cyclosporin A was observed in some cases. PTPRO, identical to glomerular epithelial protein-1 (GLEPP1), is a receptor-like membrane protein tyrosine phosphatase expressed at the apical membrane of the podocyte foot processes in the kidney. Disruption of *Ptpro* in mice results in alterations of the podocyte structure and a reduction of the glomerular filtration rate indicating a role of PTPRO for proper podocyte function.

ARHGDIA Gene Mutations in Autosomal Recessive DMS

A recessive mutation in *ARHGDIA*, encoding a regulator of Rho-GTPases, was detected in two female siblings born to consanguineous parents. Both girls presented with congenital nephrotic syndrome and DMS on renal histology [72]. The homozygous 3-bp in-frame deletion mutation in *ARHGDIA* seems to be implicated in the hyperactivation of Rho-GTPases, causing a derangement of the podocyte actin cytoskeleton. *Arghdia* knock-out mice develop podocyte damage, severe proteinuria and progressive renal failure, supporting a role of human *ARHGDIA* in the pathogenesis of proteinuric disease.

EMP2 Gene Mutations Associated with Autosomal Recessive Childhood-Onset Nephrotic Syndrome

Mutations in podocyte genes have only exceptionally been identified in children with steroid-sensitive nephrotic syndrome (SSNS) [44, 73]. However, by homozygosity mapping and whole exome sequencing in 67 families biallelic mutations in *EMP2* were identified in one pair of siblings of Turkish origin, affected by frequently relapsing nephrotic syndrome with remission after cyclophosphamide treatment. In both, onset of the disease was below 3 years of age. Subsequently, more than 1600 individuals with nephrotic syndrome were screened for recessive mutations in *EMP2* and two more patients with SRNS (of Turkish and of African origin) were identified [74]. *EMP2* encodes epithelial membrane protein 2, discussed to be involved in cell proliferation and cell-cell interactions. The knock-down of *emp2* in the zebrafish resulted in pericardial effusions, consistent with a role of epithelial membrane protein 2 in keeping-up glomerular filtration [74].

NUP Nephropathy

A novel large group of genes has recently been identified to be involved in autosomal recessive steroid-resistant nephrotic syndrome leading to CKD and ESRD. These genes encode proteins of the nuclear pore complex (NPC) [75, 76]. These proteins belong to the group of nucleoporins (NUP), assembling to form NPCs, one of the

largest protein complexes found in eukaryotic cells. NPCs are channels that span the nuclear envelope and allow the transport of proteins, RNAs, and ribonucleoprotein particles between the cytoplasm and nuclear interior [77]. Hitherto, mutations were reported in multiple genes encoding proteins of the NPC, including *NUP93, NUP205,* and *XPO5* (inner ring of the NPC) and *NUP107*, *NUP85*, *NUP133*, and *NUP160* (outer ring of the NPC) in patients with childhood-onset SRNS, accounting for approximatively 3% of cases. These human mutations seem to disturb important mechanisms of glomerulogenesis. Kidney biopsy in selected cases showed FSGS or DMS, and extrarenal symptoms identified in patients with mutations in *NUP95*, *NUP107,* and *XPO5* comprise short stature, intellectual disability, microcephaly, or dilated cardiomyopathy. However, more studies focusing on deep phenotyping will be needed to establish more reliable genotype-phenotype correlations.

Hereditary Disorders with Late-Onset Nephrotic Syndrome

Hereditary late-onset FSGS is a heterogeneous condition generally transmitted in an autosomal dominant fashion (with the exception of autosomal recessive FSGS6). Different disease loci have been mapped in affected families (FGSG1-FSGS6) and responsible genetic defects have been identified in many podocyte-associated genes, frequently involving actin cytoskeleton architecture and dynamics.

ACTN4 Gene Mutations Associated with Adulthood FSGS (FSGS1)

In 1998, a locus for autosomal dominant late-onset FSGS was mapped to chromosome 19q13 (FSGS1) [78] and mutations in *ACTN4* were identified as the underlying pathogenic cause [79]. *ACTN4* encodes for α-actinin-4, an actin-bundling protein of the cytoskeleton highly expressed in podocytes. Both a knock-down and an overexpression transgenic mouse model have been established for *Actn4*, demonstrating proteinuria and podocyte alterations. It was therefore discussed that α-actinin-4 plays an important role for the cytoskeletal function of the podocyte. Young knock-out mice present with focal areas of foot process effacement and older animals with diffuse effacement and globally disrupted podocyte morphology [80]. Moreover, *Actn4* was shown to be upregulated in the kidneys of different animal models of proteinuria. Human *ACTN4* mutations were identified in three different families with FSGS [79]. The clinical course in affected family members was characterized by progressively increasing proteinuria starting in adolescence and developing into FSGS and chronic renal insufficiency later in adult life. ESRD was observed in a number of affected individuals. All *ACTN4* mutations identified so far represent non-conservative amino acid substitutions affecting the actin-binding domain of α-actinin-4. In vitro studies demonstrated that mutant α-actinin-4 binds filamentous actin more strongly than wild-type protein. Based on this observation it was proposed that dominant mutations in *ACTN4* interfere with the maintenance of podocyte architecture: a proper organisation of the cytoskeleton seems to be important for normal functioning of podocyte foot processes. Interestingly, however, not all mutation carriers of the families reported by Kaplan et al. presented with a renal phenotype. The observed incomplete penetrance suggests that additional (genetic or non-genetic) factors are involved in the pathogenesis that in conjunction with a mutation in *ACTN4* lead to the manifestation of FSGS. *ACTN4* mutations may confer *disease susceptibility*, as also discussed for mutations in *CD2AP* and *TRPC6*. However, mutations in *ACTN4* represent a rare cause of hereditary FSGS, accounting for approximately 0–4% of familial FSGS, depending on the study cohort [45, 81, 82].

TRPC6 Gene Mutations Associated with Late-Onset FSGS (FSGS2)

In 1999, a second gene locus for autosomal dominant FSGS was mapped to chromosome 11q21-q22 using a 399-member Caucasian kindred of British heritage dating back seven generations

[83]. Fourteen deceased family members had suffered from ESRD, 14 living family members were on dialysis or had undergone renal transplantation, and 3 individuals were proteinuric. Six years later, the responsible gene *TRPC6* was identified [84, 85]. *TRPC6* encodes the transient receptor potential cation channel TRPC6 that is thought to mediate capacitative calcium entry into cells. Expression analysis revealed that TRPC6 is highly expressed in the kidney and also in podocytes at the site of the SD. A dominant missense mutation was identified in the original family of Winn et al., and five additional families with mutations in *TRPC6* were characterized by Reiser et al. Two of the missense mutations in the latter study were shown to increase the current amplitudes of TRPC6, consistent with a gain-of-function effect of the mutations. Interestingly, however, both studies describe carrier individuals with a normal renal phenotype, pointing to an incomplete penetrance of the mutations. *TRPC6* mutations have been identified in very few children; early disease onset seems to be exceptional. So far, it is unknown how the dysfunction of a cation channel is related to the development of podocyte damage and loss of the glomerular filtration barrier. One hypothesis is related to the observation that MEC-2, a *C. elegans* homologue of podocin, participates in the mechanosensation of the worm. MEC-2 is physically and functionally linked to ion channels, transducing the signals of mechanosensation. Since TRPC6 interacts with podocin and nephrin at the SD, it was proposed that podocin takes part in mechanosensation processes at the glomerular filtration barrier, transducing signals to TRPC6 which in turn modulates intracellular calcium concentrations in the podocyte. Nephrin, on the other hand, is thought to stimulate different pathways of the intracellular signaling machinery. Therefore, a complex protein network involving nephrin, podocin, CD2AP and the cation channel TRPC6 is established to maintain the SD structure of the foot process. Mutations in TRPC6 likely affect this functional network by altering the intracellular calcium concentration of the podocyte.

CD2AP Gene Mutations Associated with Adulthood FSGS (FSGS3)

In 1999, FSGS3 was shown to map to chromosome 6 and reported to be caused by haploinsufficiency for *CD2AP* [86]. *CD2AP* encodes for the CD2-associated protein CD2AP, an actin-binding protein that was originally identified as a cytoplasmic ligand of the CD2 receptor on T and natural killer cells. *CD2AP* knock-out mice presented not only with impaired immune functions but also with severe NS and FSGS, accompanied by mesangial hypercellularity and extracellular matrix deposition [87]. Electron microscopy showed the typical loss of podocyte foot process integrity with process effacement and loss of the SD structure. Screening in FSGS patients led to the identification of a dominant *CD2AP* mutation (a 2-bp substitution altering the exon 7 splice acceptor site) in two adult patients with late-onset FSGS [86]. Enhanced disease susceptibility for FSGS conferred by the change in CD2AP expression was postulated as the underlying pathogenic mechanism. CD2AP interacts with nephrin and both proteins localize to lipid rafts in the plasma membrane [33], suggesting that CD2AP is required to connect nephrin (and thus the SD) to the cytoskeleton of the podocyte. An impairment of CD2AP function might be associated with enhanced cytoskeletal fragility, predisposing to podocyte damage.

Susceptibility to Genetic Locus 22q12.3 (FSGS4), Including the Genes MYH9 and APOE1

Multiple single nucleotide polymorphisms (SNP) in the gene *MYH9* were recessively associated with idiopathic and HIV-associated FSGS and hypertensive end-stage renal disease (ESRD) in African American adult patients [88]. However, subsequent genomewide analyses in large patient cohorts suggested that a positively selected risk variant could be in a larger interval containing the *APOL* genes rather than be confined to *MYH9*. Two *APOL1* risks variants for FSGS were identi-

fied to be common in African but absent in European chromosomes. As APOL1 is a serum factor that lyses trypanosomes and in vitro assays revealed that only the kidney disease-associated APOL1 variants lysed Trypanosoma brucei rhodesiense it was speculated that evolution of a critical survival factor in Africa may have contributed to the high rates of renal disease in African Americans [89].

INF2 Gene Mutations Associated with Autosomal Dominant FSGS (FSGS5) and Charcot-Marie-Tooth Disease

Mutations in *INF2*, encoding inverted formin-2, were first identified in 11 FSGS families with onset of proteinuria in adolescence or adulthood [90]. Proteinuria was typically moderate, accompanied by microscopic hematuria and hypertension in some cases. Proteinuria was progressive, often leading to ESRD. Renal biopsies showed the presence of FSGS and unusually prominent actin bundles within the foot processes, on electron microscopy. Being part of the actin cytoskeleton Inf2/inverted formin-2 interacts with actin and is involved in both polymerization and depolymerization of actin filaments. Interestingly, mutations in *INF2* were also identified in patients with dominant intermediate Charcot-Marie-Tooth (CMT) disease and FSGS-associated proteinuria [91], localizing to a distinct area of the *INF2* gene. Mutant INF2 protein was abnormally distributed in the cytoplasm and the actin cytoskeleton and microtubule network were disorganized, not only in podocytes but also in peripheral Schwann cells, leading to disturbed myelin formation and CMT.

Mutations in MYO1E in Autosomal Recessive FSGS (FSGS6)

Recessive homozygous mutations in *MYOE1*, encoding a non-muscle membrane-associated class I myosin, were reported in children and adolescent patients of consanguineous union affected by nephrotic-range proteinuria, microhematuria, hypoalbuminemia, and edema [92]. Renal biopsy demonstrated FSGS, tubular atrophy and interstitial fibrosis. *Myoe1*-knockout mice show a similar phenotype with proteinuria, hematuria and progressive renal failure, indicating a defect in the glomerular filtration barrier. Impaired intracellular trafficking of the mutant protein seems to be implicated in the pathogenesis of *MYO1E*-associated disease.

Mitochondrial Disorders Associated with Nephrotic Syndrome

Several gene mutations in different components of the coenzyme Q_{10} (CoQ_{10}) biosynthesis pathway have recently been identified to be involved in hereditary nephrotic syndrome, frequently associated with extrarenal symptoms. Recessive mutations in *COQ2* were first identified in 2006 in a pair of siblings with early-onset glomerular lesions, steroid resistant nephrotic syndrome and CoQ_{10} deficiency [93]. The gene *COQ2* encodes for the para-hydroxybenzoate-polyprenyl transferase enzyme of the CoQ_{10} synthesis pathway. An increased number of abnormal mitochondria in podocytes and other glomerular cells was demonstrated by electron microscopy. Following this initial study, more patients were identified with a similar clinical course and loss-of-function mutations in *COQ2* [94, 95]. Extrarenal symptoms of mitochondrial disease are not obligatory but developed in a subset of affected patients to a varying degree, including encephalopathy, lactacidosis, myoclonic epilepsy and hypertrophic cardiomyopathy.

Early-onset SRNS associated with sensorineural deafness has subsequently been attributed to recessive mutations in *COQ6* encoding for CoQ_{10} biosynthesis monooxygenase 6 [96]. Renal histology revealed FSGS lesions in most cases with COQ6 mutation but DMS has also been observed.

Subsequently, mutations in *ADCK4 (=COQ8B)* were associated with disturbed CoQ_{10} biosynthesis and identified by homozygosity mapping and whole exome sequencing in children with SRNS

and school age onset of nephrotic syndrome [97]. *ADCK4/COQ8B* encodes the aarF domain containing kinase 4, a protein partially expressed in podocyte foot processes but also in podocyte mitochondria. ADCK4 colocalizes with COQ6 and COQ7. Serum CoQ_{10} levels are reduced in affected patients.

Of note, *COQ2*, *COQ6* and *COQ8B* are all nuclear genes encoding mitochondrial proteins. Therefore, the inheritance of associated disorders follows the Mendelian rules of autosomal recessive disease.

These findings indicate that the podocyte reacts very sensitively to disturbances of energy supply and it can be expected that mutations in other genes encoding mitochondrial proteins will be discovered in patients with SRNS in the future.

Most importantly and in contrast to all other hereditary disorders of the podocyte, these mitochondriopathies offer for a first time a potential causal treatment option by supplementation of $CoQ_{10.}$ In several patients affected by mutations in *COQ2*, *COQ6* and *COQ8B/ADCK4*, remarkable reductions of proteinuria were induced by oral medication with CoQ_{10}, opening a new therapeutic avenue for these patients with otherwise steroid resistant NS [96–98]. The recommended oral CoQ10 supplementation dose is 30 mg/kg/day.

Syndromal Disorders Associated with Nephrotic Syndrome

A large number of syndromes have been described on clinical grounds in patients presenting with (steroid-resistant) proteinuria in addition to various extrarenal manifestations. A genetic basis has been identified only in a minority of these syndromes. Here, we discuss two important syndromes that invariably present with SRNS, Schimke syndrome and Galloway-Mowat syndrome.

Schimke Syndrome

Schimke immuno-osseous dysplasia (SIOD) maps to chromosome 2q34–36 and is caused by recessive mutations in the *SMARCAL1* gene [99]. *SMARCAL1* encodes the SWI/SNF-related, matrix-associated, actin-dependent regulator of chromatin subfamily a-like protein 1, a protein involved in the remodeling of chromatin to change nucleosome compaction for gene regulation, replication, recombination, and DNA repair. The clinical phenotype of Schimke immuno-osseous dysplasia is characterized by growth retardation due to spondyloepiphyseal dysplasia, a slowly progressive immune defect, cerebral infarcts, skin pigmentation, and SRNS beginning in childhood. FSGS lesions are frequently observed in kidney biopsy specimen and the majority of patients progress early to ESRD. However, disease severity and age at onset follow a continuum from early onset and severe symptoms with death early in life to later onset and mild symptoms with survival into adulthood. A considerable fraction of patients with SRNS due to SIOD is oligosymptomatic, presenting only with proteinuria and short stature [100], underpinning the role of next generation sequencing (NGS) panel sequencing including *SMARCAL1* in non-syndromic unsolved SRNS cases. Proteinuria associated with very short stature may be a reliable clue to SIOD. Genotype-phenotype studies suggest that recessive loss-of-function mutations (frameshift, stop and splice-site mutations) are generally associated with a more severe course of the disease while some missense mutations allow a retention of partial *SMARCAL1* function and thus cause milder disease [99]. This genotype-phenotype correlation is typically observed for onset of extra-renal symptoms while the renal course (median age at ESKD 8 years) seems to be independent of the mutation type [100].

Galloway-Mowat Syndrome

The Galloway-Mowat syndrome (GAMOS) is characterized by microcephaly and other brain anomalies, severe mental retardation and early-onset NS (CNS) [101]. Both FSGS and DMS were observed in kidney biopsies of affected individuals [101, 102]. An important number of

patients also presents with hiatus hernia. Both males and females are affected and an occurrence in siblings of the same family has been reported. Different associated gene loci have been identified. In 2014, loss-of-function mutations in *WDR73* were described in two unrelated families [103]. In 2017, a large international consortium identified multiple mutations in KEOPS-complex genes in patients affected by autosomal recessive (*OSGEP*, *TP53RK*, *TPRKB*) or X-chromosomal linked (*LAGE3*) GAMOS [104].

Clinical Aspects

Clinical aspects of NS are discussed in all detail in former chapters. Here, we want to focus on some issues specific for genetic forms of SRNS.

Long-Term Outcome and Renal Prognosis

Large multicenter studies have provided significant data and insight into the long-term renal prognosis of hereditary forms of nephrotic syndrome. In an analysis of more than 1000 SRNS patients followed in the PodoNet Registry study the diagnosis of a genetic disease markedly impacted ESKD risk. ESKD-free survival rates were 27% and 17% in patients with a genetic diagnosis, contrasting with a favorable prognosis in children with sporadic non-genetic SRNS responsive to intensified immunosuppression, who exhibited a 15-year renal survival rate of 96% [105, 106]. Within the same study, the histopathologic diagnosis was also clearly predictive of ESKD. When adjusting for genetic status, age, proteinuria level, CKD and responsiveness to intensified immunosuppression, DMS or FSGS on biopsy implied an increased risk of progressing to ESKD [105].

Therapeutic Implications

The therapy of SRNS in general is demanding. Numerous immunosuppressive agents have shown some efficacy in a fraction of the SRNS population, including cyclosporine, mycophenolate mofetil or the anti-CD20-antibody rituximab mostly in combination with glucocorticoids. However, genetically determined forms of SRNS have mostly proven insensitive to immunosuppressive interventions, which is pathophysiologically explained by the presence of intrinsic defects in podocyte architecture and function [105, 107, 108]. A detailed review of the pertinent literature is available in the recent IPNA expert recommendations [109]. Generally, it is suggested to spare children with hereditary SRNS from immunosuppressive treatment.

Conversely, specific gene mutations have not been reported in patients with steroid sensitive NS [44], so genetic screening seems generally not indicated even in patients with reduced steroid sensitivity (such as frequent relapsers or steroid dependency). However, in former studies addressing a possible genetic basis of SSNS, associations to various gene loci and candidate genes (e.g. *CLVS1* encoding clavesin-1) have been identified [110–113].

Therefore, novel insights into the genetics and pathophysiology of SSNS can be expected.

Antiproteinuric and renoprotective pharmacological treatment with ACE inhibitors or AT1 receptor blockers (RAASi) is advised in all children with SRNS once the diagnosis is made in the maximally approved and tolerated dose in order to slow down the progression of renal insufficiency also in genetic SRNS. ACEi or ARBs should be used with caution in patients with CKD stage 4, and they should not be started or should be stopped in case of intravascular volume depletion, acute kidney injury (AKI), hyperkalemia, or frequent vomiting/diarrhea. In female adolescents, contraception should be ensured in order to avoid the teratogenic effects of RAASi [109].

Living Related Donor Transplantation

Living-related kidney transplantation is generally considered the therapy of first choice in pediatric patients with ESRD. However, in patients affected by SRNS due to germline mutations in

podocyte genes several aspects need to be considered. First, it is unknown as yet how kidneys of a heterozygous donor behave and develop in a recipient with recessive SRNS: The parents of affected children with recessive SRNS carry one mutant allele each that is also present in the transplanted kidney. It could be speculated that these kidneys are more easily prone to develop proteinuria if other pro-proteinuric factors (e.g., arterial hypertension, salt-rich diet) are superposed. While animal models of SRNS do not support this hypothesis so far, comprehensive human data addressing this question are mostly lacking. Consequences for the donor should also be considered. It is as yet unknown whether the prognosis of the remaining single kidney in the heterozygous parental donor is impaired by the gene mutation. Again, the remaining heterozygous kidney might be more susceptible to proteinuric disease than single kidneys of individuals without mutations. Up to now the experience with living-related donor transplantation in hereditary SRNS is very limited and does not support a restriction in affected children. Still, careful surveillance of both donor and recipient seems advisable.

In families of patients affected by autosomal dominant late-onset SRNS, only one of the parents is carrier of the pathogenic sequence variation. Genetic testing of family members will be helpful to delineate mutation carriers in the family. If the mutation occurred as a de novo mutation in the patient, both parents are equally suitable for living donor transplantation from a genetic point of view.

Recurrence of Nephrotic Syndrome After Renal Transplantation

Many investigators have studied the pathogenesis of increased glomerular permeability and recurrence of proteinuria after transplantation in FSGS. In general, recurrence of proteinuria after renal transplantation is observed in approximately 30% of FSGS patients [108, 114]. This risk appears higher in children than in adult patients [115]. Affected patients present with proteinuria, which is often in the nephrotic range. Frequently proteinuria recurs within few days after renal transplantation. In children, the mean time to recurrent proteinuria is 14 days post-transplant [116]. Recurrence of proteinuria/FSGS following renal transplantation negatively impacts graft survival in both children and adult patients. Risk factors are an age less than 15 years, rapid progression of renal insufficiency and diffuse mesangial proliferation in the initial biopsy of the native kidney [117]. In non-hereditary FSGS/SRNS, the recurrence of proteinuria is discussed to follow a T cell dysfunction and production of proteinuric circulating factors, including soluble urokinase receptor, hemopexin, and cardiotrophin-like cytokine-1 [118, 119].

In *NPHS2*-associated SRNS/FSGS recurrence of post-transplant proteinuria is a rare phenomenon, observed in less than 10% of transplanted patients [37, 44, 120]. The identification of a homozygous truncating *NPHS2* mutation in one patient with post-transplant NS prompted the search for anti-podocin antibodies but all results were negative excluding a de novo glomerulonephritis as underlying cause [37]. Anti-podocin antibodies were also not identifiable in a study including patients with *NPHS2* missense mutations and post-transplant NS [121].

In CNF, the risk of a recurrence of proteinuria after transplantation seems to be important: it was demonstrated that especially patients affected by the Fin major mutation have a risk of approximately 25% of post-transplant NS. Subsequent studies revealed that the pathogenesis of this recurrence is related to the development of anti-nephrin antibodies directed against the wildtype nephrin protein residing in the transplanted kidney [122], analogous to the anti-GBM antibodies against type IV collagen causing post-transplant de novo glomerulonephritis in patients with Alport syndrome. Treatment options of post-transplant NS in these patients are controversially discussed due to a relative paucity of data; a subset of patients seems to respond to rituximab or cyclophosphamide [108].

Genetic Testing

Following the rapid technological development in human genetics and genome research, different approaches can be applied in order to identify gene mutations in patients with SRNS and/or FSGS. In countries where next generation sequencing (NGS) techniques are not available there may still be a rationale for conventional Sanger sequencing in patients with specific phenotypes, e.g., sequencing of *WT1* in Denys-Drash or *LAMB2* in Pierson syndrome. Sanger sequencing can also be useful in patients with congenital NS (*NPHS1*) or school-aged patients with SRNS (*NPHS2*), where the likelihood of a positive result is relatively high. In adolescents and young adults, a different screening rationale should be applied. The *NPHS2*-p.R229Q sequence variation in compound heterozygosity with specific pathogenic *NPHS2* mutations is frequently found in late-onset SRNS [45, 50, 51]. In addition, autosomal dominant disease due to mutations in *WT1*, *TRPC6*, *INF2* and *ACTN4* can be identified in adolescents and young adults, particularly in case of dominant transmission but to a minor extent also in sporadic cases [45, 123, 124].

However, panels of podocytopathy- and even more broadly kidney-disease-associated genes have been developed by many commercial and non-commercial laboratories, which now allow standardized and simultaneous sequencing of more than 50 genes in one experimental run by next NGS techniques. In addition, whole exome and whole genome sequencing (WES/WGS) are available at low costs and has been developed for many clinical diagnostic applications. Advantages of the WES approach include the identification of gene mutations in novel genes, non-coding regions (WGS), microdeletions/microduplications, copy number variations and the unraveling of gene mutations in phenotypically complex cases. Still, the interpretation of huge data sets can be challenging and necessitates biostatistical expertise. Large databases have been established offering an annotation of sequence variations in different populations. Numerous ethical issues still need to be addressed, especially with respect to the possible incidental identification of mutations in SRNS-unrelated genes with high phenotypic penetrance associated with severe disorders, e.g. different types of cancer. In these cases, genetic counseling is demanding and of high importance.

Genetic Counseling

Positive results of mutational analysis in pediatric patients with SRNS should be followed by adequate genetic counseling. This demands close collaboration between pediatric nephrologists and human geneticists. Parents of children affected by recessive disease will have a chance of 25% to give birth to another affected child. In parents of children with dominant disease, this risk amounts to 50% (with the exception of patients with de novo mutations, in these families, the risk of recurrence is very low). Parents of affected children need to be informed that treatment options are limited in hereditary SRNS and that renal function may deteriorate rapidly. Close monitoring of renal function and early treatment of complications of chronic renal insufficiency are advised. In autosomal dominant FSGS, genetic counseling might be difficult due to the fact of incomplete penetrance and variable expressivity. It seems that individual mutation carriers can be affected to a differing degree with an obvious mild phenotype in some family members and ESRD in others. Genetic counseling is not only important for the parents but also for the affected child. Children with recessive disease will transmit a heterozygous mutation to their own children in the future. As long as the other parent is not mutation carrier, all offspring will be healthy. Patients affected by dominant FSGS will transmit the pathogenic mutation in 50% of cases and offspring carrying the mutation might be affected by FSGS.

In some cases, established genotype-phenotype correlations might be helpful to estimate the risk of a more severe clinical course. In *NPHS2*-associated SRNS, for example, some mutations have been associated with early-onset and aggravated clinical course while other muta-

tions were shown to be less pathogenic [40]. For other disease entities, the analysis of clinical symptoms of other affected family members can be of help to predict the severity of the disease: in NPS, the risk of having a child with NPS nephropathy is about 1:4 and the risk of having a child in whom renal failure will develop is about 1:10 if NPS nephropathy occurs in other family members [53]. Genetic counseling is especially important in families affected by NS with serious prognosis. In children affected by CNS with female outer appearance, mutation analysis in *WT1* is mandatory in order to rule out a risk for Wilms tumor development.

Due to the implementation of NGS techniques in the clinical routine setting, many patients are identified to carry a significant number of sequence variations of unknown relevance in different podocyte genes, not following simple Mendelian inheritance. Whether these gene variants act as modifiers, accumulate to confer a susceptibility for the development of NS or are just polymorphisms without biological function remains difficult to be designated in many cases. Genetic counseling will has to make allowance for this.

Acknowledgement I would like to thank Martin Zenker (Institute of Human Genetics, University of Erlangen-Nuremberg) for his reflections on Pierson syndrome.

Alport Syndrome and Other Type IV Collagen Disorders

16

Michelle N. Rheault and Rachel Lennon

Introduction

Several forms of familial glomerular hematuria syndromes result from genetic variants that affect type IV collagen, the major collagenous constituent of glomerular basement membranes (GBM): Alport syndrome (AS) and hereditary angiopathy with nephropathy, aneurysms and cramps (HANAC) syndrome. Persistent hematuria is a cardinal feature of each of these disorders. Variants in any of three type IV collagen genes, *COL4A3, COL4A4* or *COL4A5* can cause AS, which is characterized by progressive deterioration of kidney function with associated hearing and ocular involvement in many affected individuals. A majority of affected individuals demonstrate X-linked inheritance; however, autosomal recessive and autosomal dominant transmission is also observed. Heterozygous variants in these genes are also significant and link to a wider spectrum of kidney disease [1–3]. Variants in *COL4A3, COL4A4 or COL4A5* [4] account for about 30–50% of children with isolated glomerular hematuria seen in pediatric nephrology clinics [5–8]. HANAC syndrome arises from variants in *COL4A1* [9].

Alport Syndrome

Introduction

The first description of a family with inherited hematuria appeared in 1902 in a report by Guthrie [10]. Subsequent monographs about this family by Hurst in 1923 [11] and Alport in 1927 [12] established that affected individuals in this family, particularly males, developed deafness and uremia. The advent of electron microscopy led to the discovery of unique GBM abnormalities in patients with AS [13–15], setting the stage for the histochemical [16–18] and genetic [19, 20] studies that resulted in the identification of disease causing variants in *COL4A5* [20] followed by *COL4A3* and *COL4A4* [21, 22]. AS occurs in approximately 1:50,000 live births and accounts for 1.3% and 0.4% of pediatric and adult end-stage kidney disease (ESKD) patients in the United States, respectively [23].

Etiology and Pathogenesis

Type IV Collagen Proteins, Tissue Distribution and Genes

Six chains of type IV collagen, α1(IV)-α6(IV), are encoded by six genes, *COL4A1-COL4A6*. The type IV collagen genes are arranged in pairs on three chromosomes: *COL4A1-COL4A2* on chromosome 13, *COL4A3-COL4A4* on chromosome 2, and *COL4A5-COL4A6* on the X chromosome. The paired genes are arranged in a 5′-5′ head-to-head fashion, separated by sequences of varying length containing regulatory elements [24, 25]. All type IV collagen chains share several basic structural features: a major collagenous domain of approximately 1400 residues containing the repetitive triplet sequence glycine (Gly)-X-Y, in which X and Y represent a variety of other amino acids; a *C*-terminal noncollagenous (NC1) domain of approximately 230 residues; and a noncollagenous *N*-terminal sequence of 15–20 residues. The collagenous domains each contain approximately 20 interruptions of the collagenous triplet sequence, while each NC1 domain contains 12 conserved cysteine residues. Type IV collagen chains self-associate to form triple helical structures or "trimers". The specificity of chain association is determined by amino acid sequences within the NC1 domains and results in only three trimeric species that are found in nature: $\alpha1_2\alpha2$(IV), α3α4α5(IV) and $\alpha5_2\alpha6$(IV) [26]. Unlike interstitial collagens, which lose their NC1 domains and form fibrillar networks, type IV collagen trimers form open, nonfibrillar networks through NC1-NC1 and N-terminal interactions [27].

$\alpha1_2\alpha2$(IV) trimers are found in all basement membranes, whereas α3α4α5(IV) and $\alpha5_2\alpha6$(IV) trimers have a more restricted distribution. In normal human kidneys, α3α4α5(IV) trimers are found in GBM, Bowman's capsules, and the basement membranes of distal tubules, while $\alpha5_2\alpha6$(IV) trimers are detectable in Bowman's capsules, basement membranes of distal tubules and collecting ducts, but not GBM [28, 29]. $\alpha5_2\alpha6$(IV) trimers are also present in normal epidermal basement membranes as well as some alimentary canal, ocular, and vascular basement membranes. α3α4α5(IV) trimers also occur in several basement membranes of the eye and of the cochlea [30–32].

Pathogenic variants in any of the *COL4A3*, *COL4A4*, or *COL4A5* genes will affect the formation and composition of affected basement membranes. If any of the α3(IV), α4(IV), or α5(IV) chains are absent due to loss of function variants (deletions, frame shift variants, premature stop codons), then the other collagen chains are degraded and no α3α4α5(IV) trimers are deposited in basement membranes [33]. In this case, the embryonic $\alpha1_2\alpha2$(IV) network persists. Missense variants, particularly those that affect the glycine residues involved in triple helix formation, may lead to the formation of abnormally folded trimers that are either degraded or deposited into the basement membrane with formation of an abnormal type IV collagen network. Due to a greater number of disulfide bonds, the α3α4α5(IV) network is more highly cross-linked and is considered more resistant to proteases and therefore mechanical strain than the $\alpha1_2\alpha2$(IV) network [33, 34]. In support of this network being mechanically stronger, absence of the α3α4α5(IV) network leads to increased distensibility in the lens capsule when tested in experimental models of AS [35]. Indeed, the glomerular capillary walls of AS patients may also be mechanically weak and provoke pathologic stretch-related responses in glomerular cells [36].

Genetics

AS is described in three genetic forms: X-linked (XLAS), autosomal recessive (ARAS) and autosomal dominant (ADAS), although opinions vary as to how a single gene can cause both recessive and dominant disease (Table 16.1). XLAS, caused by variants in *COL4A5,* was classically thought to account for approximately 80% of AS patients while ARAS, caused by variants in both alleles of *COL4A3* or *COL4A4,* accounted for about 15% of the AS population. Affected males with XLAS are hemizygous and carry a single abnormal *COL4A5* allele, while affected females are heterozygous with normal and abnormal alleles. Individuals with ARAS may be either homozygous, with identical variants in both

Table 16.1 Familial glomerular hematuria due to type IV collagen variants

	Genetic locus	Protein product	Kidney manifestations	Kidney failure	GBM ultrastructure	Extrakidney manifestations
Alport syndrome						
X-linked	*COL4A5*	α5(IV)	Hematuria Proteinuria Hypertension	All males, some females	Thinning (early) Lamellation (late)	Deafness Lenticonus Perimacular flecks
Autosomal recessive	*COL4A3* *COL4A4* (biallelic or digenic)	α3(IV) α4(IV)	Hematuria Proteinuria Hypertension	All males and females	Thinning (early) Lamellation (late)	Deafness Lenticonus Perimacular flecks
Autosomal dominant	*COL4A3* *COL4A4* (heterozygous)	α3(IV) α4(IV)	Hematuria Proteinuria Hypertension	Males and females (late)	Thinning (early) Lamellation (late)	Deafness
HANAC syndrome

alleles of the affected gene or they may be compound heterozygotes, with different variants in the two alleles or even demonstrate digenic inheritance with one variant in *COL4A3* and the other in *COL4A4* [37, 38]. With the advent of next generation sequencing, studies are suggesting a higher percentage of patients with ADAS, up to 31% in one report [39]. ADAS is used by some clinicians to describe heterozygous variants in *COL4A3* or *COL4A4* with a progressive clinical course [40]. It is not clear why some individuals develop a progressive nephropathy while others have a slower or unremarkable clinical course; this may relate to the presence of co-segregating genetic modifiers [41].

Over 2500 pathogenic variants have been identified in the *COL4A5* gene in patients with XLAS [42]. Variants can be found along the entire 51 exons of the gene without identified hot spots. About 10–15% of *COL4A5* variants occur as spontaneous events; therefore, a family history of kidney disease is not required for a diagnosis of XLAS. A range of variants have been described: large rearrangements (~20%), small deletions and insertions (~20%), missense variants altering a glycine residue in the collagenous domain of α5(IV) (30%), other missense variants (~8%), nonsense variants (~5%) and splice-site variants (~15%) [43]. The type of *COL4A5* variant has a significant impact on the course of XLAS in affected males [43–45]. In males with a large deletion, nonsense variant or an indel causing a reading frame shift, the risk of developing kidney failure before age 30 is 90%. In contrast, progression to kidney failure before age 30 occurs in 70% and 50% of patients with splice-site and missense variants, respectively [43]. In addition, XLAS patients with 5′ glycine missense variants demonstrate a more severe phenotype than those with 3′ glycine variants [44]. In contrast to males with XLAS, a statistical relationship between *COL4A5* genotype and kidney phenotype has not been demonstrated in females with XLAS [46].

Clinical Manifestations

Males with XLAS and ARAS inevitably develop kidney failure at a rate that is influenced by genotype [37, 43, 45]. While most females with XLAS have non-progressive or slowly progressive kidney disease, a significant minority demonstrates progression to kidney failure [47]. The course of ARAS is similar in females and males [37]. In general, patients

with ADAS progress less rapidly than patients with XLAS or ARAS and are less likely to have extra-kidney manifestations [48].

Kidney Phenotype

Persistent microscopic hematuria (MH) occurs in all males with AS, regardless of genetic type, and is probably present from early infancy. Approximately 95% of heterozygous females with XLAS have persistent or intermittent MH [46], and 100% of females with ARAS have persistent MH. Gross hematuria is not unusual in boys and girls with Alport syndrome, occurring at least once in approximately 60% of affected males [43, 49].

In males with XLAS, and in males and females with ARAS, proteinuria typically becomes detectable in late childhood or early adolescence and progresses from microalbuminuria to overt proteinuria [50]. In one large cohort of females with XLAS, 75% had proteinuria, although the timing of onset was not investigated [46].

Blood pressure is typically normal in childhood but, like proteinuria, hypertension is common in adolescent males with XLAS or ARAS, and in females with ARAS. Most females with XLAS have normal blood pressure, but hypertension may develop, particularly in those with proteinuria.

All males with XLAS eventually require kidney replacement therapy, with 50% of untreated males reaching kidney failure by age 25, 80% by age 40 and 100% by age 60 [43]. The timing of kidney failure in patients with ARAS is similar to XLAS males, although ARAS patients with normal kidney function in their 30's and 40's have been reported [37]. In patients with ADAS, the age at which 50% of patients have progressed to kidney failure is approximately 50 years, or twice as long as XLAS males [48].

Females who are heterozygous for *COL4A5* variants demonstrate widely variable disease outcomes, with some women demonstrating only lifelong asymptomatic hematuria while others develop chronic progressive kidney disease including kidney failure [51]. About 12% of XLAS females reach kidney failure by age 45, 30% by age 60 and 40% by age 80 [46]. The explanation for the wide variability in outcomes for XLAS females is uncertain, but likely multifactorial. Risk factors for kidney failure in XLAS females include proteinuria and sensorineural deafness [46, 52]. X-inactivation, the process by which one X chromosome in females is silenced to adjust for gene dosage differences between males and females, may play a role in kidney disease progression in XLAS females [53, 54]. In a mouse model of female XLAS, modest skewing of X-inactivation to favor expression of the wild type α5(IV) was associated with a survival advantage [55].

AS nephropathy progresses predictably through a series of clinical phases. Phase I typically lasts from birth until late childhood or early adolescence, and is characterized by isolated hematuria, with normal protein excretion and kidney function. In Phase II, microalbuminuria followed by overt proteinuria is superimposed on hematuria, but the glomerular filtration rate (GFR) remains normal. Patients in Phase III exhibit declining GFR in addition to hematuria and proteinuria, and those in Phase IV have kidney failure. These phases have histological correlates, as described in the next section. The rate of passage through these phases is primarily a function of the causative genetic variant, at least in males with XLAS. Patients with *COL4A5* variants that prevent production of any functional protein (deletions, nonsense variants) proceed through these phases more rapidly than those whose variants allow synthesis of a functional, albeit abnormal, protein (some missense variants). Females with XLAS can be viewed as passing through the same phases as males, although the rate of progression is typically slower, and the journey to kidney failure may not be completed during the individual's lifetime.

Hearing

Newborn hearing screening is normal in males with XLAS, and in males and females with ARAS, but bilateral impairment of perception of high frequency sounds frequently becomes detectable in late childhood. The hearing deficit

is progressive, and extends into the range of conversational speech with advancing age. Affected individuals benefit from hearing aids since the deficit usually does not exceed 60–70 dB and speech discrimination is preserved. Sensorineural hearing loss (SNHL) is present in 50% of males with XLAS by approximately age 15, 75% by age 25, and 90% by age 40 [43]. Like the effect on kidney disease progression, missense variants in *COL4A5* are associated with an attenuated risk of hearing loss. The risk of SNHL before age 30 is 60% in patients with missense variants, while the risk of SNHL before age 30 is 90% in those with other types of variants [43]. SNHL is less frequent in females with XLAS. About 10% of XLAS females have SNHL by 40 years of age, and about 20% by age 60 [46]. SNHL is also common in ARAS, with approximately 66% of individuals affected [37].

The SNHL in AS has been localized to the cochlea [56]. In control cochleae, the α3(IV), α4(IV) and α5(IV) chains are expressed in the spiral limbus, the spiral ligament, stria vascularis and in the basement membrane situated between the Organ of Corti and the basilar membrane [57–59]. However, these chains have not been detected in the cochleae of ARAS mice [58], XLAS dogs [59] or men with XLAS [32]. Examination of well-preserved cochleae from men with XLAS revealed a unique zone of separation between the organ of Corti and the underlying basilar membrane, as well as cellular infiltration of the tunnel of Corti and the spaces of Nuel [60]. These changes may be associated with abnormal tuning of basilar membrane motion and hair cell stimulation, resulting in defective hearing. An alternative hypothesis is that hearing is impaired by changes in potassium concentration in the scala media induced by abnormalities of type IV collagen in the stria vascularis [61].

Ocular Anomalies

Abnormalities of the lens and the retina are common in individuals with AS, typically becoming apparent in the second to third decade of life in XLAS males and in males and females with ARAS. The α3(IV), α4(IV) and α5(IV) chains are normal components of the anterior lens capsule and other ocular basement membranes, and variants that interfere with the formation or deposition of α3α4α5(IV) trimers prevent expression of these chains in the eye [30, 57]. Anterior lenticonus, which is considered virtually pathognomonic for AS [62], is absent at birth and manifests during the second and third decades of life in ~13–25% of affected individuals [43, 63]. In this disorder, the anterior lens capsule is markedly attenuated, especially over the central region of the lens, and exhibits focal areas of dehiscence, leading to refractive errors and, in some cases, cataracts [64, 65]. Anterior lenticonus has been described only rarely in heterozygous females with *COL4A5* variants [47]. Dot-fleck retinopathy, a characteristic alteration of retinal pigmentation concentrated in the perimacular region [66], is also common in AS patients and does not appear to be associated with any abnormality in vision [43]. Recurrent corneal erosions [67, 68] and posterior polymorphous dystrophy, manifested by clear vesicles on the posterior surface of the cornea [69], have also been described in AS.

Leiomyomatosis

Several dozen families in which AS is transmitted in association with leiomyomas of the esophagus and tracheobronchial tree have been described [70]. Affected individuals carry X-chromosomal deletions that involve the *COL4A5* gene and terminate within the second intron of the adjacent *COL4A6* gene [71–73]. The genotype-phenotype relationship in this disorder is uncertain because deletions in this region may occur without associated leiomyomas, and conversely some families with XLAS and leiomyomas do not have deletions involving *COL4A6* [74]. Those affected tend to become symptomatic in late childhood, and may exhibit dysphagia, postprandial vomiting, epigastric or retrosternal pain, recurrent bronchitis, dyspnea, cough or stridor. Females with the AS-leiomyomatosis complex may develop genital leiomyomas, with clitoral hypertrophy and variable involvement of the labia majora and uterus.

Other Findings

AS associated with mental retardation, mid-face hypoplasia and elliptocytosis has been described in association with large *COL4A5* deletions that extend beyond the 5′ terminus of the gene [75]. Early development of aortic root dilatation and aneurysms of the thoracic and abdominal aorta, as well as other arterial vessels, have been described in AS males, perhaps due to abnormalities in the $\alpha5_2\alpha6$(IV) network in arterial smooth muscle basement membranes [76].

Kidney Pathology

Children with AS typically show limited kidney parenchymal changes by light microscopy before 5 years of age. Older patients may have mesangial hypercellularity and matrix expansion. As the disease progresses, focal segmental glomerulosclerosis, tubular atrophy and interstitial fibrosis become the predominant light microscopic abnormalities. Although some patients exhibit increased numbers of immature glomeruli or interstitial foam cells, these changes are not specific for AS.

Electron microscopy is frequently diagnostic, although the expression of the pathognomonic lesion is age-dependent and, for those with XLAS, gender-dependent. In early childhood, the predominant ultrastructural lesion in males is diffuse attenuation of the GBM. The classic ultrastructural appearance is diffuse thickening of the glomerular capillary wall, accompanied by "basket-weave" transformation; intramembranous cellular components, which have been described as podocyte protrusions; scalloping of the epithelial surface of the GBM; and effacement of podocyte foot-processes (Fig. 16.1) [77]. These changes are more prevalent in affected males, typically becoming prominent in late childhood and adolescence. Affected females can display a spectrum of lesions, demonstrating predominantly normal-appearing GBM, focal GBM attenuation, diffuse GBM attenuation, focal thickening/basket-weaving, or diffuse basket-

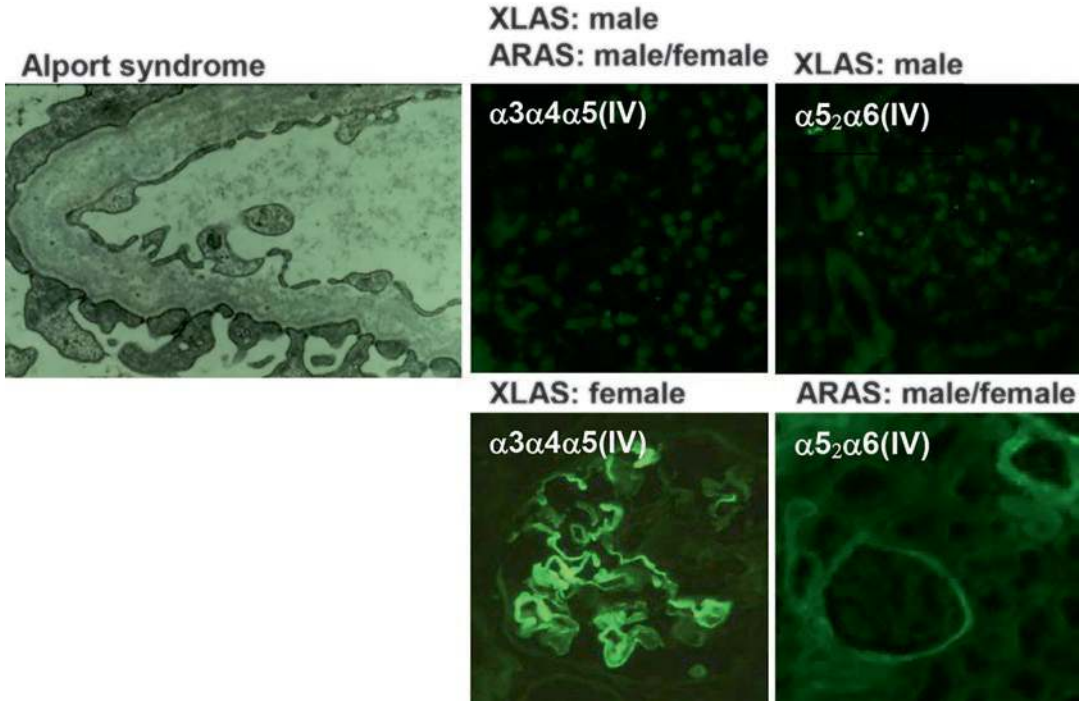

Fig. 16.1 Typical findings on electron microscopy and type IV collagen immunostaining for α5(IV) in Alport syndrome. Abbreviations: *XLAS* X-linked Alport syndrome; *ARAS* autosomal recessive Alport syndrome

weaving. The extent of the GBM lesion progresses inexorably in males, although the rate of progression may be influenced by *COL4A5* genotype. Females may have static or progressive GBM lesions. X-chromosome inactivation pattern, age and *COL4A5* genotype could all contribute to the GBM changes in affected females.

The classic GBM lesion is not found in all kindreds with AS. Adult patients who demonstrate only GBM thinning, yet have *COL4A5* variants, have been described. Although these represent a minority of Alport patients and families, they are also seen in individuals with heterozygous variants and in such patients there is an association with focal segmental glomerulosclerosis (FSGS) [1, 2]. Indeed, patients with a diagnosis of FSGS should have careful evaluation of GBM ultrastructure and, if defects are identified, genetic testing for Alport gene variants is warranted since a diagnosis of AS will enable further phenotypic evaluation in the individual as well as testing in other family members.

Routine immunofluorescence microscopy in patients with AS is normal or shows nonspecific deposition of immunoproteins. In contrast, specific immunostaining for type IV collagen α chains is frequently diagnostic, and can distinguish between XLAS and ARAS (Fig. 16.1). The utility of this approach derives from the fact that most disease-causing variants in AS alter the expression of the α3α4α5(IV) and $\alpha5_2\alpha6$(IV) trimers in kidney basement membranes. Most *COL4A5* variants prevent expression of both trimer forms in the kidney, so that in about 80% of XLAS males immunostaining of kidney biopsy specimens for α3(IV), α4(IV) and α5(IV) chains is completely negative [78]. About 60–70% of XLAS females exhibit mosaic expression of these chains, while in the remainder immunostaining for these chains is normal. The biallelic variants in *COL4A3* and *COL4A4* that cause ARAS often prevent expression of α3α4α5(IV) trimers, but have no effect on expression of $\alpha5_2\alpha6$(IV) trimers. In kidney biopsy specimens from patients with ARAS, immunostaining for α3(IV) and α4(IV) chains is negative in the GBM. However, while immunostaining of GBM for the α5(IV) chain is negative due to the absence of α3α4α5(IV) trimers, Bowman's capsules, distal tubular basement membranes and collecting duct basement membranes are positive for α5(IV) due to the unimpaired expression of $\alpha5_2\alpha6$(IV) trimers. Heterozygous carriers of a single *COL4A3* or *COL4A4* mutation have normal kidney basement membrane immunostaining for α3(IV), α4(IV) and α5(IV) chains.

The $\alpha5_2\alpha6$(IV) trimer is a normal component of the skin epidermal basement membrane (EBM). Consequently, about 80% of males with XLAS can be diagnosed by skin biopsy based on absence of α5(IV) expression in EBM. In 60–70% of XLAS females, there is a mosaic pattern of EBM immunostaining for α5(IV). EBM expression of α5(IV) is normal in patients with ARAS and in subjects with heterozygous variants in *COL4A3* or *COL4A4*.

Diagnosis and Differential Diagnosis

AS is one potential cause of familial and sporadic glomerular hematuria. Accurate diagnosis rests on careful clinical evaluation, a precise family history, selective application of invasive diagnostic techniques and, in appropriate patients, molecular diagnosis (Fig. 16.2).

The presence of isolated microscopic hematuria in a child with a positive family history for hematuria, an autosomal dominant pattern of inheritance, and a negative family history for kidney failure strongly suggests a diagnosis of heterozygous *COL4A3/4* variants (Fig. 16.2). Less common conditions associated with familial glomerular hematuria include the autosomal dominant *MYH9* disorders (Epstein and Fechtner syndromes), in which macrothrombocytopenia is a constant feature and familial IgA nephropathy. However, there may also be overlap with heterozygous Alport syndrome and a range of glomerular pathologies; large genetic sequencing studies will help to identify these disease group intersections.

When family history for hematuria is negative, the differential diagnosis of isolated glomerular hematuria, or hematuria associated with proteinuria includes AS, IgA nephropathy, C3

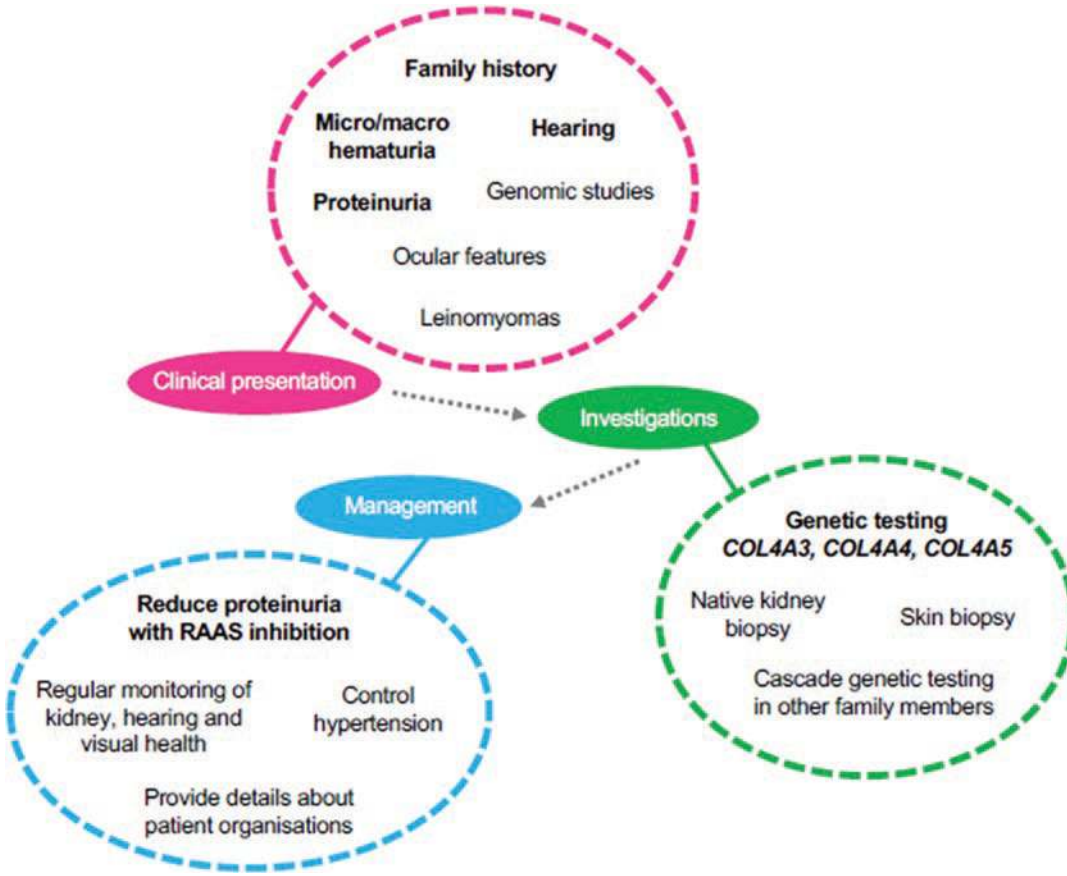

Fig. 16.2 Clinical presentation, diagnosis and management of Alport syndrome. Patients can present with a variety of clinical presentations, which should prompt investigation to confirm a diagnosis of Alport syndrome. Genetic testing for the Alport genes *COL4A3, COL4A4* and *COL4A5* is widely available and is the gold standard for diagnosis. Management includes the use of renin-angiotensin-aldosterone (RAAS) pathway inhibitors

glomerulopathy, membranous nephropathy, lupus nephritis, postinfectious glomerulonephritis, Henoch-Schönlein nephritis, and many other entities. Some of these conditions will be strongly suspected based on clinical findings (e.g., rash and joint complaints) while others will be suggested by laboratory findings, such as hypocomplementemia.

Formal audiometric and ophthalmological examinations should be considered as part of the diagnostic evaluation in children with persistent microscopic hematuria. Audiometry may be very helpful in children over age 6–8 years, especially boys, since high-frequency SNHL would point toward a diagnosis of AS. The presence of anterior lenticonus or the dot-fleck retinopathy may be diagnostic. However, these lesions are more prevalent in patients with advanced disease, and less likely to be present in the young patients in whom diagnostic ambiguity tends to be the greatest.

Genetic testing is the gold standard for diagnosing AS. Additional tissue studies are appropriate when clinical and pedigree information and genetic testing does not allow a diagnosis AS. Therefore, several options are available for confirming a diagnosis of AS, including genetic analysis, skin biopsy and kidney biopsy. Genetic analysis using Sanger sequencing is capable of identifying *COL4A5* variants in 80–90% of males with XLAS [79]. High variant detection rates in *COL4A3* and *COL4A4* in patients with ARAS are

also possible, particularly if there is parental consanguinity. Commercial genetic testing for variants in *COL4A3, COL4A4*, and *COL4A5* is available. Next generation sequencing, which allows simultaneous analysis of *COL4A3, COL4A4* and *COL4A5*, now replaces Sanger sequencing as the preferred approach. If further investigation is required, skin biopsy is often utilized as the initial invasive diagnostic procedure in patients suspected of AS it is less invasive and expensive than a kidney biopsy. On skin biopsy, the majority of subjects with XLAS will display abnormal expression of the α5(IV) chain in EBM as described above. Normal EBM α5(IV) expression in a patient with hematuria has several possible explanations: (1) the patient has XLAS, but his or her *COL4A5* mutation allows EBM expression of α5(IV); (2) the patient has ARAS, or ADAS, in which α5(IV) expression is expected to be preserved; or (3) the patient has a disease other than AS. Kidney biopsy would then provide the opportunity to diagnose other diseases, to examine type IV collagen α chain expression in kidney basement membranes, and to evaluate GBM at the ultrastructural level.

Treatment

The goal of treatment in AS is to slow the progression of kidney disease and delay the need for dialysis or transplantation. Several therapeutic approaches have demonstrated efficacy in murine ARAS, including angiotensin blockade [80–82], inhibition of TGFβ-1 [83], chemokine receptor 1 blockade [84], administration of bone morphogenic protein-7 [85], suppression of matrix metalloproteinases [34] and bone marrow transplantation [86]. Cyclosporine therapy slowed progression of kidney disease in a canine model of AS, but human studies have demonstrated significant nephrotoxicity and adverse effects and this treatment is not recommended [87–89]. Angiotensin converting enzyme (ACE) inhibition also prolonged survival in a canine XLAS model [90]. Uncontrolled studies in human AS subjects have shown that ACE inhibition can reduce proteinuria, at least transiently [91, 92]. A multicenter, randomized, double-blind study comparing losartan with placebo or amlodipine in 30 children with AS demonstrated a significant reduction in proteinuria in the losartan treated group [93]. An extension of this study showed comparable efficacy of either enalapril or losartan in reducing proteinuria in children with AS [94]. A report from the European Alport Registry, which includes 283 patients over 20 years, compared kidney outcomes in AS patients treated with ACE inhibition at various time points: at onset of microalbuminuria, at onset of proteinuria, or in chronic kidney disease (CKD) stage III-IV [95]. This retrospective review demonstrated a delay in kidney replacement therapy by 3 years in the treated CKD group and by 18 years in the treated proteinuric group [95]. These findings were confirmed in a retrospective review of kidney outcomes in men with XLAS from Japan [45]. In this study, men who received ACE inhibitors reached renal failure an average of 22 years later than those who did not receive ACE inhibitors. This beneficial effect of ACE inhibitors was also apparent in the subgroup of men with severe truncating type variants [45]. A randomized, placebo controlled trial of ramipril vs placebo in children with early Alport syndrome (microscopic hematuria alone or microalbuminuria stage) was recently reported [96]. Although not significant due to low enrollment, patients randomized to ramipril had decreased risk of progression of proteinuria and slower decline of GFR compared to patients randomized to placebo [96]. An open-label arm of this study demonstrated no safety concerns in over 200 patient years of treatment with ramipril [96].

Current clinical practice guidelines recommend treatment with an ACE inhibitor for affected males with XLAS and males and females with ARAS at the time of diagnosis if older than 12–24 months. (Table 16.2). Treatment should be started for females with XLAS and males and females with heterozygous variants in COL4A3 or COL4A4 when microalbuminuria is present [97]. Similar to other children with CKD, blood pressures

Table 16.2 Recommendations for timing of treatment with ACE inhibitors in patients with Alport syndrome

Genetic results	Indication for treatment
ARAS or male with XLAS	At time of diagnosis if age >12–24 months
XLAS female	Microalbuminuria
ADAS (heterozygous variant in *COL4A3* or *COL4A4*)	Microalbuminuria

ARAS autosomal recessive Alport syndrome; *XLAS* X-linked Alport syndrome; *ADAS* autosomal dominant Alport syndrome

should be controlled to the 50% for age, gender, and height in children with AS in order to slow the progression of kidney disease [98].

A number of additional agents are currently in clinical development for treatment of Alport syndrome kidney disease. MicroRNAs are small, highly conserved RNAs that regulate gene expression post-transcription. One of these microRNAs, microRNA-21, is upregulated in kidneys of mice with Alport syndrome and contributes to fibrosis [99]. Treatment of Alport mice with an anti-microRNA 21 agent reduces proteinuria and kidney fibrosis and prolongs lifespan [99]. This agent is undergoing testing in a randomized phase II clinical trial in adult patients with Alport syndrome (NCT02855268). Bardoxolone is a second agent currently being tested in a randomized phase II/III clinical trial in patients with Alport syndrome (NCT03019185). Bardoxolone activates Nrf-2 and inhibits NF κB to upregulate the antioxidant response and decrease proinflammatory signaling [100]. In a clinical trial in patients with kidney disease due to type 2 diabetes, bardoxolone increased eGFR; however, the trial was halted due to increased risk of hospitalization and death from heart failure in the bardoxolone treated patients [101]. Bardoxolone treated patients also demonstrated increased proteinuria [101]. It remains controversial whether patients with Alport syndrome will have sustained benefit from treatment with bardoxolone, and long-tern studies will be required to demonstrate value in slowing progression of CKD [102].

Kidney Transplantation

In general, outcomes following kidney transplantation in patients with AS are excellent [103]. Clinicians involved in transplantation of AS patients must address two important aspects of the disease. First, the donor selection process must avoid nephrectomy in relatives at risk for ESKD. Second, post-transplant management should provide surveillance for post-transplant anti-GBM nephritis, a complication unique to AS.

Informed donor evaluation requires familiarity with the genetics of AS and the signs and symptoms of the disease. In families with XLAS, 100% of affected males and ~95% of affected females exhibit hematuria. Consequently, males who do not have hematuria are not affected, and a female without hematuria has only about a 5% risk of being affected. Given an estimated 30% risk of ESKD in women with AS [46], these women should generally be discouraged from kidney donation, even if hematuria is their only symptom. A report from Germany described five women with XLAS and one ARAS carrier who served as kidney donors [104]. One donor had proteinuria prior to transplant and all had microscopic hematuria. Three donors developed new onset hypertension and two developed new proteinuria while kidney function declined by 25–60% over 2–14 years after donation in four of the donors, highlighting the increased donor risk in this population [104].

Overt anti-GBM disease occurs in 3–5% of transplanted AS males [105]. Onset is typically within the first post-transplant year, and the disease usually results in irreversible graft failure within weeks to months of diagnosis. The risk of recurrence in subsequent allografts is high. In males with XLAS, the primary target of anti-GBM antibodies is the α5(IV) chain [106, 107]. Both males and females with ARAS can develop post-transplant anti-GBM nephritis, and in these cases the primary antibody target is the α3(IV) chain [106, 108]. The α3(IV) chain is also the target of Goodpasture autoantibodies, but the epit-

ope identified by these antibodies differs from the α3(IV) epitope recognized by ARAS anti-GBM alloantibodies [109].

Hereditary Angiopathy with Nephropathy, Aneurysms and Cramps (HANAC Syndrome)

This autosomal dominant disorder results from variants in the *COL4A1* gene (Table 16.1) [9, 110, 111]. Complete absence of *COL4A1* is embryonic lethal in mice [112]. Missense variants that allow for expression of an abnormal α1(IV) chain lead to the development of HANAC syndrome. Kidney findings include gross and microscopic hematuria, cysts and CKD. Vascular anomalies include cerebral artery aneurysms and retinal arteriolar tortuosity. Affected individuals may have recurrent muscle cramps and elevated creatine kinase levels.

Pathology

No abnormalities of GBM ultrastructure or basement membrane expression of type IV collagen chains have been observed in kidney biopsy specimens from affected individuals with hematuria. Irregular thickening, lamellation and focal interruptions of Bowman's capsules, tubular basement membranes and interstitial capillary basement membranes have been described, as well as abnormalities of epidermal basement membranes and dermal arterial basement membranes.

Genetics

The reported variants in HANAC syndrome families affect highly conserved glycine residues in the collagenous domain of the α1(IV) chain, potentially affecting integrin binding sites. It is likely that a wider spectrum of disease will emerge in association with both *COL4A1* and *COL4A2* variants as well as variants in other basement membrane genes as larger cohorts of patients with kidney disease phenotypes undergo whole exome and whole genome sequencing [113].

IgA Nephropathy

17

Rosanna Coppo and Licia Peruzzi

Introduction

Primary IgA nephropathy (IgAN) is defined by the prevalence of immunoglobulin A over the others immunoglobulins in glomerular deposits as described by Berger et al. in 1968 [1]. IgAN is the commonest glomerular disease in children and adolescents who undergo renal biopsy because of isolated microscopic hematuria or hematuria with non-nephrotic proteinuria. After its initial identification, IgAN was considered a benign renal disease in adults and even more so in children. With longer follow-up in both age groups, a significant percentage of cases had a worsening of renal function, including the need for renal replacement therapy (RRT). The interest in IgAN in children increased with the recognition that most subjects with IgAN entering a chronic dialysis program were young adults [2], who displayed a slow renal function decline over decades (about 25% of the cases need dialysis in 20 years) [3]. It was therefore clear that the primary pathogenic events occurred in many cases in children. Hence, detecting IgAN at the beginning of its natural history in childhood may offer an important opportunity for early treatment, limiting factors favoring progression and controlling the complications, maximizing the benefits during childhood, and perhaps more importantly, for adulthood.

Epidemiology

The prevalence of IgAN in children varies in different reports, mostly due to the criteria for performing renal biopsy, ranging from routine practice after detection of urine anomalies by school screening programs to limiting renal biopsy to patients that have developed proteinuria. It is likely that cases of IgAN originating in the pediatric age group are missed because most patients are asymptomatic and do not undergo regular urine screening. IgAN is more frequently reported in Japan and Korea, where screening is routine, and IgAN is reported in 32 and 40% of renal biopsies in children [4, 5]. In contrast, the percentage of renal biopsies with IgAN in children are 20–26% in Europe [6], 17–20% in China, 14% in India, 10% in North America, 14% in South America, and 2.8% in Africa [7].

Data on incidence in children vary from 5 to 140 per million children/year [6, 8], similar to adult figures. The most recent biopsy series from global registries conclude that incidence varia-

tion is mainly due to biopsy policy and attitudes, and not secondary to true ethnic differences [9–11], although genetic studies seem to suggest a Northbound and Eastbound gradient of IgAN susceptibility [12]. Moreover, there is evidence in specific areas of China that incidence may vary based on humidity, air contaminants and other pollutants, such as polycyclic aromatic hydrocarbons [13].

Genetic Background

Familial aggregation of IgAN cases and accumulation of IgAN in certain populations suggest a complex heritable component. Familial clustering is consistent with autosomal dominant inheritance with variable penetrance of a polygenic trait, often manifesting as other autoimmune diseases. Familial cases often have a worse outcome.

Approximately 70% of IgAN subjects and 35% of their healthy relatives in different ethnic cohorts have Gd-IgA levels higher than geographically matched controls, suggesting that Gd-IgA by itself is not sufficient to induce the disease [14]. Gd-IgA has a greater specificity, sensitivity and heritability than total serum IgA [15].

Family linkage studies identified 6q22-23 as a candidate locus [16] and additional loci at 4q26-31, 17q12-22 and 2q36, but no causal underlying mutation was observed.

Next generation sequencing in the last years provided the technical tools to rapidly detect genetic variants at genome scale (whole genome sequencing) or on coding regions (whole exome sequencing), making possible large genome-wide association studies (GWAS) on multiethnic cohorts.

This powerful unbiased approach, [17, 18] supported by strict statistical methods and precise population stratification, was employed to explore disease association of common variants single nucleotide polymorphism (SNP) along the entire genome of large populations. Five large GWAS (reviewed in [17]) were carried out in populations of European and East Asian origin, evidencing strong signals in chromosome region 6p21, encoding for HLA genes involved in antigen presentation and immune response. HLA-DQA1 and DQB1 genes, which give origin to at least four HLA alleles, were associated with IgAN: DQA1*0101 and DQB1*0301 as risk alleles and DQA1*0102 and DQB1*0201 as protective [18].

A role of the non-HLA loci 1q32, encoding complement factor H (CFH), a critical inhibitor of the alternative pathway of complement, and five CFH-related (CFHR) genes [19] was identified.

The deletion in *CFHR3* and *CFHR1* genes, encoding for activators of the alternative complement pathway with a competitive effect on CFH, is associated with higher levels of CFH, lower complement activation and lower C3 deposition, with a protective effect on C3 activation in IgAN [20–22].

Other non-HLA regions associated with IgAN are 22q12, coding for several cytokines, 17p13, for TNFSF13, 8p23, for an alpha-defensin gene, 16p11, for alpha-integrins ITGAM and ITGAX, 1p13, for VAV37 and 9q34, for CARD9 [17]. In the Chinese population, other loci were found in 3q27.3, coding for ST6GAL1, in 11p11.2, for ACCS and 8q22.3, for ODF1-KLF10 [23].

Candidate genes are involved in antigen processing and presentation, innate immunity, NFkB signaling, gut mucosal immunity, IgA molecule biology and dysregulation of alternative complement pathway. Altogether these loci explain 6–8% of the risk, overlapping with other immune mediated diseases [18]. Genetic risk correlates with age at diagnosis and is associated with pathogen diversity, in particular helminths [24].

Moreover IgAN risk score varies in parallel to the geographic distribution of the disease, with a northbound and eastbound gradient, progressively increasing at growing distance from Africa and moving east [12].

Using whole exome sequencing, Zhou [25] in the Han Chinese population identified three candidate susceptibility genes in the non-HLA region (FBXL21, CCR6, and STAT3) and one in the HLA region (GABBR1), involved in modulation of IgA synthesis, response to mucosal infections and gut inflammatory response.

Pathogenesis

The development of IgAN represents the final event of a complex pathogenetic cascade, called the "four hit model", putting together the principles of an immune disease, with a genetic background and an environmental exposure. This causes inappropriate production of aberrantly glycosylated IgA1 (first hit), followed by a specific IgG response (second hit) and IgA immune-complexes circulation and glomerular deposition (third hit). The glomerular inflammatory response is elicited, with recruitment of multiple mechanisms leading to glomerular damage (fourth hit) (Fig. 17.1).

IgA is the most abundant immunoglobulin synthesized by the mucosal associated lymphoid tissue (MALT) and plays a major role for mucosal antigen defense and host commensal homeostasis.

IgA is synthetized in two subclasses, IgA1 and IgA2, which differ by an insertion of 18 amino acids in the hinge region between CH1 and CH2, which is only present in IgA1 [26] (Fig. 17.2a, b). The amino acid sequence includes three threonine and three serine residues bound to five short O-linked oligosaccharide chains. The O-glycosylation consists of a core N-acetyl galactosamine (GalNAc) which occurs alone or extended with β1,3 linked Gal or further with sialic acid in α2,3 or α2,6 linkage [27, 28]. In healthy subjects, serum IgA1 consists of a mixture of molecules with different O-glycoforms, whereas in patients with IgAN there are abnormal IgA1 O-glycoforms deficient in galactose (Gd-IgA1) with a high frequency of O-glycans

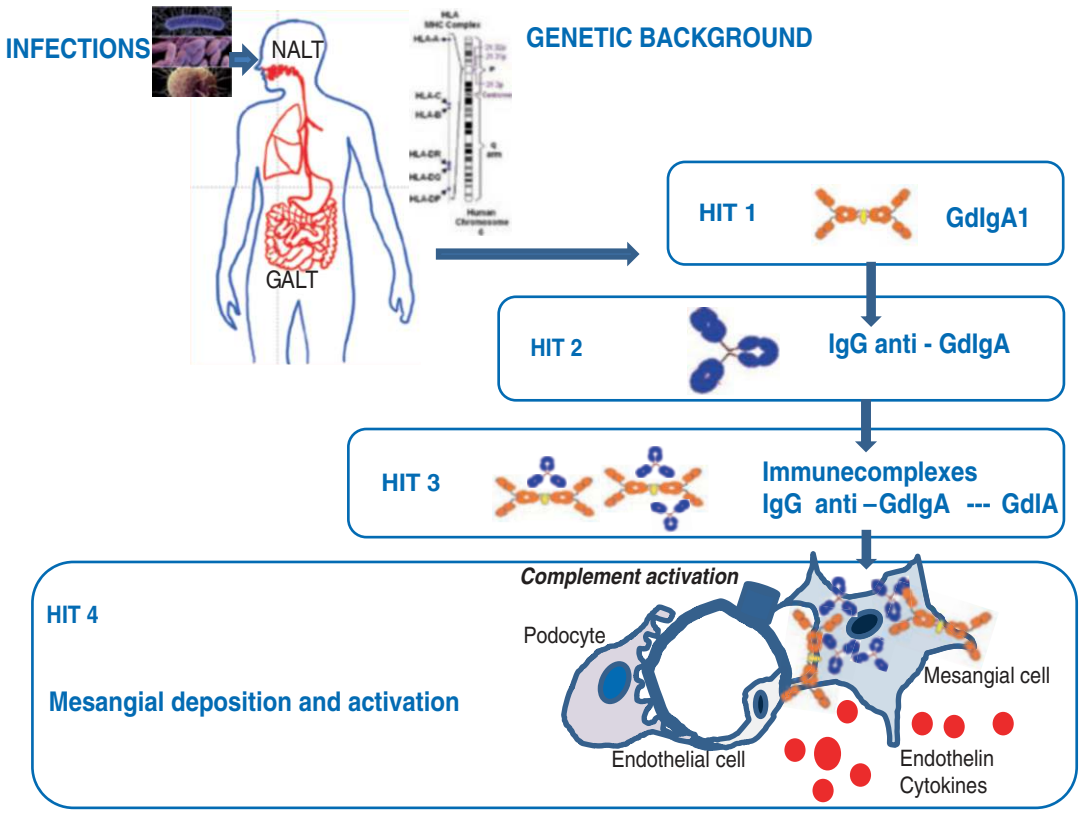

Fig. 17.1 The multihit pathogenic model

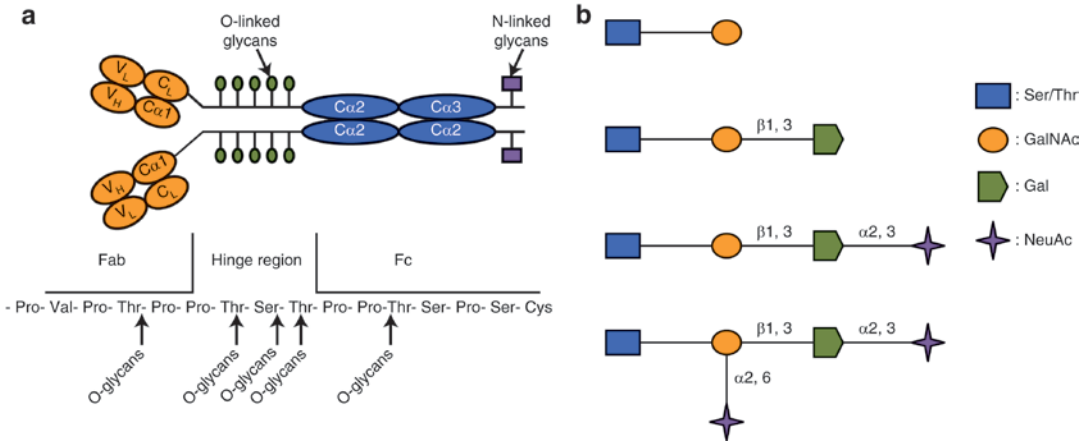

Fig. 17.2 The IgA molecule structure: (**a**) magnification of the hinge region. (**b**) Different O-glycoforms of circulating IgA1 molecules in IgAN

consisting of GalNAc alone [29–31]. Gd-IgA1 is detected in sera of up to 80% of patients with IgAN, [26, 29–33] and is prevalent in mesangial deposits of these patients [26].

The altered glycosylation of the IgA molecule confers different functional and effector mechanisms such as activation of the alternate complement pathway, Fc receptor binding, polymerization capacity and mesangial deposition due to increased affinity for matrix components. Gd-IgA1 has a hereditary component in either sporadic or familial IgAN in adults and children, [14, 15] indicated by increased plasma levels detected in healthy relatives of patients [14, 34].

Since altered glycosylation is not due to a different amino acid sequence of the hinge region [35], research efforts focused on genetically determined modifications of the B lymphocytes enzyme β 1,3-galactosyltransferase (encoded by *C1GALT1*), responsible for the terminal galactosylation of GalNAc on O-linked glycans [36] or the galactosyl transferase enzyme chaperon Cosmc (encoded by *C1GALT1C1*), but the results were not consistent with a clear genetic modification of these enzymes [34, 37].

Post-transcriptional regulation may be due to the modulatory effect of micro-RNAs, small molecules that can decrease the transcription of RNAs. Increased levels of miRNA-148b favoring the expression of the enzyme C1GALT have been detected in patients with IgAN [38].

Gd-IgA1 can circulate as monomers or participate in macromolecular self-aggregates and can elicit an IgG autoimmune response, which represents the second pathogenetic hit [29, 39]. Serum Gd-IgA1 and IgG autoantibodies have been found to correlate with disease severity and progression [40–44]. It is of interest that these IgG not only react with Gd-IgA1, but may cross-react with bacterial or viral cell-surface GalNAc-containing glycoproteins, suggesting a possible mechanism of mimicry [45]. The co-deposition of IgG in glomeruli has been demonstrated by confocal microscopy even in cases negative for routine immunofluorescence and correlates with endocapillary proliferation [46, 47].

The circulating immune-complexes (IgAIC) formed by polymeric Gd-IgA and IgG (the third hit) escape clearance by hepatic receptors and have a preferential renal deposition due to reactivity with mesangial matrix components fibronectin, laminin and collagen. The deposit on mesangial cells induces a proliferative response, matrix expansion and local inflammation [48]. IgAIC correlate with disease activity in adults and children with IgAN [40].

Macromolecular IgA also originate from interactions between human IgA1 and CD89, the soluble form of the IgA receptor [49]. The IgA1–CD89

complex binds to the transferrin 1 receptors (CD71) and transglutaminase 2 receptors (TGase2) expressed on the mesangial cell surface and increase immune deposits and inflammation [50].

The fourth pathogenic hit occurs after the renal deposition of IgAIC, Complement activation pathways are triggered and the local inflammatory process is further amplified, with release of cytokines, chemokines and inflammatory mediators acting not only on mesangial cells but also on endothelium and podocytes [51]. Mesangial cells and mesangial matrix proliferation induce a derangement of the glomerular spatial relationships, which influences podocyte behavior. Mesangial-podocyte crosstalk has been proposed as a trigger of a podocytopathy and tubulointerstitial damage, with consequent occurrence of proteinuria and disease progression [52]. In this process, activation of the RAS system also plays a crucial role [53].

The Mucosal Immunity in IgAN

The relationship between IgAN and the mucosal associated lymphoid tissue (MALT) has been considered shortly after the identification of this glomerular disease because IgA is the main product of the MALT and visible hematuria in IgAN frequently occurs during mucosal infections. About half the lymphocytes of the immune system are located in the MALT, which is at the interface with the environment [54], and thus has a major role in the defense against environmental microbes and induction of immunotolerance [55]. The principal locations of the MALT are the gut-associated lymphoid tissue (GALT) and the nasopharynx-associated lymphoid tissue (NALT), which are thought to be involved in the pathogenesis of IgAN. The GALT has up to 70% of the body's immunocytes and consists of lymphoid follicles, aggregated at the Peyer's patches, in the distal jejunum and the ileum [56]. The NALT is located in the pharynx, principally in Waldeyer's tonsillar ring, of which tonsils are the major component [57].

Peyer's patches and tonsils are the most common inductive sites where antigens prime naïve B-cells through T-cell–dependent and T-cell–independent mechanisms [58]. T cell–independent production of IgA is primarily stimulated by interleukins (IL-6 and IL-10), transforming growth factor (TGF-β), B cell activating factor (BAFF, or BLyS), and a proliferative inducing ligand (APRIL). BAFF and APRIL promote the differentiation of B cells, with class switching from IgM to IgA1 after binding to the TNF receptor homolog transmembrane activator (TACI) [59]. Activated B-cells reach the mucosal inductive sites, where they become effector cells, maturing into IgA-secreting plasma cells in the intestinal lamina propria. They produce IgA dimers, which bind a secretory component, creating secretory IgA, which is then secreted into the lumen.

The innate immune system recognizes pathogens, particularly through the activation of Toll-like receptors (TLRs), which increase IgA synthesis via promoting secretion of BAFF and enhancing lymphocytic infiltration and the expression of histocompatibility complex class II molecules on B-cells. Persistent activation of TLRs may favor increased synthesis of Gd-IgA1 in prone subjects [60].

There is a tonsil-kidney axis in IgAN. Some of the IgA eluted from renal tissue in patients with IgAN originates in tonsillar cells [61], and the number of IgA producing plasma cells in tonsils is higher in patients with IgAN than in controls [62]. These plasma cells create memory cells and may migrate to the bone marrow, where they synthesize and release Gd-IgA into the circulation. Persistent IgA deposits and hematuria were induced in mice by intranasal administration followed by systemic challenge of the respiratory Sendai virus after induction of defective mucosal tolerance [63, 64]. A microbiome study found similar tonsillar microbes in patients with IgAN and subjects with recurrent tonsillitis [65], but this observation was not confirmed [66]. Studies have shown activation of TLR9, which recognizes unmethylated DNA sequences in bacterial and

viral DNA cytosine-phosphorothioate-guanine oligodeoxynucleotides (CpG ODN) in the tonsils of patients with IgAN. TLR9 expression was associated with disease activity and clinical outcome after tonsillectomy [67]. The TLR9 ligand CpG-ODN increased the expressions of APRIL, favoring the delivery of nephritogenic IgA. Human B cells infected with Epstein-Barr virus (EBV) secrete Gd-IgA1. It has recently been hypothesized that EBV infected IgA+ cells, which have homing receptors for targeting the upper respiratory tract, may be the source of galactose-deficient IgA1. Moreover, the temporal sequence of racial-specific differences in Epstein-Barr virus infection may explain the racial disparity in the prevalence of IgAN [68].

The gut-kidney axis in IgAN [69] with dysregulated GALT was postulated after the observation of the increased association of IgAN with celiac disease [70]. This hypothesis was supported by a GWAS study showing that most loci associated with IgAN are also associated with immune-mediated inflammatory bowel diseases, maintenance of the intestinal barrier and response to gut pathogens [18]. In experimental transgenic mice overexpressing BAFF and presenting with hyper-IgA, the development of IgAN is conditioned by alimentary components and intestinal microbiota [71].

The intestinal microbiota can modulate the GALT [72] and different microbiota patterns have been reported in patients with progressive IgAN [73]. Increased intestinal permeability was detected in children and adults with IgAN [74, 75], together with high levels of IgA anti-alimentary antigens [76]. Chronic enteritis, reported in China as the second most common cause of mucosal infection, present in one third of cases of IgAN, may favor increased release of bacterial lipopolysaccharide (LPS), which can interfere with the chaperone gene Cosms, leading to production of Gd-IgA1 [77]. This hypothesis is also supported by increased expression of TLR4 (LPS specific ligand) in peripheral mononuclear cells in children and adults with IgAN [78, 79].

GALT may also be triggered by abnormal response to alimentary antigens, as detected in experimental models of oral immunization in mice [80]. Mice fed a gluten-rich diet had significantly greater IgA mesangial deposits than animals fed a gluten-free diet since birth [81]. IgA anti-alimentary components and IgAIC were reduced after a gluten-free diet in subjects with IgAN [82]. The role of gliadin was confirmed in IgA1/CD89 double transgenic mice that develop spontaneous IgAN; administration of a gluten-free diet for three generations prevented IgA deposits. The same study reported high levels of anti-gliadin IgA was associated with increased proteinuria in patients with IgAN. These data suggest a role of GALT hyper-response to intestinal alimentary components or microbes in IgAN.

Complement Activation in IgAN

The presence of C3 mesangial deposits with IgA deposits has been observed since the first description of IgAN [1], but there are many recent insights into the role of complement in IgAN. The alternative pathway is the main cascade activator in IgAN and most responsible for C3 deposition, which helps to differentiate incidental IgA mesangial deposits from true IgAN. C3 deposition is found in up to 90% of biopsies, frequently in association with C4d and usually without C1q, indicating the involvement of the alternative and lectin pathways. Properdin is present in a very high percentage of biopsies (70–100%), and CFH is present with variable frequency (30–90%) [21, 83, 84]. CFHR proteins may modulate CFH activity and *CFHR1* and *CFHR3* deletions in locus 1q32 were found to limit the alternative complement pathway activation, conferring a protective effect for development of IgAN [20]. IgAN cases with significantly higher plasma levels of FHR1 were more likely to have progressive disease [20, 85], and FHR5 plasma levels directly correlated with histologic markers of kidney injury [85–88]. Increased C3 breakdown products and IgA/C3 ratio were found to be associated with worse outcomes [89, 90].

The activation of the lectin pathway is indicated by the presence of C4d without C1q, and the detection of mannose-binding lectin (Man),

though not coincident. C4d is present in the renal biopsies of most actively progressive patients with IgAN and is a significant risk predictor for children and adults [91–94]. The terminal complement products C5-C9 may play an additive inflammatory role in the pathogenesis of IgAN; they are detected in biopsies and in in vitro experimental models [95].

Systemic oxidative stress is triggered by circulating IgAIC containing Gd-IgA1 [96]. Elevated levels of advanced oxidation protein products (AOPP) have been detected in sera of patients with IgAN and found to be correlated with the amount of proteinuria and with decreased renal function during follow-up. The association of high levels of Gd-IgA1 and AOPPs represents a risk factor for progression of IgAN.

Acquired factors which modulate the immune response are likely to be activated in some patients, with increased production of IL-4 and IL-5 by Th2 lymphocytes in IgAN leading to synthesis of Gd-IgA1 which is eventually deposited in the glomeruli.

The interaction of circulating macromolecules containing Gd-IgA1 with Fcα receptors on mesangial cells results in cellular activation and phlogistic mediator synthesis, including a variety of cytokines (IL6, platelet-derived growth factor [PDGF], IL1, TNF-α, TGFβ), vasoactive factors (prostaglandins, thromboxane, leukotrienes, endothelin, PAF, NO) and chemokines (MCP-1, IL-8, MCP-1, RANTES). The influx of monocytes and lymphocytes into the mesangium is enhanced by the C3 co-deposition.

The immune activation of mesangial cells leads to cell contraction, hemodynamic modifications and activation of the RAS [53]. Angiotensin II enhances the release of cytokines and chemokines and potentiates the actions of PDGF and TGFβ as growth factors for mesangial cells, further favoring proliferation and accumulation of extracellular matrix, and ultimately promoting sclerosis. In IgAN, there is no definite evidence of altered ACE genotype frequency, though some studies reported an association of one genotype (DD) with a faster rate of progression in IgAN and a better response to ACE-I treatment [97, 98].

Proteomics identified uromodulin as a urinary marker distinguishing IgAN from healthy controls and other glomerular diseases [99].

Renal Pathology of Children with IgAN

Light Microscopy

Primary IgAN typically presents with focal or diffuse proliferation of mesangial cells and expansion of the extracellular matrix. In both adults and children, endocapillary hypercellularity or extracapillary proliferation with crescent formation can be detected in active cases, while glomerular hyalinosis and segmental or global sclerosis or tubulointerstitial fibrosis are most prominent in patients with long lasting disease. The histological features in children are usually mild or moderate, and the rapidly progressive forms with crescents involving more than 50% of glomeruli are rare. Interstitial and arteriolar changes are infrequent. The variability of pathologic features is influenced by the approach for identifying patients to receive a renal biopsy since mild lesions are common in children with asymptomatic, microscopic hematuria detected by school screening programs [4, 5].

Several authors have proposed histological classifications of IgAN based on individual lesion intensity or extension, but all had a low clinicopathological correlation [100].

The Oxford classification for IgAN is predictive of clinical outcome in children and adults with IgAN, and it is presently universally adopted [101, 102]. It consists of a combined score of four lesions (mesangial and endocapillary hypercellularity, segmental glomerulosclerosis and tubular atrophy/interstitial fibrosis), MEST, which are predictive of outcome independent of clinical assessment (Fig. 17.3a–d). The value of crescents was not found in the original cohort, but was shown in a subsequent large study of more than 3000 patients with IgAN [103], leading to the use of the combined MEST-C score in patients of any age [52, 104].

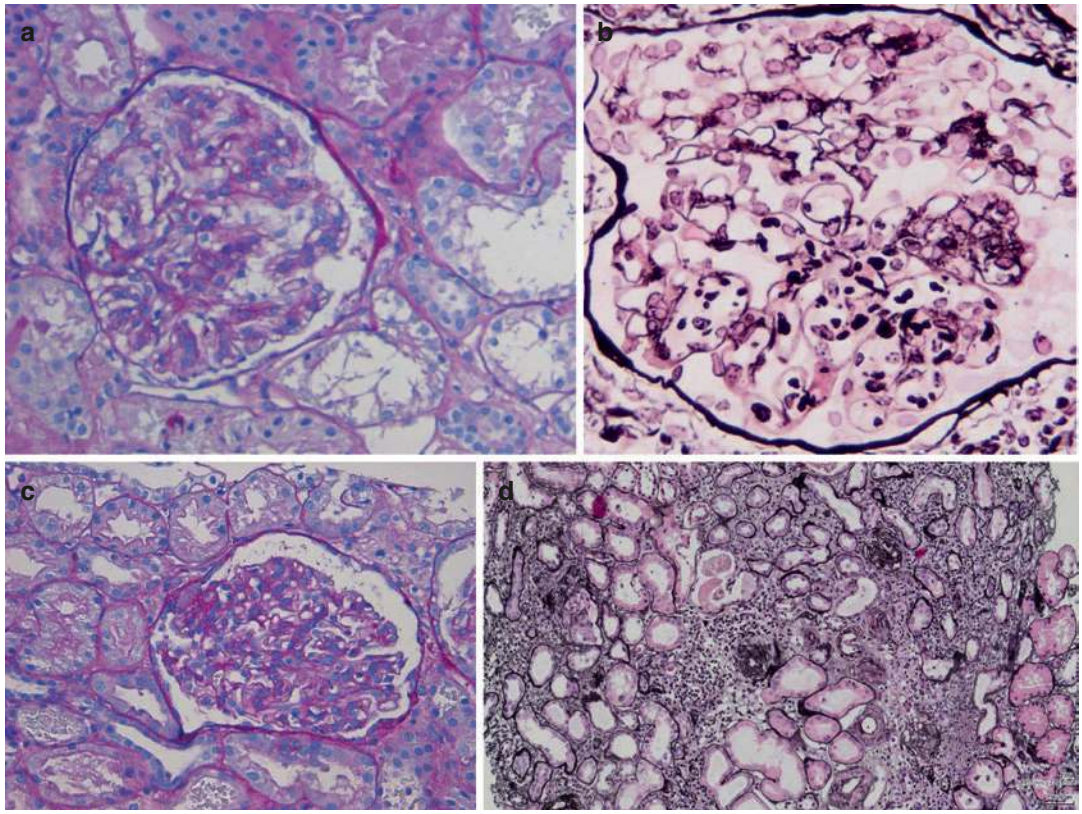

Fig. 17.3 Pathology features in IgA nephropathy. (**a**) Mesangial hypercellularity. (**b**) Endocapillary hypercellularity. (**c**) Segmental glomerulosclerosis. (**d**) Tubular atrophy/interstitial fibrosis

Although children with IgAN had more proliferative lesions and fewer chronic changes than adults, the predictive value of each lesion in the Oxford IgAN clinicopathological classification on renal survival was similar in children and adults [105].

Several validation studies have confirmed the value of the Oxford classification in children with IgAN [106–109]. The VALIGA study investigated 1147 patients with IgAN and validated the MEST score over a long-term follow-up, confirming the value of this pathology classification across the whole spectrum of IgAN, and maintaining the predictive value decades after the initial renal biopsy [110]. The search for clinical-pathological correlation and predictive value on outcome using small pediatric cohorts presents several limitations for a correct interpretation of the renal biopsy findings. The indication to perform the renal biopsy may select cases of different severity and potential risk. Moreover, the delay from clinical onset to renal biopsy detected different lesions, with higher mesangial and endothelial hypercellularity and more frequent crescents in early renal biopsies and greater segmental sclerosis and tubulointerstitial changes in delayed biopsies. The most important feature associated with outcome, in both children and adults, is tubulointerstitial damage, a marker of irreversible changes. However, much of the interest is on the predictive value of potentially reversible pathologic features, which may support a decision to initiate therapy. This occurs with podocytopathic lesions (tip lesions and podocyte hypertrophy), which, though associated with more severe proteinuria at onset and worse outcome, improved after immunosuppressive treatment [52].

Immunofluorescence

By definition, IgA is the dominant immunoglobulin present in all glomeruli (Fig. 17.4), and it is almost exclusively polymeric IgA1 with λ light chains. C3 is detectable in up to 70% of renal biopsies with the same distribution as IgA. IgG is present in 50–70% of the renal biopsies, often as intense as IgA, a feature that explains why this disease was initially called IgA–IgG nephropathy. IgM deposits are also found, but less commonly [31–66%]. The early complement components, such as C1q and C4, are rarely detected, but when present they are invariably associated with IgG and/or IgM.

The spatial distribution of IgA and C3 in mesangial deposits, studied by confocal laser microscopy, shows IgA and C3 coated by IgA in milder cases. A stronger deposition of C3c and C4d was reported in IgAN with endocapillary proliferation and active disease [91, 92, 94]. As mentioned before, the presence of C4d deposits was found to be associated with more rapid progression of IgAN in both adults and children [111]. C4d deposits often are associated with signs of thrombotic microangiopathy, suggesting that the interaction of Gd-IgA1 with endothelial cells triggers local inflammation, and activation of the complement and coagulation pathways [112].

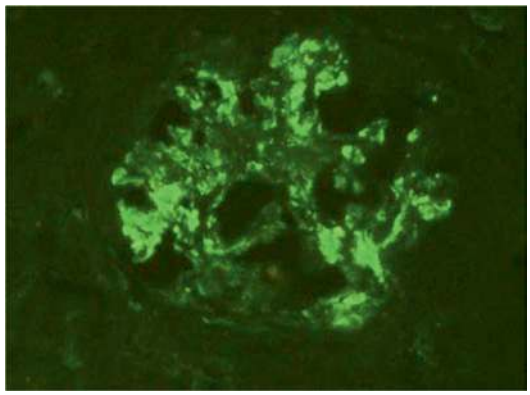

Fig. 17.4 Immunofluorescence staining with anti-IgA antibody. Mesangial distribution of IgA staining

Electron Microscopy

The most characteristic change on electron microscopy is the presence of electron-dense deposits in mesangial and para-mesangial areas.

Clinical Features

IgAN is not common in children under the age of 3 years; it is more common in adolescents [7]. In some children, the diagnosis follows an incidental finding of microscopic hematuria [113]. Asymptomatic patients may present with associated mild proteinuria (<0.5 g/day/1.73 m^2) in 3–15% of cases [114–116]. The most typical presentation of IgAN is gross hematuria coincident with upper respiratory tract infections or other mucosal inflammatory processes (in 30–40% of children). Macroscopic hematuria rarely occurs after vaccination or heavy physical exercise. The interval between the triggering event and the appearance of macroscopic hematuria is usually short (12–72 h). The macroscopic hematuria persists for few days, sometimes with flank and loin pain and fever. Some children have recurrent episodes without relevant urinary abnormalities between episodes. A transient increase in proteinuria occurs during episodes of gross hematuria. In some children, gross hematuria is associated with increased serum creatinine and hypertension [114–116], seldom with acute oliguric renal failure. In these cases, the renal biopsy shows mesangial, endocapillary and extracapillary proliferation and frequently tubular obstruction by packed red blood cells [117]. In rare cases, extensive crescentic lesions are detected [113]. Hypertension may develop during long-term follow-up or in particularly severe cases [113, 114]. An atypical presentation is nephrotic syndrome, which is reported in 7% of the cases, with podocytopathy similar to minimal change disease.

Natural History

IgAN in children is, with few exceptions, the early phase of the overall natural history of the disease. Severe clinical signs usually develop after 5–15 years, indicating the need for long follow-up, including as adults, to define the outcome of IgAN detected in childhood [118].

The natural history of IgAN varies according to the timing of performing the renal biopsy, and it differs in children diagnosed after a screening program; immediately after an onset with acute nephritic syndrome; or when there are signs of progression with decline in glomerular filtration rate (GFR). Moreover, the natural history has changed from the initial reports to the current era due to early detection and prompt therapy, including the use of RAS blockers (RASB) after diagnosis. Indeed, in the first pediatric report in 1986 of 91 French children with more than 13 years of follow-up, Levy et al. [116] reported chronic renal failure in 9%. In Finnish children, end-stage kidney disease (ESKD) from time of onset of diagnosis was found in 7% and 13% at 10 and 20 years, respectively [119]. An analysis of 500 children with IgAN in Japan showed a decrease in children reaching ESKD at 15 years from 20% to 1.2% when comparing renal biopsies before or after 1990. The European VALIGA study, over a median follow-up of 4.5 years, reported 4% of 174 children with ESKD. Since ESKD is uncommon in children, surrogate endpoints are frequently used (e.g. 50% reduction in eGFR or ESKD). In short-term follow-up studies, children seem to have a better prognosis than adults, but a 20 year survival analysis showed that IgAN in children was as progressive as in adults [115, 120]. In the long-term follow-up VALIGA study, survival to 50% reduction in eGFR or ESKD was 91% in children versus 70% in adults at 10 years and 82% in children versus 47% in adults at 20 years [110]. In a Japanese study of pediatric IgAN, patients were followed for a mean of 7 years. Clinical remission occurred in 50% and the predicted kidney survival rate was 92% at 10 years and 89% at 20 years [121]. Children with IgAN can have spontaneous remission of the urinary findings, as observed in Japanese children with IgAN and minor renal damage who did not receive medication after diagnosis [122]. Spontaneous remission could be observed after 5–8 years, but recurrences of urinary findings were detected in 20% at 5 years and in 42% at 10 years after remission. Hence, IgAN in children is a chronic disease, with phases of activity and clinical remission, rendering it difficult to provide a long-term prognosis on the basis of a short initial follow-up after renal biopsy.

Some children, usually those presenting with moderate microscopic hematuria without proteinuria and displaying the mildest lesions, do not progress to ESKD over decades of observation. In children with progressive IgAN, the clinical course is often slow and indolent. The most important factors associated with IgAN progression in adults, such as chronically reduced renal function at onset and persistent hypertension, are uncommon in children [123, 124]. The value of microscopic hematuria has been shown by some studies in adults with IgAN [125], but inter-center differences have limited the use of this urinary biomarker, so typical of IgAN, in collaborative studies.

In the VALIGA study, the clinical data, including proteinuria, blood pressure and eGFR at renal biopsy, were not significant predictors of the long-term outcome, indicating a possibility of spontaneous or drug-induced remission. Conversely, the most important risk for progression in children is the persistence of proteinuria (time-averaged) during follow-up. The threshold for time-averaged proteinuria in children is probably lower than what is accepted for adults. In adults with IgAN, only proteinuria >1 g/day is considered a significant risk for progression that deserves treatment, according to KDIGO recommendations [126]. For children, the 2021 update of KDIGO [127] suggests that those with >0.2 g/g urine protein/creatinine ratio (Up/UCr) should receive RAS inhibition. From long-term follow-up studies in children with IgAN, residual proteinuria <0.2 g/day/1.73 m^2 after treatment predicts a favorable outcome [128, 129].

In an analysis of the VALIGA cohort, only 7.5% of children with initial proteinuria >0.5 g/day/1.73 m^2 had persistent proteinuria <0.5 g/

day/1.73 m^2 at last follow-up, indicating a partial but not complete remission. The median value of proteinuria during a median 4.5 years of follow-up was 0.56 g/day/1.73 m^2, suggesting that most children with IgAN are exposed to a significant risk of progression over the following decades [106, 130].

Risk Prediction

There is a need to predict disease progression in children with IgAN to assess risk-based treatment decisions. An International IgAN Prediction Tool for adults with IgAN was recently developed to predict a 50% decline in eGFR or ESKD using clinical risk factors and MEST histology scores [131]. The variability of clinical and histological features of IgAN in children, the small number of children followed in individual centers, the short follow-up and the small number of outcome events (ESKD or 50% reduction in eGFR) represent substantial limitations for the detection of risk factors associated with progression in children. The use of the adult prediction tool was not satisfactory; hence, the global IgAN network updated the Prediction Tool for use in children using a multi-ethnic international cohort of 1060 children with IgAN followed into adulthood [132]. The Tool defined an end point of 30% reduction in eGFR or ESKD, which is considered an acceptable surrogate outcome in children with IgAN and proved to be well-calibrated. The trajectory of eGFR over time in children was different from adults: it was non-linear, with an increase in eGFR until 18 years of age followed by a linear decline similar to adults. A higher predicted risk was associated with a smaller increase in eGFR followed by a more rapid decline. This suggest that children at risk of a 30% decrease in eGFR will eventually experience a larger 50% decrease in eGFR and these two outcomes are analogous between the pediatric and adult Prediction Tools. The conclusion of this large collaborative effort was that the updated pediatric Prediction Tool could accurately predict the risk of a 30% decline in eGFR or ESKD in children with IgAN. The Prediction Tool uses a combination of commonly used clinical risk factors, and the MEST-C histology score, and is available online and in a mobile-app (www.qxmd.com/calculate-by-qxmd). The predicted risk of a 30% decline in eGFR or ESKD from the pediatric Prediction Tool at a given time horizon are similar to the predicted risks 2–3 years later of a 50% decline in eGFR or ESKD from the adult Prediction Tool.

Collectively, these results demonstrate that the Prediction Tool models are predicting clinically relevant outcomes in both children and adults and therefore can be used to identify higher-risk patients along a continuum of non-linear eGFR decline that spans the full age spectrum of patients with IgAN.

A low-risk condition according to the 2021 KDIGO recommendations, which should be the aim of treatment of children with IgAN, is persistent proteinuria <0.2 g/1.73 m^2/day and a normal GFR.

Treatment

Tonsillectomy

One of the first treatments considered for IgAN, particularly in children with recurrent gross hematuria, was tonsillectomy, which aimed to interrupt the pathogenic process initiated by an upper respiratory tract infection leading to hematuria. Tonsillectomy can eliminate a relevant source of pathogens, which multiply in tonsils, while also removing macrophages and T cells in lymphoid tonsil follicles, a potential source of aberrantly glycosylated IgA1. In children, it remains controversial whether adenotonsillectomy ultimately results in decreased serum immunoglobulins levels or, if so, whether such a decrease is associated with increased susceptibility to upper respiratory tract infections. In a randomized trial in children without IgAN [133], the IgA levels were significantly decreased after one year of follow-up; however, no relation was found between immunoglobulin levels and frequency of subsequent respiratory infections. Moreover, in children with repeated infections

despite tonsillectomy, IgA levels increased again, indicating that the remaining MALT can compensate for the loss of tonsils and adenoid tissue [133]. Even though tonsillectomy can reduce the frequency of gross hematuria and produce some benefits, this intervention lacks sufficient evidence and KDIGO 2012 suggested tonsillectomy not be performed in patients with IgAN without a clinical indication beyond IgAN [134]. This is confirmed in the 2021 KDIGO [127]; however, it takes into consideration the results of tonsillectomy in two large retrospective Japanese studies which reported benefits on renal function decline after a follow-up of more than 10 years [135]. Hence, some potential benefit in Japanese patients might be considered.

Tonsillectomy has a clear indication when tonsils are a true infectious focus and in cases of recurrent tonsillitis (>3 per year). Otherwise, the efficacy of the procedure is often supported only in association with other therapy and the benefit is unclear [136]. In Europe, a VALIGA collateral study failed to show clinical benefit on outcome of a subgroup of patients who had received tonsillectomy [137].

Inhibition of the Renin-Angiotensin System

In all children with IgAN, blood pressure (BP) control should be strict. All patients should be targeted below the 90th percentile, with a target of the 50th percentile or the maximally tolerated drug dose, if proteinuria is present. This is consistent with the target recommended in adults by KDIGO [126]. The drugs of choice for BP control in IgAN are RASB, either angiotensin converting enzyme inhibitors (ACE-Is) or angiotensin receptor blockers (ARBs).

Children with IgAN and heavy proteinuria are at risk for progressive disease. RAS inhibition has a strong rationale for use in IgAN, not only because it improves two risk factors for progression (hypertension and proteinuria), but also because it can inhibit the long series of potentially negative effects caused by angiotensin II on mesangial cells, particularly in the presence of mesangial immune deposits.

A European multicenter randomized controlled trial (RCT) included children and young patients (3–35 years old) with a constant level of proteinuria (>1 < 3.5 g/day/1.73 m^2 over the 3 months before enrolment) and normal or moderately reduced renal function. Patients were randomized to receive benazepril 0.2 mg/kg/day or placebo and the primary outcome of renal disease progression was >30% decrease in eGFR and/or worsening of proteinuria to nephrotic range. Treatment with ACE-I was an independent predictor of prognosis, while no effect on the progression of renal damage was found for gender, age, baseline GFR, systolic or diastolic blood pressure, mean arterial pressure, or proteinuria [138].

On the basis of this study, KDIGO suggested to treat children with IgAN and persistent proteinuria >0.5 and < 1 g/day/1.73 m^2 with RAS inhibition. There are no data to indicate a preference between ACE-Is or ARBs, except for fewer side effects with ARBs. No significant additional benefit was found in a RCT that investigated the addition of ARB to ACE-I in children with IgAN [139].

No RCT has addressed the effects of ACE-I in children with minimal proteinuria <0.5 g/day/1.73 m^2, but some benefits were suggested by a single-arm, collaborative, Japanese study that treated patients for 2 years [140].

Glucocorticoids

Based on the results of RCTs in adults [135, 141, 142], KDIGO in 2012 suggested that if proteinuria >1 g/day persisted unchanged after 3–6 months of RAS inhibition, glucocorticoids should be considered for treatment of IgAN in children and adults [126, 143]. In children, lower levels of persistent proteinuria (>0.5 g/day/1.73 m^2) may be considered for initiating treatment. Protocols included months regimens, using either 3 intravenous pulses of methylprednisolone (1 g) and oral prednisone (0.5 mg/kg on alternate days) [141], or oral prednisone 0.8–1 mg/kg/day for 2 months, with weaning

over 6 months [142, 144]. However, subsequent RCTs in adults suggested a more cautious approach in cases with slow decline of GFR. The STOP-IgAN trial [145] did not show a superior effect of immunosuppressive therapy (monotherapy with methylprednisolone pulses for 6 months in patients with eGFR >60 ml/min; oral prednisone and cyclophosphamide followed by azathioprine in patients with lower eGFR) versus supportive care for three years. The Therapeutic Evaluation of Steroids in IgA Nephropathy Global (TESTING) study [144] compared oral methylprednisolone versus placebo. Recruitment was discontinued after 2 years because of excess serious adverse events (mostly infections, including two deaths) in patients receiving corticosteroids. The preliminary results were consistent with potential renal benefit, but early termination of the study did not allow any conclusions. These recent studies have focused attention on the potential side effects and limited benefits of corticosteroids in adults with IgAN.

In children, evidence-based reports on the effect of corticosteroids in treating IgAN are scarce [146]. Small studies in children with variable baseline data and different treatment regimens provided conflicting results [147–149]. The best results were reported in severe cases with crescentic IgAN successfully treated with pulse steroid therapy [149].

A US RCT using prednisone (60 mg/m^2 every other day for 3 months, then 40 mg/m^2 every other day for 9 months, then 30 mg/m^2 every other day for 12 month) or fish oil (4 g/day for 2 years) failed to find significant benefit of treatment [150]. However, the relatively short follow-up period, inequality of baseline proteinuria, and small numbers of patients precludes a definite conclusion.

The only RCT proving efficacy of corticosteroids in children with IgAN was performed in Japan; it enrolled children with severe mesangial proliferation. The children were randomized into two groups, with one arm (intervention) receiving prednisone, azathioprine, heparin-warfarin and dipyridamole and the other arm (control) receiving heparin-warfarin and dipyridamole. This 2 year study reported a significant reduction in proteinuria, serum IgA concentration, mesangial deposition, and prevention of increased number of sclerosed glomeruli in the intervention arm [151]. After a follow-up of 10 years free of additional treatment, the children in the intervention arm (who had previously received the immunosuppressive combination therapy) were less likely to reach the end point of GFR <60 ml/min/1.73 m^2. In another study, a similar combination therapy produced a disappearance of IgA mesangial deposits after 2 years of treatment [152]. These reports suggest that early aggressive treatment in children with modifiable histologic risk factors for progression can in the long-term protect the kidneys from sclerosis. Side effects and limited if any benefit of prolonged anticoagulation and anti-platelet therapy suggest that they do not provide a net benefit when added to immunosuppressive therapy [153]. In adults, the addition of azathioprine to corticosteroids failed to add further benefits and caused side effects [154].

A French, uncontrolled, retrospective study [155] reported the outcome of children with severe clinical presentation and acute histologic features who received therapy with either corticosteroids (sometimes in association with cyclophosphamide) and RASB, or RASB alone. Although the two groups had different baseline proteinuria and time from onset to treatment, a large benefit of corticosteroid/immunosuppressive therapy was reported, with improvement in eGFR and decrease in proteinuria after a short follow-up of 6 months.

According to KDIGO 2021 [127], in children with proteinuria >1 g/day/1.73 m^2 and/or mesangial hypercellularity, most pediatric nephrologists will treat with glucocorticoids in addition to RAS blockade from time of diagnosis. The most common protocol is oral prednisone 1–2 mg/kg/day for 4 weeks tapered over 4–6 months. Regimens including intravenous methylprednisolone are also used. KDIGO 2021 reports that there is scarce evidence for the additional use of non-glucocorticoid immunosuppressants, but this approach may be considered in more severe cases. Children with nephrotic syndrome and his-

tological features of minimal change disease (MCD) associated with IgAN should be treated as MCD. IgAN with rapidly progressive renal deterioration of renal function (>50% decline in eGFR in <3 months) irrespective of the percentage of glomeruli involved with crescents, may benefit from steroids and cyclophosphamide, analogous to the treatment of ANCA vasculitis [126]. Prompt use of aggressive immunosuppressive treatment, sometimes in association with plasmapheresis, has shown some benefit in slowing the progression of these difficult cases [156]. Finally, KDIGO 2021 suggests to strictly follow children with IgAN even when they enter remission, since recurrence is always possible.

New Formulations of Corticosteroids

An enteric formulation of budesonide has been developed that targets release of the drug in the distal ileum, an area within the GALT. The NEFIGAN trial compared this targeted release formulation (TRF) of budesonide with placebo in patients with persistent proteinuria despite optimized RAS blockade [157]. At 9 months, mean proteinuria decreased significantly more in TRF budesonide-treated patients than in placebo–treated patients. GFR stabilized with TRF budesonide, but decreased in the placebo arm. No increase in serious adverse events, and particularly infections, were reported in treated patients. Results from further RCT and studies in children are expected.

Mycophenolate Mofetil

The KDIGO guideline does not recommend mycophenolate mofetil in IgAN, even though some benefit in Asian adult patients have been reported [158]. A RCT that included children, young subjects and adults investigating the effects of corticosteroids, mycophenolate mofetil and fish oil was prematurely terminated for lack of benefit [159].

Cyclophosphamide

This drug, in combination with corticosteroids, was tested in adults with particularly active disease in several uncontrolled case series, and a small RCT [160] reported a protective effect of cyclophosphamide in progressive cases of adult IgAN. However, this was not confirmed by the STOP-IgAN study [145].

Rituximab

Rituximab, in a small RCT in adult patients with IgAN, had no effect on eGFR decline or remission of proteinuria [161].

Calcineurin Inhibitors

A recent meta-analysis reported limited effects of calcineurin inhibitors when used in addition to small doses of prednisone, while reporting more adverse events [162].

Future Therapies for IgAN

Hydroxychloroquine combined with RAS inhibitors significantly reduced proteinuria over 6-months in adults with IgAN [163]. Results in children are expected.

Inhibitors of endothelin-1 receptors combined with RASB are being tested in a large collaborative phase III RCT. A study in children is in preparation.

Explorative trials with Inhibitors of the BAFF-TNF receptor family (BAFF, APRIL TACI) using humanized monoclonal antibodies against these mediators are ongoing [164]. Several complement inhibitors are under investigation, including anti-C5 (eculizumab), anti-C5a receptor inhibitors (CCX168), anti-C3 (compstatin), anti-factor D (lampalizumab), and MASP-2 inhibitors (OMS721) [164, 165].

A Practical Approach to Treatment of Children with IgAN

The prospects for successful treatment of IgAN to improve long-term outcomes in children seems promising since children are more likely than adults to be treated in the early stages of the disease, when mesangial proliferative lesions/endocapillary proliferations are more prominent than sclerosis, and when proteinuria is not massive. On the other hand, we must take into consideration the toxicity and side effects of these treatments, which are particularly undesired in patients with mild disease, and the possibility of spontaneous remission in mild cases [166].

According to KDIGO 2012 and 2021 [127] recommendations, the treatment of IgAN in adults and in children is mostly driven by the level of proteinuria at renal biopsy, with advanced renal failure suggesting disease beyond "the point of no return" being the only limitation. These recommendations originate from the available evidence in the literature. However, proteinuria can be associated with active lesions, but also be the clinical manifestation of sclerotic lesions. The recent identification of pathologic features that are risk factors independent from proteinuria, blood pressure and GFR at renal biopsy, strongly suggests that there should be an integrated approach to treatment as indicated in Fig. 17.5.

For all children with IgAN, a general approach is to carefully follow BP and to target blood pressure < 50th percentile for sex and age or maximally tolerated dose using RAS inhibition if proteinuria is present.

For children with mild IgAN disease, presenting with normal GFR, urinary protein/creatinine ratio (Up/Ucr) <0.2, normal BP and with all MEST (see legend for Fig. 17.5) negative [0], watchful waiting is suggested, and prescribing a RASB if Up/Ucr exceeds 0.2 g/g.

For children with IgAN and moderate/severe IgAN (Up/Ucr >0.5), at risk of GFR decline by the prediction tool, which considers MEST scores, without severe irreversible sclerotic changes, glucocorticoids should be added to a RASB. Methylprednisolone pulses [143] or oral steroids over 6 months can be adopted.

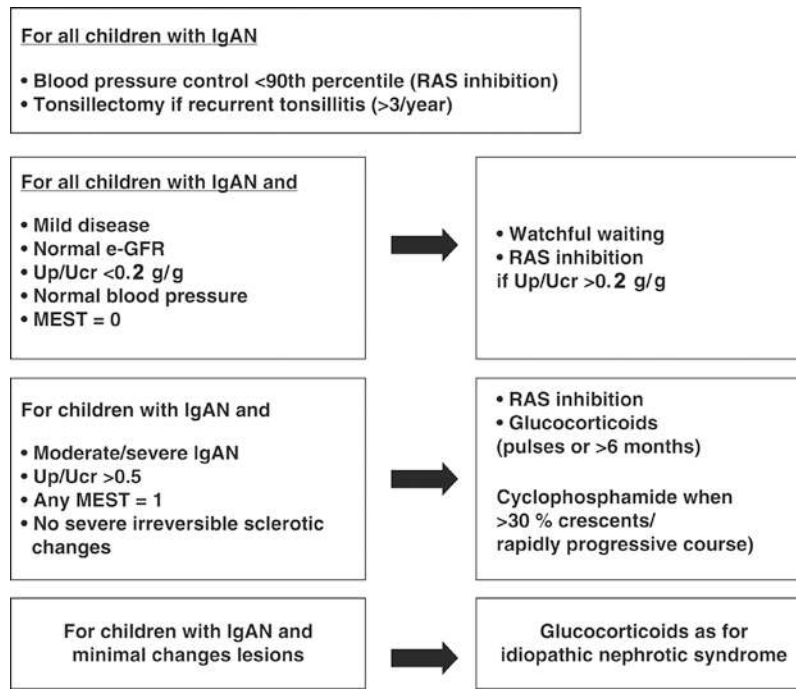

Fig. 17.5 Treatment of children with primary IgA nephropathy (IgAN). e-GFR: estimated glomerular filtration rate in children calculated with updated Schwartz formula; up/Ucr: urinary protein/creatinine ratio; normal blood pressure: <90th percentile corrected for height, sex and age; MEST: scores derived from Oxford classification of IgAN [101, 102]; M: mesangial hypercellularity; E: endocapillary hypercellularity; S: segmental sclerosis; T: tubular atrophy/interstitial fibrosis

In cases with severe endocapillary proliferation, or with crescent formation involving >30% of the glomeruli, with a rapidly progressive course, cyclophosphamide may be effective. In children with IgAN, minimal change lesions and nephrotic syndrome, a protocol similar to that recommended for idiopathic nephrotic syndrome is a suitable choice.

Membranous Nephropathy

18

Myda Khalid and Laurence H. Beck Jr

Incidence

Nephrotic syndrome is one of the most common kidney disorders encountered in a pediatric nephrology practice. In children, it occurs at a reported incidence of 2 per 100,000 per year and a cumulative prevalence of 16 per 100,000 children. Compared to other more commonly occurring nephrotic disorders in this population, such as minimal change disease and primary focal and segmental glomerulosclerosis, membranous nephropathy (MN) is relatively rare. Given its rarity in children, there is scant data on the true incidence, prognosis and best management practices. It is estimated that 1.5% of children with nephrotic syndrome will have membranous nephropathy based on the International Study of Kidney Disease in Children report in 1978 [1]. The incidence is higher, approaching 22%, in adolescents compared to younger children [2].

Because many children with steroid-sensitive nephrotic syndrome will never be biopsied, the relative prevalence of MN versus minimal change disease and focal segmental glomerular sclerosis is unclear. Another bias is the age range of the population. In a series from Pakistan that investigated 538 children who underwent biopsy for idiopathic nephrotic syndrome, there was a significant difference between the 3% rate of MN in children aged <13 years and the 18.5% rate found in adolescents aged 13–18 years [3]. Similar rates were found in adolescents in two different cohorts [2, 4].

MN has been reported to account for only 0.6% of pediatric chronic and end-stage kidney disease (ESKD) cases, with a median age at onset of ESKD being 16 years based on the 2007 North American Pediatric Renal Trials and Collaborative Studies report and 2012 United States Renal Data System. This is in contrast to adults, in whom MN is one of the more common forms of nephrotic syndrome and a significant contributor towards ESKD (Table 18.1).

Table 18.1 Differences between pediatric and adult membranous nephropathy

Feature	Pediatric MN	Adult MN
Disease type/subtype		
Proportion of all primary nephrotic syndrome cases that is MN	<5% (children); 5–20% (adolescents)	15–30%
MN that is primary ("idiopathic")	Minority	Majority
Proportion of primary MN that is PLA2R-associated	Less than 50% (more frequent in adolescents)	70–80%
Demographic and clinical features		
Male predominance	Variable	Yes
Full nephrotic syndrome	40–75%	75%
Microscopic hematuria	70–90% (can be macroscopic)	50%
Hypertension	<10%	30%
Thromboembolic events	<5%	10–20%
Spontaneous remission	Common	30%
Progressive renal impairment	<25%	30–40%
Pathologic features		
Mesangial deposits	Up to 50%	30%
Segmental distribution of deposits	Occasional	Very rare

MN membranous nephropathy

Etiology

The etiologies of MN have traditionally been divided into *idiopathic* (now more commonly called *primary*) and *secondary* causes. While primary MN typically reflects a kidney-specific autoimmune response, the glomerular process in secondary MN can usually be attributed to a systemic disease process, a drug or toxin, infection, or malignancy. Recent progress in the identification of target autoantigens and other specific biomarkers of MN has led the field to consider moving toward an antigen-based approach to naming the different types of MN, irrespective of primary or secondary designations [5]. However, it is still useful to subdivide MN into its autoimmune (idiopathic or primary) forms in which there is loss of tolerance to a self-antigen within the glomerulus, and secondary forms in which the antigen may be exogenous. Distinction between primary and secondary MN relies on a systematic evaluation of historical (drugs, exposures), clinical, laboratory, and histological features, as will be discussed further later in this chapter.

Although primary autoimmune forms of MN can occur in children, there has historically been a higher frequency of secondary forms of MN when compared to adults. The main etiologies of secondary disease in the pediatric population are infections and systemic autoimmune diseases such as lupus (Table 18.2). Drugs and malignancy are less frequent causes of MN in children,

Table 18.2 Secondary causes of membranous nephropathy

A. Autoimmune diseases
1. Systemic lupus erythematosus
2. Autoimmune thyroiditis
3. Sarcoidosis
4. Sjögren syndrome
5. Rheumatoid arthritis
B. Infectious diseases
1. Hepatitis B
2. Other viruses (HIV, HCV, EBV, CMV)
3. Quartan malaria
4. Schistosomiasis
5. Filariasis
6. Congenital syphilis
C. Drugs and exposures
1. Non-steroidal anti-inflammatory agents
2. Penicillamine
3. Bucillamine
4. Mercury salts
5. Recombinant enzymes used in enzyme replacement therapy
D. Neoplastic
1. Rare associations with disparate types of malignancy
E. Other conditions
1. Familial truncating mutations in *MME* (gene for NEP)
2. Anti-cationic BSA antibodies
3. *De novo* MN after kidney transplantation
4. Immune dysregulation or deficiency syndromes (IPEX, CVID)
5. Stem cell transplantation

Abbreviations: *HIV* human immunodeficiency virus; *HCV* hepatitis C virus; *EBV* Epstein Barr virus; *CMV* cytomegalovirus; *MME* membrane metalloendopeptidase; *NEP* neutral endopeptidase; *BSA* bovine serum albumin; *IPEX* immunodysregulation, polyendocrinopathy, enteropathy, X linked; *CVID* common variable immunodeficiency

but certainly need to be considered as potentially causal when the processes are concurrent. As in adults, sarcoidosis and autoimmune thyroid disease can be linked to MN in children. Hepatitis B has historically been a major cause of secondary MN in parts of the world in which the virus is endemic [6]. Fortunately, the incidence of hepatitis B-associated MN has decreased worldwide with the introduction of vaccination programs [7–9]. Additional viral infections such as HIV, EBV, and CMV have been reported as secondary causes of childhood MN. Infections such as schistosomiasis, filariasis, malaria and congenital syphilis are also important conditions linked to development of MN in areas where these diseases are prevalent.

Dysregulation of the immune system as occurs in IPEX syndrome [10] or combined variable immunodeficiency [11] can be a cause of MN in children. Exposure of host immune system to donor antigens (or vice versa), as occurs following hematopoietic stem cell transplantation or after kidney transplantation, can lead to alloimmune forms of membranous nephropathy [12, 13].

Pathophysiology

Despite the various etiologies that can lead to the histological pattern of membranous nephropathy and its consequent clinical manifestations, much of the underlying pathophysiology is fundamentally similar. Pediatric disease has provided important conceptual information about adult disease, and vice versa.

Membranous nephropathy (also variably called membranous glomerulonephritis or glomerulopathy) is named due to a thickening of the glomerular capillary walls as visualized by light microscopy, especially with prolonged disease [14]. The thickening is a result of (1) immune complexes that deposit beneath the basal surface of the podocyte at the outer aspect of the glomerular basement membrane (GBM) and (2) the additional extracellular matrix material that is eventually secreted between and around these deposits. The subepithelial immune deposits reliably consist of several components, which aid in the pathological detection and classification of MN. The immune complexes themselves are formed by immunoglobulin (most often IgG) and a target antigen, the identities of which have been identified over the past 15 years. Components of the complement system such as C3, C4, and C5b-9, activated by these immune complexes, are also consistently found within the immune deposits. These factors are routinely identified by immunostaining of the kidney biopsy (see Pathology below). The ability to detect the specific antigen within the deposits has been an important development in both pediatric and adult MN.

The field of MN has benefited both from well-studied animal models such as Heymann nephritis as well as important insights from human disease such as the identification of a growing number of targets antigens (Fig. 18.1). The ability to detect and follow circulating antibodies against these target proteins has opened up a new era for the diagnosis and monitoring of MN from early infancy to adulthood [15, 16].

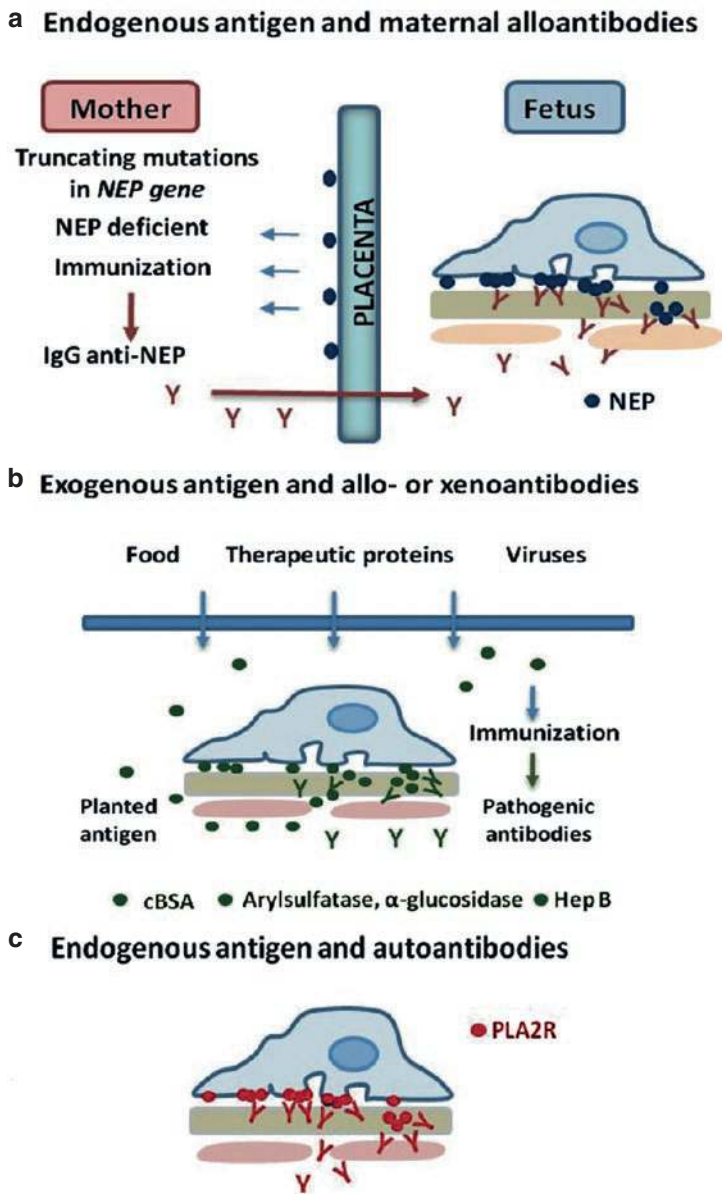

Fig. 18.1 Schematic representation of membranous nephropathy etiologies in children. (**a**) NEP-related alloimmune glomerulopathy. Neutral endopeptidase (NEP, blue dots) serves as a pathogenic antigen in the podocyte cell membrane. Antibodies to this protein originate in women who genetically lack NEP because of truncating mutations in *MME* (which encodes NEP). Immunization occurs during pregnancy when the mother's immune system is first exposed to NEP, which is strongly expressed by placental cells and by fetal cells entering the mother's blood. From about the 18th week of gestation, maternal antibodies are actively transported across the placenta to the fetus, where they bind to the NEP antigen expressed on podocytes. (**b**) Exogenous antigen-induced membranous nephropathy. Foreign, exogenous proteins commonly induce the production of antibodies. Owing to unusual physicochemical properties, these antigens can be trapped in the glomerular basement membrane where they can serve as a target for circulating antibodies, leading to the formation of in situ immune complexes. Green dots represent cationic bovine serum albumin (cBSA) from the diet, infused enzymes used in enzyme replacement therapy (arylsulfatase, α-glucosidase in this example) or hepatitis B antigens (Hep B). (**c**) PLA2R-associated primary (autoimmune) membranous nephropathy. The phospholipase A2 receptor (red dots), an integral membrane glycoprotein of podocytes, is a target antigen for circulating autoantibodies

Heymann Nephritis, the First Experimental Model of MN

An important animal model that established much of the pathophysiological paradigm for human membranous nephropathy was developed in 1959 by Walter Heymann, a pediatrician from Cleveland (Ohio, USA) and his colleagues. Lewis rats were immunized with crude extracts of rat kidney in what became known as the active Heymann nephritis model [17] and yielded a glomerular and clinical phenotype that was remarkably similar to human MN. As the experimental disease could be induced by immunizing rats with a rat proximal tubular brush border fraction, the source of the predominantly glomerular deposits was initially felt to be due to glomerular trapping of circulating immune complexes of brush border antigens and corresponding anti-brush border antibodies. Development of passive Heymann nephritis models in which the anti-brush border antibodies were first raised in rabbits or sheep and then transferred to the rats raised doubts about the importance of circulating immune complexes. Two groups, using ex vivo and isolated perfused rat kidney systems, independently demonstrated that the anti-brush border antibodies bound to an antigenic target on the podocyte (in fact, common to the podocyte and brush border) and suggested that the subepithelial deposits formed locally [18, 19].

The antigenic target common to the rat podocyte and tubular brush border was ultimately identified by Kerjaschki and Farquhar in the early 1980's as gp330 or megalin [20, 21], now known as the low-density lipoprotein receptor-related protein 2 (LRP2). Megalin was found to reside in clathrin-coated pits at the basal surface of the podocyte foot process, where it could interact with circulating anti-megalin antibodies from the capillary lumen to form immune complexes in situ. The subepithelial deposits were felt to grow in size as polyclonal anti-megalin antibodies formed highly-cross linked immune complexes with megalin that continued to be delivered to the basal surface in clathrin-coated vesicles [22]. Cleavage of the transmembrane protein megalin to release its large extracellular region into the immune complexes likely facilitated deposit formation [23].

These findings established the paradigm that a podocyte derived antigen that was expressed at the basal surface of the podocyte could react with anti-podocyte antibodies to initiate the pathologic process of MN. The search began for anti-megalin antibodies as an explanation for human MN, but it was quickly realized that human podocytes do not routinely express megalin and that other target antigens were likely the cause of human disease. Of note, anti-brush border antibodies (ABBA, now known to be anti-LRP2) are responsible for an autoimmune form of human interstitial nephritis that consistently exhibits segmental subepithelial deposits that may be due to limited megalin/LRP2 expression by aging podocytes [24].

Alloimmune Neonatal MN: Neutral Endopeptidase as the Target Antigen

The first podocyte-expressed target antigen in human MN was identified in a neonate born with MN [25] (Fig. 18.1, upper). Under the assumption that maternal antibodies might have caused this immune-complex disease in the developing fetal kidney, both maternal and infant serum was used to screen human, rat, and rabbit kidney tissue for candidate antigens. The culprit protein was identified as neutral endopeptidase (NEP) and NEP was found to co-localize with IgG and C5b-9 within the immune deposits of the infant's kidney biopsy [25, 26]. Experiments in which a pregnant rabbit was injected with IgG from the mother demonstrated that these anti-NEP antibodies were able to transfer disease [27].

NEP (which has several alternative names such as neprilysin, CD10, common acute lymphoblastic leukemia antigen or CALLA) is a product of the *MME* (membrane metalloendopeptidase) gene. It is an enzyme responsible for the degradation of biologically active peptides such as enkephalin, natriuretic peptides, endothelin, bradykinin and substance P in the vicinity of their receptors. It is present in many organs as

well as granulocytes; in the kidney, NEP is detected at the podocyte surface, in the brush border and in vessel walls.

The mother of the index case of NEP-associated antenatal MN, despite having high titers of circulating anti-NEP, did not exhibit any manifestations of nephrotic syndrome herself, and it was hypothesized that she might be genetically deficient in NEP. This was confirmed at the genetic level, showing the presence of truncating mutations within the *MME* gene [26] and by the lack of reactivity of her granulocytes with a panel of anti-NEP antibodies [25]. This mother was likely alloimmunized to NEP from a prior pregnancy which was miscarried, during which NEP of paternal origin was expressed by the syncytiotrophoblastic cells of the placenta. Four additional families with maternofetal alloimmune MN were identified. All immunized mothers were NEP deficient as a result of truncating mutations in exon 7 and exon 15 of the NEP gene [26, 28].

Since the anti-NEP antibodies were of maternal origin, transferred to the fetal circulation across the placenta, it is not surprising that most of these infants exhibited rapid improvement in their renal function and proteinuria as the maternal IgG cleared from their system and the glomerular deposits were resorbed. An exception was one newborn with a long duration of kidney failure requiring dialysis. The mother in this case possessed anti-NEP with an abundance of the IgG1 subclass, in contrast to other cases in which IgG4 was predominant. In addition to possibly better activating the complement system within the glomerular deposits, this IgG1 anti-NEP was also shown to possess enzyme inhibitory function that may have had renal vascular consequences [28].

NEP-associated alloimmune antenatal MN therefore represents the first type of human MN in which an intrinsic podocyte protein was implicated as the target antigen. Furthermore, anti-NEP IgG from the mother could induce disease when transferred to a rabbit. This maternofetal incompatibility due to a maternal genetic defect leading to an alloimmune response in the fetus is rare, but could be considered in other situations in which the mother is genetically deficient in a podocyte protein normally expressed in the fetal kidney.

M-Type Phospholipase A_2 Receptor-Associated MN

As idiopathic MN in adults did not demonstrate the presence of antibodies to either megalin/LRP2 or to NEP, the search continued to identify target antigens in this disorder. A breakthrough came in 2009 with the identification of the M-type phospholipase A_2 receptor, now better known as PLA2R [29]. Sera from adult cases of MN possessed circulating IgG4 that could detect a distinct glycoprotein by immunoblotting extracts from human glomeruli. Through the use of a candidate antigen approach that was informed by a mass spectrometric analysis of human glomerular proteins immunoprecipitated with IgG from MN cases, the target antigen was ultimately identified as PLA2R [30]. Seventy to 80% of idiopathic (primary autoimmune) MN are PLA2R-associated.

Like NEP and megalin (in the rat), PLA2R is expressed as a transmembrane receptor on the podocyte surface, where circulating antibodies can target one or more epitopes in the extracellular domain (Fig. 18.1, lower). It is of interest that, like megalin, it is also delivered to and recycled from the plasma membrane in clathrin-coated vesicles. Its role within the podocyte is not clear, but it may help to internalize small secreted phospholipase A_2 enzymes that pass through the GBM. PLA2R is not expressed by podocytes in small animals and thus passive administration of human anti-PLA2R antibodies (PLA2R-ab) has not been able to transfer disease as was the case for anti-NEP alloantibodies.

The identification of PLA2R as the target antigen in the majority of adult idiopathic MN cases paved the way for a new era of diagnosis, monitoring, and understanding in MN. As the major target antigen in adult MN and after more than a decade of study, this autoantibody-target antigen system now represents the paradigm by which we understand the link between circulating antibod-

ies and clinical manifestations of disease. We will focus on this system in the paragraphs below.

The identification of specific target antigens (like PLA2R) in MN allows for immunodetection of that antigen within immune deposits of the kidney biopsy, as well as assaying for the presence of autoantibodies to the target antigen in the circulation. Serologic assays to detect PLA2R-ab are based on ELISA using the recombinant human PLA2R protein or by immunofluorescence (IFA) of PLA2R transfected cells and are now commercially available in most countries as a clinical test. The specificity of the presence of circulating PLA2R-ab for MN is nearly 100%, especially when borderline or low-titer positive ELISA tests are confirmed by the more-sensitive IFA. Normal individuals or those with other proteinuric disease will not have PLA2R-ab. Such specificity has even led to the suggestion that a positive test for PLA2R-ab is diagnostic and may obviate the need for kidney biopsy, especially in those with normal kidney function and without other potential secondary causes of MN [31]. In situations where biopsy is difficult due to a patient already being on anticoagulation due to thromboembolic events resulting from the nephrotic state, a solitary kidney, or other relative contraindications to kidney biopsy, seropositivity for PLA2R-ab may be diagnostically sufficient to guide subsequent therapy.

A low prevalence of PLA2R-ab has been observed in forms of MN found in association with SLE, infectious disease, therapeutic drug use (especially nonsteroidal anti-inflammatory agents) or malignancy [32–35]. It is often quite difficult to assign causality of the MN to the associated condition, and in many cases a coincidental occurrence of the PLA2R-related MN and underlying disorder cannot be excluded. There may be exceptions: indeed, patients with MN associated with active sarcoidosis or replicating hepatitis B appear to have a high prevalence of PLA2R-related disease, which suggests that the immunologic setting of sarcoidosis and hepatitis B might trigger or enhance immunization against PLA2R [34, 36, 37]. Because therapeutic strategies are different for patients with idiopathic and secondary MN, discriminating between these two groups of patients is of utmost clinical importance.

In the majority of cases of MN, a biopsy is performed, and immunodetection of the PLA2R antigen (by immunofluorescence or immunohistochemistry) within the deposits in a fine, granular peripheral capillary wall pattern can establish the type of MN as PLA2R-associated. Immunostaining for PLA2R is more sensitive for PLA2R-associated MN than are the serologic assays [38], for the reason that circulating PLA2R-ab may not be detectable or not be present due to rapid absorption in the kidney in early disease or due to the achievement of immunological remission in individuals who remain proteinuric in later disease. This test enables the retrospective diagnosis of MN in archival, paraffin-embedded biopsy specimens, which is crucial for the monitoring of patients who will benefit from a kidney graft. It should be noted that there is a small proportion of cases of biopsy-proved MN who have detectable circulating PLA2R-ab, but do not stain for PLA2R within the deposits [37, 38]. It is possible that the antigen is masked by abundant PLA2R-ab targeting multiple epitopes or by another protein that limits detection with the commonly used commercial antibodies. Further study of such cases is needed to see if the circulating PLA2R-ab correlate with disease activity (see below) or if the PLA2R-ab might be non-pathogenic and an epiphenomenon.

A fundamental observation that has revolutionized the manner in which we monitor disease activity in MN is that, as the disease resolves, circulating PLA2R-decline and disappear in a manner that precedes and predicts clinical disease activity [39]. First noted in MN patients treated with the B cell depleting agent rituximab [40], the relationship between declining autoantibody and declining proteinuria holds for all immunosuppressive agents used in the treatment of PLA2R-associated MN [41–43]. PLA2R-ab are typically present in the setting of active nephrotic syndrome, are absent at clinical remission, and return with disease relapse [44] or in the setting of recurrent PLA2R-associated MN in the kidney allograft [45, 46]. Because high titers of

PLA2R-ab tend to take longer to disappear and/or are more resistant to therapy, they are associated with a lower chance of spontaneous [47] or immunosuppressive therapy induced remission [48] and with a higher risk of deterioration of kidney function [49]. A proposal for using PLA2R-ab in clinical practice was published several years ago [50] and the main tenets were incorporated into the 2021 Kidney Disease: Improving Global Outcomes (KDIGO) guidelines for glomerulonephritis (www.kdigo.org).

Role of PLA2R-ab-Related MN in Childhood

Although the bulk of the studies investigating the utility of monitoring PLA2R-ab has been from the adult MN literature, it is likely that the same principles could be applied to pediatric MN. However, the incidence of this type of MN is clearly less in children than adults, although exact numbers are not yet known. It is exceptionally rare for a child younger than 10 years old to have PLA2R-associated MN.

With more clinical and pathological testing for PLA2R and some of the more recently described types of MN, the field is gaining an understanding of the relevance of these forms of "adult" MN within the pediatric MN population. A number of studies have assessed the prevalence of PLA2R-associated MN by immunostaining pediatric MN biopsy registries in a retrospective manner for the presence of PLA2R within immune deposits. An early study focused on 22 MN cases with no clinical evidence for secondary disease, most between the ages of 10 and 17, and identified 10 cases (45%) positive for PLA2R [51]. In contrast, the PLA2R-negative cases were more likely to have secondary features on biopsy, although no clear secondary causes emerged with 3 years of follow up. These findings suggest a more diverse and currently incompletely explained set of etiologies in pediatric MN.

International studies confirm this prevalence of PLA2R-associated MN, largely within an adolescent population. A study of adolescents (10–19 years old) with primary MN in India revealed that the majority had PLA2R staining on biopsy, circulating PLA2R-ab antibodies, or both [52]. A higher prevalence of PLA2R-associated MN in children over the age of 10 is also suggested by a report from Japan [53]. These authors found 2 cases of PLA2R-associated disease amongst 19 patients in the 10 to 15-year-old group, but no cases amongst 15 patients aged 3–9 years old. A study from China also confirms a prevalence of PLA2R-associated disease in adolescents that is similar to that found in adult primary MN and a lower rate in younger children [54]. In this cohort, the mean age of the 16 PLA2R-associated cases was 12.9 years old, while that of the PLA2R-negative cases was 6.8 years old. Nearly 82% (9/11) of MN within the older 13–17-year-old group was PLA2R-associated, whereas only 7 of 27 (25.9%) were PLA2R-associated in the 1–12-year-old group. The authors do not report the ages of these seven PLA2R-positive cases. A final case series from Japan may have identified the youngest known patient with PLA2R-associated MN. Amongst 11 pediatric (age 4–14) patients with MN, a 6 year old with 2 g/day of proteinuria was found to have PLA2R-positive granular immune deposits on biopsy; serology was not available to confirm [55].

Pregnancy and Exposure to Maternal PLA2R-ab

Although no infants have ever been shown clinically to mount an autoimmune response to PLA2R, they can rarely be exposed to maternal PLA2R-ab in utero. This scenario is theoretically similar to the cases of alloimmune fetomaternal MN with anti-NEP in which podocyte-reactive antibodies cross the placenta to cause glomerular deposits in the fetus. There are several reports of pregnancy and active PLA2R-associated MN in a 39-, 43-, 33-, and a 21-year-old mother [56–59]. In three cases, the infant was born without any evidence of proteinuria or other abnormalities. In the fourth case [58], the infant was delivered early due to worsening oligohydramnios and at birth had similar PLA2R-ab levels as the mother, but levels subsequently declined. However, with

close follow-up, the infant was subsequently found to have developed proteinuria and an increased PLA2R-ab titer, which was felt to be due to ingestion/absorption of PLA2R-ab secreted in the mother's breast milk. A retrospective review of 27 women with primary MN and pregnancy showed adverse maternofetal outcomes in 10 cases [60]. Seropositivity for PLA2R-ab and the inability to achieve remission during pregnancy were risk factors for adverse events.

Additional Target Antigens Since PLA2R

Although PLA2R is the most common target antigen in primary adult MN, comprising about 80% of cases, more recent findings have implicated other target antigens or biomarkers that reveal other types of MN, some with different clinical and histologic phenotypes than the more common PLA2R-associated MN.

Thrombospondin Type-1 Domain-Containing 7A (THSD7A)

Five years after the description of the major target antigen PLA2R in adult MN, a second podocyte antigen called THSD7A was identified [61]. This protein is a well-conserved transmembrane protein that sits at the basal surface of the podocyte, directly beneath the slit diaphragms [62]. In much the same manner as the PLA2R/PLA2R-ab system, circulating antibodies to THSD7A were found in a minority of adult patients with primary MN, and appeared to correlate with disease activity [61]. THSD7A and IgG co-localized within immune deposits. Remarkably, several cases of malignancy associated MN were found to have been caused by tumor overexpression of THSD7A and regional lymph node activation of the humoral response [63, 64]. The association with malignancy may not be as common as initially reported, but is clearly greater than seen in PLA2R-associated MN [65].

THSD7A-associated MN is not common in children but can occur. The youngest patient identified with anti-THSD7A antibodies is a 4-year-old whose anti-THSD7A declined in response to treatment with rituximab [66]. A small retrospective cohort study from Germany demonstrated that 50% of their 12 pediatric MN cases had circulating antibodies to PLA2R [67], with tissue staining for PLA2R on biopsy also confirmed in two of these cases. The other six had no identifiable circulating antibodies to THSD7A, cationic bovine serum albumin (see below), or neutral endopeptidase. When Zhang and colleagues stained their 22 PLA2R-negative pediatric cases for THSD7A, none was positive [54]. It is not clear at this time what the overall prevalence of THSD7A-associated disease may be in children or adolescents.

Additional Antigens with Potential Secondary MN Associations

New findings may help to characterize cases of pediatric MN that fail to exhibit staining for PLA2R or THSD7A. Using the technique of laser capture microdissection followed by mass spectrometric analysis, Sethi and colleagues have identified a number of novel target antigens in forms of MN that were previously uncharacterized [5]. Several recent additions to the MN target antigen (or biomarker) repertoire have been identified using this methodology. NELL1 has been identified as a target of circulating antibodies in adults with MN [68]. The median age of patients diagnosed with this form of MN was nearly 67 years old, and one third of the cases were associated with underlying malignancy [69]. Several other markers or target antigens have been found that can point to underlying lupus as the etiology behind the MN. The exostosins 1 and 2 (EXT1/EXT2) are partners of a glycosyltransferase complex and seem to be a specific biomarker within deposits in a subset of secondary MN associated with lupus and other autoimmune diseases [70]. In similar manner, neural cell adhesion molecule 1 (NCAM-1) has

been found as the antigen targeted by circulating antibodies and present within immune deposits in more than 6% of class V (membranous) lupus nephritis cases and in a smaller percentage of apparently primary cases. The median age for these two types of MN was in the 30's so it is possible that adolescents and young adults could develop these types of disease.

Semaphorin 3B

Another of these novel target antigens is semaphorin-3B (Sema3B), which seems to associate with a type of MN more commonly found in the pediatric population [71]. In the initial report, 73% of cases were pediatric, with a mean age of 6.9 years old, while the remainder were adults with a still younger-than-average mean age of 36.3 years old. Nearly half of the pediatric cases were under the age of 2. Unique features of this type of MN are the presence of tubular basement membrane immune deposits (exclusively found in those cases <2 years old), a predominance of the IgG1 subclass within the deposits, and a possible inherited pattern of disease in some cases [71]. In addition, although circulating anti-Sema3B antibodies could be detected in the serum, these antibodies could only recognize the recombinant human Sema3B protein under conditions in which disulfide bonds were reduced, suggesting the presence of a cryptic epitope that would not normally be available to the anti-Sema3B antibodies when the protein is in its native state. It is hoped that similar techniques as the laser capture microdissection followed by mass spectrometry method will be useful for identifying further antigens specifically in the subset of pediatric MN.

Food Antigen-Related MN

An unusual form of secondary MN in children has been described in which there are high levels of antibodies to bovine serum albumin (BSA) [72]. These four children (all younger than 5) were found to have BSA in their bloodstream that was cationic (positively charged) which is atypical for the normal protein. BSA was detected in subepithelial immune deposits only in children with both anti-BSA antibodies and high levels of circulating cationic BSA, and it colocalized with IgG, in the absence of PLA2R-ab. IgG eluted from kidney biopsy samples of children with BSA deposits belonged to IgG1 and IgG4 subclasses and specifically reacted with BSA, but not with human serum albumin.

The source of BSA in children is most likely cow's milk, and the increased permeability of the intestinal barrier in infants and young children, possibly exacerbated by episodes of gastroenteritis, is hypothesized to have allowed the entry of the whole molecule into the circulation. The precise source of the cationic form of BSA is unknown, but this modification could be due to differences in food processing (powdered infant formula) or intestinal microbiota. It is of pathophysiological and historical interest that this type of human MN seems to be equivalent to a rabbit experimental model of MN developed in the 1980's in which cationic (but not the normally anionic) BSA could induce MN [73] (Fig. 18.1, middle). These clinical findings strongly support the scenario of "planted" antigens in human disease. Based on this finding, other ingested antigenic sources or non-dietary antigens from the environment should be considered as potential targets in cases of pediatric MN in which the cause remains a mystery.

Enzyme Replacement Therapy as a Cause of Alloimmune MN

The administration of recombinant enzymes or factors as replacement therapy for a genetic deficiency can lead to the development of alloantibodies. Alloantibodies may be without clinical significance or may lead to hypersensitivity reactions and decreased bioavailability and efficacy of the therapeutic proteins. They may also lead to formation of immune complexes of the replacement enzyme and alloantibody that occasionally become planted in a glomerular subepithelial location. This has occurred in a patient with

mucopolysaccharidosis type VI treated with human recombinant arylsulfatase B (rhASB) [74] (Fig. 18.1, middle). The clinical circumstances in this case, particularly the resolution of proteinuria when ERT was suspended, and the finding that IgG eluted from the biopsy specimen reacted specifically with rhASB, strongly suggested that the alloimmune response to the recombinant enzyme was the cause of the disease. Other cases of nephrotic syndrome associated with MN-like subepithelial immune complexes have been induced by immune-tolerance induction regimens in which increasing doses of enzyme replacement therapy (e.g., alpha-glucosidase in Pompe disease) [75] or factors (factor IX in hemophilia B) [76] have been administered in an attempt to limit inhibitory alloantibodies.

The Case of Secondary MN

Despite our knowledge of specific proteins that comprise the immune deposits in the forms of MN described earlier in the chapter, the molecular characterization of the immune complexes in most secondary forms remains limited. Hepatitis B, hepatitis C and Helicobacter pylori antigens, tumor antigens, thyroglobulin, and DNA containing material have been detected by elution from or immunostaining of subepithelial deposits in patients with secondary MN [77, 78]. These antigens may have been trapped in the GBM owing to unusual physicochemical properties similar to what is thought to occur with cationic BSA. Alternatively, small-sized, circulating, non-precipitating IgG4 complexes containing these antigens could become deposited in the GBM as in the chronic serum sickness model, although there is no experimental evidence yet supporting this hypothesis in humans.

Genetic Factors

The finding that different forms of MN occur in different age groups may imply a complex interaction of environmental influences with an underlying genetic susceptibility. It has long been known that European Caucasians show a strong association of MN with the HLA-B8 DR3 haplotype and other HLA class II loci [79, 80]. The first genome-wide association study (GWAS) conducted, with only 556 white European adults with idiopathic MN was, sufficient to show a highly significant interaction with *HLA-DQA1* as well as *PLA2R1* [81]. The risk variants at these sites displayed an unusually strong genetic interaction such that homozygosity for the risk variants at both locations conferred an almost 80-fold increase in the risk of MN [82]. These genetic data were confirmed in ethnically distant populations from Europe [49, 83] and Asia [84–86]. Robust genetic data are lacking in children, where the prevalence of PLA2R-related MN is much lower.
