Subsequent work has raised appealing suggestions as to what might underlie the robust genetic interaction between the HLA class II locus and PLA2R1 [87]. Although there was early speculation that rare single nucleotide variants leading to amino acid changes in the sequence of PLA2R might alter protein conformation, this theory was felt not to be the case as there were not specific coding variants that associated with disease [88]. A higher resolution GWAS conducted across 3782 cases of MN and over 9000 controls points to an intronic, regulatory region of *PLA2R1* that might confer increased expression of the antigen within the kidney or potentially other tissues [89]. Since the PLA2R protein is highly disulfide bonded and difficult to express in experimental settings, a genetically driven overexpression of the protein could lead to protein misfolding and presentation of aberrant protein to the immune system.

A series of studies largely from China have pointed to discrete regions within the class II MHC molecules that have been genetically linked to MN [90–92]. The most significant genetic associations can be pinpointed to variants that are predicted to alter the amino acid sequence within the binding groove of the molecule that presents peptides to the T cell receptor [89, 91, 92]. Such variants are predicted to allow PLA2R fragments to bind with potentially higher affinity to the HLA molecules encoded by the risk variants than

to molecules encoded by other alleles and may therefore represent a mechanism why some genetically-predisposed individuals might more easily mount an autoimmune response to the self-protein PLA2R.

Other non-HLA alleles also predispose individuals towards the development or progression of MN such as the tumor necrosis factor (TNF) allele G308A, and polymorphisms in genes encoding IL-6, STAT4, nephrin, and plasminogen activator inhibitor type-1 (PAI1) [93]. A very large GWAS performed in MN on an international scale [89] points to two other risk loci: one in the gene for interferon response factor 4 (*IRF4*) and one within nuclear factor kappa B (*NFKB1*), suggesting that susceptibility lies in other arms of the immune regulatory system as well. Overall, these data suggest that a combination of gene variants initiates disease, and that modifier genes controlling glomerular permeability, inflammation and fibrosis might be involved in the pathogenesis of MN.

Clinical Presentation

Children with MN classically present with nephrotic syndrome or isolated sub-nephrotic proteinuria. They have hypoalbuminemia, proteinuria and may have edema on presentation. Most children have normal renal function at presentation. Microscopic hematuria is commonly seen in children, and in one study was found in 77% of children at the time of biopsy [94]. In the same pediatric cohort, eGFR at the time of biopsy was normal at 107 mL/min/1.73 m^2 [94]. The incidence of thromboembolism in children at presentation and during the course of the illness was significantly lower compared to adults [94].

It is not uncommon for children to be initially treated with oral corticosteroids for presumed minimal change disease and for MN to be discovered instead when a biopsy is performed weeks later after the patient is found to be partially responsive or non-responsive to steroids. It is also possible that there is a subset of children with MN that either spontaneously remit or respond to prednisone, who do not get biopsied. This would be another factor limiting the determination of the true incidence of MN in children.

Distinguishing primary from secondary MN based on presentation alone is challenging. A detailed history for concomitant illnesses, recent travel and review of systems may elicit signs and symptoms of an underlying illness that would predispose a child to secondary MN. The incidence of serum PLA2R-ab and tissue PLA2R positivity at diagnosis in children has not been widely studied, with reports showing a varying degree of seropositivity, ranging from 45 to 70% [51, 95], and the specificity of these findings for primary disease is not known. Secondary etiologies of MN may present in similar fashion to primary disease, and an underlying cause is not always readily apparent. Due to the decreasing prevalence of HBV-associated MN, SLE is now the most common secondary etiology of pediatric MN. Very importantly, class V lupus nephritis can be the initial presentation of SLE in the absence of extra-renal manifestations and of serological manifestations of SLE such as hypocomplementemia or anti-double stranded DNA antibodies, which will often appear later.

Laboratory Investigations

The child or adolescent that presents with features of nephrotic syndrome should undergo standard serological workup that includes antinuclear antibodies (with anti-double stranded DNA as a confirmatory test), levels of C3 and C4, and screening tests for hepatitis B infection. Due to the possibility of finding serologically active MN, testing for PLA2R-ab should be considered in the older child or adolescent even before a biopsy diagnosis of MN is available. Specialized tests, such as anti-Sema3B, may one day be clinically available, but are currently limited to the research setting.

Children with hepatitis B-related MN show positivity of hepatitis B surface antigen (HBsAg) and usually hepatitis B surface antibody is not detected. The hepatitis B early antigen (HBeAg) can be detected in serum of 90% of patients.

Hypocomplementemia (low C3 and C4) is observed at disease onset, but levels of C3, C4 return to normal later in the disease course. Circulating immune complexes are detected in 80% of patients. Serum levels of transaminases may be elevated on presentation, which may lead the clinician to order viral hepatitis testing.

Histopathology

The glomerular features seen in membranous nephropathy are a result of the subepithelial deposits and the extra basement membrane material that is laid down surrounding them in response.

The typical *light microscopic* findings in adult MN are normal-to-enlarged glomeruli with thickened and rigid capillary walls, but without elements of proliferation. With the use of Jones' methenamine silver stain, which stains the GBM, there are spikes of new matrix between deposits in the GBM, and the deposits may be suggested by craters of absent staining (Fig. 18.2). Biopsy features in pediatric disease are similar, although mesangial deposits and a segmental distribution of the deposits seem to be more common in pediatric versus adult disease (Table 18.1). Features such as mesangial hypercellularity should prompt the clinician to look for evidence of secondary causes of disease, especially lupus.

In addition to the glomerular findings, it is important to also consider the overall health of the renal parenchyma, as prolonged glomerular disease may lead to tubulointerstitial injury. As with many glomerular diseases, the presence of glomerulosclerosis, interstitial fibrosis and tubular atrophy are signs of chronicity and tend to be associated with diminished GFR and a poorer prognosis. Intraparenchymal B cell infiltrates forming tertiary lymphoid structures have been demonstrated in human MN and other autoimmune glomuleronephritides [96, 97].

Immunofluorescence (IF) can be the most sensitive of the imaging modalities to suggest the presence of MN. In most cases of MN, there are fine granular deposits of IgG (Fig. 18.3) and C3 decorating the peripheral capillary walls in a global and diffuse distribution. The degree of complement deposition has been correlated with

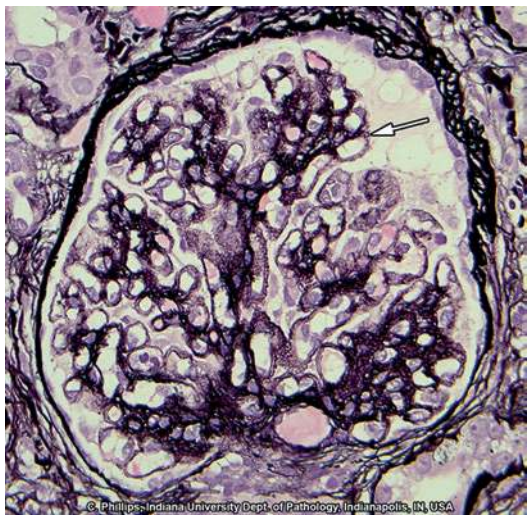

Fig. 18.2 Brightfield microscopy. Jones' silver stain of a paraffin tissue section reveals pinholes (arrow) and spikes along glomerular basement membranes (GBM) from a patient with membranous nephropathy. This GBM distortion is in response to deposition of immunoglobulin and complement (original magnification 400×). Image courtesy of Carrie L. Phillips MD, Department of Pathology, Indiana University School of Medicine

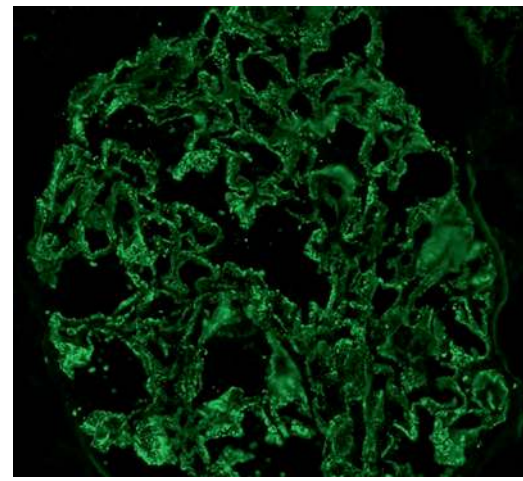

Fig. 18.3 Widefield epifluorescence microscopy. Direct immunofluorescence using fluorescein-tagged antibody to IgG shows granular deposits along glomerular capillary loops in a patient with membranous nephropathy (original magnification 400×). the rate of progression of kidney dysfunction [98]. The detection of additional immunoreactants such as C1q, IgA, and IgM can point to the presence of a secondary cause of MN. The target antigen (PLA2R, THSD7A, Sema3B) when assayed will yield a similar pattern, and co-localization studies on the same tissue section will show nearly identical patterns. Although most cases of adult MN demonstrate the global pattern in which all capillary loops exhibit immune deposits, a minority of pediatric cases will show a segmental pattern, with some loops apparently being spared from the deposits. The pathophysiological reasons behind this are currently not known.

Electron microscopy (EM) can be helpful, but it is often not needed to make the diagnosis (Fig. 18.4). EM is useful for detecting the size and distribution of deposits, and the degree of matrix reaction to the deposits. In primary disease, the deposits are largely subepithelial, while the presence of significant mesangial and/or subendothelial deposits suggests secondary etiologies of disease. The presence of tubuloreticular inclusions in endothelial cells, a sign of the interferon response, usually points to the presence of lupus or a viral infection such as HIV. Features of podocyte injury and simplification on EM are the effacement of the basal foot processes and loss of slit diaphragms, as well as the microvillous change on the apical side of the podocyte cell body.

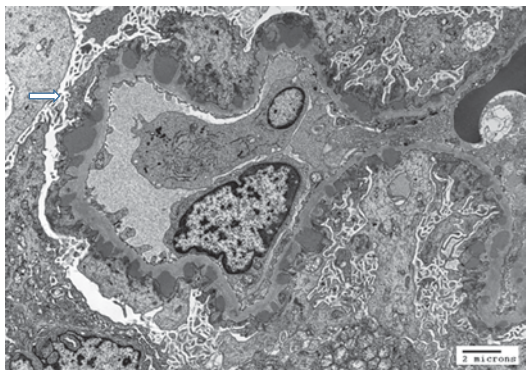

Fig. 18.4 Transmission electron microscopy. This electron micrograph shows subepithelial electron dense deposits (white arrow) along glomerular basement membranes, including some separated by spikes of extracellular matrix. Podocyte foot process effacement is extensive. Image courtesy of Carrie L Phillips MD, Department of Pathology, Indiana University School of Medicine

The appearance of the electron-dense subepithelial deposits has traditionally been described as morphological stages [99]. The stages based on combination of light and electron microscopic features are as follows:

- Stage 1. Light microscopy shows normal GBM in thickness and appearance. The electron dense deposits are small and flat but discrete. The smaller deposits are often located at the site of the slit diaphragm, while larger deposits are located immediately adjacent to the effaced foot processes.
- Stage 2. Thickening of the GBM is discernible by light microscopy. The electron dense deposits are increased in number and size. These deposits are flanked by prominent spikes in almost every capillary loop.
- Stage 3. The basement membrane material (spikes) completely surrounds the deposits. These are larger and acquire intramembranous position. The capillary wall is irregular and has a moth-eaten appearance.
- Stage 4. The GBM is severely altered and irregularly thickened. The deposits are only a few in number or completely absent. The vacuolated appearance of GBM is discernible. The loss of deposits is seen as electron-lucent areas in the basement membrane.

Investigators have more recently introduced a Stage 0 in the setting of recurrent MN in the kidney allograft [100], often seen in early protocol biopsies or biopsies conducted to explore delayed graft function. In this stage, fine granular deposits of IgG can be seen by the highly sensitive IF technique, while there are no discernible electron dense deposits by EM. This stage is virtually never seen in native kidney biopsies, as there are no clinical features present at that time that would warrant a kidney biopsy.

The most common stages of deposits found in childhood MN are stages 2 and 3, which can occur in a mixed (heterogeneous) pattern. Since children with nephrotic syndrome are often tri-

aled on corticosteroid therapy prior to consideration of biopsy, the potentially longer duration between clinical symptoms and biopsy may explain the paucity of earlier, stage 1 lesions.

Specific Diagnostic Approaches

Many of the etiologies of pediatric MN are rare, and it may be difficult to rule out all potential causes. Research or clinical groups who specialize in such disorders should be contacted for further advice on testing. Much of the testing will rely on immunostaining the biopsy in a validated protocol to look for the presence of potential antigens (e.g., Sema3B, NEP, BSA) within the immune deposits. It is not expected that a renal pathologist will have the resources to look for all such antigens, and thus the availability of extra sections to send to specialized centers might be critical in making a diagnosis. Serological tests may be available for certain antigens in the future. Some specialized centers have the ability to query the proteins that accumulate over time in the deposits by means of laser capture microdissection of the glomeruli from tissue sections and then to perform mass spectrometry. This methodology is not clinically available, but may provide a diagnosis in the research setting.

Prognosis and Predictors

The course of primary MN is variable. As a general rule in adult MN, approximately one third of patients undergo spontaneous remission and maintain normal renal function with or without occasional relapses [101, 102]. Another third of patients display persistent proteinuria of variable degree, with normal or mildly impaired but stable GFR. The remaining patients develop progressive chronic kidney disease (CKD) eventually leading to ESKD. In a review of natural history studies in untreated adults with MN, 50% of these patients either died or developed ESKD within 10 years of disease onset [101].

Children seem to have a relatively better overall outcome than adults [103], with some of the more recent series reporting overall remission rates of 75% [1, 104] (Table 18.1); however, most studies still show decreased kidney function in about 20% of patients at final follow-up [1, 105]. It should be emphasized that the existing information about natural history and treatment outcomes of primary MN in children is not only uncontrolled, but there is considerable variability regarding the therapeutic protocols used and the definition of remission. Individually based decisions are therefore of paramount importance to minimize the risk of progression to renal failure.

Unfortunately, predictors of outcome are still poorly defined in children. The degree of proteinuria seems to be a valuable predictor of outcome, which is excellent in children with asymptomatic, non-nephrotic proteinuria; however, approximately 25% of those with nephrotic syndrome will develop renal failure within 1–17 years. In one cohort, all patients who developed CKD presented with nephrotic syndrome [106]. Hypertension and interstitial fibrosis on biopsy might be further predictors of adverse outcome [104, 105].

In adults, there is no difference in response to treatment between PLA2R-ab positive and PLA2R-ab negative patients, although the response rate to rituximab appears to be lower in patients with a high titer of antibodies [107]. Further studies are required to assess how the PLA2R-ab antibody titer may be of prognostic value in children.

As with adults, in children with PLA2R-related MN the quantification of PLA2R-ab antibodies will likely become an invaluable tool for the monitoring of disease immunological activity and the titration of immunosuppressive treatments. Antibodies disappear before proteinuria in patients treated with rituximab [40, 42], which leads to consideration of withdrawal of immunosuppressive treatment at the time of immunological remission before renal remission is achieved. The time-lag between immunological and renal remission most likely corresponds to the time required for restoration of the glomerular capillary wall. PLA2R-ab antibody levels at the end of therapy may also predict the subsequent course. In a series of 48 patients treated with immuno-

suppressive agents, 58% of antibody-negative patients were in persistent remission after 5 years compared with none of antibody-positive patients [107]. However, further prospective studies on large cohorts of patients are needed before drawing definitive conclusions and extrapolating them to children.

Treatment

The first step in the approach to treatment is ruling out secondary causes of MN including lupus, hepatitis B and C. In cases of secondary MN, treating the underlying condition results in resolution of MN. Removal of potential offending agents such as non-steroidal anti-inflammatory agents or cow's milk in infants with suspected cationic-BSA induced MN is required in these specific situations. The treatment of pediatric membranous (class V) lupus nephritis is discussed at the end of this section.

Currently, no randomized controlled trials addressing treatment of primary MN in children exist, which represents a substantial limiting factor in determining the most efficacious regimens for children with MN. Even studies predicting natural disease course are scant and limited to small cohorts. Therefore, most treatment recommendations stem from the data in adult patients. This also has its limitation given that the underlying disease mechanism in children may be different from that in adults. Serum PLA2R positivity in children appears to be lower at around 45% in children compared to 70% in adults, suggesting different pathophysiological mechanisms are often present in the pediatric population [51].

A second step in deciding on treatment course is to determine the degree of nephrosis. As with adults, it seems reasonable that children with asymptomatic, non-nephrotic presentation may be treated conservatively with angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) for their anti-proteinuria and nephroprotective effects, along with lifestyle modifications, including a low-salt diet. This would give time for spontaneous remission to occur, which would obviate the need for immunosuppression. Therapy in children who subsequently develop or initially present with the nephrotic syndrome and nephrotic range proteinuria remains controversial. In the adults, there is a growing body of literature suggesting superiority of treatment with rituximab compared to other immunosuppressive agents. Regimens described in the pediatric and adult cohorts are discussed in detail below.

The 2021 KDIGO guidelines (www.kdigo.org) are based on evidence from adult studies and recommend conservative treatment in subjects with eGFR >60 mL/min/1.73 m^2 and proteinuria <3.5 g/day. If, however, one or more risk factors for disease progression are present then treatment with rituximab, a combination of cyclophosphamide and steroids for 6 months, or tacrolimus therapy for at least 6 months should be considered. Risk factors for disease progression include: eGFR <60 mL/min/1.73 m^2, proteinuria >4 g/day and no decrease in 6 months despite conservative therapy, high PLA2R-ab titers, significant low-molecular-weight proteinuria or life-threatening complications of nephrotic syndrome. There are no specific treatment recommendations in children, but it is noted that therapy is often initiated prior to 6 months and that rituximab and calcineurin inhibitors have been used as treatment options in children.

There is a report of the clinical characteristics and treatment response in a large, prospectively followed cohort of 48 children in India ranging from age 1 years to 20 years with primary MN [95]. The median follow-up was for 29 months and the median age was 17 years. All except one patient, who underwent a spontaneous remission, were treated with immunosuppression. The predominant treatment regimens were a minimum of 3 months with a combination of cyclophosphamide with glucocorticoids (GC; 53%), tacrolimus with GC (21%), and rituximab (15%). Response rates in the three treatment groups were similar. Remission rates were 62.2% and 70.5% at 6 and 12 months, respectively. Of note, in subjects with resistant or relapsing disease, rituximab was used as a second agent with considerable success. Serum PLA2R-ab positivity was similar to that in adult primary MN patients at 72.9% (35

subjects). In addition, the study observed a reduction in PLA2R-ab titer with disease remission/resolution [95].

Another study reported treatment patterns in a North American and European cohort of 37 children with primary MN enrolled in the Cure Glomerulopathy Network [94]. The median age was 14 years with a follow-up of 23 months. Children who had received 6 weeks or less of glucocorticoids prior to the time of the kidney biopsy were considered immunosuppression naïve and enrolled in this cohort since most children are initially treated for presumed minimal change disease without a biopsy. Twenty-three (59%) of the children were placed on immunosuppressive therapy (IST) within 6 months after biopsy, with 70% initiating IST at any time within the follow-up period. The median time to initiate IST after the diagnostic biopsy was 1.9 months. It is important to highlight that 30% of the children did not receive any IST, which is in line with some other studies. Renin-angiotensin-aldosterone system (RAAS) inhibitors were used in 73% of the children [94]. Interestingly, the first line IST treatment most commonly prescribed in children in this group were calcineurin inhibitors (46% of the 26 children that were treated). However, since this cohort included children who may have had GC prior to biopsy, it is possible that the true exposure to GC is higher if including the treatment pre-biopsy. Seven children (27%) received 30 days or more of GC as a first line single agent. Rituximab as a single agent and first line therapy was used in 4 children (11%) and mycophenolate mofetil in two children. As part of combination therapy, up to 76% of children in the treated group received GC. Seven of 26 children were transitioned to a second-line agent [94]. There were no differences observed in clinical characteristics at presentation in the group of children that were treatment with IST compared with the children who were managed with conservative therapy. This study emphasizes the variability in approach in treating children with MN, probably a result of limited evidence for a specific treatment strategy.

In an older series that predated the use of rituximab, Valentini et al. reported treatment outcomes in 12 children with biopsy proven primary MN [108]. The mean age was 11.9 years and mean follow up time was 27 months. Two patients did not receive any IST and entered spontaneous remission. The remaining ten patients were treated with oral prednisolone 2 mg/kg/day (maximum 80 mg/day) for 4–8 weeks. One patient responded to GC alone, four patients were partially-responsive, and five patients did not respond. Cyclophosphamide (2 mg/kg/day orally for 12 weeks) was used as a second line agent for the five steroid resistant patients, one partial responder, and one initially steroid-responsive subject who became steroid dependent. This treatment regimen resulted in complete remission in all but one subject who was steroid resistant [108]. There were no clinical differences at presentation in the nine children that ultimately demonstrated complete remission compared to three children that did not.

A report from India described five children with MN, ages 5–13 years. All had positive PLA2R staining of the kidney biopsy tissue and three had a positive PLA2R-ab titer at the time of biopsy [52]. These subjects had already received oral prednisolone prior to the biopsy. Two patients were treated with the modified Ponticelli protocol (pulse methylprednisolone, oral prednisone and cyclophosphamide). The remaining three were treated with tacrolimus and oral prednisone [52]. All 5 patients were in complete or partial remission by 12 months. PLA2R-ab disappeared at 6 months in one patient with complete remission and declined by 50% in another patient with a partial remission. This study suggests that in children with PLA2R-ab positivity, a response to therapy will trend with reduction in PLA2R-ab titer.

A retrospective study performed before the era of PLA2R-ab described a Korean cohort of 19 children with primary MN with a median age of onset of 11 years [1]. There were 11 children with nephrotic syndrome at presentation and eight children with proteinuria without nephrotic syndrome at presentation. In the latter group, children without nephrotic syndrome, three children did not receive any IST and entered spontaneous remission. Five children received varied

regimens of corticosteroids and some also received cyclosporine. All five subjects eventually entered remission at time ranging from 1 month to 33 months after treatment. In the second group, 11 children with nephrotic syndrome, all were treated with either prednisone alone (varied regimens) or in combination with cyclosporine. Six entered remission by a median time of 12 months, but five children did not demonstrate any response to steroids or additional IS. The authors report that at last follow-up, in the 11 children with nephrotic syndrome at presentation, six had entered remission, two had persistent proteinuria with normal renal function, one patient had CKD and two patients had progressed to ESKD [1].

Current treatment recommendations are from clinical trials in the adult MN population. The GEMRITUX trial in France compared nonimmune antiproteinuric therapy (NIAT), defined as ACE inhibitor or ARB, for 6 months to the use of rituximab 375 m/m^2 given IV for two doses 1 week apart along with NIAT [109]. When this trial was initiated, there was no objective evidence of the benefits of rituximab outside of smaller pilot studies [110–112] and a large observational cohort [42, 113] in adult patients with primary MN. The patients in the GEMRITUX study were age 18 years or older, had biopsy proven primary MN and nephrotic syndrome at the time of enrollment. At 6 months, 35% of the patients receiving NIAT-rituximab combination therapy had achieved remission compared to 21% in the group receiving NIAT alone. A significant reduction in PLA2R-ab was noted in the group receiving NIAT-rituximab. By 6 months, 50% of the NIAT-rituximab group had achieved immunologic remission (disappearance of PLA2R-ab) compared to only 12% in the NIAT alone group [109]. Complication rates in the two groups were similar.

In 2019, the MENTOR trial compared the use of rituximab 1000 mg IV given in 2 doses 14 days apart, with an additional cycle at 6 months if needed, to cyclosporine taken orally at a dose of 3.5 mg/kg/day for 12 months [114]. Study subjects had 5 g/day or more of proteinuria, a GFR of 40 mL/min/1.73 m^2 or greater and had received ACE inhibitor or ARB for at least 3 months. At one-year, complete or partial remission rates were similar: 60% in the rituximab group and 52% in the group receiving cyclosporine. However, at 24-months, complete or partial remission was more common in the rituximab group (60%) than in the cyclosporin group (20%) [114] due to a high number of relapses during cyclosporine tapering and withdrawal.

The results of the GEMRITUX and MENTOR trials support the effectiveness of rituximab in adults with primary MN. In addition, rituximab likely has a more favorable side effect profile than cytotoxic agents and glucocorticoids. The most effective dosing regimen for treating MN with rituximab is not clear. This was partially addressed by a comparison of the use of two infusions of 1 g of rituximab at a 2-week interval in 28 patients from the NICE cohort to rituximab dosed at 375 mg/m^2 given as two infusions at a 1-week interval in 27 participants from the GEMRITUX cohort [115]. Patients in both cohorts had high levels of PLA2R-ab. At 6 months, 64% of the participants from the NICE cohort were in remission compared to 30% from the GEMRITUX cohort [115]. The median time to achieve remission in the NICE cohort was 3 months and 9 months in the GEMRITUX cohort. Participants in the NICE cohort had lower levels of PLA2R-ab at 6 months compared to those in the GEMRITUX study. This suggests that a higher dose of rituximab in adults with primary MN may result in an improved response. The ideal dosing regimen in children remains unknown.

One of the main drawbacks of the use of calcineurin inhibitors such as cyclosporine and tacrolimus for treatment of MN is the high proportion of patients that experience a relapse once the medication is tapered and discontinued. The dramatic drop in the number of clinical remissions observed between 12 and 24 months in the MENTOR trial provides recent evidence of this limitation [114]. The STARMEN trial sought to reduce the rate of relapse by introducing a single dose of rituximab prior to tapering the calcineurin inhibitor [116]. In this study, 6 months of the modified Ponticelli regimen (6 months of alter-

nating corticosteroids and cyclophosphamide) was compared to a 6 month course of tacrolimus, with 1 g rituximab given at 6 months, before a 3 month tacrolimus taper. The corticosteroid-cyclophosphamide group had a significantly higher rate of clinical remissions at 24 months (83.7% partial or complete remissions) versus the 58.1% rate in the tacrolimus-rituximab group [116]. Despite this outcome, there were fewer (12%) relapses after tapering tacrolimus than the 30–40% rate that is typically observed.

The RI-CYCLO trial was a randomized trial in adults comparing rituximab 1 g on days one and 15 to a 6 month cyclic regimen of corticosteroids alternated with cyclophosphamide every other month [117]. The cumulative dose of cyclophosphamide per patient was 180 mg/kg. Outcomes and adverse events in both groups were similar. At 12 months, 62% of the patients in the rituximab group were in complete or partial remission, and this number increased to 85% at 24 months. In comparison, 73% of patients in the cyclic treatment group were in complete or partial remission at 12 months, and by 24 months the percentage had increased to 81% [117].

Safety

The potential adverse effects of immunosuppression should be considered when deciding on treatment. Since pediatric MN may undergo spontaneous remission more often than in adults, many patients can be monitored, with the clinical course and PLA2R-ab levels in some patients determining whether the disease is likely to improve without intervention or cause long-term morbidity. For cyclophosphamide, gonadal toxicity and bone marrow suppression leading to heightened infection risk are major concerns. Peripheral blood counts should be monitored and the cytotoxic agents withheld at a total leukocyte count <3000/mm^3 or in the presence of an active infection. Calcineurin inhibitors have less of an infection risk, but there is a risk of nephrotoxicity with prolonged blood levels above the therapeutic range. Trough blood levels be monitored regularly, and whenever there is an unexplained rise in the serum creatinine (>20%) during therapy. Rituximab can be associated with infusion reactions, reactivation of latent infections, or hypogammaglobulinemia. Potential long-term adverse effects, especially in the pediatric population, are not yet known due to its relatively recent introduction for treatment of nephrotic syndrome in children.

Class V (Membranous) Lupus Nephritis

Nearly half of pediatric lupus cases will be complicated by some form of lupus nephritis, and of these, more than one quarter have class V lesions, either in isolation (16%) or in combination with other (class II, III, or IV) lesions (12%) [118]. GFR tends to be better preserved over time in patients with pure class V lesions than in patients with overlap with class III or IV, but the vast majority of pediatric lupus MN patients are treated with immunosuppressive therapy, often due to the presence of additional extrarenal features. Data from the Childhood Arthritis and Rheumatology Research Alliance, representing a majority of pediatric rheumatology centers across the United States, demonstrate that most patients with class V lupus nephritis receive hydroxychloroquine (98.7%), mycophenolate (91.9%) and daily corticosteroids (96%), with smaller proportions treated with cyclophosphamide, rituximab, calcineurin inhibitors or azathioprine [118]. As with primary MN, the majority of patients are nephrotic, and one center reported that 78% of cases received RAAS inhibitors [119]. In this single center cohort, 74% of isolated class V lupus nephritis patients achieved complete remission at 24 months, but no specific predictors of clinical outcome were found [119]. Achievement of complete remission was not rapid, and can take years. Proliferative features were present in 13% on repeat biopsy; close monitoring of renal function, proteinuria and hematuria is essential.

Conclusions

Membranous nephropathy is an uncommon cause of nephrotic syndrome in children. The diagnosis is usually established when the children are biopsied after being labeled as steroid resistant. It is imperative to evaluate the patient for secondary etiologies since these may respond to treatment of the underlying condition. The initial management of idiopathic MN should generally be conservative. Immunosuppressive therapy should be considered in those children with nephrotic-range proteinuria and/or progressive renal dysfunction. We anticipate that advances from adult disease, including the identification of new target antigens and experience using circulating autoantibodies to guide treatment decisions, will be incorporated into improved treatment and monitoring of pediatric MN.

19 Postinfectious and Infectious Glomerulopathies

Velibor Tasic and Mignon McCulloch

Introduction

It is important to utilize the correct terminology when describing the infection-related glomerulopathies. In order to better understand the pathogenesis and management of infection-related glomerulonephritis (GN), Nadasdy and Hebert suggest classification as either postinfectious GN or the GN of active infection [1]. Acute postinfectious GN (APIG) is the most common pathology in lower and middle-income countries (LMIC) and is due to a wide spectrum of infective agents. The prototypical APIG is acute poststreptococcal GN (PSGN). In APIG the infection is mild and has usually resolved spontaneously or with antibiotics at the onset of GN, 1–3 weeks later.

Conversely, in GN due to active infection the patient develops infection which does not resolve spontaneously; very often antibiotics are not administered since the infection is not recognized or not considered to be serious. Several weeks after infection begins the patient develops GN, which manifests with hematuria, proteinuria, acute nephritic syndrome or kidney failure. In contrast to postinfectious GN, where antibiotics have no effect on the course of the GN, administration of antibiotics in GN due to active infection eliminates antigen production, ultimately leading to resolution of the GN.

The clinical presentation of infection-related GN varies from subclinical disease to severe acute kidney injury, with the majority of patients having a mild clinical course. There is a growing list of organisms which may cause infection-related GN (Table 19.1).

The pathogenesis of infection-related GN is secondary to (1) formation and deposition of circulating immune-complexes in glomeruli (2) implantation of the antigen in glomerular structures, initiating immunologic reactions and formation of immune-complexes in situ or (3) modifications of native glomerular structures, which become autoantigens [2]. The end result is activation of the complement system and coagulation cascade, and production of proinflammatory cytokines, adhesion molecules and chemoattractants. This leads to proliferation of glomerular cells and infiltration with polymorphonuclear cells.

The most common histological presentation of infection-related GN is diffuse endocapillary or proliferative GN (group A Streptococcus, Streptococcus viridans, Staphylococcus aureus, Diplococcus, Brucella melitensis, measles, mumps, varicella, Cat scratch disease and others),

Table 19.1 Etiological agents associated with infection-related glomerulonephritis

Bacterial	Viral	Fungal	Parasites
• Streptococcus group A, C, G • Streptococcus viridans • Staphylococcus (aureus, albus) • Pneumococcus • Hemophilus • Neisseria meningitis • Mycobacteria • Salmonella typhosa • Klebsiella pneumoniae • E.coli • Yersinia enterocolitica • Legionella • Brucella melitensis • Listeria • Leptospira • Treponema pallidum • Corynebacterium bovis • Actinobacilli • Cat-scratch bacillus	• Coxsackievirus • Echovirus • Cytomegalovirus • Epstein Barr virus • Hepatitis B, C • HIV • Rubella • Measles • Varicella • Vaccinia • Parvovirus • Influenza • Adenovirus • Rickettsial scrub typhus • Mumps • Hantavirus • Rotavirus	• Coccidioides immitis • Candida • Histoplasma	• Plasmodium malariae • Plasmodium falciparum • Schistosoma mansoni • Leishmania • Toxoplasma gondii • Filariasis • Trichinosis • Trypanosomes • Echinococcus

but it may present as focal or diffuse crescentic GN (Streptococcus, Staphylococcus aureus, varicella, Treponema pallidum). Mesangiocapillary GN is associated with hepatitis C virus and Streptococcus viridans infections. Membranous GN occurs in infections with hepatitis B virus, syphilis, filaria, schistosoma, mycobacterium, and Plasmodium falciparum. Mesangioproliferative GN (focal or diffuse) is associated with Diplococcus, salmonella, hepatitis B virus (childhood vaccination has resulted in decline in this condition), influenza virus, and adenovirus infections. Focal segmental, necrotizing and sclerosing GN is seen in bacterial endocarditis; mesangiolytic GN occurs with ECHO virus infections.

The initial infection may be mild or severe. Examples of more severe infections include pneumonia, meningitis, sepsis, endocarditis, and ventriculoatrial shunt infection [3–6]. The GN may be mild (asymptomatic proteinuria and hematuria), but patients may develop hypertension, circulatory congestion, nephrotic syndrome, and acute kidney injury. Usually there is transient hypocomplementemia.

As previously reviewed, kidney biopsy shows various glomerular lesions, of which the most common is acute endocapillary and proliferative GN, but tubulointerstitial injury also may be present [7]. Immunofluorescence (IF) studies show granular deposits of immunoglobulins and complement. Treatment of GN of active infection must include antibiotics to address the infection, with additional interventions if the infection does not respond to antibiotics alone (e.g., shunt removal, abscess drainage).

In LMIC countries, the incidence of PSGN has declined over the past 5 decades, although is still commonly seen in some countries. In contrast, Staphylococcus aureus, including methicillin-resistant strains, has increased as an etiology of GN, particularly in older adults and diabetics, who often have worse clinical features and outcomes [1, 8–10]. Kidney biopsy shows diffuse glomerular endocapillary hypercellularity with neutrophil infiltration on light microscopy; dominant IgA deposits on IF; and the presence of subepithelial humps on electron microscopy (EM). This entity was entitled IgA dominant postinfectious GN and should be differentiated from classic IgA nephropathy because of different treatment strategies. Kimata et al. [11] described the youngest patient, a 6 year old girl with methicillin-resistant Staphylococcus aureus-

associated GN who initially presented with pneumonia. Vigorous antibiotic treatment resulted in resolution of the GN; in contrast, corticosteroid treatment failed.

It is believed that the outcome of infectious related GN is benign, but in the case of acute kidney injury and crescents on biopsy, corticosteroids, methylprednisolone pulses and cyclophosphamide may be benefitial [6]. The literature is sparse with studies dealing with long-term prognosis of non-streptococcal GN. In a study from Milan 50 adult patients with infection associated GN have been followed for 90 ± 78 months; at the last observation 37% had renal insufficiency or were on hemodyalisis [12]. The unfavourable outcome was due to the underlying disease and presence of interstitial infiltration on kidney biopsy.

Post-streptococcal Glomerulonephritis

PSGN is still the most common glomerulopathy in LMIC countries. The disease is characterized by the acute onset of nephritis, potentially including hematuria, edema, hypertension, oliguria and azotemia [2, 13]. It was recognized as a complication of scarlet fever in the eighteenth century. Due to improved living standards and medical care, PSGN is uncommon in western countries, mainly occurring as sporadic cases [14–16].

Epidemiology

PSGN occurs worldwide [17–22]. It is a complication of pyoderma due to hot climate and high humidity in tropical countries. Skin injuries, insect bites (such as scabies), and poor hygiene and sanitation predispose to infection with group A beta hemolytic streptococcus (GABHS) [23]. In countries with moderate and cold climates, PSGN is usually a complication of upper respiratory tract infections (pharyngitis) during the winter months. Streptococcal M types 2, 47, 49, 55, 57, 60 are associated with PSGN following pyoderma, while M types 1, 2, 3, 4, 12, 25 and 45 are associated with PSGN following pharyngitis. While typically seasonal, isolated cases of PSGN may be seen throughout the year. In the past, epidemics of PSGN following impetigo were reported. In some areas (Trinidad, Maracaibo), epidemics occurred every 5–7 years; there is no satisfactory explanation for this phenomenon [13]. Populations at increased risk include children and soldiers, due to intimate contact, overcrowded living conditions, and poor hygiene and sanitation. The ratio male:female is up to 2:1, but when subclinical cases are included, there is no male predominance. The disease is most common in children aged 3–12 years, although PSGN has been reported in infants [24, 25]. The risk for developing PSGN after infection with a nephritogenic strain of GABHS is about 15%; for M type 49, it is 5% after pharyngeal infection and 25% after pyoderma [26]. Rarely, PSGN occurs as a complication of piercing [27] or circumcision [28]; presents in a kidney allograft [29]; or occurs secondary to immune reconstitution inflammatory syndrome in pediatric HIV infected patient [30]. Besides GABHS, streptococci from group C and G can also cause acute GN [31–33], but the concept of a common nephritogenic antigen is questionable [34].

Pathogenesis

There is clear evidence that PSGN is an immune complex disease, but the identity of the nephritogenic antigen is uncertain [35, 36]. The proposed mechanisms are;

1. Deposition of circulating immune complexes containing nephritogenic antigen in glomeruli
2. Implantation of the nephritogenic antigen into glomerular structures and in situ formation of immune complexes
3. Molecular mimicry between streptococcal antigens and glomerular antigens, which react with antibodies against streptococcal antigens
4. Direct activation of the complement system by implanted streptococcal antigens. Many proteins such as endostreptosin, preabsorbing antigen, nephritis strain–associated protein,

streptococcal pyrogenic exotoxin B (SPEB), nephritis-associated plasmin receptor (NaPlr) have been considered as potent nephritogenic antigens in PSGN [37–45].

There are several reports of infection-related GN caused by pathogens other than Streptococcus group A and C with detection of NAPlr in kidney biopsies. This lists includes Streptococcus pneumoniae, Staphylococcus aureus, Mycoplasma pneumoniae and Aggregatibacter actinomycetemcomitans [46–49].

Evidence that an antigen is nephritogenic should include identifying the antigen in kidney biopsy specimens from patients with PSGN; extracting the same antigen from streptococci obtained from PSGN patients; not identifying the antigen in streptococci cultured from patients with rheumatic fever; and demonstrating significant titer of antibodies against the nephritogenic antigen in sera from PSGN patients in the convalescent phase. Lange and his group [39, 40] considered that endostreptosin (ESS) was an ideal nephritogenic antigen because it fulfilled the these criteria. Interestingly, ESS was identified in early but not in late biopsy specimens,. In animal experiments, ESS was implanted on the glomerular basement membrane very early in the course of the disease. Late in the disease course, there was production of anti-ESS antibodies, which bound ESS and thus enabled detection of the ESS. The two main disadvantages of this theory are (1) endostreptosin is an anionic antigen and this cannot explain its implantation on the glomerular basement membrane (GBM) (2) injection of ESS has never induced histological changes and clinical features compatible with PSGN.

Vogt et al. provided evidence that cationic antigens were responsible for the immunopathogenesis of PSGN; they identified cationic antigens in 8 out of 18 biopsy specimens from PSGN patients and confirmed that streptococci cultured from PSGN patients produced cationic antigens [42]. Later this antigen was confirmed to be streptococcal pyrogenic exotoxin B (zymogen, SPEB), a plasmin binding membrane receptor. Glyceraldehyde phosphate dehydrogenase (GAPDH) and NAPlr/Plr are also candidate nephritogenic antigens [36, 44, 50, 51]. Both antigens induce long lasting antibody responses; antibodies against NaPlr can be detected 10 years after an acute episode. This may explain why second attacks of PSGN are rare. Nephritogenic potential is not limited to GABHS, but extends to groups C and G, with sporadic and epidemic cases of PSGN reported after infection with these streptococcal groups. The common pathway for both antigens is binding to plasmin, which activates complement, and promotes chemotaxis and degradation of GBM components. Bound plasmin can cause tissue destruction by direct action on the GBM, or by indirect activation of procollagenases and other matrix metalloproteinases. This allows circulating immune complexes to transit the damaged GBM and accumulate in the subepithelial space, seen as humps by EM.

NAPlr has been isolated from both groups A and C streptococci, and was considered as a putative antigen in the Japanese population with serum antibodies detected in 92% of convalescing PSGN patients and in 60% of patients with uncomplicated streptococcal infections [44]. Glomerular deposits and serum antibodies against these two putative antigens were examined concurrently in biopsies and sera from PSGN patients [45]. This study suggests that SPEB is the most likely major antigen involved in the pathogenesis of PSGN in patients from Latin America, US and Europe. Subsequently, a genome study of *S. equi* subsp. *Zooepidemicus* strain MGCS10565, a Lancefield group C organism that caused an epidemic of nephritis in Brazil, found that this organism lacked a gene related to SPEB and challenges the hypothesis that SPEB or antibodies reacting with it singularly cause PSGN [34].

Immune complexes deposited from the circulation or formed in situ activate the complement cascade. This leads to production of various cytokines and other cellular immune factors which initiate an inflammatory response manifested by cellular proliferation and edema of the glomerular tuft [52, 53].

In some PSGN patients, rheumatoid factor, cryoglobulins, and antineutrophil cytoplasmic antibodies (ANCA) are present [54–58]. The significance is unknown.

Pathology

The typical presentation on light microscopy is diffuse enlargement of all glomeruli due to hypercellularity (Fig. 19.1). There is swelling of the endothelial cells, which leads to the obliteration of the capillary loops. The number of mesangial cells is increased. There is recruitment of numerous inflammatory cells in the glomeruli, mainly polymorphonuclear leukocytes and monocytes; thus, this pathological picture is termed exudative proliferative GN. Polymorphonuclear leukocytes may be seen in the tubular lumen. If the mesangial proliferation is axial, then the glomerulus has a lobular appearance. Capillary walls are not thickened. Arterioles and tubules are not affected. There may be edema of the interstitium and infiltration with inflammatory cells. Rarely, proliferation of parietal cells of Bowman's capsule may result in formation of crescents; a high percentage is associated with a rapidly progressive course.

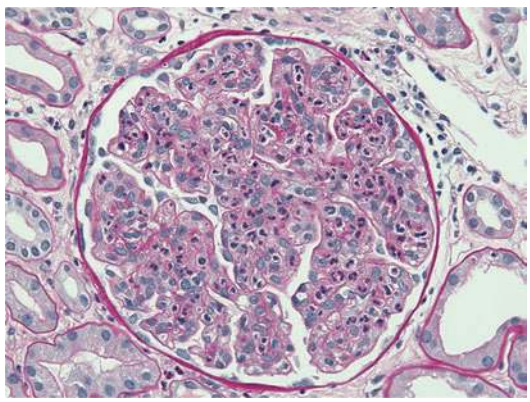

Fig. 19.1 Acute post-streptococcal glomerulonephritis, light microscopy. The glomerulus is enlarged and hypercellular; capillary loops are obliterated; and there is infiltration with polymorphonuclear leukocytes (hematoxylin and eosin, ×400). Courtesy of Prof. N. Kambham, MD, Dept. of Pathology, Stanford University

By IF, the most common finding in the acute phase is an irregular, granular capillary and mesangial staining for complement alone, or complement and immunoglobulins. During the resolving phase, there is only mesangial staining (Fig. 19.2). The predominant finding is C3 and IgG, but C4, C1q, IgM, fibrinogen and factor B may be found. Sorger et al. described three types of immune deposits in PSGN [59]. Starry sky pattern is the fine granular deposition of C3 and IgG along the capillary walls in the first week of the disease (Fig. 19.2a). Mesangial pattern is found between the fourth and sixth week after the disease onset; the only immune reactant is C3, which is found in a mesangial location (Fig. 19.2b). The garland pattern is characterized by dense, confluent deposits along the capillary loops, while mesangial and endocapillary locations are preserved (Fig. 19.2c). Subepithelial location of the deposits correlates with the humps seen on EM. The garland pattern is associated with massive proteinuria and does not correlate with the time of kidney biopsy [60]. In clinically atypical cases with acute kidney injury and nephrotic syndrome, NAPlr staining of the glomeruli is a useful tool for confirmation of the diagnosis of PSGN [61].

The typical finding on EM in the acute phase is deposits on the subepithelial side of the GBM (humps), Fig. 19.3. These deposits disappear after the sixth week of disease onset [62].

Parallel to the clinical resolution of the disease, there is marked improvement of the histological picture, with resolution of exudative and endocapillary changes; there is residual mesangial proliferation in the convalescent phase (resolving mesangioproliferative GN). Subepithelial deposits disappear or decrease in number after the sixth week; immune deposits decrease in parallel. Complete histologic resolution usually occurs by 1 year after onset.

Clinical Features

The latent period between the upper respiratory infection (pharyngitis) or pyoderma and nephritis is usually 10–14 days or 2–4 weeks, respectively. One third of PSGN patients develop discrete microscopic hematuria and/or proteinuria in the latent period. Usually the disease has acute onset, with development of nephritic syndrome (oedema, oliguria, azotemia hematuria, hypertension). Evidence of nephritis within 2–3 days of the onset of an upper respiratory tract infection is suggestive of other etiologies such as IgA nephropathy or Alport syndrome. At the onset of the disease, non-specific symptoms may be present, such as pallor, malaise, low-grade fever, lethargy, anorexia and headache.

Gross hematuria is present in 30–70% of patients with PSGN, while microscopic hematuria is present in all patients. Microscopic examination of the urine reveals dysmorphic red blood cells and casts. The urine is described as being smoky, cola colored, tea colored or rusty. Gross hematuria may be present continuously or only a few hours during the day. Usually it resolves after 1–2 weeks and transforms into microscopic hematuria. Once gross hematuria has seemingly resolved, it may reappear after physical exercise or intercurrent infections. A few patients have minimal urinary finding (few red blood cells/per high power field), yet have a severe clinical presentation of the disease [63, 64].

Edema in PSGN results from retention of salt and water. Despite the sodium retention, the increased level of atrial natriuretic peptide in plasma of PSGN patients indicates unresponsiveness of the kidneys to its action [65]. Parents often do not appreciate the edema, but it becomes clear during the diuretic phase when there is a marked weight loss. Most children have mild morning periorbital edema; this location is due to reduced tissues resistance. There may also be pretibial edema or generalized

edema (anasarca), including pleural effusions and ascites. Early salt and water restriction may prevent the consequences-circulatory congestion and hypertension.

Hypertension occurs in up to 70% of hospitalized children. Hypertension in PSGN is low renin type due to retention of water and salt, which leads to expansion of the extracellular fluid volume with consequent suppression of the renin-angiotensin-aldosterone axis. Usually it is mild and has a biphasic character. Hypertension that is severe and associated with retinal changes is suggestive of pre-existing renal disease. Normalization of the blood pressure correlates with diuresis and recovery of the kidney function. Hypertension beyond 4 weeks after disease onset may indicate rapidly progressive disease or chronic GN.

Complications

Circulatory congestion is the most common complication in hospitalized children with PSGN. If severe, it can lead to pulmonary oedema, which represents an emergency state and requires prompt and appropriate therapy. The signs and symptoms of circulatory congestions are tachycardia, dyspnoea, orthopnea, rales and cough. Sometimes clinical signs may be subtle, but a chest radiograph shows signs of congestion. Since children and young individuals have healthy cardiovascular systems, cardiac failure is rarely seen.

Posterior reversible encephalopathy syndrome (PRES), previously called hypertensive encephalopathy, is another serious complication found in 0.5–10% of hospitalized patients [13]. The most common clinical signs and symptoms are nausea, vomiting, headache, and impairment of consciousness, which varies from somnolence to coma. The children may manifest seizures, hemiparesis, amaurosis and aphasia. These symptoms are a consequence of sudden elevation of the blood pressure that impairs cerebral autoregulation leading to vasogenic edema. Electroencephalography has non-specific changes, which resolve in parallel with resolution of the neurological symptoms. Analysis of the cerebrospinal fluid may reveal the presence of protein, but no cells. On magnetic resonance imaging, there is alteration of the posterior white matter, which is termed reversible posterior leukoencephalopathy syndrome [66, 67]. The images show edematous lesions primarily involving the posterior supratentorial white matter and corticomedullary junction. Neurological complications in PSGN cannot be attributed exclusively to hypertensive encephalopathy or abnormal serum biochemistry, particularly in those patients with normal blood pressure during the incident (e.g. seizures). With advances in neuroimaging, there is evidence that some children develop cerebral vasculitis [68, 69]. This has practical implication because it may require different treatment.

PSGN may also be complicated by severe acute kidney injury. Some patients require dialysis.

Clinical Variants

Approximately 90% of patients have subclinical disease and never seek medical care due to absence of symptoms [13]. Rarely, patients may have nephrotic syndrome (0.4%) or rapidly progressive disease (0.1%). The incidence of subclinical disease (expressed as ratio subclinical: clinical disease) varies from 0.03 to 19.0 [70, 71]. This is most likely due differences in methodology and study populations, which has included epidemic contacts [26], family contacts [70, 72, 73], or patients with well-documented streptococcal infections [71, 74]. The population at risk has been tested for urinary abnormalities and hypocomplementemia once or sequentially. More frequent testing increases the likelihood of detecting abnormalities, which may be transitory and normalize within a week.

Sagel et al. followed 248 children from New York 4–6 weeks after well-documented streptococcal infections [71]. Abnormal urinalysis with hypocomplementemia was detected in 20 children, but only one had symptomatic disease. The incidence of nephritis after streptococcal infection in this report was 8.08% and the

ratio subclinical/clinical nephritis 19.0. Kidney biopsy was performed in all 20 children and showed histological lesions varying from mild focal cellular proliferation to classical exudative and proliferative GN. Only one child had normal histology and lack of immune deposits. The authors concluded that only a minority of PSGN cases are detected. Yoshizawa et al. performed a similar study in Japan; 12 out of 49 patients with well-documented streptococcal infection developed subclinical nephritis (24%) and all 12 patients had abnormal kidney biopsies [74].

In a study of family contacts from Macedonia, the incidence of nephritis in parents and siblings was 0% and 9.4%, respectively [73]. It seems that parents are "protected" from developing PSGN. The ratio of subclinical/clinical nephritis in contacts was 1.28. An additional number of family contacts had glomerular type microhematuria and elevated ASO titre; thus, it is possible that they also had subclinical PSGN and that their complement levels normalized before occurrence of nephritis in the index cases. Lange et al. pointed that the finding of significant titers of endostreptosin antibodies in patients with chronic GN or on hemodialysis suggested the possibility of previous undetected subclinical PSGN [39, 75].

Nephrotic syndrome occurs in 4–25% of hospitalized children with PSGN. It usually resolves within 2–3 weeks; persistence beyond 3 weeks is associated with a poor outcome. Less than 1% of hospitalized children develop rapidly progressive disease, which is characterized by prolonged oligo-anuria, uremia, hypertension, anemia and persistent nephrotic syndrome. Crescents are present on kidney biopsy, and the percentage of crescents correlates with the severity of the disease and the outcome.

Cerebral vasculitis is an infrequent complication; cutaneous and gastrointestinal vasculitis have also been reported in PSGN patients and may mimic Henoch-Schönlein purpura [76]. PSGN is uncommonly associated with rheumatic fever [77, 78]. An unusual or atypical course of the disease is reported in patients with concurrent IgA nephropathy, diabetes mellitus, hemolytic uremic syndrome, reflux nephropathy and bilateral kidney hypoplasia [79–82]. Simultaneous occurrence of acute immune thrombocytopenia has also been reported in a few PSGNpatients [83–85]. The most likely mechanism is production of autoantibodies that cross-react against GABHS and platelets [84].

Laboratory Findings

Proteinuria and hematuria are found in almost all patients with PSGN. The presence of red blood cell casts and dysmorphic erythrocytes confirms the glomerular origin of the hematuria. In a few patients, minimal urinary findings occur despite a severe clinical presentation.

A mild dilutional anemia may be seen at the onset of the disease and is due to expansion of the extracellular fluid volume. Thrombocytopenia is extremely rare; its presence suggests the possibility of systemic lupus erythematosus or hemolytic uremic syndrome. If there is no significant impairment of glomerular filtration rate (GFR), blood chemistry is almost normal; severe reduction of renal function leads to hyperkalemia, uremia and acidosis. Hypoproteinemia, hypoalbuminemia and hyperlipidemia are evident if there is associated nephrotic syndrome.

Patients should be evaluated for evidence of previous streptococcal infection. Cultures from the throat or skin should be obtained, depending on the site of the initial infection. Antibodies against streptococcal antigens (antistreptolysin O, antihyaluronidase, anti-DNA-se B titer), or combination of antigens (streptozyme) should be measured serially during the course of the disease. Of note, in postpyodermal disease there is an insignificant rise in antistreptolysin O titres. Testing anti-zymogen titres is very sensitive and specific for diagnosing streptococcal infection in PSGN patients, but this test is not available for routine practice. A high titre of antibodies against glyceraldehydes phosphate dehydrogenase is found in PSGN patients.

There is marked depression of CH50 and C3 due to activation of the alternative pathway. In some patients, there is also depression of C2 and C4, suggesting activation of both classical and

alternative pathways [86]. Usually, complement levels normalize within 6–8 weeks; persistence of hypocomplementemia beyond 3 months suggests an alternative diagnosis (membranoproliferative GN).

Complement activation was analyzed in 34 children with APIG and low C3 level at onset [87]. They demonstrated that anti-factor B (anti-FB) antibodies enhance alternative pathway convertase activity in vitro, confirming their pathogenic effect. They identified anti-FB autoantibodies in 31 of 34 (91%) children with APIG and in four of 28 (14%) children with C3 GN. Sensitivity and specificity of anti-FB antibodies for APIG diagnosis were 95% and 82%, respectively. Anti-FB antibodies were not detected in 15 patients with IgA nephropathy and 26 with lupus nephritis. During the follow-up, the anti-FB antibody levels became negative or decreased in children with APIG. The authors hypothesize that streptococcal infection may cause transient anti-FB autoantibodies, which overactivate complement with subsequent deposition of complement C3 breakdown products in the glomeruli.

Kozyro et al. tested children with PSGN for the presence of antibodies against C1q and found that 8 of 24 were positive for anti-C1q [88]. They found that anti-C1q positive children had more severe disease (hypertension, proteinuria) and unfavourable resolution of the disease.

Kidney Biopsy and Differential Diagnosis

Usually children with PSGN have a favourable disease course and outcome; thus, kidney biopsy is not necessary. In cases of severe or atypical clinical presentation or delayed recovery, then kidney biopsy is mandatory. Indications for kidney biopsy are summarized in Table 19.2.

PSGN should be differentiated from the following diseases: IgA nephritis (short latent period from infection), hereditary nephritis (family history, short latent period), MPGN (persistent hypocomplementemia and unresolving nephritic syndrome), lupus nephritis (persistent hypocomplementemia, systemic manifestations), GN in acute and chronic infections (evidence for other non-streptococcal infection), vasculitides (polyarteritis nodosa, Henoch Schönlein purpura), haemolytic uremic syndrome (hemolysis, thrombocytopenia).

Table 19.2 Indications for kidney biopsy

Early stage	Recovery phase
• Age <2 years • Short latent period • Anuria • Rapid progressive course • Hypertension >2 weeks • Depressed GFR >2 weeks • Normal complement levels • No elevation of antistreptococcal antibodies • Extrarenal manifestation	• Depressed GFR >4 weeks • Hypocomplementemia >12 weeks • Persistent proteinuria >6 months • Persistent microhematuria >18 months

Vernon et al. described a girl who developed chronic kidney disease and persistent hypocomplementemia after streptococcal throat infection. Kidney biopsy 1 year after presentation revealed features of C3 glomerulopathy while genetic studies detected a heterozygous mutation in the complement factor H-related protein 5 gene (CFHR5) [89]. A group from the Mayo Clinic presented a series of 11 patients who had atypical postinfectious GN [90]. Kidney biopsy was performed due to persistent proteinuria, hematuria, and depressed C3. On light microscopy, there were exudative and proliferative changes; IF studies revealed dominant C3 mesangial deposits while EM revealed subepithelial humps. In 10 of 11 patients, there was an underlying defect in the alternative pathway of the complement, either autoantibodies against C3 convertase or mutations in complement regulatory genes.

Treatment

Bedrest and limited activity are indicated in the early stage of the disease, particularly if circula-

tory overload and hypertension are present. There is no evidence that prolonged bedrest hastens recovery.

In most cases, fluid and salt restriction are sufficient to prevent edema and hypertension. Salt intake should be limited to less than 1.0 g/day. Usually protein intake should be limited to 1.0 g/kg/day. In case of marked azotemia, calories should be provided from carbohydrates and fats. to the diet is individualized based on clinical and biochemical indices. Diuresis and body weight should be monitored every day. Loop diuretic (furosemide 1–2 mg/kg/day) is indicated if there is moderate circulatory congestion. Higher doses, up to 5 mg/kg per dose intravenously are indicated if there is pulmonary oedema, although caution is indicated if there is severe azotemia because of potential ototoxicity.

Moderate hypertension should be treated with diuretics and oral antihypertensive drugs; amlodipine is now widely used. Angiotensin converting enzyme inhibitors (ACEIs) may be effective, but there is concern for worsening hyperkalemia [91]. In a hypertensive emergency, options include intravenous labetalol (bolus or continuous infusion) and nicardipine or nitroprusside by continuous infusion. Short-acting, oral or sublingual nifedipine has been used for hypertensive emergencies without encephalopathy. However, given the occurrence of serious and fatal adverse effects in adults, it should be administered in children with great caution [92]. Amlodipine or isradipine may be safer options.

Hyperkalemia should be prevented with restricted potassium intake. If present, conservative treatment should be started immediately to prevent fatal complication. Severe hyperkalemia, azotemia, acidosis, uncontrolled hypertension, cardiovascular insufficiency and pulmonary edema are indications for urgent dialysis.

There is no clear evidence that immunosuppressive therapy has a beneficial effect in children with crescentic PSGN. In those with >30% crescents one may attempt pulse methylprednisolone 0.5–1.0 g/1.73 m^2 for 3–5 days. In ten children with crescentic PSGN, five were given quintuple therapy (including immunosuppressive drugs) and five were given only supportive treatment [93]. At the end of the follow-up, the outcomes were similar, though patients who received quintuple treatment had faster normalization of serum creatinine and decreased duration of hospitalization. Nevertheless, based on efficacy in other forms of rapidly progressive GN, some clinicians administer high-dose intravenous methylprednisolone for 3–5 days for severe disease based on kidney function and percentage of crescents.

Antibiotic therapy is indicated if there are still signs of streptococcal infection (pharyngitis, pyoderma) or patients have positive throat or skin culture. Oral penicillin V (or erythromycin for allergic patients) is preferred over parenteral treatment. Antibiotic treatment does not alter the course of the PSGN, but it is important to prevent spread of nephritogenic strains of GABHS. Long-term antibiotic prophylaxis is not justified since second attacks of PSGN are rare [94].

Prognosis

The prognosis of PSGN in children in the acute phase is excellent, with mortality less than 1% due to improved conservative management and availability of dialysis. There are conflicting data regarding long-term outcomes. For example, Baldwin et al. [95, 96] suggest unfavourable outcomes in many patients while Potter et al. [97] describe excellent outcomes. This is mainly due to different criteria for selection of patients for prognostic studies, excellently reviewed in detail by Cameron [98]. It is important to remember that only clinical cases (10%) are included in the analysis, while those with subclinical and mild disease may escape medical attention. Moreover, some are not referred to a nephrologist and only a small percentage have a kidney biopsy. The series describing prognosis differ in respect to following parameters: pediatric/adult, sporadic/epidemic, evidence/no evidence for previous streptococcal infection, with/without kidney biopsy, and with/without crescents on kidney biopsy.

In a study by Vogl et al. [99], 36 children and 101 adults had biopsy and serological confirmation of PSGN and had been followed for 2–13 years; none of the children reached end stage kidney disease (ESKD), but 10% had elevated serum creatinine between 1–2 mg/dL. Clark et al. provided excellent information concerning long-term outcome of PSGN in children [100]. Although their series was small, it was exclusively pediatric, with adequate documentation of streptococcal infection and initial biopsy in all children and rebiopsies in some of them. Thirty children were followed for 14.6–22 years (mean: 19 years). Urinary abnormalities were present in 20% of patients during the follow-up, but none had reduced GFR, assessed with creatinine clearance. Clark et al. questioned the role of kidney biopsy for diagnosis and follow-up of children with typical PSGN.

Baldwin et al. reported unfavourable data on long-term prognosis of PSGN [95, 96]. In their series, 37 out of 126 patients were children; 11 patients progressed to terminal uremia, nine in the first 6 months. During the follow-up of 2–15 years, proteinuria, hypertension and reduced GFR were documented in half of the patients. A total of 174 kidney biopsies were performed; in the first years after the acute episode there was a prevalence of proliferative changes, while in 2/3 of the late biopsies there were sclerosing lesions, which Baldwin considered as an indicator of chronicity. The poor outcomes may seem likely secondary to a highly selected patient population; 20% presented with nephrotic syndrome. Patients who died or rapidly progressed to uremia had crescentic nephritis at biopsy. A substantial number of patients were lost to follow-up, with selection of those who had more severe disease. Furthermore, GFR in this study was not corrected for sex, age and body surface area. The same group reported six patients with PSGN who progressed to terminal uremia 2–12 years after resolution of acute nephritis and normalization of the GFR [101]. Of note, five of six patients had nephrotic syndrome at the disease onset. Gallo et al. presented data on the morphologic alteration in kidney biopsies from patients who recovered from PSGN; they found that the incidence of glomerular and vascular sclerosis increased with time [102]. The clinical consequence of this healing process is reduced kidney functional reserve after a protein loading test [103, 104].

The two studies from Maracaibo, Venezuela also pointed to the progressive character of PSGN [105, 106]. One hundred and twenty patients (101 children) who had survived the epidemics in 1968 were evaluated between 1973–1975. Proteinuria, microhematuria, hypertension or reduced GFR were found in 36.7% of adult patients compared with 8.7% of pediatric patients. Kidney biopsies showed advanced glomerulosclerosis in all patients with abnormal findings. Mild to moderate mesangial proliferation and glomerulosclerosis were present even in those patients who had no history of any clinical abnormality.

Herrera and Rodríguez-Iturbe investigated the incidence of ESKD among Goajiros Indians, a semi-nomadic tribe that live in the northwestern part of Venezuela [107]. The incidence of ESKD was 1.7 times higher than the incidence for the country. Also, the attack rate of PSGN was double compared with the general population in the neighboring Maracaibo city. Low birth weight was common among Goajiros Indians (23% of newborns weigh less than 1000 g). The authors concluded that high attack rate of PSGN and low nephron endowment were responsible for the increased risk of ESKD in this population.

In contrast, Dodge et al. [108] and Travis et al. [109] reported excellent clinical and histological healing of the disease in their pediatric series. Dodge et al. found that the presence of proteinuria was present despite histological healing; it had an orthostatic character before definitively cleared [108]. In a study from Macedonia, 40 post-nephritic children were investigated 3 months to 10 years after the acute episode, but no increase in proteinuria was found after moderate to strenuous physical activity [110]. Perlman et al. reevaluated 61 children 10 years after the original epidemics in 1963 [111]. All children had normal GFR, 3 had proteinuria >100 mg/24,

but all had normal morphology on kidney biopsy. Sixteen children had a kidney biopsy; four patients had minimal focal proliferation, but no sclerosing lesions were seen.

Three studies from Trinidad evaluated medium and long-term prognosis of PSGN. These are the largest studies, predominantly pediatric, with excellent outcomes concerning presence of urinary abnormalities, hypertension or impaired renal function [97, 112, 113]. Renal biopsy was not performed in many studies for diagnosis and follow-up of PSGN in children, but the diagnosis was based on firm clinical and serological documentation of previous streptococcal infection and transitory hypocomplementemia. Results of these studies confirmed the benign course of PSGN in children, with very low percentage having persistent urinary abnormalities, hypertension or reduced GFR [114–116]. Besides clinical healing, there was complete functional recovery in almost all patients. Drukker et al. found that natriuretic response was excellent in post-nephritic children after intravenous saline loading [117].

In some indigenous communities in Australia and New Zealand, there is still high attack rate of PSGN [118, 119]. Repeated episodes of PSGN and low number of nephrons due to higher rate of prematurity contribute to higher prevalence of chronic kidney disease in the Aboriginal population [120, 121].

From analysis of multiple studies, the following risk factors for unfavourable outcome were identified: older age, high serum creatinine at presentation, nephrotic syndrome and crescents on kidney biopsy. Even after initial normalization of the kidney function, impairment of the GFR may ensue many years after disease onset; thus, children who present with crescents need indefinite follow-up [122].

Prognosis of PSGN caused by group C *Streptococcus zooepidemicus* appears less favorable. After a mean follow-up of 5.4 years after epidemics in Brazil, a relatively high percentage of patients had microalbuminuria, hypertension and reduced GFR [123]. However, it was impossible to draw conclusions for children since few were evaluated.

Shunt Nephritis

Immune complex GN associated with infection of a ventriculoatrial shunts was first reported in 1965 by Black et al. [124]. Shunt infections are common, but few patients develop GN (2%). Ventriculoperitoneal shunts are now preferred over ventriculoatrial shunts because of lower rates of complications, including shunt infections. The clinical features of shunt nephritis are variable and include proteinuria, hematuria, hypertension, nephrotic syndrome, anemia and compromised kidney function [10, 125]. Symptoms of shunt infections may be present and include fever, anemia, malaise, hepatosplenomegaly and cerebral symptoms. Colonization of the shunt may persist for months and years in otherwise asymptomatic patients. Low-grade fever may be the only sign of active shunt infection and this may result in delay of diagnosis. Staphylococcus epidermidis is the most common pathogen, occurring in 75% of shunt infections. This is a skin contaminant most likely introduced during the surgical procedure. Other isolated pathogens are S. aureus, corynebacterium, listeria, pseudomonas, Propionibacterium acnes, and Bacillus species [10, 126].

Laboratory investigations demonstrate low C3 in 90%, elevated erythrocyte sedimentation rate, cryoglobulinemia and positive blood or cerebrospinal fluid cultures. Patients with ventriculoatrial shunt with unexplained hematuria, proteinuria, or compromised kidney function should have prompt diagnostic work up for subacute shunt infection, even in the absence of fever and leukocytosis [10]. Kidney biopsy shows membranoproliferative pattern on light microscopy in the majority of patients [125]. IF studies demonstrate granular deposits of C3, IgM and IgG in subendothelial and mesangial locations. Persistent antigenemia is responsible for immune complex formation, but it is unclear whether the immune complexes are formed in the circulation or *in situ*. Their presence induces complement activation through the classical pathway, which further mediates injury to glomerular cells (through the C5–9 complex) and generates che-

motactic peptides (C3a, C5a) that perpetuate local inflammation.

The prognosis of shunt nephritis is excellent, with normalization of kidney function and resolution of proteinuria, if the infected shunt is removed and appropriate antibiotic treatment is administered. Kidney function normalizes within a few weeks and hypocomplementemia also resolves [10, 125]. Delayed removal of the infected shunt may result in progressive worsening of kidney function and lead to ESKD.

Endocarditis-Associated Glomerulonephritis

Infective endocarditis (IE) is mainly a complication of congenital or rheumatic heart disease in children and still has high mortality despite appropriate antibiotic therapy. Kidney involvement occurs in about 25% of the patients with IE and manifests as kidney infarcts, GN, and interstitial nephritis [10]. The most common pathogen is Streptococcus viridians, whose indolent clinical course enables prolonged antibody response and formation of circulating immune complexes which predispose to the development of GN. Other causative pathogens include S. epidermidis, enterococcus, Hemophilus influenza, actinobacillus, chlamydia, Bartonella henselae, and Coxiella burnetti [126].

Children with acute IE) present with severe illness, including fever, anemia, heart murmur, hepatosplenomegaly, skin purpura and retinal hemorrhages (Roth spots). In contrast, those with a subacute course may have subtle symptoms that are only recognizable during the work-up of the GN. GN usually ensues within 7–10 days of clinical illness. Duration of endocarditis does not increase the risk of developing GN. The clinical presentation is variable, from mild proteinuria and hematuria to a severe, rapidly progressive course. The most common presentation is acute nephritic syndrome. Laboratory investigation reveals hypocomplementemia, which correlates with the severity of kidney disease and infection. Rheumatoid factor may be positive and some patients have ANCA that react against proteinase 3.

The kidney biopsy findings are diverse; focal segmental proliferation is the most common finding, followed by diffuse endocapillary proliferation. Exudative features are similar to those seen in PSGN. Crescents and glomerular necrosis may also be present, and in some patients may affect >50% of glomeruli [6]. The tubular atrophy and fibrosis correlates with the extent of glomerular necrosis and crescents. Rarely, membranoproliferative GN resembling MPGN type I may be present and the biopsy shows diffuse mesangial and endocapillary proliferation, lobular accentuation, and GBM reduplication. During resolution of the GN, mesangial proliferation is the dominant histological pattern. IF studies show dominant deposits of C3 and less intense IgG and IgM in mesangial areas and in capillary walls. EM detects subepithelial deposits in the early phase; latter in the course of the disease they are located in subendothelial and mesangial areas.

Endocarditis-associated GN represents an immune complex disease with deposition of circulating immune complexes in the glomeruli, but also there is evidence for in situ formation of complexes. The nephritogenic bacterial antigens were identified within the affected glomeruli in S. aureus and streptococcal infections. Treatment consists of antibiotic therapy and surgery to remove valvular vegetations and eradicate the infection. Most infective and non-infective complications of IE resolve on treatment with appropriate antibiotics. In a few patients with proliferative lesions and no improvement with antibiotics, corticosteroids and cyclophosphamide may be useful [6, 127]. Patients with crescentic GN may benefit from plasmapheresis.

HIV Related Kidney Disease

The implementation of the successful prevention of mother-to-child transmission (PMTCT) program has dramatically decreased new cases of pediatric HIV infection [128, 129]. Highly active antiretroviral therapy (HAART) has significantly

decreased the mortality rate in children who acquire perinatal HIV infection. However, managing and preventing contraction of HIV remains a major part of adolescent care in Africa [130]. HIV is currently the second leading cause of death among adolescents worldwide. Women aged 15–24 are the group with the highest rate of new HIV infection in sub-Saharan Africa [131].

Increased survival and complications of therapy have led to a variety of non-infectious complications in patients with HIV infection, and kidney disease is an important concern. Chronic kidney disease in children with perinatal HIV infection is the consequence of primary HIV infection, antiretroviral therapy, and other nephrotoxic drugs, including aminoglycosides. The spectrum of kidney disease includes chronic glomerular disorders, such as HIV associated nephropathy (HIVAN) and HIV immune complex kidney disease (HIVICK); the thrombotic microangiopathies (atypical haemolytic uremic syndrome and thrombotic thrombocytopenic purpura); disorders of proximal tubular function; and acute kidney injury [132].

The histology of HIVAN in children is classical FSGS, with or without mesangial hyperplasia. Other features may include microcystic tubular dilatation and interstitial inflammation. This contrasts with adults, where collapsing FSGS is the typical histological finding. Two pediatric studies have reported collapsing FSGS in 14% and 32.5% [133, 134]. This has important prognostic implications in children since collapsing FSGS has more rapid and progressive course towards ESKD compared with the classical form.

In the pathogenesis of HIVAN, the initial event is infection of the kidney epithelial cells by HIV-1, but it is still enigmatic how the virus enters the epithelial cells since podocytes and renal tubular cells do not express CD4 or other co-receptors. The injured podocytes undergo proliferation and apoptosis; then the remaining podocytes hypertrophy and leave bare segments of basement membrane that promotes the development of the sclerotic lesions that characterize HIVAN. HIV nef and tat genes are implicated for the glomerular pathology while vpr genes are responsible for tubular lesions. Host genetic factors predispose to development of HIVAN and progression to ESKD [132]. This is supported by the observation that African-Americans have a higher incidence of HIVAN, with a rapid and unfavorable course. Polymorphisms G1 and G2 in the APOL-1 gene are highly associated with FSGS and HIVAN. These risk polymorphisms are found with increased frequencies in African populations.

HIVICK occurs as the result of deposition of circulating immune complexes in the glomeruli or their formation in situ. Immune complexes contain viral core and envelope antigens. In addition, HIV patients may have other immune complex mediated diseases (IgA nephropathy, membranous GN or membranoproliferative GN, very often associated with hepatitis A, B and C coinfection). Lupus-like GN may be also found by IF and EM studies in the absence of clinical and serological features of systemic lupus erythematosus.

In Black and Hispanic populations, FSGS with or without collapsing glomeruli and microcystic tubular dilatation are common while mesangial hyperplasia and immune complex-type disease predominates in whites. Other glomerular pathologies may be also detected in HIV infected children and adults such as postinfectious GN, minimal change disease, diabetic nephropathy, amyloidoses, and thrombotic microangiopathies.

Persistent proteinuria ($\geq$1+ on dipstick; urinary protein/creatinine ratio > 2.0 mg/mg) and microhematuria point to HIVAN [132, 135–137]. Additional suggestive features are finding of microcysts (shed epithelial cells) in the urinary sediment, highly echogenic kidneys, Black race, and nephrotic range proteinuria with or without edema or hypertension. These criteria are suggestive but not confirmatory; definitive diagnosis of HIVAN should be established by a kidney biopsy [132].

Children with perinatal HIV infection can shave tubulointerstitial nephritis, and may present with non-specific manifestations of acute kidney injury. It may be secondary to medication

exposure, including non-steroidal antiinflammatory drugs, trimethoprim-sulfamethoxazole, indinavir, and ritonavir. Various electrolyte and acid-base disturbances may be found in children with perinatal HIV infections because of malnutrition, gastroenteritis, pneumonia, intracranial infections, and syndrome of inappropriate antidiuretic hormone. Antiretroviral agents such as tenofovir can cause proximal tubular dysfunction, nephrogenic diabetes insipidus, and acute kidney injury.

Children with HIVAN should be treated with HAART. If already receiving HAART, it may suggest inadequate disease control, which is supported by low CD4 counts and a high viral load. Resistance testing enables selection of the optimal HAART regimen. Since many antiretroviral drugs are excreted via the kidneys, modification of dosages based on GFR is necessary. Nephrotoxic drugs should be avoided or carefully monitored.

Although there are no controlled, randomized trials, ACEIs and angiotensin receptor blockers have been used with HAART therapy in many centers in order to decrease proteinuria. Steroids and immunosuppressive agents are not recommended for treatment of children with HIVAN [132].

Both dialysis modalities are used in HIV infected children with ESKD. Those on peritoneal dialysis have increased risk of recurrent peritonitis and worsening of malnutrition, while those on hemodialysis with central venous lines have high risk of tunnel infections and thrombosis. In the pre-HAART era, there were major concerns about transplantation in otherwise immunocompromised patients. With better control of the disease with HAART, improved prophylaxis and treatment of opportunistic infections, transplantation, as in other causes of pediatric CKD, is now the optimal treatment modality for these children. However, this requires stability on HAART with undetectable viral load for 6 months and an adequate CD4 count, and an understanding of the need for adherence to a combination of life-long HAART and immunosuppression [138].

A shortage of donor kidneys has led to adult HIV-positive kidney donors being utilized in adult HIV kidney positive transplants recipients with good success [139]. In pediatrics, this has not been described in kidney transplantation, although a successful case of living donor liver transplantation from an HIV-positive mother to her HIV-negative child has been performed as a lifesaving measure [140, 141].

Conclusion

Infectious and post-infectious GN have been important causes of pediatric kidney disease. However, there has been a decrease in these etiologies of GN due to the introduction of successful vaccines (hepatitis A and B, meningococcus, varicella and COVID-19); public health initiatives (efforts to decrease transmission of malaria and scabies); and maternal screening (HIV and syphilis).

The management of post-infectious GN focuses on addressing the clinical consequences of the GN. In contrast, eradicating the underlying infection is critical for infectious GN, although management of the GN is also important.

Rapidly Progressive Glomerulonephritis

20

Shina Menon and Arvind Bagga

Rapidly progressive glomerulonephritis (RPGN) is a rare syndrome in children, characterized by clinical features of glomerulonephritis (GN) and rapid loss of renal function. Histology shows crescentic extracapillary proliferation in Bowman space affecting the majority of glomeruli. This may be seen in any form of GN, including post-streptococcal GN, renal vasculitis, IgA nephropathy, systemic lupus erythematosus (SLE) and membranoproliferative GN. RPGN is a medical emergency, which if untreated rapidly progresses to irreversible loss of renal function. Prompt evaluation and specific therapy is necessary to ensure satisfactory outcome in most cases.

Definition

RPGN is a clinical syndrome characterized by an acute nephritic illness accompanied by rapid loss of renal function over days to weeks [1]. The histological correlate is the presence of crescents (crescentic GN), usually involving greater than 50% of glomeruli. The presence of crescents is a histologic marker of severe glomerular injury, which may occur in a number of conditions, including postinfectious GN, IgA nephropathy, SLE, renal vasculitis and membranoproliferative GN [1, 2]. The severity of clinical features correlates with the proportion of glomeruli that show crescents. While patients with circumferential crescents involving more than 80% of glomeruli present with more severe acute kidney injury (AKI), those with non-circumferential crescents in less than 50% of glomeruli have a relatively milder course.

Although the terms RPGN and crescentic GN are used interchangeably, similar presentation, with rapidly evolving AKI, might occur in conditions without crescents, including hemolytic uremic syndrome, diffuse proliferative GN and acute interstitial nephritis. Table 20.1 lists common conditions that present with RPGN in childhood.

Table 20.1 Causes of rapidly progressive glomerulonephritis (RPGN)

Immune complex GN
Post infectious GN. Poststreptococcal nephritis, infective endocarditis, shunt nephritis, *Staphylococcus aureus* sepsis, other infections: HIV, hepatitis B and C, syphilis
Systemic disease. Systemic lupus erythematosus, IgA vasculitis, cryoglobulinemia, mixed connective tissue disorder, juvenile rheumatoid arthritis
Primary GN. IgA nephropathy, MPGN, membranous nephropathy, C1q nephropathy
Pauci-immune crescentic GN
Microscopic polyangiitis, granulomatosis with polyangiitis (Wegener granulomatosis), renal limited vasculitis, eosinophilic granulomatosis with polyangiitis (Churg-Strauss disease)
Idiopathic crescentic GN
Medications: penicillamine, hydralazine, hydrocarbons, propylthiouracil
Anti-glomerular basement membrane GN
Anti-GBM nephritis, Goodpasture syndrome, post-renal transplantation in Alport syndrome
Post-renal transplantation
Recurrence of IgA nephropathy, IgA vasculitis, MPGN, systemic lupus erythematosus
RPGN without crescents
Diffuse proliferative GN

GN glomerulonephritis; *MPGN* membranoproliferative GN; *GBM* glomerular basement membrane; *HIV* human immunodeficiency virus

Pathophysiology

Crescent formation is usually secondary to a nonspecific inflammatory response to severe injury to the glomerular capillary wall. While the underlying inciting reason may differ, the final pathway is often similar.

Underlying Triggers for Crescent Formation

In immune complex crescentic GN, the underlying trigger is deposition of immune complexes in the glomerular capillary tufts. These immune complexes may be formed in the circulation or within the glomerular capillary wall.

Pauci-immune crescentic GN is associated with anti-nuclear cytoplasmic antibody (ANCA), directed against either myeloperoxidase (MPO), proteinase 3 (PR3), or both. While the mechanisms by which ANCA arise have not been clearly elucidated, there is increasing evidence that they activate neutrophils and set off an inflammatory cascade which subsequently causes endothelial and microvascular injury, and damage to the glomerular capillary wall. Activated neutrophils result in the extrusion from the cell of neutrophil extracellular traps (NETs) containing entrapped MPO, PR3, and complement components [3, 4]. Subsequently, neutrophils undergo a form of cell death, NETosis. NETs also mediate direct injury to endothelium, transfer MPO/PR3 to vascular endothelium for antigen presentation and activate the alternate complement pathway. Involvement of the alternate complement pathway, specifically anaphylatoxin C5a and C5a receptor (CD88), has been shown in studies from an anti-MPO model in complement-deficient mice [5]. It has been proposed that there may be an amplification loop wherein activated neutrophils release properdin, activate the alternate pathway and generate C5a, resulting in additional neutrophil priming and activation. There is also emerging evidence that ANCA-negative pauci-immune GN maybe secondary to activation of the alternate and terminal pathway of complement caused by a genetic or acquired defect in the alternative pathway [6].

Finally, in anti-glomerular basement membrane (GBM) GN, there are circulating IgG antibodies directed against the non-collagenous domain of the α3 chain of type IV collagen that is present in the GBM and alveolar basement membrane.

Pathogenesis of Crescent Formation

Crescents are defined as the presence of two or more layers of cells in Bowman space. The chief components of crescents are coagulation proteins, macrophages, T cells, fibroblasts and parietal and visceral epithelial cells [1, 7]. There is evidence that podocytes also have a role in crescent formation [8]. Perturbations of humoral

immunity as well as the T helper type 1 cellular immune response contribute to the pathogenesis [1, 2]. Various pathways involving T cells, including disturbances in regulatory T cell function and stimulation of toll-like receptor 4, have been described [9, 10].

Initiation of Crescent Formation

The initial event in formation of crescents is the occurrence of a physical gap in the glomerular capillary wall and the GBM, mediated by macrophages and T lymphocytes. Breaks in the integrity of the capillary wall lead to passage of inflammatory mediators and plasma proteins into Bowman space with fibrin formation, influx of macrophages and T cells, and release of inflammatory cytokines (*e.g.,* interleukin-1 (IL-1) and tumor necrosis factor-α). Similar breaks in Bowman capsule allow cells and mediators from the interstitium to enter Bowman space and for contents of the latter to enter the interstitium, resulting in inflammation. It is proposed that podocytes, which are terminally differentiated and stationary cells, change into a migratory phenotype and contribute to crescent formation [11].

Formation

The development of a crescent results from the participation of coagulation factors and different proliferating cells, chiefly macrophages, parietal epithelial cells and interstitial fibroblasts. The presence of coagulation factors in Bowman space results in formation of a fibrin clot and recruitment of circulating macrophages. Activated neutrophils and mononuclear cells release procoagulant tissue factor, IL-1 and tumor necrosis factor-α (TNF-α), serine proteinases (elastase, PR3) and matrix metalloproteinases. The proteases cause lysis of the GBM proteins and facilitate entry of other mediators in Bowman space. Release of IL-1 and TNF-α result in expression of adhesion molecules, leading to macrophage recruitment and proliferation. Apart from macrophages, major components of the crescents are proliferating parietal and visceral epithelial cells [12].

Resolution of Crescents

The stage of inflammation is followed by development of fibrocellular and fibrous crescents. The expression of fibroblast growth factors and transforming growth factor-β is important for fibroblast proliferation and production of type I collagen, responsible for transition from cellular to fibrocellular and fibrous crescents. Transition to fibrous crescents, which occurs over days, is important since the latter is not likely to resolve following immunosuppressive therapy. The plasminogen-plasmin system is responsible for fibrinolysis and resolution of crescents.

Causes and Immunopathologic Categories

Based on pathology and immunofluorescence (IF) staining patterns, crescentic GN is classified into three categories, which reflect different mechanisms of glomerular injury [1].

1. Immune-complex GN with granular deposits of immune complexes along capillary wall and mesangium
2. Pauci-immune GN with scant or no immune deposits, and associated with systemic vasculitis
3. Anti-GBM GN with linear deposition of anti-GBM antibodies

Immune Complex Crescentic GN

These patients form a heterogeneous group in which multiple stimuli lead to proliferative GN with crescents. Immunohistology shows granular deposits of immunoglobulin and complement along capillary walls and in the mesangium. The causes include infections, systemic diseases and primary GN.

Systemic infections Poststreptococcal GN can rarely present with crescentic histology. While most patients recover completely, the presence of

nephrotic range proteinuria, sustained hypertension and crescents is associated with an unsatisfactory outcome [13, 14]. Other infectious illnesses associated with crescentic GN include infective endocarditis, infected atrioventricular shunts and visceral abscesses. Crescentic GN might be associated with infection with methicillin resistant *Staphylococcus aureus,* hepatitis B and C virus, leprosy and syphilis.

Systemic immune complex disease RPGN with glomerular crescents might be seen in patients with IgA vasculitis (formerly known as Henoch Schönlein purpura) and lupus nephritis (class IV more commonly than class III).

Primary GN Patients with IgA nephropathy, immune complex mediated membranoproliferative GN (MPGN), C3 glomerulopathy (C3 GN and dense deposit disease), and membranous nephropathy may occasionally present with rapid loss of renal function and crescentic GN [13–16].

Pauci-immune Crescentic GN

This form of GN is characterized by few or no immune deposits on IF microscopy [2, 17]. This includes renal-limited vasculitis, and the renal manifestations of microscopic polyangiitis (MPA), granulomatosis with polyangiitis (GPA; formerly Wegener granulomatosis), or eosinophilic granulomatosis with polyangiitis (formerly Churg-Strauss syndrome). Most (80%) show antineutrophil cytoplasmic autoantibodies (ANCA) in blood and are collectively classified as ANCA-associated vasculitides (AAV). Some cases of ANCA positive disease might be induced by drugs, including penicillamine, propylthiouracil, minocycline and hydralazine.

In addition, approximately 10–30% of patients with pauci-immune crescentic GN are ANCA negative [18]. These patients have fewer constitutional and extrarenal symptoms than those who are ANCA-positive. Studies show differences in outcome between these groups, suggesting a different pathophysiological basis.

Anti-GBM Crescentic GN

This condition is uncommon in childhood, accounting for less than 10% of RPGN cases in children [1, 14, 19–21]. The nephritogenic autoantibody is directed against a 28 kDa monomer located on the α3 chain of type IV collagen (Goodpasture antigen). Pulmonary involvement (Goodpasture syndrome) is uncommon. Approximately 5% of patients with Alport syndrome who receive a renal allograft develop anti-GBM autoantibodies and anti-GBM nephritis within the first year of the transplant [22]. Unlike de novo anti-GBM nephritis, pulmonary hemorrhage is not observed in post-transplant anti-GBM nephritis because the patient's lung tissue does not contain the antigen. The risk of post transplantation anti-GBM nephritis is low in subjects with normal hearing, late progression to end-stage kidney disease (ESKD), or females with X-linked Alport syndrome.

Idiopathic RPGN

This group includes patients with immune complex crescentic GN who do not fit into any identifiable category, and those with ANCA-negative pauci-immune disease. While both conditions are uncommon, the proportion varies across different regions.

Epidemiology

The incidence of RPGN in children is not known. Crescentic GN comprises about 5% of unselected renal biopsies in children. While there are no population-based studies in children, a report from Romania suggested an annual incidence of 3.3 per million adult population [23]. The 2010 NAPRTCS Annual Transplant Report shows that idiopathic crescentic GN contributes to 1.7% of all transplanted patients [24]. This figure is an underestimate since other conditions in the database, including membranoproliferative GN (2.5%), SLE (1.5%), systemic immune disorders (0.3%), GPA (0.6%), chronic GN (3.2%) and IgA

Table 20.2 Causes of crescentic glomerulonephritis in children (%)

Others	3		3		8.1

GN glomerulonephritis

nephropathy and IgA vasculitis (2.4%), might present as RPGN.

Table 20.2 outlines the underlying conditions in five series of crescentic GN reported from India [25], United States [19], Thailand [21], Germany [20] and Saudi Arabia [26]. Immune complex GN is the most common pattern of crescentic GN in children, accounting for 75–80% cases in most reports. Pauci-immune crescentic GN, while common in adults, is less frequent in children, accounting for 15–20% cases. The decline in the incidence of postinfectious GN has resulted in a change in the profile of crescentic GN.

Clinical Features

The spectrum of presenting features in RPGN is variable, and includes macroscopic hematuria (60–90% patients), oliguria (60–100%), hypertension (60–80%) and edema (60–90%) [14, 17]. The illness is often complicated by occurrence of severe hypertension with end organ involvement, pulmonary edema and cardiac failure. Occasionally, RPGN may have an insidious onset with initial symptoms of fatigue or edema. Nephrotic syndrome is rare and seen in patients with less severe renal insufficiency. Systemic complaints, involving the upper respiratory tract (cough, sinusitis), skin (vasculitic rash), musculoskeletal system (joint pain, swelling) and nervous system (seizures, altered sensorium) are common in patients with pauci-immune RPGN, with or without ANCA positivity. Relapses of systemic and renal disease occur in one-third of patients with vasculitis [2, 17]. Patients with anti-GBM antibody disease may present with hemoptysis and, less often, pulmonary hemorrhage. Similar complications are found in GPA, SLE, IgA vasculitis and severe GN with pulmonary edema. The kidney disease is most severe with anti-GBM disease, followed by pauci-immune GN and finally immune complex crescentic GN [1, 24].

Investigations

Hematuria, characterized by dysmorphic red cells and red cell casts, is seen in all patients; most also have gross hematuria. A variable degree of non-selective proteinuria (2+ to 4+) is present in more than 65% of patients. Urinalysis also shows leukocyte, granular and tubular epithelial cell casts. Severe AKI is often present at diagnosis. Anemia, if present is usually mild, though may be more severe in select cases due to pulmonary hemorrhage or autoimmune hemolytic anemia in SLE; peripheral smear shows normocytic normochromic red cells. Non-specific markers of inflammation, including CRP and ESR, are elevated.

Serology

Serological investigations assist in evaluation of the cause and monitoring disease activity (Table 20.3, Fig. 20.1). Low levels of total hemolytic complement (CH50) and complement component 3 (C3) are seen in postinfectious GN and SLE. Patients with lupus may additionally show reduced levels of C1q and C4 due to activation of the classic complement pathway. Complement-mediated MPGN is usually associated with low C3; however, other complement factors may be affected depending on the site of dysregulation in the alternate pathway. Positive antistreptolysin O titers and antideoxyribonuclease B suggests streptococcal

Table 20.3 Diagnostic evaluation of patients with rapidly progressive glomerulonephritis

Complete blood counts; peripheral smear for type of anemia; reticulocyte count; erythrocyte sedimentation rate, coagulation profile
Blood levels of urea, creatinine, electrolytes, calcium, phosphate, uric acid
Urinalysis: proteinuria; microscopy for erythrocytes and leukocytes, casts
Complement levels (C3, C4, CH50); additional evaluation may be required based on biopsy findings Antistreptolysin O, antinuclear antibody, anti-double stranded DNA antibodies; anti-extractable nuclear antibodies Antinuclear cytoplasmic antibodies (ANCA): Indirect immunofluorescence, ELISA
Renal biopsy (light microscopy, immunofluorescence, electron microscopy)
Required in specific instances
Anti-GBM IgG antibodies
Blood levels of cryoglobulin, hepatitis B and C serology
Chest: radiograph, CT (patients with Goodpasture syndrome and vasculitides)
Sinuses: radiograph, CT (patients with granulomatosis with polyangiitis)

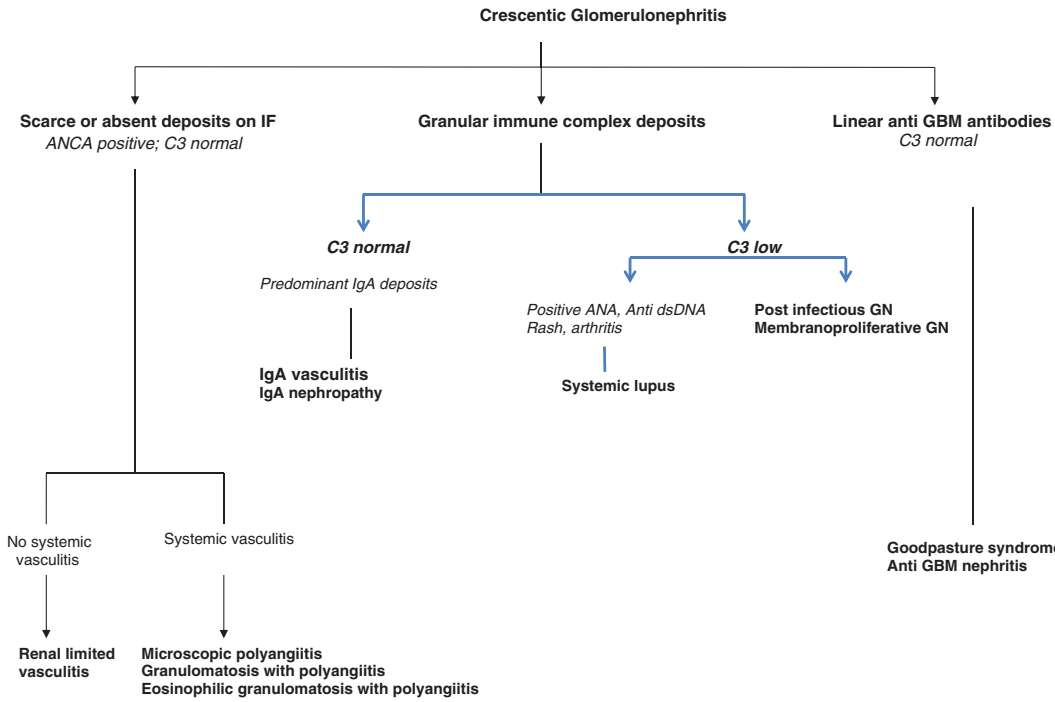

Fig. 20.1 Diagnostic evaluation of crescentic glomerulonephritis, based on renal histology and serological findings

infection in the past 3 months. Patients with SLE show antinuclear (ANA) and anti-double stranded DNA autoantibodies.

Elevated levels of ANCA suggest an underlying vasculitis, and are present in most patients with pauci-immune crescentic GN. Most ANCA have specificity for MPO or PR3. ANCA should be screened by indirect IF and positive tests confirmed by PR3-ELISA and MPO-ELISA. In patients with pauci-immune crescentic GN, negative results from IF should be tested by ELISA because 5% serum samples are positive only by the latter. GPA is associated with PR3 ANCA, which produces a cytoplasmic staining pattern on IF (c-ANCA). Renal limited vasculitis and drug induced pauci-immune crescentic GN are typically associated with MPO ANCA that shows perinuclear staining on IF (p-ANCA). Patients with MPA have equal distribution of MPO ANCA/p-ANCA and PR3 ANCA/c-ANCA. Approximately 10% of patients with GPA or MPA have negative assays for ANCA. P-ANCA autoantibodies are also found in 20–30% patients with anti-GBM GN, and occasionally in idiopathic immune complex RPGN, inflammatory bowel disease, rheumatoid arthritis and SLE [27].

Apart from diagnosis, ANCA titers have also been used for monitoring activity of systemic vasculitis. Persistent or reappearing ANCA positivity in patients in remission may be associated with disease relapse in AAV. The risk of relapse in patients who show persistently negative ANCA titers is low. An isolated rise in ANCA titers should not be used for modifying treatment in patients with systemic vasculitis [28]. The persistence or recurrence of ANCA positivity, or an increase in ANCA titers are only modestly predictive of future disease relapse and should not be used to guide treatment decisions. Such patients should be closely followed and diagnostic efforts intensified to detect and treat relapses.

Patients with AAV occasionally show autoantibodies to human lysosome-associated membrane protein-2 (hLAMP-2) [29]. These antibodies were also seen in a few patients with pauci-immune focal necrotizing crescentic GN who were negative for ANCA [30]. The hLAMP-2 autoantibodies became undetectable following initiation of immunosuppressive treatment and were detected during clinical relapse.

High titers of anti-GBM IgG antibodies, demonstrated by IF or ELISA, are seen in anti-GBM nephritis or Goodpasture syndrome and correlate with disease activity. About 5% of ANCA positive samples are also anti-GBM positive and approximately 20–30% of anti-GBM positive samples are ANCA positive. Serology for ANCA is therefore recommended in all patients with either anti-GBM antibodies in blood or linear IgG deposition along the GBM. The initial clinical outcome for these patients is similar to that of anti-GBM disease, though relapses may occur as in systemic vasculitis [1].

Renal Histology

Light Microscopy

Renal histological findings in various forms of crescentic GN are similar. A glomerular crescent is an accumulation of two or more layers of cells that partially or completely fill Bowman space. The crescent size varies from circumferential to segmental depending on the plane of the tissue section and the underlying disease. Crescents in anti-GBM nephritis or AAV are usually circumferential, while they are often segmental in immune complex GN. Interstitial changes range from acute inflammatory infiltrate to chronic interstitial scarring and tubular atrophy. Once the glomerular capillary loop is compressed by the crescent, tubules that derive their blood flow from that efferent arteriole show ischemic changes.

Crescents may be completely cellular or show variable scarring and fibrosis. Cellular crescents are characterized by proliferation of macrophages, epithelial cells and neutrophils (Fig. 20.2). Fibrocellular crescents show an admixture of collagen fibers and membrane proteins amongst the cells (Figs. 20.3 and 20.4). In fibrous crescents, the cells are replaced by collagen. Renal biopsies from patients with vasculitis show crescents in various stages of progression, indicating episodic inflammation. Early lesions have segmental fibrinoid necrosis with or without an

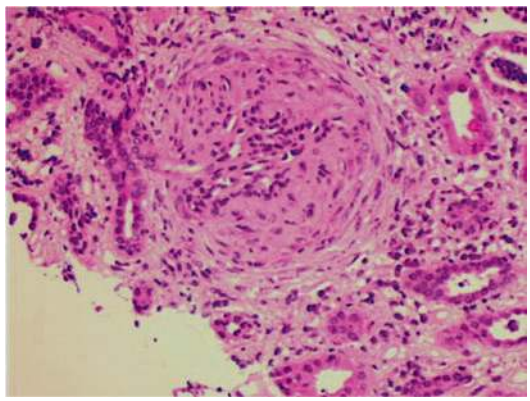

Fig. 20.3 Fibrocellular crescent with compression of glomerular tuft and partial sclerosis. There is chronic interstitial inflammation, tubular atrophy and interstitial fibrosis in surrounding area. Hematoxylin and eosin–stained, original magnification ×800

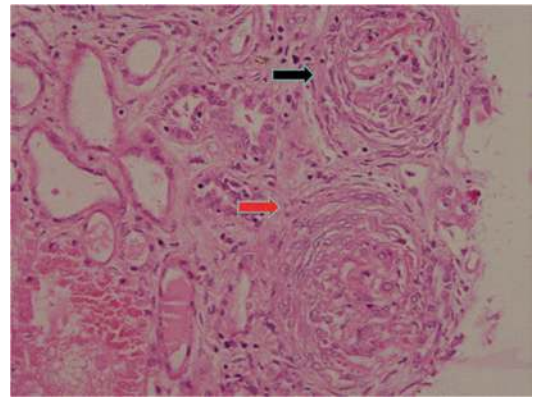

Fig. 20.4 Glomeruli showing cellular (red arrow) and fibrocellular crescents (black arrow) causing compression of underlying glomerular tuft. Note the disruption of Bowman capsule. Hematoxylin and eosin–stained, original magnification ×200

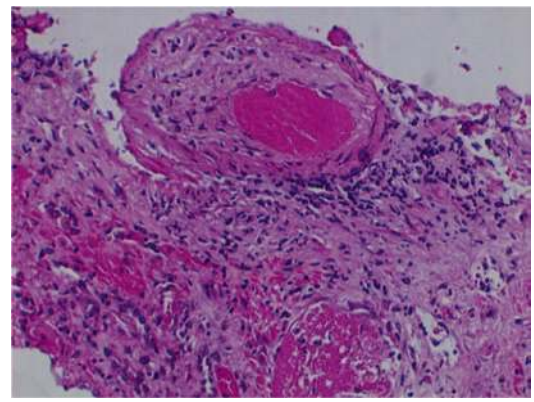

Fig. 20.5 A patient with pauci-immune crescentic glomerulonephritis. A small artery shows features of active vasculitis; its wall shows neutrophil infiltration, fibrin deposition and lumen occluded by a thrombus. The perivascular area shows interstitial hemorrhage and inflammation. Hematoxylin and eosin–stained, original magnification ×600

adjacent small crescent. Severe acute lesions show focal or diffuse necrosis in association with circumferential crescents. Features of small vessel vasculitis, affecting interlobular arteries (Fig. 20.5) and rarely angiitis involving the vasa recta might be seen.

ANCA associated GN is classified based on light microscopy findings [31]. Biopsies are categorized as focal, crescentic and sclerotic based on the predominance of normal glomeruli, cellular crescents, and globally sclerotic glomeruli, respectively. A fourth category represents a mixed or heterogeneous phenotype. Although the classification system is believed to have prognostic value for 1- and 5-year renal outcomes, and may guide therapy, it needs to be validated in children.

Immunohistology and Electron Microscopy

The presence, location and nature of immune deposits on IF and electron microscopy can help

determine the underlying cause of crescentic GN. The crescents stain strongly for fibrin on IF [32]. Mesangial deposits of IgA are found in IgA nephropathy and IgA vasculitis. While IgA is dominant or co-dominant in IgA nephropathy, deposits of IgG, IgM, fibrinogen, and C3 may also be seen in the glomeruli. Postinfectious GN has granular, subepithelial deposits of IgG and C3. Full house capillary wall and mesangial deposits of granular IgG, IgA, IgM, C3, C4 and C1q are seen in SLE. Immune complex-mediated MPGN is characterized by the immunoglobulin and complement deposits, while C3 glomerulopathy is characterized by glomerular complement deposits in the absence of significant immunoglobulins. Electron microscopy usually shows subendothelial and mesangial deposits in C3 glomerulopathy and MPGN.

Anti-GBM disease is characterized by linear staining of the GBM with IgG (rarely IgM and IgA) and C3 (Fig. 20.6).

The third group of crescentic GN has few or no immune deposits by IF or electron microscopy. The majority of these patients are ANCA positive, though some may have ANCA-negative, pauci-immune crescentic GN.

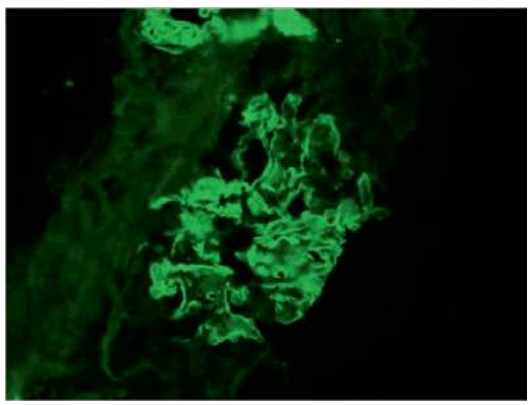

Fig. 20.6 Immunofluorescence microscopy (original magnification ×1200) in a patient with anti-glomerular basement membrane antibody-mediated crescentic glomerulonephritis showing linear deposition of IgG on the capillary wall

Evaluation and Diagnosis

It is necessary to make an accurate and rapid diagnosis in RPGN as treatment strategies vary and delay in instituting treatment increases the risk of irreversible damage. All patients should undergo a kidney biopsy promptly. While the majority have crescentic GN, the detection of thrombotic microangiopathy (affecting interlobular arteries and arterioles) or diffuse proliferative GN is not unusual. The diagnosis of the etiology of crescentic GN depends on integration of clinical data and findings on serology and renal histology (Table 20.3, Fig. 20.1).

Treatment

The heterogeneity and unsatisfactory outcome of RPGN has led to institution of multiple treatments. Evidence-based data is limited and treatment guidelines for children are based on data from case series and prospective studies in adults.

Empiric therapy with daily intravenous (IV) pulses of methylprednisolone (15–20 mg/kg, maximum 1 g) for 3 days should be initiated in patients with severe disease, particularly if kidney biopsy is likely to be delayed. This empiric initial therapy will not alter the histologic abnormalities on a kidney biopsy that is performed within a few days. Plasmapheresis can be considered in the empiric initial phase, especially if the patient presents with hemoptysis.

More specific therapy is started once the diagnosis is established. Treatment of RPGN typically comprises two phases: *induction* of remission and *maintenance* (Table 20.4). The first phase aims at control of inflammation and the associated immune response. Once remission is induced, the maintenance phase attempts to prevent further renal damage and relapses. All patients with RPGN, irrespective of the underlying diagnosis, will benefit from supportive man-

Table 20.4 Treatment of crescentic glomerulonephritis

Induction
Methylprednisolone 10–30 mg/kg (maximum 1 g) IV daily for three doses
Prednisolone 1.5–2 mg/kg/day oral for 4 weeks; taper to 0.5 mg/kg/day for 3 months; then, 0.5 mg/kg on alternate days for 3 months
[a]Cyclophosphamide 500–750 mg/m^2 IV every 3–4 weeks for six doses
[b]Plasma exchange (1–1.5 volume) on alternate days for 2 weeks
[c]Rituximab: 750 mg/m^2 (maximum 1000 mg), every 2 weeks for two doses
Maintenance
Azathioprine 1.5–2 mg/kg/day for 12–18 months
Alternate day low-dose prednisolone
Consider mycophenolate mofetil (1000–1200 mg/m^2/day) if disease activity is not controlled with azathioprine or patient does not tolerate azathioprine
Rituximab can be used for maintenance, given every 6 months or when B lymphocytes reconstitute
Agents for refractory disease
Intravenous immunoglobulin, TNF-α antibody (infliximab), rituximab

[a]The dose of cyclophosphamide is increased to 750 mg/m^2 if there is no leukopenia before the next dose. Dose reduction is necessary in patients showing impaired renal function. Alternatively, cyclophosphamide is given orally at a dose of 2 mg/kg/day for 12 weeks

[b]Plasma exchange can be initiated early, especially if patient is dialysis-dependent at presentation or if the biopsy shows severe histological changes (>50% crescents). It is useful in anti-GBM nephritis and may be useful in ANCA-associated vasculitis. It can be considered in patients with immune complex crescentic GN if there is unsatisfactory renal recovery after steroid pulses

[c]Rituximab may be used as first line in children and adolescents with AAV, particularly PR3-AAV. It may be used as an alternative initial treatment in patients with less severe disease or in whom cyclophosphamide is contraindicated

agement, including maintenance of fluid and electrolyte balance, provision of adequate nutrition, and control of infections and hypertension. Some patients require dialysis at diagnosis or soon thereafter.

Medications

Steroids After the initial IV pulses, steroids are typically given as high-dose oral prednisone (1.5–2 mg/kg daily) for 4 weeks, with tapering to 0.5 mg/kg daily by 3 months and alternate day prednisone for 6–12 months. Based on recent studies, a reduced-dose, tapering regimen of oral glucocorticoids-could be considered for a patient with new onset or relapsing AAV [33].

Cyclophosphamide Historically, cyclophosphamide has been an important part of induction regimens. Most centers prefer the use of IV compared to oral therapy. The European Vasculitis Study Group (EUVAS) compared IV pulse cyclophosphamide (15 mg/kg every 2 weeks for 3 pulses, followed by pulses at 3-week intervals until remission, and then for another 3 months) with daily oral cyclophosphamide (2 mg/kg/day) for induction of remission [34]. They showed that the time to remission and proportion of patients in remission at 9 months was similar in both groups. The cumulative dose of cyclophosphamide in the daily oral group was twice that in the IV group (15.9 g *vs.* 8.2 g; $P < 0.001$), and the latter had a lower rate of leukopenia. A meta-analysis of nonrandomized studies showed that pulse cyclophosphamide was significantly more likely to induce remission and had a lower risk of infection and leukopenia. Pulse cyclophosphamide dosing may, however, be associated with a greater risk of relapses, exposing patients to further immunosuppression [35]. The dose of oral and IV cyclophosphamide is 2 mg/kg/day and 500–750 mg/m^2, respectively. The dose should be adjusted to maintain a nadir leukocyte count of 3000–4000/μL 2 weeks post-treatment. While most of the data on cyclophosphamide is from AAV or lupus nephritis, a similar regimen is recommended for crescentic IgA nephropathy or IgA vasculitis.

Rituximab B cell depletion with rituximab has similar efficacy as cyclophosphamide in many studies. It has been used successfully in patients with refractory lupus nephritis and AAV [36]. The Rituximab in ANCA-Associated Vasculitis (RAVE) trial compare rituximab with standard therapy for inducing remission in patients with AAV [37]. Patients received either rituximab (375 mg/m^2/week for 4 weeks) or cyclophosphamide (2 mg/kg/day). Both groups received 1–3

pulses of methylprednisolone (1000 mg each), followed by tapering dose of prednisone. At 6 months, 64% in the rituximab group achieved remission vs. 53% in the control group. Of the subgroup that had relapsing disease, rituximab was superior to cyclophosphamide in inducing remission (67% versus 42%) at 6 months. Thus, therapy with rituximab was not inferior to treatment with cyclophosphamide for induction of remission. Patients from the RAVE study who achieved complete remission were followed through month 18 [38]. During follow-up, those treated with rituximab received no further therapy, while those treated with cyclophosphamide were converted to azathioprine. At 18 months, the proportion of patients remaining in complete remission was similar (39% rituximab vs. 33% cyclophosphamide). Interestingly, a post hoc analysis of the RAVE trial found a higher remission rate for the PR3-AAV subgroup at 6 months treated with rituximab [39]. A similar association was not seen with MPO-AAV.

The RITUXVAS study randomized patients with AAV to receive a standard steroid regimen plus either rituximab (375 mg/m^2/week for 4 weeks) with two IV cyclophosphamide pulses, or IV cyclophosphamide for 3–6 months followed by azathioprine [40]. There was no significant difference in the rate of remission, severe adverse events, and death in the two groups.

Mycophenolate mofetil (MMF) MMF has been used in observational studies as part of induction therapy for vasculitis, though it may have a greater role in the maintenance phase. Results from the EUVAS MYCYC trial showed that MMF was non-inferior to cyclophosphamide for remission induction in AAV, but resulted in a higher relapse rate [41]. MMF has also been used as an alternative to azathioprine for maintenance therapy in patients with AAV. However, the IMPROVE trial (International Mycophenolate Mofetil Protocol to Reduce Outbreaks of Vasculitides) showed that relapses were significantly more common in patients receiving MMF compared to azathioprine, with no difference in severe adverse events [42]. The Kidney Disease Improving Global Outcomes (KDIGO) Clinical Practice Guideline for Glomerulonephritis recommends using azathioprine as the first choice for maintenance therapy in ANCA vasculitis and considering MMF as an alternative in patients who are allergic to or intolerant of azathioprine [43].

Intravenous Immunoglobulin (IVIG) A number of studies have examined the efficacy of IVIG in subjects with AAV and RPGN, and reported benefit lasting for up to 3 months [44]. The exact mechanism of action is unclear with evidence for both non-specific anti-inflammatory and anti-cytokine effects and specific correction of immunoregulatory defects. In a study of AAV patients with persistent disease activity, 14/17 patients in the IVIG group had reduction in disease activity, compared to 6/17 in the placebo group [45]. The indications for initial or adjunctive treatment with IVIG is not defined.

Methotrexate The NORAM study compared the effectiveness of orally administered methotrexate and cyclophosphamide in adult patients with early systemic vasculitis and mild renal involvement [46]. Induction of remission was similar at 6 months, but relapses were more frequent after treatment withdrawal in methotrexate treated patients. Methotrexate is not recommended for patients with moderate to severe renal dysfunction.

Azathioprine Most patients with AAV need long-term maintenance immunosuppression due to the risk of relapses. Extended treatment with cyclophosphamide has been used in adults but has significant risks and is not the preferred approach for children. While azathioprine is not effective at inducing remission, it is useful for long-term prevention of relapses. The timing of the switch from cyclophosphamide to azathioprine was clarified by the CYCAZAREM trial, which compared switching from cyclophosphamide to maintenance azathioprine at 3 versus 12 months [47]. At 18 months, the two groups had similar remission rates, renal function and patient survival. There is uncertainty regarding the appropriate duration of maintenance treatment, with most patients with pauci-immune crescentic GN treated for 2 or more years.

Newer Agents

T lymphocyte depletion with Campath 1-H (alemtuzumab), an anti-CD52 monoclonal antibody, has been tried with variable success in patients with GPA and other vasculitides [48]. In a retrospective cohort study, 85% of patients with refractory AAV achieved remission after alemtuzumab, but the majority relapsed after a median of 9 months [45].

A multicenter, double-blind, placebo-controlled study evaluated belimumab for preventing relapses in patients with AAV [49]. Belimumab is a monoclonal antibody that prevents the survival of B lymphocytes by blocking the binding of soluble human B lymphocyte stimulator protein to receptors on B lymphocytes. Patients were randomized to receive azathioprine, low-dose oral steroids and either IV belimumab or placebo for maintenance of remission. The addition of belimumab did not reduce the risk of relapse.

Avacopan, which targets the complement system by blocking the C5a receptor, has been investigated as an approach to reduce corticosteroid exposure in AAV. A phase II trial showed that avacopan was well-tolerated and safe in the short-term and may be able to replace high-dose corticosteroids [50]. This was followed by a phase III randomized, controlled trial comparing avacopan with a tapering schedule of prednisone in patients with AAV concurrently treated with cyclophosphamide (followed by azathioprine) or rituximab [51]. Avacopan was noninferior to prednisone taper for the end-point of remission at week 26 and was superior to prednisone taper for sustained remission at week 52. The number of steroid-related adverse events was higher in the prednisone group than in the avacopan group.

Plasmapheresis

Plasmapheresis or plasma exchange has been used for the treatment of crescentic GN with variable success. The mechanism of action is not clear, but is believed to involve removal of pathogenic autoantibodies, complement proteins, coagulation factors and cytokines. Plasma exchange has been shown in controlled trials in adults to have therapeutic benefit in anti-GBM disease, with clearance of auto-antibodies, lower serum creatinine and improved patient and renal survival [52]. However, adults who were anuric with severe azotemia, dialysis dependent or those who had more than 85% crescents on renal biopsy had minimal benefit. The role of intensive plasma exchange versus IV methylprednisolone, in addition to oral steroids and cyclophosphamide, was examined by the MEPEX trial in patients with AAV and serum creatinine >500 μmol/L (5.65 mg/dL) at presentation [53]. Patients receiving plasma exchange were more likely to be off dialysis at 3-months (69% *vs.* 49%) and had a lower risk of ESKD at 12 months, but there were limited benefits on long-term renal function or survival. Another study showed that plasma exchange improved medium-term renal survival, even when initiated in patients with serum creatinine levels >250 μmol/L (2.85 mg/dL) [54].

More recently the PEXIVAS trial looked at initial treatment with plasma exchange vs. no plasma exchange (with either cyclophosphamide or rituximab administered to all patients) and two different regimens of oral steroids in patients with severe AAV [33]. The study failed to demonstrate that plasma exchange delayed the time to ESKD or death.

Retrospective data in children with RPGN show benefits of plasma exchange if commenced within 1 month of disease onset [55]. Anecdotal reports confirm the efficacy of plasmapheresis in patients with RPGN due to lupus, IgA vasculitis and severe proliferative GN, and in life-threatening pulmonary hemorrhage. Prospective studies in patients with pauci-immune crescentic GN suggested that kidney outcomes were better with plasma exchange and immunosuppression vs. immunosuppression alone [56]. However, a meta-analysis of renal vasculitis or idiopathic RPGN concluded that adjunctive plasma exchange did not improve renal and patient survival [57].

According to the KDIGO Guidelines, the routine use of plasma exchange is not recommended for patients presenting with a GFR <50 mL/min/1.73 m^2, but it can be considered in those with more severe AKI or in those with alveolar hemorrhage and hypoxemia. The dose recommended for adults is 60 mL/kg volume replacement [43]. For AAV, seven treatments over 14 days are prescribed and for patients with anti-GBM antibodies, daily exchanges are performed for 14 days or until anti-GBM antibodies are undetectable.

In our practice, we consider plasma exchange for patients with severe AKI or alveolar hemorrhage with hypoxia, and use 1–1.5 volume exchange per the schedule discussed above.

Immune Complex Crescentic GN

Therapy for immune complex crescentic GN depends on the underlying disease. The treatment of IgA nephropathy and lupus nephritis presenting with RPGN is discussed in their respective chapters. Patients with idiopathic immune complex crescentic GN should be treated similarly to those with pauci-immune crescentic GN.

Postinfectious RPGN

Poststreptococcal GN presenting with extensive crescents is rare and the benefits of intensive immunosuppressive therapy are unclear, since most patients recover spontaneously. Nevertheless, immunosuppressive therapy with corticosteroids and alkylating agents has been used in patients with renal failure and extensive glomerular crescents [58]. Despite the lack of evidence-based data, we usually treat patients with postinfectious RPGN and crescents involving 50% or more glomeruli with 3–6 IV pulses of methylprednisolone, followed by tapering doses of oral steroids for 6 months. Eradication of the infection and/or removal of infected prostheses are necessary for resolution of immune complex GN associated with active infections.

Pauci-immune Crescentic GN

Standard induction therapy is IV pulses of methylprednisolone daily for 3 days followed by oral prednisone and cyclophosphamide or rituximab. For cyclophosphamide, the choice between oral (2 mg/kg/day for 3 months) and IV (15 mg/kg every 2 weeks for three doses and then every 3 weeks for 3–6 months or 500–750 mg/m^2 every 2 weeks for 3–6 months) depends on institutional practice. While both oral and IV regimens are effective, IV is preferred due to the lower cumulative dose and lower risk of toxicity. After approximately 3–6 months, cyclophosphamide is replaced by a medication with a lower risk of toxicity. Rituximab, for induction is usually dosed at 750 mg/m^2 (maximum dose 1000 mg), with two 2 doses 14 days apart. Therapeutic plasma exchange can be added to the induction regimen for children who are dialysis dependent, those with pulmonary hemorrhage and hypoxia or not responding satisfactorily to induction treatment [33, 53].

Therapy during the maintenance phase is tapering doses of oral prednisolone and azathioprine, usually for 18–24 months. For most patients, a reduced-dose glucocorticoid tapering regimen can be used, particularly after studies like PEXIVAS showed that patients on the reduced-dose tapering regimen had similar rates of remission and fewer adverse effects compared with those on standard-dosing regimens [33].

A longer duration of therapy (3 years or more) may be needed in patients showing relapses, elevated ANCA titers and those with PR3-ANCA [2]. Approximately one-third of patients have one or more relapses, requiring reinstitution of induction therapy. Since intensive immunosuppression is associated with increased risk of infection, the use of prophylactic antimicrobials against *Pneumocystis carinii* and *Candida* may be required during induction.

For AAV, the KDIGO guidelines recommend using rituximab for children and adolescents, and for those with relapsing disease or PR3-AAV. They also suggest that for those with severe GN and creatinine >4 mg/dL, a combination of two pulses of cyclophosphamide with rituximab can be used for induction.

Anti-GBM Crescentic GN

Prompt institution of plasma exchange is necessary in these patients. Double volume exchange is done daily, and subsequently on alternate days until anti-GBM antibodies are no longer detectable (usually 2–3 weeks) [1, 59]. The patients are also treated with IV methylprednisolone (three doses of 20 mg/kg on alternate days) followed by high-dose oral prednisolone. Co-administration of cyclophosphamide (typically PO, 2 mg/kg daily for 3 months; IV may also be used) is effective in suppressing further antibody production. Pulmonary hemorrhage responds to plasma exchange and IV steroids. As anti-GBM disease does not usually have a relapsing course, long-term maintenance therapy is not required and steroids can be tapered over the next 6–9 months. Patients treated early in the course of their illness do satisfactorily. In patients who develop ESKD, transplantation should be deferred until anti-GBM antibodies are undetectable for 12 months, at which point disease recurrence is unlikely.

A proportion of patients with anti-GBM nephritis also show positive ANCA, most often p-ANCA. While the precise significance of the dual positivity is unclear, their outcome is similar to isolated anti-GBM disease. In view of a higher risk of relapses, these patients require a longer course of maintenance immunosuppressive therapy (as for ANCA-associated GN).

Outcome

The outcome for patients has improved in the last decades, such that almost 60–70% patients have normal long-term renal function. Patients with poststreptococcal crescentic GN have a better prognosis, with most showing spontaneous improvement. The prognosis is better in patients with poststreptococcal crescentic GN with subepithelial, rather than subendothelial or intramembranous deposits. Outcomes in patients with pauci-immune crescentic GN, MPGN and idiopathic RPGN are less favorable than IgA vasculitis or SLE. ESKD may occur on the long-term in up to 25% patients with AAV.

The outcome is determined by the severity of renal failure at presentation and promptness of intervention, renal histology and underlying diagnosis. Studies have shown that the use of plasma exchange, high percentage of normal glomeruli, and absence of glomerulosclerosis, tubular atrophy and arteriosclerosis, were associated with better renal recovery [60]. The potential for recovery correlates with the relative proportion of cellular or fibrous components in the crescents, and the extent of tubulointerstitial scarring and fibrosis.

Post-transplant Recurrence

Based on experience in adult patients, we suggest that patients with ANCA positive vasculitis should have sustained remission for 1 year before considering a transplant [61]. A positive ANCA titer at the time of transplantation does not increase the risk of allograft recurrence. Conditions associated with higher risk of histological recurrence include MPGN, IgA nephropathy, IgA vasculitis and lupus. Graft loss due recurrence is uncommon and occur in <5% of cases.

Part V

Complement Disorders

The Role of Complement in Kidney Disease

21

Michael Kirschfink and Christoph Licht

The Emerging Concept of Complement-Mediated Diseases

As a key mediator of inflammation complement also significantly contributes to tissue damage in various clinical disorders [1]. Clinical and experimental evidence underlines the prominent role of complement in the pathogenesis of numerous inflammatory diseases including immune complex and autoimmune disorders, such as systemic lupus erythematosus and autoimmune arthritis [2–4]. Complement deficiencies represent approximately 4–5% of all primary immunodeficiencies, in part closely connected with renal disorders [5].

In clinical practice, overactivation of the complement system is the cause of several inflammatory diseases and life-threatening conditions, such as adult respiratory distress syndrome (ARDS) [6], the systemic inflammatory response syndrome (SIRS), sepsis [7], and multi-organ failure after severe trauma, burns or infections [8]. Complement has also been implicated in neurodegenerative disorders, such as Alzheimer's disease, multiple sclerosis, and Guillain-Barré syndrome. In recent years complement activation has also been recognized as a major effector mechanism of ischemia/reperfusion injury [9, 10].

Over the past two decades our understanding of the role of complement in renal disorders has considerably advanced and genomic studies have revealed multiple strong associations of genetic variants of complement proteins with kidney disease [11, 12].

The inflammatory response induced by artificial surfaces in hemodialysis and other extracorporeal circuits may lead to organ dysfunction. Here, complement activation has been associated with transient neutropenia, pulmonary vascular leukostasis and occasionally even with anaphylactic shock of variable severity [13, 14].

The Complement System

With more than 50 proteins acting as components within the activation cascade and as regulators or receptors on multiple cells, complement is a vital part of the body's innate immune system which provides a highly effective means for the destruction of invading microorganisms and elimination of immune complexes [15, 16]. In addition, complement also modulates the adaptive immune response through modification of

T- and B-cell function employing specific receptors on various immune cells [17]. Moreover, a normally functioning complement system also participates in hematopoiesis, reproduction, lipid metabolism and tissue regeneration [18]. Essential intracellular immune modulatory functions of the complement system have recently been discovered promoting the survival and activation of T-lymphocytes [19].

Most complement proteins are secreted by the liver and contribute to the acute phase response. However, other tissues like the kidney also produce complement proteins to a significant amount [20]. Complement genes are distributed across different chromosomes, with 19 genes comprising three significant complement gene clusters in the human genome [21].

Complement can be activated via three pathways (Fig. 21.1), the classical, the alternative, and the lectin pathway, all of which merge in the activation of complement C3 and subsequently lead to the formation of the cytolytic membrane attack complex (MAC), C5b-9 [22, 23]. Following complement activation, the biologically active peptides (anaphylatoxins) C3a and C5a are released and elicit a number of proinflammatory effects, such as chemotaxis of leukocytes, degranulation of phagocytic cells, mast cells and basophils, smooth muscle contraction, and increase of vascular permeabiltity [24, 25]. C3a activates mesangial cells leading to proliferation and secretion of extracellular matrix [26]. It also induces in tubular epithelial cells the production of proinflammatory cytokines [27]. Upon cell activation by these complement split products the inflammatory response is further amplified by subsequent generation of toxic oxygen radicals and the induction of synthesis and release of arachidonic acid metabolites and cytokines. Consequently, an (over-)activated complement system represents a considerable risk of harming the host by directly and indirectly mediating

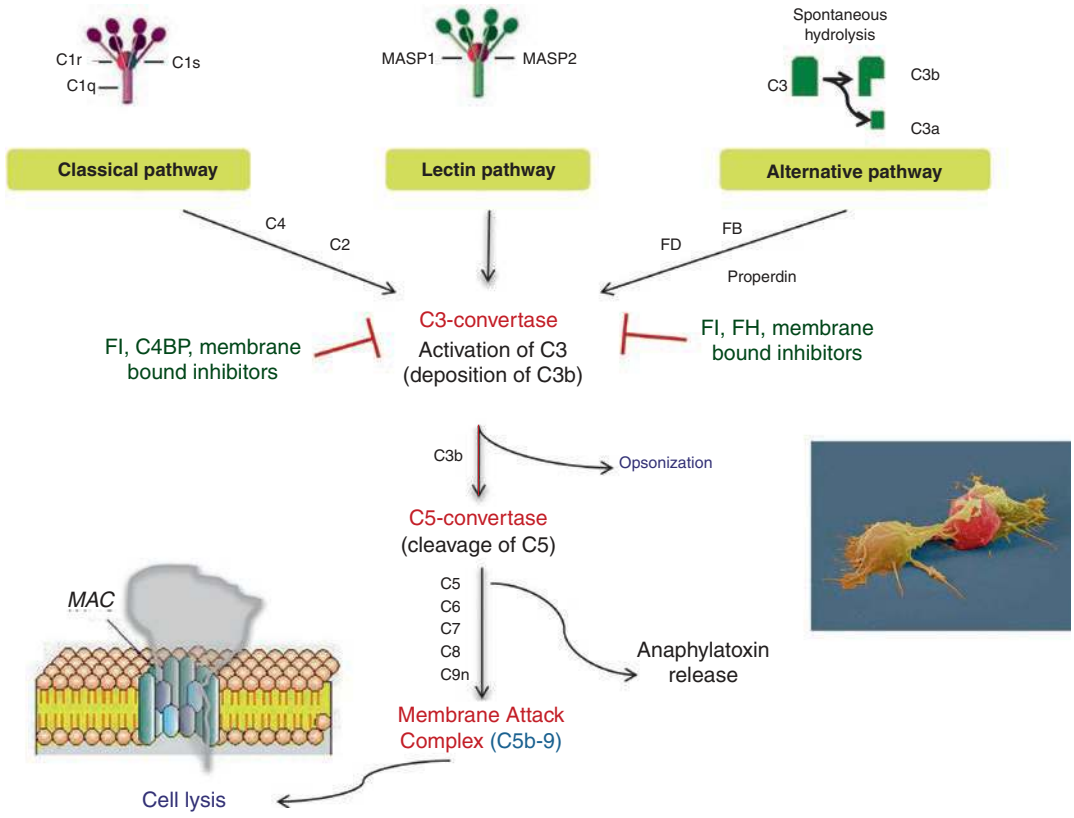

Fig. 21.1 A schematic overview of complement activation via the classical, lectin and alternative pathways

inflammatory tissue destruction [1]. Multiple interactions exist between the complement, coagulation and fibrinolytic systems altogether being of utmost importance in the pathogenesis of thrombotic microangiopathy (TMA) [28].

Under physiological conditions, activation of complement is effectively controlled by the coordinated action of soluble as well as membrane-associated regulatory proteins [29]. Soluble complement regulators, such as C1 inhibitor, C4b-binding protein (C4bp), Factors H (FH) and I (FI), clusterin and S-protein (vitronectin) restrict the action of complement in body fluids at multiple sites of the cascade (Fig. 21.1). In addition, each individual host cell is protected against the attack of homologous complement by surface proteins, such as the complement receptor 1 (CR1/CD35), the membrane cofactor protein (MCP/CD46), the glycosylphosphatidylinositol (GPI)-anchored proteins, decay-accelerating factor (DAF/CD55), and protectin (CD59) [29, 30].

Diagnosing Complement-Mediated Nephropathies

Detecting Complement Activation

In recent years, great progress has been made in complement analysis to better define disease severity, evolution and response to therapy (Tables 21.1 and 21.2) [31]. However, a comprehensive analysis going beyond C3 and C4 is still performed only in specialized laboratories (http://www.ecomplement.org/list-of-diagnostic-labs.html). The diagnostic work-up of a patient with a suspected complement-associated disease should start with the assessment of the total activity of the classical (CH50) and alternative (AH50) pathway. For rapid deficiency analysis, an ELISA has been developed that examines all three activation pathways in parallel [32]. These global tests provide information about the integrity of the entire complement cascade. A missing or

Table 21.1 Biochemical complement analysis

Functional assays	*Total complement activity (screening for complement deficiency)* • CH50 and AH50 hemolytic assays for CP and AP activity • Enzyme immunoassays (ELISA) for specific evaluation of CP, LP and AP activity using C5b-9 as readout
	Functional activity of single components • Hemolytic assays for single components (e.g. C3) using corresponding deficient sera as test system • ELISA for MBL/MASP functional activity using deposition of C4 as readout • C1 inhibitor assay (chromogenic assay or EIA) for diagnosis of HAE and acquired angioedema
Proteins	*Concentration of single components by immunoprecipitation (RID), nephelometry, ELISA* • C3 and C4 to detect "hypocomplementemia" • Follow-up of a low activity detected in total complement activity screening (any component) • C5-C9, Properdin, MBL at recurrent neisserial infections • C1 inhibitor for diagnosis of HAE and acquired angioedema
Activation products	*Concentrations of split products or protein-protein complexes by ELISA, preferentially based on antibodies to neoepitopes expressed selectively on the activation products* • Split products from components after proteolytic cleavage (e.g. C3a, C3d, C4a, C4d, C5a, Ba, Bb) • Complexes between the activated component and its inhibitor (e.g. C1rs-C1 inhibitor) • Macromolecular complexes (e.g. the AP convertase C3bBbP and the terminal sC5b-9 complex)
Autoantibodies	*Assessment of autoantibody concentrations by ELISA or functional assay* • Anti-C1q—SLE; anti-C1 inhibitor—angioedema; anti-FH—aHUS; C3 NeF/C5 NeF—MPGN, DDD/C3G
Surface proteins	*Flowcytometric quantification* • DAF/CD55 and CD59 for diagnosis of PNH

Table 21.2 Recommended complement analysis in nephropathies

Disease	Analysis
Systemic Lupus Erythematosus	CH50, C1q, C4 (C4A/B), C3, C3d or SC5b-9, anti-C1q autoantibodies
Atypical Hemolytic Uremic Syndrome	CH50, APH50, C3, C3a/C3d, SC5b-9, CFH, CFI, CFB Anti-CFH autoantibodies *C3, CFB, CFH, CFHRs, CFI, MCP/CD46, THBD/CD141 (molecular analysis)*
C3 Glomerulopathy (DDD, C3GN)	CH50, APH50, C3, C3a/C3d, SC5b-9, C3 NeF, CFH Anti-CFH autoantibodies *C3, CFB, CFH, CFHRs, CFI, MCP/CD46, THBD/CD141 (molecular analysis)*

greatly reduced activity in either test indicates primary complement deficiency affecting the classical or the alternative or both pathways but may also be due to secondary deficiency caused by increased consumption. Age- and sex-related diffrerences in the complement system should be taken into account in data interpretation [33].

Analysis of individual components and regulators provide insight in which portion of the complement cascade either a lack of function or an (over-)activation occurs. Recently, an algorithm to differentiate primary from secondary aHUS has been proposed based on the assumption that primary aHUS is caused by permanent (genetic or autoimmune) complement dysregulation as opposed to transient complement dysregulation in secondary aHUS. In brief, eculizumab treatment is proposed in TMA patients with evidence for complement activation aimimg to normalize terminal complement activity (MAC/C5b-9) in a first step. In a second step, proximal complement activity (C3 consumption; FH and FI levels) should be evaluated and eculizumab treatment should be continued in patients with proximal complement dysregulation only (primary aHUS), but not in patients with normal proximal complement activation (secondary aHUS) [34].

Analysis of the plasma concentrations of individual complement components such as C3 and C4 is still performed in many clinical laboratories. These tests, however, detect both native and activated, i.e., already "consumed" complement proteins and are strongly influenced by fluctuations in protein synthesis, in particular during the early acute-phase reaction. Modern complement analysis focuses on the quantification of complement-derived split products (e.g., C3a, C3d, C5a or Bb) and/or protein-protein complexes (e.g., sC5b-9), thereby providing comprehensive insight into the actual activation state of the complement system. The choice of the appropriate parameters allows to determine exactly which pathway is activated [35, 36]. The soluble activation product of the terminal complement cascade, sC5b-9, has received considerable attention, as unrestricted progression to its final steps has been linked to specific pathology, i.e. aHUS [37], and has recently been suggested as severity criteria in transplantation-associated thrombotic microangiopathy [38]. The therapeutic efficacy of C5 antibodies in treating aHUS patients is reflected by sC5b-9 suppression [39]. More recently, endothelial cell based ex vivo assays detecting C3 and/or C5b-9 deposition on cultured human microcvascular endothelial cells (HMEC) are offered to detect complement dysregulation in individual patients on target tissue rather than in the circulating blood [40, 41]. While not routinely available, yet, such tests add valuable insights to the complement diagnostic repertoire and have also proven to being successful in determining treatment duration [42].

Of note, complement dysregulation can be primary due to genetic (mutations in complement components and/or regulators) or autoimmune (autoantibodies) alterations, or secondary in context of underlying conditions such as infections, drugs, or mechanical stress (i.e., hypertension) of endothelail cells [43].

A recommended algorithm of complement analysis for both primary and secondary nephropathies is shown in Fig. 21.2.

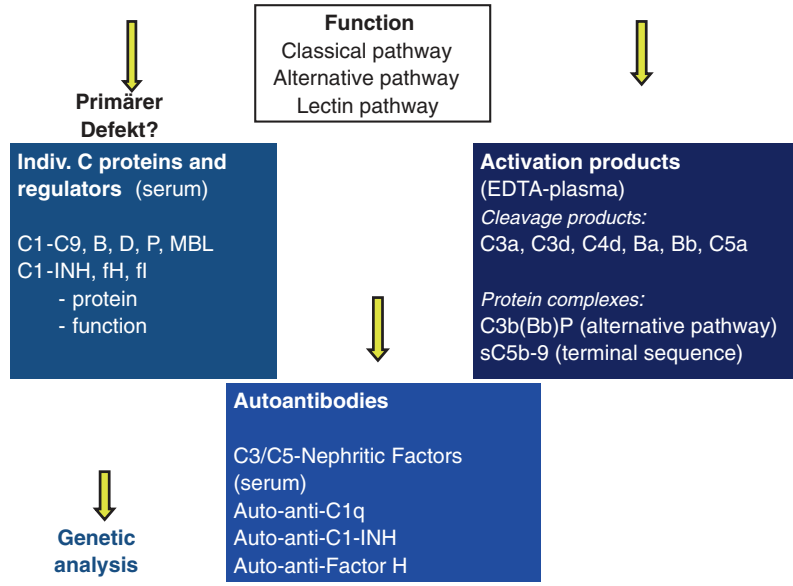

Fig. 21.2 Algorithm of complement analysis

Detecting Autoantibodies

Similar to *loss* or *gain of function* mutations in complement regulators or activating components, overactivation of complement can also be caused by autoantibodies. Autoantibodies to FH (DEAP HUS) [44], FB (DDD) [45], C1q (SLE) [46], or to C1 inhibitor (hereditary angioedema) [47] can be detected by ELISA with the respective purified complement proteins immobilized on a microtiter plate. Results from serial dilutions of patient sera or plasma should be interpreted in comparison with data from large control panels.

Nephritic factors comprise a heterogeneous group of autoantibodies against neoepitopes generated in the C3 and C5 convertases of the complement system, causing its dysregulation [48]. C3 nephritic factor (C3NeF), found in all types of MPGN [49], but especially in dense deposit disease (DDD), can be measured in a decay assay as C3NeF stabilizes the alternative pathway C3 convertase, C3bBb. In this semi-quantitative screening assay C3NeF stabilizes the C3 convertase on sheep erythrocytes, thereby causing increased complement activation and eventually hemolysis [50]. Fluid-phase conversion of C3 upon mixture of normal serum and C3Nef containing patient serum can also be visualized as emerging protein bands of C3b and C3c at lower molecular weight using an immunofixation assay [51]. Recently an ELISA for C3NeF has been reported [36]. Both C3 and C5 nephritic factors correlate with C3 consumption, while only C5 nephritic factors correlated with sC5b-9 levels [52].

Collecting Blood and Urine Samples

Proper collection of (blood and urine) samples for diagnostic analysis is essential [53]. Sample collection should aim at freezing the complement activation status of the patient at the time of blood draw. Without inhibition, physiological and pathological complement activation would continue, thereby obscuring the actual complement activation status and preventing meaningful data interpretation. Therefore, EDTA at $\geq$10 mM final concentration is used as standard anticoagulant since it blocks the *in vitro* activation of the complement system by way of its Mg^{2+} and Ca^{2+} complexing properties. Heparin and citrate are less useful [54]. Centrifuged plasma should be kept

on ice or in a refrigerator if analyzed on the same day; for later processing, the sample should be aliquoted, frozen and stored at −70 °C (−20 °C for short-term [days] storage). Repeated freezing and thawing of aliquots should be avoided because of the risk of *in vitro* activation (above). If needed, frozen samples should be shipped on dry ice.

In urine, the measurement of activated complement components (such as C3) or degradation products (such as C3a or sC5b-9) can be affected by high amounts of urea and urine proteases, so that the immediate addition of protease inhibitors at sampling is required. However, as oberved by us (Kirschfink, unpublished) and shown by van der Pol et al. [55], appearance of complement activation products in proteinuria may also be the consequence of extrarenal (artificial) rather than intrarenal complement activation.

Immunohistological Diagnosis

The diagnosis of many autoimmune (or immune complex diseases) is based on the detection of immunoglobulins and complement deposition in various tissues. For immunohistochemical diagnosis, antibodies against C1q, C3b, C4b, C4d, and C5b-9 are suitable and are available for frozen and in part also for paraffin fixed tissue. Positive staining identifies a direct impact of complement in the disease process, indicates disease activity and allows for the differentiation of the complement activation pathways involved. The presence of C3b suggests ongoing inflammation, while C3d deposits in the absence of C3b point to a non-active disease process. While its specificity is debatable, for long time C4d has been accepted as biomarker of humoral renal graft rejection [56, 57]. However, more recent studies question the clinical significance of C4d in antibody-mediated rejection [58], whereas it appears as if combined C4d and C3d deposition in IgAN is associated with faster disease progression [59].

Targeting Complement in the Treatment of Kidney Disease

The unraveling of a key role for complement dysregulation in an increasing spectrum of kidney diseases provides an unprecedented treatment approach to diseases, previously only poorly managed and often progressing to ESRD and/or death [60]. Furthermore, despite significant progress in biocompatibility of hemodialysis membranes complement activation during extracorporeal treatment still remains a relevant issue [61].

The overarching principle is the restitution of proper complement control. This may be achieved by replacement of missing or defective complement factors or removal of inhibiting autoantibodies via plasma exchange (PLEX)/plasma infusion (PI). Further strategies include the replacement or supplementation of endogenous soluble complement inhibitors (such as C1-inhibitor, FH, recombinant soluble complement receptor 1 [rsCR1]), the administration of antibodies to block key proteins of the cascade reaction (e.g., C5) or to neutralize complement-derived anaphylatoxins, especially C5a (reviewed in [62–66]).

The use of C1INH (Berinert®) in patients receiving deceased donor kidney transplants with high risk for delayed graft function (DGF) may show significant improvement in outcomes post transplant [67].

Both, eculizumab and ravulizumab prevent the release of the highly potent inflammatory anaphylatoxin C5a and the assembly of the membrane attack complex C5b-9 with the advantage of leaving the activation phase of complement up to the generation of the C3 opsonins C3b and iC3b intact. Despite excellent results of treatment with eculizumab and ravulizumab in cinical trials, their is still a great uncertainty with respect the optimal treatment strategy, especially on the decision how to proceed when a patient is stable and in remission [68]. The potential risk of aHUS recurrence after discontinuation of eculizumab treatment

raises the question how long eculizumab should be administered [69]. Risk factors for aHUS recurrence after eculizumab discontinuation include a positive family history of aHUS, presence of pathogenic genetic variants, and extra-renal manifestations of aHUS prior to eculizumab treatment [70]. In a recent survey, Fakhouri et al. confirmed the central role of complement mutations for aHUS recurrence but also concluded that a strategy of eculizumab discontinuation guided by the genetic diagnosis was in most patients reasonable and safe [71]. Collection of outcome data in patients with aHUS, either receiving eculizumab or other treatments, will certainly help to optimize therapy. While the treatment of aHUS with eculizumab has been highly successful in most cases [72–74], its use for other complement-mediated renal diseases is still a matter of ongoing clinical research [75, 76]. The off-label use of eculizumab in patients with C3 glomerulopathy (C3G) including dense deposit disease (DDD) and C3 glomerulonephritis (C3GN) has yielded mixed responses thus far, without uniformly countering key pathological markers (that is, proteinuria), which has prompted the evaluation of alternative therapeutics interferring with the complement cascade more proximally.

Eculizumab is currently being used in renal transplantation and has been evaluated in several clinical trials to minimize the consequences of ischemia-reoxygenation injury (IRI), prevent or treat relapsing or de novo aHUS, and to prevent and cure humoral rejection in patients at high immunological risk (i.e., DSA; ABO-incompatibility) [77, 78]. However, the C5 inhibitor appears less effective in preventing delayed graft function [78].

A second anti-C5 monoclonal antibody with increased half-life, named ravulizumab, has recently been approved by the US Food and Drug Administration for paroxysmal nocturnal haemoglobinuria (PNH) and aHUS in adults and children from 1 months of age [79]. With an extended plasma residence it only requires administration every 8 weeks instead of biweekly, an important step in improving patient management. The long-lasting anti-C5 antibody Ravulizumab has successfully been used in adult and pediatric aHUS [79, 80], and is currently being tested in clinical trials for lupus nephritis and IgA nephropathy.

Besides monitoring of eculizumab-treated patients on the basis of traditional parameters such as lactate dehydrogenase (LDH), hemoglobin (Hb), haptoglobin, platelets and serum creatinine, additional analyses of complement activation including CH50 and AH50 (reflect inhibitory efficacy), sC5b-9, C3 and C3d (indicating potential ongoing *in vivo* activation) provide valuable informations on therapeutic efficacy and may allow—together with drug monitoring—for the re-evaluation of the use and dosage of eculizumab in the heterogeneous group of complement-mediated renal diseases [68, 81].

In certain indications, broader inhibition of complement at the level of C3 may warrant investigation, leveraging clinical benefits over existing therapies, and C3-targeted therapeutics are now being evaluated in long-awaited phase II/III trials [65, 82, 83]. Specifically, alternative C3 convertase (C3bBb) inhibitors at the level of FB or C3 have successfully been tested in paroxysmal nocturnal hemoglobinuria (PNH), and are currently clinically trialed in C3 glomerulopathy (C3G).

Ongoing clinical trials are examining the efficacy of specific blockade in C3G with narsoplimab, sut-imlimab, and danicopan, all of which inhibit complement activation more proximally. Other renal diseases, such as IgA nephropathy, lupus nephritis, and membranous nephropathy are also under study with complement inhibiton. (Gavrillaki and Brodski, 2020) While broader intervention at the level of C3 or the overactive AP seems mechanistically more justified, targeted C5aR1 inhibition using the orally available drug candidate avacopan has shown early clinical promise in C3G and ANCA vasculits [84]. Moreover, an anti-MASP2 mAb is currently being evaluated in clinical trials for various nephropathies, such as IgA nephropathy, aHUS and Lupus Nephritis. Inhibitors targeting the lectin pathway, of FB, FD and C3 are currently at varying stages of clinical development [65, 85].

Summary and Perspectives

The complement system, a complex network of proteins and critical part of the innate immune response significantly contributes to the pathogenesis of inflammatory kidney diseases. A thorough understanding of the basic disease mechanism and careful follow-up are needed for optimal therapy. Comprehensive modern serological and molecular complement analysis is indispensable for correct differential diagnosis of the renal disorders.

Selective complement targeting to inhibit cascade activation can halt or even reverse renal disease. However, to delineate which pathway(s), and at what level, intervention could be effective still requires further translational and clinical research to open new avenues for successful treatment strategies for renal disease.

Atypical Hemolytic Uremic Syndrome

22

Michal Malina, Veronique Fremeaux-Bacchi, and Sally Johnson

Introduction

The hemolytic uremic syndrome (HUS) is a thrombotic microangiopathy (TMA) characterized by the triad of thrombocytopenia, nonimmune microangiopathic hemolytic anemia, and acute kidney injury [1]. The most frequent form of HUS in children is secondary to Shiga toxin (Stx)—producing *Escherichia coli* (STEC) and the term atypical HUS (aHUS) was initially used to designate any HUS not caused by STEC. It is now clear that within the umbrella of aHUS are a number of specific causes of HUS—for example *Streptococcus pneumoniae* infection, cobalamin C defect, Diacylglycerol kinase ε (DGKε) defect and various underlying conditions.

Atypical HUS without coexisting disease or specific infection is mostly a disease of complement alternative pathway (AP) overactivation, due to hereditary mutations in complement genes or acquired autoantibodies against complement factor H (FH). The clinical characteristics of patients, patient outcome and genotype-phenotype correlations were described [2–7]. Therefore, the term aHUS is today preferentially used to designate HUS without coexisting disease or specific infection [5, 6, 8–11]. Plasma exchange (PE) was the mainstay of treatment for aHUS until 2009, with considerable morbidity in children [12, 13]. Since 2009, terminal complement blockade therapy by eculizumab has dramatically changed the hitherto dismal outcome of the disease [14, 15]. The aims of this chapter are to summarize the previous era of treatment, to review new knowledge in the domain of atypical HUS and to scan the horizon for future developments in the management of atypical HUS.

Definition of Atypical HUS

Atypical HUS is one of a number of causes of TMA—life or organ threatening diseases characterized by microthrombi in small blood vessels which can be classified according to etiology and/or physiopathology [16–19] (Fig. 22.1). The two most important TMAs to exclude when suspecting aHUS are thrombotic thrombocytopenic purpura (TTP) and shigatoxin associated HUS (STEC HUS). The latter is the most common TMA affecting the kidneys in children. It is caused by

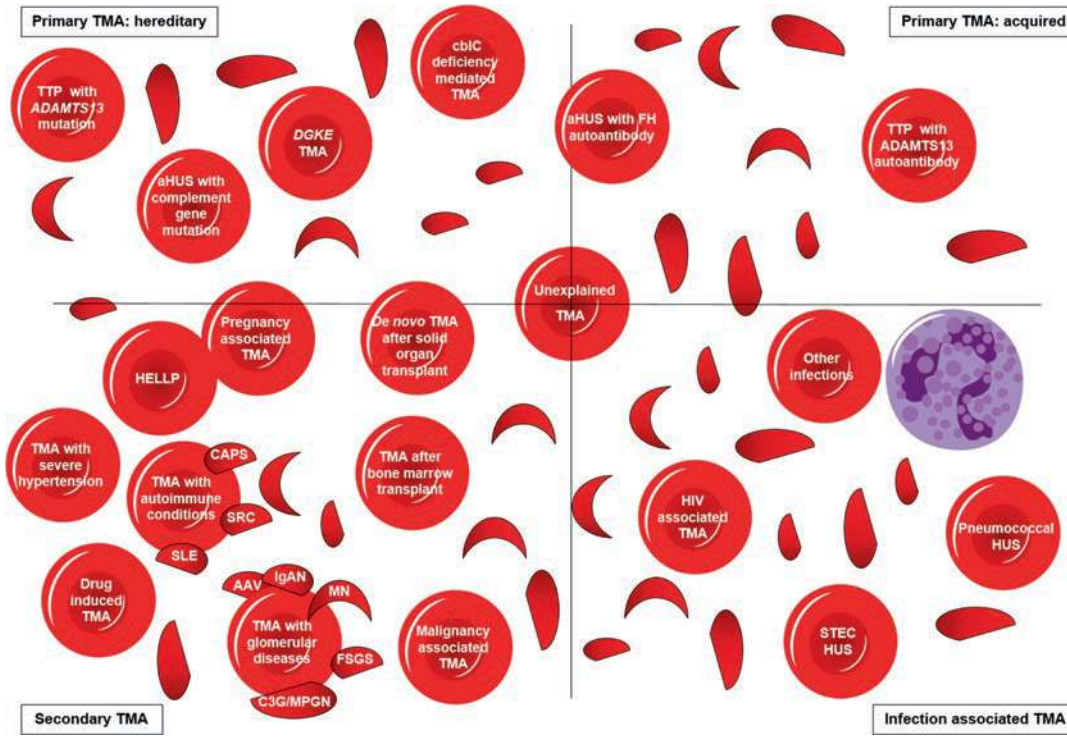

Fig. 22.1 Thrombotic microangiopathies are classified into: Inherited or acquired primary; secondary; or infection associated TMAs. Current classifications define primary TMAs as hereditary (mutations in ADAMTS13, MMACHC (cb1c deficiency), or genes encoding complement proteins) or acquired (autoantibodies to ADAMTS13, or autoantibodies to complement FH, which is associated with homozygous CFHR3/1 deletion). TMA is associated with various infections: in STEC-HUS and pneumococcal HUS, distinct mechanisms result in TMA; in other infections, the processes are not defined and in some cases the infection may trigger manifestation of a primary TMA. Secondary TMAs occur in a spectrum of conditions, and in many cases the pathogenic mechanisms are multifactorial or unknown. The classification presented here is not unequivocal: in some secondary TMAs, for example pregnancy-associated TMA or de novo TMA after transplantation, a significant proportion of individuals will have a genetic predisposition to a primary TMA. *AAV* ANCA-associated vasculitis; *ADAMTS13* a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13; *aHUS* atypical hemolytic uremic syndrome; *C3G* C3 glomerulopathy; *CAPS* catastrophic antiphospholipid syndrome; *cblC* cobalamin C type; *DGKE* gene encoding diacylglycerol kinase ε; *FH* factor H; *HELLP* syndrome of hemolysis, elevated liver enzymes, and low platelets; *HUS* hemolytic uremic syndrome; *IgAN* IgA nephropathy; *MN* membranous nephropathy; *MPGN* membranoproliferative glomerulonephritis; *SRC* scleroderma renal crisis; *STEC* shiga toxin–producing Escherichia coli; *TMA* thrombotic microangiopathy; *TTP* thrombotic thrombocytopenic purpura. Reproduced from Brocklebank et al. [19]

intestinal infection by certain strains of E coli carrying a plasmid for producing shigatoxin, particularly serotypes O157:H7, O104:H4 and O26 and in rare cases by Shigella dysenteriae [20, 21]. This type of HUS was previously labeled as typical or D+, however this classification is now obsolete.

TTP is an important cause of TMA that must be ruled out before making a diagnosis of aHUS. It is due to a severe deficiency (<10%) in ADAMTS13 (A Disintegrin And Metalloproteinase with a ThromboSpondin type 1 motif, member 13) activity, either from a congenital absence of functional protein caused by homozygous or compound heterozygous mutations in the *ADAMTS13* gene, or due to anti-ADAMTS13 antibodies [22].

TMA can also occur secondary to a coexisting disease or condition, such as malignancy or autoimmune disease. This is more common in adults than children, with the exception of post-hematopoietic stem cell transplant (HSCT) TMA.

As the classification of TMA has evolved with increasing understanding [23], there is general agreement that the term aHUS defines patients with HUS without a coexisting disease or specific infection [5, 6, 8–11]. This chapter is focused on aHUS according to this definition.

Incidence and Prevalence of Atypical HUS

Atypical HUS, defined as indicated above, is an ultra-rare disease. In the United States, aHUS is considered to have an annual incidence rate of two new pediatric cases per million total population [24]]. An incidence of approximately 0.11 new pediatric cases per million total population per year was also observed between July 2009 and December 2010 in an exhaustive cohort of children with aHUS from France, the United Kingdom, Spain, Netherlands and Canada [13]. A recent systematic review has reported an overview of global incidence and prevalence of aHUS [25]. Eight studies were reviewed from Europe, Australia, and New Zealand [5, 26–32]. In Europe the reported incidence (all ages) ranged between 0.23 and 1.9 per million annually [5, 32]. In Australia a pediatric study reported a calculated incidence of 0.44 per million annually [28]. Studies reporting incidence for individuals under 20 years of age ranged between 0.26 and 0.75 per million annually [27, 32]. A systematic review by Yan reported that in individuals under 20 years of age, the prevalence of aHUS ranged between 2.21 and 9.4 per million people [25].

The Alternative Pathway of Complement

The alternative pathway (AP) of the complement system plays a predominant, though not exclusive role in aHUS (Fig. 22.2) [33–46]. The complement system is composed of plasma proteins that react with one another to opsonize microbes and induce a series of inflammatory responses that help the immune cells to fight infection. There is mounting evidence that complement participates not only in the defense against pathogens, but also in host homeostasis [47–52]. The complement cascade can be activated by three different pathways. While the activation of the classical and the lectin pathways occurs after binding to immune complexes or microorganisms respectively, the AP is continuously activated and generates C3b which binds indiscriminately to pathogens and host cells. On a foreign surface, C3b binds factor B (FB), which is then cleaved by Factor D to form the C3 convertase C3bBb. The C3 convertase, which is stabilized by its binding to properdin, induces exponential cleavage of C3b and the generation of C3bBbC3b complexes with C5 convertase activity. The C5 convertase cleaves C5 to generate C5a—the most potent anaphylatoxin—and C5b which initiates the formation of the membrane attack complex (MAC or C5b-9), able to lyse pathogens [52] (Fig. 22.2). The CAP amplification loop is normally strictly controlled at the surface of the host quiescent endothelium, which is protected from the local formation of the C3 convertase by complement regulatory proteins. These include regulators in serum, such as FH and Factor I (FI), as well as membrane bound CD46 (membrane cofactor protein (MCP), which cooperate locally to inactivate C3b. FH is the most important protein for the regulation of the CAP and consists of 20 short consensus repeats (SCRs) and contain two C3b-binding sites (Fig. 22.3). MCP is a widely expressed transmembrane glycoprotein that binds C3b and inhibits complement activation on host cells. The serine protease FI cleaves C3b in the presence of various cofactors including FH, complement receptor 1 (CR1, CD35) and MCP. Coagulation regulator thrombomodulin (THBD) enhances FI-mediated inactivation of C3b in the presence of FH [47, 52].

Over the past 20 years, genetic discoveries have substantially improved our understanding of the mechanisms responsible for aHUS and driven development of novel therapeutic strategies) [33–46] (Fig. 22.4). In a large genetic screen of 794 aHUS patients, rare variants in one the 5 genes (*CFH*, *C3*, *CFI*, *CFB*, or *CD46*) that encode proteins involved in the regulation of the alternative pathway of complement were identified in 41% of patients and combinations of mutations were noted

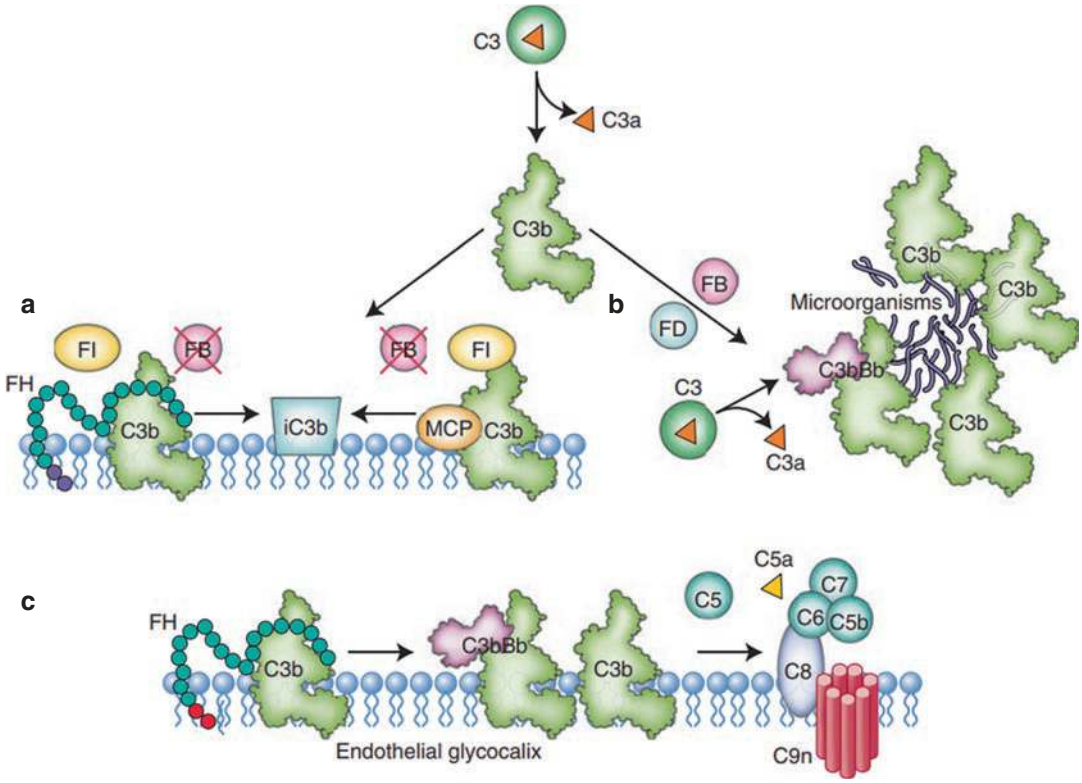

Fig. 22.2 Complement activation and its regulation. aHUS is the prototype of a disease resulting from inefficient protection of endothelial cells against complement activation. (**a**) Protection of cells surface. The AP is permanently active, with a continuous formation of small amounts of the C3 convertase C3bBb at the cell surface. To prevent unopposed complement activation resulting in cell damage, the complement system is tighly regulated. The glycocalyx is a multifunctional thick carbohydrate layer containing glycoaminoglycans (GAG) (heparin sulphate, sialic acid, polyanions) that covers all endothelial cells, in particular the glomerular endothelium in the kidney. FH binds to GAG and C3b. MCP is constitutionally anchored to endothelial membrane. Under normal conditions, the C3 convertase formation is stopped by the interaction of FH or MCP with C3b, which makes further binding of FB to C3b impossible. C3b is then cleaved by FI to iC3b, which cannot bind FB. (**b**) Activation of complement and covalent attachment of C3b to the microbial surfaces. The major function of complement is to act as a defense mechanism against microbes. Very small amounts of C3b are normally present in plasma due to low levels of spontaneous C3 cleavage but C3b can bind to bacteria. Once C3b is covalently bound to the surface of microorganisms, FB binds to it and becomes susceptible to cleavage by Factor D (FD). The resulting C3bBb complex is a C3 convertase that will continue to generate more C3b, thus amplifying C3b production. C3b attaches to bacterial surfaces for opsonization by phagocytes and simultaneous activation of the cytolytic terminal complement cascade. (**c**) In the case of aHUS, AP activation is uncontrolled and C3 convertase C3bBb and C5 convertase C3bC3bBb are formed. During complement activation, C5 is split into C5a and C5b. C5b together with complement proteins C6, C7, C8 and C9 form the C5b9 complex in sublytic quantities that activate endothelial cells to produce prothrombotic factors. *AP* alternative pathway, *C3bBb* C3 convertase; *C3bC3bBb* C5 convertase; *FB* complement factor B; *FD* complement factor D; *FH* complement factor H; *FI* complement factor I; *MCP* membrane cofactor protein (CD46)

in 3% of patients [53]. Predisposition to aHUS is inherited in an autosomal recessive or autosomal dominant manner with incomplete penetrance.

An updated database describing all rare variants identified in aHUS is available at https://www.complement-db.org [54, 55] and these genetic abnormalities are described in more detail in specific sections of this chapter. In addition, acquired autoantibodies to the FH protein (anti-FH) have been demonstrated in patients with aHUS, also described in more detail below.

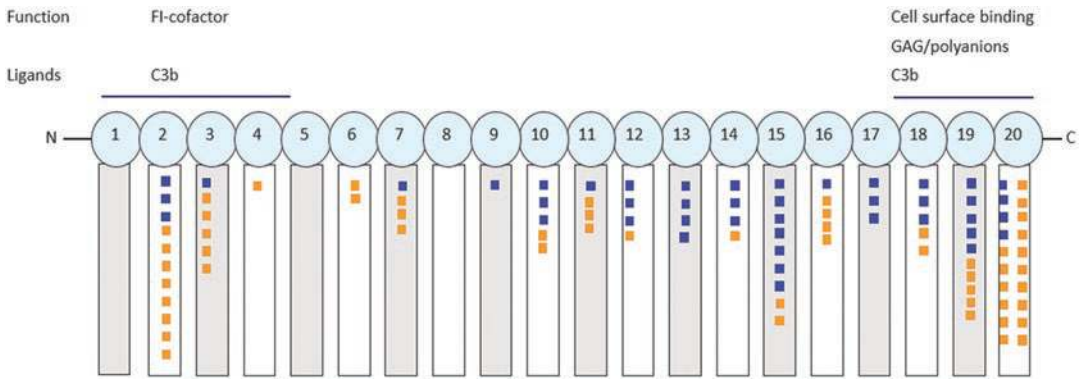

Fig. 22.3 Complement factor H. FH is a plasma protein consisting in 20 domains called short consensus repeats (SCRs) (*numbered circles*). FH has two C3b binding sites: one is localized within the N-terminal SCR 1–4, implicated in the cleavage of C3b by FI and the other in the C-terminal SCR 19–20, implicated in cell surface binding. FH regulates the formation, stability and decay of the C3 convertase C3bBb. *94* rare variants in *CFH* reported in the aHUS database https://www.complement-db.org are shown within columns. Blue squares indicate frameshift, deletion, nonsense and conserved cysteine affected variants (prediction of quantitative FH deficiency), orange squares indicate missense variants (with or without demonstrating functional consequences). 20% of all variants are located in the C-terminus SCR 20 and are mostly associated with normal FH plasma level. *FH* complement factor H; *FI* complement factor I; *GAG* glycoaminoglycans; *SCR* short consensus repeat

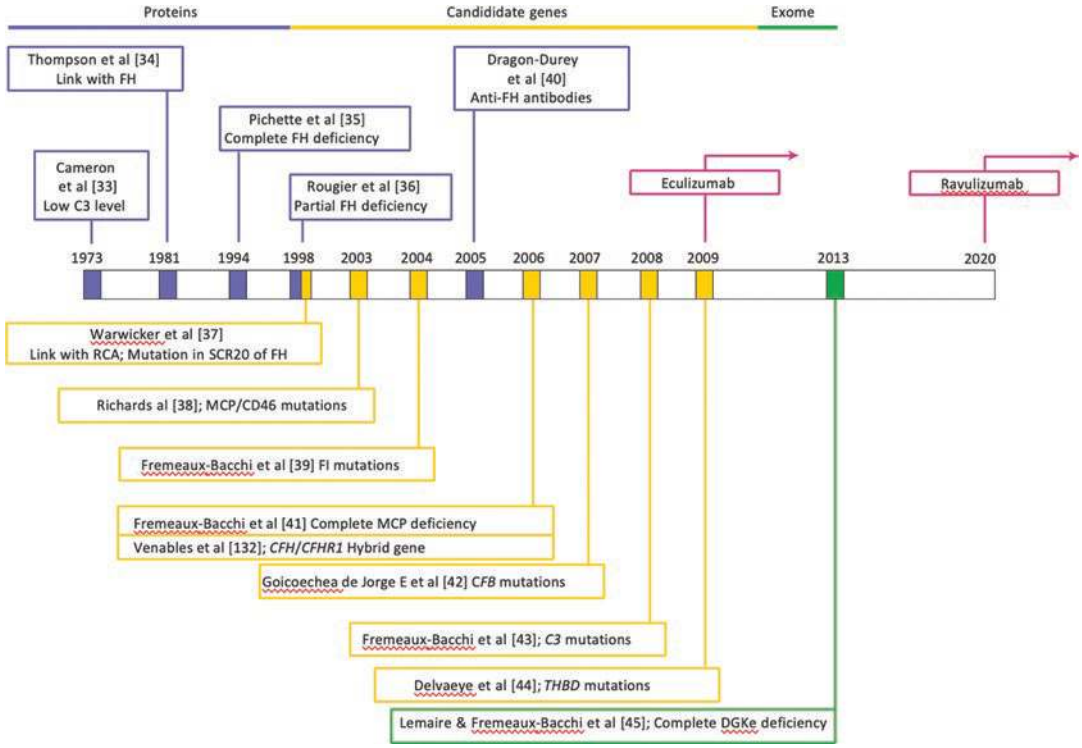

Fig. 22.4 Discoveries that allowed a better understanding of the pathophysiology of aHUS during the last decades. This led to the approval of eculizumab for the treatment of patients with aHUS, to control the overactivation of complement. *FB* complement factor B; *FH* complement factor H; *FI* complement factor I; *DGKE* diacylglycerol kinase ε; *MCP* membrane cofactor protein (CD46); *THBD* thrombomodulin; RCA regulators of complement activation; *CFHR* complement factor H related protein

Clinical Presentation

The majority of children with aHUS present with the complete triad of HUS; microangiopathic hemolytic anemia (with hemoglobin <10 g/dL, presence of schistocytes, high lactate dehydrogenase (LDH), decreased haptoglobin levels) thrombocytopenia with platelet count <150 × 10^9/L and acute kidney injury (serum creatinine above the upper limit of normal). Approximately 60% of them require dialysis at the first episode. Severe hypertension is common. However, the complete triad may be missing at admission and a gradual onset is possible. Particularly, platelet count may be >150 × 10^9/L (approximately 15% of patients) and hemoglobin may be >10 g/dL (approximately 5% of patients) [5]. Children may also have normal serum creatinine at presentation (approximately 15%) [56] and/or present with proteinuria/nephrotic syndrome/hematuria/hypertension as the only kidney manifestations. Thus, any association of two components of the triad with the third one missing can be a manifestation of HUS. While kidney biopsy is not required to establish the diagnosis when full-blown HUS is present, it is useful when hematology criteria are missing or incomplete and any time the diagnosis of HUS is uncertain, to document that the underlying histological lesion is TMA.

Age and Gender

In a cohort of French children with aHUS (66.2% of whom had a proven genetic or acquired complement abnormality), the mean age at onset was 1.5 years (0 to <15 years). 56% (50/89) of children had onset between birth and 2 years of age (28% between birth and 6 months, 28% between 6 months and 2 years) [5], similar to the proportion of 22% (10/45) of children having onset between 1 month and 1 year in another series [4] and 36.3% (53/146) less than 2 years and 19.8% (29/146) less than 1 year in another [57]. Atypical HUS in children is as frequent in females as in males (female-to-male ratio 0.9), in contrast with the female preponderance when the disease presents in adulthood (female-to-male ratio 3) [4, 5]. In a large series from the Global aHUS Registry, 387/851 (45%) of patients with aHUS presented before the age of 18 years (mean 3.8 years) and 166/387 (43%) of those with pediatric onset were female.

Age at onset in children varies according to the underlying genetic or acquired abnormality (more information about specific genetic/acquired abnormalities is given below). Onset between birth and 1 year of age has been reported in the majority of aHUS patients (37/50) reported to date with *DGKE* mutation [45, 46, 58–61] and all children with homozygous *CFH* mutation. It is also frequent in children with heterozygous *CFH* or *CFI* mutation-associated HUS. Conversely, *MCP* mutation-associated HUS in children exceptionally starts before the age of 1 year but most often between age 2 and 12 years. Anti factor H autoantibody associated HUS (anti-FH HUS) is also mostly a disease of late childhood and adolescence (onset between 5 and 12 years, mean age 7.6–9 years in five series including a total of over 500 patients with this form of aHUS [62–67]. *C3* or *CFB* mutation-associated HUS and aHUS without complement mutation or anti-FH antibodies appears to start at any age [2, 5, 25].

Family History

As indicated above, despite aHUS being a genetic disease, a family history of HUS is present in only 20–30% of patients [2, 4, 5] due to incomplete penetrance. The diagnosis of HUS may be unknown in the family and questioning should ask about cases of acute or chronic kidney failure, thrombocytopenia, anemia, hypertension, dialysis and graft failure in the pedigree as well as about consanguinity, which is significant for homozygous mutations in *CFH*, *MCP* and *DGKE*. No familial case of anti-FH antibody-associated HUS has been reported [68].

Triggering Events

Atypical HUS episodes in children are frequently triggered by intercurrent infections, whatever the genetic background. Specific reported infections include varicella [69], influenza [70, 71], Bordetella pertussis [72] and recently SarsCov2 virus [73].

Diarrhea precedes the onset of aHUS in at least one third of children and upper respiratory tract infections in at least 10% [4, 5]. This frequency of diarrhea at onset of aHUS explains why the former "post-diarrheal" or "non post-diarrheal" (or D+/D-) criterion to differentiate STEC-HUS from aHUS was frequently misleading. It is, however, often unclear whether gastrointestinal symptoms in aHUS are linked to an infectious trigger or whether they are manifestations of intestinal TMA. Rare patients (approximately 1%) have been reported in whom the first episode of aHUS was caused by STEC gastroenteritis, with the diagnosis of aHUS being retained because the patient had subsequent relapses and a familial history of aHUS (one patient with *MCP* mutation) [5], a severe course possibly favored by the genetic complement abnormality (one patient with *CFH* mutation) [74] or recurrence after kidney transplantation (two patients with *CFI* or *MCP* mutation—the latter also in the mother who donated the kidney) [75] . In a cohort of 75 patients with proven STEC HUS, four patients (5%) were found to have pathogenic variants in complement genes, including one patient with severe outcome. In aHUS secondary to anti-FH antibodies, a gastrointestinal prodrome (such as diarrhea, vomiting and/or abdominal pain) has been reported in 27.7% [65, 76, 77]. This type of aHUS is more common in the Asian subcontinent where it comprises 56% of cases compared with 10–25% of European cohorts [66, 77]. A recent study looking for gastrointestinal pathogens in aHUS secondary to anti-FH antibodies showed that twice as many patients had evidence of gastrointestinal pathogens compared with those without anti-FH (62.5% compared with 31.5%) including Clostridium difficile, Giardia intestinalis, Salmonella, Shigella, Rotavirus, Norovirus and Entamoeba histolytica. No stool was positive for Shigatoxin [78]. However, STEC has been reported as the trigger for HUS in a couple of patients with anti-FH HUS [62, 65]. Interestingly, the association of homozygous *MCP* mutation with common variable immunodeficiency has been reported [41]. Therefore, patients with homozygous *MCP* mutation should be investigated for immunodeficiency that may require immunoglobulin therapy to prevent infections—and thus decrease the frequency of HUS relapses triggered by infections.

Lastly, pregnancy is the trigger for aHUS in 20% of adult women [5] and 86% of women with pregnancy—associated HUS (mostly in the postpartum period) have a complement mutation [79]. For this reason, pregnancy-associated HUS is now classified as aHUS.

Histology of Atypical HUS

The underlying histological lesion of aHUS is TMA involving afferent arterioles and glomerular capillaries. Characteristic features during the acute phase are platelet and fibrin thrombi within glomerular capillaries and the thickening of glomerular capillary walls related to endothelial cell swelling and detachment and the accumulation of flocculent material (proteins and cellular debris) between the endothelial cells and the basement membrane, with double contour appearance. Mesangiolysis (fluffy mesangial expansion) is also common. Bloodless and ischemic glomeruli related to the narrowing or occlusion of the capillary and arteriolar lumen can be observed. Arterial changes range from endothelial swelling and intramural fibrin to fibrinoid necrosis with occlusive thrombi and fragmented red blood cells. Immunofluorescence studies for immunoglobulin G or C3 deposits are generally negative. C5b-9 staining has been reported in microangiopathy attributed to complement abnormalities and other causes, however its presence is not reliable.

Chronic lesions are characterized by mesangial sclerosis, thickening of capillary walls with sparse or diffuse double contours, ischemic changes of glomeruli and mucoid intimal hyperplasia and narrowing of the arterial lumen (onion-skinning). The time course for histological resolution of TMA is unknown and therefore it is difficult to know if presence of chronic features points to an ongoing active TMA process or to a chronic sequel [80, 81].

There is a general consensus that it is not possible to determine the etiology of TMA from histological morphology [82].

Manifestations Outside the Kidneys

Although the TMA process predominates in the kidney vasculature, other organs may be involved. The most frequent manifestation outside the kidneys during acute episodes of aHUS is brain involvement, reported in 15–20% of children with aHUS [5, 83–86]. Symptoms can be seizures, altered mental status, altered consciousness, visual problems (diplopia, sudden visual loss), paresis and coma. Computed tomography scan is useful to rule out cerebral bleeding. Magnetic resonance imaging (MRI) shows hyperdensities of variable severity and extension. Focal cerebral infarction is possible. The prognostic significance of MRI abnormalities is generally uncertain. The frequency of cardiac involvement is poorly documented, but life threatening ischemic myocardiopathy may occur, which makes sequential troponin level assay, electrocardiography and echocardiography advisable during acute episodes [86–89] . Peripheral acute ischemia leading to gangrene of fingers/hands and toes/feet [90], skin necrosis [91–93] or retinal ischemia with sudden visual loss [94] have been reported in a few patients. Manifestations outside the kidneys may also include pancreatitis (increase in pancreatic enzymes with or without clinical/radiologic signs) and/or hepatitis (increase of hepatic enzymes) (5–10% of patients) and, exceptionally, intra-alveolar hemorrhage, severe gastrointestinal manifestations including intestinal perforation or life-threatening multiorgan failure (2–3% of patients [5, 91]. Severe gastrointestinal symptoms (abdominal pain, vomiting, diarrhea, biochemical pancreatitis and hepatitis), myocardial and neurological manifestations appear to be particularly frequent in patients with anti-FH antibodies [62, 65, 77, 84, 90].

Four children with aHUS have been reported who developed cerebral ischemic events due to stenosis of cerebral arteries after several years on dialysis [95–98]. One of them also had stenosis of coronary, pulmonary and digestive arteries [96]. These observations have suggested that local complement activation during acute episodes and/or subclinically in the long term, may lead to such macrovascular complications, independently or as aggravating factors of the vascular consequences of long-term dialysis. Prospective studies are required to document whether aHUS patients have an increased risk of cardio-or cerebro-vascular events and of arterial disease due to the local complement activation [99].

Experience of eculizumab to treat manifestations of aHUS outside the kidneys is limited to case reports. However, eculizumab was impressively effective in two children with acute distal ischemia [90] or skin necrosis and intestinal perforation [91], respectively. Eculizumab may rescue central nervous system manifestations, as suggested by nine case reports, including four in children [85, 86, 88, 100, 101]. Eculizumab also appeared life-saving in four children with myocardial involvement [86–89]. Lastly, two children who had developed cerebral artery stenosis stopped having ischemic events under eculizumab therapy, with non-progression of arterial stenosis documented in one [95, 97].

Making the Diagnosis of Atypical Hemolytic Uremic Syndrome

When the features of HUS are present (as summarized in Table 22.1), careful assessment is required to exclude possible causes before a provisional diagnosis of aHUS can be reached [102, 103] (Fig. 22.5 and Table 22.2).

Table 22.1 Investigations to support the presence of a thrombotic microangiopathy

Test to confirm a TMA	Result in aHUS	Comment
Haemoglobin	Low	
Platelet count	Low	
Blood film	Fragmented red blood cells	
Direct antiglobulin test	Negative	May be positive in pneumococcal HUS
Reticulocyte count	High	Low suggests either bone marrow problem or ESKD

Table 22.1 (continued)

Test to confirm a TMA	Result in aHUS	Comment
Lactate dehydrogenase	High	
Creatinine	High	Previous measurements are helpful to exclude CKD
Urinalysis	Blood, protein	
Kidney ultrasound scan	Normal sized or large kidneys, often echobright	Small kidneys suggest ESKD
Plasma C3	Low or normal	Not sensitive or specific for aHUS

ESKD end stage kidney disease; *CKD* chronic kidney disease

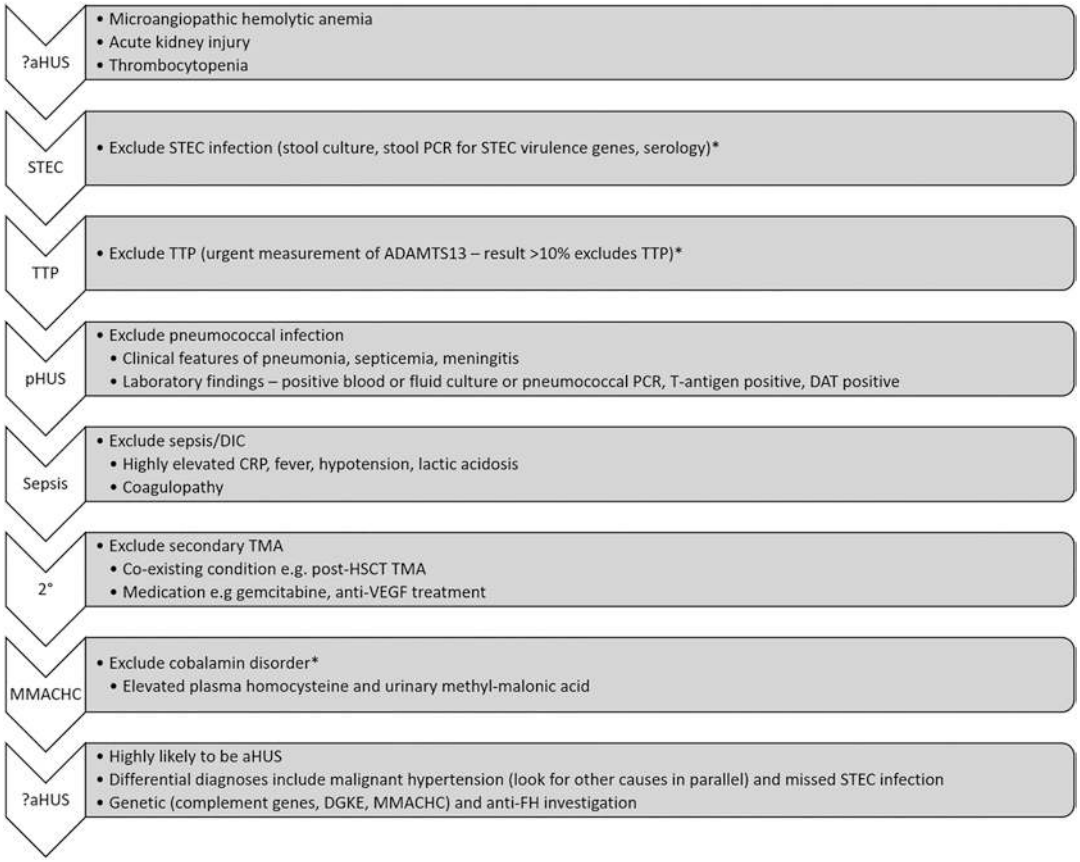

Fig. 22.5 Suggested approach to making the diagnosis of atypical HUS. When the clinical triad of microangiopathic hemolytic anemia, acute kidney injury and thrombocytopenia are present without clinical evidence of STEC infection, further evidence should be sought for STEC and pneumococcal infection. TTP should be excluded, along with secondary causes of TMA. The triad of HUS may indicate sepsis, which should be sought and excluded. Evidence for cobalamin disorder should also be sought. *these investigations may take some time to return and treatment with anti-C5 therapy should not be delayed if results are not available and the diagnosis of aHUS is strongly suspected. In practice, if an alternative diagnosis is secured after commencement of anti-C5 therapy, it can be discontinued. *STEC* shiga-toxin producing Escherichia coli; *PCR* polymerase chain reaction; *TTP* thrombotic thrombocytopenic purpura; *ADAMTS13* a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13; *pHUS* pneumococcal haemolytic uremic syndrome; *DAT* direct antigen test; *TMA* thrombotic microangiopathy; *HSCT* hematopoietic stem cell transplant; *VEGF* vascular endothelial growth factor; *DIC* disseminated intravascular coagulation; *CRP* C-reactive protein; *DGKE* Diacylglycerol Kinase Epsilon; *MMACHC* methylmalonic aciduria and homocystinuria type C, FH factor H

Table 22.2 Investigations to rule out an alternative diagnosis

Tests for differential diagnoses	Result	Differential diagnosis
ADAMTS13 activity	<5%	TTP
Stool culture for E. coli O157	Positive	STEC HUS
Stool PCR for STEC virulence genes	Positive	STEC HUS
Serology for STEC	Positive	STEC HUS
T-antigen	Positive	Pneumococcal HUS
Pneumococcal PCR (blood/fluid)	Positive	Pneumococcal PCR
Coagulation	Prolonged PT/PTT and low fibrinogen	Sepsis/DIC
C-reactive protein	High	Sepsis/infection[a]
Plasma homocysteine	High	Cobalamin C disorder
Urinary MMA	High	Cobalamin C disorder
ECG/Echocardiogram	Evidence of left ventricular hypertrophy	Malignant hypertension
Anti-double stranded DNA antibodies	Positive	Systemic lupus erythematosus
Renal transplant—donor-specific antibodies	Positive	Antibody mediated rejection
Renal transplant—C4d staining	Positive	Antibody mediated rejection
Anti-phospholipid antibody	Positive	Anti-phospholipid antibody syndrome
Serum/urine electrophoresis[b]	Paraprotein	Plasma cell dyscrasia
Serum free light chains[b]	Positive	Plasma cell dyscrasia

ADAMTS13 a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13; *STEC* shiga toxin producing E. coli; *PT* prothrombin time; *PTT* partial thromboplastin time; *DIC* disseminated intravascular coagulation; *MMA* methylmalonic acid

[a] Infection can be a trigger for an episode of aHUS in a susceptible individual

[b] Unlikely in children

Since the most common cause of HUS in children is STEC infection and because STEC infections may be asymptomatic, thorough microbiological assessment is required. This is reviewed in Chap. 24, but in brief requires stool culture (which commonly only detects E. coli serotype O157:H7) and stool polymerase chain reaction (PCR) for STEC virulence genes. Serological assessment may also be helpful. Medical history and physical examination usually eliminate HUS secondary to a coexisting condition—mostly HSCT- and generally suffice for the diagnosis of *Streptococcus pneumoniae*-HUS, that occurs mostly in children less than 2 years of age presenting with symptoms of invasive infection (pneumonia, meningitis, bacteremia) (see Chap. 2). Malignant hypertension can be difficult to distinguish from aHUS, and careful assessment for alternative causes of hypertension may help in this differential diagnosis. TTP must be excluded by urgent assessment of ADAMTS13 activity, since there is treatment dichotomy depending on the result. Evidence for a cobalamin C defect (raised plasma homocysteine and raised urinary methylmalonic acid) must also be sought since alternative treatment will be required [20, 102, 104–114].

Biological Assays to Support the Clinical Diagnosis of Atypical HUS

STEC infection should be ruled out as soon as possible when aHUS is suspected. Stools should be collected at admission or rectal swab performed if no stools are available, allowing stool culture and fecal PCR or immunologic assay for Stx (see Chap. 26). Negative results, mostly due to delayed stool collection or prior administration of antibiotics, are observed in at least 30% of cases classified clinically as STEC-HUS [21, 106]: in such cases, the clinical diagnosis should prevail. Congenital TTP requires urgent plasma infusion (PI) and acquired TTP requires urgent plasma exchange (PE) plus corticosteroids and rituximab. Blood samples collected before PE/PI

are required for ADAMTS13 activity assays, which most commonly rely on the cleavage by plasma ADAMTS13 of the von Willebrand Factor (VWF) peptide containing the cleaving site of VWF (Fret-VWF 73). Results can be available within a few hours [115, 116]. A limitation is the interference of hyperbilirubinemia [117]. Results of commercial kits show reasonable though not full agreement (80–90% concordance) with Fret-VWF [116, 118, 119].

Lastly, assays to detect a cobalamin defect should be part of the initial biological sampling in any child suspected to have aHUS. Cobalamin defect—associated HUS, which can be rescued by hydroxocobalamine treatment, may occur in neonatal forms presenting with neurological, cardiac or multivisceral involvement, but at least as frequently in late-onset forms presenting with predominant or isolated HUS during childhood or early adulthood [110, 111, 120–122].

Complement Investigations in Patients Suspected to Have aHUS

All patients suspected of having aHUS should have blood sampling before PE/PI for measurement of C3, C4, FH, FI and FB plasma levels and screening for anti-FH antibodies. A recent publication from seven European laboratories reports the standardization of the enzyme linked immunosorbent assay technique for anti-FH antibodies [123], which could be developed in other countries. MCP surface expression on polymorphonuclear or mononuclear leucocytes is also required.

As indicated above, decreased C3 levels are observed in only 30% of children with aHUS [2, 4–6]. Therefore, a normal C3 level does not rule out the diagnosis of aHUS. Normal C4 concentration associated with decreased C3 level confirms activation of the AP as would a decreased FB concentration. As the C3 level is normal in patients with isolated MCP mutation and decreased in patients with high titer anti-FH antibodies, aHUS in a pre-adolescent or adolescent child—the age of onset in these two subgroups of complement-dependent HUS—is most likely MCP mutation-associated-HUS if C3 level is normal or anti-FH antibody-associated HUS if C3 level is low.

As indicated above, decreased FH or FI plasma levels are observed in approximately 50% and 30% of patients with mutations in *CFH* or *CFI* genes, respectively [5, 6]. Therefore, a normal FH or FI plasma level does not exclude a mutation in the corresponding gene.

Recent data suggest that levels of C5a and soluble C5b-9 (sC5b-9) are elevated during acute episodes of aHUS and may be biological markers to differentiate aHUS from TTP [124]. Increased C5a and sC5b-9 plasma levels have been confirmed in approximately half of aHUS patients during acute phases of the disease and also during remission [125]. However, a normalization of complement activation products levels after remission, including sC5b-9, has been reported by another group [126]. This, and the fact that sC5b-9 may be elevated in conditions which are not aHUS [127], means that the usefulness of these markers for routine clinical care remains to be determined.

Genetic Screening in Patients with Atypical HUS

Genetic screening results are not required for urgent therapeutic decisions but are necessary to establish whether the disease is complement-dependent or not, prognosis, risk of relapses and of progression to kidney failure, genetic counselling, decisions for complement blockade treatment duration and for kidney transplantation. The six complement genes identified as susceptibility factors for aHUS (*CFH*, *CFI*, *MCP*, *C3*, *CFB* and *THBD*) should be analysed by direct sequencing or next generation sequencing analysis. Multiplex ligation dependent probe amplification (MLPA) is required to detect hybrid *CFH* genes (5% of patients) and copy number variations in *CFH* and CFH Related (CFHR) protein genes. Because of the frequency of combined mutations indicated above, all six genes should be screened for mutations in all patients. Screening for *DGKE* mutations should be per-

formed in children with onset of aHUS before the age of 1–2 years and maybe in older children if further reports indicate *DGKE* mutation-associated HUS may occur later in life. Sequence variants in complement genes have been identified in 5 of 13 patients with anti-FH antibody—associated HUS in one series [128], but none of 26 patients in another series [62]. Genetic analyses even when anti-FH antibodies are present may be justified. If the patient has anti-FH antibodies and a mutation, treatment should be decided according to the antibody titer and the functional consequences of the mutation [103]. Next-generation sequencing analysis allows the simultaneous study of all potentially relevant genes and should reduce the turnaround time for results and the cost of genetic analysis. Exome sequencing, which was successfully used to identify *DGKE* mutations [45], is still limited to research laboratories.

Rare Coding Variants in the CFH Gene

The role of *CFH* in aHUS was first suggested more than 40 years ago (Fig. 22.4). A decrease of plasma C3 level was first reported in 1973 in five patients with severe HUS [33] and low FH plasma levels were first reported in 1981 in a 8-month-old boy with HUS [34]. However, it is only in 1998 that Warwicker et al., by linkage analysis, could establish the link between aHUS and the Regulators of Complement Activation (RCA) region in chromosome 1q32, and the presence of mutations in *CFH*, mainly in the SCR 20, despite normal plasma levels of FH and C3 [37] .

During the last 15 years, at least 90 different rare variants of *CFH* with minor allele frequencies (MAF) <0.1% including missense or nonsense variants, short deletions or insertions, located everywhere in the gene, have been identified and referenced in the FH aHUS mutation database. The type I mutations, which induce a quantitative deficiency of the FH protein (low FH plasma levels), are located everywhere in the gene. By contrast, the mutations which induce a decreased ability of FH to bind to endothelial cells-bound C3b while plasma levels of FH are normal (namely type II mutations), are mostly located in SCR 20 (Fig. 22.3). More than 90% of reported mutations have been heterozygous and plasma C3 levels are decreased in approximately 50% of patients [2, 5, 45, 58, 65]. Less than 20 children (2–4% of reported children with aHUS), mostly from consanguineous families, carried a *CFH* homozygous variant or two heterozygous variants leading to complete FH deficiency, with permanently very low C3 levels. *CFH* pathogenic variants are the most common among aHUS patients, accounting for 20–30% of all aHUS cases in registries from the United States and Europe [1, 3–5] (Table 22.3).

The *CFH* gene is in close proximity to genes encoding for the five *CFHR* proteins that are thought to have arisen from several large genomic duplications. All *CFHRs* share a high degree of homology, which makes the region particularly prone to genomic rearrangement. The C-terminal SCR domains of CFHR1 proteins show a high level of amino acid sequence identity to the C-terminal recognition region of FH, representing the central combined cell surface anchoring- and C3b recognition region of FH. Using MLPA, genetic rearrangements between CFHR1 and FH, which result in a hybrid CFH/CFHR1 gene leading to the formation of hybrid CFH/CFHR1 protein have been reported in several unrelated aHUS patients from distinct geographic origins [129–132]. Two types of factor H/CFHR1 hybrid proteins have been described. One hybrid protein comprises the first 18 SCRs of FH linked to the C-terminal two SCRs of CFHR1. The second fusion protein has the first 19 SCRs of FH linked to SCR5 of CFHR1. Both hybrid factor H/CFHR1 proteins differ from their native C-terminal FH domain 20 by two amino acids only, at positions S1191L and V1197A [132]. They lack proper FH cell binding and protection from complement and are directly implicated in the disease pathogenesis [132].

Conversely, two types of hybrid CFHR1/CFH genes that encode a fusion protein with the first three short consensus repeats (SCRs) of FHR1 and the last two SCRs of FH or with the first four SCRs of FHR1 and the terminal SCR20 of FH have been identified in aHUS patients. Functional

Table 22.3 Frequency of complement and DGKE abnormalities in children and adults with atypical hemolytic uremic syndrome in four cohorts from Europe and the USA

CFB complement factor B; *CFH* complement factor H; *CFI* complement factor I; *DGKE* diacylglycerol kinase ε; *MCP* membrane cofactor protein (CD46); *THBD* thrombomodulin
% percentage of patients; – not documented
[a]DGKE mutations were identified in seven children who were previously within the group with no complement mutation identified [5]

studies revealed that the hybrid protein causes complement dysregulation at the cell surface by acting as a competitive antagonist of FH.

Rare Coding Variants in the CFI Gene

To date more than 100 *CFI* distinct rare variants have been published, located everywhere in the gene. All but one variants are heterozygous [4]. *CFI* pathogenic variants induce a default of secretion of the mutant protein (de Jong) and less frequently disrupt its cofactor activity, with altered degradation of C3b in the fluid phase and on surfaces. However, 40% of *CFI* mutations have no identified functional consequences and their link with the disease remains unclear. Plasma C3 levels are below the normal range in approximately 50% of patients with *CFI* variants and FI levels are slightly decreased in 30% [5]. *CFI* rare variants account for 4–8% of aHUS cases [5].

Rare Coding Variants in the MCP Gene

More than 100 distinct rare variants in *MCP* gene have been reported in cohorts of patients with aHUS. Fifty percent of variants identified in MCP gene are splice site nonsense or frameshift variants. In the French aHUS cohort, one third of *MCP* mutations are homozygous and two-thirds are heterozygous [5]. Over 80% of the pathogenic variants induce a reduction in MCP expression on granulocytes. Plasma C3 level is normal in patients with isolated *MCP* mutations [5].

Rare Coding Variants in the C3 Gene

Screening the French aHUS cohort for mutations in the C3 gene led to the discovery of heterozygous pathogenic variants including a recurrent C3 variant (p.R139W) in aHUS patients. Functional studies showed that the nucleotide change induces either a defect in the ability of C3 to bind the regulatory proteins MCP and FH (indirect gain of function mutation) or an increase in the capacity of C3 to bind FB (direct gain of function mutation). In both cases, the genetic change induces enhanced C3bBb convertase formation and complement activation on cell surfaces [133]. There are now at least 90 distinct C3 mutations reported in hundreds of aHUS patients,

however few functional studies have been reported. It is estimated that ~2–10% of incident aHUS patients will carry a C3 pathogenic mutation. The majority of these patients have persistently low plasma C3 levels [43].

Rare Coding Variants in the CFB Gene

Very few pathogenic variants of *CFB* with functional consequences have been identified. Therefore, *CFB* mutations account for only 1–2% of aHUS patients (Table 22.3). Functional analyses demonstrated that aHUS-associated *CFB* mutations are exclusively gain-of-function mutations that result in enhanced formation of the C3bBb convertase [134, 135]. *CFB*-mutated patients exhibit a permanent activation of the alternative pathway with very low C3.

Out of 9 *CFB* rare variants characterized using functional *in vitro* assays, only 5 revealed a gain-of-function phenotype; the other variants are classified of undetermined significance [134].

Combined Complement Gene Mutations

Only 8–10% of patients with mutations in *CFH*, *C3*, or *CFB* had combined mutations, whereas approximately 25% of patients with mutations in *MCP* or *CFI* had combined mutations [53].

Mode of Inheritance and Penetrance

Twenty to 30% of patients have a familial history of aHUS. More frequently the disease is sporadic with only one case per family. However, *de novo* mutations are exceptional [135]. Among pedigrees with familial aHUS, transmission of the disease is autosomal recessive in cases with homozygous or compound heterozygous mutations in *CFH* or *MCP*. Transmission is autosomal dominant in cases with a heterozygous mutation. Disease penetrance in family members who carry the heterozygous mutation has been evaluated to be approximately 50%, as only half of these subjects develop the disease. This may be an overestimate, due to the issue of reporting bias, since pedigrees with more that one affected individual are more likely to be studied than those with just one patient. The identified mutation therefore appears to be a risk factor for the disease rather than its direct and unique cause and aHUS has to be regarded as a complex polygenic disease which results from a combination of genetic risk factors. Homozygous haplotypes (defined by five frequent genetic variants transmitted in block) in CFH (at risk CFH tgtgt), MCP at risk (MCP ggaac) [136] and CFHR1*B allele [137] have been demonstrated to be more frequent in patients with aHUS than in controls. In addition, precipitating events or triggers appear required for the disease to manifest in patients genetically at risk.

Complement Alternative Pathway: From Gene Change to TMA Lesion

Mutations in the genes *CFH*, *MCP* and *CFI* impair the mechanisms that regulate AP activation and gain of function variants in C3 and CFB increase AP activation. Whatever the pathogenic variants identified, endothelial cells are no longer protected from complement activation [138, 139]. The increased production of MAC at the endothelial cell surface induces alterations of these cells, which become procoagulant by producing high molecular weight multimers of von Willebrand Factor, thus triggering the formation of thrombi [140–142]. In addition, complement activation at the surface of platelets triggers platelet activation and aggregation and this contributes to the formation of thrombi within the microcirculation [143]. This physiopathological model is corroborated by transgenic animal models. Mice which express a *FH* variant lacking the C-terminal 16–20 domain responsible for the interaction of FH with C3b and the endothelium develop HUS similar to the human disease [144].

Variants of Unknown Significance in Complement Genes: Disease Relevant or Benign?

Over the coming decade, the challenge will be to optimize and to implement at scale, strategies that use human genetics to further the understanding of disease, and to maximize the clinical benefit of those discoveries. The modern genetic screening test to identify genetic abnormality in aHUS patients includes next generation sequenc-

ing (NGS) with at least a panel of 5 genes (*CFH*, *CFI*, *MCP*, *C3* and *CFB*), Sanger sequencing and MLPA with an interpretation of the clinical consequences.

Not all detected complement gene variants have clinically relevant consequences. The standards and guidelines published in 2015 by the American College of Medical Genetics (ACMG) lay out an extensive framework of evidence for interpretation of sequence variants, including guidance for using population data and computational and predictive tools. The variants are classified along a gradient ranging from those that almost certainly have a pathogenic role to those that are very likely benign. However functional characterization of aHUS associated *FH* variants reveals limitations of routinely used variant classification methods. Access to resources that catalogue genetic variation across populations (such as gnomAD) has enabled the confident exclusion of genetic variants too common in population-level data to be plausible causes of rare diseases. As a general rule, variants with a MAF <0.1% might be considered relevant for the pathogenesis of aHUS or other complement-mediated disorders.

In 2021 this rule cannot be applied for variants in the complement genes. Genetic data are now available for >140,000 individuals from diverse populations in the Genome Aggregation Database (gnomAD). These data indicate that rare variants in the five complement genes with MAFs of <0.1% are present in 3.7% of healthy individuals and pathogenic variants can be found in 1% of samples of DNA from healthy blood donors. Only 9 out the 15 genetic changes in *CFB* identified in patients with aHUS led to functional activity changes compared to the wild-type protein [134]. Furthermore, only 29 of 79 rare variants in the *CFH* gene with a MAF <0.1% that have been identified in patients with aHUS are classified as pathogenic based upon the demonstration that they impair CFH regulatory activity [145]. The classification of complement gene variants relies on tools that help predict the potential pathogenicity of a variant [146].

In clinical practice, analysis of functional alterations in complement proteins takes into account the level of expression of the encoded protein (in plasma for CFH and CFI and at the granulocyte surface for CD46), the impact of the variant on the function of the encoded protein (assessed using *in vitro* assays and prediction of the pathogenicity of a variant based on functional domains) and *in silico* analyses. Establishing a causal relationship is difficult with the lack of experimental data. According to ACMG guidelines, more frequently the variants have only moderate evidence for pathogenicity and the variant will be classified as a variant of undetermined significance VUS). The current classification of complement gene variants is not optimal and the clinical relevance of individual variants should therefore be regularly re-evaluated.

In summary, not all detected gene variants have clinically relevant consequences. In practice, where a VUS is found in a complement gene of a patient with aHUS, it is important that other causes of a TMA are still excluded, rather than attributing causality. In addition, it is important not to screen family members for the presence of a VUS, since this could attribute risk where none exists or conversely, falsely reassure when risk still exists.

Genetic Abnormalities in Genes Not Related to Complement

Diacylglycerol Kinase ε Mutations

Diacylglycerol kinase ε (DGKε) is an intracellular lipid kinase highly expressed in glomerular capillaries, podocytes and platelets of healthy mice and humans. DGKs are enzymes that phosphorylate diacylglycerol molecules to phosphatidic acid. Using exome sequencing, deficiency in DGKε was established as a novel cause of pediatric onset aHUS in 2013 [45]. Subsequent to the first publication of 13 aHUS children from 9 kindreds, 6 new cases from 4 kindreds have been identified [58, 59], followed by a third cohort with clinical information on 15 patients based on data from the UK National Renal Complement

Therapeutics Centre including patients from UK, United Arab Emirates and New Zealand [46]. This cohort also established the presumed prevalence and incidence of DGKε-aHUS in the UK population at 0.009 per million per year, when the incidence rate of complement-mediated aHUS was 0.47 per million per year [46]. The phenotypic spectrum and outcome of *DGKE* disease was reviewed by Azukaitis et al. in a global cohort of 44 (including 10 previously unpublished) cases [60].

Transmission of *DGKε* mutations follows an autosomal recessive pattern and all patients reported to date carry homozygous or compound heterozygous nonsense, splice site or frameshift mutations. A likely explanation for the pathogenesis of *DGKε* mutations is that the loss of DGKε enhances protein kinase C activation in endothelial cells, platelets and podocytes, which may result in upregulation of prothrombic factors and platelet activation and altered podocyte function [45, 147]. However, the pathophysiological mechanisms of DGKε nephropathy have not yet been fully understood.

The aHUS relapses are clustered in early life and appear to be less prevalent later. In addition to presentation with aHUS, patients carrying *DGKε* mutations can also present with proteinuria without aHUS or steroid resistant nephrotic syndrome with MPGN pattern on biopsy. The symptoms can overlap in individuals, when in early life patients present with nephrotic range proteinuria and relapsing course of aHUS progressing further to chronic kidney disease (CKD) later in life with proteinuria, microscopic hematuria and hypertension. Neither the UK nor the global cohort found predictors that increase the risk of reaching end stage kidney disease or evidence of a significant role for complement activation on progression and relapses of *DGKε*-aHUS [46, 60]. These resolve regardless of therapy including complement blockade by eculizumab. Moreover, there were aHUS episodes or relapses during treatment with complement blocking therapy. Therefore, complement blocking therapy is probably not beneficial in this specific cohort of aHUS and patients should be managed supportively and in those already on eculizumab, withdrawal should be considered. DGKE nephropathy appears to take a slowly progressive course; only 20% of patients reach ESRD within 10 years of diagnosis [60]. There are no reports of DGKE nephropathy recurrence after transplantation (6 transplant cases reported as of October 2019) [46, 60]; therefore, individuals who progress to end-stage kidney disease (ESKD) should undergo kidney transplantation without the need for preemptive eculizumab [46, 60].

Cobalamin C Metabolism Defect Related HUS

A defect in the remethylation pathway caused by cobalamin C deficiency can lead to a clinical presentation very similar to HUS. It can present fulminantly in the neonatal period or later in life. The triad of HUS is also accompanied by other metabolic symptoms like delayed development and growth, seizures, hypo or hypertension and leucopenia. The inheritance is autosomal recessive, and it is usually caused by a defect in the *MMCHC* gene.

The major markers are elevated homocysteine and methylmalonic acid levels in plasma. Levels of homocysteine over 50 μM/L with normal levels of vitamin B12 and folate are pathognomonic. TMA in cobalamin C deficiency is believed to be caused by the endothelial toxicity of high plasma homocysteine levels.

Treatment is by loading dose of intramuscular vitamin B12 (hydroxycobalamin) followed by lifelong supplementation [110, 121]. Although rare, Cblc deficiency should not be missed since the prognosis of undiagnosed patients is dismal, it can easily be treated once detected. Hence, plasma homocysteine should be included in the routine diagnostic panel of aHUS.

Rare Variants in Genes with Debatable Clinical Relevance

Genetic defects in *THBD*, which encodes thrombomodulin, a protein that interconnects the coagulation cascade and complement system, have been suggested to contribute to the pathogenesis of aHUS. Few mutations in *THBD* affecting the

functions of the protein have been identified to date, with a frequency varying from 0 to 5% of all aHUS cases [2, 3, 44] (Table 22.3). Burden or aggregate association tests, in which all rare variants affecting the same gene are combined into one test, are used to increase the statistical power for rare variant association. Although rare variants in *THBD* have been reported in 41 patients with aHUS, their frequency is not significantly higher in these patients than in controls the general population [148]. Therefore, the link of *THBD* with aHUS remains debatable.

The potential clinical relevance of rare variants in genes such as *PLG* (which encodes plasminogen) [149], *INF2* (which encodes inverted formin 2) [150], *VTN* (which encodes vitronectin) [148] and *CLU* (which encodes clusterin) [151] identified in patients presented with some features of HUS warrant further assessment.

Acquired Complement Abnormalities in Atypical HUS

Anti-factor H Autoantibodies

Anti-factor H (anti-FH) autoantibodies are identified in 5–11% in European aHUS cohorts and in about 20% in Asian aHUS cohorts [65, 76, 79]. Interestingly, they are identified in more than 56% cases from India [80]. A Czech cohort showed a rather outlying large proportion of anti FH antibodies in comparison to other European cohorts of aHUS at 61% which could be due to small sample size and sampling method [67].

Anti-factor H autoantibodies associated HUS (anti-FH HUS) usually manifests later than genetic types of aHUS caused by factor H mutations, usually between 5 and 15 years of age [77]. An international aHUS registry reported a median of age of 13.1 (6.1–31.3) years at presentation [81] for this group of patients. However, the youngest reported aHUS patient with anti-FH antibodies identified was younger than 1 year and the oldest reported patient was over 75 years old. Most of the published series show a slightly higher prevalence of anti-FH HUS in males.

Anti-FH antibodies bind mostly to SCR 19 and 20 of FH but also to other epitopes of FH and thus inhibit the majority of regulatory functions of FH at cell surfaces [153]. Plasma C3 level is decreased in 40–60% of patients with anti-FH antibodies during the acute phase, while FH levels are decreased in only approximately 20% of patients [62]. C3 levels are significantly lower in patients with very high anti-FH antibody titer.

Ninety percent of patients with anti-FH antibodies have a complete deficiency of *CFHR1* and *CFHR3* due to a homozygous deletion of *CFHR1-R3*, a polymorphism carried by 2–9% of European, 16% of African and ≤2% of Chinese healthy controls [128, 154]. The reason why individuals with *CFHR1-R3* deletion develop anti-FH antibodies is uncertain. The current theory linking the deletion in CFHR1 with the generation of antibodies is based upon the interaction of the FH protein that is used by pathogens for immune evasion. In individuals with *CFHR1 gene* deletion, CFHR1 protein is recognized as foreign by their immune system. When a CFHR1-deficient individual is infected by an organism that can bind CFHR1, CFHR3 and FH proteins, the FH protein is changed by the infectious organism to resemble CFHR1 and host immunity mounts a response, leading to production of anti-FH inhibiting FH, thus leading to endothelial dysfunction and symptoms of aHUS. This is corroborated by structural differences found between CFHR1 and FH [155].

Fujisawa et al. described three aHUS patients where anti-FH antibodies affected platelets directly [82]. Washed platelets aggregated more when in contact with plasma from these patients compared to plasma from healthy controls or from aHUS patients with complement genetic variants.

Anti-factor I Antibodies

Two cases of anti-FI antibody-associated HUS have been reported to date [156]. The clinical relevance of these antibodies is difficult to establish, also given their extreme rarity.

Outcome of Atypical HUS Prior to the Availability of C5 Inhibition Therapy

In the era before eculizumab became available the death rate in children with aHUS was 8% [5], 9% [4] and 14% [2] in three pediatric series at average follow-up times of 3.8, 7.5 and 3 years, respectively. Most deaths occurred in children less than 1 year of age and at first episode or during the first year after onset. Approximately 20% of children progressed to ESKD or died at first episode or within <1 month after onset, 30% within 1 year and 40% at 5 years follow-up. The most severe outcome was in children with *CFH* mutations, of whom one third progressed to ESKD or died at first episode, half at 1 year and two thirds at 5 years follow-up. The prognosis of *CFI* and *C3* mutation-associated HUS was hardly less severe than that of *CFH* mutation-associated HUS. *MCP* mutation-associated HUS in children had the best prognosis, with an ESKD risk of 25% at median follow-up of 18 years. aHUS in children with no complement mutation identified also had a relatively favorable outcome [5].

Lastly, the outcome of anti-FH antibodies associated HUS was poor when treatment was limited to PE, including death in 10% of patients, CKD in 40% and ESKD in one third at mean follow-up 39 months [62, 152]. Early treatment with a combination of PE, corticosteroids and immunosuppressants allowed a more favorable outcome, similar to that of *MCP* mutation—associated HUS [5, 64].

Less than 10% of children with *DGKE*-aHUS progress to ESKD in the first year after onset, but patients with this form of aHUS develop proteinuria and nephrotic syndrome, severe hypertension and progress to CKD stages 4–5 (eGFR 15–29 mL/min/1.73 m^2 or ESKD) between the age of 20 and 25 years [45, 46, 60].

In the pre-eculizumab era, several series suggested that approximately half of children with aHUS experienced relapses [4, 5]. Among children who had not died or reached ESKD at first episode or at 1 year follow-up, 25% had relapses during the first year and 47% after the first year. However, a high relapse rate after the first year was mostly in patients with *DGKE* (83% during the first year, 50% up to 5 years) or *MCP* mutations (25% during the first year, 92% after the first year), while relapse rate after the first year was 20–30% in other genetic subgroups [5, 45, 46, 60]. Despite this risk of relapses in the long term, *MCP* mutation-associated HUS has the best prognosis in children, as indicated above. Last, anti-FH HUS had a relapsing course in two third of patients when untreated or treated only with PE/PI [62, 65], which was reduced to approximately 10% by early treatment combining PE + immunosuppressants + corticosteroids [5, 64].

Treatment of Atypical HUS Prior to the Availability of C5 Inhibition Therapy

Plasma Therapy

PE (or PI when PE was not possible) was first line treatment for aHUS until recent year [12] Approximately 15 case reports, mostly in children with *CFH* mutation, showed that early, intensive plasmatherapy, followed by maintenance PE/PI, could prevent relapses and preserve kidney function at follow-up up to 6 years [8, 9, 157]. However, although plasmatherapy was associated with complete or partial remission (hematologic remission with kidney sequels) in approximately 80% of aHUS episodes in children, half of them had died or reached ESKD at 3 years follow-up [2]. In addition, plasmatherapy carried significant morbidity. An audit of complications in children receiving PE for aHUS revealed 31% developed catheter-related complications (including infection, thrombosis and hemorrhage) and 11% developed plasma hypersensitivity [13]. The benefit of PE/PI is uncertain in *DGKE* mutation-associated HUS, as proteinuria, the main marker of a progressing course in *DGKE* mutation–associated HUS, persisted in 9 of the 12 patients who received plasmatherapy [45, 46, 60].

Kidney Transplantation

The risk of post-transplant recurrence of aHUS was 60% in the pre-complement blockade era [2, 104]. Forty percent of recurrences occurred during the first month after transplantation and 70% during the first year. Graft survival was 30% at 5 years follow-up in patients with recurrence, compared to 68% in those without recurrence [104]. Eighty percent of patients who had lost a prior graft from recurrence had recurrence after retransplantation. The main independent risk factor for recurrence was the presence of a complement mutation. The highest risk (approximately 80%) was in patients with *CFH* and *C3* or *CFB* gain of function mutation, the risk in patients with *CFI* mutation was approximately 50% and patients with no complement mutation identified had the lowest risk (approximately 20%) [104]. The risk of post-transplant recurrence in patients with *MCP* mutation has been shown to be low (<10%) if the mutation is isolated (the graft brings the non-mutated MCP protein), while it is approximately 30% if the *MCP* mutation is associated with a mutation in *CFH*, *CFI* or *C3* [53]. No post-transplant recurrence was observed in four patients with *DGKE* mutations [45, 46, 60]. The risk is low in anti-FH HUS if the antibody titer is low at the time of transplantation, while substantial if elevated [62, 65, 66] [128, 158]. One patient with *THBD* mutation has been reported to have had post-transplant recurrence [159].

This shows that genetic screening is necessary before listing a patient for kidney transplantation to predict the risk of post-transplant recurrence and guide decisions for the choice of the donor and the prevention of recurrence.

PE/PI for post-transplant recurrence generally failed to avoid graft loss [2, 104]. Therefore, prophylactic PE/PI was recommended [160]. The efficacy of this strategy is poorly documented. However, graft survival rate free of recurrence was significantly higher in nine patients who received prophylactic PE/PI than in 62 patients without prophylactic PE/PI [104]. Interestingly, calcineurin inhibitors (CNI) did not significantly increase the risk of recurrence in a recent series, while mTOR inhibitor use was an independent significant risk factor for recurrence, possibly related to the anti-VEGF (vascular endothelium growth factor) action of these drugs [104]. The current consensus is that aHUS is not per se a contraindication to CNI. Strict monitoring of blood levels and overdosage avoidance is recommended, while CNI-free mTOR based immunosuppressive regimens should be avoided [161].

Treatment Recommendations

During the initial manifestation of HUS, unless it is a relapse in a patient already know to carry a risk variant in genes associated to aHUS, diagnosis is challenging, and aHUS cannot be excluded purely on clinical grounds or complement markers. Children with suspected aHUS should ideally be transferred to a children's kidney center capable of kidney replacement therapy and intensive care. In contrast to adults, and because the incidence of acquired TTP in children is very low, immediate PE whilst awaiting ADAMTS13 results is not routinely recommended. Children in whom complement driven aHUS is strongly suspected or proven should receive eculizumab (see below) as first line treatment, to avoid PE and the complications of central catheters [103]. Confirmation of a complement mutation is not required for the decision of treatment initiation in such cases. As treatment delay may affect recovery of kidney function, eculizumab treatment should be initiated as soon as possible, ideally within 24–48 h of onset or admission. In addition to targeted treatment with eculizumab, symptomatic care is based on general recommendations for AKI [162] and on consensus from observational studies. The cornerstone is appropriate fluid management, kidney replacement therapy in patients with high urea or unsafe electrolyte profile and stopping of nephrotoxic drugs. Red blood cell transfusions should be given to patients who have symptoms of severe anemia or when hemoglobin falls rapidly. Platelet transfusions are not advised unless patient has a life threating bleeding or requires invasive procedure like placement of vascular catheter for adequate dialysis.

Eculizumab

Eculizumab, a monoclonal humanized anti-C5 antibody, prevents C5 cleavage and the formation of C5a and C5b-9, thus blocking the C5a pro-inflammatory and the C5b-9 pro-thrombotic consequences of complement activation. It has been the accepted treatment of paroxysmal nocturnal hemoglobinuria (PNH), another complement dependent disease, for more than 15 years [163].

The rationale for treatment with complement C5 blockade was first proposed based on first two aHUS patients treated successfully with eculizumab in 2009 [164, 165], followed by plethora of successful cases [15, 85, 87, 89–91, 166–170].

Four observational prospective single-arm non randomized multinational trials [14, 171, 172] demonstrated the efficacy of eculizumab to stop the TMA process, allowing sustained remission of aHUS with improved or preserved kidney function in the majority of patients. One of these trials [172] specifically studied eculizumab in children with aHUS. Figure 22.6 shows the remarkable efficacy of eculizumab in these patients. Data from the trials also suggested that an early switch from PE/PI to eculizumab or the use of eculizumab as first line therapy gave patients the best chance of full recovery of kidney function. Treatment was well tolerated, with no increase of adverse events over time. However, two of the 100 patients who entered these trials developed meningococcal meningitis. Eculizumab is administered by intravenous infusion according to the weight-directed dose and schedule shown in Table 22.4.

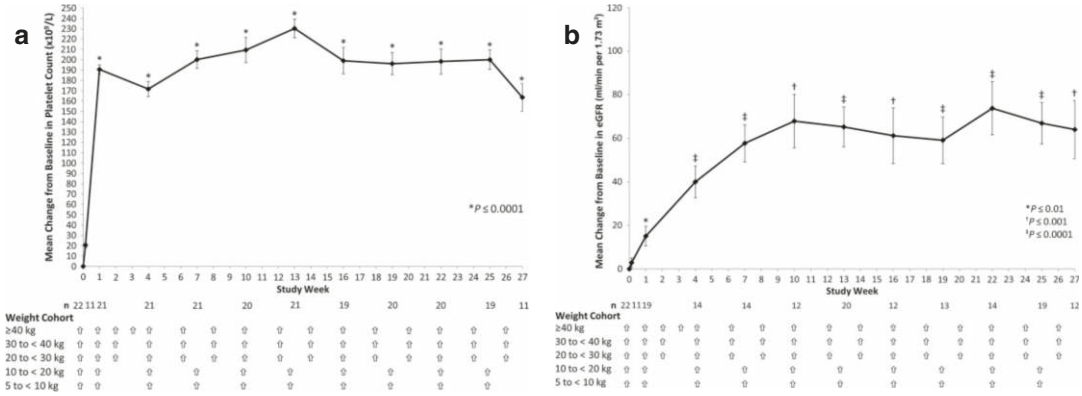

Fig. 22.6 (**a**) Improvement in platelet count over 27 weeks of eculizumab treatment in 22 children with aHUS. N values <5 were not included. Bars represent standard error of the mean (SEM). (**b**) Improvement in estimated glomerular filtration rate (eGFR) over 27 weeks of eculizumab treatment. N values <5 were not included. Bars represent SEM. Arrows denote administration of eculizumab

Table 22.4 Dosing of eculizumab based on European Medicines Agency: Summary of product characteristics Soliris, https://www.ema.europa.eu/en/documents/product-information/soliris-epar-product-information_en.pdf, February 2022

		Initial dose	Maintenance dose
Adult dosing schedule (intravenous infusion)		900 mg every week for first 4 weeks	1200 mg at week 5 then 1200 mg every 14 days
Paediatric dosing schedule according to body weight (intravenous infusion)	>40 kg	Dose as per adult schedule	Dose as per adult schedule
	30–40 kg	600 mg every week for first 2 weeks	900 mg at week 3 then 900 mg every 14 days
	20–30 kg	600 mg every week for first 2 weeks	600 mg at week 3 then 600 mg every 14 days
	10–20 kg	600 mg first week only	300 mg at week 2 then 300 mg every 14 days
	5–10 kg	300 mg first week only	300 mg at week 2 then 300 mg every 21 days

Eculizumab is currently approved by both the Food and Drug Administration and the European Medicines Agency for the treatment of atypical HUS. The cost of the drug and the presumption that patients should receive lifelong treatment played a major role in approving the cover of the costs by healthcare systems. Access and funding are achievable in USA, Australia, United Kingdom and in most states of the European Union, with exception of Bulgaria and Romania. Other countries with availability include Israel and Japan. African and Asian countries, including China and India, have no access to the drug. The availability generally corresponds to the countries' economic position (apart from New Zealand where access is very limited).

Ravulizumab

A second generation complement inhibitor, ravulizumab, has recently been developed by targeted re-engineering of eculizumab. Two structural changes were incorporated, aimed at extending the terminal half-life. The first change enhanced the dissociation rate of the mAb:C5 complex at pH 6.0, eliminating the target mediated antibody clearance. The second change enhanced the affinity of the antibody to human neonatal Fc receptor [173].

Ravulizumab has not been directly compared to eculizumab in a clinical trial. However, efficacy and safety were confirmed in a phase 3 single-arm trial in adult patients (n = 56) with aHUS naïve to complement inhibitor treatment [174]. Complete TMA response, defined as normalization of platelet count and LDH and ≥25% improvement in serum creatinine, was achieved in 53.6% of patients in the 26 week study period. This lower response rate than reported within the eculizumab trials may have been due to broader eligibility criteria for recruitment (only 20.5% had genetic complement mutations or anti-FH identified compared with 76% in the equivalent eculizumab trial). There were no severe treatment-related events reported. Four deaths were reported, none of which were considered treatment-related by the study investigator [175].

Two trials tested the efficacy and safety of ravulizumab in children under 18 years of age with aHUS. Fourteen of 18 complement-inhibitor naïve patients with aHUS (78%), achieved complete TMA response with ravulizumab. Ten aHUS patients who were already receiving eculizumab, switched to ravulizumab for a period of 26 weeks without significant safety issues and showed unchanged kidney function and hematological remission of aHUS even after extended observation of one year. No unexpected adverse events, deaths, or meningococcal infections occurred. There were not enough data to demonstrate the effectiveness of ravulizumab in children weighing less than 10 kg [176, 177].

Taken together, these trials indicate that ravulizumab, is effective for the long-term treatment of patients with aHUS. Current evidence suggests an acceptable safety profile, although longer-term surveillance will be required. The main risk of ravulizumab treatment is similar to that of eculizumab arising from the same principle of C5 blockade. Therefore, all patients must strictly adhere to the same prevention protocols against meningococcal infection as with eculizumab. Dose and schedule information for ravulizumab are shown in Table 22.5.

There are now two licensed treatments for patients with aHUS. Clinicians and patients now have a choice between short-acting and long-acting C5 inhibition. Since the diagnosis of aHUS is complex and not all patients initiated on C5 inhibition will continue with long-term therapy, it may be an option to commence initial treatment with eculizumab, with a switch to long-acting therapy once a need for long-term treatment is established (Fig. 22.7). This approach would minimise the risk of prolonged C5 blockade for those in whom treatment is discontinued due to an alternative diagnosis (for example, a subsequent positive STEC result). However, commencing with ravulizumab at time of initial presentation is also an option.

A subcutaneous ravulizumab formulation is currently undergoing evaluation in a phase 3 trial in adult patients with PNH [177] and may be a future option also for patients with aHUS.

Table 22.5 Dosing of ravulizumab based on European Medicines Agency: Summary of product characteristics Ultomiris, https://www.ema.europa.eu/en/documents/product-information/ultomiris-epar-product-information_en.pdf, February 2022

		Initial dose	Maintenance dose
Adult dosing schedule (intravenous infusion)	≥40 to <60 kg	2400 mg loading dose followed by maintenance dose in 2 weeks	3000 mg every 8 weeks
	≥60 to <100 kg	2700 mg loading dose followed by maintenance dose in 2 weeks	3300 mg every 8 weeks
	≥100 kg	3000 mg loading dose followed by maintenance dose in 2 weeks	3600 mg every 8 weeks
Paediatric dosing schedule according to body weight (intravenous infusion)	>40 kg	Dose as per adult schedule	Dose as per adult schedule
	30–40 kg	1200 mg loading dose followed by maintenance dose in 2 weeks	2700 mg every 8 weeks
	20–30 kg	900 mg loading dose followed by maintenance dose in 2 weeks	2100 mg every 8 weeks
	10–20 kg	600 mg loading dose followed by maintenance dose in 2 weeks	600 mg every 4 weeks

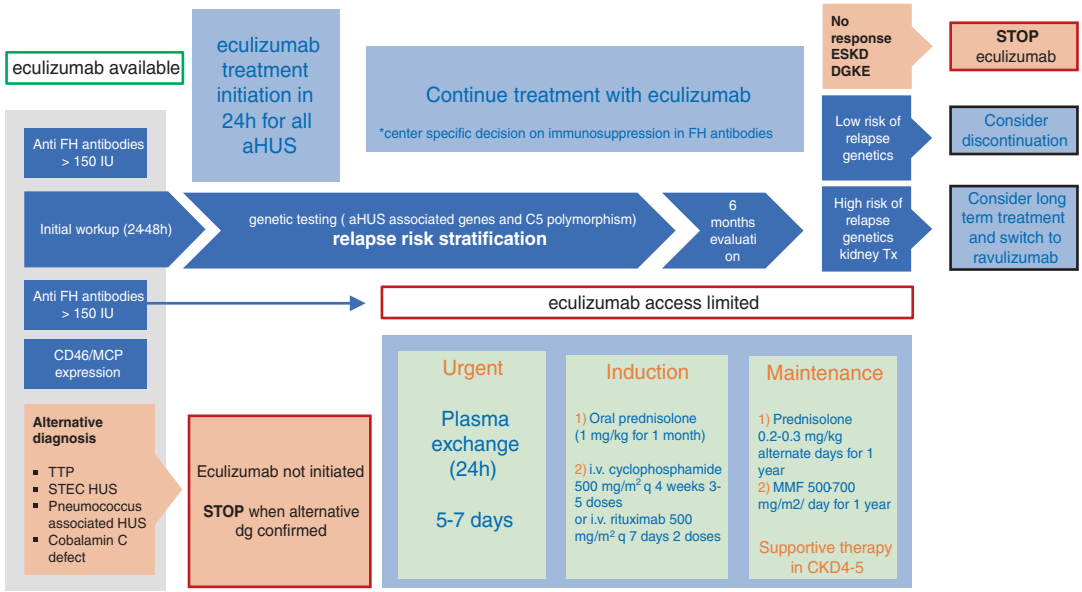

Fig. 22.7 Recommended management approach when atypical HUS is suspected

Risk of Meningococcal Infection on C5 Inhibition Therapy and Its Prevention

The host defense against *Neisseria meningitis* depends on the lytic terminal complement complex C5b-9. The incidence of meningococcal infections in patients with hereditary complete deficiency of terminal complement factors is 0.5% per year, corresponding to a 1000 to 2000-fold relative risk increase compared to the normal population [178]. Patients undergoing eculizumab or ravulizumab treatment have the same risk as these patients. Therefore, prevention of meningococcal infection is crucial, relying on vaccination and antibiotic prophylaxis. Tetravalent conjugated vaccines protect against serogroups A, C, W135 and Y. Polysaccharide

vaccines against serogroup B are also available and recommended for all patients receiving eculizumab.

The frequency of invasive meningococcal infection has been approximately 0.5/100 patient years in patients with PNH treated with eculizumab, despite meningococcal vaccination (not anti-B) [179].

Two of the 100 aHUS patients treated within trial protocols and one among approximately 80 case reports developed invasive meningococcal infection despite being vaccinated [180]. The more recent analysis of eculizumab safety from the Global Atypical HUS registry showed meningococcal infection in two adult cases (0.17 per 100 patients years) and one pediatric patient (0.11 in 100 patient years) out of 1321 patients ever treated with eculizumab. Two patients recovered completely, and one case was fatal [181].

Whilst long-term antibiotic prophylaxis for patients on C5 inhibition is not mandated by the manufacturer, many clinicians add this to their patients' treatment (phenoxymethylpenicillin or erythromycin if penicillin allergic). This is strongly recommended for children and in some countries, this is obligatory [103]. Neither vaccines nor antibiotic prophylaxis guarantee full protection, hence the importance of patient and family education on signs of meningococcal infection and the provision of alert cards to be carried by the patient or their caregiver to present to their health care provider when unwell, in order to minimize delay in recognition.

Treatment of Anti-factor H Antibody Associated HUS

The first large series of patients with anti-FH HUS (treated mostly with PE without immunosuppressants) suggested that many of these patients suffer a relapsing course, leading to end stage kidney disease [62]. A much more favorable outcome, similar to that of *MCP* mutation-associated HUS, has been reported in children with this form of HUS, treated early with PE, immunosuppressants and corticosteroids [5].

The largest experience with the approach to decrease anti-FH antibodies with immunosuppressive treatment comes from India, where 55.8% of their 781 aHUS patients presented with anti-FH antibodies [66].

Combined Plasma exchange (PE) and immunosuppression improved long-term outcomes (HR 0.37; $P = 0.026$); maintenance therapy with corticosteroids and MMF reduced the relapse risk (HR 0.11; $P < 0.001$) [66].

Maintenance treatment with corticosteroids and mycophenolate mofetil (MMF) or azathioprine significantly decreased the risk of relapses, from 87% to 46% at last follow-up [64, 157].

Eculizumab was documented as an effective treatment of HUS symptoms in anti-FH HUS in several cases [88, 182].

In a cohort of 17 patients with anti-CFH antibody associated aHUS, four patients were treated with first-line eculizumab rather than PE. Patients treated with eculizumab achieved remission in 100% of cases, whereas treatment with PE and immunosuppression was associated with a poor rate of renal recovery in 7 of 11 treated. Therefore, treatment with eculizumab did not appear inferior to PE and immunosuppression [183]. This gives patients and clinicians different treatment options with different adverse effect profiles—broad immunosuppression with rituximab or cyclophosphamide, or more targeted treatment with eculizumab [103]. The National Renal Complement Therapeutics Centre in the UK recommends initial treatment with eculizumab for anti-FH HUS based upon a more favorable adverse effect profile .

Global Variations in Atypical HUS Treatment Recommendations

Eculizumab has revolutionized the management of aHUS. The current best recommendations and guidelines are challenging to implement globally, particularly in resource-limited healthcare settings due to the prohibitive cost of eculizumab and its successor ravulizumab. In response to this, the Indian Society of Pediatric Nephrology

have published consensus guidelines for countries lacking access to eculizumab and complex diagnostic facilities [157].

These pragmatic guidelines are mirroring the best recommendations from the pre-eculizumab era [64]. (See also Fig. 22.7).

They recommend treating aHUS where anti-FH antibodies are not suspected with prompt initiation of PE using fresh frozen plasma (The dose is recommended as 1.5 times of the plasma volume or 60–75 mL/kg) and repeated daily until hematological remission is achieved (platelets over 100 × 10^9/L, schistocytes under 2% and LDH in normal range). The tapering follows after 5 days of daily PE or when remission is achieved followed by alternate days PE and 2–3 weeks of twice a week PE.

In case of positive anti-FH antibodies, additional immunosuppression is administered, starting with prednisolone 1 mg/kg daily for 4 weeks followed by alternate day dosing for another 4 weeks and tapering down for 1 year. Cyclophosphamide (500 mg/m^2 q 4 weeks, 3–5 doses) or Rituximab (500 mg/m^2 q 7 day, 2 doses) are given to further decrease the production of antibodies. Mycophenolate mofetil (500–750 mg/m2/day) or azathioprine (1–2 mg/kg/day) are used as additional long-term immunosuppression [157].

C5 Inhibition Therapy Monitoring

Data from the prospective studies show that complete complement blockade is obtained within 1 h after the first dose of eculizumab and is maintained long-term in patients receiving the recommended treatment schedule [184]. The role of assessment of complement blockade during routine use of eculizumab is uncertain. If there are features of inadequate disease control, this should be assessed. Incomplete blockade may be due to insufficient dose (especially in children with a weight just below a weight threshold requiring a higher dose) or heavy proteinuria with nephrotic syndrome (leakage of the drug in the urine). A genetic cause might also have to be considered in aHUS patients of Japanese or Asian origin with poor response to eculizumab and/or complement non-blockade, such as the C5 variant which impairs the binding of eculizumab to C5 [185]. For the long term, complement blockade assessment is mostly required in cases of apparent resistance to eculizumab, including relapse of HUS but also isolated abnormalities in platelet count, LDH and/or haptoglobin levels, appearance or increase of proteinuria or serum creatinine, especially if kidney biopsy suggests ongoing TMA.

Currently available assays of complement blockade under eculizumab are a CH50 or other hemolytic-based assays or the Wieslab Complement System [186]. Due to the site of action of eculizumab, low C3 levels as seen in some mutations are not expected to normalize under eculizumab, and this has been observed [125]. Soluble C5b-9 remains detectable or increased in aHUS patients under eculizumab and therefore cannot be recommended to monitor the efficacy of eculizumab [125, 187]. Most aHUS patients treated within the prospective trials who received the protocol schedule had suppression of CH50 activity and eculizumab trough levels ≥150 μg/ml [14]. However, the correlation between drug levels and complement activity in aHUS patients is not fully established and the availability of plasma eculizumab measurement is currently limited. An additional consideration is that hemolytic assay monitoring may be less accurate for ravulizumab than for eculizumab. One recent study showed that full inhibition of CH50 was not achieved despite high levels of ravulizumab present in plasma [188].

Some authors have reported using assays of hemolytic activity as a tool to lengthen the interval between doses, in an attempt to reduce cost and infusion burden [189]. This approach is not recommended by the manufacturer. It has been recommended that increasing the interval between doses should be considered only in patients who maintain CH50 activity <10% despite longer intervals or lower doses [186].

Duration of C5 Inhibition Therapy in Children with aHUS in Their Native Kidneys

Lifelong treatment with inhibition of C5 for patients with aHUS has been the accepted paradigm. However, there is no definitive evidence for persisting use. The recommendation of not stopping C5 blockade is being reconsidered for some patients with aHUS in their native kidneys based on estimating the risk of relapse by genetic testing.

Having a safe strategy for discontinuation of treatment would be beneficial not only for reducing the significant cost of the therapy but also for safety of the patients and the long-term quality of their life.

Even in the pre-eculizumab era, not all patients relapsed after successful PE. A report of 214 patients, of which 146 were treated with PE, showed that 42% of children were relapse free after 5 years of observation [5]. A Dutch cohort reported sustained remission in 25% of patients [4] and even a cohort of patients with aHUS with changes in the *CFH* gene had normalized kidney function in 22.5% [190]. Following several case reports and series of successful eculizumab discontinuation [170, 189, 191–193], more evidence to support the safety of eculizumab withdrawal appeared from larger studies. The report on this topic from the Global aHUS Registry showed that 33/151 (22%) patients experienced TMA recurrence, particularly in those with pathogenic variants in genes associated with aHUS or with a family history of aHUS. Eight percent then progressed to end-stage kidney disease and 5% required subsequent kidney transplant [194]. During an unprecedented event between 2016 and 2019 when distribution of eculizumab supply was disrupted in Brazil, the effect of discontinuation without stratifying patients based on genetic risk was demonstrated. There were 11 relapses in a cohort of 24 patients, of which 8 occurred in patients with a *CFH* gene variant [195].

A prospective, single-arm study conducted in France stopped eculizumab after at least 6 months of treatment in 55 patients of which 19 were children and showed an overall aHUS relapse rate of 23% (n = 13). Twenty-eight patients (51%) had rare variants in complement genes (*MCP* n = 12, *CFH* n = 6, *CFI* n = 6, FH antibodies, n = 4). Six out of 19 children (32%) relapsed [196]. All 13 patients who relapsed were carrying a variant in genes associated with aHUS except one that was subsequently found to have hereditary ADAMTS13 deficiency (and therefore did not have aHUS). C5 blocking therapy was restarted in all 13 patients. Eleven returned to their baseline kidney function and two remained with decreased function, one progressing to ESKD. Therefore, prompt identification of relapse in aHUS patients who stopped C5 blocking therapy seems to be crucial for preventing long term kidney damage [196].

The overall evidence suggests that patients with no mutation in known complement genes who achieve stable remission for at least 6 months are at low risk of relapse after stopping the treatment. Patients with mutations relapse at much higher rate and in this situation C5 blocking therapy must be restarted promptly to prevent loss of kidney function.

Further safety data for the withdrawal of C5 inhibition in patients with aHUS are required, particularly for patients with mutations. An ongoing trial of stopping eculizumab in patients with aHUS in UK (SETS, EudraCT Number**:** 2017-003916-37) [197] aims to corroborate the current evidence for safe stopping. If all evidence supports safe withdrawal of C5 inhibition in patients with aHUS, the challenge for patients and clinicians will be to implement individualized care plans to enable rapid detection of signs of relapse and facilitate immediate access to C5 inhibition when a relapse occurs. Without this in place, there is a risk that aHUS will cause ESKD.

Current evidence suggests that eculizumab can be withdrawn in a significant proportion of patients and pragmatic recommendations can be drawn from the experience and protocols used in the described trials. The prerequisite is that patient has achieved remission of HUS with no signs of TMA, normalization of platelets, LDH and stable kidney function. The duration from initiation of treatment to its discontinuation is not established, yet the arbitrary duration of 6 months

chosen for the trials could be used as base recommendation. Genetic testing and testing for anti-FH antibodies could help stratifying risk of possible relapse. Patients with no mutation and no anti-FH antibodies (or low titers) are at lowest risk of relapse. Patients with variants of unknown significance and those with pathogenic variants in *CFI* and *CD46* are making a middle tier with slight risk of relapse. Patients with anti-FH antibodies in high titres, pathogenic *FH, FB* and *C3* mutations are at highest risk and the discontinuation of treatment can likely lead to relapse. Most of the relapses would occur in the first weeks after discontinuation and patients need to be reviewed frequently, ideally weekly, with testing eGFR and blood count to identify relapse quickly and restart the treatment.

Further lifelong specialist follow-up of patients who discontinued complement blocking treatment, their education and providing them with straight pathway for review and restarting treatment in case of possible relapse is essential part of the process. There is limited data on another try to stop in case of relapse and restart and it is likely these patients will need lifelong treatment, ideally with long-acting C5 complement blocker, ravulizumab.

Specific patient group are the patients after kidney transplant, where approach needs to be individualized, based on weighing the benefits of continuous or restrictive therapy.

Kidney Transplantation for aHUS Patients Today

Complement blockade therapy has transformed the approach to kidney transplantation for aHUS patients and there are international consensus guidelines regarding the use of eculizumab in this situation (KDIGO 2017). The guidelines state:

1. Kidney transplantation should be deferred until at least 6 months after the start of dialysis because limited kidney recovery may occur several months after starting eculizumab
2. The decision to use anti-complement therapy during transplantation should be based upon recurrence risk
   (a) Those with a high risk (50–100%) of recurrence include patients with previous recurrence, pathogenic mutation or gain of function mutation. They should be treated with prophylactic eculizumab to start on the day of transplantation and to continue indefinitely
   (b) Those with moderate risk of recurrence include patients with no mutation identified, isolated CFI mutations, complement gene variants of unknown significance or persistently low titer anti-FH antibodies. They can be treated with prophylactic eculizumab or PE or without preventative strategy (left to the discretion of the clinician).
   (c) Those with low recurrence risk of recurrence (<10%) include isolated *MCP* mutation or persistently negative anti-FH antibodies. These patients do not require prophylactic treatment with PE or eculizumab. NB with subsequent data, DGKE HUS can also be viewed as low recurrence risk [46].
3. Living donor transplantation can be considered, with the decision relying on a careful assessment of the risk of aHUS in the donor after kidney donation. A risk assessment for potential living related donation requires full genetic screening of the recipient and the donor, leading to the following possible outcomes:
   (a) If the mutation found in the recipient is undeniably responsible for the occurrence of HUS (e.g., *CFH* mutation in C terminus SCR 19 or 20) and is not found in the donor, the risk of HUS is low for the donor and living-related donor transplantation can proceed.
   (b) If the donor has the same mutation as the recipient, the risk of HUS is present for the donor and living-related donor transplantation should not proceed.

(c) If the role of the variant found in the recipient is uncertain (not reported in databases, unknown functional consequences) the risk of HUS is intermediate for the donor, who may share with the recipient an unknown risk factor, and living-related donor transplantation is not advised.
(d) If no mutation is identified in the recipient and the donor, the risk to the donor is not quantified. KDIGO advises that if there is no evidence of alternate complement pathway activation in the donor, donation is feasible.

In general, additional endothelial damaging factors should be avoided, such as delayed graft function (prolonged ischemia time, non-heart-beating donor), cytomegalovirus infection, high levels of CNI and the association of CNI + mTOR inhibitors and hypertension.

Prior to the availability of eculizumab, isolated liver transplantation and combined liver-kidney transplantation were recognized treatment approaches for patients with mutations in FH, C3 and FB (all synthesized in the liver). These had relatively high morbidity and mortality (for example, 20% of patients who received combined liver-kidney transplant for aHUS died) [103, 198, 199]. Eculizumab represents a safer treatment option, but liver transplantation may still have a role when eculizumab is not available [161].

Potential Future Therapies

Current therapies are limited to monoclonal antibodies against C5. Numerous drugs that inhibit complement via different targets are undergoing clinical development, some of which may be suitable for use in aHUS. OMS721 (Narsoplimab) is a monoclonal antibody targeting mannan-binding lectin associated serine protease-2, the effector enzyme of the lectin pathway of the complement system and is currently undergoing a phase 3 clinical trial in adult patients with aHUS (NCT03205995. LMP023 (Iptacopan) is an oral FB inhibitor also undergoing a phase 3 clinical trial in adult patients with aHUS (NCT04889430) [102].

Conclusion

The journey to an effective treatment for aHUS is a striking demonstration that understanding the pathophysiology of a disease opens the way to new therapies. The demonstration that aHUS was mostly a disease of complement dysregulation paralleled the development of the anti-C5 monoclonal antibody eculizumab. Prospective trials as well as off-label clinical experience confirmed the efficacy of complement blockade to prevent progression to ESKD in aHUS patients and allowed successful kidney transplantation in those on dialysis. This new era in the field of aHUS emphasizes the need for an etiology/pathophysiology-based classification of the various forms of TMAs. Hopefully, new discoveries will identify the etiology of the 30% of aHUS cases that remain unexplained today, and the aHUS denomination will then disappear.

An important current question is that of the duration of eculizumab treatment, and prospective studies are underway to define whether discontinuation can be considered, in which patients, and when. Should withdrawal be shown as feasible in some patients, this would decrease the burden and risks of continuous treatment for patients, but also the cost for health care systems.

The addition of long acting ravulizumab to the treatment armamentarium for aHUS brings choices for patients and clinicians that may improve quality of life. Over the next decade, it is possible that further agents will be shown to be effective for the treatment of aHUS. Thus, future treatment of aHUS might comprise a decision about specific treatment and mode of delivery, followed by a decision regarding continuation or discontinuation of therapy with appropriate monitoring. Such options were not imaginable by aHUS patients 20 years ago.

C3 Glomerulopathies

23

Christoph Licht, Marina Vivarelli, Magdalena Riedl Khursigara, and Patrick D. Walker

Introduction

Membranoproliferative glomerulonephritis (MPGN) was originally described as a pattern of glomerular injury seen in patients with Bright's Disease [1]. By mid-1970, MPGN had become a disease of children with three primary subtypes sorted by electron microscopy presenting clinically with nephrotic syndrome and hypocomplementemia [2, 3]. But over the next 40 years, as it became associated with an ever increasing variety of diseases, each with different clinical presentations and etiologies, MPGN has returned to being a pattern that only vaguely points the way to a clinicopathologic diagnosis [4].

Due to the significantly increased understanding of the role of complement in glomerular diseases, two distinct entities have arisen from the MPGN morass, i.e. C3 Glomerulopathy (C3G) and Immune-complex mediated MPGN (Table 23.1). Glomerular diseases associated with abnormalities of the alternative pathway of complement are grouped under the term C3G [5]. There are two major subtypes, C3 glomerulonephritis (C3GN) and dense deposit disease (DDD) sorted by changes seen on electron microscopy. C3G is caused by various genetic abnormalities with or without the development of antibodies against different components of the complement pathway, so-called nephritic factors. Idiopathic MPGN also has two subtypes but these are separated by immunofluorescence findings on renal biopsy. Immune complex-mediated MPGN has dominant or co-dominant immunoglobulins with C3. There is also an immune negative variant of MPGN. The idiopathic forms of these two variants are extremely rare and a detailed search for an underlying cause is required [6]. However, otherwise idiopathic forms of MPGN may be due to abnormalities in the alternative pathway of complement, that is, C3G with immunoglobulin deposition.

Table 23.1 Classification of IC-MPGN/C3G

	Characteristic findings in C3G	Characteristic findings in IC-MPGN
Light microscopy	– Membranoproliferative pattern – Mesangial glomerulopathy – Necrotizing and crescentic glomerulonephritis – Acute proliferative and exudative glomerulonephritis	– Membranoproliferative pattern – Mesangial glomerulopathy with endocapillary hypercellularity, mesangial hypercellularity and mesangial matrix expansion
Immunofluorescence microscopy	– Dominant C3 deposition along capillary loops and in mesangial areas – IgG, IgM, IgA, C1q can be present but at much lower intensity	– C3 and IgG staining (similar intensity) along capillary loops and mesangial areas
Electron microscopy	– Dense deposit disease: ribbon-like, extremely dense transformation of glomerular basement membranes – C3GN: subendothelial deposits along glomerular basement membranes and in the mesangial matrix	– Immune-complex type electron dense deposits along the subendothelial spaces and in the mesangium

Table 23.1: Overview of biopsy findings in C3G and IC-MPGN. Both entities are indistinguishable on light microscopy. IF staining will determine whether a biopsy is classified as C3G or IC-MPGN. EM can diagnose cases of DDD. C3GN and IC-MPGN are indistinguishable on EM

Histopathology of C3 Glomerulopathy

Light Microscopy (LM)

Historically, dense deposit disease and the more recently described C3 glomerulonephritis were considered to be a form of membranoproliferative glomerulonephritis (MPGN). This despite the fact that DDD and C3GN have a membranoproliferative pattern in only 25% to 30% of patients at presentation. A mesangial glomerulopathy is most common (40–50%), while necrotizing and crescentic glomerulonephritis (~10%) and acute proliferative and exudative glomerulonephritis (~10%) make up the rest (Fig. 23.1) [3, 7–9]. The name membranoproliferative glomerulonephritis describes the pathologic features found in this pattern of glomerular injury. There is new glomerular basement membrane (GBM) formation producing double contours. The proliferative component includes endocapillary and mesangial hypercellularity as well as the cellular interposition between the GBM double contours. At the time of presentation, biopsies of patients with C3G almost always have a very mild membranoproliferative pattern, particularly as opposed to patients with immune-complex mediated MPGN (see below). Mesangial glomerulopathy is limited to variable mesangial changes without GBM alterations. The changes can be so mild that the biopsy appears almost normal. In the well-developed form, there is diffuse mesangial expansion with mesangial hypercellularity. Crescentic C3G at presentation typically shows extensive cellular crescents with necrotizing areas. Where the glomerular tufts can be seen, there is usually some endocapillary and mesangial hypercellularity with neutrophilic infiltration. However, occasionally the glomerular tuft is bland, though the neutrophilic infiltration is most often still present. Acute proliferative and exudative glomerulonephritis is indistinguishable from an infection-related glomerulonephritis and most likely explains why this variant was not described in the early series [3, 10–12]. There is glomerular enlargement due to diffuse endocapillary hypercellularity with neutrophilic infiltration.

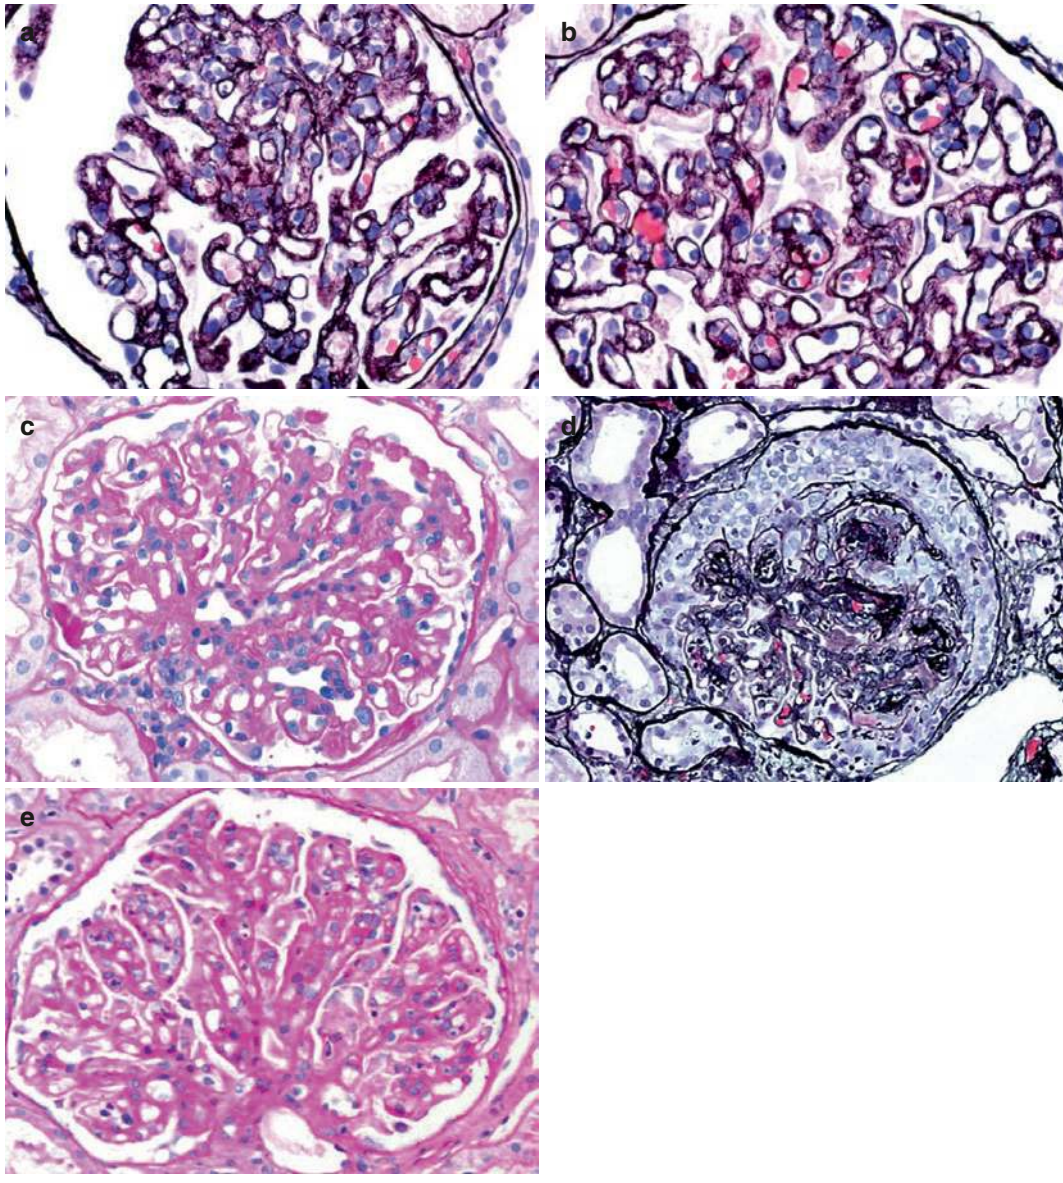

Fig. 23.1 Light microscopy findings in C3G. (**a**, **b**) Mild membranoproliferative pattern with glomerular basement membrane double contours, endocapillary and mesangial hypercellularity with mesangial matrix expansion (Jones silver stain, original magnification 600×). (**c**) Mesangiopathic glomerulopathy with mild mesangial cell and matrix increase (Periodic acid-Schiff reaction (PAS), original magnification 400×). (**d**) circumferential cellular crescent (Jones silver stain, original magnification 400×). (**e**) Acute proliferative and exudative glomerulonephritis (PAS, original magnification 400×)

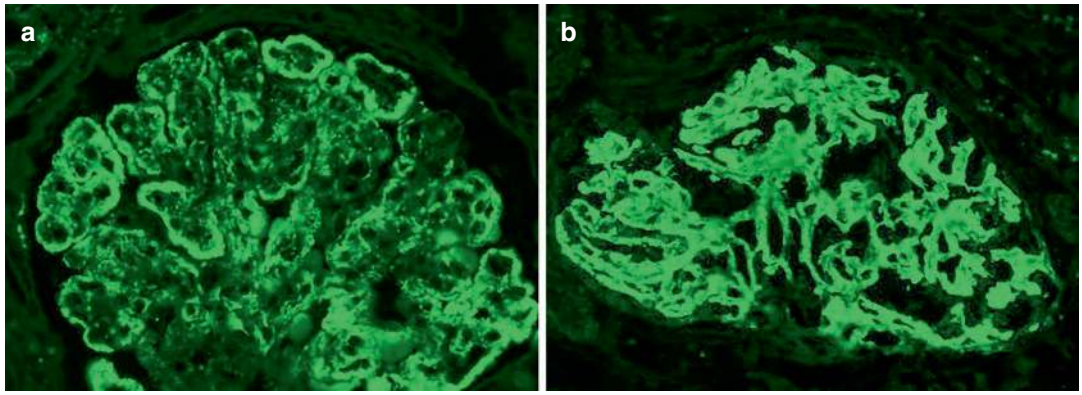

Fig. 23.2 Immunofluorescence microscopy findings in C3G. (**a**, **b**) Intense C3 staining along capillary loops and mesangial areas (fluorescein-conjugated, anti-human anti-C3c, original magnification 400×)

Immunofluorescence Microscopy (IF)

Dominant C3 deposition along capillary loops and in mesangial areas is a required feature for the diagnosis of C3G (Fig. 23.2). IgG, IgM and/or IgA are present in lower intensities in up to 36% of cases [7, 8, 13]. Surprisingly, C1q is seen in up to 30% of biopsies, again at lower intensity [7, 8]. In a large study of C3G, immunoglobulins were present in 46% of patients with C3GN and 36% with DDD [13]. Paraffin IF may reveal a dominant or co-dominant immunoglobulin [14]. The presence of immunoglobulins present on routine IF or on paraffin IF, though often found in C3G, raises the possibility of an infection-related glomerulonephritis or an autoimmune disease. Given that the latter entities are far more common than C3G, they must be ruled out before a diagnosis of C3G is made.

Electron Microscopy (EM)

C3GN is distinguished from DDD on the basis of EM (Fig. 23.3). Dense deposit disease is characterized by extremely electron dense transformation of the glomerular basement membranes with similarly dense spheroids in the mesangium. Large and equally dense sub-epithelial hump-like deposits are present in up to 50% of cases [13]. C3GN most often has electron dense deposits indistinguishable from immune-complex deposits. However, in many cases the deposits have a smudged charcoal gray appearance in the subendothelial space and in mesangial areas. Subepithelial hump-like deposits are commonly seen.

Transition from Acute Proliferative and Exudative Glomerulonephritis to C3G

There is a challenging subset of patients with C3G who initially present with an acute proliferative and exudative glomerulonephritis [15, 16]. Immunofluorescence shows C3 often with IgG in the mesangium and in a granular pattern along the capillary loops. Though this LM pattern and the finding of immunoglobulins on IF are common in C3G, these patients are thought to have an infection-related glomerulonephritis and are treated as such. The diagnosis of an infection associated GN is not surprising given that up to 40% of patients have an infection at the time of diagnosis [13]. Usually there is some renal function improvement, but continued low C3 levels and/or hematuria and proteinuria lead to a repeat biopsy and the diagnosis of C3G is made usually within months but can take several years [16–19].

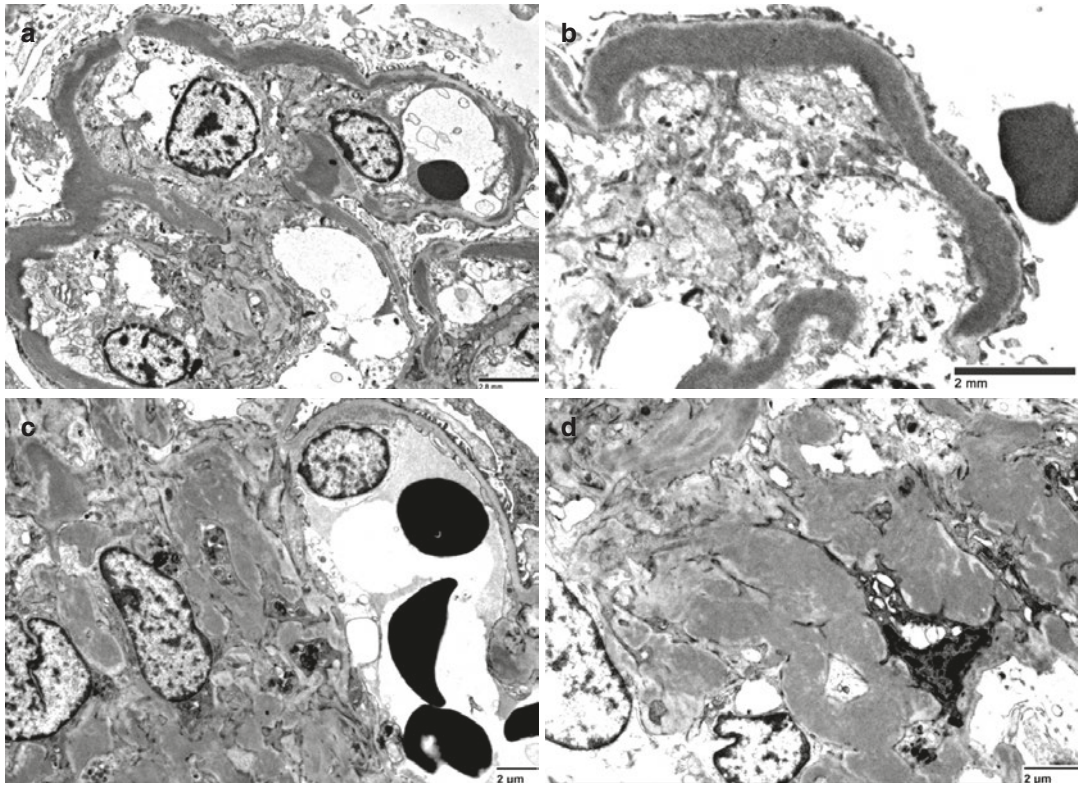

Fig. 23.3 (**a**, **b**) Dense deposit disease. Extremely electron dense transformation of the glomerular basement membranes forming ribbons. Similarly dense spheroids in the mesangium (**a**. unstained, original magnification 8000×; **b**. unstained, original magnification 20,000×). (**c**, **d**) C3GN. Smudgy gray deposits in the mesangium and in subendothelial spaces (**c**. unstained, original magnification 6000×; **d**. unstained, original magnification 8000×)

Histopathology of Immune Complex Mediated Membranoproliferative Glomerulonephritis

By definition, these patients have a membranoproliferative pattern of glomerular disease. There are glomerular basement membrane double contours with cellular interposition accompanied by endocapillary hypercellularity, mesangial hypercellularity and mesangial matrix expansion sometimes forming lobules. IF demonstrates capillary loop and mesangial deposition of C3 and immunoglobulin(s), almost always IgG with or without IgM. EM confirms the LM findings of glomerular basement membrane duplication with cells between the layers and endocapillary hypercellularity. The mesangium is expanded by cell and matrix increase. Immune-complex type electron dense deposits are found along the subendothelial spaces and in the mesangium (Fig. 23.4) [20, 21].

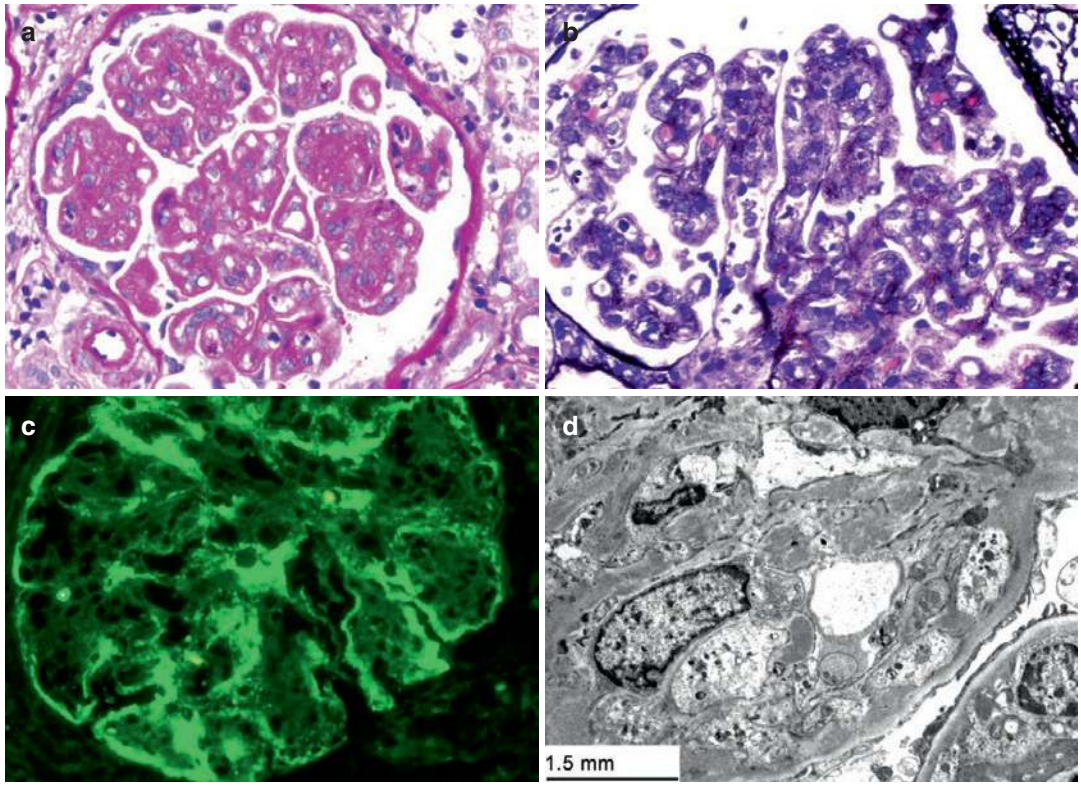

Fig. 23.4 IC-MPGN (**a**) Mesangial cell and matrix increase forming lobules. Endocapillary hypercellularity and thick glomerular basement membranes (PAS, original magnification 400x). (**b**) Endocapillary hypercellularity and mesangial cell and matrix expansion. (Jones silver, original magnification 600x). (**c**) Peripheral granular staining (fluorescein-conjugated, anti-human anti-C3c, original magnification 600x). (**d**) Mesangial and endocapillary hypercellularity. New basement membrane formation with cellular interposition. Electron dense deposits in the mesangium and in subendothelial spaces of the glomerular basement membranes (unstained, original magnification 8,000x)

Classification of C3G

The classification of C3 glomerulopathies (C3G) is based on the pattern and intensity of immunofluorescence seen on renal biopsy (Table 23.1). Prevalent Ig staining prompts the diagnosis of a *secondary* MPGN (see above), and work-up including a panel of auto-antibodies, viral serologies and, exceptionally in pediatric patients, searching for cryoglobulins and monoclonal gammopathies is warranted. However, predominant C3 staining prompts the diagnosis of a primary disease, referred to as C3 glomerulopathy (C3G). Within this category, electron microscopy assessment allows for the differentiation of patients with dense deposit disease (DDD; previously known as MPGN II), in whom dense, sausage-like very intensely osmiophilic deposits are present along the glomerular basement membrane, and patients with predominant mesangial C3 staining and possible presence of subepithelial humps as described in post-infectious mesangial glomerulonephritis. The latter group is diagnosed with MPGN I or C3 glomerulonephritis (C3GN), with MPGN I traditionally being favored in patients with membranoproliferative lesions. Of note, C3G may be familial or sporadic.

Pathogenesis

Much has been learned about C3G and MPGN by studying patients and both spontaneously occurring and genetically engineered animal models (Fig. 23.5). In summary, C3G and IC-MPGN result in principle from dysregulation of the complement alternative pathway in the fluid phase with possible terminal complement pathway (TP) activation, complement (split product) deposition in the kidney and an accompanying inflammatory response. In humans, CAP dysregulation can result from mutations in complement proteins or the presence of autoantibodies.

In animal models, Factor H (FH) deficiency resulted in C3 deposition along the GBM, terminal pathway (TP) activation followed by electron dense transformation of the GBM together with varying degrees of glomerular inflammation and structural damage, hallmark features of MPGN [22, 23]. When C5 activation was prevented by inter-crossing the Cfh−/− strain with C5-deficient mice, the abnormal glomerular C3 deposition remained unchanged but the severity of glomerulonephritis was decreased [23]. However, altering C3 convertase activation by deleting Factor B (FB) or Factor D (FD) prevented MPGN. In Cfh−/− mice that are also deficient in Factor I (FI), activated C3 remains as C3b only. Interestingly, whilst abnormal glomerular C3 developed in both strains, the C3 in the mice with combined deficiency of FH and FI was mesangial in location, whilst in the Cfh−/− strain the C3 was located along the GBM. These data indicate that during uncontrolled C3 activation the nature of the activated C3 fragment may determine the site of its glomerular deposition [24]. What those animals models have shown us is that FH is the critical regulator of glomerular C3 homeostasis, and administration of either mouse or human FH to Cfh−/− mice reduced glomerular C3 staining and increased circulating C3 levels [25]. Mutations in FH are typically associated with atypical hemolytic uremic syndrome (aHUS) indicating that defects in the CAP can give rise to at least two distinct renal phenotypes: thrombotic microangiopathy (TMA) like HUS and glomerulonephritis like C3G. The majority of aHUS-associated CFH mutations does not result in complete deficiency of FH but selectively impairs the surface C3b recognition domains of the protein. In keeping with this, mice expressing a mutant FH molecule that functionally mimicked aHUS-associated mutations known from patients developed TMA not C3G, [23] and this was dependent on C5 [26].

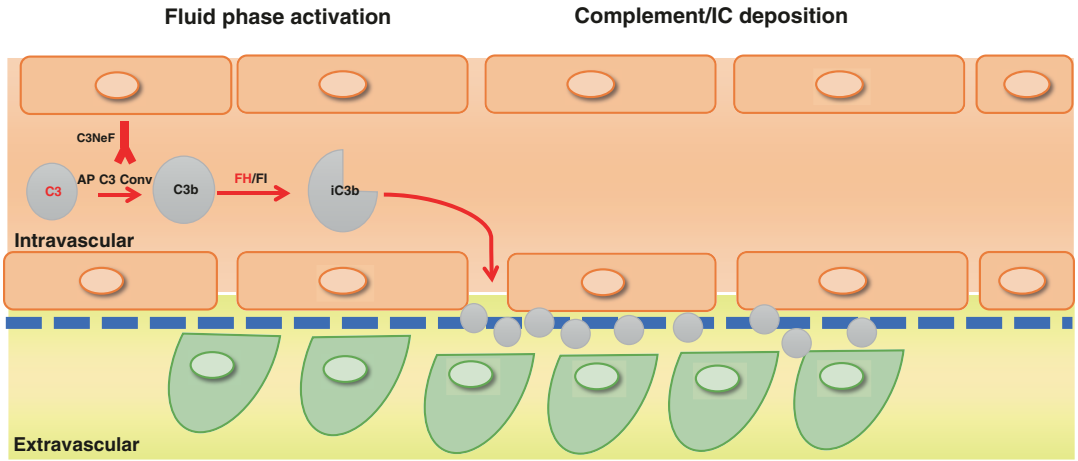

Fig. 23.5 Pathogenetic *concept* of C3G: Genetic or autoimmune factors result in fluid phase dysregulation of the complement alternative pathway at the level of the (alternative) C3 convertase. Excessive C3 activation results—in the presence of proteases (e.g. CFI) and their corresponding cofactors (e.g. CFH)—in the generation of copious amounts of C3 split products which deposit in the glomerular filter triggering local inflammatory responses

On the other hand, complement dysregulation in C3G patients may occur via different scenarios:

- Antibodies stabilizing the CAP C3 convertase and prolonging the natural decay of the CAP C3 convertase, rendering it overactive.
- Mutations or antibodies to FH or FHR that result in the absence or loss of function of FH resulting in loss of control of the CAP C3 convertase and its enhanced activity.
- Mutations in C3 or FB that result in an exceedingly stable C3 convertase with prolonged decay and enhanced function.

In all scenarios, the functional consequence is an enhanced activation rate of C3 mainly in the fluid phase. Autoantibodies associated with C3G (see below) prolong the half-life of the CAP C3 convertase, or the (CAP or CP) C5 convertase and therefore result in TP activation [27, 28].

Autoimmune Forms of C3G

Decreased serum C3 levels were long reported in patients with MPGN, which led to the hypothesis of a circulating factor leading to increased C3 cleavage [29]. When an antibody binding to a neo-epitope of the complement CAP C3 convertase (C3bBb)—delaying its natural decay and thus enhancing its function—was found, it was named C3 Nephritic Factor (C3NeF) [27, 30]. C3Nef is an autoantibody capable of binding the CAP C3 convertase, C3BbB, therefore conferring resistance to its inactivation by regulatory factors such as FH.

More recently, additional autoantibodies or nephritic factors were detected which prolong the half-life of the CAP and CP C3 and C5 convertases:

- *Antibodies that stabilize the CAP and/or CP C3 convertase:* C3NeF [31, 32], C4NeF [33, 34], Anti-Factor B antibodies [35, 36] and Anti-C3b antibodies [35];
- *Antibodies that stabilize the C5 convertase:* C4NeF [34], C5NeF [37];
- *Antibodies impairing CAP (fluid phase) regulation:* Anti-Factor H antibodies (recognizing FH N-terminus) [38–40].

C3NeF is the most prevalent antibody and was detected in 86% of DDD, 46% of C3GN, and up to 50% of patients with IC-MPGN, respectively, and is associated with decreased C3 levels [41, 42]. C3NeF might fluctuate and not correlate with disease activity and might co-exist with complement mutations [43, 44]. Therefore, a positive C3NeF still warrants comprehensive complement diagnostics. Anti-C3b and Bb antibodies, both stabilizing the CAP C3 convertase, have been reported in several patients with C3G and IC-MPGN and are associated with worse outcome if both occur at the same time [36].

Servais et al. identified mutations in complement genes in 18% of C3G patients, while the presence of circulating C3Nef was detected in 59% of cases [45]. More than half of the patients carrying complement gene mutations were also C3NeF positive. C3Nef was more frequent in patients with DDD (86%) and was associated with significantly lower levels of circulating C3. A report of 3 patients with DDD showed a correlation of moderate increases in C3Nef and slight reduction on C3 and disease recurrence post-transplant [46]. In other reports, lower circulating levels of C3 were found in patients with a membranoproliferative pattern of disease, [41] while others have reported that children have significantly lower C3 levels and more frequent C3Nef positivity compared to adults [7].

However, as reviewed by Pickering M et al. [47], C3NeF can be detected in different ways [31, 48]. It is possible that patients may be positive in some but not all available assays. C3NeF and other auto-antibodies found in MPGN were also detected in other kidney diseases, such as systemic lupus erythematosus (SLE) [49], postinfectious GN [50], and meningococcal meningitis [51]. C3Nef levels are occasionally also found in healthy individuals [52], rendering the interpretation of their pathogenic value controversial.

Therefore, the significance of C3Nef in the pathophysiology of C3G and its correlation with

disease course and with response to treatment is still debated and warrants further investigation [47, 53].

Genetic Forms

Early studies found a genetic cause in approximately 18% of patients with IC-MPGN and C3G. By contrast, Bu et al., studying a larger panel of genes by next-generation sequencing (NGS), found a genetic diagnosis in up to 43% [32, 54]. Iatropoulos et al. detected mutation carriers in 17 and 18% of patients with IG-MPNG and C3G, respectively [42]. To date, mutations have been reported in the following complement genes: CFH, CFHR5, CFI, MCP, C3 and CFB and can occur in a heterozygous or homozygous fashion (Table 23.2).

Additional mutations or internal duplications in genes encoding FH related proteins (CFHR), or formation of hybrid genes, have been associated with C3G [55, 56]. In 2009 Gale et al. described 26 individuals of Cypriot ancestry with

unexplained renal disease and a variation in CFHR5 comprising duplication in its dimerization domain, termed CFHR5 nephropathy [57]. Several more mutations and hybrid variants in CFHR genes have been detected since and are associated with C3G [58]. The role of FHR in C3G was unclear until the report, that FHR1, FHR2 and FHR5 form homo- and heterodimers amongst themselves and with FH. In the dimeric form these proteins are able to compete with FH for C3b binding and protect C3b from inactivation and the complement CAP C3 convertase from decay. This process, termed "deregulation," was increased in patients with CFHR hybrids or CFHR5 mutations [59].

Interestingly, Ozaltin et al. published several patients with MPGN with a homozygous mutation in DGKE, an intracellular lipid kinase that modulates phosphoinositol signaling in the plasma membrane [60]. DGKE mutations can also be found in thrombotic microangiopathy [61]. Bu et al. found heterozygous variants in DGKE in several patients with C3G, as well as in Thrombomodulin, Plasminogen and ADAMTS13. The clinical relevance of these gene variants is still unclear [54].

Risk haplotypes were identified in CFH, C3 and MCP/CD46, with the CFH Y402H haplotype more frequently reported in DDD, and the MCP-652A4G polymorphism in C3G. The presence of two or more complement haplotypes increased the risk of disease [32, 62].

Clinical Presentation

MGPN, C3GN and DDD are rare diseases with an individual annual incidence estimated at 1–2 per million per total population (both pediatric and adult) [63, 64]. C3 glomerulopathies typically present with (possibly nephrotic range) proteinuria and hematuria and hypertension coupled with low circulating C3 levels [65, 66]. However, C3G has a very heterogeneous clinical presentation. This heterogeneity reflects the variety of pathogenetic mechanisms leading to a dysregulated, uncontrolled activation of the CAP.

Presentation at Onset of Disease

Age at onset is very variable, with the earliest reported case being at age 1 [67]. In the most comprehensive cohorts that include adult and pediatric patients, disease onset below age 16 years was described in 59–68% of DDD and 25–31% of C3GN patients [32, 64]. In a pediatric cohort median disease onset was approximately 10 years for both patients with IC-MPGN and C3G [68]. A slight prevalence of males (60%) was reported in some cohorts, [32, 64] but not in the cohort that included pediatric patients only [68].

Clinical symptoms are listed in Table 23.3. Data taken from the 3 cohorts indicate that patients with C3G and IC-MPGN commonly present with microscopic hematuria, significant proteinuria including nephrotic syndrome in up to 40%, hypertension and reduced renal function. Incidence of macrohematuria was reported in 10–23% [7, 64].

Disease onset is often associated with an infection as described in a report of children with DDD, in whom the appearance of renal symptoms was preceded by a respiratory infection in 57% of cases [7]. Recurrent macrohematuria during trivial infectious episodes, a clinical feature typically associated with IgA nephropathy, is not uncommon in C3G [69].

The large variation of age at presentation is probably linked to the fact that in some cases this disease has a subclinical and spontaneously remitting disease course. Hence, microhematuria and low-grade proteinuria can remain undetected for many years, leading to a delayed diagnosis when proteinuria reaches nephrotic range or when kidney failure develops. However, early onset with nephrotic proteinuria and renal failure, though less common, has been reported (patient 9 in [41]).

Worse renal function was found in pediatric patients with C3G and in adult and pediatric patients with C3GN compared to DDD. Low C3 was commonly found in patients with C3G, especially in patients with DDD and IC-MPGN. Over the course of time, C3 can normalize in some patients but might stay low in others, a persistently low C3 was more commonly found in patients with IC-MPGN [68]. C3 levels do not correlate with disease outcome [70].

Family history of glomerulonephritis must be investigated as familial forms have been described in 11% of cases [32] and genetic investigations may be channeled more effectively in these cases.

As the classification system for MPGN has recently evolved, our understanding of the differences in the clinical presentations of MPGN versus C3GN is limited. There are no unique features that clearly distinguish MPGN, DDD and C3GN on clinical grounds. An exception to this rule appears to be CFHR5 associated C3GN, which presents in childhood with persistent microscopic hematuria, synpharyngitic gross hematuria, and a strong family history of ESKD. At present this form of G3GN has been reported primarily in the Cypriot population, but also in two patients with non-Cypriot heritage [57, 71]. Patients with CFHR5 associated C3GN are also reported to have normal serum C3 concentrations.

Table 23.3 Clinical presentation of IC-MPGN and C3G

	Kirpalani (pediatric only)	Medjeral-Thomas	Servais
Number of patients	42 IC-MPGN/ 43 C3G	21 DDD/59 C3GN	29 DDD/56 C3GN
Microscopic hematuria	81/62%	76/65%	19/30%
Proteinuria	–/–	3/3 g/d	5.6/3.6 g/d
Nephrotic syndrome	22/12%	43/44%	38/27%
Hypertension	57/58%	60/39%	21/38%
Creatinine	94/168 µmmol/L	80/124 µmmol/L	–/–
eGFR (ml/min/1.73 m^2)	76/83	–/–	76/66
C3	0.26/0.39 g/L	Low 79/48%	Low 46/46%

Extra-Renal Manifestations

C3G is a complement-mediated disease, secondary to CAP dysregulation. Given that this dysregulation occurs in the fluid phase of blood, extra-renal features of disease are to be expected. In DDD, patients may develop acquired partial lipodystrophy (APL) and ocular lesions similar to soft drusen seen in age-related macular degeneration (AMD) [72].

APL—like DDD and C3GN—is associated with dysregulation of CAP on adipocytes [73] and becomes manifest in the loss of subcutaneous fat tissue, which typically occurs in the upper half of the body (starting from the face and extending to involve the neck, shoulders, arms and thorax) and precedes the onset of renal disease by several years. The median interval between the onset of APL and DDD is about eight years [74]. The majority of APL patients present with low C3 levels and, in addition, are C3NeF positive, which leads to enhanced CAP activation. MPGN was described in about 25% of patients with APL. Patients with combined disease are more likely to present with decreased C3 levels and develop APL earlier in life (about 7.7 years of age) [74].

Patients with DDD can also develop ocular lesions in the form of drusen. Drusen are retinal changes seen as crystalline yellow or white dots, which lie between the retinal pigment epithelium and Bruch's membrane [75]. Drusen can develop in the second decade of life and are responsible for visual disturbances in up to 10% of patients with DDD [72]. The drusen seen in patients with DDD are similar to those seen in age-related macular degeneration (AMD).

Diagnosis

The clinical presentations of MPGN, DDD and C3GN are extremely variable and overlap with many other glomerular diseases, ranging from subtle/subclinical to acute and severe, as exemplified in the following scenarios:

- An incidental finding on routine urinalysis of non-nephrotic proteinuria, often accompanied by microscopic hematuria.
- Macrohematuria concomitant or 2–3 weeks after an intercurrent infectious episode, most frequently of the upper respiratory tract.
- Nephrotic range proteinuria, with or without clinical signs of nephrotic syndrome and renal function impairment.
- Very rarely, an overlap with thrombotic microangiopathy.

Diagnosis of C3G is made with a renal biopsy, which includes light microscopy, immunofluorescence and electron microscopy. Extensive C3 staining allows for the diagnosis of C3GN, predominant IgG staining on the other hand is characteristic for IC-MPGN and electron dense deposits favors the diagnosis of DDD. Despite different features on biopsy, the underlying pathophysiology is similar and requires further workup for complement activation, auto-antibodies and mutations in complement genes.

Differential Diagnosis

The presentation of a nephritic/nephrotic clinical picture is compatible with a variety of diagnoses at disease onset. The clinical picture can be indistinguishable from IgA nephropathy (IgAN), particularly if circulating C3 is normal and macrohematuria in the setting of an infection is observed [69]. Familial disease does not exclude the diagnosis of C3G, particularly but not exclusively in patients of Cypriot descent [55, 57]. Renal biopsy, in particular the immunofluorescence, allows clear discrimination between C3G, in particular the familial forms, and IgAN.

In the presence of reduced levels of circulating C3, particularly in context of an infection during the preceding 2–3 weeks, the diagnosis of acute post-infectious glomerulonephritis (PIGN) is likely, but C3G is also possible though less frequent. In this case, a renal biopsy may not be

definitive as the presence of "humps" in the electron microscopy is common to both, C3G and PIGN [9]. The latter presents with reduced circulating C3 levels, which typically normalize within 12 weeks from disease onset [76]. As C3 levels may be normal also in C3G and given the heterogeneity of the clinical picture of this new disease entity, we suggest that in the case of a clinical picture common to C3G and PIGN, even with normalizing C3 levels and absent proteinuria, patients be advised to perform urinalysis every 3–6 months for 2 years following resolution of the acute clinical picture and to seek medical attention if macrohematuria or significant proteinuria re-appear.

Decreased C3 and C4 are hallmark features of SLE, which can present with proteinuria, microscopic hematuria and hypertension. Low C4 was reported in a small amount of patients with C3G (5–36%) and therefore cannot be used as the differentiating factor [32, 64]. A thorough history and physical examination with attention to extrarenal disease manifestations such as arthritis, rash, neurologic, hepatic, lung or cardiac involvement combined with ANA and anti-dsDNA antibody titers, laboratory evidence of hemolysis, leukopenia, coagulopathy, or hepatitis, strongly support a diagnosis of SLE as opposed to C3G.

Laboratory Evaluation

When the diagnosis of C3G has been made by renal biopsy, analysis of the CAP is warranted:

1. Circulating complement factors including C3, C4, CFH, CFB and markers for complement pathway activation (CH50, APH50, C3d) and terminal complement activation (C5b-9).
2. Circulating autoantibodies such as C3 Nephritic Factor (C3NeF) and anti-FH autoantibodies.
3. Other antibodies that are only measured in specialized research labs can be added in specific cases: anti-CFB antibodies, C4 Nephritic Factor, C5 Nephritic Factor and anti-C3b antibodies.
4. Mutations in genes involved in the regulation of the C3 convertase such as Factor H (FH), Factor I (FI), membrane cofactor protein (MCP/CD46), C3, and Factor B (FB) and screening of the FHR locus with MLPA to detect deletions, duplications or fusion genes. Other genes associated with C3G or IC-MPGN include thrombomodulin and DGKE.
5. When family history is positive for C3G, suggesting a familial form, the FHR locus should also be screened for an internal duplication within the FHR5 gene, described mainly but not solely in individuals of Cypriot origin [57].

In patients with IC-MPGN we also recommend a detailed investigation for secondary causes as listed in Table 23.4.

Table 23.4 Causes of secondary MPGN

Immunoglobulin mediated
Infectious diseases:
Hepatitis B, C, E, EBV, HIV
Endocarditis, shunt nephritis, visceral abscess, empyema
Tuberculosis, leprosy
Brucellosis, Q Fever
Malaria, schistosomiasis
Onchocerca volvulus, Wucheria bancrofti, Loa loa infections
Systemic immune diseases:
Cryoglobulinemia
Systemic lupus erythematosus
IgA vasculitis
Sjögren's syndrome (secondary to cryoglobulinemia)
Hypocomplementemic urticarial vasculitis
Rheumatoid arthritis (Zand et al. [79])
X-linked agammaglobulinemia
Neoplasms/dysproteinemias:
Plasma cell dyscrasia
Monoclonal gammopathy of unknown significance
Fibrillary glomerulopathy
Immunotactoid glomerulonephritis

(continued)

Table 23.4 (continued)

Proliferative glomerulonephritis with monoclonal immunoglobulin deposition (Nasr et al. [7]
Proliferative glomerulonephritis with isolated light chain deposition
Membranoproliferative glomerulonephritis with masked monotypic immunoglobulin deposits
Light-chain and/or heavy-chain deposition disease
Leukemias and lymphomas (with or without cryoglobulinemia)
Bone marrow transplant
Carcinomas, Wilms' tumor, malignant melanoma
Angiofollicular lymph node hyperplasia with or without TAFRO syndrome[a]
Sinus histiocytosis with massive lymphadenopathy
Other:
Alpha-1-antitrypsin deficiency with severe liver disease
Gluten-sensitive enteropathy (celiac disease)
Immunoglobulin negative
Thrombotic microangiopathy including drug induced forms
Sickle-cell disease
Transplant glomerulopathy
POEMS syndrome[b]

[a]TAFRO = Thrombocytopenia, Anasarca, Fever, Renal dysfunction (or Reticulin myelofibrosis) and Organomegaly
[b]POEMS syndrome = Polyneuropathy, Organomegaly, Endocrinopathy, Monoclonal gammopathy and Skin changes

Outcome

Data on long-term outcomes in both native and transplant kidneys based on the new classification is limited and vary dependent on the cohort and disease onset. Medjeral-Thomas, comparing outcomes of DDD and C3GN in a cohort of 80 patients, with 50% having a pediatric onset of disease, reported progression to ESKD in 47% of DDD patients and 23% of C3GN patients with a median follow-up of 28 months. Multivariate analysis suggested crescentic changes, DDD and disease onset over 16 years of age as independent predictors for ESKD [64].

The French cohort of 134 patients reported 10-year renal survival at 63.5%, with no difference between groups (MPGN, DDD, C3GN). Median time from first observation to end-stage renal disease was about 10 years, and in the patients that underwent renal transplant, disease recurrence was observed in over half of the cases, with an additional 17% experiencing thrombotic microangiopathy (TMA) [32, 41].

A large retrospective study comprising 165 children with both IC-MPGN and C3G confirmed that children have a better outcome than adults. After a mean follow-up of 4 years kidney function was preserved, and at 10 years 80% of children analyzed did not meet the composite outcome of eGFR <30 ml/min/1.73 m^2, 50% eGFR reduction or need for kidney replacement therapy [68]. Although hypertension remained prevalent in 42.5% of the cohort at the last follow-up, and the urine protein/creatinine ratio remained elevated (mean 253.8 [range 91.9–415.7] mg/mmol).

Disease recurrence of MPGN and DDD in transplants is common (Table 23.5). Data from the ESPN/ERA-EDTA registry shows an average renal allograft loss of 32.4% at 5-years post-transplant in children [77]. Data suggesting that pediatric patients with DDD are at greater risk of graft loss from disease recurrence has also been reported in the NAPRTCS database [78]. The reason(s) for the increased risk of recurrence in children is not clear. Several limited case series confirm an increased risk of disease recurrence for C3GN and the potential negative impact on allograft survival. Disease recurrence is strongly associated with graft loss [64]. Zand et al. reported outcomes on 21 patients with C3GN, 14 (66.7%) had disease recurrence with median time to graft failure of 77 months (6.4 years) [79]. Concerning risk of relapse following renal transplantation for DDD, in one study the degree of proteinuria was strongly associated with disease recurrence, and the presence of glomerular crescents in biopsies of renal allografts had a significant negative correlation with graft survival [78].

Table 23.5 Disease recurrence post transplantation

	Medjeral-Thomas	Servais
Number of patients	7 C3GN 6 DDD	14 IC-MPGN 10 C3GN 11 DDD
MPGN	–	43%
C3G	57%	60%
DDD	100%	55%

In the familial form of C3G secondary to CFHR5 mutations described in individuals of Cypriot descent [57] prognosis differed significantly between sexes: men were by far more likely to progress to ESKD than women (78% versus 22%).

Treatment

At present, there is no treatment standard or at least a therapeutic agent of proven effectiveness in C3G available. The rarity of this disease, coupled with its protracted and variable natural history, makes clinical trials logistically challenging and the use of different end-points make uniform interpretation of results difficult [80]. However, considering that about 50% of patients proceed to ESKD and may face a high risk of disease recurrence post-renal transplant, concerted efforts to define effective treatment strategies are necessary. Several therapeutic regimens have been employed, utilizing immunosuppressive agents (glucocorticoids, mycophenolate mofetil, calcineurin inhibitors), anti-platelet agents, plasma exchange or infusion and, much more recently, complement blockers [81–83]. Renoprotective agents (such as angiotensin-converting-enzyme inhibitors, ACEi, or angiotensin II receptor antagonists, ARBs) are associated to these treatments almost invariably. As our understanding of the pathophysiology of C3G and of IC-MPGN is rapidly expanding and changing, while reviewing published cases is reasonable, its usefulness in guiding future therapeutic strategies may be limited [47].

The optimal therapeutic strategy should be driven by clinical parameters, such as the degree of proteinuria and impairment in renal function, and also by diagnostic test results (Fig. 23.6). In

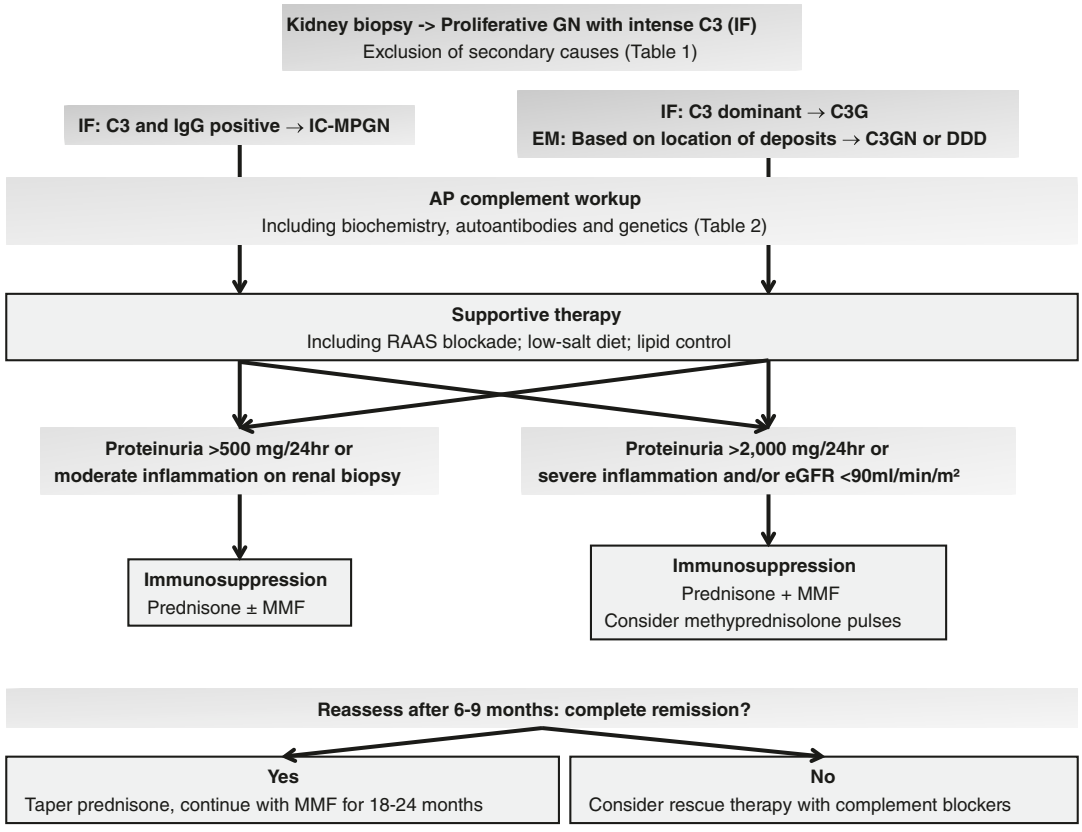

Fig. 23.6 Therapeutic algorithm for IC-MPGN/C3G

the near future, the availability of new therapeutic agents may drastically alter this strategy. Clinicians need to be aware that clinical practices in this field may evolve rapidly.

In the following paragraphs regarding treatment, for all options except eculizumab the literature cited is about different forms of IC-MPGN and C3G. Because evidence is very limited, a consensus of expert opinion currently still provides the most reasonable therapeutic approach to this disease (KDIGO) [84].

Immunosuppressive Agents

There are no published trials on the use of **prednisone** in C3G. Existing literature pertains to primary membranoproliferative glomerulonephritis of all subtypes. In children with all subtypes of primary MPGN, prednisone—specifically, long-term low-dose use of prednisone—was found to have a beneficial effect with respect to the degree of proteinuria and renal survival [85–88]. This observation was confirmed by subsequent studies, in which therapy with prolonged alternate day prednisone delayed deterioration of renal function [87, 89].

However, the response of MPGN patients to glucocorticoids is not homogenous. A MPGN subtype-specific analysis revealed a lack of efficacy in patients with MPGN II/DDD, despite a beneficial effect on all MPGN patients irrespective of the MPGN subtype [87].

Altogether, in all forms of IC-MPGN and C3G, glucocorticoids may be effective, but their nonspecific nature and adverse effects mean that a high price is paid for any beneficial effect on the renal lesion [90]. A reasonable approach based on current knowledge may be that of utilizing 60 mg/m^2 daily for 4 weeks followed by 40 mg/m^2 alternate-day prednisone for other 4 weeks then tapered for a total of 6–9 months in patients with C3G that present with nephrotic-range proteinuria, with or without renal failure, or in patients with persistent proteinuria >500 mg/day despite optimal renoprotective treatment. In children who present intense inflammation in the renal biopsy with marked endo and extracapillary proliferation, or who present an acute deterioration in renal function, intravenous methylprednisolone boluses (e.g., 1000 mg/1.73 m^2 repeated 3 times) may be added at disease presentation. If no significant reduction of proteinuria is observed, steroids should be tapered and discontinued [91]. It is important to recognize that a number of patients with C3G will not respond to this therapeutic approach [47].

Other Immunosuppressive Agents

In idiopathic MPGN patients, **MMF** was administered alone or in combination with corticosteroids, and generated encouraging results [92]. Another report of 13 adult patients with idiopathic MPGN resistant to glucocorticoid treatment (8 weeks at 1 mg/kg/day) showed that adding MMF led to significant reduction of proteinuria and increase of eGFR [93]. MMF in addition to pulse and long-term steroid treatment was also found effective in a pediatric patient [94].

In C3G, recent evidence, albeit retrospective, encourages the use of MMF. Initial findings by Rabasco et al. [95] were recently confirmed and expanded in a study by Caravaca-Fontan et al. [96] which described 97 patients (81 with C3GN, 16 with DDD, 74% adults and 26% children, median age 32 years), 42 of whom received corticosteroids plus MMF. This subgroup showed a significantly higher rate of remission (79%) and a lower likelihood of renal failure (14%) compared to patients receiving other immunosuppressive drugs, eculizumab or renoprotective treatment. The superiority of this therapeutic approach was seen both in patients with genetic complement abnormalities and in patients with autoantibodies to complement components. The only factor significantly associated with a lack of response to this approach was the amount of proteinuria at baseline. Previously, a study performed in 30 young adults [97] with a median age of 25 years showed that this combination therapy induced remission in 67% of cases with a 50% relapse rate upon discontinuation of MMF. In children, retrospective studies describe use of different immunosuppressive agents in small numbers of patients, which makes drawing meaningful con-

clusions difficult. Overall, similar results have been obtained [98–100]. In our experience, MMF is beneficial in patients both with IC-MPGN and with C3G with intense proteinuria. Following tapering and interruption of prednisone in 6–9 months, usually MMF monotherapy is continued for 12–18 months.

Calcineurin inhibitors (i.e. cyclosporine and tacrolimus) are also used in the treatment of MPGN. The efficacy of cyclosporin was recently tested with encouraging results in a trial involving 18 patients with refractory MPGN who also received small doses of prednisolone (0.15 mg/kg/day). Long-term proteinuria reduction with preservation of renal function was observed in 17 of the patients [101]. In two children with idiopathic MPGN with suboptimal response to a prolonged course of steroids, rapid and complete remission of the nephrotic syndrome was achieved after initiation of tacrolimus [102].

Contradictory results are published about the efficacy of cyclosporin A in the treatment of patients with MPGN II/DDD. Kiyomasu et al. report the successful treatment of a patient with MPGN II/DDD resulting in the recovery from nephrotic syndrome using a combination of alternate-day low-dose prednisone and cyclosporin [103]. The numbers of reported children in whom calcineurin inhibitors have been used are too small to draw valid conclusions. This immunosuppressive approach may reasonably be attempted, in the absence of alternatives, when MMF plus corticosteroids have failed to improve proteinuria significantly in a patient with preserved renal function.

The use of **rituximab** has been suggested in the presence of circulating C3 Nephritic Factor (C3Nef), an autoantibody that binds to C3BbB antagonizing its inactivation by circulating regulatory factors. However, to the best of our knowledge, while there are no published results showing this treatment to be effective, there are a few single case reports of its inefficacy [104, 105].

The use of **cyclophosphamide** may theoretically be considered in forms with crescentic glomerulonephritis and rapidly progressive onset, but available data is truly anecdotal.

Taken together, limited uncontrolled data suggest that especially MMF in combination with glucocorticoids may be of use in patients with C3G and intense proteinuria, while at present there is insufficient evidence to support the first-line use of calcineurin inhibitors, cyclophosphamide or rituximab in children with this disease [91].

Plasma Infusion or Plasma Exchange

As reviewed by Smith et al., [53] in FH-deficient mice with C3G, renal C3 deposition and its depletion in plasma are rapidly reversed when (either mouse or human) CFH is administered [25, 106]. These outcomes suggest that in some C3G patients with FH mutations, FH replacement therapy could restore the underlying defect and correct the disease. This has been shown in two siblings with DDD secondary to a functional FH defect in whom chronic plasma infusion prevented disease progression and development of ESKD [107, 108]. Whether administration of exogenous FH to patients without FH mutations would be therapeutically successful is not clear, but this treatment should at least in theory not be effective in patients with a known C3 mutation, in whom a C3 convertase that is resistant to regulation by FH is formed [109].

In all scenarios characterized by deficiency or functional defect of one or more complement components, replacement of this factor/these factors by either plasma infusion or plasma exchange could theoretically be effective [110].

Because of discordant reports in the literature and lack of prolonged efficacy, plasma therapy currently is used very sporadically in children with C3G and IC-MPGN. However, this therapy may be attempted, in the absence of response to immunosuppression, in rapidly progressive forms, particularly if defective FH is found.

Complement Inhibitors

The pathophysiology of C3G suggests therapeutic targeting of CAP dysregulation by complement inhibition. Based on the pathology of disease, anticomplement therapy warrants consideration. This could include (1) C3 convertase inhibition, which may have its greatest utility in

limiting C3 breakdown product deposition on (glomerular) basement membranes; (2) C5 or terminal complement pathway inhibition [47]. Currently, the only commercially available options are the anti-C5 monoclonal antibodies eculizumab and its long-lasting analogue ravulizumab.

Effectiveness of anti-C5 therapy in a mouse model of DDD (*Cfh* deficient mice) [111] provided the rationale and led to the use of a humanized anti-C5 monoclonal antibody (eculizumab) in patients with different forms of C3G [104, 105, 112–115].

Eculizumab is a humanized monoclonal antibody directed against C5, which blocks C5 cleavage, preventing the release of C5a, a potent anaphylatoxin, and C5b, the initial protein of the cytotoxic membrane attack complex (MAC; C5b-9). Its use is well established for aHUS, the classic model of renal disease mediated by the CAP. In C3G, following initial encouraging single case reports and small series, [104, 112, 113, 115] two more recent larger studies have provided disappointing results.

A retrospective French study [116] evaluated 26 patients, 13 of whom pediatric, with a median treatment duration of 14 months. In this study, 6 patients (23%) had a global clinical response, 6 (23%) had a partial clinical response and 14 (54%) no response. The only prospective study that has evaluated eculizumab in IC-MPGN and C3G, the EAGLE study [117] confirmed these negative findings. It evaluated 10 patients, (6 with MPGN, 4 with C3G), all with normal renal function, severe (>3500 mg/24 h) proteinuria and highly elevated sC5b9 (>1000 ng/ml), who were treated with eculizumab for 2 sequential 48-week periods separated by one 12-week washout period. Primary outcome was change in 24-h proteinuria at 24 and 48 weeks. While terminal complement pathway inhibition was achieved in all patients, only 3/10 patients obtained partial remission of proteinuria. During the first treatment period, median proteinuria, albuminemia and lipid profile improved, but these mild benefits were lost during the washout period and never regained in 7/10 patients. More recently, two patients with a mixed aHUS/C3G phenotype benefiting from treatment for eculizumab have been described, suggesting than in patients with an endothelial CAP dysregulation as is present in aHUS, eculizumab is most likely to be beneficial [118].

However, new complement-modulating agents are now in the pipeline. Avacopan, an oral anti-C5aR inhibitor which has proven safe and effective in ANCA-associated vasculitis [119], is currently being investigated in adults and adolescents with C3G and IC-MPGN. As shown in Table 23.6, other agents which target the complement cascade upstream, at the level of the C3 convertase, are also available and studies investigating their safety and efficacy in IC-MPGN and C3G are underway or planned in the near future.

A potential benefit of complement inhibition in the treatment of complement-mediated diseases needs to be balanced against the detrimental effect of complement inhibition in situations when complement activation is required as part of the immune defense of the host, and thorough clinical trials are required before the use of these novel substances in children can be recommended.

Given the heterogeneity of potential and described mechanisms leading to CAP dysregu-

Table 23.6 Complement targeting treatment in IC-MPGN and C3G

Drug	Target	Mechanism	Clinical trial number
ACH0144471	Factor D	Prevents formation of C3 and C5 convertases	NCT03369236, NCT03459443 and NCT03124368
LNP023	Factor B	Prevents formation of C3 and C5 convertases	NCT03832114, NCT03955445
APL2	C3	Prevents formation of C3 and C5 convertases	NCT03453619
AMY101	C3	Prevents formation of C3 and C5 convertases	NCT03316521
OMS721	MASP2	Blocks initiation of lectin pathway	NCT02682407
Avacopan	C5aR1	Blocks anaphylatoxin formation (C3a, C4a and/or C5a)	NCT03301467

lation, it is most likely that no single anti-complement treatment will be universally effective. Rather, patient-tailored therapies chosen on the basis of each patient's specific alteration are the optimal therapeutic strategy. Therefore, upon diagnosis of C3G, extensive and expert assessment of the CAP in each patient is of pivotal importance and this work-up is indispensable in designing future therapeutic trials.

Renoprotective Agents

About 80% of patients are placed on ARBs or ACEi, both first line agents used to improve renal dynamics, decrease proteinuria, control blood pressure and limit glomerular leukocyte infiltration [53]. This approach, coupled with low-sodium diet and lipid-lowering agents when appropriate is recommended for all children with IC-MPGN or C3G. It can be used as exclusive treatment in two cases:

1. Non-nephrotic proteinuria with or without microhematuria and normal renal function/absence of acute renal failure. Close follow-up is needed to assess progression of disease based on renal function, proteinuria, and urine microscopy. Target proteinuria should be below 200 mg/day in children, and additional treatment should be initiated if this target is not reached within a few weeks of optimal dosing of these agents.
2. Histological evidence of advanced chronicity of the renal lesions on the biopsy. Patients with advanced chronic kidney disease (CKD), severe tubulointerstitial fibrosis (TIF), small kidney size, or other findings consistent with chronic disease sequel should—in the absence of systemic disease manifestations—not be treated with immunosuppression [91].

Treatment of Recurrence Post-Renal Transplantation

There is no proven beneficial therapy for recurrent C3G in the renal allograft following transplantation. Therapeutic approaches are similar to those used in primary disease and are therefore not discussed in detail here. Reported treatment of *recurrent idiopathic MPGN* besides conservative medications like RAAS antagonists to control proteinuria and hypertension, includes antiplatelet/anticoagulant agents [120], corticosteroids [121], cyclosporin [122], cyclophosphamide [123], and plasmapheresis [121, 124]. Reported treatment of *recurrent DDD* includes dose reduction, discontinuation or switch (cyclosporin to tacrolimus) of the calcineurin inhibitors used as part of the posttransplant immunosuppression regimen, modification of the prednisone dose (increase; switch from daily to alternate-day), pulse methylprednisolone, or plasmapheresis/plasma exchange [78, 125]. More recently, the use of terminal complement inhibition with eculizumab has been evaluated in adults with C3G post-renal transplant recurrence, once again with variable outcomes [126, 127].

Summary

In summary, the therapeutic options in C3G depend on the level of proteinuria and kidney failure and on the results of the panel of diagnostic tests performed at diagnosis. In the vast majority of patients, the empiric use of ACEi or ARBs as drugs of first choice to treat hypertension and decrease proteinuria is a common practice, which may delay the progression of renal disease [90]. Plasma therapy or, in the future, purified FH may be useful in some cases in which there is clear evidence of a FH deficiency or of the presence of anti-FH autoantibodies. There is little evidence of the effectiveness of immunosuppression, which should therefore be employed only in cases where disease is very active and proliferative with intense inflammation in the renal biopsy and nephrotic-range proteinuria.

Preliminary results on the use of complement blockers such as eculizumab are encouraging in some but not in all patients.

Lastly, improvement in renal outcome for patients with C3G largely relies on the evaluation of more targeted agents in future studies [90].

The Kidney and Systemic Disease

Postinfectious Hemolytic Uremic Syndrome

24

Martin Bitzan and Anne-Laure Lapeyraque

Abbreviations

ADAMTS13	A disintegrin and metalloprotease with a thrombospondin type 1 motif, member 13
aHUS	Atypical hemolytic uremic syndrome
AKI	Acute kidney injury
AP(C)	Alternative pathway (of complement)
C3	Complement factor 3
C4	Complement factor 4
C5	Complement factor 5
CDC	Centers for Disease Control and Prevention
CFB	Complement factor B
CFH	Complement Factor H
CKD	Chronic kidney disease
CNS	Central nervous system
CRP	C-reactive protein
CRRT	Continuous renal replacement therapy
DIC	Disseminated intravascular coagulation
EAEC	Enteroaggregative *E. coli*
eGFR	Estimated glomerular filtration rate
EHEC	Enterohemorrhagic *Escherichia coli*
eHUS	Enteropathogen (or *Escherichia coli*) induced hemolytic uremic syndrome
ELISA	Enzyme-linked immunosorbent assay
EPEC	Enteropathogenic *Escherichia coli*
ER	Endoplasmic reticulum
ESKD	End stage kidney disease
Gb3	Globotriaosylceramide
Gb4	Globotetraosylceramide
Hb	Hemoglobin
HC	Hemorrhagic colitis
HD	Hemodialysis
HUS	Hemolytic uremic syndrome
IA	Immunoabsorption
iHUS	Influenza-induced hemolytic uremic syndrome
IPD	Invasive pneumococcal disease
LDH	Lactate dehydrogenase
LPS	Lipopolysaccharide
mAb	Monoclonal antibody
MAHA	Microangiopathic hemolytic anemia
NA	Neuraminidase
NanA	Neuraminidase A

NM	Non-motile
NSAID(s)	Non-steroidal anti-inflammatory drug(s)
OR	Odds ratio
PCR	Polymerase chain reaction
PD	Peritoneal dialysis
PE	Plasma exchange
PI	Plasma infusion
pnHUS	Pneumococcal (*Streptococcus pneumoniae*) hemolytic uremic syndrome
PRBC	Packed red blood cell(s)
RBC	Red blood cell(s)
RRT	Renal replacement therapy
SC5b-9	Serum (soluble complement factor) C5b to 9 complex (see TCC)
SD1	*Shigella dysenteriae* type 1
SLT	Shiga-like toxin
SMX/TMP	Sulfamethoxazole/trimethoprim
STEC	Shiga toxin producing *Escherichia coli*
STPB	Shiga toxin producing bacteria
Stx	Shiga toxin
TCC	Terminal complement complex
TF	Thomsen-Friedenreich (antigen)
TMA	Thrombotic microangiopathy
TTP	Thrombotic thrombocytopenic purpura
UTI	Urinary tract infection
VT	Vero(cyto)toxin
VTEC	Vero(cyto)toxin producing *Escherichia coli*

Introduction

For the purpose of this chapter, we define postinfectious hemolytic uremic syndrome (HUS) as HUS [1] caused by specific infectious organisms in patients with no identifiable HUS-associated genetic variants or autoantibodies. HUS can follow infections by Shiga toxin (Stx) producing bacteria, mainly *Escherichia coli* (STEC) and *Shigella dysenteriae* type 1, [2, 3] neuraminidase producing organisms, mainly *Streptococcus pneumoniae* and *Clostridium species* [4–7], influenza virus [8], SARS-CoV-2 [9] or HIV [10]. Biologically diverse mechanisms affecting vascular endothelial cells, platelets and red blood cells (RBCs) have been uncovered involving Stx, neuraminidase and potentially complement that mediate thrombotic microangiopathy (TMA) [11, 12]. TMA is characterized by the simultaneous appearance of intravascular hemolysis, thrombocytopenia and acute organ injury, most commonly acute kidney injury (AKI). TMA is an umbrella term of diverse forms of HUS and thrombotic thrombocytopenic purpura (TTP). The majority of HUS episodes in children can be linked to STEC infections, depending on the geographical latitude and agricultural systems. This contrasts with HUS caused by the dysregulation of the alternative pathway of complement associated with pathogenic variants and/or autoantibodies (mainly to complement factor H), or to other genetic and metabolic causes (Box 24.1). However, HUS can arise following infection by a "specific" agent in a patient with a primary complement disorder; the "atypical" nature of such HUS is uncovered by its clinical presentation (relapsing course, recurrence after transplantation or family history) and/or genetic screening.

Box 24.1: Classification of Thrombotic Microangiopathies (TMA): HUS and TTP

1. Infection-induced HUS (caused by endothelial injury due to specific infectious agents)
   - (a) Shiga toxin-producing bacteria
     - (i) Shiga toxin-producing *Escherichia coli* (STEC)
     - (ii) *Shigella dysenteriae* type 1
   - (b) Neuraminidase-producing bacteria
     - (i) *Streptococcus pneumoniae*
     - (ii) *Clostridium spp.*
   - (c) Influenza virus (A/H3N2, A/H1N1, B)
   - (d) Severe acute respiratory syndrome corona virus-2 (SARS-CoV-2)
   - (e) Human immunodeficiency virus (HIV)

2. Hereditary/genetic forms of HUS
   (a) Mutations of regulatory proteins and components of complement and coagulation pathways (soluble and membrane-bound, usually heterozygous)
   (b) Genetic abnormalities without known complement dysregulation, usually autosomal recessive (examples: methylmalonic aciduria and homocystinuria, cblC type; diacylglycerol kinase-ε)
3. Autoimmune HUS
   (a) Autoantibodies against complement regulatory proteins (example: anti-CFH antibody)
4. Thrombotic thrombocytopenic purpura (TTP)
   (a) Hereditary TTP (Upshaw Shulman Syndrome)
   (b) Autoimmune TTP (anti-ADAMS13 antibody)
5. Other forms
   (a) Endotheliotoxic therapeutics (examples: cancer drugs, anti-VEGF antibody)
   (b) NYED (not yet etiologically defined)
6. Secondary forms
   (a) SLE, anti-phospholipid syndrome, bone marrow transplantation etc.

The historical terms diarrhea-positive (D^+) and diarrhea-negative (D^-) HUS, introduced to distinguish STEC-induced HUS from "atypical" forms, have become obsolete. At least 1/3 of patients with complement-mediated "atypical" HUS present with diarrhea or even colitis [13, 14]. The D^+/D^- dichotomy also failed to differentiate postinfectious forms, such as *S. pneumoniae* HUS (pnHUS), from "atypical" HUS. An etiology-based classification and diagnosis, where possible, is essential for patient management [15].

Finally, there is emerging evidence of transient complement activation in postinfectious forms of HUS in the absence of a demonstrable genetic defect or anti-CFH autoantibodies. The precise mechanism of complement activation and its pathological significance are presently under investigation. With the evolving understanding of the complement system and of the pathogenesis of different forms of HUS, some of the descriptions and assumptions in this chapter will have to be revised in the future [8, 11, 16–19].

Shiga Toxin-Producing *Escherichia coli* HUS

History of HUS and Definitions

The term "hemolytic uremic syndrome" was first used in 1955 by the Swiss hematologist Conrad von Gasser, who described five children presenting with the triad of acute hemolytic anemia, thrombocytopenia and kidney failure [1]. It was not until 1983 when Mohamed Karmali and his group identified vero(cyto)toxin producing *Escherichia coli* as the as the cause of typical childhood HUS [2, 20]. In the same year, Allison O'Brien recognized that a toxin, produced by a newly described *E. coli* O157:H7 serovar, bore close similarity with *Shigella dysenteriae* type 1 (Shiga). Soon it became clear that verotoxin and Shiga-like toxin belong to a family of closely related bacterial protein exotoxins, subsequently name Shiga toxins (Stx), with the major subdivision Stx1 and Stx2 (and several related variants) [21]. We will use the terms STEC-HUS to describe patients with "typical" HUS, the predominant form of pediatric HUS in many countries [22].

More than 200 *E coli* serotypes have been described carrying Stx phage(s) and producing Stx, but only a limited number has been associated with human disease [23]. Shiga toxin-producing bacteria encompass STEC and *S. dysenteriae* type 1, and the occasional *Citrobacter freundii* isolates capable of Stx production [24–26].

While *E. coli* O157:H7 is responsible for the majority of sporadic hemorrhagic colitis (HC) and HUS cases and outbreaks worldwide, non-O157:H7 STEC serotypes, including *E. coli*

O111:H11/NM and O26:H11/NM have also been implicated in severe human disease [27–29]. The large-scale *E. coli* O104:H4 outbreak in Germany in 2011 [30, 31] with >850 mostly adult victims of HUS and 50 deaths represents a unique scenario where an enteroaggregative *E. coli* incorporated an *stx2* phage; this novel strain contaminated sprouts, that are usually eaten raw [31, 32].

Epidemiology of STEC Infections and STEC-HUS

The annual incidence of sporadic STEC HUS is 1–1.5 per 100,000 pediatric population (median age 2.7 years) [33, 34]. The vast majority of patients is diagnosed during the warm season. The primary reservoir is cattle and cattle manure. STEC O157:H7 can survive for months or years and multiply at low rates even under adverse conditions.

Outbreaks of STEC infections and HUS in the early 1990s were linked to the consumption of STEC O157:H7-contaminated ground beef [35, 36]. They caused widespread media attention and expensive lawsuits, and eventually resulted in improved hygiene in slaughterhouses and warnings against the consumption of undercooked meat. Consequently, the role of processed meat as the predominant outbreak vehicle diminished, and more recent epidemics were due to contaminated well water [37], aquaculture spillover [38], or agricultural produce [31, 39–42].

Non-O157:H7 STEC serotypes have been increasingly recognized as a cause of sporadic and epidemic infections and HUS. Isolation frequencies of non-O157:H7 STEC strains belonging to more than 50 *E. coli* serogroups approach or exceed those of *E. coli* O157:H7 strains in North America, Europe and elsewhere [43–47]. Transmission occurs in about equal proportions through food and person-to-person spread [48–51].

The HUS risk following STEC infection varies substantially between STEC serotypes: in pediatric populations it is between 8 and 15% for O157:H7 [52, 53], and about ten-fold lower for most non-O157:H7 serotypes [45, 54], with some notable exceptions [28, 55–59]. The global burden of STEC infections is about 2.8 million annually leading to 3890 cases of HUS, 270 cases of end-stage kidney disease (ESKD), and 230 deaths [22]. Table 24.1 summarizes large or clinically significant outbreaks of STEC infections highlighting the spectrum of involved STEC serotypes and toxins, the vehicle of transmission and calculated HUS risks.

Pathogenesis of STEC Disease and HUS

STEC display a sophisticated machinery involving bacterial and host proteins, high contagiosity and resistance to environmental factors. The central pathogenic factor leading to HC and HUS is the ability to produce Stx and to deliver it into the blood stream. STEC are not tissue invasive, and bacteremia is not a feature of STEC diarrhea or HUS.

Ingested STEC bind to epithelial cells in the terminal ileum and Payer's patches. Bacterial interaction with host cells elicits signals that enhance bacterial colonization and release of bacterium-derived pathogenic factors including lipopolysaccharide (LPS) and Stx. Tight adherence of STEC to gut epithelium facilitates toxin translocation into local microvasculature and systemic circulation without killing the epithelial cell [60, 61] (Fig. 24.1). STEC and free fecal toxin excretion often diminish when HUS becomes manifest [53, 62–64]. The concentration of measurable, circulating toxin is extremely low. This can be attributed to its avid binding to endothelial cells and transport in shed microvesicles [65, 66]. Of note, evidence of coagulation system activation and intravascular fibrin deposition can be demonstrated well before, or even in the absence of the clinical manifestation of HUS [67, 68].

Table 24.1 STEC-HUS outbreaks and epidemics

Location [year]	Vehicle	Outbreak strain (Stx type)	Cases (hospitalized)	HUS	HUS risk	Mortality	Reference
Upper Bavaria, (Germany) [Sept–Nov 1988]	?	*E. coli* O157:NM (*stx2*)	6	6 (4–17 months; dialysis 6)	100%	0/6	[362]

Shiga Toxin and Its Glycolipid Receptor

Shiga toxins consist of an enzymatically active 32.2 kDa A subunit and a receptor-binding B subunit, composed of 5 identical 7.7 kDa proteins (Fig. 24.2). The B subunit interacts with the terminal sugars of the glycolipid receptor, globotriaosylceramide (Gb3) [69]. Gb3 is identical with CD77 and the P^k blood group antigen [70–73] (Fig. 24.3). Although Stx1 and Stx2 display subtle differences in their affinity to Gb3, this does not readily explain why the vast majority of STEC-HUS cases are linked to Stx2 producing strains compared with Stx1 producers [74, 75].

Gb3 is the only functional receptor for Stx1 and most Stx2. Gb3 synthase knockout mice are resistant to the toxic actions of Stx [76]. Gb3 is found on microvascular endothelial cells (including glomerular and peritubular capillary endothelium), glomerular epithelial cells (podocytes), platelets and germinal center B-lymphocytes [77], and peripheral and central neurons [78, 79]. Cellular toxicity requires efficient transport of Stx to the endoplasmic reticulum and subsequent ribosomal RNA (rRNA) depurination [69, 80] (Fig. 24.4). Very few molecules are needed to paralyze the cell, making it one of the most potent known toxins. The action of Stx on the ribosome induces a ribotoxic stress response characterized by the activation of the MAP kinase pathway and apoptotic cell death [81, 82]. Evidence of apoptosis in kidney and other tissues has been demonstrated *ex vivo* in kidney biopsies from patients with STEC-HUS and in animal models of STEC infection [83–85].

Injured microvascular endothelial cells become prothrombotic. The mechanism(s) leading to intravascular hemolysis and acute thrombocytopenia are less well understood. Stx interacts with blood and plasma components and induces shedding of platelet and monocyte microparticles loaded with tissue factor and complement [86, 87] (Fig. 24.5). Biologically active microparticles and (direct) Stx-induced apoptosis of endothelial cells, including the externalization of plasma membrane phosphatidylserine [88], may provide a mechanism how microvascular thrombosis is initiated [89]. The molecular and human cellular biology of Shiga toxins has been summarized in excellent review articles [65, 90, 91].

Laboratory Diagnosis of STEC Infections

Tests must be sensitive, specific and easily accessible. Rapid microbiological diagnosis of STEC diarrhea is essential [92] and can be aided by PCR tests. The clinician should provide the labo-

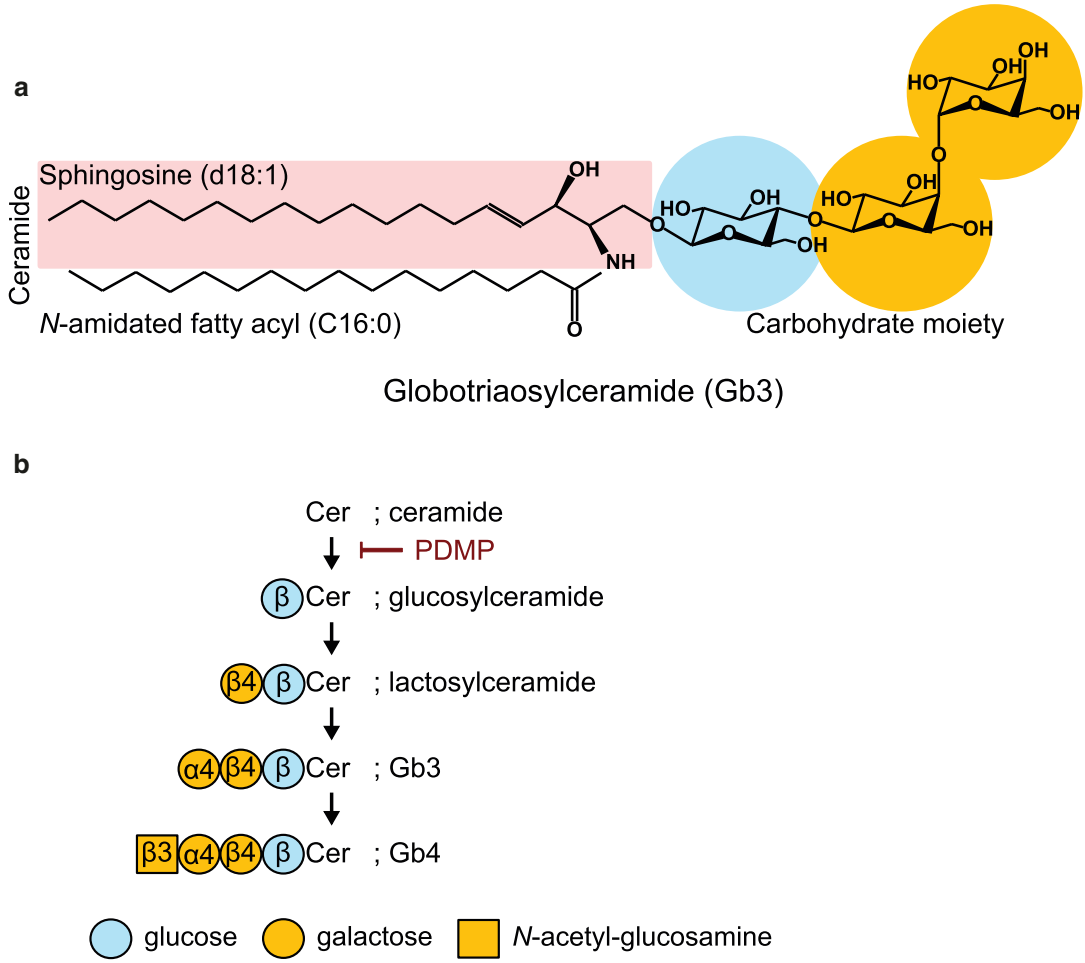

Fig. 24.3 (**a**) Structure of the Shiga toxin receptor Gb3. Glucose and galactose of the carbohydrate moiety are shown in *blue* and *yellow*, respectively. The ceramide moiety consists of a sphingosine backbone (in *pink*) and a variable fatty acid chain. ratory with meaningful clinical information, including the presence of painful or bloody diarrhea, or signs of HUS, and if there is a suspected outbreak. If the stool culture of an index patient is STEC negative, the pathogen may be identified in other family members [93].

An etiological diagnosis is important. It separates STEC-HUS from other HUS forms and impacts on acute treatment decisions and long-term follow-up [15, 94]. STEC detection has implications for close contacts, care facilities, restaurants/kitchens and the food industry. STEC infections are notifiable and require isolation measures to curb further transmission during an epidemic [95, 96]. In the bigger picture, bacterial isolation allows monitoring of epidemiological changes, such as the emergence of new strains and virulence traits.

Current recommendations stipulate that stools be plated simultaneously on an *E. coli* O157:H7 selective agar (or alternative bacteriological methods) and tested for the presence of Stx using a fresh stool suspension or overnight broth culture [97, 98]. Stx immunoassays or multiplex PCR

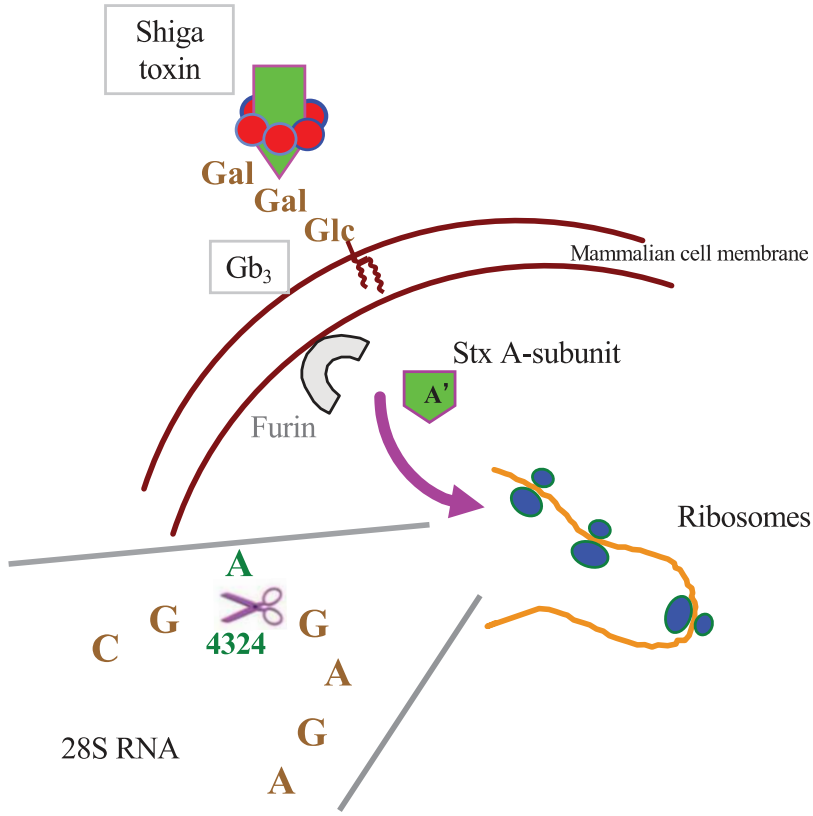

Fig. 24.4 Schematic diagram of the biological action of Stx in susceptible mammalian cells. The holotoxin binds to lipid raft-associated membrane globotriaosyl ceramide (Gb3) and enters the cell via clathrin-mediated endocytosis. A and B subunits become disengaged and the A subunit is cleaved and activated by intracellular furin. Upon "retrograde" passage through the Golgi apparatus, the A′ subunit selectively removes a specific adenine residue from the 28S RNA of the large ribosomal subunit (N-glycosidase activity). This results in (1) blockade of active (translating) ribosomes (translational inhibition), and (2) a ribotoxic cellular stress response with activation of c-jun and p38 (MAP) kinases and/or apoptotic cell death. (Used with permission of author and Elsevier from Loirat et al. [286])

alone are not sufficient for clinical samples [99]. Cell culture-based assays, although highly sensitive and specific, are not routinely performed.

Before the use of Shiga toxin assays and PCR, the isolation of non-O157:H7 STEC strains among commensal gut flora by traditional microbiological techniques was laborious, which contributed to the delayed appreciation of non-O157:H7 STEC clones as a cause of enterocolitis and HUS.

The yield of the stool diagnostic diminishes when the sample is delayed beyond 4 days after diarrhea onset [53, 63]. If stool culture or toxin assay(s) are negative, serological assays can be employed to search for elevated (or rising) IgM class antibodies to one of the more common STEC O-groups (LPS antigens) [62, 100–102]. Saliva IgA and IgM provide an alternative to serum antibodies [102, 103]. However, serodiagnostic assays are only offered in a few laboratories. Testing for Stx-specific antibodies has been used as an epidemiological tool [104, 105], but its clinical utility is limited [106].

From Colitis to HUS

The spectrum of STEC disease ranges from mild diarrhea and HC to severe HUS, and death [41, 53, 107]. The diarrhea is typically painful and

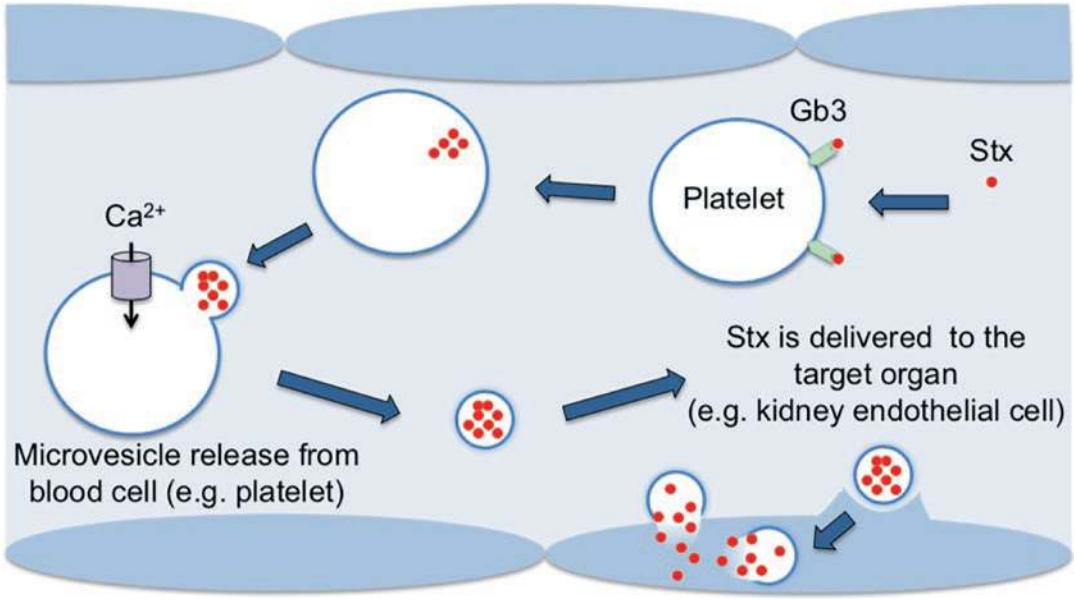

Fig. 24.5 Pathophysiological model incorporating the postulated role of microvesicles in the transfer of Shiga toxin (Stx) to target endothelium. Once in the bloodstream, Stx binds to platelets, neutrophils and red blood cells (RBC) via the toxin receptor, globotriaosylceramide (Gb3). The toxin is internalized and the activated blood cell releases microvesicles into the circulation containing the toxin. Upon reaching the target organ the microvesicles are taken up by microvascular endothelial cells, where Stx is released. In the kidney, this has been shown to occur within glomerular and peritubular capillary endothelial cells. (Used with permission from Karpman et al. [11])

frequent, with >15 small, soft or liquid stools that turn bloody by day 2 or 3 in >80% of children with STEC O157:H7 infection. The amount of visible blood varies from a few specks to frank hemorrhage. About 50% of patients develop nausea and vomiting; low-grade fever is present in one third [32, 53, 67, 92, 107]. Infections by non-O157:H7 STEC serotypes are generally milder [32, 108]. Exceptions are infections by STEC clones belonging to serogroups O26, O55, O91, O111, among others, that can be clinically indiscernible from those by classical *E. coli* O157:H7 [28, 55, 57, 109–115].

The HUS risk is greatest at the extremes of age, in children <5 years and the elderly; it decreases during childhood and adolescence, and is <0.1% in young and middle-aged adults [53, 116, 117]. Conversely, STEC colitis can lead to AKI and death without HUS, particularly in the elderly [116, 118]. Other variables impacting on the HUS risk are the STEC serotype or clone, the toxin type(s) produced, and preexisting immunity [105].

HUS starts abruptly, about 3–10 days (median 6 days) after the onset of diarrhea [53] (Fig. 24.6). Patients present from one day to the other with fatigue and pallor, become listless and may develop petechiae, often after transient clinical improvement of the colitis. Absent bowel movements during the acute phase of HUS should raise the suspicion of intussusception or ileus.

The clinical diagnosis of HUS is generally straightforward, based on the defining triad of intravascular hemolysis, thrombocytopenia and AKI. Hemolytic anemia of HUS—characterized by RBC fragmentation with schistocytes in the peripheral blood smear, with or without thrombocytopenia—is a microangiopathic hemolytic anemia (MAHA). With disease progression, serum creatinine levels rise and oligoanuria, hypertension and edema may appear, usually within 1–2 days of first HUS-related symptoms. Some patients may recover before the full picture of HUS develops. They may only demonstrate hemolytic anemia without apparent AKI, while

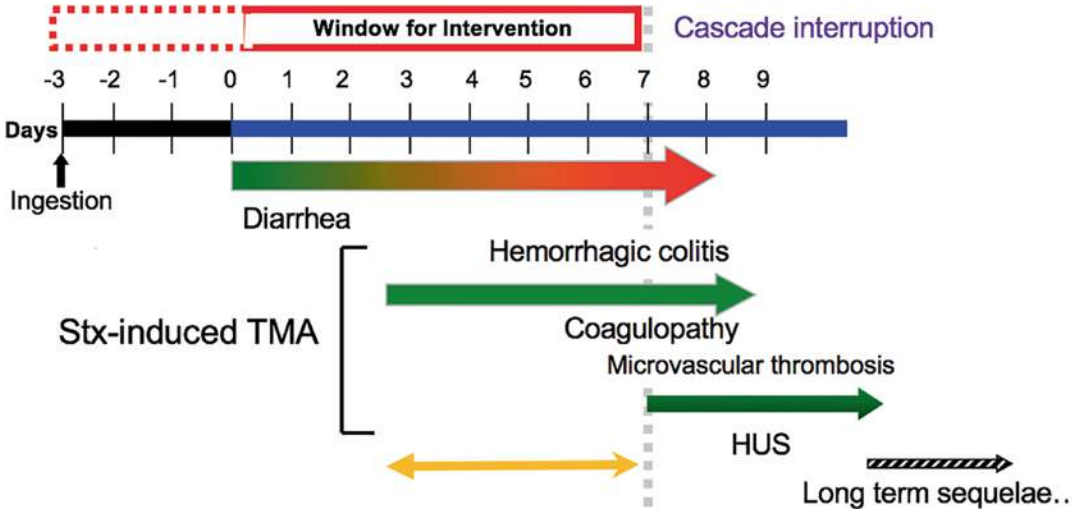

Fig. 24.6 Schematic diagram of the development of Shiga toxin-producing *E. coli* (STEC) colitis and HUS and possible window of therapeutic intervention

platelets may briefly dip within or slightly below the reference range ("partial HUS") [52, 119].

A predictive biological marker of impending HUS is the degree of systemic inflammation during the preceding colitis, particularly neutrophilia with a high-percentage shift to band forms, and a sharp rise of acute phase reactants, such as C-reactive protein or procalcitonin [41, 120–124]. Patients who progress to HUS more often have a peripheral neutrophil count above 20×10^9/L than patients without HUS [122, 125–127].

Hematologic Manifestations of STEC-HUS

Commonly, the hemoglobin level drops precipitously to <80 g/L in STEC-HUS. Hemolysis is accompanied by a rapid fall of platelet numbers, usually <50, at times $<30 \times 10^9$/L. Direct antiglobulin (Coombs) test is negative. Rising indirect bilirubin, free plasma hemoglobin and serum lactate dehydrogenase (LDH), the latter often more than five times the upper limit of normal, and haptoglobin depletion are consistent with rapid (intravascular) hemolysis. The peripheral WBC (neutrophil) count, already increased during the colitis phase, may continue to rise and, if associated with a leukemoid reaction, can herald a severe course with poor intestinal or kidney outcomes [33, 128, 129]. The severity of anemia and thrombocytopenia does not correlate with the degree of acute or chronic kidney injury.

Some authors noted an inverse relationship between Hb and disease severity [129–131]. A plausible explanation for the latter observation is the hemo concentration seen in patients with intravascular volume depletion during the first 4 days of STEC colitis [129, 132]. The recognition that hemo concentration increases the HUS risk in children with STEC diarrhea led to the development of an "HUS risk score." It is considered "high," where the sum of the concentrations of Hb plus 2x creatinine (in g/dL and mg/dL, respectively) exceeds a value of 13 [131]. The correlation between a high risk score and severe HUS/poor outcome was independently confirmed [133, 134], yet its clinical utility remains to be seen.

Thrombocytopenia and hemolysis usually resolve within 2 weeks. A rising platelet count heralds the cessation of HUS activity; platelets may transiently rebound to $>500 \times 10^9$/L. Anemia can persist for weeks after disease recovery without signs of active hemolysis.

AKI in STEC-HUS

Kidney injury in STEC-HUS ranges from microscopic hematuria and proteinuria to severe kidney failure and oligoanuria. Up to 50% of children with STEC-HUS will need acute dialysis [33, 34, 135, 136]. Arterial hypertension is common in the acute phase of HUS and may not be due to volume overload. Blood pressure instability and hypotension are not a typical feature of STEC-HUS and should raise the suspicion of sepsis. Time to recovery of kidney function ranges from a few days to weeks or even months. The risk of long-term kidney impairment (CKD, chronic hypertension, proteinuria) increases with the duration of oliguria (dialysis). A commonly cited threshold for the risk of diminished kidney recovery is anuria lasting >2–3 weeks [137, 138]. Primary ESKD is rare and should prompt investigations into a non postinfectious form of HUS [139].

Extrarenal Manifestations

There is hardly an organ system that may not be affected in STEC infection or STEC-HUS. Rare, but important extrarenal and extraintestinal manifestations are myocarditis and congestive heart failure, cardiac tamponade, pulmonary hemorrhage, pancreatitis, hepatic injury, and central nervous system (CNS) complications [140–143]. Patients with multiple organ involvement generally also have severe kidney failure and often poor outcome [141, 142, 144]. Postulated mechanisms underlying organ injury in STEC-HUS are Stx load and direct tissue toxicity, and ischemic injury [141], as evidenced by histological and autopsy findings.

Rectal prolapse and intussusception may result in transmural bowel necrosis with perforation and peritonitis [145–147]. Serum amylase and lipase activities, indicative of exocrine pancreas injury, are elevated in up to 20% of patients [145]. Transient glucose intolerance or, albeit rare, chronic insulin-dependent diabetes mellitus has been reported [146, 148–150]. Hepatomegaly and/or rising serum alanine amino transferase (ALT) are noted in up to 40% of cases. Acute myocardial insufficiency occurs in less than 1% of cases [141, 151–153]. Skeletal muscle involvement is exceedingly rare and may manifest as rhabdomyolysis [143].

Three to >41% of patients experience CNS manifestations [124, 143, 154–157]. Signs and symptoms can be vague and nonspecific and are probably underappreciated. Patients may present with irritability, lethargy or decreased level of consciousness. Brief seizures are relatively common and may reflect fluid and electrolyte imbalances and inadequate volume replacement [158]. Abnormal electroencephalograms have been reported in up to 50% of patients with HUS. Prolonged seizure activity, usually associated with acute respiratory deterioration, is an ominous sign and may indicate cerebral stroke or hemorrhage. Acute, transient or persistent isolated palsy, dysphasia, diplopia, retinal injury and cortical blindness have been noted [142, 143, 155]. Severe neurological events are associated with poor prognosis and even death [142].

Magnetic resonance imaging (MRI) of the brain is helpful in the differentiation of structural from ischemic or transient injury. In the acute phase, basal ganglia and white matter abnormalities with apparent diffusion coefficient restriction are common and reversible MRI findings [159–164] (Fig. 24.7). However, the described changes do not appear to be specific for STEC-HUS [164]. CNS lesions may be compounded by the occurrence of posterior reversible encephalopathy syndrome or hemodialysis-associated disequilibrium [164]. Peripheral nervous system involvement has been described, but pathogenesis and medical treatment of this rare complication remain unclear [165].

The *E. coli* O104:H4 HUS outbreak in Europe highlighted the occurrence of psychiatric symptoms [166, 167]. Described manifestations include cognitive impairment [168] and, in a few cases, hallucinations and affective disorders, such as severe panic attacks [166].

Histopathology of STEC-HUS

Few pathological descriptions are available from kidney biopsies of patients with acute STEC-HUS [85, 169–173]. Macroscopically, the kidneys appear swollen, with numerous petechial

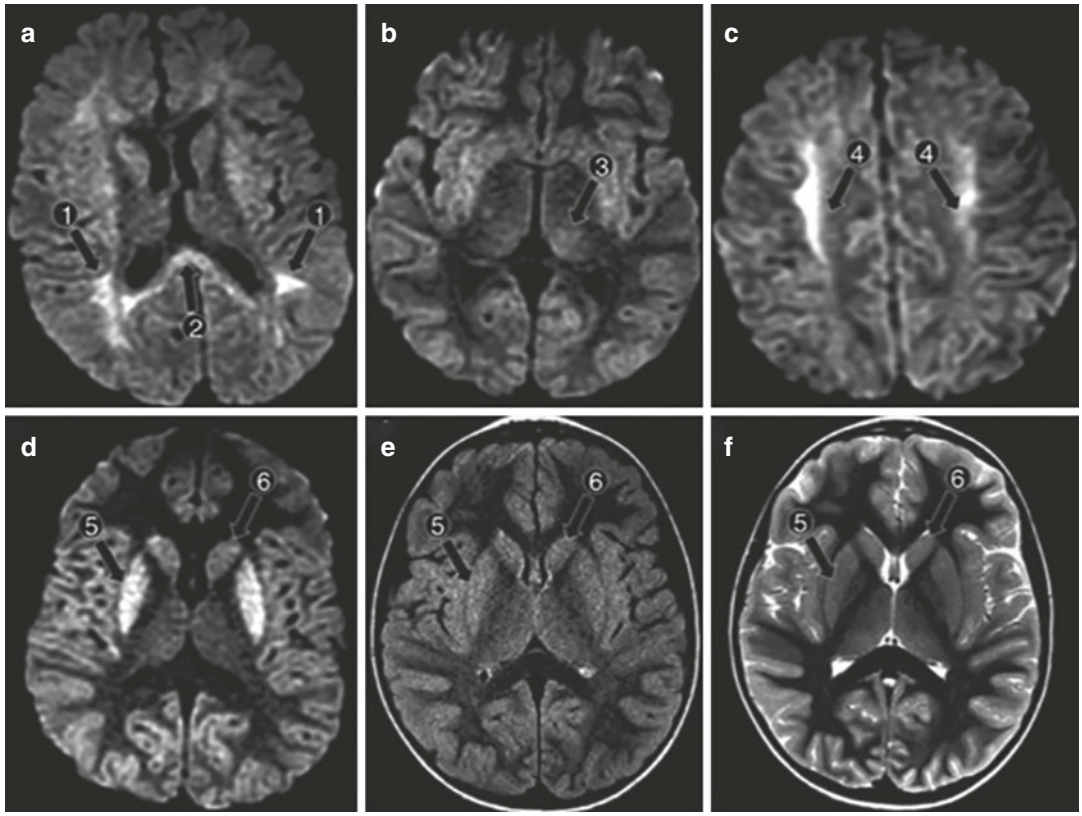

Fig. 24.7 Brain magnetic resonance imaging of patients with STEC-HUS acquired within the first 24 h after the onset of neurological symptoms. (**a–d**) Diffusion-weighted images (DWI) which demonstrate (*1*) hypersignal involving deep white matter; (*2*) corpus callosum; (*3*) thalamus, (*4*) centrum semiovale; (*5*) putamen; and (*6*) caudate nucleus. (**d–f**) Brain MRI of one of the two patients who died. T2- and FLAIR-weighted images of all the surviving patients were normal (not shown). (Used with permission of John Wiley and Sons from Gitiaux et al. [164])

hemorrhages on the external surface; on section, the cortex will show areas of hemorrhage and infarction. Focal hemorrhage has also been noted in the collecting system and ureter (Chantal Bernard, unpublished communication). Prominent *light microscopic* features are the presence of fragmented RBC in *glomerular* capillary loops. Glomerular capillary and renal arteriolar microvascular thrombosis may demonstrate prominent fibrin staining. Endothelial and mesangial cell changes are also evident by *electron microscopy* (Fig. 24.8). *Immunofluorescence* is variably positive for fibrin. Immune deposits are not a feature of STEC-HUS. While glomerular histological changes dominate, the *tubulointerstitial compartment* can also be affected. In fact, all biopsies from a series of patients examined during the 2011 German HUS outbreak, including those without evidence of glomerular TMA, showed severe acute tubular injury [173].

Post-mortem studies of children with STEC-HUS [169, 170, 174] demonstrated that STEC-HUS is a systemic microangiopathy characterized by ubiquitous endothelial cell swelling and injury. There was diffuse hemorrhage with mucosal ulcerations and hemorrhage of the bowel wall as well as congestion of the serosa and extensive vascular thrombosis. The pancreas appeared enlarged and swollen, with areas of necrosis and hemorrhage (Chantal Bernard, unpublished

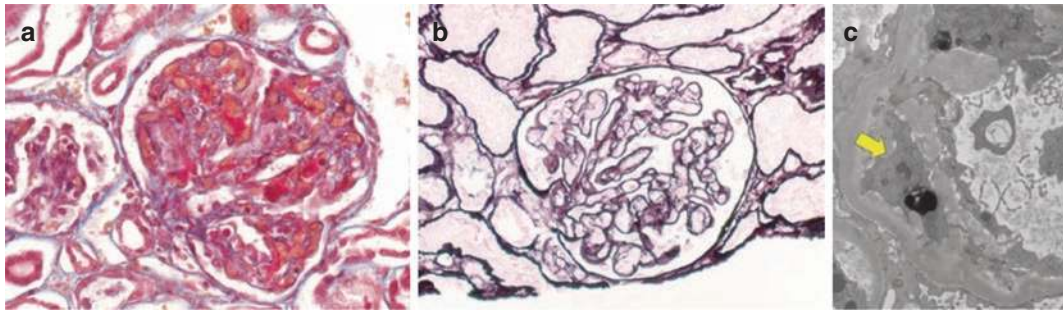

Fig. 24.8 Kidney biopsy, culture-proven STEC-HUS. (**a**) Trichrome stain of glomerulus showing fibrin and RBCs (*orange* and *red*, respectively). (**b**) Silver stain, emphasizing glomerular and tubular basement membrane structures. observations). CNS changes consisted of brain swelling and bilateral, symmetric necrotic lesions, mainly of the corpus striatum, and scattered necrotic lesions in the cortex and elsewhere [175].

Prevention and Treatment of STEC Disease

Preventive strategies focus on the implementation of hygienic measures. This applies to cattle farming, the management of drinking water and agricultural produce, safe practices of food preparation and consumption, and containment of the spread of the organism when cases are identified [95, 96, 176–178]. The risk of transmission is reduced by adherence to essential hygienic measures: frequent hand washing and avoiding touching the face [177, 179]. Children with proven STEC infection should only return to childcare or school 48 h after the cessation of diarrhea. Preventive measures and advice for patients and caregivers can be found in various publications [176, 177, 179].

Vaccines

Active immunization of humans, targeting the O157 LPS antigen [180, 181] and/or Stx and other bacterial antigens remains an elusive goal [182, 183]. Progress has been reported, however, in the vaccination of cattle [183, 184].

Therapeutic Interventions During STEC Colitis

Considerable work has been invested to better understand factors that facilitate the progression from colitis to HUS and to intervene at a stage where the process can be reversed, and HUS prevented or at least mitigated. Potential strategies are the elimination of STEC (or Stx) from the gut and toxin neutralization in the circulation [185–187]. None of these approaches have shown convincing results [188]. Randomized, controlled HUS prevention trials in a conventional format are extremely challenging due to the low incidence of STEC infections and the overall low risk of progression to HUS [187, 189–191].

Fluid Therapy

Volume expansion with isotonic saline administered intravenously during early STEC colitis may ameliorate the severity of HUS. In a retrospective cohort study of children with *E. coli* O157:H7 HUS [132], patients who became oligoanuric and needed dialysis had received significantly less intravenous fluid during the first 4 days of diarrhea than children who had preserved urine output and who were not dialyzed. The authors concluded that early parenteral volume expansion before the onset of HUS attenuates AKI and reduces the need for dialysis. Subsequent studies reproduced the initial findings [130, 190, 192, 193]. The “volume hypoth-

esis" is further supported by observations linking higher Hb concentrations at presentation—as a surrogate marker of volume depletion—to severe HUS, including neurological complications [75, 131, 134, 154, 193].

The administration of isotonic solutions is not expected to affect Stx production or tissue binding, but is intended to alleviate incipient acute tubular necrosis and AKI [132, 194]. Saline infusion may also mitigate abdominal cramps caused by STEC induced ischemic colitis [193, 195]. Considering HUS rates of 8–15% in an "under 5" target population, the number needed to treat to prevent one case of HUS is about 7–12.

For practical purposes, rapid confirmation of STEC infection, mainly by PCR (ideally with a multiplex platform that allows testing for *stx1* and *stx2*, and various pathogenic bacteria and viruses in the same stool sample) and easy-to-follow protocols targeting children with bloody and non-bloody diarrhea are needed. Including non-bloody diarrhea cases is relevant, since up to 57% of STEC-HUS patients lack a history of bloody diarrhea or colitis [75, 196].

Figure 24.9 shows an abbreviated, practical algorithm to estimate the individual child's risk of HUS and initiate treatment as soon as STEC colitis is diagnosed or suspected. The risk of fluid overload and cardiopulmonary complications due to saline infusion is negligible, provided the patient is hospitalized and supervised by an experienced team [190]. Hospital admission simplifies patient monitoring. It may also mitigate parental anxiety and reduce the spread of the potentially dangerous organisms [95, 96].

Analgesia

When volume expansion with isotonic saline fails to alleviate the ischemic colitis pain, pharmacological therapy may be warranted. Acetaminophen can be tried. Morphine may be administered sparingly, although it tends to worsen post-colitis constipation or ileus. Non-steroidal anti-inflammatory analgesic drugs

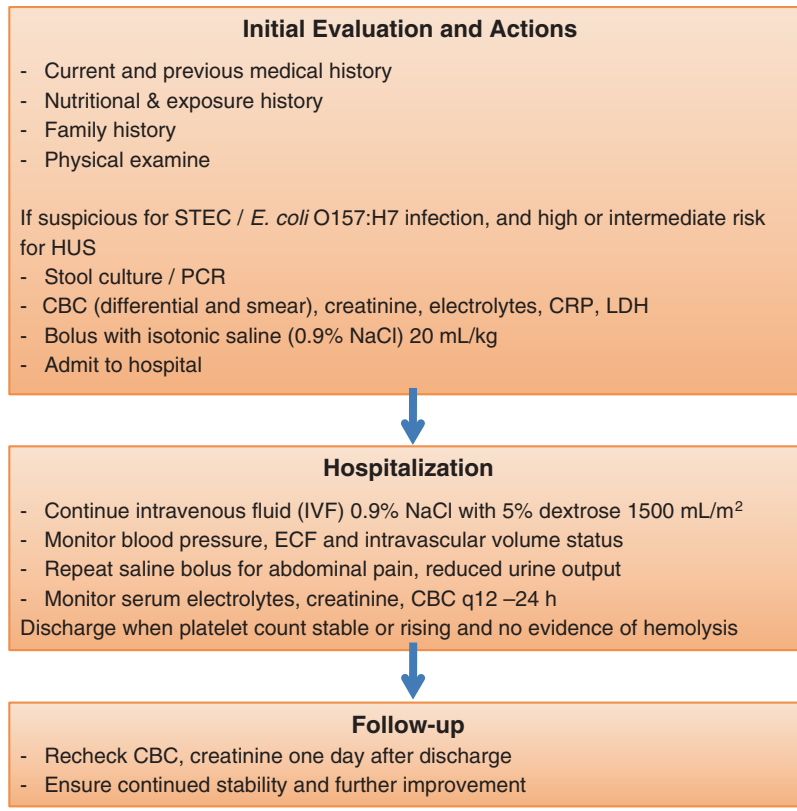

Fig. 24.9 Initial evaluation, monitoring and intervention for STEC infection. Risk of Stx HUS: Age group (>6 months) and diarrhea <4 to 7 days that is frequent, turned bloody after 2–3 days and/or is associated with abdominal cramps; recent or current hemorrhagic colitis or HUS in family or community. Rapid PCR (stool or rectal swab) or antigen assay, and culture for STEC (at least *E. coli* O157:H7), *Campylobacter*, *Salmonella*, *Shigella*, *Yersinia spp*. (Used with permission of AGA Institute from Holtz et al. [92], with modifications)

(NSAIDs) should not be used in patients with STEC colitis or HUS who may be intravascularly volume depleted and at risk of ischemic injury of the gut and kidneys.

Anti-Motility Drugs and Antibiotics

Antidiarrheal and antimotility agents have been associated with an increased risk of HUS and should therefore be avoided [32, 126, 154, 197–199]. The observed link between antimicrobial therapy and an increased HUS risk or fatal outcome is supported by experimental studies demonstrating that certain antibiotics stimulate Stx phage induction and toxin production [200–202]. However, the risk of HUS differs according to the class of the antibiotic and the timing of its administration [203, 204]. Evidence is emerging that rifaximin, azithromycin or fosfomycin may limit the spread of the organism and reduce the rate of complications during STEC epidemics [203–207].

Therapeutic Intervention During STEC-HUS

Symptomatic treatment of HUS follows general principles established for patients with AKI, but with specific recommendations related to the often profound hemolysis and thrombocytopenia. All patients need careful monitoring of vital signs, fluid balance and cardiac, respiratory, metabolic and neurological status. Treatment focuses on the normalization of intravascular volume status, acid-base balance, serum electrolytes, glucose and uric acid. As with other critically ill children, providing appropriate nutrition is part of the treatment. Early transfer to an experienced pediatric center is recommended, where extracorporeal purification techniques and a critical care environment can be provided 24/7. Most patients with HUS receive packed red blood cells (PRBCs) [135]. The threshold for PRBC infusions is clinically defined: symptoms (tachycardia and tachypnea) and the velocity of intravascular RBC destruction as gauged by LDH and free Hb levels in plasma. A practical cut-off is a Hb of 60 g/L. 12–15 mL of PRBC per kg body weight can be transfused over 2–4 h. A loop diuretic can be given in case of fluid overload or hyperkalemia and (some) preserved urine output. If necessary, PRBC transfusions can be timed to coincide with dialysis sessions, particularly if hyperkalemia or volume overload are a concern. RBCs should be leucocyte and platelet depleted, as practiced in most pediatric hospitals. Peritoneal and central venous catheters can be placed safely in most children with HUS without a need for platelet transfusion [208].

AKI Management in STEC-HUS

Assessment of intravascular volume status helps guide initial treatment toward fluid replacement or restriction, and administration of diuretics or dialysis. Patients are monitored for fluid intake and changes in urine output, along with frequent measurements of blood pressure (BP) and heart rate. Weight changes correlate poorly with effective circulatory volume. Intravascular volume may be decreased due to intestinal losses and reduced oral intake during the early phase of the disease and may result in hypoperfusion of the kidneys. Third spacing, especially in the gut, and generalized edema—due to endothelial injury and capillary leak—may mask intravascular depletion and, if not corrected, worsen ischemic injury. Patients warrant diligent intravascular volume expansion to improve organ perfusion, particularly of the gut, kidneys and brain.

Fluid restriction may be necessary in patients with fluid overload secondary to oliguric kidney failure. If intravascular volume is replete, a trial with furosemide at a dose of 1–2 mg/kg may be attempted to induce diuresis and delay dialysis, particularly in patients with hyperkalemia or cardiopulmonary compromise. Aggressive challenge with high-dose loop diuretics, advocated in the past to prevent progression to oligoanuric failure and avoid dialysis [209] should be avoided.

Antihypertensive Therapy

Arterial hypertension is common in STEC-HUS. It may be caused by renal microvascular thrombosis, direct vascular endothelial cell injury or activation, and intravascular fluid overload. Systemic hypertension can lead to CNS complications, such as PRES. It is reasonable to use dihydropyridine calcium channel blockers (nifedipine, amlodipine or PO/IV nicardipine).

Treatment with renin-angiotensin system (RAS) blockers has to be balanced against concerns over impairment of kidney perfusion and hyperkalemia. However, RAS inhibition is a rationale choice for the long-term treatment of patients with HUS-induced CKD and/or chronic hypertension or proteinuria [210, 211].

Kidney Replacement Therapy

There is no evidence that early dialysis changes the evolution of acute STEC-HUS or long-term outcome. However, delaying dialysis unduly increases the risk of complications. The North American Synsorb Pk® trial protocol mandated that dialysis not be started until 72 h post diagnosis of HUS, if clinically acceptable by the responsible physician. Under these restrictive conditions, 39% of the 49 placebo-treated patients were dialyzed for a mean of 3.6 days [135]. Indications for dialysis initiation in HUS are similar to those for other causes of AKI and may evolve rapidly: severe electrolyte imbalance (hyperkalemia, hyperphosphatemia), acidosis or fluid overload refractory to medical/diuretic therapy, or symptomatic uremia.

The choice of the dialysis modality depends on clinical and practical aspects, such as availability of PD and HD and adequately trained personnel, patient size for central access creation, local preference and experience, particularly when dialyzing young children and infants. Diarrhea or colitis are not considered contraindications for peritoneal dialysis (PD) [135, 189, 212].

Continuous renal replacement therapy (CRRT) or "slow" HD offer alternatives to conventional HD in patients with severe fluid overload, cardiovascular instability, with or without sepsis, and multiorgan failure. Both are typically performed in a critical care setting. HD and CRRT can be tried with minimal or no heparin, provided there is sufficient blood flow through the circuit. Regional, citrate-based anticoagulation offers an alternative to heparin, specifically in patients with cerebral stroke or hemorrhage, or after surgery.

Some pediatric centers consider severe, life-threatening STEC-HUS an indication for plasma exchange (PE) as "rescue" therapy, especially for patients with CNS complications [189, 213]. This approach may have been influenced by the success of PE in aHUS and TTP. However, the benefit of plasma therapy (PE or plasma infusion) in STEC-HUS remains unproven [214–217]. The European Paediatric Study Group for HUS excluded STEC-HUS from PE [94]. In young children, PE requires the insertion of a large-bore central venous access (HD line), which confers additional morbidity to children not already undergoing HD [19]. The guidelines for the use of apheresis by the American Society for Apheresis (ASFA) categorized STEC-HUS as III, i.e. a disorder where the role of apheresis treatment is not established, with weak recommendation and low-quality evidence (2C) [218].

Immunoadsorption (IA) is a specialized apheresis technique for the selective removal of humoral factors such as immunoglobulins and complement from plasma via a high-affinity adsorbent column [219]. However, reports of its use for STEC-HUS is anecdotal [220–222].

Anticomplement Therapy in STEC-HUS

The role of the complement system in the pathogenesis of STEC-HUS gained traction over the past decade [223–227]. Several events stimulated scientific inquiry and clinical interest: progress in the understanding of atypical HUS caused by genetic or acquired dysregulation of the alternative pathway, availability of a potent, well-tolerated anti-C5 antibody (eculizumab), and its compassionate use during the *E. coli* O104:H4 epidemic in Northern Germany.

Increased plasma levels of complement activation products derived from factor B (CFB) and C3, and of the terminal complement complex sC5b-9 [86, 227, 228] as well as the deposition of C5b-9 in post-mortem tissue (Fig. 24.10) suggests that complement is activated in STEC-HUS. Interestingly, no correlation was found between the levels of complement products in plasma or platelet derived microparticles and the presence or absence of kidney or extrarenal complications [86, 228].

Data on the use of eculizumab in (severe) STEC-HUS have been recently summarized [229, 230]. Despite signals indicating clinical improvement,

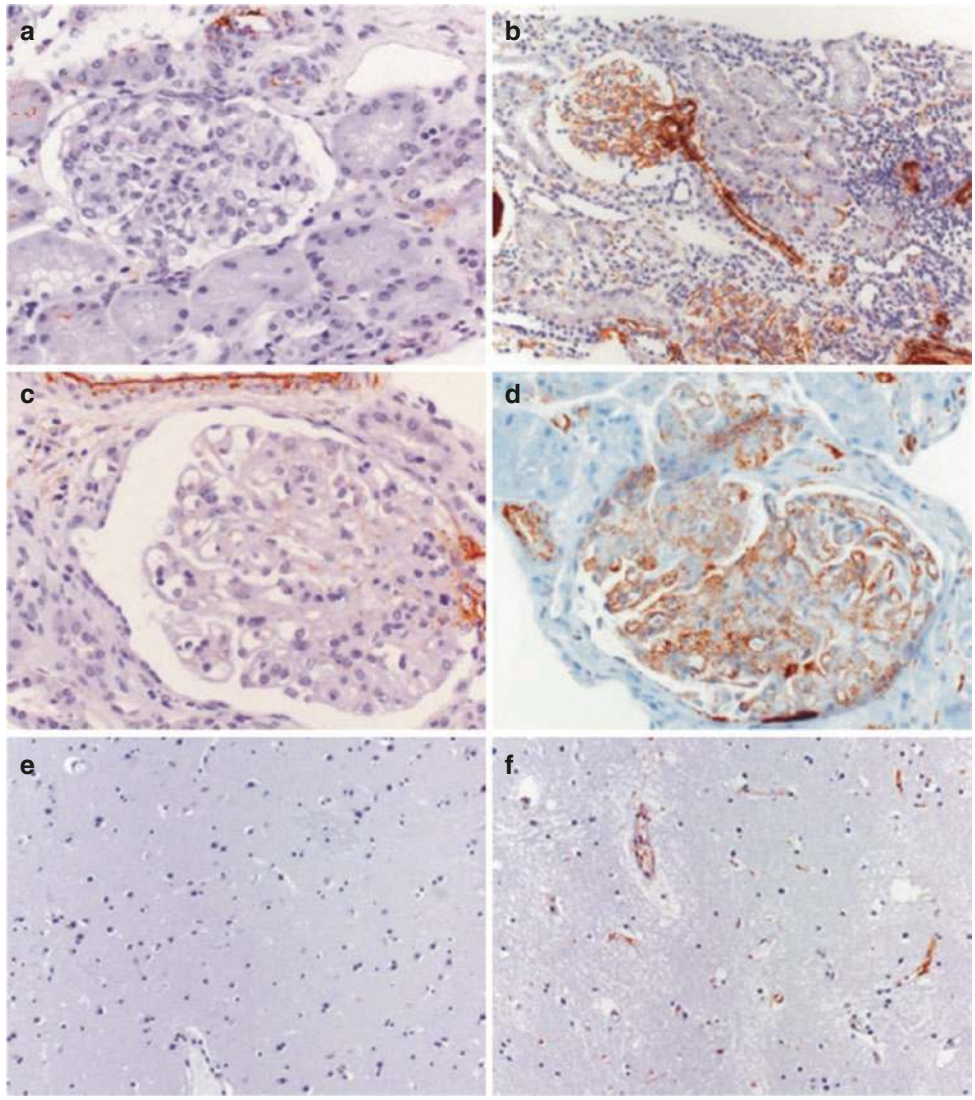

Fig. 24.10 C5b-9 (membrane attack complex, MAC) deposition in kidney and CNS sections of a child who died of STEC O157:H7 HUS. (**a**) Control (kidney). (**b**) Strong staining of kidney arteriole and glomerular capillaries with anti-MAC antibody (1:200). (**c**) Staining of afferent and efferent arterioles, minor staining within the glomerulus. mainly of neurological complications, the overall quality of evidence is low [230, 231]. It remains to be shown, if and under which conditions Stx-associated complement activation becomes deleterious and requires targeted treatment. While awaiting definitive trial results [232, 233], the off-label use of anticomplement agents in patients with STEC-HUS should be reserved for severe forms (especially in cases with CNS or cardiac involvement) and balanced against potential adverse effects and costs.

Complications and Long-Term Outcome

AKI due to STEC-HUS is frequently self-limited. Hematological improvement (decreas-

ing LDH, increasing platelet count) generally precedes kidney recovery. Overall, the outcome of STEC-HUS has improved substantially since its first description. Reported mortality rates typically vary between <1% and 5% [234], mostly due to CNS, cardiac, or gastrointestinal complications. About 70% of patients recover completely from the acute episode [125, 129, 142, 146, 152, 153, 234–236]. Complications appear to be more frequent in adults with STEC-HUS than in children, and the lethality in the elderly population may be as high as 50% [117, 237–240].

Long-Term Outcome and Monitoring

Long-term kidney complications have been reported in 5 to 25% of patients [113, 129, 241, 242]. 15–30% of patients have proteinuria, typically mild, and 5 to 15% have arterial hypertension. CKD has been noted in approximately 10% of surviving patients and ESKD in 3% [113, 125, 138, 234, 243]. Up to one-third of children with severe HUS (defined as anuria >8 days or oliguria >15 days) developed long-term sequelae [137, 138, 244]. Yearly evaluation of kidney function, BP and urinalysis has been recommended for at least 5 years, and indefinitely for patients with decreased GFR, proteinuria and/or hypertension [113, 138, 148, 234, 243].

Up to 30% of children with CNS manifestations during HUS will develop long-term neurological sequelae [235]. There is probably underdiagnosis of subtle neurological problems such as learning and behavioral difficulties, reduced fine motor coordination, and attention deficit and hyperactivity disorder [245].

STEC-HUS and Kidney Transplantation

For the small percentage of STEC-HUS patients who progress to ESKD, kidney transplantation is the optimal therapy [113, 246]. When a genetic cause of complement dysregulation is ruled out, graft and patient survival are comparable to other kidney transplant recipients [246–250].

Shigella dysenteriae HUS

HUS due to *Shigella dysenteriae* type 1 (SD1) is rare. Yet it is the leading cause of death in outbreaks of SD1 infections [251–254]. Unlike STEC, *S. dysenteriae* is an invasive organism. It penetrates the bowel wall and enters the blood stream. Patients with SD1 infection should be treated early with appropriate antibiotics [255]. The spread of highly resistant SD1 strains is a challenge [256]. Antimicrobial treatment after the first 4 days of diarrhea has been identified as a risk factor for HUS [257].

HUS occurs four to 17 days after the onset of bloody diarrhea, and occasionally after diarrhea has improved. Shiga toxin (Stx) is involved in the pathogenesis of *S. dysenteriae* colitis and HUS. The incidence of HUS among children with SD1 dysentery is less than 0.4% (median age 3 years) [258] (Table 24.2). A high peripheral neutrophil count has been associated with the development and the severity of HUS [259, 260]. Oliguric AKI has been described in 90% of SD1-HUS cases, dialysis in 52%, and disseminated intravascular coagulation in 21% [261]. Additional complications are listed in Table 24.3.

The reported mortality of SD1-HUS is substantially higher than the mortality due to STEC-HUS. However, most of the burden of S. *dysenteriae* infections and SD1-HUS is carried by under resourced countries [255, 257, 262].

Pneumococcal (*Streptococcus pneumoniae*) HUS

Epidemiology

Invasive pneumococcal disease (IPD) may lead to HUS, referred to as pneumococcal HUS (pnHUS). It occurs in <0.7% of IPD episodes [263, 264] and affects mostly infants before the age of 2–3 years [264–266], although older children and adults are also affected [267]. The 10-year incidence is about 1.2 per 100,000 children under 15 years [268]. Indigenous populations may have a higher

Table 24.2 Pediatric *Shigella dysenteriae* type 1 (SD1) HUS [a]

Country	# of reported cases	Age in years (mean or median)	Interval between onset of diarrhea and diagnosis of HUS (days)	Case fatality rate (%)	Reference

	Cardiomyopathy	3.7
	Infective endocarditis	1.2
Hematological	Leukemoid reaction	91.3

[a] Extracted from Bhimma et al. [261]. Percentages are from 81 of 107 cases of HUS, admitted between July 1994 and February 1996 in KwaZulu/Natal

disease burden than other groups [265, 268, 269]. pnHUS accounts for approximately 5% of pediatric HUS cases, and 40% of non-STEC-HUS cases [264, 270, 271]. The majority of patients presents during the winter [265, 271].

Increased vaccine coverage may have led to a decline in the incidence of pnHUS, Yet *S. pneumoniae* serotype 19A was missing in the first generation pneumococcal 7-valent conjugate vaccine (PCV7) and has emerged as the predominant isolate during the last decade [265, 266, 272–275]. It is incorporated into the present 13-valent vaccine (PCV13) [276] and the 23-valent pneumococcal polysaccharide vaccine

(PPV23). pnHUS continues to occur, e.g., due to vaccine failure and emergence of non-vaccine replacement serotypes [7, 275].

Pathogenesis

pnHUS typically develops in a patient with pneumonia or meningitis [265, 266, 274, 277, 278]. HUS has been associated with abundant *in situ* production of bacterial neuraminidase [4, 279], in particular neuraminidase A (NanA) [280]. Neuraminidases cleave terminal sialyl residues from membrane glycoproteins and glycolipids [12, 280–282]. The exposed O-glycan core is known as Thomsen-Friedenreich disaccharide (TF antigen) [283]. The TF "neo" antigen is recognized by the lectin *Arachis hypogaea*, which has been used to detect and quantify the *in vivo* effect of neuraminidase on RBCs and tissues in patients with pnHUS [4, 5, 280] (Fig. 24.11).

It was postulated that the interaction of preformed anti-TF antibodies with the exposed neoantigen induces hemolysis, platelet agglutination, microvascular thrombosis, and tissue injury [5]. However, anti-TF antibodies are generally of the IgM class and of low affinity at body temperature [284–287]. Furthermore, desialylation of RBCs is not specific for HUS: it can be found in patients with IPD without progression to HUS [288–290], and pnHUS can develop in the absence of TF antibodies [282].

Presentation of pnHUS and Clinical Course

A practical approach for diagnosing pnHUS is shown in Table 24.4. Patients with pnHUS typically present with fever and respiratory distress due to lobar pneumonia (70–80%) that is complicated in two thirds of cases by pleural effusion or empyema [265, 291]. The remaining 20–30% have pneumococcal meningitis, acute otitis media or pneumococcal sepsis. The majority (80%) is bacteremic at the time of diagnosis [292]. The interval between onset of *S. pneumoniae* infection and HUS is 1–2 weeks [289].

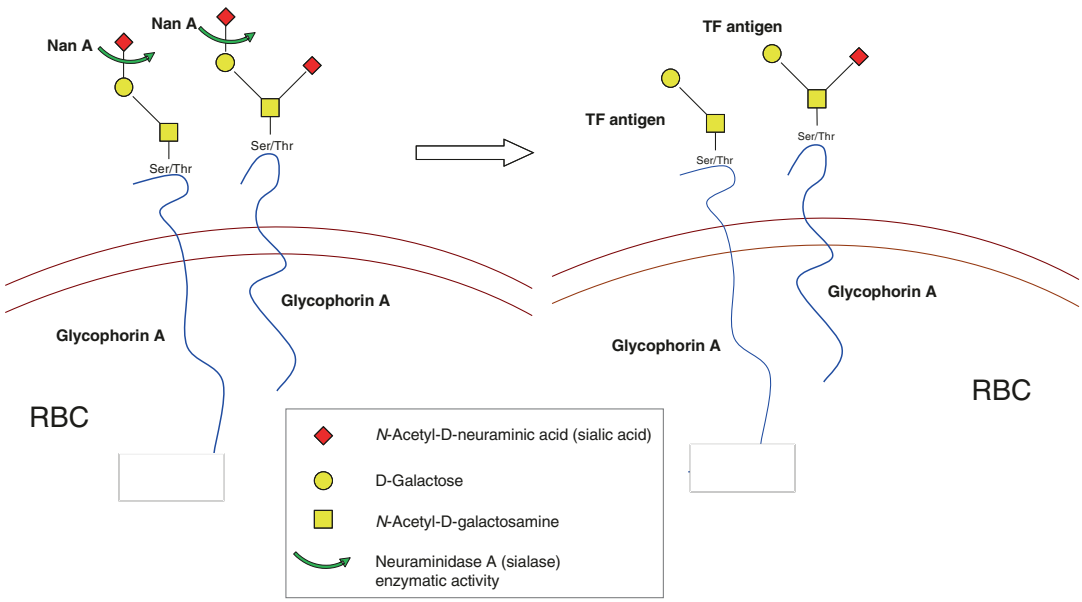

Fig. 24.11 Neuraminidase action on RBC membrane. Nan A (pneumococcal neuraminidase A) removes the terminal sialic acid. The *Arachis hypogea* lectin specifically recognizes the residual disaccharide β-D-galactose (1–3)-N-acetyl-D-galactosamine (Thomsen-Friedenreich antigen) that is O-glycosidically linked to the serine/threonine residue of glycophorin A (Used with permission of author and Elsevier from Loirat et al. [286])

The disease course can be severe or even fatal. A large proportion of patients will be admitted to the intensive care unit, of whom >50% will require mechanical ventilation and chest tube placement. About 70–85% of patients become oliguric or anuric, often with rapid clinical deterioration, and need acute dialysis [265, 291, 292]. Median time of dialysis in a large series was 10 days (range 2–240 days) [265].

In addition to microangiopathic hemolytic anemia with profound thrombocytopenia, the laboratory findings include a rapid rise of acute phase reactants (CRP, procalcitonin) [289]. The direct Coombs is positive in 58–90% of patients during the early phase of pnHUS [278, 293–295].

Patients may have DIC [278, 294, 296, 297]. *S. pneumoniae* sepsis with mild anemia, thrombocytopenia, DIC, hypotension and AKI can masquerade as HUS. Furthermore, Coombs positive hemolytic anemia may occur without thrombocytopenia and kidney injury [288, 298]. Hence, it is useful to choose a methodical approach diagnosing pnHUS [269, 274, 278] (Table 24.4).

Laboratory Studies and Biomarkers

The defining criterium is the detection of *S. pneumoniae* in a sterile fluid (blood, pleural effusion, cerebral spinal fluid, middle ear aspirate, etc.). In case of preceding antibiotic therapy, pneumococcal PCR or antigen detection should be tried.

Laboratory workup includes demonstration of TF exposure on PRBCs, a direct Coombs test and screening for DIC. It is recommended to measure C3, C4, CH50, and serum immunoglobulin levels and exclude congenital or acquired immune deficiencies that are known to predispose to invasive pneumococcal disease [299]. Serial CRP measurements are useful to confirm effective antimicrobial therapy.

No other HUS presents with a positive Coombs test or TF antigen exposure. However, the frequency of Coombs test positivity in IPD without HUS is unclear [278]. Sensitivity and specificity of TF antigen detection was reported as 86% and 57%, respectively, for pnHUS or isolated hemolytic anemia. The positive predictive value for HUS was 76%. Conversely, in

Table 24.4 Diagnostic Criteria for pnHUS[a]

pnHUS	Criteria		Details
Definite	1	Evidence of HUS	Intravascular hemolytic anemia, thrombocytopenia and acute kidney injury
	2	Evidence of invasive *S. pneumoniae* infection	Pneumococcal growth/antigen detection or positive PCR from physiologically sterile biological fluid
	3	No evidence of disseminated intravascular coagulation (DIC)	Fibrinogen consumption, prolonged prothrombin or partial thromboplastin time, and/or d-dimers *at the time of diagnosis*
Probable	1	Evidence of HUS	See above
	2	Evidence of invasive *S. pneumoniae* infection	See above
	3	a) Evidence of DIC ***and*** b) Positive Coombs test and/or evidence of TF antigen exposure	Usually cold agglutinins; TF antigen detection by *Arachis hypogaea* or specific lectin/monoclonal antibody binding [298]
Possible	1	Evidence of HUS	See above
	2	Suspected (undocumented) invasive *S. pneumoniae* infection	Negative culture/antigen detection or PCR from sterile fluid
	3	(a) No evidence of DIC, ***or***	
		(b) Positive Coombs test and/or TF antigen exposure	With or without evidence of DIC (see above)

Abbreviations: *TF* Thomsen-Friedenreich

[a]Modified from Copelovitch et al. [274]

children with IPD, positive and negative predictive values of TF antigen detection for pnHUS were 52 and 100% [290]. Among hospitalized patients with severe pneumococcal disease, TF antigen exposure levels peak 5–10 days after disease onset [300].

Complement and pnHUS

Informative studies on underlying complement abnormalities in pnHUS patients are scarce [287, 301, 302]. Complement consumption, primarily due to activation of the alternative pathway, is common in patients with pnHUS. Removal of sialic acids by NanA was noted to increase complement activity in whole blood, while absence of NanA blocked complement activation implying that the enzymatic removal of sialic acids can trigger pnHUS [12]. Transient CFH desialylation may play a role in disease pathogenesis [303]. While *S. pneumoniae* infection can trigger HUS in children with damaging mutations of complement regulator genes, similar to patients with "atypical" HUS, disease relapses due to *S. pneumoniae* have not been described. The emergence of specific (protective) immunity is surmised.

Treatment of pnHUS

Treatment of patients with pnHUS includes appropriate antibiotics and supportive care [278, 286]. Dialysis is required in up to 80% of patients. Previous recommendations to restrict blood transfusion to "washed" RBCs and to avoid administration of plasma which contains anti-TF antibodies [304, 305] are not based on evidence [17, 268, 278, 286, 287, 306, 307]. Indeed, plasma infusion and plasma exchange therapy have been described in pnHUS patients without apparent worsening of hemolysis or kidney function [265, 306, 308, 309].

Therapeutic complement blockade in the absence of pathogenic complement gene variants has not been systematically studied [307, 310]. Pneumococcal vaccination is an important measure for disease prevention [7].

Outcome of pnHUS

Unfavorable outcome has been noted in 20% of patients [265]. In another series, 3% of patients had died [292], 13% had neurologic sequelae, and 10% underwent kidney transplantation [292]. Important CNS complications are intracranial hemorrhage and infarction that can result in obstructive hydrocephalus [265, 268]. Waters et al. found that only 2 of 13 patients with pnHUS and meningitis had a normal neurodevelopmental outcome [265]. Pulmonary complications in addition to empyema include pneumatoceles and necrotic pneumonia [268]. Most deaths are not caused by HUS or kidney injury, but are due to meningitis and septic shock. Residual kidney dysfunction and proteinuria are expected in 20–25% [265, 311]. Kidney transplantation following pnHUS is rare, but HUS recurrence has not been reported [275, 312, 313].

Clostridium HUS

Early descriptions of HUS were traced to infections by *Clostridium perfringens*, the cause of gas gangrene, necrotizing fasciitis, and necrotizing enterocolitis [306, 314]. *C. perfringens* and other clostridial species produce neuraminidases, along with a range of other proteases and toxic enzymes [315]. A pathogenetic role of neuraminidase in clostridium HUS has been postulated [306, 314]. Newer reports have also implicated *C. difficile* in cases of HUS [316–322]. Treatment is supportive, in addition to appropriate antibiotics.

Influenza HUS

There is an established link between influenza virus infection, mostly influenza A, and HUS, but the mechanism remains speculative [8, 16].

Influenza virus shares with *S. pneumoniae* the production of neuraminidase (NA). Hemagglutinin (HA) and NA are defining and important viral pathogenicity factors in infections. NA shedding is minimal compared to *S. pneumoniae*, and it remains to be shown whether and how much it contributes to the pathogenesis HUS.

Infection of endothelial cells by influenza virus can induce apoptosis, [323] which triggers platelet adhesion directly and via extracellular matrix exposure [88, 324]. The virus also activates platelets and causes thrombin generation [325, 326]. Furthermore, influenza virus is a potent activator of complement [327–329]. Excess complement activation may lead to temporary consumption of C3 or may trigger HUS in individuals with risk variants of complement genes.

Patients with influenza HUS should be tested for plasma C3 and sC5b-9 concentrations, and ADAMTS13 activity. The presence of concomitant or complicating pneumococcal pneumonia or sepsis must be ruled out [16].

Supportive care is the main therapeutic intervention. It is unknown if the NA inhibitor oseltamivir prevents or ameliorates influenza HUS. The role of plasma therapy (PI, PLEX) or eculizumab in influenza HUS is unproven. However, recommendations for the treatment of aHUS should be followed if defective complement regulation is proven or suspected, particularly in instances of preceding HUS episode(s), a positive family history of aHUS, or recurrence of HUS after kidney transplantation [13, 94, 286].

COVID-19 and HUS

SARS-CoV-2, the virus causing COVID-19, injures the vascular endothelium, which can result in thrombotic complications [330]. SARS-CoV-2 can induce a fulminant cytokine response, including activation of the complement system and release of the chemokines C3a and C5a [331]. Multisystem inflammatory syndrome in children (MIS-C) is the most severe form of this pathologic reaction [332, 333], which may also involve the kidneys, but generally without overt TMA [334–336]. However, TMA has been observed in SARS-Cov-2 infected patients [337, 338] and after COVID-19 vaccination [339–342].

COVID-19 may cause TMA in patients without genetically determined complement abnormalities [9, 343, 344]. SARS-CoV-2 activates the alternative and lectin pathways of complement, likely via its spike surface protein [337, 345]. The pathogenic role of complement activation in COVID-19 is supported by the experimental observation that C3 deficient mice are protected against SARS-CoV-2 disease [346]. Finally, complement activation may also contribute to the hypercoagulable state in COVID-19 patients [347]. Some clinical observations, however, indicate that eculizumab may not prevent severe COVID-19 and associated endothelial cell injury [348], suggesting that blocking the terminal complement pathway is not sufficient.

HIV HUS

TMA in the context of AIDS has been variably described as HUS or TTP, and TTP has been listed as an AIDS defining condition [349, 350]. The incidence of HIV TMA has decreased since the advent of effective HIV therapies [351].

Clinical observation and animal experiments suggest that HIV can cause HUS directly [352], although the mechanism(s) remain unclear. HIV infects glomerular endothelial and mesangial cells, but not epithelial cells *in vitro* [353]. Intriguingly, a viral surface glycoprotein, pg120, binds to Gb3, the Stx receptor; this interaction has been linked to the occurrence of HIV HUS [352, 354–356]. Conversely, Gb3 has been described as natural resistance factor for the prevention of HIV infection, e.g. when given as a soluble agent [356, 357]. Kidney biopsies may show features of TMA [351, 358, 359].

Treatment of HIV TMA consists of effective antiviral therapy and supportive care, with the anecdotal use of fresh-frozen plasma infusions and plasmapheresis [351, 358–360].

Introduction

Vasculitides are a wide range of disorders where the primary pathological feature is inflammation in a blood vessel wall. The clinical presentation depends on the site of involvement, vessel size, and the type and severity of pathological changes. Patients usually present with fever and constitutional symptoms, such as fatigue, weakness, weight loss, and skin lesions. Laboratory markers show inflammation, and signs of multiorgan involvement may be present at presentation. Nevertheless, the most common vasculitis in childhood, IgA vasculitis (IgAV), can present mildly, with cutaneous purpura of the lower limbs, or as a severe renal vasculitis. Vasculitis is often aggressive and can be organ- or life-threatening. Renal involvement, when present, is often rapidly progressive glomerulonephritis (RPGN) since it is extremely aggressive with severe hypertension and rapid deterioration of renal function, requiring intervention within hours of initial presentation to preserve residual kidney tissue. Classic histological features are the presence of severe inflammation with intense endocapillary and extracapillary proliferation, leading to crescents and necrosis, and in many cases (excluding IgAV and lupus nephritis) a negative (pauci-immune) immunofluorescence. Vasculitis may affect any part of the body, and patients should be treated by a multidisciplinary team including rheumatologists, nephrologists, pulmonologists, dermatologists, and neurologists. Although more common in adults, renal vasculitis occurs in childhood and may present as an isolated kidney disorder or associated with a systemic disease.

Classification of Vasculitides

Traditionally, vasculitis has been classified according to the size of the affected vasculature (Figs. 25.1 and 25.2). Large-vessel vasculitis or

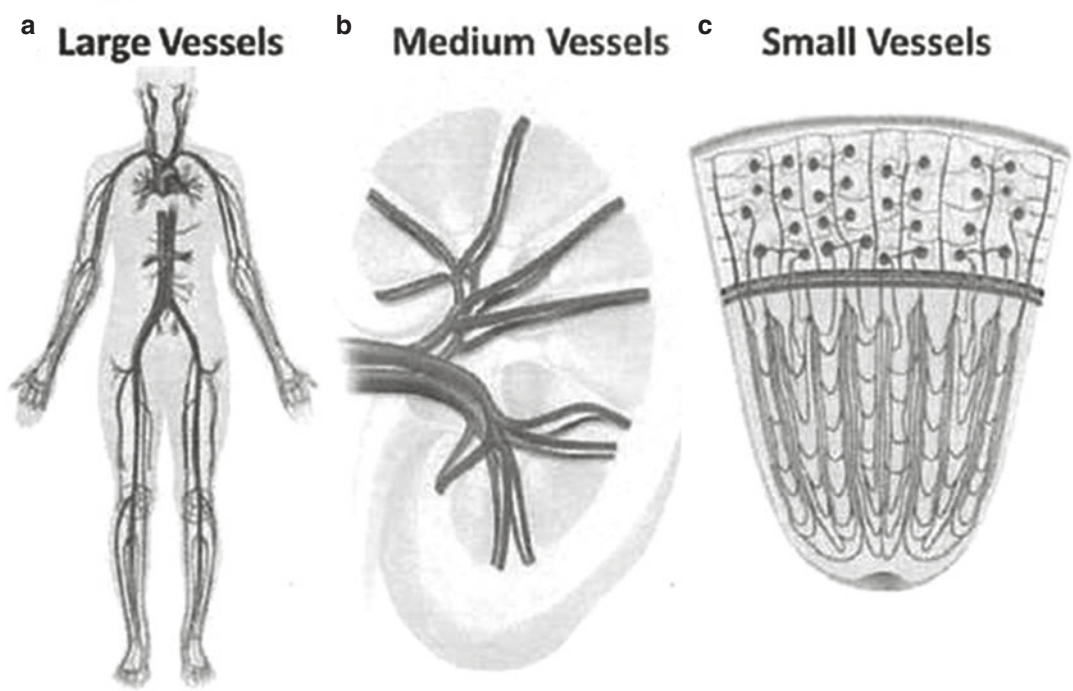

Fig. 25.1 The definition of vessel size [1]. (Reference: Jennette JC et al.:2012 Revised International Chapel Hill Consensus Conference Nomenclature of Vasculitis Arthritis & Rheumatism, 65:1–11, 2013)

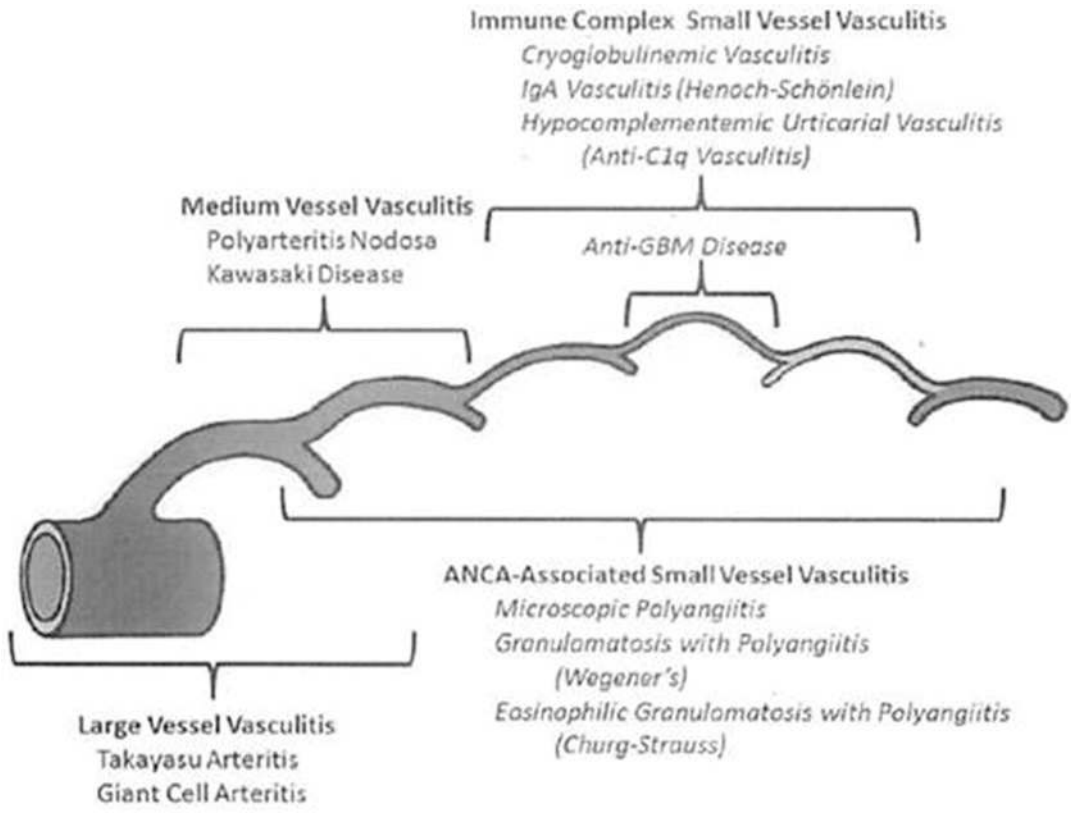

Fig. 25.2 Vasculitis and vascular size (CHCC 2012) [1]. (Reference: Jennette JC et al.:2012 Revised International Chapel Hill Consensus Conference Nomenclature of Vasculitis Arthritis & Rheumatism, 65:1–11, 2013)

arteritis affects the aorta and its major branches in diseases such as giant-cell arteritis and Takayasu arteritis, which can reduce the caliber of the abdominal aorta or of renal arteries, leading to renal ischemia and renovascular hypertension. Medium-vessel vasculitis involves medium or small arteries, leading to infarction and hemorrhage of the affected organ, and includes polyarteritis nodosa (PAN) and Kawasaki disease (KD), the only large-vessel or medium-vessel vasculitides that involves mainly infants and small children. Small-vessel vasculitides, affecting capillaries and venules, are the only forms which can by definition cause glomerulonephritis (GN). They comprise a large group of diseases; the two most common are IgAV and antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis (AAV). The current nomenclature system was established at the International Chapel Hill Consensus Conference on the Nomenclature of Systemic Vasculitides in 1994 and further modified in 2012 (CHC2012), presented in Table 25.1 [1]. The most prominent modifications comprise the adoption of new names for several diseases, consistent with the trend of replacing eponyms with names that reflect the pathophysiology, the formalisation of the term AAV and categories for secondary forms of vasculitis. Monogenic forms of vasculitis, recognized more recently, were not included in the 2012 classification. The chapter includes information about rare monogenic forms of vasculitis that can affect the kidney and occur in children. The American College of Rheumatology (ACR) published a classification in 1990 of 7 vasculitides [2], which has become inadequate, and currently a joint ACR/The European Alliance of Associations for Rheumatology (EULAR) classification that will include new diagnostic criteria is being developed [3].

Table 25.1 Names for the vasculitides adopted by the CHC2012 [1]

Large-vessel vasculitis	Takayasu arteritis Giant cell (temporal) vasculitis Both of these occur usually in patients over 50 years old
Medium-sized vasculitis	Polyarteritis nodosa Kawasaki disease (KD)
Small-vessel vasculitis	Antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis (AAV) Microscopic polyangiitis (MPA) Granulomatosis with polyangiitis (Wegener's) (GPA) Eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome) (EGPA) Immune complex small-vessel vasculitis Anti-glomerular basement membrane disease Cryoglobulinemic vasculitis nephritis IgA vasculitis (Henoch-Schönlein purpura) (IgAV) Hypocomplementemic urticarial vasculitis (anti-C1q vasculitis)
Variable-vessel vasculitis	Behcet syndrome Cogan's syndrome
Single-organ vasculitis	Cutaneus leukocytoclastic angiitis Cutaneus arteritis Primary central nervous system vasculitis Isolated aortitis Others
Vasculitis associated with systemic disease	Lupus vasculitis Rheumatoid vasculitis Sarcoid vasculitis Others
Vasculitis associated with probable etiology	Hepatitis C virus-associated cryoglobulinemic vasculitis Hepatitis B virus-associated vasculitis Syphilis-associated aortitis Drug-associated immune complex vasculitis Drug-associated ANCA-associated vasculitis Cancer-associated vasculitis Others

Classification of Childhood Vasculitis

The most common vasculitis in childhood is IgAV, followed by KD. In certain parts of the world, such as Japan, KD is more common. Although KD may cause infarction of any organ, kidney involvement is rare, and management is the same as for any other severe form of KD. Other forms of vasculitis are rare in childhood, and there are large-vessel vasculitides, such as temporal arteritis and giant cell arteritis, that usually occur in patients over 50 years of age, and are not seen in pediatric patients. The 2005 EULAR/Paediatric Rheumatology European Society (PReS) criteria [4], which were revised and validated in children in 2008 [5], are generally used for classification of vasculitis in pediatric patients. These criteria provide detailed classification for the most common childhood vasculitides, while rare forms are under the umbrella of "other vasculitides" (Table 25.2).

Table 25.2 EULAR/PReS classification of childhood vasculitis [5]

Predominantly large vessel	Takayasu arteritis
Predominantly medium-sized vessel	Childhood polyarteritis nodosa
	Cutaneus polyarteritis nodosa
	Kawasaki disease
Predominantly small vessel	Granulomatous Eosinophilic granulomatosis with polyangiitis (EGPA or Churg Strauss) Granulomatosis with polyangiitis (GPA) Nongranulomatous Microscopic polyangiitis (MPA) IgA vasculitis Isolated cutaneus leukocytoclastic vasculitis Hypocomplementemic urticarial vasculitis
Other vasculitides	Behcet syndrome Secondary vasculitides due to infection, malignancy, or drugs, including hypersensitivity vasculitis Isolated vasculitis of the central nervous system Cogan's syndrome Unclassified

Large Vessel Vasculitis

Takayasu Arteritis

The EULAR recommendations on adult-onset Takayasu arteritis may be used in paediatric Takayasu arteritis patients [6].

Medium-Vessel Vasculitis

Polyarteritis Nodosa

PAN is a necrotizing vasculitis of medium-sized arteries that rarely occurs in children. Peak age of childhood onset is 7–11 years, with a slight male predominance [7]. The histological hallmark is a necrotizing vasculitis associated with aneurysmal nodules along the walls of medium-sized arteries, which can be visualized by conventional angiography. Importantly, a renal biopsy is not recommended due to a high risk of bleeding and arteriovenous fistulae, and it may not be informative. In the recent pediatric classification of PAN [5], characteristic histology or angiography findings are mandatory for diagnosis of PAN in addition to at least one of five criteria that include skin involvement, myalgia/muscle tenderness, hypertension, peripheral neuropathy and renal involvement. PAN limited to the skin is defined as cutaneous PAN and is more common in children. It can vary from classic purpura to necrotic lesions associated with peripheral gangrene. Renal involvement can be visualized by angiography of renal arteries with the characteristic "pruned tree" images (aneurysms, perfusion defects, arterial cutoff and lack of crossing of peripheral renal arteries) and may be indirectly proven by demonstrating patchy areas within the renal parenchyma of decreased isotope uptake on Tc-99 m dimercaptosuccinic acid (DMSA) scan [7].

PAN can be caused by a viral illness or cancer, and there are genetic etiologies [8]. Renal involvement was present in 19% of cases in the largest described cohort of 69 children with PAN followed in a single center [9]. Of the eight renal biopsies performed in this study, two showed focal segmental GN, two showed >10% crescents and the remaining 4 showed membranoproliferative GN with necrotizing vasculitis. Fibrin deposition with vessel occlusion was noted in 3 of the 8 renal biopsies. Management approach is the same as for AAV. Notably, a multicenter, open-label, randomized clinical trial (RCT) comparing mycophenolate mofetil (MMF) versus cyclophosphamide for the induction of remission of childhood PAN (the MYPAN trial) was completed, although not yet published as of 2021 [10].

Kawasaki Disease

KD is an acute, self-limited vasculitis, occurring most frequently in infants and small children. Its main manifestations are fever (persisting for 5 days or more), peripheral extremity changes, a polymorphous exanthema, bilateral conjunctivitis, oral mucosal changes (e.g. red, dry, cracked lips and strawberry tongue) and non-purulent cervical lymphadenopathy [7]. It frequently affects the coronary vessels, causing aneurysms and other cardiac abnormalities; KD is one of the main causes of acquired cardiac disease in children. Renal manifestations are infrequent and their pathogenesis is unclear: pyuria, proteinuria and renal failure have been described, as well as tubulointerstitial nephritis which may be secondary to intravenous (IV) immunoglobulin, which together with aspirin is the mainstay of therapy [11].

Small-Vessel Vasculitis

The most common vasculitides affecting kidneys in children are IgAV (covered in Chap. 54) and AAV, which includes granulomatosis polyangiitis (GPA), *microscopic polyangiitis (MPA) and eosinophilic granulomatosis with polyangiitis (EGPA)*. AAV can be classified based on the autoantigen specificity. The two most recognized autoantigens are myeloperoxidase (MPO) and proteinase 3 (PR3). The categorization of a patient AAV should include both the clinicopathological phenotype and the autoantigen. The other forms of vasculitis are briefly addressed below, and the remainder of the chapter focuses on AAV.

Anti-Glomerular Basement Membrane Disease

Anti-glomerular basement membrane (GBM) disease is a rare form of small-vessel vasculitis caused by autoantibodies directed against the so-called Goodpasture antigen or non-collagenous domain 1 (NC-1), a neo-epitope of the α3 subunit of type IV collagen expressed in the GBM, where autoantibodies cause a rapidly progressive crescentic and necrotizing GN, and in pulmonary alveoli. The disease can occur in adolescents, and may be renal-limited or may, in approximately 50% of cases, involve small-vessels in the lungs as well, leading to pulmonary hemorrhage (Goodpasture syndrome). Exposure of the neo-epitope NC-1 is due to a perturbation of the structure of type IV collagen, which may be secondary to environmental exposure to reactive oxygen species (e.g. industrial hydrocarbon, cigarette smoke), systemic inflammation (e.g. AAV, which can co-exist with anti-GBM disease in approximately 25% of cases) or membranous nephropathy. Without aggressive and timely treatment, the disease is generally fulminant, and both patient and kidney survival are poor. Recommended treatment relies on the use of plasma exchange (PLEX) or immune-adsorption and immunosuppression with glucocorticoids and cyclophosphamide [12]. Treatment should be commenced without waiting for a renal biopsy when this diagnosis is suspected, and should be continued until the anti-GBM antibodies are undetectable [13].

Cryoglobulinemic Vasculitis

Cryoglobulinemic vasculitis is a rare systemic vasculitis resulting from circulating immune complex deposition in the small vessels which occurs when the temperature falls below 37° C. It has variable clinical features, including signs of hyperviscosity syndrome such as Raynaud's phenomenon, cold-induced acral ulcerations, livedo reticularis, headache and confusion, or signs of immune complex-mediated vasculitis of small vessels such as purpura, arthralgia, GN, and peripheral neuropathy. Cryoglobulinemia can result from infections (mainly hepatitis C virus and hepatitis B virus), cancer or autoimmune disease, or it can be essential. In children, essential forms predominate (72%), and renal involvement occurs, as in adults, in approximately 10% of cases [14]. Treatment is aimed at eliminating the cause, and rituximab (RTX) has been used with

success. In severe forms, such as those with RPGN or symptomatic hyperviscosity, PLEX is necessary. IV immunoglobulin is contraindicated in cryoglobulinemic vasculitis as it can exacerbate immune complex precipitation, leading to multiorgan failure.

ANCA-Associated Vasculitis

Renal Pathology

The pathology of renal vasculitis is characterized by its grade of severity and anatomical location. Although there may be several stimuli that trigger vasculitis, endothelial cells are its basic target. The early pathology is an endothelitis, which is frequently seen with any endothelial injury. The more severe phenotypes are fibrinoid necrosis and occasional rupture of the corresponding vasculature, resulting in interstitial hemorrhage (Fig. 25.3a). In some cases, vasculitis is recognized by severe inflammatory infiltrates in the vascular wall; other cases show fewer inflammatory infiltrates with necrosis, such as PAN (very rare) or KD.

The key histological feature of AAV is necrotizing vasculitis, with few or no immune deposits, predominantly affecting small vessels. This can be associated with granulomatous lesions in GPA and with eosinophil-rich (and often granulomatous) inflammation in EGPA. Tissue biopsies are essential to make the diagnosis of AAV.

When renal involvement is present in patients with suspected or confirmed AAV, renal biopsy is the gold standard for diagnosis, and is an important predictor of renal outcome. ANCA-associated GN is characterized by pauci-immune immunofluorescence; necrotizing and crescentic lesions in the affected glomeruli by light microscopy; and subendothelial oedema, microthrombosis, and degranulation of neutrophils by electron microscopy [15].

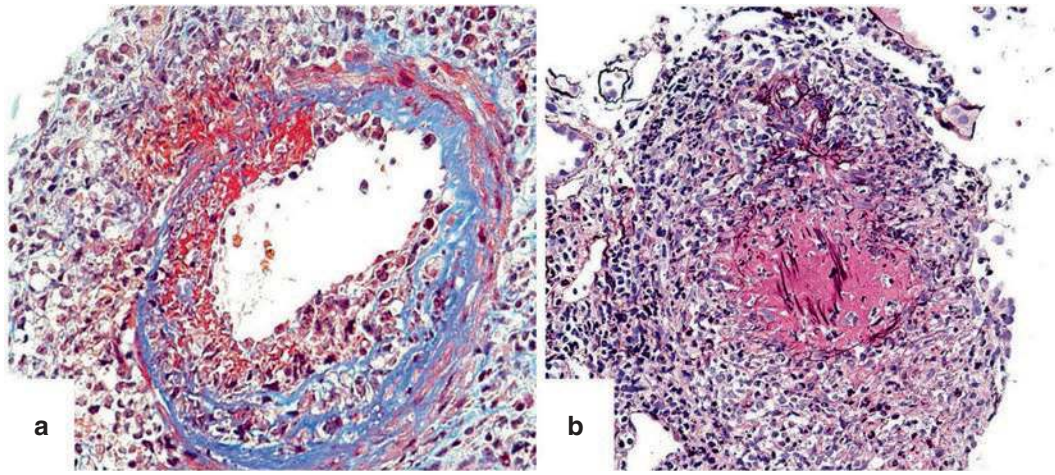

Fig. 25.3 Necrotizing angiitis and glomerulonephritis in patients with ANCA-associated vasculitis/glomerulonephritis. (**a**) Necrotizing vasculitis. Interlobular artery is affected by intimal inflammatory infiltrates particularly neutrophils. Note rupture of vascular wall with substantial fibrin deposition (Masson Trichrome Stain, ×400). (**b**) Severe vasculitis involves entire glomerulus with granulomatous changes (Periodic Acid Methenamine-Silver Stain, ×400). (**c**) Necrotizing capillaritis in the glomerulus. Note numerous neutrophils accumulation at the site of fibrinoid necrosis (Masson Trichrome Stain, ×400). (**d**) Segmental fibrinoid necrosis with nuclear fragmentation in the neutrophils (Periodic Acid Schiff Stain, ×550). (**e**) Peritubular capillaritis and interstitial inflammatory infiltrates (Masson Trichrome Stain, ×400). (**f**) Interstitial inflammatory infiltrates by electron microscopy. Note neutrophils predominant infiltration (×2000)

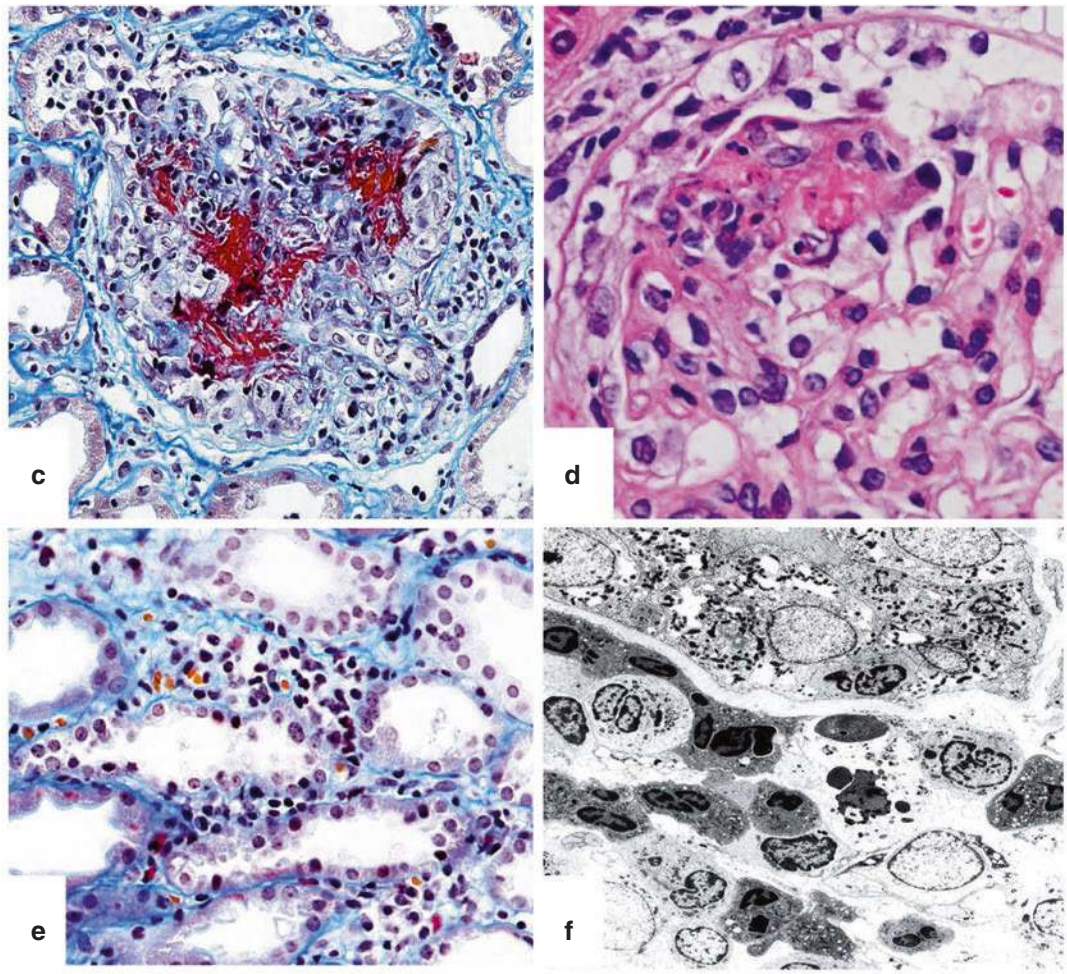

Fig. 25.3 (continued)

Light Microscopy

Renal vasculitis affects endothelial cells, causing inflammation, which manifests as endothelial cell swelling and proliferation and by inflammatory cell infiltration, in AAV mainly by neutrophils, into the subendothelial space. The typical sites of vasculitis in AAV are arterioles, glomeruli, and peritubular capillaries. In arterioles, following endothelial cell swelling, accumulation of inflammatory cells leads to intimal thickening, deposition of active coagulation product (fibrinoid necrosis), and thrombosis (Fig. 25.3a). If the lesion progresses, it leads to a defect or rupture of the vascular wall. In GPA-associated forms of AAV, angiitis can occur, targeting the glomerular hilum and resulting in the destruction of the entire glomerular structure, which is replaced by granulomatous inflammation (Fig. 25.3b). In the glomeruli, capillaritis causes necrotizing crescentic GN, which frequently progresses to glomerulosclerosis (Fig. 25.3c, d). In addition to glomerular involvement, there is also a tubulointerstitial nephritis in AAV; tubular lesions are important predictors of outcome, especially in patients treated with B-cell depleting therapy [16]. Peritubular capillaritis (Fig. 25.3e) is characterized by dilatation and adherence of inflammatory cells on the endothelium of cortical

peritubular capillaries. Occasional rupture leads to interstitial hemorrhage.

GN in MPA differs from GN in GPA by the absence of granulomatous lesions and the more frequent occurrence of chronic lesions (e.g. glomerulosclerosis, fibrous crescents, interstitial fibrosis).

In 2010, an international working group of renal pathologists proposed a histopathologic classification of ANCA-associated GN that was predictive of long-term renal outcome in adult patients. Renal pathological features were divided into four categories: focal, crescentic, sclerotic, and mixed (Table 25.3). These categories predicted renal outcomes at 1 and 5 years (Fig. 25.4). Patients with focal lesions had an excellent renal outcome, whereas renal survival was poor in the sclerotic class, and severe patients also presented an increased mortality risk [17]. This classification system was confirmed in other adult cohorts [18] and in a pediatric retrospective study with biopsy-proven ANCA-associated GN (MPA and GPA) [19]. The biopsy specimens were focal in 13 patients (32.5%), crescentic in 20 (50%), mixed in 2 (5%), and sclerotic in 5 (12.5%). Mixed and crescentic were combined for analyses. This study showed rapid progression to end-stage kidney disease (ESKD) for patients in the sclerotic class, mild disease in the focal, and a slower decline over 2 years in the crescentic/mixed classes. The probability of having an estimated glomerular filtration rate (eGFR) >60 ml/min per 1.73 m^2 at 2 years was 100% for the focal, 56.5% for the crescentic/mixed, and 0% for the sclerotic biopsy categories. Renal biopsies were repeated to determine progression or because of relapses in a subset of patients. Among children with crescentic patterns who had a repeat biopsy, 80% progressed to sclerosis on a second biopsy. Among the focal group, only one child had a repeat biopsy and was reclassified as mixed. These data demonstrate a clear prognostic value of the histopathological classification and suggest for children with sclerotic class (at least 50% globally sclerotic glomeruli) that aggressive immunosuppression is unlikely to result in recovery of renal function. Therefore, it is likely that risks outweigh benefits in this setting and that when extensive sclerosis is present intense treatment should be avoided. Conversely, patients with more florid lesions require early and intensive treatment. Prospective studies are needed to achieve the objective of tailored management based on histological parameters.

Table 25.3 Classification scheme for ANCA-associated glomerulonephritis [17]

Class	Inclusion criteria[a]
Focal	≥50% normal glomeruli
Crescentic	≥50% glomeruli with crescents
Mixed	<50% normal, <50% crescentic, <50% globally sclerotic glomeruli
Sclerotic	≥50% globally sclerotic glomeruli

[a]Pauci-immune staining pattern on immunofluorescence micrography and ≥1 glomerulus with necrotizing or crescentic glomerulonephritis on light microscopy are required for inclusion in all four classes

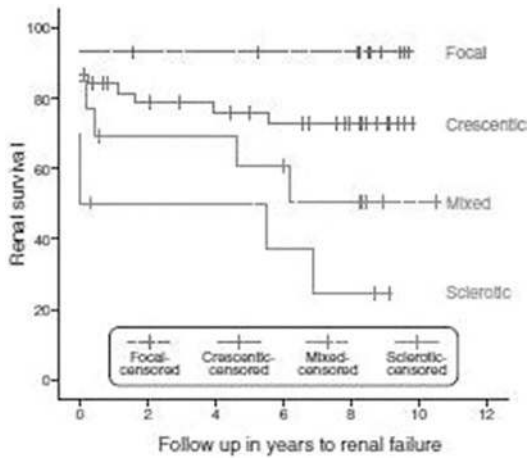

Fig. 25.4 Renal survival is depicted according to the four histological categories [17]. (Reference: Berden et al. Histological classification of ANCA-associated glomerulonephritis. JASN 21:1628–1639, 2010)

Immunofluorescence

Falk and Jennette defined "pauci-immune" as not more than 2+ staining of any immunoglobulin (on a scale of 0 to 4+) and the absence of immune-complex type electron-dense deposits by electron microscopy [20]. However, in a study of electron micrographs of 124 cases of ANCA-associated crescentic GN, 54% of the biopsies had glomeru-

lar immune-complex deposition [21], although the immunofluorescence staining was relatively weak (≤2+). Moreover, Manenti et al. evaluated 27 renal biopsies of adult patients with AAV for glomerular complement deposition by immunohistochemistry and found strong C3c staining in 11 of 27 patients (41%) and positive discrete glomerular deposition of C4d in 8 patients and of C5b-9 in 5 cases (20%), while Bb was usually negative. In this study, there was no association between tissue deposition of complement fractions and outcome [22]. In a subsequent study, patients with glomerular C3d deposition had a worse prognosis [23].

Electron Microscopy

By electron microscopy, neutrophil infiltration into the interstitium and degranulation is visible (Fig. 25.3f), together with neutrophil degranulation, subendothelial edema, and microthrombosis. Moreover, as reported above [21], in about 50% of cases immune-complex deposition was visible. These immune complexes were often few in number. Nonetheless, their presence was associated with more frequent glomerular tuft hypercellularity, greater proteinuria, and trends toward higher serum creatinine level and more widespread crescent formation compared with cases lacking deposits on electron microscopy.

Pathogenesis

The initiating events leading to AAV are multifactorial, but several risk factors and possible triggers have been recognized, including genetic factors, environmental exposures, and previous infections. The pathogenicity of ANCA plays an important role in initiating and amplifying the inflammation, and the ANCA-induced neutrophil activation is an important cause of vascular injury. The pathogenesis is presented in Fig. 25.5 [24].

Genetic Factors

Differences in the prevalence of AAV between ethnic groups, familial association studies, and genetic associations studies, including large genome-wide association studies (GWAS) [25–28], all support the role of genetics. The strongest associations are those in the genes for human leukocyte antigen (HLA) [25–28], *SERPINA1* [25, 26, 29] and multiple genes encoding inflammatory mediators. Links with the HLA region support the central role of autoreactivity and autoimmunity in AAV. Candidate gene and GWAS studies not only indicated a highly significant association between AAV and HLA regions, but also showed genetic distinctions between different clinical phenotypes and ANCA specificity. In general, genetic associations are more closely linked with the auto-antigen specificity than with the clinical syndrome. GPA and PR3-ANCA AAV are associated with HLA-DPB1 and HLA-DPA1, while MPA and MPO-ANCA AAV are associated with HLA-DQB1 and HLA-DQA2 [25, 26, 30]. HLA-DPB1 is associated with EGPA [28]. Moreover, HLA alleles are associated with the mortality and relapse of AAV [30]. *SERPINA* codes for α1-antitrypsin, which is a major inhibitor of PR3. Involvement of the *SERPINA1* gene confirms the role of ANCA in the pathogenesis of AAV as the genetic variants may lead to decreased function α1-antitrypsin, resulting in PR3 accumulating in tissues and potentially triggering ANCA formation. Nevertheless, in a meta-analysis, not only PR3-ANCA positive patients but MPO-ANCA-positive patients and both c-ANCA and p-ANCA-positive patients are associated with *SERPINA1* [29]. One proposed hypothesis is that patients with AAV and these genetic variants have a reduced ability to inhibit PR3 released by activated neutrophils; consequently, these variants increase PR3-mediated proteolytic vessel damage. Nevertheless, the changes in *PRTN3*, which encodes PR3, were present only in PR3-ANCA-positive patients, independent of the clinical diagnosis [25, 26]. A wide range of associations in immunoregulatory genes were found, the strongest with *CTLA-4, PTPN22,* and *TLR9* [29, 30].

Environmental Factors

Infections are a known potential trigger of autoimmune disease. In AAV, more than 50% of

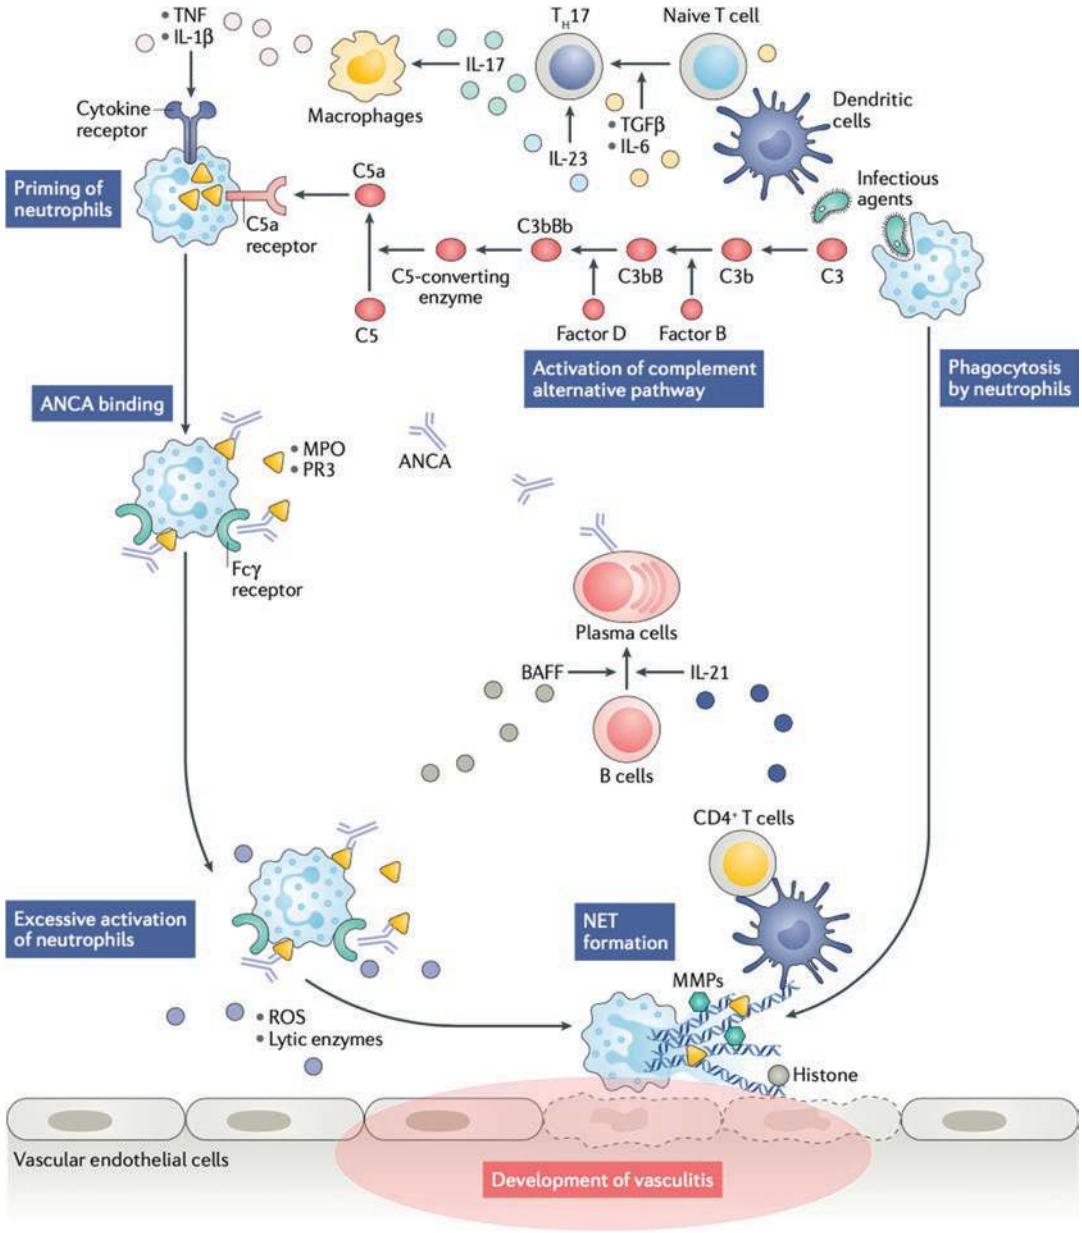

Fig. 25.5 Pathogenesis of AAV. Modified from Nature reviews Rheumatology [24]. (Reference: Nakazawa D, Masuda S, Tomaru U, Ishizu A. Pathogenesis and therapeutic interventions for ANCA-associated vasculitis. Nat Rev. Rheumatol. 2019;15(2):91–101)

patients are t nasal carriers of *Staphylococcus aureus* at the time of diagnosis, which is significantly higher than the general population. Nasal carriage of *Staphylococcus aureus* is associated with an increase risk of disease relapse [31, 32]. The underlying mechanisms is not known [32]. The human lysosome-associated membrane protein 2 (LAMP-2) epitope has complete homology with the bacterial adhesin FimH, and human LAMP-2-ANCA may cross react with this microbial protein. This supports the hypothesis of infection driven immune dysregulation in

AAV. The human antibodies directed against LAMP-2 are somewhat controversial because they have been shown in a rat model to elicit ANCA-associated GN [33], but the results were not replicated [34]. Drugs, including hydralazine, minocycline, propylthiouracil, and levamisole, may cause the development of ANCA [35, 36]. In a case series of AAV in seven children who received propylthiouracil, the most common of the recognized drugs used in childhood, the prognosis was better than non-drug induced AAV [37]. Geographic clustering, temporal clustering, seasonal variation in disease onset, and differences in urban/rural disease prevalence all suggest an environmental trigger [38]. Environmental exposure to air pollutants was investigated, with the strongest evidence for silica dust [39], which is further supported by outbreaks of AAV, mainly MPO-ANCA positive with intense pulmonary involvement, after three large earthquakes in Asia [38]. Pesticides, ultraviolet radiation, and smoking are all believed to contribute to the pathogenesis, but none is by itself sufficient to trigger the disease [38].

The Pathogenicity of ANCA

Substantial clinical and experimental data show that ANCAs are pathogenic. First, there is a strong association of the disease with ANCA, as >90% of MPA and GPA patients and >75% of EGPA patients and GN have positive ANCA. Second, there is also a partial correlation of titer with disease activity. Third, transplacental transfer of ANCA was able to induce disease in humans [40], as was the infusion of anti-MPO IgG in rat and mice models [41, 42]. Fourth, drug-induced ANCAs have a similar clinical presentation [35]. However, healthy individuals can have circulating autoantibodies against PR3 and particularly MPO, also called natural or non-pathogenic ANCAs. In comparison with ANCA from patients, the natural ANCAs have lower titers, lower avidity, less epitope specificity, and less capability to activate neutrophils [43, 44]. The transformation of natural ANCA to pathogenic is most probably an interplay between previously mentioned genetic, environmental and immunologic triggering events. The current hypothesis is that the first reaction is not against autoantigen, but against a peptide that is complementary to the autoantigen. The anti-idiotypic antibody is a response to this first immune response and it cross-reacts with the autoantigen epitopes that are complementary to the initial immunogenic peptide [45, 46]. Multiple microbial peptides are homologues of complementary PR3, including *S. aureus*.

Pathogenesis of Vascular Inflammation

Primed neutrophils, activated by ANCA, are the primary drivers of vascular inflammation in AAV. Different inflammatory signals, for example C5a, bacterial lipopolysaccharide, and TNF, can prime neutrophils to release the MPO/PR3 target autoantigens to the cell surface, where they interact with ANCA. This immune complex further activates neutrophils and causes a respiratory burst; neutrophil enzymes are degranulated; free radicals are released; and neutrophil extracellular traps (NETs) are extruded. NETs in AAV contain MPO and PR3, and further interact with ANCA. All of the above leads to injury and death of endothelial cells. Disrupted endothelium allows plasma to enter the vascular and perivascular tissue, and the following coagulation cascade results in fibroid necrosis [34, 47]. In addition, monocytes can express autoantigens (MPO and PR3) and can be activated by binding of ANCA to Fc-γ receptors (FcγRs). When activated, monocytes release proinflammatory cytokines, such as interleukin-8 (IL-8) and monocyte chemoattractant protein-1 (MCP-1). While IL-8 further activates neutrophils, MCP-1 attracts monocytes and macrophages, presumably shifting the inflammation into the next stage, from predominantly neutrophil-rich to predominantly monocyte/macrophage-rich, which includes granulomatous inflammation.

Pathogenesis of Granulomatosis

Granulomas are foci of extravascular inflammation; the exact mechanism of their formation is not known. It is believed that there is no antigen-specific response, but rather the secondary innate

monocyte/macrophage response, triggered by acute vascular inflammation caused by ANCA-primed neutrophiles [47].

The Role of the Alternative Complement Pathway

The significance of the alternative complement pathway in AAV was first shown in animal studies. Ablation of C5, depletion of C3 and factor B deficiency completely inhibited disease development in a transferred anti-MPO IgG mouse model, while deficiency of classical pathway components did not prevent disease [48]. Later studies documented that the inflammatory process initiated by anti-MPO IgG is further amplified by C5aR activation on inflammatory cells, and a C5 inhibiting monoclonal antibody prevented or strongly attenuated GN development [49, 50]. The human biopsy specimens of MPO-ANCA associated GN had deposition of factor B, C3d, and the membrane attack complex (MAC) in glomeruli and small blood vessels [51]. In addition, increased levels of C3a, C5a, soluble C5b-9, and Bb were observed in the plasma of patients with active AAV, and lower levels of properdin were seen in the plasma of patients in remission. The levels of classical pathway proteins did not differ [52, 53]. Neutrophils, C5a and ANCAs create an inflammatory amplification loop, with C5a attracting and priming more neutrophils for activation by ANCAs, which causes further activation of the alternative complement pathway and consequent release of more C5a [54].

The Role of B and T Cells

The pathogenicity of ANCA, neutrophils, and complement are enabled by a defect in the regulation of the immune system. The regulatory FOXP3+ T cells are decreased and dysfunctional in AAV patients [55], even more so during active disease [56]. The subset of B cells with mostly regulatory suppressive function highly expresses CD5, and in the sera of patients with active AAV, the CD5+ B cells are reduced in number, which normalizes in remission after treatment with RTX [57, 58]. Furthermore, the sera of patients with active AAV has elevated levels of B-cell-activating factor (BAFF), which stimulates B cells and inhibits apoptosis. The ligand for BAFF is released by activated neutrophils [59, 60]. In this way, ANCA-activated neutrophils, along with dysfunctional T- and B-cell regulation, augment the production of more ANCA.

Clinical Features

Patients typically present with non-specific systemic symptoms, such as fatigue, malaise, fever, anorexia, and weight loss. Rhinosinusitis and epistaxis can be early signs that sometimes go unnoticed, while a purpuric rash may be the first obvious reason to seek medical care. Arthralgia or overt arthritis, hematuria, hypertension, cough, diarrhea, and dyspnea can also be among the presenting features. The clinical symptoms may start suddenly or develop slowly over days or weeks.

Granulomatosis with Polyangiitis (GPA)

Upper and lower respiratory tract inflammation together with GN and positive ANCA, especially PR-3 ANCA, is typical for GPA in childhood. Granulomas are found in the tissue. The largest published cohort is the multicenter ARChiVe (A Registry for Children with Vasculitis) study, which included 183 children with GPA. A comparison of presenting features is shown in Table 25.4 [61]. Over half of the patients were female and white, while the median age at disease onset was 14 years. The median time to diagnosis was 2.1 months, but varied from 0–71 months. The most common presenting features were constitutional (88%), renal (83%), pulmonary (74%), ear, nose and throat (70%), musculoskeletal (65%), and cutaneous (47%). Renal manifestations included proteinuria (72%), hematuria (72%), decreased GFR creatinine clearance (54%), and nephrotic syndrome with edema (11%). Almost all of the patients with a biopsy had GN (94%). Thirteen percent had renal failure requiring dialysis and 7% progressed to ESKD. In the available renal biopsy specimens, pauci-immune and/or necrotizing GN was pres-

Venous thrombosis	0 (0)	3 (2)

ent in 80% of GPA patients [61]. In a single-center Canadian study of 25 patients with GPA, 88% had GN and 20% required dialysis at disease onset. Twenty-eight percent had elevated creatinine at disease onset and an additional 16% had an elevated creatinine during follow-up [62]. A large cohort from the PRINTO vasculitis database included 56 children with GPA. The demo-

graphic and most of the clinical data confirms results of the ARChiVe data, but patients from the PRINTO registry were younger (median 11.7 years), and had more frequent inflammation of the ears, nose, and throat (91%) and the eyes (35%) [63]. Sixty-seven percent were ANCA-PR3 positive [61, 63].

Microscopic Polyangiitis (MPA)

MPA characteristically involves small vessels of the kidneys and lungs and patients are positive for MPO-ANCA, and there are no granulomas in the pathologic specimens. The ARChiVe database included 48 pediatric MPO patients, who were significantly younger than GPA patients, with a median age at the time of diagnosis of 12 years. At presentation, the most common clinical manifestations were constitutional symptoms (85%), renal (75%), gastrointestinal (58%), musculoskeletal (52%), and cutaneous (52%). Results are shown in Table 25.4 [61]. The kidneys were more severely affected in MPA compared to GPA. The serum creatinine was moderately to severely elevated in almost half of the MPA (48%) patients. The rates of proteinuria and hematuria were 69% and 60%, similar to GPA, but almost one-quarter of patients presented with nephrotic syndrome with edema, and one-quarter of patients required dialysis. Ten percent progressed to ESKD [61]. Where renal biopsies were obtained, pauci-immune and/or necrotizing GN was seen in 78% [61]. Renal disease was a hallmark of MPA, present in 94% of MPA patients in the meta-analysis that included 130 pediatric patients [64]. The study bias was that it included studies from 1950 and MPA was previously not clearly defined. In ARChiVe, more than half of the patients had MPO-ANCA and/or p-ANCA (55%) and only 17% had PR3-ANCA and/or c-ANCA. ANCA was not present in 26% of the patients [61].

Eosinophilic Granulomatosis with Polyangiitis

EGPA is characterized by asthma or allergic rhinitis, skin disease, and vasculitis, which mostly involves small vessels and eosinophilic infiltration accompanies extravascular granulomas [65]. It is very rare in childhood, with only two out of 114 children with AAV having EGPA in the Canadian registry [66]. The largest pediatric cohorts include from 9–14 children with EGPA [67–69].

Laboratory Results

Marked elevation of inflammatory markers is typical, both erythrocyte sedimentation rate (ESR) and c-reactive protein. In half of GPA patients and one-third of MPA, total white blood cells and neutrophils are elevated. Eosinophil levels are normal for most patients with GPA and MPA. Over 80% of all patients have anemia and approximately one-third have elevated platelet counts. Von Willebrand antigen may also be elevated [61]. More than half of MPA patients and around 26% of GPA patients have MPO-ANCA and/or p-ANCA; whereas 67% of patients with GPA and 17% of patients with MPA have PR3-ANCA [61, 63]. ANCA, tested by either immunofluorescence or ELISA, was not present in 26% of MPA patients and 5% of GPA patients in ARChiVe [61, 66].

Disease Activity Assessment

Assessing disease activity and disease damage are important to help guide treatment decisions. Standardized tools are lacking in the field of childhood vasculitides. The most commonly used score in adult systemic vasculitides is the Birmingham Vasculitis Activity Score (BVAS), that was designed in 1994 [70], while the BVAS version 3 from 2009 is the most recent [71]. It is a composite score of 56 clinical features from 9 organ systems. Each feature is enumerated, according to the severity. Symptoms are categorized as new, persistent, or worsening [71]. The BVAS/WG is a disease-specific, modified version, validated for use in GPA [72]. To acknowledge the differences in childhood vasculitis, the Pediatric Vasculitis Activity Score (PVAS) was developed and validated [73]. PVAS was created by modifying BVAS. The pediatric vasculitis reg-

istry was reviewed to identify clinical features missing in the BVAS version; consequently, eight additional pediatric items were added, and others redefined, making 64 active items in nine categories. Age-specific reference ranges for blood pressure and renal function, and a pediatric definition of weight loss are incorporated. The score correlated well with physicians' global assessment, treatment decisions, and ESR [73].

Disease Damage Assessment

In 1997 the Birmingham Vasculitis Group developed and validated the Vasculitis Damage Index (VDI), a standardized tool for clinical assessment of damage in the systemic vasculitides [74]. Damage was defined as irreversible change resulting from scars. Currently, the PReS.

Childhood Arthritis and Rheumatology Research Alliance joint effort to make a pediatric version of VDI (pVDI) is underway. Vasculitis damage is defined as the presence of irreversible features present for at least 3 months since the onset of vasculitis and the pVDI contains 72 items in 10 systems [75]. Morishita et al. used pVDI to assess early outcomes in children with AAV [76].

Table 25.5 represents a roadmap of investigations suggested in all (first-line) and in certain (second-line) children with renal vasculitides [77].

Renal Transplantation

Due to the severity and rapid progression of the renal involvement in AAV, a substantial proportion of children progress to ESKD and require renal transplantation. In a recent single-center study assessing outcome of renal transplantation in these patients, seven children (3 with GPA, 4 with MPA) were described [78]. Time from diagnosis to transplant was 30 ± 12 (range, 17–48) months. Median duration of follow-up post transplantation was 27 months (range, 13–88 months). Median eGFR at last follow-up was 77 ml/min/1.73 m^2 (range, 7.9–83.5). One patient lost her transplant to acute cellular rejection following non-adherence to immunosuppression after

Table 25.5 Laboratory investigations in pediatric AAV. Modified from Plumb et al. [77]

First-line investigations	Second-line investigations
Hematology: Full blood count, Erythrocyte sedimentation rate, coagulation profile	Histology: renal/lung biopsy
Immunology: Lymphocyte subsets with CD19 count (pre-RTX), Immunoglobulins (Ig): IgG, IgM, IgA, IgE	Imaging: fibroendoscopy/X-ray sinuses, Chest high resolution computed tomography, MRI/MR angiography head
Biochemistry: Urea, creatinine and electrolytes, Liver function tests, Lactate dehydrogenase, Creatinine kinase, Thyroid function, Pancreatic function (amylase/lipase), Urine protein: creatinine ratio	Immunology: Anti-glomerular basement membrane antibodies, Coeliac screening
Infectious: Serology HBV, HCV, parvovirus B19, HIV, EBV, CMV, Mycoplasma, VZV and Anti-Streptolysin titre; Mantoux and/or QuantiFERON-TB testing, Blood culture, Urine microscopy and cell culture	Neurological: Nerve conduction studies
Autoantibody panel: Anti-neutrophil cytoplasmic antibodies, Antinuclear antibodies, Anti-double stranded DNA antibodies, Anti-cardiolipin and anti-phospholipid antibodies, Lupus anticoagulant	Ambulatory blood pressure monitoring; fundus oculi
Complement (C) function: C3, C4	Birmingham vasculitis activity score
Chest X-ray, Electrocardiography, Echocardiography	Renal angiography, Renal dimercaptosuccinic acid (DMSA) scan

21 months of stable transplant function. No patient had recurrence of vasculitis, either renal or extrarenal.

Monogenic Forms of Renal Vasculitis

Recently, monogenic forms of autoinflammatory diseases have been identified that present predominantly with features of systemic vasculitis in childhood. Their discovery has shed light on new pathophysiological pathways which may allow innovative management, both in terms of monitoring biomarkers of disease activity and in terms of targeted therapeutic approaches [79].

Type I Interferonopathies

Type I interferons (IFNs) are regulatory proteins involved in immune response against viral infections. Their activation is induced by recognition of foreign nucleic acids and is tightly regulated by a complex network of pathways that involve both the innate and adaptive immune system. Type I interferonopathies are a group of rare monogenic disorders associated with constitutive overproduction of type I IFNs and provide unique insights into the mechanisms of differentiating self nucleic acids from non-self nucleic acids [80]. There is a marked overlap of clinical features across different type I interferonopathies, particularly the involvement of the central nervous system and skin as well as lung inflammation in certain genotypes. The clinical expression of type I interferonopathies may be influenced by differential exposure to environmental) triggers such as infection [81, 82].

Stimulator of interferon genes -associated vasculopathy with onset in infancy.

Stimulator of interferon genes (STING)-associated vasculopathy with onset in infancy (SAVI) is a type I interferonopathy caused by a gain-of-function mutation in the transmembrane protein 173 gene (*TMEM173*) [83]. *TMEM173* encodes STING, which is a transmembrane protein localized in the endoplasmic reticulum and functions in the transduction of a type I IFN response to different) types of cytosolic DNA. In patients with SAVI, constitutively activated STING leads to increased transcription of the type I IFN gene *IFNB1* and production of IFN-β, which further up-regulates the transcription of IFN-response genes.

SAVI is clinically characterized by neonatal-onset systemic inflammation, a severe cutaneous vasculopathy and major interstitial lung disease [83]. Over-expression of STING induces endothelial cell activation resulting in a severe inflammatory vaso-occlusive process leading to tissue loss on hands and feet at an early age. Renal involvement in SAVI is rare and usually mild, with microscopic hematuria and mild proteinuria associated) with hypertension [84]. One patient with SAVI developed kidney involvement with apolipoprotein L1 (APOL1)-associated collapsing glomerulopathy suggesting the role of IFN pathways in the pathogenesis of APOL1-associated nephropathy [85]. Systemic inflammation in patients with SAVI is refractory to conventional immunosuppressive medications, but treatment with JAK inhibitors (tofacitinib, ruxolitinib and baricitinib) could suppress the expression of STING-induced IFN-response genes and lead to clinical improvement.

Coatomer Associated Protein Subunit Alpha Gene Syndrome

Coatomer associated protein subunit alpha gene (COPA) syndrome is an autosomal dominant syndrome caused by mutations in the coatomer associated protein subunit alpha (COPα) gene (*COPA*) [86]. It is characterized by interstitial lung disease, inflammatory arthritis and kidney disease in childhood. COPα is part of the coatomer protein complex I involved in retrograde movement of vesicles from the Golgi apparatus to the endoplasmic reticulum (ER). Mutations in COPA lead to defective intracellular transport, resulting in immune dysregulation that can promote both autoinflammation and autoimmunity. Immunologically, COPA syndrome is associated with autoantibodies, significant skewing of CD4 T cells toward a T helper type 17 (Th17) phenotype implicated in autoimmunity, and proinflammatory cytokine expression such as IL-1β, IL-6

and IL-23. Patients with COPA syndrome have a strong upregulation of type I IFN-stimulated genes similar to patients with SAVI [87, 88].

Renal disease was reported in 45% of patients with COPA syndrome and typically presents as GN with proteinuria and decreased renal function [88, 89]. Kidney biopsy findings were heterogeneous, including crescentic GN and focal mesangial hypercellularity with immune complex deposition ranging from isolated IgA deposits to a "full house" immunofluorescence (IgM, IgG and C1q) resembling lupus nephritis. Increased type I IFN signaling suggests that JAK inhibitors as a possible treatment for COPA syndrome [87, 88].

Deficiency of Adenosine Deaminase 2

Deficiency of adenosine deaminase type 2 (DADA2) is a monogenic vasculitis syndrome caused by loss-of-function mutations in the adenosine deaminase type 2 (*ADA2*) gene, and clinically presents as an inflammatory vasculopathy [90, 91]. *ADA2* is a highly polymorphic gene, and more than 60 disease-causing mutations have been described, mostly missense variants.

Adenosine deaminase proteins regulate purine metabolism, and in the absence of ADA1 toxic deoxyadenosine nucleotides accumulate in lymphocytes leading to the severe combined immunodeficiency. ADA2, in addition to its deaminase activity, functions as a growth factor for endothelial cells and is involved in leukocyte development and differentiation. ADA2 appears to be critical for the maintenance of vascular integrity and in cross-talk between macrophages and pericytes. Increased production of proinflammatory cytokines was found in skin biopsies and blood samples from patients with DADA2 [92].

The disease has a highly variable clinical presentation, with 77% of patients presenting before the age of 10 years. A characteristic clinical feature is an inflammatory vasculopathy of small- and medium-sized arteries, with manifestations ranging from livedo reticularis to PAN and life-threatening ischemic or hemorrhagic stroke. Patients with DADA2 usually present with fever, increased acute phase reactants and a vasculitic skin rash such as livedo reticularis, nodules, purpura, skin ulcers and digital gangrene. Vasculitis in DADA2 can affect other organs, including intestine, liver and kidney. The most common renal manifestations in patients with DADA2 are arterial hypertension, renovascular aneurysms, renal artery stenosis and kidney inflammation with dense lymphocytic infiltration and glomerular scarring [91, 93].

Genetic testing for DADA2 and measurement of ADA2 enzymatic activity should be considered for patients with early-onset PAN-like systemic vasculitis, refractory PAN and familial vasculitis. The mainstay of treatment for DADA2 is anti-TNF-α biologic drugs, which are effective in reducing fever episodes, vasculitic disease activity and preventing ischemic strokes, but are not effective for the immunodeficiency [94, 95].

Hypocomplementemic Urticarial Vasculitis Syndrome

Hypocomplementemic urticarial vasculitis syndrome (HUVS), or McDuffie syndrome, is a small vessel vasculitis associated with urticaria, hypocomplementemia (both C3 and C4) and anti-C1q circulating antibodies [96]. It affects the skin, joints, eyes, lungs and kidneys. Diagnostic criteria have been formulated [97] and diagnosis requires the presence of chronic urticarial exanthema and hypocomplementemia plus at least two minor diagnostic criteria (leukocytoclastic vasculitis, arthralgia/arthritis, GN, uveitis/episcleritis/conjunctivitis, abdominal pain, positive anti-C1q antibodies) and exclusion of autoimmune disease (systemic lupus erythematosus [SLE], Sjögren syndrome, cryoglobulinemia). It affects predominantly females with an 8:1 ratio, typically in the fifth decade of life. In a recent review of 60 cases described in the literature [98], renal involvement was identified in 14–50% of cases of HUVS. The most frequent presenting symptoms were hematuria and proteinuria (70% of patients). One third of patients with renal involvement had reduced kidney function at pre-

sentation (eGFR below 60 ml/min/1.73 m^2). The most frequent glomerular pattern of injury was membranoproliferative GN (35%), followed by mesangioproliferative (21%) and membranous (19%) GN. Crescents were found in 23% of cases and were associated with a more severe presentation, as expected. By immunofluorescence, positivity for IgG, IgM, C1q and C3 was found in the mesangium and along the glomerular capillary walls, indicating immune-complex deposition. This finding, together with the observation that 50–55% of patients with HUVS have a positive ANA, indicates that this disease has similarities to SLE. Indeed, in about 50% of patients disease progression, if not prevented, leads to the development of SLE [99].

In the cohort of HUVS patients with renal involvement [98], 18% were children, and in children the male to female ratio was 1:1. Renal involvement in HUVS led to ESKD in 15% and 17% of cases in adults and children, respectively. Treatment should therefore be aggressive and timely, following the indications given below for other forms of renal vasculitis in children.

Studies in familial forms have revealed that HUVS can be caused by a homozygous mutation in *DNASE1L3* [100]. The protein encoded by *DNASE1L3* is an endonuclease capable of cleaving both single- and double-stranded DNA. Individuals harboring mutations in this gene develop HUVS in infancy/childhood, have a substantial risk of developing severe organ (kidney, lung) involvement and full-blown SLE, and may require life-long immunosuppressive treatment.

Treatment and Management of Renal Vasculitis

Renal vasculitides in children are extremely rare, though they determine significant morbidity and mortality, particularly if there is diagnostic delay [101]. Therefore, conducting traditionally designed randomized clinical trials is not feasible in children, and current therapeutic strategies are based on small case series or data derived from RCTs performed in adults. Despite these limitations, there have been substantial improvements in management of these conditions. This progress is related to the use of different immunosuppressive medications and newer biologic agents, and to the broader recognition of monogenic forms, which may benefit from targeted therapy. Moving forward, innovative trial design tailored to small numbers is necessary, as is a standardized approach to the management of these rare pediatric diseases. Consequently, there are now recommendations based on consensus and, where possible, on evidence, for management of these conditions. The European consensus-based recommendations on diagnosis of rare pediatric vasculitides are a successful example of this approach [6]. As described above, the AAV include GPA (formerly known as Wegener's granulomatosis), MPA, EGPA (previously referred to as Churg-Strauss syndrome) and renal-limited microscopic vasculitis, also known as pauci-immune or crescentic GN (GN). Pauci-immune GN is a fulminant, relapsing disease in children [102, 103] and is frequently associated with RPGN, characterized by clinical features of GN and rapid decline of renal function, with pathology exhibiting crescent formation affecting the majority of glomeruli. RPGN and its treatment are covered in Chap. 50 of this textbook.

A possible therapeutic approach is outlined in Table 25.6. Treatment consists of an aggressive induction treatment, aimed at switching off the fulminant inflammatory disease process, followed by a maintenance phase aimed at consolidating remission. There is no clear consensus as to when and how treatment should be discontinued. However, following induction, assessment of organ damage and of the side effects of therapy should be considered when designing a maintenance strategy that balances risks and benefits. Even in terms of induction, recent positive results from studies assessing RTX and avacopan should be considered, with the objective of minimizing long-term toxicity, such as sterility, malignancy, stunted growth and osteoporosis/aseptic necrosis, which is especially important in children. While GPA and MPA are considered separate entities, they are managed identically.

Table 25.6 AAV treatment. Modified from Pediatric Kidney Disease 2nd edition [144]

Agent	Route	Administration dosage and duration
Induction treatment		
Pulse Methylprednisolone[a]	IV	400–600 mg/m^2/day (max 1000 mg/day) for 3–5 consecutive days
Prednisone[a] Prednisolone[a]	Oral	1.5–2.0 mg/kg/day (max 60 mg/day) for 4 weeks Gradually taper down over 6–12 months
Cyclophosphamide[b]	IV	Start at 500 mg/m^2/day Increase monthly by 125 mg/m^2/day to 750–1000 mg/m^2/day (max 1000 mg/day) for 6–10 times
Cyclophosphamide	Oral	2 mg/kg/day for 2–3 months
Rituximab[c]	IV	375 mg/mg/m^2/day weekly for 4 times
Plasmapheresis		Double volume on alternate day for 2 weeks
Maintenance treatment		
Azathioprine	Oral	2.0 mg/kg/day for 9 months Switch from cyclophosphamide at 3 months
Rituximab[d]	IV	Optimal dose and timing in children not available

IV intravenous
[a] Methylprednisolone pulses followed by oral prednisone or prednisolone 1.5–2.0 mg/kg/day for 4 weeks, with gradually tapering until discontinuation over 6–12 months
[b] Cyclophosphamide followed by azathioprine switching from cyclophosphamide at 3–6 months
[c] Given with pulse and oral corticosteroids
[d] No data available on use of RTX for maintenance if it has been used at induction

Induction Treatment

Cyclophosphamide and Glucocorticoids

Cyclophosphamide and glucocorticoids are well-established induction treatment of AAV. Therapy with cyclophosphamide and oral prednisone/prednisolone for 3–6 months was found to lead to clinical remission in 93% of adult patients with AAV [104], and improved remission rate from 56% to 84.7% and decreased relapse rate by approximately 50% [105]. At disease onset, given the rapidity and severity of renal manifestations, pulse IV methylprednisolone is recommended [6] at 400–600 mg/m^2/day (maximum dose 1000 mg/day) for 3–5 consecutive days. This treatment should be followed by oral prednisone/prednisolone 1.5–2.0 mg/kg of ideal body weight daily (maximum dose 60 mg/day) for 4 weeks, followed by gradual tapering over 6–12 months. Cyclophosphamide can be administered in oral or IV pulse regimens. Daily oral cyclophosphamide should start at a dose of 2 mg/kg/day and continue for 2–3 months while adjusting the dose to keep the nadir leukocyte count above 3000/mm^3. When a regimen of IV pulsed cyclophosphamide is used, the initial dose should be approximately 500 mg/m^2 and increased monthly by 125 mg/m^2 to 750–1000 mg/m^2 (maximum dose 1000 mg/day) every 4 weeks for 6–10 doses. Cyclophosphamide should be given with adequate oral or IV hydration and with mesna, a drug which binds the cyclophosphamide metabolite which is toxic for the bladder mucosa, to minimize the risk of hemorrhagic cystitis. Subsequent doses should be adjusted depending on the 2-week post-treatment nadir leukocyte count. A RCT of IV pulse cyclophosphamide versus daily oral cyclophosphamide for induction of remission in AAV with renal involvement has been conducted [106]. This trial demonstrated that IV pulse and daily oral cyclophosphamide had similar remission rates and times to remission. Patients receiving the pulse regimen were administered approximately one-half of the cumulative dose of cyclophosphamide of the oral regimen and experienced a significantly lower rate of leukopenia for the same duration of therapy [106]. In a meta-analysis of RCTs, the pulse regimen was associated with fewer infections, increased risk of relapse, less leukopenia, and a trend toward a higher rate of requiring renal replacement therapy [107]. Because of a lower cumulative dose and a lower risk of side effects, the pulse regimen is recommended as the first line of induction therapy for pediatric pauci-immune GN. Combination therapy with oral cyclophosphamide (2 mg/kg/day) and pulse methylprednisolone followed by oral prednisolone resulted in a high remission rate (70–100%) and low mor-

tality in pediatric ANCA-associated GN [108–110]. Thus, the duration of continuous oral cyclophosphamide should usually be limited to 3 months, with a maximum of 6 months, but whether the same duration can be applied to IV pulsed cyclophosphamide is unclear [111].

Other agents employed in remission induction include anti-TNF-α antibodies and MMF. It is now recognized that RTX is as effective as cyclophosphamide in severe or relapsing disease, particularly for those patients at risk for glucocorticoid or cyclophosphamide toxicity. PLEX and IV immunoglobulin therapy may also be used as adjuvant therapy to induce remission in more severe cases.

The only randomized study of pulse methylprednisolone is the MEPEX trial [112]. This study investigated whether the addition of PLEX to oral corticosteroids and cyclophosphamide was more effective than pulse methylprednisolone (1 g × 3) for renal recovery in patients who presented with renal failure. In this study, there was no difference in mortality and safety, but PLEX appeared more effective than pulse methylprednisolone in preserving kidney function.

Rituximab

Despite its effectiveness, the induction regimen with high-dose glucocorticoids and cyclophosphamide has significant morbidity in the long-term, which is particularly relevant in children. In a cohort of eight adults who presented with childhood-onset AAV, at a median of 19 years of follow-up, seven suffered from infections, four were infertile, two had skeletal complications, and one developed malignancy [113].

RTX is a chimeric monoclonal antibody that targets the CD20 antigen on the surface of B cells. Several case series and small studies have reported the efficacy of RTX in refractory AAV. Two randomized trials examined RTX as induction therapy for AAV. In the RITUXVAS trial, 44 patients with newly diagnosed AAV were randomized to either RTX or cyclophosphamide groups. The RTX group received four 375 mg/m^2 doses of RTX given weekly and IV cyclophosphamide at a dose of 15 mg/kg, 2 weeks apart for a total of two doses. The cyclophosphamide group received 15 mg/kg of IV cyclophosphamide every 2 weeks × 3 doses, and then every 3 weeks for a maximum of 10 doses. Both groups received IV methylprednisolone, followed by oral corticosteroids. There were no significant differences in the rates of remission and serious adverse events [114]. In the RAVE trial, 197 ANCA-positive patients with either GPA or MPA were randomized to treatment with either RTX or conventional cyclophosphamide followed by azathioprine. The RTX group received four weekly doses of 375 mg/m^2. The cyclophosphamide group received 2 mg/kg/day orally for 3 months, followed by oral azathioprine at a dose of 2 mg/kg/day for 3 months. Both groups received 1–3 pulses of methylprednisolone (1000 mg each), followed by prednisone at a dose of 1 mg/kg/day, tapered by 5 months. At 6 months, 64% of the patients in the RTX group, compared with 53% of the patients in the cyclophosphamide–azathioprine group, experienced complete remission. There were no significant differences between the two treatment groups in the rates of complete remission, adverse events, or relapse [115]. At 12 and 18 months, 48% and 39%, respectively, of the patients in the RTX group had maintained complete remission, compared with 39% and 33%, respectively, in the cyclophosphamide–azathioprine group. There were no significant differences between the two groups in the duration of complete remission, the frequency or severity of relapses, and adverse events. This study shows that RTX is equivalent to cyclophosphamide in efficacy for the induction and maintenance of remission over 18 months [116] Following these important results obtained in adult clinical trials, the use of RTX in children with AAV is being evaluated in the Pediatric Polyangiitis Rituximab Study (PEPRS) [117]. This is an open-label study which has enrolled 25 children with newly diagnosed or relapsing GPA or MPA. They have received weekly IV RTX for 4 weeks at a dose of 375 mg/m^2 as well as glucocorticoids (1 mg/kg/day [max 60 mg/day]) tapered to 0.2 mg/kg/day (max 10 mg/kg/day) by 6 months. All patients received three doses of IV methylprednisolone at 30 mg/kg/day with a maximum of 1 g/day prior to the first RTX infusion.

The safety profile and pharmacokinetics were comparable to adults with GPA or MPA. No new safety signals have emerged thus far [118]. Basu et al. reported a retrospective analysis of 11 pediatric MPA patients treated with a cyclophosphamide free, RTX- and MMF-based protocol with a median follow-up period of 20.9 months [119]. Patient and renal survival at 1 year were 100%. Despite varying degrees of renal involvement at presentation, kidney function recovered in all patients, with a median eGFR of 79.5 ml/min/1.73 m^2. At last follow-up, 91% of patients were in complete remission and one (9%) child was in partial remission.

Hence, it seems reasonable to use RTX in children with severe AAV when cyclophosphamide is not available or not advisable. In terms of RTX dose, it is possible that an alternate regimen of 2 doses at 750 mg/m^2 (max 1000 mg) administered 14 days apart as in rheumatoid arthritis may be comparable to the classic regimen [77] RTX in AAV and other autoimmune disorders has been shown to induce hypogammaglobulinemia [120]: 56% of adults had IgG hypogammaglobulinemia during follow-up; IgG replacement was initiated because of recurrent infection in 4.2% of patients. No association was found between IgG levels and cumulative RTX dose.

Plasma Exchange

In severe AAV, especially with pulmonary haemorrhage or RPGN, or when the patient has significant deterioration despite an appropriate induction regimen, therapy is often augmented by PLEX, a strategy targeted towards removing the pathogenic antibodies [121–123]. Following the first positive report on PLEX in nine patients with crescentic GN, of whom five rapidly recovered renal function, [25, 124] the use of PLEX was recommended only in patients with the most severe renal disease (creatinine >500 μmol/L equivalent to >5.66 mg/dl) [125] due to the results of studies demonstrating a beneficial effect of PLEX only in dialysis-dependent patients [126, 127]. The MEPEX trial [112] compared PLEX to pulse methylprednisolone in addition to oral prednisolone and oral cyclophosphamide in patients with a new diagnosis of AAV and serum creatinine >500 μmol/L. PLEX was associated with a significantly higher rate of kidney recovery at 3 months (69% with PLEX vs. 49% with pulse methylprednisolone), and also with a reduction in risk for progression to ESKD at 12 months. On the other hand, patient survival and the rate of severe adverse events were similar in both groups [112].

More recently, the PEXIVAS trial included all patients with a GFR <50 ml/min/1.73 m^2 and thus aimed to answer the question of whether PLEX is a good option for patients with moderate kidney function impairment. PEXIVAS showed that after a follow-up of almost 3 years routine PLEX did not provide reduce the rate of the composite outcome of ESKD or death. Taken altogether, these results indicate that PLEX should be reserved for severe cases of AAV with marked reduction in kidney function or requiring dialysis [128].

The 2021 KDIGO guidelines suggest to consider plasmapheresis for patients with refractory disease due to drug intolerance, non-adherence, concomitant morbidities, a secondary drive for vasculitis such as malignancy, drugs or infection, and true treatment failure and for patients with diffuse alveolar bleeding with hypoxemia. They recommend plasmapheresis for patients with combined AAV and anti-GBM GN, according to the proposed criteria and regimen for anti-GBM GN [129].

Mycophenolate Mofetil

Another agent which has been investigated in AAV induction as a safer, less toxic alternative to cyclophosphamide is MMF, an orally administered lymphocyte suppressive agent with short duration of action, which in small studies appeared beneficial in AAV, both in adults and in children [130, 131]. TA RCT assessed whether MMF was non-inferior to cyclophosphamide for remission induction in newly diagnosed AAV patients [132]. All patients received the same oral glucocorticoid regimen and were switched to azathioprine following remission. The primary endpoint was remission by 6 months and compliance with the tapering glucocorticoid regimen. MMF was non-inferior to cyclophosphamide for

remission induction in AAV, but resulted in a higher relapse rate. Therefore, if other options are unavailable or unadvisable, MMF can be considered for induction in patients with non-severe or life-threatening AAV.

Anti-TNF Therapy

In AAV, TNF-α may have a pathogenic role, both in the formation of granulomas and in neutrophil priming, which enhances the expression of endothelial adhesion molecules on the cell surface and the capability of ANCA to stimulate neutrophil degranulation, a driver of vascular damage [77]. Etanercept, infliximab and adalimumab have been investigated in this setting with mixed results, and evidence is insufficient to recommend their use at this time [118].

Avacopan

Evidence of a role of complement, especially of C5a, a powerful anaphylatoxin which recruits neutrophils to the inflammatory site, and of the C5aR, in the pathogenesis of AAV [18] led to the use of complement inhibition with the oral C5aR antagonist avacopan. Efficacy, safety and steroid-sparing effects of avacopan in patients with GPA/MPA were shown in two phase II trials [133, 134] and a phase III trial [135]. In the phase III RCT, adult patients with AAV were randomized in a 1:1 ratio to receive oral avacopan at a dose of 30 mg twice daily or oral prednisone on a tapering schedule. All patients received either cyclophosphamide (followed by azathioprine) or RTX. The first primary end-point was remission, defined as a BVAS score of 0 at week 26 and no glucocorticoid use in the previous 4 weeks. The second primary end-point was sustained remission, defined as remission at both weeks 26 and 52. Both end-points were tested for non-inferiority and for superiority. Avacopan was non-inferior, but not superior to prednisone taper with respect to remission at week 26 and was superior to prednisone taper with respect to sustained remission at week 52. This remarkable result needs to be confirmed in a pediatric population, but suggests the possibility of a prednisone-free induction treatment for AAV.

Adjunctive Measures

The SHARE initiative European recommendations on management of pediatric vasculitides suggest the use of antiplatelet agents to prevent thrombotic complications associated with systemic vasculitis in the young [136]; antibiotic prophylaxis to prevent Pneumocystis jiroveci pneumonia at induction; osteoporosis prophylaxis with vitamin D in children treated with prednisone/methylprednisolone; and gastric protection (e.g. with protein pump inhibitors) in case of gastric pain.

Maintenance Treatment

Following induction of remission, maintenance therapy is necessary to prevent relapse. Long-term toxicity (infertility, risk of bladder cancer and lymphoproliferative disorder) makes cyclophosphamide an unattractive option for maintenance after successful induction. The CYCAZAREM trial (cyclophosphamide vs. azathioprine for early remission phase of vasculitis) found that azathioprine was as effective as continuous cyclophosphamide at maintaining remission and was associated with fewer side effects [104]. In this study, both study groups received the same induction therapy, consisting of oral cyclophosphamide and prednisolone. Once remission had been achieved, between 3 and 6 months, patients were randomly assigned to treatment with azathioprine (2 mg/kg/day) or to continued cyclophosphamide therapy (1.5 mg/kg/day), with the same dose of prednisolone (10 mg/day) up to 12 months. Subsequently, from 12 to 18 months, all patients received azathioprine (1.5 mg/kg/day) and prednisolone (7.5 mg/kg/day). The primary outcome was relapse at 18 months, and there was no difference between the groups. Once azathioprine was established as a suitable alternative therapeutic agent for maintenance, its optimal duration was not evaluated. The REMAIN study addressed this question and found that azathioprine given in association with low-dose glucocorticoids for 48 months compared to 24 months reduced the risk of relapse threefold. Moreover,

the 48-month group had improved renal survival and reduced incidence of ESKD compared to the 24-month group [137]. The use of LEF in maintaining remission is less well studied, but results of 1 prematurely ended randomized study indicated that, at a dose of 30 mg/day, leflunomide was more effective than methotrexate at preventing relapse despite being associated with a higher rate of adverse events [138].

The use of MMF was evaluated in the IMPROVE study, which at a median follow-up of 39 months showed that MMF was inferior to azathioprine at preventing relapses during maintenance [139]. In this study, patients with AAV who attained remission with cyclophosphamide and prednisolone, were randomized to either MMF at a dose of 2000 mg/day or azathioprine at a dose of 2 mg/kg/day. Relapse was more common in the MMF group than in the azathioprine group. Both groups had similar adverse event rates. Therefore, azathioprine is preferred to MMF or cyclophosphamide for maintenance therapy in AAV.

Recently, the use of RTX for the maintenance of AAV has been investigated. The MAINRITSAN trial compared the use of repeated doses of RTX (500 mg at weeks 0 and 2, then every 6 months for 5 courses) with daily azathioprine after cyclophosphamide induction for new and relapsing patients [140]. The adult patients received azathioprine or RTX. RTX was significantly better than AZA since at 28 months major relapse had occurred in 29% of patients in the azathioprine group and in 5% of patients in the RTX group, without significant differences in severe adverse events. In considering the results of this trial, it is important to note that only a cyclophosphamide induction was used. This trial does not provide information about RTX maintenance after RTX induction. The RTX dose utilized was also different from previous trials (500 mg twice at a 14-day interval after remission is achieved, with subsequent 500 mg doses every 6 months for 5 courses), while the azathioprine dose was tapered between months 12–22, possibly to a sub-therapeutic dose [118]. The RITAZAREM trial investigated the use of RTX for the treatment of relapses in adults with AAV. RTX in conjunction with glucocorticoids demonstrated a high level of efficacy for the reinduction of remission in patients with AAV who have relapsed [141]. Seventy-nine percent and 36% had previously received cyclophosphamide and RTX, respectively. The vast majority (90%) achieved remission by 4 months. The use of RTX therefore appears promising, although not validated in a pediatric cohort, and the optimal dose and timing are not yet established.

The use of a B cell modulator, belimumab (a monoclonal antibody directed against BAFF, a B cell survival factor), has been investigated in the BREVAS study [142]. In this double-blind, placebo-controlled study, adult patients with AAV were randomized 1:1 to receive azathioprine (2 mg/kg/day), low-dose oral glucocorticoids (≤10 mg/day), and either IV belimumab (10 mg/kg) or placebo, following remission induction with RTX or cyclophosphamide along with glucocorticoids. Belimumab, although safe, did not reduce the risk of relapse of vasculitis; therefore, its use is not warranted for maintenance of AAV.

Treatment of Relapses

Relapses are not infrequent in AAV. A relapse is defined as the reactivation of vascular inflammation. It is important to assess the severity of the relapse by identifying which organs are affected. Most guidelines recommend basing treatment on what was used previously at induction and then switching (for example from cyclophosphamide to RTX or vice versa). However, if the patient responded fully to RTX at induction, it can be reasonable to repeat this therapeutic approach [143].

Lupus Nephritis

26

Stephen D. Marks, Matko Marlais, and Kjell Tullus

Introduction

Juvenile onset systemic lupus erythematosus (JSLE) is a lifelong, life-limiting, multi-system, autoimmune disorder, which is episodic in nature with a broad spectrum of clinical and immunological manifestations. JSLE is characterised by widespread inflammation of blood vessels and connective tissues affecting the skin, joints, kidneys, heart, lungs, nervous and other systems. There is a higher rate and more severe organ involvement in children than in adults (especially with respect to haematological and renal disease) [1–4]. Renal involvement with biopsy-proven lupus nephritis (LN) occurs in up to 80% of all cases of JSLE and is a major determinant of the prognosis. We currently have an increasing armamentarium of immunosuppressive agents that can be used to treat active disease with newer agents on the horizon. However, there is still a significant morbidity and mortality for severe disease with considerable physical and psychosocial morbidity due to the variable, and often progressive, clinical course of JSLE. This results from both the sequelae of disease activity and the side-effects of medications, including the infectious risks from over-immunosuppression, and longer-term risks with accelerated atherosclerosis [5].

There are differences between clinical diagnosis of JSLE and the utility of classification criteria of patients, which can be used in clinical trials. The American College of Rheumatology classification criteria for SLE gives 95% sensitivity and 96% specificity in clinical practice when 4 of 11 criteria are met (Table 26.1) [6, 7]. The Systemic Lupus International Collaborating Clinics (SLICC group) revised and validated the ACR classification criteria with improved methodology in order to improve clinical relevance and incorporate better understanding of the aetiopathogenesis and immunology of SLE [8]. These classification criteria have been validated in multicenter studies of children and young people with SLE [9, 10]. There has been a recent adaptation with the development of a Childhood Lupus Improvement Index (CHILI) as a tool to measure response to therapy in JSLE [11].

	Elevated anti-Smith antibodies
	Positive antiphospholipid antibodies (previously lupus erythematosus cell tests or false positive *Treponema pallidum* immobilisation/Venereal Disease Reference Laboratory)
11.	**Elevated anti-nuclear antibodies (after exclusion of drug-induced lupus)**

Epidemiology

JSLE accounts for up to 20% of all SLE cases, with epidemiological studies demonstrating a minimum incidence in a paediatric population of 0.28 per 100,000 children at risk per year [12] with a prevalence in children and adults from various epidemiological studies of between 12.0 and 50.8 per 100,000 [13–20]. However, SLE has been reported to be more common in children from China, Hong Kong and Taiwan and three times more frequent in Afro-Caribbean than Caucasian children [21, 22]. The prevalence is increased in minority ethnic backgrounds in the United Kingdom where patients were diagnosed sooner as age at diagnosis was lowest (but not age at symptom onset) in Black African/Caribbean patients compared to White Caucasians [23]. In addition, the severity of renal and neuropsychiatric lupus is increased in Afro-Caribbean children [24]. Asian and Afro-Caribbean children are over six times more likely to be affected when compared to Caucasian children in the United Kingdom [25]. SLE is more prevalent in females of childbearing age, possibly due to the hormonal influences, and is commoner over the age of 10 years [26, 27].

Etiopathogenesis

SLE is a multifactorial disorder with multigenic inheritance and various environmental factors implicated in its etiopathogenesis with abnormal regulation of cell-mediated and humoral immunity that lead to tissue damage. The developing immune system is immature compared to adults and the heterogeneity of the clinical manifestations probably reflects the complexity of the disease pathogenesis.

The immune system in SLE is characterised by a complex interplay between overactive B cells, abnormally activated T cells and antigen-presenting cells, which lead to the production of an array of inflammatory cytokines, apoptotic cells, diverse autoantibodies and immune complexes. They in turn activate effector cells and the complement system leading to tissue injury and damage; these are the hallmarks of the clinical manifestations [28]. Several autoantibodies against cell wall components or circulating proteins can produce specific disease manifestations. However, it is interesting that some healthy children have positive ANA titres and that 88% of adult SLE patients have autoantibodies (including ANA, anti-dsDNA and anti-Smith) present up to 9.4 years before SLE is ever diagnosed [29]. It is generally assumed that anti-dsDNA antibodies play an important role in the pathogenesis of LN. This is because an increase in anti-dsDNA titre often precedes onset of renal disease, immune deposits are present in glomeruli and eluates of glomeruli are enriched for anti-dsDNA. However, the classical concept of deposition of DNA-anti-DNA complexes inciting glomerular inflammation is questionable as free, naked, DNA is not present in the circulation and

injection of these complexes hardly leads to glomerular localisation. The pathogenicity of anti-DNA has been proven with circulating immune complexes, in situ immune complexes, direct binding to renal and non-renal antigens, penetration into cells, and stimulation of cytokines in the form of immune complexes.

Neutrophil extracellular traps (NETs) are fibrous networks found in different clinical situations from infection to malignancy and from atherosclerosis to autoimmune diseases, such as SLE, where there is an imbalance between the process by which NETs are formed, called NETosis and their degradation. The key players in NETosis are neutrophils, interleukin-8 and anti-neutrophil cytoplasmic antibodies where prolonged exposure to NETs increases the change of organ damage. Neutrophils accumulate in the kidneys of patients with LN where the pathogenesis may be due to neutrophil products and low-density granulocytes [30].

Genomic and gene expression studies in patients with SLE have revealed novel gene mutations and cytokine alterations that may explain many of the features of the disease as well as the genetic susceptibility. There is a familial incidence of SLE in 12–15% of cases with a 10–20-fold increased risk of developing the disease if a sibling is affected compared to the general population (prevalence increases from 0.4% of populations up to 3.5% if there is a first degree relative with SLE) [14]. The concordance rate of SLE in monozygous twins is 24% compared with 2% in heterozygous pairs highlighting the importance of genetic (including HLA haplotypes, complement components and Fcγ receptor polymorphisms) and environmental factors in the etiology of SLE [31–34].

The genetics of SLE is now better understood with inroads made in the last decade in identification of susceptible loci, as there is a complex, multifactorial inheritance with associated environmental factors. Genetic linkage studies using microsatellite markers and single nucleotide polymorphisms have identified at least seven loci displaying significant linkage to SLE, including 1q23 (FcγRIIA, FcγRIIB, FcγRIIIA), 1q25-31, 1q41-42, 2q35-37, 4p16-15.2, 6p11-21 (MHC haplotypes), and 16q12. Genome-wide association studies have revealed further loci which are associated with susceptibility to lupus and specifically to LN [35]. New loci continue to be discovered and relate to various biological pathways associated with lupus risk, for example B-cell receptor signaling and CTLA4 co-stimulation for T-cell activation [36]. Findings from such genetics studies not only help further understanding of etiopathogenesis to develop new therapeutic options, but also may enable better diagnosis and prognostication in the future, with the publication of genetic risk scores to aid prognostication which may become applicable in future clinical practice as genetic technology advances [37].

Complement activation is involved in tissue damage with initial murine lupus models and later human studies revealing homozygous deficiencies of the components of the classical complement pathway (C1q, C1r, C1s, C2 and C4) predispose to the development of SLE. The complement system is an important part of the immune system which when dysregulated can result in the development of SLE, which occurs in 75% and 90% of patients with complete deficiencies of C4 and C1q, respectively [38]. Although initially anti-C1q was neither specific nor sensitive for SLE, in vitro testing has shown that anti-C1q is pathogenic in conjunction with complement-fixing antibodies and immune complexes with an increased prevalence in LN. Anti-C1q auto-antibodies are strongly associated with renal involvement in SLE and deposit in glomeruli together with C1q [39]. Anti-C1q antibodies are especially pathogenic in patients with SLE as they induce overt renal disease in the context of glomerular immune complex disease [40].

There are profound alterations in the B cell compartments of both children and adults with SLE [41, 42] with characteristic hypergammaglobulinemia and increased serum autoantibody titres, explaining why B cell depletion may be an effective therapy [43, 44]. In addition to autoantibodies and immune complexes, autoreactive T cells cause tissue damage in SLE with evidence of alterations in human SLE T cell signalling molecules and loss of self-tolerance [45]. Compared to healthy T cells, there are increased

and accelerated signaling responses in T cells from patients with SLE with hyper-reactivity to antigenic triggers, which may be due to genetic influences [46, 47]. Many cytokines, including interferon and interleukins (IL-6, IL10, IL12 (p40) and IL-18), which are elevated in the serum of SLE patients, correlate with disease activity [48].

DNA microarray technology has helped in understanding some of the complex pathogenesis of SLE through genome-wide profiling and earlier studies using microarray analysis of peripheral blood mononuclear cells (PBMCs). There is evidence of dysregulation of inflammatory cytokines, chemokines, and immune response-related genes, as well as genes involved in apoptosis, signal transduction, and the cell cycle. Interferon (IFN)-regulated genes are highly overexpressed in the peripheral blood and kidney glomeruli, supporting a crucial role for interferon in SLE. Future studies focusing on target tissues or organs in SLE may further contribute to our understanding of the etiopathogenesis while providing new targets for therapy [49].

Type I interferons are associated with SLE and genes that are regulated by IFN-alpha are upregulated in JSLE patients, with gene deletion of the IFN-alpha/beta receptor in experimental lupus-like NZB mice resulting in reduced disease activity (although conversely, IFN-beta is a well-established treatment in multiple sclerosis). There are several underlying mechanisms of IFN-beta therapy involving cellular (decreased T cell proliferation and infiltration of leucocytes into the kidney) and humoral (decrease in IgG3 isotypes) immune responses and a reduction in nephrogenic cytokines have been identified. IFN-beta treatment of LN in MRL-Fas(lpr) mice is beneficial and suggests that IFN-beta may be a therapeutic candidate for subtypes of human SLE [50]. IFN-alpha-inducible proteins represent a novel class of autoantigens in murine lupus, and experiments suggest additional roles for IFN-alpha in SLE [51].

The increase in autoantigens in SLE may be due to impaired immune complex clearance and apoptosis. There is evidence of defective clearance of apoptotic cells in some SLE patients, due to the genetic deficiency of molecules, including complement component deficiencies, with autoantigens undergoing structural modifications during the process of apoptosis that may induce immunogenicity [52]. The development of SLE may be attributable to genetic susceptibility with changes in the hormonal milieu, environmental, pharmaceutical and toxic agents (including crystalline silica, solvents and pesticides) [53]. However, there is also an association with infectious conditions influencing the developing immune system of children who develop SLE, including Epstein-Barr virus [54, 55].

Clinical Presentation

Children and young people with JSLE have different clinical presentations, although typically there are non-specific symptoms of being generally unwell with fatigue, malaise, lethargy, aches, pains, episodic fever, anorexia, nausea, vomiting and weight loss with a typical butterfly rash over a period of a few weeks or months. Most organ systems can be involved (Table 26.2) [56] although unusual presentations are sometimes encountered, which is why SLE has been called one of the great mimickers [57]. In view of the relatively low incidence of JSLE compared to many other paediatric

Table 26.2 Presenting symptoms of SLE

Malaise, weight loss, growth retardation	96%
Cutaneous abnormalities	96%
Hematological abnormalities	91%
Fever	84%
Lupus nephritis	84%
Musculoskeletal complaints	82%
Pleural/pulmonary disease	67%
Hepatosplenomegaly and/or lymphadenopathy	58%
Neurological disease	49%
Other disease manifestations (including cardiac, ocular, gastro-intestinal, Raynaud's phenomenon)	13–38%

health problems, there can be a significant delay between onset of symptoms and eventual diagnosis. Pediatricians require a high index of suspicion to ensure this disease is not missed.

The majority of children with SLE present during their adolescence. From one of the largest cohort of 201 children with SLE from Toronto, Canada, 6 children (3%) presented before the age of 6 years, 41 (20%) between 6 and 10 years, 62 (31%) between 11 and 13 years and 92 between 14 and 18 years of age [58]. There was a female predominance of 80%, with a slightly higher proportion of male patients than in adulthood.

Lupus Nephritis

There is evidence of renal involvement in up to 60–80% of children and young people with SLE close to the onset of the disease [56]. In a review of the presentation of LN from different studies involving 208 children, 55% presented with nephrotic syndrome and 43% with proteinuria of lesser degrees (Table 26.3). Most children have microscopic haematuria while few (1.4%) presented with macroscopic haematuria. Fifty percent of children and young people have impaired renal function at onset while only 1.4% have acute kidney injury requiring renal replacement therapy. A small proportion will present with a rapidly progressive glomerulonephritis with biopsy-proven crescentic glomerulonephritis. Hypertension was found in 40% of children.

Table 26.3 Presenting features of lupus nephritis

Nephrotic syndrome (>3 g/day)	55%
Proteinuria (<3 g/day)	43%
Macroscopic haematuria	1.4%
Microscopic haematuria	79%
Hypertension	40%
Reduced GFR (<80 mL/min/1.73 m^2)	50%
Acute renal failure	1.4%

Other Organ Systems

Dermatological

The butterfly or malar rash is the classical rash over the cheeks and nose with photosensitivity to sunlight. However, other rashes can be present, including maculopapular eruptions or purpuric rashes, discoid lesions, livedo reticularis, urticaria and more severe cutaneous vasculitis with ulceration, including mucosal ulceration. Hair loss and brown discolouration of the nails are common findings.

Cerebral

Neurological symptoms, including headache, migraines, seizures and mood disorders are among the most severe manifestations in SLE. There are more severe forms of cerebral lupus with ataxia, chorea, cerebrovascular accidents and deteriorating level of consciousness. The psychiatric symptoms can range from fatigue and depression to confusion, delirium, frank psychosis, hallucinations and catatonic states. Poor academic achievement is a common problem of multifactorial origin that is important to address in these children and young people [59].

Haematological

Coombs-positive haemolytic anaemia, leucopenia, thrombocytopenia and pancytopenia are common findings in children with SLE. Erythrocyte sedimentation rate (ESR) is markedly raised in most children with SLE, while high C-reactive protein (CRP) is found in only a small minority. Therefore, CRP can be helpful in differentiating between flares of lupus disease activity or an infectious complication, such as septicaemia due to the disease or treatment.

Rheumatological

Generalised pain involving the musculo-skeletal system is a very common finding in SLE patients due to myalgia and arthralgia, with severe arthritis less common.

Other Organs

All serous membranes including pleura and pericardium are frequently affected so presentation may be with dyspnoea or pleuropericardial and intermittent chest pain. Hepatosplenomegaly and lymphadenopathy are commonly found in children and young people with SLE. Growth delay is often seen in children, partly related to pubertal delay. Primary and secondary amenorrhoea are manifestations of SLE and LN, but also complications of high doses of cyclophosphamide treatment.

Antiphospholipid Syndrome

Antiphospholipid syndrome (APS) was first described in 1987 as an autoimmune disorder characterised by hypercoagulability of any blood vessel size or type of any organ with the presence of antiphospholipid antibodies [60–62]. Thromboembolism results from the involvement of larger vessels (arteries and veins), whereas thrombotic microangiopathy results from involvement of smaller vessels (capillaries, arterioles and venules). APS with anticardiolipin antibodies and/or lupus anticoagulant are found in 65% of children and young people with SLE [63]. Livedo reticularis has been documented as a marker of APS with increasing tendency to develop both venous and arterial thrombosis. Primary APS is rare in children and is unlikely to progress to SLE. APS is an independent risk factor for more severe renal disease due to microangiopathy in the kidneys and may require treatment as outlined below.

Classification Criteria

The American College of Rheumatology (ACR) classification criteria are utilised in classifying and not diagnosing patients with SLE (Table 26.1). The diagnosis of SLE is made in typical cases with classical organ involvement, elevated autoantibodies and hypocomplementaemia. However, in some cases, the initial diagnosis is more difficult due to the evolution of disease and these cases may not initially fulfil the criteria developed by ACR which have been refined for children [6, 7]. They consist of 11 different criteria of which four should be fulfilled for the diagnosis of SLE; however, meeting these criteria is not sufficient for a diagnosis of SLE because many children with other diseases can also formally match a number of these criteria.

The Systemic Lupus International Collaborating Clinics (SLICC) classification criteria for SLE was published in 2012 [8] where patients are classified if they have biopsy-proven LN with either positive ANA or anti-dsDNA antibodies or at least four criteria (at least one clinical [acute and chronic cutaneous lupus, oral or nasal ulceration, non-scarring alopecia, arthritis, serositis, renal, neurologic, haemolytic anaemia, leucopenia and thrombocytopenia] and one laboratory [ANA, anti-dsDNA, anti-Smith, anti-phospholipid antibodies, hypocomplementaemia (C3, C4, CH50) and direct Coombs test (which is not counted if haemolytic anaemia is present)] criteria and this has now been validated in children [9].

Disease Activity Scoring Systems

There are various disease activity and damage scoring systems, which are very helpful in monitoring disease activity and damage in children and adolescents with SLE with respect to both clinical long-term follow-up and scientific studies. Scales of indices of disease activity continue to evolve and include SLEDAI (Systemic Lupus

Erythematosus Disease Activity Index), SLAM (Systemic Lupus Activity Measure) and ECLAM (European Consensus Lupus Activity Measure). The British Isles Lupus Activity Assessment Group (BILAG) index is another scoring system that can be used and has been evaluated in children [64]. The BILAG index is based on the principle of the physician's intention to treat and is a clinical measure of disease activity in SLE patients, which has been validated to be reliable, comprehensive and sensitive to change. It was developed to report disease activity in eight different systems (general, mucocutaneous, neurological, musculoskeletal, cardio-respiratory, vasculitis, renal and haematological), which differentiates it from other lupus activity indices.

Investigations

The initial investigations of a child with suspected SLE include haematological, biochemical and immunological investigations. Further investigations are warranted depending on organ involvement so a percutaneous renal biopsy and imaging of relevant organ systems are often required.

Blood Investigations

The initial blood test should include a full blood count with a blood film, ESR and reticulocyte count. Anaemia, leucopenia and thrombocytopenia are common findings during active disease that normally improve with effective treatment. Iron studies should also be considered when there is anemia, but caution must be used in the interpretation of these in the setting of systemic inflammation. The leucocyte count, in particular the neutrophil count, should be monitored during active immunosuppressive treatment as the presence of neutropenia influences the doses of immunosuppressive therapies. However, lymphopenia is often seen with treatment and is mostly regarded as a "desired" side effect, which can sometimes be a marker of the effectiveness of treatment. ESR is a marker of disease activity, which can be clinically useful, although it is not uncommon for it to be markedly elevated even during clinical and serological remission. A direct Coombs test should be performed to look for evidence of haemolysis. Macrophage activation syndrome should be screened for in those children and young people with unexplained fever with check of ferritin, lactate dehydrogenase and consideration of bone marrow aspirate and trephine biopsy to exclude malignancy.

The biochemistry profile should include estimation of renal function with plasma creatinine and urea, serum electrolytes, bone, thyroid and liver function tests (including serum albumin), pancreatic enzymes, 25-hydroxyvitamin D levels and CRP (where sepsis is clinically suspected). Creatinine kinase may be useful if evidence of myalgia and parathyroid hormone level when there is evidence of chronic kidney disease. It is useful to calculate the estimated glomerular filtration rate using the Schwartz formula [65].

Immunology Testing

There is evidence of immune dysregulation in almost all children with SLE with positive immunological tests and anti-nuclear antibodies (ANA). ANA can sometimes be a non-specific finding but the use of anti-double-stranded DNA (dsDNA) and the extractable nuclear antibodies (ENA) and C1q levels and anti-C1q antibody testing increases the specificity (Table 26.4). The

Table 26.4 Auto-antibodies in patients with lupus nephritis

	Frequency	Specificity	Association with disease activity
Anti-dsDNA	40–90%	High	Yes
Anti-SSA/Ro	35%	Low	No
Anti-SSB/La	15%	Low	No
Anti-Sm	5–30%	High	No
Anti-C1q	80–100%	High	Yes

dsDNA double stranded DNA, *Anti-SSA/Ro* anti-Sjögren's syndrome A, *Anti-SSB/La* anti-Sjögren's syndrome B, *Anti-Sm* Anti-Smith, *Anti-C1q* Anti-complement factor C1q

pathogenic significance of these antibodies is debated and they can be found in serum sometimes several years before the development of symptoms [29]. However, it is clear that dsDNA and anti-C1q can be used to monitor disease activity, as a marker of improvement or a pending flare of disease. Anti-C1q antibodies have also been shown to predict more severe renal involvement [66]. Knowledge of patients' VZV IgG levels is important for future exposure to varicella. In some settings where the prevalence of tuberculosis is high, the Quantiferon-TB (interferon gamma release assay) may also be indicated. Antibodies against aquaporin-4 (AQP4) and myelin oligodendrocyte glycoprotein (MOG) may be helpful in patients with cerebral lupus.

Complement C3 and C4 are mostly reduced during the active phases of disease and can also be useful markers of disease activity, although some patients with inherited complement deficiencies may never normalise their serum values. Anticardiolipin antibodies and lupus anticoagulant should be regularly monitored. Hypergammaglobulinaemia is a feature of SLE and it is useful to monitor serum immunoglobulins, especially in patients treated with B-cell depletion with intravenous (IV) rituximab. It remains controversial whether hypogammaglobulinaemia should be supplemented with IV immunoglobulin if patients are free of infections. B-lymphocyte counts should be monitored in children treated with IV rituximab by measuring the number of CD19 positive cells.

Urine Investigations

Early morning urine should be regularly monitored in all children and young people with SLE with urinalysis by dipstick performed for haematuria and proteinuria. Urine microscopy is also helpful in looking for red blood cells and casts during the acute phase of LN. Some standardised measurement of proteinuria or albuminuria should be regularly followed, which in most centres is carried out by analysing an early morning spot urine sample relating the urine excretion of protein or albumin to the urine levels of creatinine. Evidence of tubular dysfunction may help to identify LN prior to the onset of albuminuria by measuring NAG (N-acetyl-beta-D-glucosaminidase):creatinine ratio, RBP (retinol binding protein):creatinine ratio or other tubular markers [67].

Other Investigations

It is important to base treatment decisions on the histopathology of percutaneous renal biopsies as it has been shown that the severity of the renal involvement sometimes is difficult to predict from clinical symptoms and signs. Estimated or formal measurements of glomerular filtration rate should be performed when there is a clinical suspicion of impaired renal function. Even in patients with unimpaired GFR the histological findings can be significant and therefore a "normal" eGFR or serum creatinine should not be overly reassuring. Pulmonary function tests, electrocardiography, echocardiography and chest X-rays are important investigations in selected children. Electroencephalography and cerebral imaging with cranial MRI and MRA is advocated in children with neuropsychiatric evidence of cerebral lupus, when lumbar puncture examining cerebrospinal fluid may be performed in appropriate cases.

Follow-Up

Each child should at every clinic visit have a full clinical evaluation including weight, height and a disease activity score (as above). They should have their blood pressure monitored and their urine tested for proteinuria and haematuria. Regular blood tests should include full blood count, ESR, CRP, renal and liver function tests, electrolytes, C3 and C4, and autoantibodies, including dsDNA. Anticardiolipin antibodies and in particular in children treated with rituximab

immunoglobulins and lymphocyte subsets should be regularly monitored. Fasting blood lipids including cholesterol, triglycerides, HDL, LDL and VLDL should be monitored at least once annually. Bone density should be measured in children with long-term daily corticosteroid therapy on a regular basis.

Histological Classification of Lupus Nephritis

The histological classification of LN was initially formatted in 1975 by the World Health Organisation (WHO) and modified in 1982 and 1995. It describes the spectrum of LN as the type and extent of renal lesion and provides information on the immunosuppression required and prognosis. There was a revision of this classification by the International Society of Nephrology (ISN) and Renal Pathology Society (RPS) Working Group after their consensus conference in 2002 in order to standardise definitions, emphasise clinically relevant lesions, and encourage uniform and reproducible reporting between centres (Table 26.5) [68, 69]. This classification facilitates clinical management by increased comprehension of the etiopathogenesis of SLE and guides the clinician with treatment decisions, protocols and clinical research. However, there is widespread variation of the timing, type and distribution of histological lesions, including immune-complex mediated vasculitis, fibrinoid necrosis, inflammatory cell infiltrate and collagen sclerosis.

Table 26.5 International Society of Nephrology and Renal Pathology Society Working Group (ISN/RPS) revised histopathological classification of lupus nephritis

1. **Minimal mesangial lupus nephritis (LN)**
Normal glomeruli by LM, but mesangial immune deposits by IF
2. **Mesangial proliferative lupus nephritis (LN)**
Purely mesangial hypercellularity of any degree or mesangial matrix expansion by LM with mesangial immune deposits, with none or few, isolated subepithelial or subendothelial deposits by IF or EM not visible by LM
3. **Focal lupus nephritis (LN)**
Active or inactive focal (<50% involved glomeruli), segmental or global endo- or extracapillary GN, typically with focal, subendothelial immune deposits, with or without focal or diffuse mesangial alterations
III (A) active focal proliferative LN
III (A/C) active and sclerotic focal proliferative LN
III (C) inactive sclerotic focal LN
* Indicate the proportion of glomeruli with active and with sclerotic lesions
* Indicate the proportion of glomeruli with fibrinoid necrosis and/or cellular crescents
4. **Diffuse segmental (IV- S) or global (IV- G) LN**
Active or inactive diffuse (50% or more involved glomeruli), segmental or global endo- or extracapillary GN with diffuse subendothelial immune deposits, with or without mesangial alterations. This class is divided into diffuse segmental (IV-S) when at least 50% of the involved glomeruli have segmental lesions, and diffuse global (IV-G) when at least 50% of the involved glomeruli have global lesions
IV (A) Active diffuse segmental or global proliferative LN
IV (A/C) Diffuse segmental or global proliferative and sclerotic LN
IV (C) Diffuse segmental or global sclerotic LN
* Indicate the proportion of glomeruli with active and with sclerotic lesions
* Indicate the proportion of glomeruli with fibrinoid necrosis and/or cellular crescents
5. **Membranous lupus nephritis**
Numerous global or segmental subepithelial immune deposits or their morphologic sequelae by LM and IF or EM with or without mesangial alterations
May occur in combination with III or IV in which case both will be diagnosed. May show advanced sclerosis
6. **Advanced sclerotic LN**
90% or more glomeruli globally sclerosed without residual activity

ISN/RPS Classes I and II LN denote purely mesangial involvement (I, mesangial immune deposits without mesangial hypercellularity; II, mesangial immune deposits with mesangial expansion and hypercellularity), ISN/RPS Class III LN denotes focal glomerulonephritis (involving less than 50% of total number of glomeruli), with subdivisions for active and chronic lesions. ISN/RPS Class IV LN denotes diffuse glomerulonephritis (involving at least 50% of total number of glomeruli with examples in Figs. 26.1, 26.2a–d, and 26.3a–d) either with segmental (ISN/RPS Class IV-S) or global (ISN/RPS Class IV-G) involvement, and also with subdivisions for active and chronic lesions, ISN/RPS Class V denotes membranous LN (combinations of membranous and proliferative glomerulonephritis (i.e., ISN/RPS Class III and V or Class IV

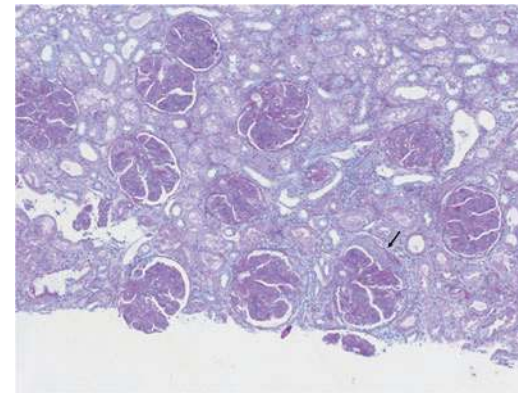

Fig. 26.1 Photomicrograph of a case of lupus nephritis demonstrating predominant diffuse endocapillary proliferative change with scattered superimposed extracapillary proliferative lesions (*Arrow*), Lupus nephritis Class IV-G (A/C) (PAS, original magnification ×100) (Used with permission of Taylor & Francis from Marks et al. [70])

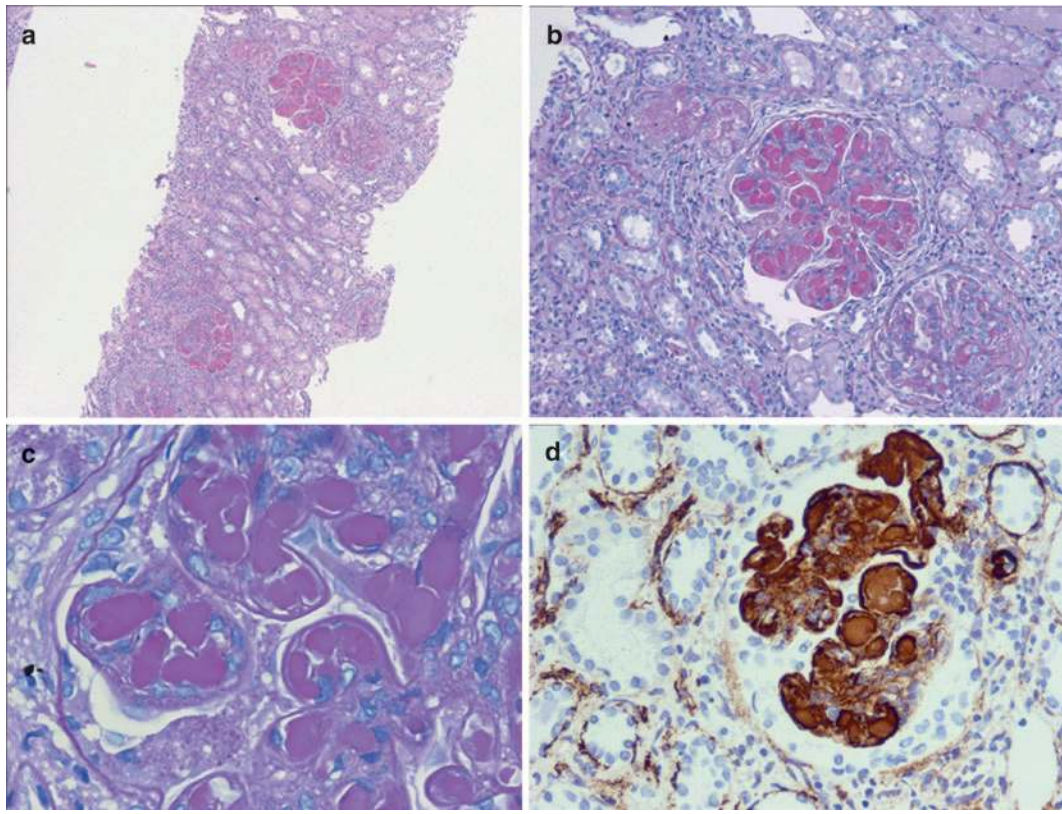

Fig. 26.2 Photomicrographs of a case of lupus nephritis presenting as apparent acute renal failure, demonstrating diffuse endocapillary proliferative change with scattered crescent formation (**a**, **b**) and extensive subendothelial deposits visualised as wire-loop and hyaline drop lesions (**b**, **c**). Immunostaining revealed a characteristic 'full-house' pattern of immunoglobulin and complement deposition. (**d**) Lupus nephritis Class IV-G (**a**) (PAS and immunostain, original magnifications ×40–400) (Used with permission of Taylor & Francis from Marks et al. [70])

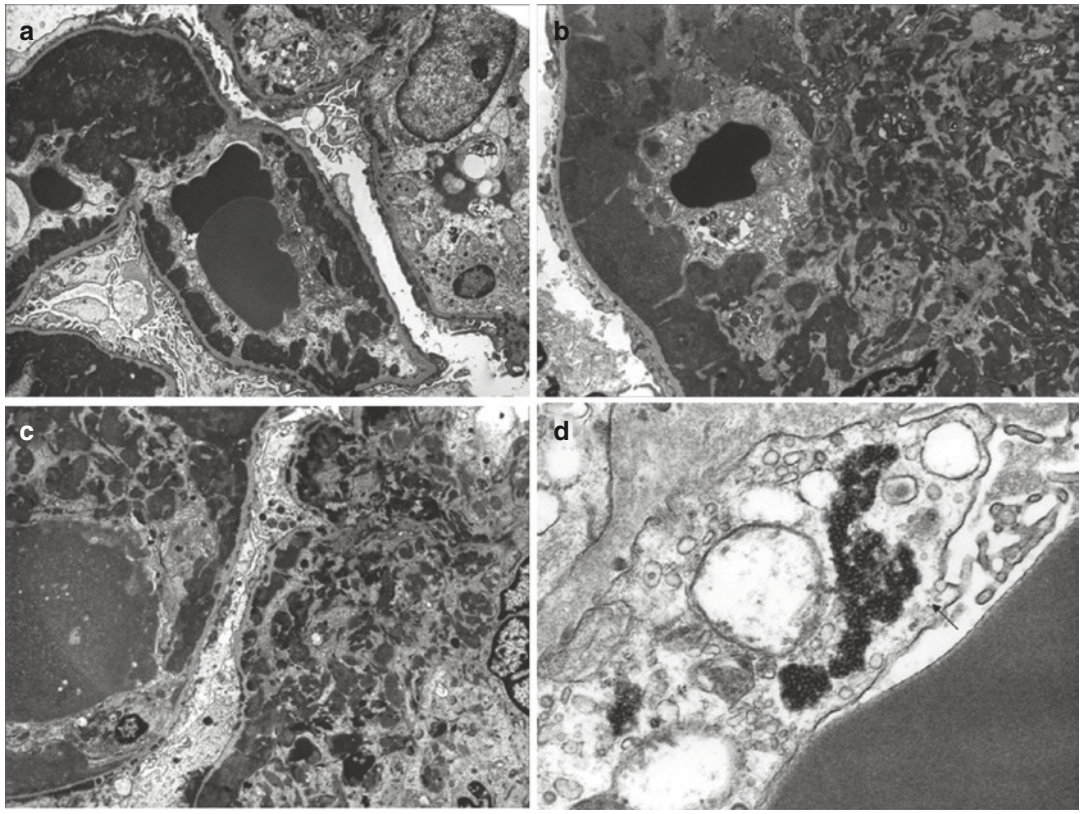

Fig. 26.3 Electron micrographs of lupus nephritis demonstrating extensive mesangial and paramesangial electron dense deposits in association with massive subendothelial deposits (**a**–**c**) (**a**) corresponds to the case in Fig. 26.1 and (**b**, **c**) correspond to the case in Fig. 26.2). In addition, some cases may demonstrate the presence of tubuloreticular inclusions. (**d**) (Used with permission of Taylor & Francis from Marks et al. [70])

and V) should be reported individually in the diagnostic line) and ISN/RPS Class VI for advanced sclerosing lesions (which now for the first time categorically states that at least 90% of glomeruli need to be globally sclerosed without residual activity). In addition, the ISN/RPS classification includes overlap cases (see Fig. 26.4a–d for an example of mixed ISN/RPS Class IV and Class V LN).

The histopathological features of LN includes the delineation of active and chronic histological lesions, which has been extensively reported in the various classification systems (Table 26.6) [71].

The active glomerular and tubulointerstitial lesions, which are potentially reversible and are scored up to 24 (with 12 denoting poor renal prognosis), include endocapillary hypercellularity, fibrinoid necrosis, karyorrhexis, cellular crescents, hyaline thrombi, wire loops (subendothelial deposits), haematoxylin bodies, leucocyte infiltration and tubulointerstitial disease with tubular atrophy and mononuclear cell infiltration. The chronic lesions are irreversible and include glomerular sclerosis, fibrous crescents, fibrous adhesions, extramembranous deposits, and tubulointerstitial disease with interstitial fibrosis and tubular atrophy.

The clinicopathological correlation of LN has been evaluated in both adults and children according to different histopathological classifications. The largest adult series investigating the clinicopathological outcomes according to the ISN/RPS classification of LN followed 60 Japanese subjects for 1–366 (mean 187) months (Fig. 26.5) [72]. The primary outcome was

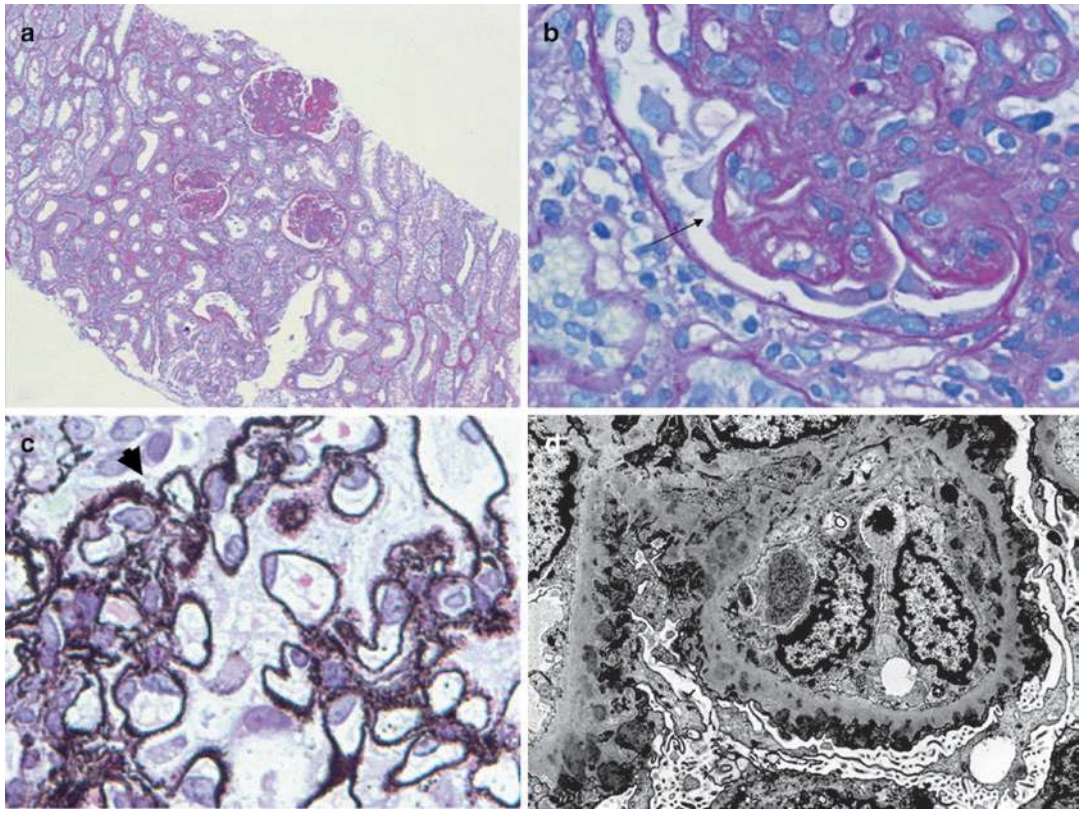

Fig. 26.4 Photomicrographs of a case of lupus nephritis presenting with nephrotic syndrome demonstrating diffuse endocapillary proliferative change with subendothelial deposits ((**a**, **b**) PAS, original magnifications ×40 and 400 respectively). In addition some glomeruli show florid 'spike' formation on silver staining (**c**) PAMS, original magnification ×400) with mesangial, subendothelial and subepithelial deposits on ultrastructural examination (**d**). Lupus nephritis, mixed Class IV and Class V changes (Used with permission of Taylor & Francis from Marks et al. [70])

Table 26.6 Activity and chronicity indices of lupus nephritis

	Activity index	Chronicity index
Glomerular	Endocapillary hypercellularity Fibrinoid necrosis Karyorrhexis Cellular crescents Hyaline thrombi Wire loops (subendothelial deposits) Haematoxylin bodies Leucocyte infiltration	Glomerular sclerosis Fibrous crescents Fibrous adhesions Extramembranous deposits
Tubulointerstitial	Mononuclear cell infiltration	Interstitial fibrosis
	Tubular necrosis	Tubular atrophy

defined as developing end-stage kidney disease (ESKD) with secondary outcome as patients' death and/or ESKD. The primary and secondary outcomes of all subjects were 82% and 78% at 10 years, and 80% and 73% at 20 years, respectively. The primary outcome of subjects with nephrotic syndrome (n = 21 versus 39 non-nephrotic) was statistically poorer (p = 0.0007) with hazard ratio of 3.39 as the mean time of 50% renal survival was 200 ± 29 months.

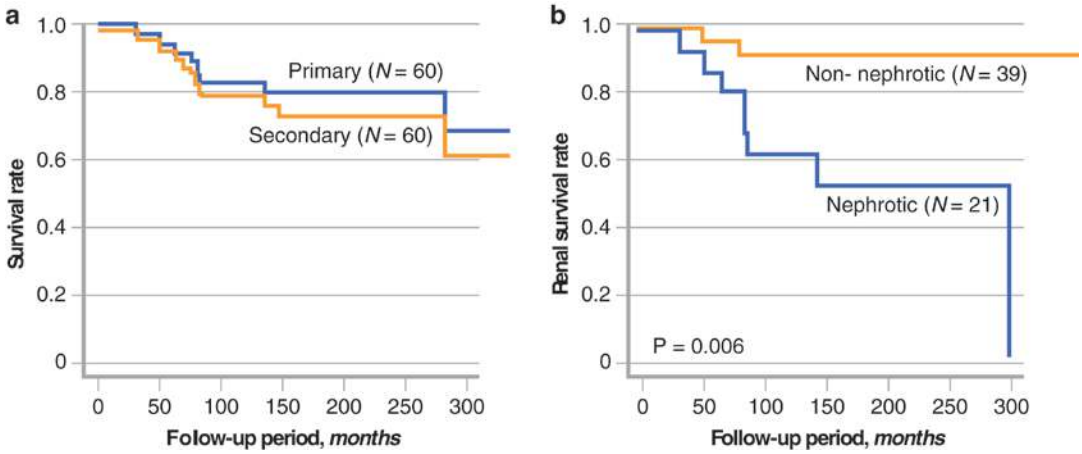

Fig. 26.5 Prognosis of lupus nephritis. The primary (ESKD) and secondary (patients' death and/or ESKD) outcomes (**a**) of 60 Japanese adult lupus nephritis subjects with and without nephrotic syndrome (**b**) at mean follow-up of 187 months (Used with permission of Nature Publishing Group from Yokoyama et al. [72])

In comparison with adult-onset SLE, there are usually less patients in the series of childhood cases of LN. There have been larger series investigating clinicopathological outcomes of 39–67 children according to the WHO classification [73] and the ISN/RPS classification of LN [74], which provide evidence that up to half of children with LN will have the most severe class (ISN/RPS Class IV or diffuse LN). The classification demonstrated that the subgroup of diffuse global sclerosing (ISN/RPS IV-G(C)) LN was associated with the worst clinical outcome [74].

Treatment

The optimal treatment of children and adolescents with SLE is provided by a multi-disciplinary team of health professionals, including a paediatric nephrologist, paediatric rheumatologist and other paediatric specialists, with a dedicated specialist nurse and members of a psychosocial team. Treatment should be guided by the most severe organ system involved.

Drug Treatment

The treatment of lupus with or without nephritis is based on evaluation of the severity of the disease. The treatment should be individually tailored depending on the presenting symptoms and severity of renal involvement, with emphasis on renal dysfunction and the degree of proteinuria. In all cases with suspected renal involvement, the histopathological grading of the renal biopsy is very helpful in deciding further treatment. Other potentially life-threatening symptoms, such as cerebral lupus should also be taken into consideration when deciding on the initial treatment. Most treatments have common or potential side-effects, which need to be considered for the individual child.

The treatment of JSLE is not based on large randomised controlled trials, but there is an increasing number of studies in adult and adolescent patients and published clinical experience in children. The recommendations below describe the most commonly used protocols for treating children with SLE. Consensus reports on the treatment of paediatric lupus have been published [75–79]. The armamentarium of immunosuppressive agents is presently developing quickly with new drugs being introduced [80], so guidelines may change in the not too distant future.

Traditionally treatment has been divided into induction therapy to gain control of acute disease and maintenance therapy to maintain control over the disease. This is a helpful approach, but it is not an uncommon clinical situation that a flare of disease activity is difficult to define.

Severe Multisystem Disease with or Without Nephritis (ISN/RPG Class III–V)

The treatment is divided into induction therapy to get control of acute disease and maintenance therapy to maintain control over the disease. Clinicians need to consider the severity of the disease but also the potential side-effects from treatment in considering which combination of immunosuppressive agents are used. At the onset of each treatment, it is important to discuss side effect profiles and risks of non-adherence. There is growing evidence to suggest the use of belimumab for adults as well as tacrolimus for induction, particularly in membranous (ISN/RPS Class V) LN. Evidence in adults has shown best results when using tacrolimus in combination with MMF and corticosteroids.

Induction Therapy

A common presentation to the nephrologist is a child that over a few weeks or months has developed generalised symptoms and at assessment is found to have an acute nephritic and/or nephrotic syndrome with a suspicion of SLE that is later confirmed by serology. It is important in cases with significant renal disease to commence treatment early without unnecessary delay to protect the kidneys from developing chronic damage.

The mainstay of induction treatment is based on corticosteroids to rapidly halt disease with rapid wean by addition of other immunosuppressive agent(s) (Table 26.7). Historically, this used to be cyclophosphamide (CyC), but is now more commonly mycophenolate mofetil (MMF). For children and young people with active disease, including severe renal dysfunction, B-lymphocyte depletion therapy with IV rituximab is often added to corticosteroids and MMF [44, 81]. In children with a crescentic glomerulonephritis, we and others have additionally tried plasma exchange.

Table 26.7 Induction therapy of ISN/RPS Class III, IV and V lupus nephritis

Methylprednisolone (intravenous) pulses × 3	600–1000 mg/m^2 (maximum 1 g)
Prednisolone (oral)	0.5–1 mg/kg/day (maximum 30–60 mg/day with rapid weaning)
Mycophenolate mofetil[a]	600 mg/m^2 twice daily (maximum of 2–3 g/day in two divided doses)
In severe cases or if not responding to the above:	
Plasma exchange	Daily for 5–10 days
Rituximab	See protocol in text

[a]Induction therapy with cyclophosphamide or azathioprine are alternatives in selected cases

Corticosteroids

IV pulses of methylprednisolone should be given during three consecutive days (600–1000 mg/m^2) with a maximum of 1 g, infused over at least 30 min. In severe cases, these pulses may need to be repeated. There is increasing evidence that low (and even no chronic oral) corticosteroid exposure can but utilised for some patients [82, 83].

The methylprednisolone pulses are followed by high doses of oral prednisolone (0.5–2 mg/kg/day to a maximum dose of 30–60 mg/day). This high dose is dictated by the severity of the clinical situation, but should be weaned rapidly. This treatment will inevitably result in cushingoid side-effects, which can be debilitating for adolescents (such as fluid and water retention with increased appetite and weight gain with rounded facies, striae and growth delay). Other important side effects include mood changes, hypertension, diabetes mellitus, osteoporosis and osteopenia. Therefore, in order to maximize long-term adherence to therapy, it is very important to reduce the corticosteroid dose as quickly as the clinical situation allows in order to minimise these side-effects.

Mycophenolate Mofetil

There is now increasing evidence from studies that MMF in adult patients has equivalent effectiveness to CyC for induction. The first study to

show this was in 42 adult patients from Hong Kong treated with 12 months of oral MMF therapy or 6 months of CyC followed by 6 months of azathioprine. Both groups responded equally well to the treatment, but there were significantly more side-effects in the CyC group [84].

The Aspreva Lupus Management Study (ALMS), the largest study on the treatment of SLE with MMF, included 370 patients with ISN/RPS Class III, IV and V LN [85]. It consisted of two treatment stages: one 24 week induction phase and subsequently, a 3 year study of the maintenance phase. In the induction study, the 370 patients were randomised to either MMF (target dose 3 g/day) or IV CyC given as monthly pulses of 500–1000 mg/m^2. All patients received prednisolone tapered from a maximum dose of 60 mg/day. The response to treatment was defined as achieving the primary efficacy endpoint, which was decrease in urine protein/creatinine ratio to below 3 mg/mg if baseline was ≥3 mg/mg or by 50% if baseline <3 mg/mg *and* stabilisation (±25%) or improvement of serum creatinine. The ALMS study showed no difference between MMF and CyC: 56% and 53% of patients responded in the two groups, respectively. There was also no significant difference in the rate of side effects.

In a further publication, it was shown that the therapeutic response varied with race, in that Black and Hispanic patients responded better to MMF (60%) compared to CyC (39%), p = 0.03 [86]. The authors have also looked separately at patients with ISN/RPS Class V LN (i.e., a membranous pattern on the kidney biopsy) and again no difference was found between the MMF and CyC treated groups [87].

A meta-analysis comparing MMF and CyC as induction treatment has been published [88]. Four trials with 668 patients were included and no difference in clinical efficacy was found between the two drugs with the overall RR (relative risk) for renal remission being 0.67 (95% CI 0.35–1.28). However, there was significantly less alopecia (RR 5.77; 95% CI 1.56–21.38) and amenorrhoea (RR 6.64; 95% CI 2.00–22.07) with MMF, but no other side effects were significantly different.

There are no randomised controlled studies on the use of MMF in juvenile-onset SLE. We published one of the largest case series with 31 children and adolescents that were treated with MMF either initially or converted from azathioprine [89]. Seventy-three per cent of the treated children showed a response to the drug without any recorded major side effects. MMF should now be regarded as part of the standard treatment for children with severe lupus.

The main problems with MMF are the gastrointestinal side effects with abdominal pain and diarrhoea. These can mostly be avoided by increasing the dose slowly (e.g. starting with a dose of 300 mg/m^2 twice daily and slowly increasing to the target dose of 600 mg/m^2 twice daily). If gastrointestinal side effects are a continuing problem then the daily dose may be divided three or even four times a day.

Cyclophosphamide

IV pulses of CyC have been the most important corticosteroid-sparing agents in achieving remission in severe SLE and LN. However, this treatment has substantial short and long-term side effects, including nausea (which can be alleviated with routine use of ondansetron), alopecia, haemorrhagic cystitis and infectious risk of septicaemia due to neutropenia. Many girls develop amenorrhoea and with high doses; there is a risk for developing infertility. The modified National Institute of Health protocol of IV CyC (500–1000 mg/m^2 with dose reduction in renal dysfunction) can be administered as monthly pulses for 6 months. It is important to keep the child well hydrated and to give MESNA to protect the child from developing haemorrhagic cystitis.

Controlled studies in adult patients show that IV CyC causes significantly more side-effects, including severe infections, compared to oral azathioprine or MMF [84, 90–92]. Therefore, it is important to closely monitor the total white cell, neutrophil and lymphocyte counts with the nadir usually occurring around 7–10 days after the infusion. Subsequent doses may need to be reduced based on haematological side effects.

There is a long-term increased risk for developing malignancies and for infertility. Up to 14% of CyC treated patients younger than 41 years

have premature ovarian failure, which is a common consequence of CyC treatment. CyC is thus a drug that still has a place in the treatment of LN, but it is gradually being replaced by other drugs.

Rituximab

Rituximab is a humanised anti-CD20 antibody that was designed for treatment of B-cell lymphoma and in adults has been increasingly used for B-cell depletion therapy in autoimmune diseases such as rheumatoid arthritis or SLE [43]. We have used IV rituximab in over 200 children with SLE or vasculitis and published the results of our first children [44, 93]. Our patients have shown very good responses to the treatment and we have not experienced a significant increase in severe side effects.

A relatively large randomised, placebo-controlled study of IV rituximab, called the LUNAR trial, was performed in 144 adult patients with ISN/RPS Class III or IV LN [94]. The primary endpoint was the renal response at week 52. A complete response was normalisation of serum creatinine, no red blood cells (<5/hpf) in the urine and a urine protein/creatinine ratio of <1.0 mg/mg.

Only 31% of patients in the placebo group and 25% of the rituximab treated patients fulfilled these very strict criteria for a complete response. The patients that showed no response to the treatment were 43% in the rituximab and 54% in the placebo group ($p = 0.18$). There were more serious side effects in the placebo group: 74/100 patient years vs. 43/100 patient years in the rituximab group. Greater improvements of complement levels ($p = 0.025$) and antibodies to dsDNA ($p = 0.007$) were recorded in the rituximab group compared to placebo [95].

The negative result of this study was surprising, but several potential reasons have been postulated. Rituximab was given in addition to other treatments that in normal circumstances would have been regarded as sufficient. In addition, the endpoints were quite strict and difficult to fulfil. There are plans for further studies on rituximab with different designs. This study, along with another randomised study in lupus patients without renal involvement (the EXPLORER trial) [96], have not shown any severe side-effect profiles.

A further large case series of 164 adult patients with biopsy proven LN showed a complete response, partial response and no response in about a third of the treated patients [97]. These results, together with the paediatric case series that show a good therapeutic response, means that we continue to recommend the use of rituximab in many situations, as is becoming standard of care in ISN RPS Class III, IV and V LN as well as those with severe life-threatening disease and those patients with active disease despite standard treatment.

Different protocols have been used and our protocol involves two administrations of IV rituximab as an infusion of 750 mg/m^2 (rounded up to the nearest 100 mg with a maximum dose of 1 g) with 14 days in between. In addition, an IV dose of 100 mg methylprednisolone is given immediately prior to each rituximab infusion.

Plasma Exchange

We consider the use of plasmapheresis in very severe and refractory cases of SLE with cerebral lupus and/or crescentic glomerulonephritis, with five to ten plasma exchanges as an adjunct in some patients [81]. However, this is a controversial area and a controlled trial in adult patients with severe LN could not confirm any benefits from adding plasma exchange to the standard treatment of methylprednisolone and CyC [98], which was confirmed in a meta-analysis [99].

Intravenous Immunoglobulin

IV immunoglobulin (at a dose of 2 g/kg to a maximum of 70 g) can be useful, particularly in children with severe haematological disease. Some children benefit from regular infusions (such as every 6 weeks) (Table 26.8).

Table 26.8 Maintenance therapy of lupus nephritis

Prednisolone (oral)	0–5/10 mg alternate or every day
Mycophenolate mofetil (oral)	600 mg/m^2 twice daily (maximum of 2–3 g/day in two divided doses)
Alternatively,	
Azathioprine (oral)	2–2.5 mg/kg once daily
Hydroxychloroquine (oral)	4–6 mg/kg/day Normal dose 200 mg once daily

Maintenance Therapy

All cases of severe lupus require maintenance therapy for a long period, although the length of treatment is not well defined. We advocate maintenance therapy for at least 2–3 years and possibly indefinitely in many cases, especially those with active LN.

Corticosteroids

After the initial rather rapid reduction of the oral corticosteroid, the prednisolone dose should be continuously weaned; many patients may not require long-term oral corticosteroids if adequate immunosuppression is given (e.g., MMF and IV rituximab). The clinical response will decide how quickly the dose can be reduced. Long-term treatment with corticosteroids for several years is often required, although there are quite different approaches on preferred maintenance dose. Our opinion is that it is very important to reduce the dose as quickly as possible. This is important to reduce side effects, but also to improve adherence. Teenagers do not like the cushingoid appearance they develop with corticosteroids so some stop taking their medications when the acute symptoms have resolved. This can lead to non-adherence with other treatments. Our goal is to wean corticosteroids, and either t discontinue or utilize alternate day treatment at a dose in the order of 5–10 mg every other day. These doses of prednisolone should allow the child to grow normally [100].

Mycophenolate Mofetil

MMF is most likely the best choice for long-term maintenance therapy. After the 24 week induction part of the ALMS trial, 227 patients were randomised to 3 years of maintenance therapy with MMF (2 g/day) or azathioprine (2 mg/kg/day) [101]. In this study, MMF was superior to azathioprine with respect to the primary end-point, time to treatment failure; hazard ratio was 0.44 (95% CI 0.25–0.77; p = 0.003). Treatment failure occurred in 16% of the patients in the MMF group and 32% in the azathioprine group. Serious adverse events occurred in 24% of patients treated with MMF compared to 33% treated with azathioprine and the withdrawal due to adverse events was significantly higher in the azathioprine group (40% versus 25%; p = 0.02) [102].

MMF was also compared to azathioprine in the MAINTAIN trial [103]. In this study, 105 patients were treated with similar doses of azathioprine and MMF as in the maintenance phase of ALMS. There was a tendency to fewer renal flares in the MMF group, but the number of patients was not high enough for this to achieve statistical significance.

Azathioprine

Azathioprine at a dose of 2–2.5 mg/kg/day has historically been first line maintenance therapy and has a generally favourable side-effect profile. In the comparison of azathioprine or MMF used as maintenance therapy, MMF was shown to be better than azathioprine (which is the opposite of maintenance treatment of vasculitis) [102, 103]. Some centers advocate testing of thiopurine methyltransferase activity before commencement of azathioprine, but in our practice we advocate close monitoring of full blood counts [104].

Hydroxychloroquine

The use of antimalarial drugs (such as hydroxychloroquine at a dose of 4–6 mg/kg/day) should be considered for all lupus patients. It is especially helpful in children with marked skin or lung disease, lethargy and arthritis. Hydroxychloroquine also seems to reduce blood lipids and possibly the risk for later atherosclerosis. Some clinicians advocate a high dose of 10 mg/kg (up to 400 mg/day) for patients with severe lung disease. Ophthalmology referral and monitoring should take place, as there is a significant risk of retinopathy, particularly with long-term hydroxychloroquine use [105]. In the UK, national guidance suggests at least annual ophthalmology monitoring after 5 years of therapy.

Emerging Therapeutic Options

A number of new therapeutic options for SLE have emerged, with many more currently in development. Belimumab is a fully humanized monoclonal antibody targeting B-lymphocyte stimulator (BLyS) which has been licensed in a number of countries for adults and children with SLE. Adult studies have shown efficacy in SLE [106] and a recent randomized, controlled trial of belimumab in adults with LN showed an improved renal response and a lower risk of renal-related events or death when belimumab was given in addition to standard therapy alone [107]. Belimumab has also been approved for JSLE in a number of countries; the results of the ongoing Phase 2 PLUTO trial in children aged 5–17 years with SLE has shown a favorable side-effect profile with improved efficacy of belimumab compared to placebo [108].

In addition to the use of rituximab for induction therapy, there is increasing interest in its use as maintenance therapy for SLE. Currently, data are limited; a recent observational study in adults did not find any difference in relapse risk in those receiving maintenance rituximab compared to those who had a single course [109]. There may, however, be a role for maintenance rituximab particularly in adolescents or young adults with difficult to treat disease or medication adherence issues on oral treatment.

There is ongoing research into the use of other B-cell depleting monoclonal antibodies. There are reports of the use of other humanized B-cell depleting antibodies such as ofatumumab in patients with SLE. These are currently limited to case series and may be useful in certain situations such as infusion reactions or allergy to rituximab [110, 111].

There is increasing interest in the use of tacrolimus as therapy for SLE, particularly in patients with membranous (Class V) LN or with proteinuria as a predominant feature [112]. Adult studies have shown it is non-inferior to MMF, but the highest efficacy seems to come from combined tacrolimus and MMF, although many studies to date have been conducted in Asian patients so further work is needed to confirm this in different ethnic groups [113–115]. Although there are no studies beyond case reports of tacrolimus for JSLE, its use can be considered in difficult cases and in particular with a membranous appearance on histology. A recent study on voclosporin in combination with MMF showed a superior renal response, but also higher rates of adverse events [116].

The type 1 interferon pathway has also been targeted in SLE, and the monoclonal antibody anifrolumab has recently completed phase 3 RCTs in adults, showing some efficacy in reducing composite disease activity endpoints [117]. Many other therapeutic targets are currently under investigation for SLE, and while these are currently not likely to reach children and adolescents with JSLE for some years, there is hope for many more treatment options in the future.

Treatment of Antiphospholipid Syndrome (APS)

Treatment for APS includes reducing lupus disease activity and appropriate anticoagulation treatment (such as life-long aspirin or warfarin if severe thromboembolic disease).

General Renal Management

As outlined in other parts of this book, general renal care is important in all children with renal impairment. This includes monitoring and treatment of hypertension and proteinuria; blood pressure targets are around 50th centile for age, sex and height centile and albuminuria and proteinuria should be minimised (which may be due to active disease, which requires increasing immunosuppression or chronic damage,which requires treatment with angiotensin converting enzyme inhibition or angiotensin receptor blockers). It is important to continuously evaluate renal function of these children with estimated GFR and, if appropriate, a formal GFR measurement. Supportive treatment of chronic kidney disease and ESKD is required in some of these children.

General Management

Sun Protection

All children with SLE and especially those with active skin disease should be advised to always use appropriate sunscreen and protect themselves from the sun, with regular monitoring of 25-hydroxyvitamin D levels and appropriate vitamin D supplementation.

Immunisations

Children with SLE, treated with immunosuppressive drugs, should avoid immunisation with live vaccines. Vaccination with killed vaccines should be carefully considered as they might induce a flare of the disease and also might have decreased efficacy. In the United Kingdom and in other countries, pneumococcal vaccinations are recommended for all patients likely to be on corticosteroids for more than a month.

Management of Infection

Children on immunosuppressive treatment are more susceptible to severe infections than other children and it should be emphasised to the parents and the children that they should seek medical advice early in the case of fever or symptoms of an infection.

Prognosis

In the era before treatment became available, the prognosis of patients with SLE was very poor with very few patients with a severe nephritis surviving more than 2 years [118]. The introduction of corticosteroids and immunosuppressive treatment with CyC and azathioprine made a huge impact on the long-term prognosis. Cameron showed already more than 25 years ago a general and renal survival of about 20% after 20 years [56]. He could also show that between the years 1965 and 1991 the 10-year patient survival improved from 10 to 20%.

The proportion of death from SLE improved very rapidly in high-income countries from the 1960s to the 1970s, with slower improvement thereafter. In contrast, in low and middle-income countries there was a pronounced increase in survival between 1970 and 1990 followed by a plateau or a decreased survival. There is now a significant difference in both 5- and 10-year survival between high and middle/low income countries. Five year survival estimates of 0.99 and 0.85, respectively and 10-year survival estimates of 0.97 and 0.79, respectively [119].

The proportion of children dying from their renal failure is now lower, although the prognostic factors for developing renal failure remain the same (male gender, non-Caucasian race, nephrotic syndrome at onset and severity of disease on renal biopsy [73]).

Another important measurement of success in the treatment of LN is the proportion of children achieving full renal remission. A recent German study in 79 pediatric lupus patients showed a rate at one year of complete remission of 38%, and 41% partial remission [120]. An Italian study found a rate of a complete remission of about 50% while children from South Korea showed the highest rate of complete remission at 59.7% [121, 122]. Remission was defined as normal kidney function and no proteinuria. There is thus still a need to improve long-term kidney survival. In recent years, it has also become evident that patients with SLE confront another important threat to their long-term survival due to an increased risk of atherosclerosis.

Treatment Related Complications and Mortality

In recent studies, infections have been the main cause of death, therefore suggesting that the most important short-term goal is to find therapies which are as good as current treatments but with fewer side effects. Recent comparative studies in adults showed that CyC treatment was associated with significantly more severe infections compared to treatment with azathioprine or MMF [84, 90–92]. This emphasises the importance of monitoring white cell and neutrophil counts during therapy and early treatment of infectious complications. However, infections can sometimes be difficult to differentiate from a flare of

disease activity, especially in children who are in ESKD on renal replacement therapy. CRP can be used as a helpful tool in these situations as very few patients even with active lupus have raised CRP levels [56] while most children with septicaemia do.

Severe viral infections, in particular with varicella zoster virus are seen, and children exposed to the virus or with early symptoms of varicella (or more often herpes zoster virus) should be treated with aciclovir therapy to reduce the risk of generalised infection.

Growth failure is a major problem in children with lupus, which can be related to the inflammatory disease or a complication of corticosteroid treatment. Sometimes it can be difficult to differentiate between them and this is a controversial area, but it is our opinion that ongoing inflammation more often causes the growth failure than the treatment with low corticosteroid doses. Therefore, increasing immunosuppression rather than reducing treatment is often more beneficial for the growth of these children.

SLE patients have an increased risk of osteoporosis, partly caused by their long-term treatment with steroids [123]. Treatment with calcium and vitamin D supplementation is advocated by some centres, but unfortunately it seems as if the beneficial effects from that treatment only persist during the treatment [124]. However, an increased nutritional calcium intake does seem to be able to improve bone accretion over a longer time [125]. It is recommended that children with SLE should be monitored with regular bone density scans.

Children on long-term immunosuppressive treatment have an increased risk for developing malignancies, in particular skin cancers and lymphoma, and should be advised to use sun protection. Bladder cancer has been associated with the use of CyC in children with SLE [126]. A 10 year follow-up of a large cohort of 1000 adult lupus patients found that 23 developed malignancies, with breast and uterine cancers being the most common [127]. Therefore, the risk of malignancy does not seem to be excessive.

Active lupus often causes amenorrhoea and delayed puberty, whereas treatment with CyC can also reduce fertility. A study of 39 women younger than 40 years old showed that 12.5% (2 out of 16) receiving seven IV doses of CyC developed sustained amenorrhoea compared to 39% (9 out of 23) receiving 15 or more doses (with a higher risk in women older than 25 years) [128].

Thrombosis

In the aforementioned 10-year follow up of 1000 adult patients, 9.2% [129] developed thrombosis, and of the 68 patients who died, 26.5% had a thrombotic event. Thrombosis is more common in children with antiphospholipid syndrome. A 10-year follow-up of 149 children with SLE from Toronto showed that 24 were positive for lupus anticoagulant and that 13 of them experienced 21 thromboembolic events [130]. The authors emphasised the need to treat this subgroup of children with life-long anticoagulation.

Cardiovascular Disease

A Swedish registry study on 4737 patients with SLE from 1964 to 1994 showed a 16-fold increased risk of death from cardiovascular diseases [129]. Therefore, it is our new challenge to try to prevent atherosclerosis and to improve our patients' long-term survival. This increased risk for cardiovascular death is multifactorial and includes classical risk factors, such as hypertension, hyperlipidaemia and corticosteroid treatment and disease-related risk factors such as proteinuria, vasculitis, low-grade systemic inflammation, antiphospholipid syndrome and elevated levels of homocysteine [131].

Carotid plaque and coronary artery calcifications are significantly increased in lupus patients [132, 133]. Efforts to decrease atherosclerosis include good control of inflammation, aggressive treatment of hypertension and proteinuria and prevention of corticosteroid-induced obesity. A randomised placebo controlled study on treatment with atorvastatin did not significantly reduce progression of the surrogate marker for atherosclerosis, carotid intima-media thickness [134]. The active treatment did, however, reduce levels of high sensitivity CRP and total cholesterol and low-density lipoprotein. A secondary analysis suggested that atorvastatin reduced atherosclerosis progression in paediatric lupus patients with higher CRP values

[135]. Hydroxychloroquine has been shown to have a beneficial effect on the cardiovascular risk profile [136].

Adherence to Treatment

One important prognostic factor in children with LN, as in all children with chronic kidney disease, is adherence with treatment, especially during puberty. Non-adherence in adolescents is a common reason for relapse of symptoms, and may cause acute kidney injury after initially successful treatment. In such serious clinical situations, we would advocate the use of IV therapies (with rituximab treatment now our preferred option, which can be given at six-monthly intervals as maintenance treatment irrespective of peripheral CD19 counts) instead of oral treatments to ensure adherence and disease control.

Renal Replacement Therapy

The optimal therapy for patients with ESKD due to LN is renal transplantation, especially as patients seem to do equally well compared to matched controls, with less than 10% recurrence of LN and similar long-term patient and renal allograft survival [137, 138]. Patients should be in remission for 6 months prior to transplantation, and the transplant immunosuppression regimen should be standard, unless there are immunological concerns. However, it should be noted that the risk for thromboembolic complications was higher in the SLE group. Patients with SLE can have peritoneal or haemodialysis prior to transplantation, but in view of hypocomplementaemia and immunosuppression, clinicians should be wary of clinical presentation of flare of disease activity (which can be difficult to diagnose) versus infectious complications. Patients on peritoneal dialysis presenting with peritonitis should be treated with IV and intraperitoneal antibiotics.

Conclusion

The prognosis for children with SLE has improved over recent decades, with improved survival and fewer debilitating symptoms. There is, however, still a major challenge to obtain full remission of LN, which is essential for optimizing long-term kidney function. Another important challenge is to minimise treatment related mortality and morbidity. This has led to less CyC use, which has been replaced by other less toxic drugs, mainly MMF. Rituximab is now also routinely used in some centers, but further studies are needed to fully delineate its role. It is also important to find ways to reduce the burden of premature cardiovascular disease in these children.

27 IgA Vasculitis Nephritis (Henoch-Schönlein Purpura Nephritis)

Jae Il Shin

Introduction

Immunoglobulin A (IgA) vasculitis, formerly called Henoch-Schönlein purpura (HSP), was first described by William Heberden [1], a London physician, in 1801 and was named after the description of the clinical entity characterized by purpura and joint pain by Johann Schönlein in 1837 [2] and of the frequent association of gastrointestinal symptoms and kidney involvement by Edouard Henoch in 1874 [3]. IgA vasculitis is the most common form of systemic vasculitis in children; it mainly affects the skin, joints, gastrointestinal tract and kidneys. IgA vasculitis is usually self-limited to 1–4 weeks, but relapses can occur. The overall prognosis of IgA vasculitis is favorable, but the long-term prognosis is dependent on the degree of renal involvement [4, 5].

Diagnostic Criteria

The American College of Rheumatology (ACR) proposed in 1990 that the presence of any 2 or more of the following criteria was required for the diagnosis of IgA vasculitis: (1) an age of less than 20 years at disease onset, (2) palpable purpura, (3) acute abdominal pain, and (4) biopsy showing granulocytes in the walls of small arterioles or venules [6]. In 2005, the diagnostic criteria for IgA vasculitis were modified by the European League Against Rheumatism/Paediatric Rheumatology European Society (EULAR/PRES) [7]. In this new diagnostic system, the age criterion was deleted, 'predominant IgA deposition' was included in the definition of the 'biopsy' criterion, and arthritis and renal involvement were added as independent criteria [7]. Therefore, IgA vasculitis is diagnosed as follows: palpable purpura (mandatory criterion) in the presence of at least one of the following four features: (1) diffuse abdominal pain, (2) any biopsy showing predominant IgA deposition, (3) arthritis or arthralgia (acute, any joint), and (4) renal involvement (any hematuria and/or proteinuria) [7]. Skin biopsy is rarely performed to diagnose IgA vasculitis, but may be necessary in doubtful cases such as isolated purpura or atypical characteristics to differentiate from leukocytoclastic vasculitis. The latter will show no IgA deposits [7, 8].

Epidemiology

The prevalence of IgA vasculitis varies from 3.0/100,000 to 26.7/100,000 children [9, 10]. IgA vasculitis is more common in preschool aged children and in males, and there seems to be an increased frequency in autumn and winter. The pathogenesis of IgA vasculitis is unclear, but it is considered as a complex disease caused by various genetic and triggering environmental factors [9]. It is often preceded by an upper respiratory tract infection 1–3 weeks prior to the onset of symptoms. Various infectious agents, such as parvovirus B19, hepatitis B and C virus, adenovirus, Group A β-hemolytic streptococcus, staphylococcus aureus, and mycoplasma, and various drugs, vaccinations, cancers, insect bites or exposure to cold weather have been reported as triggering factors for IgA vasculitis [9, 10]. Familial cases of IgA vasculitis have also been reported [11].

Clinical Findings

Skin

Palpable purpura is the most common finding, but petechiae, maculae, papulae, urticaria, ecchymosis or bullae can also occur. Skin lesions are generally distributed symmetrically over the extensor surfaces of the lower legs (gravity or pressure-dependent areas), arms and buttocks, but trunk, face, eyelids, earlobes and genitalia can also be involved [12]. In young children, edema of the scalp, hands and feet can be observed. The skin findings usually resolve within 1–2 weeks, but persistent (>4 weeks) or relapsing skin manifestations are observed in about 25% of children with IgA vasculitis, and may be associated with the occurrence and severity of renal involvement [13–15].

Joints

Joint symptoms occur in about 80% of children with IgA vasculitis, and large joints of the lower extremities, such as the ankles and knees, are usually affected [12]. Joint pain is a frequent finding and periarticular swelling and tenderness, usually without synovial fluid effusion, may be present. Joint symptoms resolve with time without any deformity or erosions [12].

Gastrointestinal Tract

Gastrointestinal involvement is reported in about 50–70% of children with IgA vasculitis and usually presents as diffuse abdominal pain, which can be increased after meals, nausea, emesis, and bloody stools such as melaena and hematochezia [12, 16]. Gastrointestinal symptoms are caused by bowel wall edema and submucosal hemorrhage due to vasculitis. Severe gastrointestinal complications can occur, including intussusception, bowel infarction, gangrene or perforation, duodenal obstruction, massive gastrointestinal hemorrhage requiring blood transfusion, appendicitis, pancreatitis, hydrops of the gall bladder, protein losing enteropathy and formation of fistulas or strictures.

Other Nonrenal Organ Involvement

Although rare, IgA vasculitis can be complicated by various other manifestations, such as neurologic findings (obtundation, seizure, paresis, cortical blindness, chorea, ataxia and cranial or peripheral neuropathy), urologic complications (orchitis, epididymitis, and stenosing ureteritis, presenting as renal colic), carditis, myositis or intramuscular bleeding, pulmonary hemorrhage, and anterior uveitis [17]. Because some of these manifestations can be rapidly fatal, close observation and monitoring of affected patients is important.

Kidney

The incidence of renal involvement in IgA vasculitis varies from 20 to 80% in published case series [13–15]. Renal involvement includes iso-

lated haematuria (14%), isolated proteinuria (9%), both hematuria and proteinuria (56%), nephrotic-range proteinuria (20%) and nephrotic-nephritic syndrome (1%) [15]. Hypertension may develop at the onset of disease or during recovery, even with minimal or no urinary abnormalities [18]. In a large UK primary care database of 10,405 patients with childhood-onset IgA vasculitis, there was a significantly increased risk of hypertension and stage 3–5 chronic kidney disease (CKD) compared with age-matched and sex-matched controls, although there was no evidence of association with ischaemic heart disease, cerebrovascular disease or venous thromboembolism [19]. Therefore, appropriate surveillance for hypertension and CKD in children with IgA vasculitis may be necessary, and risk factor modification could improve long-term outcomes in these patients [19].

The first urinary abnormalities are detected within 4 weeks of disease onset in 80% of children with IgA vasculitis and within the next 2 months in the remainder, although a small number of patients present with urinary abnormalities several months later or as the initial feature [20]. Minor urinary abnormalities usually resolve with time, whereas severe renal involvement such as nephrotic syndrome and acute nephritic syndrome, can progress to CKD. In a systematic review of 1133 children with IgA vasculitis observed in 12 studies, the overall incidence of long-term renal impairment (defined as persistent nephrotic syndrome, nephritis, or hypertension) was 1.8%. Permanent renal impairment occurred in none of the 65.8% children with normal urinalysis during the acute disease, in 1.6% of the 26.9% with isolated haematuria and/or proteinuria, and in 19.5% of the 7.2% patients initially presenting with nephritic or nephrotic syndrome [20].

Risk Factors for Renal Involvement

Some authors reported that an older age at onset, persistent purpura (>4 weeks), severe abdominal symptoms, decreased factor XIII (fibrin stabilizing factor) activity, and a relapsing disease pattern are significant risk factors for renal involvement in children with IgA vasculitis, and these factors were linked to each other and all indicated a severe disease course [13–15]. In addition, persistent purpura, severe abdominal symptoms, and relapse were associated with the development of significant proteinuria [14]. A recent meta-analysis showed that significant risk factors associated with renal involvement in IgA vasculitis were male gender, abdominal pain, gastrointestinal bleeding, severe abdominal pain, persistent purpura, relapse, a high white blood cell count ($>15 \times 10^9$/L), a high platelet count ($>500 \times 10^9$/L), elevated anti-streptolysin O (ASO) titer and decreased complement component 3 (C3) [13].

Atypical Presentation

IgA vasculitis is diagnosed clinically, but atypical presentation often causes difficulties in the diagnosis. Gastrointestinal symptoms precede the cutaneous rash in about 25% of children with IgA vasculitis, [16] and joint symptoms or scrotal pain may precede the skin rash [16]. In addition, some diseases such as systemic lupus erythematosus, microscopic polyangiitis or Crohn disease can mimic IgA vasculitis [21]. Since atypical presentation of IgA vasculitis can lead to an incorrect diagnosis, causing unnecessary therapies and procedures (e.g., appendectomy) and unfavorable outcomes, it is important to include IgA vasculitis in the differential diagnoses, although diagnosis can be very difficult in those settings.

Laboratory and Radiologic Investigations

Because IgA vasculitis is diagnosed clinically, there is no specific diagnostic test for IgA vasculitis. Recommended initial investigations are complete blood count to evaluate for anemia or leukocytosis, erythrocyte sedimentation rate to evaluate for inflammation, coagulation profile to exclude bleeding disorders, biochemical profile

to screen for acute kidney injury or hypoalbuminemia, ASO titer, urine dipstick and protein/creatinine ratio to evaluate for renal involvement and tests to screen for sepsis if the diagnosis is unclear and purpura is present (e.g., blood culture for meningococcemia) [22]. Antinuclear antibody titer, anti-double stranded DNA antibody, antineutrophil cytoplasmic antibody (ANCA), complement levels (C3 and C4) and immunoglobulins (IgG, IgA and IgM) may also be necessary to differentiate IgA vasculitis from other vasculitides or overlapping diseases.

IgA vasculitis has a bleeding tendency due to abnormal platelet aggregation, decreased factor XIII levels by vasculitic process and increased von Willebrand factor (vWF) levels by endothelial injury despite normal platelet count and clotting factors [23, 24]. Plasma D-dimer levels can be increased [24]. A stool test for occult blood can be used to detect gastrointestinal hemorrhage.

Serum IgA levels (mostly IgA1) are increased in 50% of children with IgA vasculitis, and IgA-rheumatoid factor, IgA-containing immune complexes, IgA-fibronectin aggregates and cryoglobulins have been found [25, 26]. Serum IgE and eosinophil cationic protein (ECP) levels can be elevated, [27, 28] and C3, C4, and CH50 levels are occasionally decreased in the acute stage of disease [29]. ANCAs (c-ANCA and p-ANCA) are generally negative in IgA vasculitis except in rare cases [30, 31], but IgA-ANCA has been detected in the acute stage of disease [32, 33]. Antiphospholipid antibodies may be positive [34].

Imaging studies may be necessary to detect complications of IgA vasculitis, with selection based on the clinical picture [22]. Chest X-ray can detect pulmonary involvement; abdominal X-ray can identify ileus or perforation of the gastrointestinal tract. Renal ultrasound can detect increased echogenicity of the kidneys or hydronephrosis; abdominal ultrasound can identify thickened bowel wall or intussusception [22].

Renal Histopathologic Findings

Light Microscopy Findings

The light microscopic findings of IgA vasculitis nephritis (IgAVN) are characterized by mesangial proliferative glomerulonephritis with varying degrees of mesangial hypercellularity (Fig. 27.1a), segmental sclerosis (Fig. 27.1b) and crescents (Fig. 27.1c), similar to the predominant findings in IgA nephropathy (IgAN) [35, 36]. These glomerular changes are usually graded according to the International Study of Kidney Disease in Children (ISKDC) classification system (Table 27.1) [37]. Crescents are reportedly much more common in IgAVN than in IgAN [25] and are frequently seen in association with capillary wall destruction and endocapillary cell proliferation with subendothelial immune deposits of IgA and complement [38]. Crescents are classified as cellular, fibrocellular or fibrous. Crescents are cellular at the onset of the disease and evolve with time towards fibrous, causing global glomerulosclerosis (Fig. 27.1d).

Because the ISKDC classification does not include tubulointerstitial changes and other histologic features in IgAVN, some authors have used histopathologic scoring systems, such as activity and chronicity scores [39, 40]. Acute changes included mesangial matrix increase, mesangial hypercellularity, endothelial swelling, hyalinosis, basement membrane adhesion to Bowman's capsule, glomerular lobulations, glomerular neutrophils, fibrinoid necrosis, nuclear debris, interstitial vasculitis with leukocytoclastic reaction, tubular damage, interstitial edema and interstitial mononuclear infiltrate [39]. Chronic changes include interstitial fibrosis, tubular atrophy, fibrous crescents, global sclerosis, vascular hyalinosis and intimal hyperplasia [39]. The degree of tubulointerstitial lesions is correlated with the glomerular pathology [35].

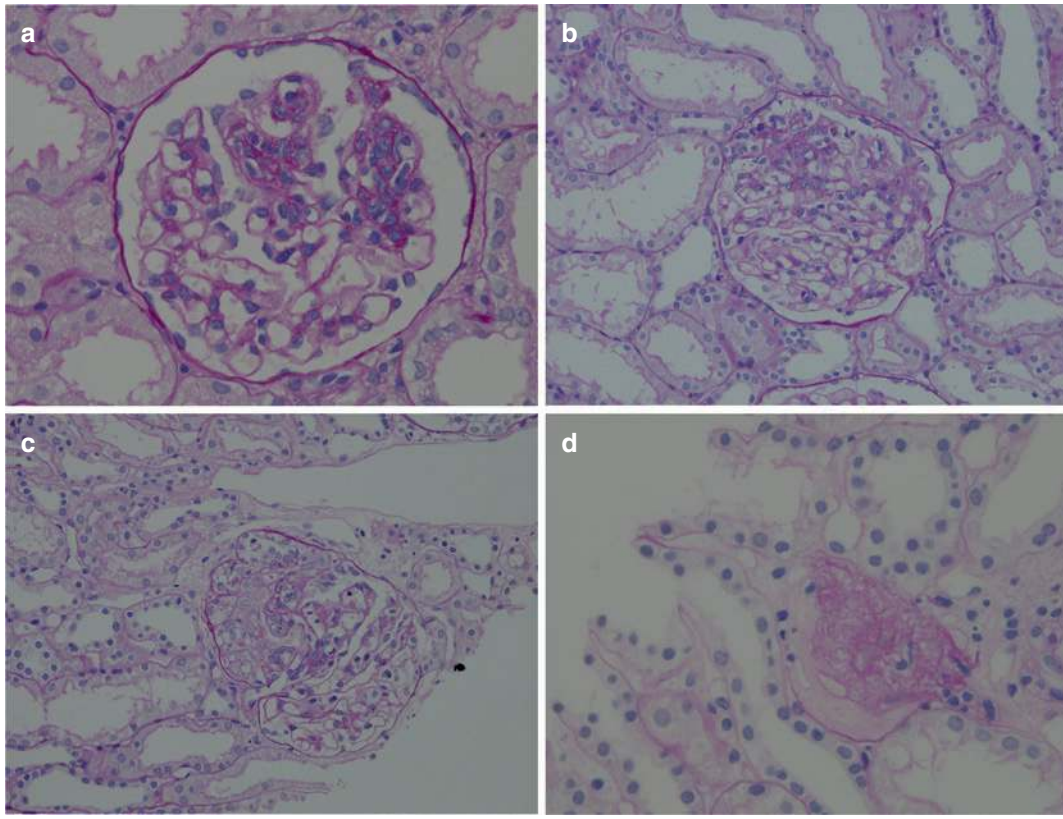

Fig. 27.1 Light microscopy findings in IgA vasculitis nephritis. (**a**) Mild mesangial cell proliferation (PAS, ×400). (**b**) Glomerulus with segmental sclerosis (PAS, ×200). (**c**) Glomerulus with cellular crescent (PAS, ×200). (**d**) Glomerulus with global sclerosis (PAS, ×400)

Table 27.1 The classification of IgA vasculitis nephritis in the International Study of Kidney Disease in Children

Grade I		Minimal alterations
Grade II		Mesangial proliferation without crescents
Grade III	IIIa	Focal mesangial proliferation or sclerosis with <50% crescents
	IIIb	Diffuse mesangial proliferation or sclerosis with <50% crescents
Grade IV	IVa	Focal mesangial proliferation or sclerosis with 50–75% crescents
	IVb	Diffuse mesangial proliferation or sclerosis with 50–75% crescents
Grade V	Va	Focal mesangial proliferation or sclerosis with >75% crescents
	Vb	Diffuse mesangial proliferation or sclerosis with >75% crescents
Grade VI		Membranoproliferative glomerulonephritis

Immunofluorescence Findings

Granular deposits of IgA (predominantly IgA1) in mesangial areas are characteristic of IgAVN (Fig. 27.2a). The IgA deposits are diffuse, in contrast to the frequent focal and segmental changes of glomeruli. C3 (Fig. 27.2b) and the alternative complement pathway components are frequently found, but the components of the classic complement pathway, such as C1q and C4, are rarely detected [38, 41]. IgA and C3 can be deposited in arterioles and capillary walls [25, 36, 38]. IgG and IgM are less frequently detected [38, 42]. Glomerular fibrin deposits (Fig. 27.2c) are more frequently found in IgAVN than in IgAN, [25, 38] and are associated with the formation of crescents.

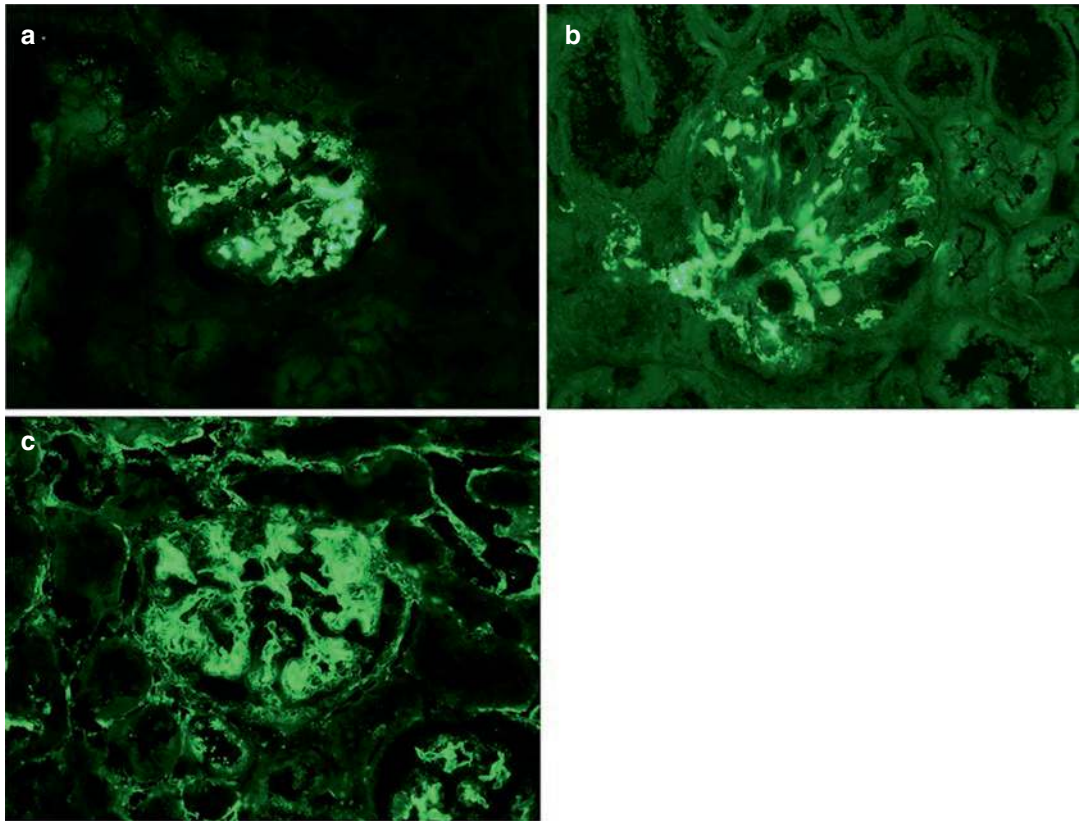

Fig. 27.2 Immunofluorescence findings in IgA vasculitis nephritis. (**a**) Mesangial IgA deposition (×100). (**b**) Mesangial C3 deposition (×200). (**c**) Mesangial fibrinogen deposition (×100)

Electron Microscopy Findings

Electron-dense deposits are mainly found in mesangial areas (Fig. 27.3a), but the deposits can be detected in subendothelial areas (Fig. 27.3b); rarely, hump-like deposits are found in subepithelial areas [25, 35, 41]. There are varying degrees of foot process effacement of visceral epithelial cells, depending on the degree of glomerular injury [25, 35, 41].

Clinicopathologic Correlations

In general, a good correlation between the severity of renal involvement and pathologic grading is observed in IgAVN and the severity of proteinuria at onset is a significant determinant of renal pathologic findings such as crescent formation, endocapillary proliferation, and tubular atrophy [43]. Proteinuria is also correlated with the ISKDC grade [44]; however, even mild to moderate proteinuria may be associated with severe morphological changes [44]. Hence, renal biopsy may be indicated, not only in patients with nephrotic syndrome, but also in those with mild proteinuria.

Although there are few reports on follow-up renal biopsies in IgAVN, there is also a generally good correlation between the clinical course and histopathologic changes [45]. IgAVN children who achieve clinical remission show a decrease in IgA deposits and regression of mesangial proliferation or crescents on follow-up renal biopsy, while those who have persistent nephritis demonstrate severe histologic findings with chronic lesions [45]. However, some reports emphasized that abnormal renal histologic findings can per-

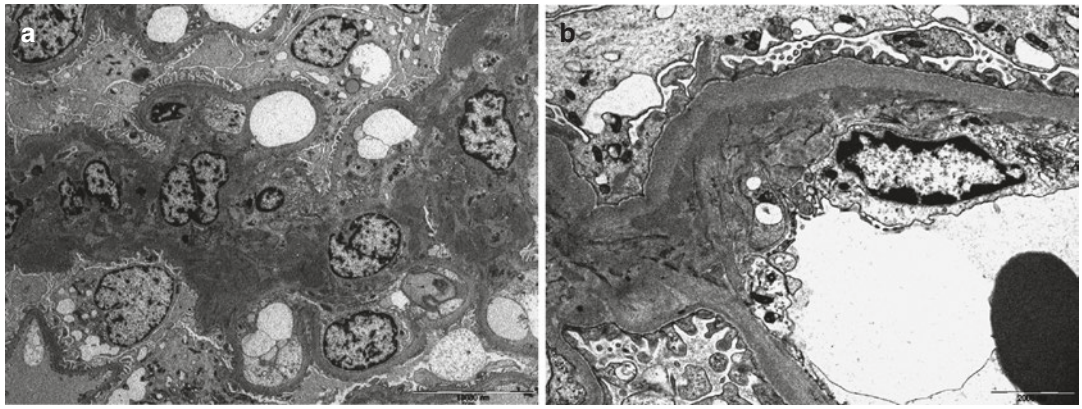

Fig. 27.3 Electron microscopy findings in IgA vasculitis nephritis. (**a**) Electron dense deposits in mesangial areas (×3000). (**b**) Electron-dense deposits in subendothelial areas (×10,000)

sist despite clinical remission [46, 47]. Algoet et al. reported that renal histologic findings were normal only in 25% of patients who had achieved complete clinical remission 5–9 years after the onset of IgA vasculitis [46]. Shin et al. also showed persistent histologic abnormalities in all patients of a IgAVN cohort after immunosuppressive treatment regardless of clinical improvement, suggesting the kidneys were not completely healed even in those with clinical remission [47].

Risk Factors for Poor Prognosis

The clinical presentation at the onset of IgAVN is predictive of long-term outcome [20]. The risk of progression to CKD was highest in IgA vasculitis children who presented with nephritic-nephrotic syndrome (45–50%) followed by those with nephrotic syndrome (up to 40%), acute nephritic syndrome (up to 15%), hematuria and non-nephrotic proteinuria (5–15%) and microscopic hematuria with or without minimal proteinuria (<5%) [20, 48]. In a systematic review, the risk of long-term renal impairment was 12 times higher in IgAVN patients with nephritic or nephrotic syndrome than in those with only abnormal urinalysis, and was 2.5 times higher in females than males [20]. Additional information is provided by very long-term outcome studies of IgAVN [49, 50]. Revisiting a cohort of IgA vasculitis patients at an average of 23 years after first manifestation, Goldstein et al. observed highly unpredictable late outcomes; 7 of 78 patients with normal urinalysis or apparent complete recovery showed active renal disease or ESRD [49]. Ronkainen et al. also showed that even patients with mild renal symptoms at the onset of IgA vasculitis have a risk for severe long-term complications [50].

Also, the clinical course during follow-up may be important to predict the prognosis [48, 51, 52]. Bunchman et al. showed that a creatinine clearance <70 mL/min/1.73 m^2 3 years after onset predicted progression to ESRD, whereas a clearance >125 mL/min/1.73 m^2 predicted normal renal function at 10-year follow-up [51]. Coppo et al. demonstrated that the risk for progression was related to increasing mean proteinuria levels during follow-up in both children and adults with IgAVN [52].

Histopathological lesions related to poor prognosis are a high grade by ISKDC, crescents in >50% of glomeruli, glomerular sclerosis or tubulointerstitial changes [48, 53, 54]. However, the initial renal biopsy may not predict the outcome of IgAVN since patients with mild histopathological disease activity (ISKDC II-III) usually receive less aggressive immunosuppressive therapy [55]. Therefore, some investigators suggested that serial biopsies might be helpful to establish the ultimate outcome in IgAVN patients with renal exacerbations [46]. A younger age at onset was an independent determinant of histo-

logical regression. The activity index at the follow-up biopsy correlated positively with changes in mesangial IgA deposits and the chronicity index at the follow-up biopsy correlated positively with the time immunosuppressive therapy was started [47]. One report suggested that the serum IgA/C3 ratio might be a useful marker for predicting serial histologic lesions of IgAVN because it correlated with the severity of renal pathology and clinical outcome in children with severe IgAVN [56].

Schärer et al., in a comprehensive multivariate analysis, demonstrated that initial renal insufficiency, nephrotic syndrome, and the severity of histological alterations (as defined by the percentage of glomeruli with crescents) are significant independent predictors of progressive renal failure in patients with IgAVN [54].

From a systematic review of 12 unselected IgA vasculitis populations, it was recommended that if the urinalysis is normal at presentation, monitoring can be limited to 6 months in patients with persistently normal urine findings [20]. However, the recommended duration of follow-up remains controversial since in individual children with normal urinalysis at onset renal involvement may still develop after several years [49, 50].

Pathogenesis

While the complete pathogenesis of IgA vasculitis remains to be elucidated, abnormalities of IgA have an important role. IgA vasculitis develops as a consequence of leukocytoclastic vasculitis due to IgA deposition in the wall of capillaries and post-capillary venules of various organs, including skin, gastrointestinal tract and the mesangium of the kidney [10, 12, 21]. Genetic predisposition, activation of complement, cytokines, autoantibodies and coagulation abnormalities are also involved in the pathogenesis of IgA vasculitis [21].

Genetic Predisposition

Although IgA vasculitis occurs mostly as sporadic cases, familial clustering has been reported [11]. Various candidate genes and genetic polymorphisms have been associated with the risk for IgA vasculitis or IgAVN [21]. These include human leukocyte antigen (HLA-A, B, B35, DRB1, DQA1), cytokines (interleukin (IL)-1ß,IL-1 receptor antagonist, IL-18, transforming growth factor (TGF)-ß), adhesion molecules (P-selectin, intracellular adhesion molecule-1), cytotoxic T-lymphocyte antigen 4, the MEFV gene (encoding pyrin, an important active member of the inflammasome), the renin-angiotensin system genes (angiotensin converting enzyme, angiotensinogen) and the C1GALT1 gene (encoding ß 1,3-galactosyltransferase, an important role in the glycosylation of the IgA1 hinge region).

Abnormalities of IgA

Elevated serum levels of IgA, principally IgA1, and circulating IgA-containing immune complexes are observed in patients with IgAVN [57, 58]. One study reported that the number of IgA-producing cells was increased in IgA vasculitis, but not in other forms of leukocytoclastic vasculitis [59]. Both increased IgA synthesis and decreased clearance have been reported as contributors to the pathogenesis of IgAVN [25]. It has been hypothesized that production of polymeric IgA by the mucosal immune system in response to various mucosally presented antigens [60] may be increased, and the reticuloendothelial system function impaired [61]. In addition, all patients with IgA vasculitis have IgA1-circulating immune complexes of small molecular mass, while only those with nephritis have additional large-molecular-mass IgA1-IgG-containing circulating immune complexes [58].

There are two subclasses of IgA (IgA1 and IgA2) and ~90% of serum IgA is IgA1. IgA1 and

IgA2 differ structurally in the hinge region of the heavy chain. IgA1, unlike IgA2, has a proline-rich hinge region composed of 5–6 O-linked glycosylation sites. An abnormal glycosylation of the IgA1 hinge region occurs in the context of a deficiency of galactose and/or sialic acid [21, 57]. Such an aberrantly glycosylated IgA1 is prone to cause IgA aggregation and may change IgA1 structure, modifying interactions with IgA receptors and matrix proteins, leading to mesangial deposition of IgA1 [21, 57]. Although no confirmed genetic loci for IgA vasculitis have been identified to date, it was recently reported that aberrant glycosylation of IgA1 is inherited in both pediatric IgAN and IgAVN [62]. However, Kiryluk et al. reported that an increase of the poorly galactosylated IgA1 *O*-glycoforms levels may be insufficient to cause IgAN or IgAVN because first-degree relatives had high serum levels of poorly galactosylated IgA1 *O*-glycoforms without any signs of either IgAN or IgAVN [62]. They suggested that a 'second hit,' such as the formation of glycan-specific IgG (and IgA) antibodies, which could form large circulating immune complexes prone to deposition, might be required to develop overt disease [62].

Activation of Complement

Activation of complement, mainly via the alternative pathway, is an important mechanism of tissue injury in IgA vasculitis. Complement components are found in skin and glomeruli, and breakdown products of complement in plasma [29, 63, 64]. C4A and C4B deficiencies have been described in patients with IgAVN, [65] and glomerular deposition of C3 and properdin has been reported in 75–100% of patients with IgAVN [66]. Activation of the lectin pathway of complement has also been demonstrated in patients with IgAVN, which might contribute to the development of advanced glomerular injury and long-term urinary abnormalities in IgAVN [64]. The lectin pathway is initiated by mannose-binding lectin (MBL). MBL also forms complexes with MBL-associated serine proteases (MASP-1, MASP-2 and MASP-3) [64]. Hisano et al. reported that MBL/MASP-1 might be associated with glomerular deposition of fibrinogen [64].

Activation of Eosinophils

Activation of eosinophils has also been proposed to contribute to the pathogenesis of IgAVN [27, 28]. Elevated plasma IgE levels were more common [27] and serum eosinophil cationic protein (ECP) levels were significantly higher in children with IgA vasculitis than in those with IgAN or healthy controls [28]. Davin et al. speculated that the IgA-containing immune complexes could enhance IgE production locally by stimulation of the dermal and intestinal mast cells and deposition of IgA immune complexes was further enhanced by a subsequent increase in local capillary permeability [27].

Cytokines and Coagulation Abnormalities

Several proinflammatory cytokines, including tumor necrosis factor (TNF)-α, IL-1β, IL-2, IL-6, IL-8, IL-17, TGF-β, and vascular endothelial growth factor, have been reported to be involved in the development of IgA vasculitis. They are likely secreted by vascular endothelial cells, thus initiating and propagating the inflammatory reaction [21].

Circulating immune complexes can cause vascular endothelial injury and coagulation abnormalities in IgA vasculitis; plasma vWF levels are elevated at the acute stage of IgA vasculitis [24]. Factor XIII activity can also be decreased during the acute stage of IgA vasculitis, possibly due to degradation of factor XIII by proteolytic enzymes from inflammatory cells [23].

Mesangial Proliferation and Crescent Formation

Once IgA-containing complexes are deposited in glomerular mesangium, various components of IgA-containing complexes, such as Fcα and Fcγ

fragments, fibronectin, or C3b, can bind to their receptors on the surface of mesangial cells and trigger proliferation of mesangial cells, production of extracellular matrix and synthesis of cytokines, such as monocyte chemoattractant protein-1 and IL-8, recruiting neutrophils and monocytes [25, 36, 67–71]. Other cytokines (TNF-α, IL-1, IL-6 and TGF-β) involved in the pathogenesis of IgA vasculitis can also stimulate mesangial cells [69–71].

In addition, local complement activation and intraglomerular coagulation by mesangial fibrin deposition can destroy the glomerular basement membrane. Attraction of macrophages and proliferation of cytokine-induced epithelial cells in Bowman's space can disrupt capsular integrity, leading to interstitial fibroblast infiltration into Bowman's space, causing crescent formation [25, 36, 38, 72].

Treatment

Prevention of Nephritis in IgA Vasculitis

Corticosteroids are commonly administered in the acute stage of IgA vasculitis to reduce the severity and duration of abdominal pain or arthralgia [73]. A number of retrospective studies, randomized controlled trials (RCTs), systematic review and meta-analyses have addressed the use of corticosteroids for preventing nephritis, with conflicting results [48, 73–76]. A well-conducted, randomized, double-blind, placebo-controlled trial showed no benefit of prednisone (4-week treatment) in preventing the development of nephritis in IgA vasculitis, but observed more rapid resolution of nephritis [73]. These results might be due to the reduction of mesangial proliferation and crescent formation by prednisone [77]. In addition, another randomized, double-blind, placebo-controlled trial reported that early 2-week treatment with prednisolone did not reduce the prevalence of proteinuria 12 months after disease onset in children with IgA vasculitis [74]. Based on this evidence, the Kidney Disease Improving Global Outcome (KDIGO) guidelines recommend not using corticosteroids to prevent nephritis in children with IgA vasculitis [78].

Although the general use of prednisone to prevent nephritis is not supported, IgA vasculitis patients with extrarenal symptoms might benefit from early treatment. Some IgA vasculitis patients cannot tolerate oral medications due to abdominal pain; in these, initial intravenous followed by oral steroid therapy could be a useful and effective therapeutic strategy [79].

Treatment of IgAVN

Treatment of IgAVN should be aimed to prevent long-term renal morbidity in patients at risk, but there have been few RCTs to establish the optimal treatment due to the rarity of severe IgAVN. Therefore, the treatment of IgAVN remains controversial.

The KDIGO Guidelines and Therapeutic Considerations in Pediatric IgAVN

The KDIGO initiative recently published guidelines on the treatment of IgAVN [78]. The guidelines suggest that IgAVN children with persistent proteinuria of >0.5–1 g/day/1.73 m^2 should be treated with angiotensin converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARB), and children with GFR >50 mL/min/1.73 m^2 and persistent proteinuria >1 g/day/1.73 m^2, after a trial of renin–angiotensin system (RAS) blockade, should receive a 6-month course of corticosteroids (same as for IgAN). For cases with >50% crescents on biopsy, the guidelines recommend steroids and cyclophosphamide. If plasma creatinine is >500 μmol/L, oral prednisone should be preceded by 3 methylprednisolone (MP) pulses, and the patient should also receive plasma exchange. These guidelines are the same as for crescentic IgAN and ANCA vasculitis, and are independent of the patient's age [78]. However, there was concern by some pediatric nephrologists that the KDIGO guidelines might delay the initiation of effective treatment and increase the long-term risk of CKD due to undertreatment of IgAVN [80]. They argued

that (1) the guidelines suggested for adults and children with IgAVN are based on randomized, controlled trials performed in adults with IgAN. However, IgAVN and IgAN are different diseases and have different outcomes despite similarities; (2) it is very important to treat initial episodes adequately without delay in IgAVN, and following the KDIGO guidelines might delay a potentially more effective treatment, increase the risk of CKD progression in patients with ISKDC grade IIIa, and cause a higher cumulative exposure to immunosuppressive therapy; (3) cyclophosphamide was ineffective in the treatment of IgAVN in the randomized controlled pediatric trials of the ISKDC; and (4) the KDIGO guidelines do not suggest addition of immunosuppressive drugs to steroids in patients with <50% crescentic glomeruli, even in the presence of nephrotic syndrome and/or deterioration of GFR, but more aggressive treatments, such as MP pulses, other immunosuppressive drugs or plasma exchange, may be required in these patients [80].

There are three aspects regarding the treatment of IgAVN that warrant additional commentary. First, the highly heterogenous spontaneous evolution of IgAVN should be considered. Many children with severe proteinuria at onset achieve spontaneous remission, but some children presenting with mild proteinuria develop severe renal pathology and progress to renal failure in the long-term [44, 81]. Second, the choice of therapy should be driven by the purpose of treatment. In most glomerular diseases, proteinuria reduction is accepted as an adequate surrogate marker of renal disease remission [82]. In IgAVN, however, some long-term studies have shown that clinical remission may not uniformly translate into a favorable long-term outcome [49, 50]. One study showed a discrepancy between clinical remission and histological improvement [47]. Therefore, it may be important to induce histological regression in addition to reduction of proteinuria in treating severe IgAVN. Third, it should be considered whether treatment should be based on clinical presentation or renal pathology in IgAVN. Ronkainen et al. reported that the first renal biopsy did not predict the outcome of IgAVN. The outcome of patients with ISKDC grades II–III was worse than of those with grades IV–V, probably because the latter received more aggressive immunosuppressive treatment. The authors suggested that the treatment of IgAVN should be based on clinical presentation rather than biopsy findings [55].

Indications for Renal Biopsy

Although clear outcome-based indications for renal biopsy in IgAVN have not been established, biopsy is usually recommended in patients with (1) nephrotic syndrome, (2) nephritic syndrome, (3) decreased renal function, (4) nephrotic-range proteinuria, and (5) non-nephrotic proteinuria persisting for more than 3 months [22]. Although the utility of renal biopsy in IgAVN with persistent mild to moderate proteinuria may be controversial, Halling et al. argued for biopsy since severe morphological changes are found in some of these patients [44]. It is also important to recognize that the interval between disease onset and the time of renal biopsy may affect histopathological findings; the percentage of crescents may increase markedly within days in patients with active disease [39, 80]. Repeat renal biopsies should be considered in patients showing worsening of renal symptoms or poor response to treatment [80].

Treatment of Mild or Moderately Severe IgAVN

Patients with mild IgAVN, such as microscopic hematuria or gross hematuria of short duration, generally do not require any medications.

In IgAVN children with persistent proteinuria of 0.5–1 g/day/1.73 m^2, the KDIGO guidelines recommend the use of ACE inhibitors or ARB [78]. In a study of 31 patients with moderately severe IgAVN (ISKDC grade I–III and serum albumin >2.5 g/dL), proteinuria was reduced efficiently by RAS blockers, except a single case of a clinical relapse at one year [83]. Davin and Coppo suggested that the use of RAS blockers is appropriate in cases lacking acute inflammation and crescentic lesions, whereas delaying effective anti-inflammatory treatment may be detrimental in patients with acute inflammatory

glomerular lesions [80]. This is supported by two studies: one showed that 9 of 13 patients with mild to moderate proteinuria had severe morphological changes; the second showed that 18% of patients with mild proteinuria at onset had a poor prognosis [44, 81]. Hence, a rational therapeutic approach could be as follows: in patients with non-nephrotic proteinuria and a normal serum albumin early in the course of IgAVN, monotherapy with a RAS blocker may be used for 1–2 months and the further course observed. In patients with non-nephrotic proteinuria and mildly decreased serum albumin levels at onset of IgAVN, combined oral steroids and RAS blockade may be used for 1–2 months. In patients with persistent (>2–3 months) non-nephrotic proteinuria and/or decreased serum albumin levels during the course of IgAVN despite these treatments, renal biopsy should be performed and more potent anti-inflammatory treatments considered guided by the histopathological findings. These treatments may include MP pulses, azathioprine, mycophenolate mofetil (MMF) or a calcineurin inhibitor, combined with oral steroids and RAS blockade. The beneficial effect of alternative treatments such as fish oil, rifampin or tonsillectomy on moderately severe IgAVN has not been established [48, 84].

Treatment of Severe IgAVN

Although the definition of severe nephritis in IgAVN differs among studies, it generally includes nephrotic syndrome, acute nephritic syndrome, nephrotic range proteinuria (>40 mg/m^2/h) or proteinuria >1 g/day and histopathological lesions exceeding ISKDC grade IIIa [50]. Treatment of severe IgAVN remains controversial due to a paucity of RCTs [48, 84, 85]. Most published work relies on retrospective analyses of small cohorts with heterogenous disease severity. However, there is consensus that intense initial therapy is indicated in severe IgAVN, considering a 15% overall long-term CKD risk and well-documented unfavorable outcomes of untreated patients, reduced CKD risk following intense treatment, and worse outcomes with delayed treatment [86–89].

Oral steroids have been shown to be ineffective in severe nephritis [5, 87, 88]. Niaudet et al. suggested that intravenous MP pulses should be started early in the course of severe IgAVN before crescents become fibrous, because renal scarring by extensive glomerular damage during the acute episode may be irreversible and lead to progressive CKD [88]. Hence, in patients with very severe IgAVN, intravenous MP pulses should be initiated immediately. Oral steroids can be utilized and tapered following the MP pulses. In addition, RAS blockers can be used as an add-on therapy concurrently as a nephroprotective, proteinuria-minimizing therapy [80].

An RCT performed by the ISKDC showed no differences in outcome between oral cyclophosphamide (90 mg/m^2/day for 42 days) and supportive therapy in children with severe IgAVN [90], although retrospective case series had suggested a beneficial effect [91, 92]. A placebo-controlled, prospective study comparing cyclophosphamide plus prednisone to prednisone alone demonstrated the lack of efficacy of cyclophosphamide in adults with IgAVN [93]. In view of these negative results and the potential side effects, cyclophosphamide is not recommended in severe IgAVN [80].

Another randomized clinical trial in a limited number of children suggested that cyclosporin A was non-inferior to intravenous MP pulses in children with severe IgAVN. Resolution of nephrotic-range proteinuria was achieved within 3 months in all 11 cyclosporin-treated patients, while it was not achieved with the initial treatment of MP pulses in 6 of the 13 due to slower response [94]. Additional immunosuppressive treatment was not necessary in any of the cyclosporin-treated patients, but was needed in 6 patients treated with MP pulses [94]. Repeat renal biopsy findings performed after 2-year follow-up showed similar improvement in both treatment arms [94].

Hence, calcineurin inhibitors are an alternative first choice or follow-up therapy in patients who do not respond rapidly to intravenous MP pulses. Azathioprine, MMF or other immunosuppressive drugs can also be used, although the

claim of efficacy for these drugs is based exclusively on non-randomized or uncontrolled studies [39, 40, 95–102]. In a recent meta-analysis of 9 articles, IgAVN patients treated with combined therapy (immunosuppressive agents plus steroids) demonstrated a significant increase in complete remission rates when compared with steroids alone and children seemed to benefit more from combined treatment than adults [99]. Administration of azathioprine and cyclosporin was associated with histological regression with reduced IgA deposits in severe IgAVN [40, 97, 98]. In one study, rituximab was shown to be effective for induction and maintenance of long-lasting remission in adults with severe refractory IgAV with biopsy proven crescentic nephritis; 10 of the 12 patients had a complete response [100]. However, the role of rituximab in children with severe IgAVN requires additional study.

Persistence of urinary abnormalities is an ominous sign in severe IgAVN [40, 52]. Hence, in patients with persistent proteinuria after initial intensive therapy, a follow-up renal biopsy may be needed to assess the histopathological effects of initial treatment. Subsequent therapy may be guided by the extent and acute vs. chronic nature of the remaining renal lesions. If persistent active histological lesions are found, adjustment of the immunosuppressive therapy should be considered. Although rare, in persistent, severe IgAVN resistant to azathioprine late remission was induced by switching to cyclosporin or MP pulses [103, 104]. RAS blocker monotherapy is a valid approach in cases of persistent proteinuria with a high chronicity index at the follow-up renal biopsy [80]. Conversely, it should be emphasized that proteinuria can resolve spontaneously years after discontinuation of immunosuppression in patients with severe IgAVN [40, 98].

In patients presenting with impaired renal function with rapidly progressive course or crescentic IgAVN affecting more than 50% of glomeruli (ISKDC IV and V), several intensive therapies have been suggested, emphasizing that early treatment is important in achieving a successful outcome [54, 87–89, 105–112]. Plasmapheresis has been utilized for rapidly progressive IgAVN to remove circulating immune complexes, immunoglobulins and mediators of inflammation; it has been used either alone or with other immunosuppressive drugs [54, 89, 105–108]. Hattori et al. reported that plasmapheresis as the sole therapy was effective in improving the outcome of patients with rapidly progressive IgAVN, particularly if instituted early in the course of the disease [89]. Schärer et al. suggested that plasmapheresis might delay progression, albeit not prevent eventual ESRD in children with crescentic IgAVN [54]. Therefore, plasmapheresis can be utilized promptly in patients who have nephritic and nephrotic syndrome and progressive decline in kidney function associated with ISKDC IV or V, and in those who are resistant to steroids and other immunosuppressive drugs.

In addition, combinations of several drugs, including cyclophosphamide, have been tried in the setting of rapidly progressive IgAVN, although cyclophosphamide alone was not effective in treating severe IgAVN [109–112]. Öner et al. reported a beneficial effect of triple therapy (MP pulses, cyclophosphamide, dipyridamole) in 12 patients with rapidly progressive IgAVN [109]. Iijima et al. also suggested the efficacy of combined therapies (MP pulses, cyclophosphamide, heparin/warfarin, dipyridamole) in 14 patients with rapidly progressive IgAVN (ISKDC IV or V) [110].

It has been speculated that fibrinolytic urokinase treatment might decrease crescent formation by reducing glomerular fibrin deposition [72, 111, 112]. Kawasaki et al. found methylprednisolone and urokinase pulse therapy (MUPT) which includes methylprednisolone (MP) pulses, urokinase, warfarin, dipyridamole was effective in patients with rapidly progressive IgAVN [111]. Addition of cyclophosphamide to MUPT was more effective than MUPT alone in the treatment of rapidly progressive IgAVN [112].

The experimental nature of these therapeutic approaches should be emphasized. The relative efficacy of individual and combined treatments in severe and rapidly progressive IgAVN awaits demonstration in RCTs with strict inclusion

criteria and standardized treatment protocols. In addition, a prospective cohort study, Cure Glomerulonephropathy (CureGN), includes patients with IgAVN and is expected to provide insights on the course and prognosis of the disease and efficacy of various therapies [113].

Special Conditions

Renal Transplantation

IgAVN may recur after renal transplantation. In 1994, the risk of clinical recurrence was 35% and the risk of graft loss due to recurrence 11% at 5 years after renal transplantation [114]. A study published in 2011 showed lower post-transplant IgAVN recurrence rates and the risk of graft loss related to recurrence was 2.5% and 7.5% at 5 and 10 years, respectively [115]. Although the risk of graft failure due to recurrence is increased in IgAVN, the diagnosis of IgA vasculitis does not affect overall renal allograft survival [116–118]. Graft survival of IgA vasculitis was similar to that of renal hypoplasia or dysplasia [117]. Histologic recurrence is frequently observed on routine renal biopsies, but often does not cause clinical consequences [117]. The severity of IgAVN at presentation and the types of immunosuppression after renal transplantation did not affect the risk of IgAVN recurrence [115, 118].

Pregnancy

Women with a history of IgA vasculitis during childhood may be at increased risk for renal complications during pregnancy [22, 50, 119]. Ronkainen et al. reported that 16 (70%) of 23 pregnancies were complicated by hypertension, proteinuria, or both and 5 (56%) of the 9 women with complicated pregnancies had a poor renal outcome [50]. Therefore, close monitoring during pregnancy is recommended in women with a history of childhood IgA vasculitis.

Metabolic Disorders Affecting the Kidney

28

Aude Servais, Olivia Boyer, Myriam Dao, and Friederike Hörster

Introduction

Inherited diseases of metabolism are a heterogeneous group of rare diseases, most often of autosomal recessive inheritance. These include energy metabolism disorders, intoxication diseases, and abnormalities in the synthesis or catabolism of complex molecules involved in intracellular maturation (lysosomal, peroxisomal, glycosylation abnormalities, etc.).

Kidney involvement may be inaugural, or more often complicate the evolution of an already diagnosed metabolic disorder. Improved survival in patients with metabolic diseases has led to the discovery of renal features that were not apparent at the time of the initial description of the condition (e.g., methylmalonic acidemia), and extrarenal manifestations in renal or urologic diseases that were thought to be primary and isolated (e.g., cystinosis). Metabolic disorders should be considered in the presence of kidney involvement, especially when children present with extrarenal symptoms.

The renal clinical spectrum of inherited diseases of metabolism is wide:

- Fanconi syndrome (proximal tubulopathy): the proximal renal tubule is most often affected in metabolic disorders due to a very high energy expenditure.
- chronic tubulointerstitial nephropathy, resulting from acute or chronic toxic tubular epithelium injury (e.g., myoglobinuria in fatty acid oxidation defects, methylmalonic acid in methylmalonic acidemia).
- glomerular damage with proteinuria, nephrotic syndrome, hematuria and/or hypertension, due to the abnormal deposition of storage material (e.g., Fabry disease), or structural defects (e.g., glycogenosis type 1, respiratory chain defects).
- hemolytic uremic syndrome, as a result of toxic damage to endothelial cells (e.g., in methyl-malonic acidemia vitamin B12-sensitive, or cobalamin C deficiency).
- nephrocalcinosis and urinary lithiasis, resulting from a defect in the reabsorption of a specific solute (e.g., cystine in cystinuria) or from the urinary excretion of solutes accumulated

in the plasma (e.g., oxalate in primary hyperoxaluria).
– renal cysts as a result of developmental defects.
– urine colour abnormalities (e.g. dark or reddish in porphyria, black in alkaptonuria);
– renal consequences of rhabdomyolysis.

These pathologies can lead to chronic kidney disease (CKD) and sometimes to kidney failure requiring renal replacement therapy and kidney transplantation.

When the cause of the inherited metabolic disorder is unclear, the type of renal involvement can be suggestive (Table 28.1).

Table 28.1 Renal involvement in inherited diseases of metabolism

Clinical features	Etiologies
Proximal tubulopathy (Fanconi syndrome)	Cystinosis Mitochondriopathies Tyrosinemia type 1 CDG syndrome Fructosemia Galactosemia Glycogenosis type 1 Bickel-Fanconi syndrome Wilson disease Lowe disease Dent disease Lysinuric Protein Intolerance
Other tubular defects, chronic TIN	MMA Mitochondriopathies Glycogenosis type 1 Pyruvate carboxylase deficiency Carnitine palmitoyl transferase (CPT) type 1 deficiency Adenosine deaminase deficiency Transaldolase deficiency Fatty acid Beta-oxidation disorders Imerslund-Gräsbeck syndrome
Glomerulopathy Proteinuria, nephrotic syndrome nephrotic syndrome, haematuria and/or hypertension	Fabry disease Mitochondriopathies Glycogenosis type 1 Mucopolysaccharidosis (MPS) type 1 (Hurler) Lysinuric protein intolerance Gaucher disease LCAT (lecithine cholesterolacyl transferase) deficiency
Kidney cysts	Mitochondriopathies: Pearson syndrome Zellweger syndrome CDG syndrome Glutaric acidemia type II Smith-Lemli-Opitz syndrome

Methylmalonic Acidemia and Propionic Acidemia

Methylmalonic acidemias comprise a family of diseases which share the common feature of elevated concentration of methylmalonic acid in blood, urine and other body fluids. There are secondary forms related to vitamin B12 deficiency and different primary diseases of cobalamin metabolism and methylmalonyl-CoA mutase deficiency leading to this biochemical phenotype. It is useful to differentiate between isolated methylmalonic acidurias and combined methylmalonic acidurias, which additionally show elevated concentrations of homocysteine (Table 28.2) [1–3].

Methylmalonyl-CoA mutase is located within the metabolic pathway linking degradation of certain aminoacids (isoleucine, methionine, threonine and valine), odd-chain fatty acids and cholesterol side chains to the citric acid cycle. Propionic acidemia is caused by deficiency of propionyl-CoA carboxylase, an enzyme upstream

Table 28.2 Methylmalonic acidemia and propionic acidemia

	Gene	MIM number
Methylmalonic acidemia: isolated forms		
mut type (*mut*^{0}, *mut*$^-$)	*MUT*	#25100
cblA type	*MMAA*	#251100
cblB type	*MMAB*	#251110
cblD variant 2	*MMADHC*	#277410
Methylmalonic acidemia: combined forms with homocystinuria		
cblC type	*MMACHC*	#277400
cblD-variant 1	*MMADHC*	#277410
cblF type	*LMBRD1*	#277380
cblJ type	*ABCD4*	#614857
Propionic acidemia	*PCCA* *PCCB*	#606054

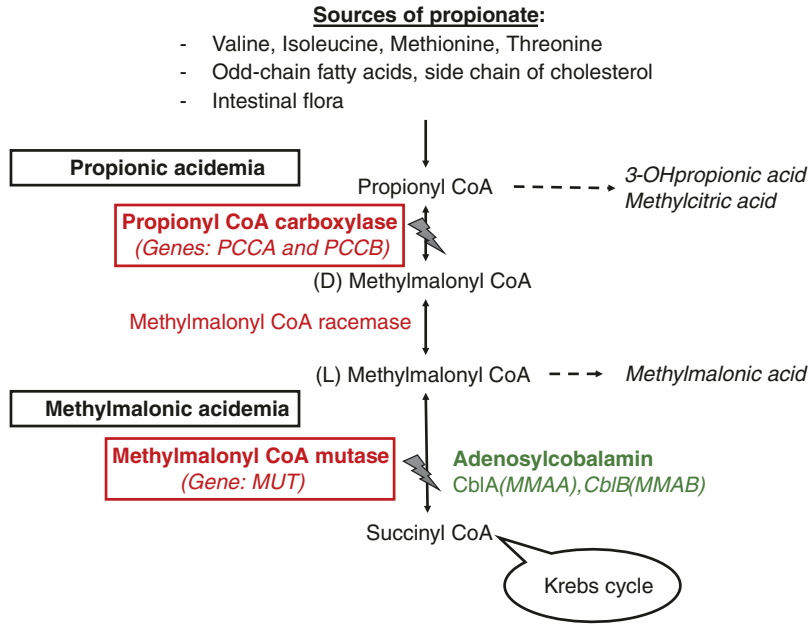

Fig. 28.1 Methylmalonic acidemia and propionic acidemia

of methylmalonyl-CoA mutase (Fig. 28.1). These diseases are the most frequent classical organoacidemias with an estimated incidence of 1:50,000 (isolated methylmalonic acidemias) and 1:150,000 (propionic acidemia). Within the group of isolated methylmalonic acidemias, most patients are affected by a complete deficiency of methylmalonyl-CoA mutase (mut^0) [1].

Clinical Picture of Isolated Methylmalonic Acidemias

Acute manifestation is a life-threatening metabolic decompensation characterized by profound metabolic acidosis, ketosis and hyperammonemia leading to deep coma and death, if not treated adequately. Most patients manifest within the neonatal period, the others later in life. Metabolic crises are often preceded by a catabolic state, typically induced by minor infections. A severe crisis can lead to irreversible neurologic sequelae such as basal ganglia necrosis, epilepsy or mental retardation, but a growing number of patients show normal psycho-motor development. Apart from the development of chronic renal failure (see below), failure to thrive and recurrent vomiting often complicate the clinical course. Acute or chronic pancreatitis are rarer but potentially dangerous complications.

If suggestive clinical symptoms occur, the diagnostic work-up of a patient can be started by measurement of acylcarnitines in dried blood spots or directly by measurement of organic acids in urine [4]. The differential diagnosis of the several genetic defects is actually performed by molecular genetic testing, but several different genes have to be considered [4].

Disease severity differs considerably between subtypes: late onset patients who are responsive to hydroxocobalamin tend to have a better outcome if treated adequately, in contrast to patients affected by a complete deficiency of methylmalonyl-CoA mutase (mut^0) [5–7]. Synergistic impairment of different targets within mitochondrial energy metabolism by different metabolites is the key to understand the pathophysiology of these diseases as multisystem disorders [8–10].

Clinical Picture of Combined Methylmalonic Acidurias

The most common disorder in this group is *cblC* disease (more than 500 reported cases). The majority of patients has an early disease onset, which is defined as disease onset before 12 months of age. In addition to acute metabolic crisis, patients may show signs of prenatal damage (intrauterine growth retardation and/or congenital heart disease) and thrombotic microangiopathy (atypical hemolytic uremic syndrome). Visual impairment and nystagmus due to optical nerve atrophy and retinopathy are typical complications within the disease course. Patients develop a complex neurological phenotype with brain atrophy and white matter disease leading to developmental delay, psychiatric problems and peripheral neuropathy.

Elevated concentration of plasma homocysteine levels is the biochemical hallmark of the disease: usually homocysteine levels are below 50 μmol/L (depending on the individual laboratory cut-offs), but in untreated patients levels above 100 μmol/L are found. It is recommended to measure total homocysteine in blood [3]. For further diagnostic work-up, investigation of plasma amino acids to identify low levels of methionine and organic acids in urine to identify elevated levels of methylmalonic acid are recommended. To rule out deficiency, plasma levels of vitamin B12 and folate should also be investigated [3]. Molecular genetic analysis of the *cblC* gene is possible and the three most common mutations show a genotype-phenotype correlation according to early or late disease onset [3].

Kidney Involvement

Chronic kidney disease (CKD) is a common complication of MMA, manifesting in childhood in half of the patients [5, 7, 11]. It is most frequently observed in mut° and cblB phenotypes, less frequently in patients with cblA and mut- phenotypes [12]. Median age at onset varies from 6.5 to 11.9 years (range: 1.5–33 years). Twelve to fourteen percent of patients evolve to end-stage renal disease (ESRD) requiring renal replacement therapy [5, 7]. The mechanisms responsible for renal failure in MMA remain poorly understood [5, 8, 13, 14]. It has been suggested that CKD in MMA is the consequence of tubular dysfunction. The hypothesis of chronic tubulopathy is supported by experimental studies [8, 13, 14].

A recent experimental study demonstrated a link between MMA, diseased mitochondria, mitophagy dysfunction and epithelial stress in tubular renal cells [15]. However, only few clinical case reports found proximal tubulopathy or distal tubular acidosis type 2 [16–18]. Kidney biopsy studies showed severe interstitial fibrosis and tubular atrophy with ultrastructural (enlarged mitochondria in proximal tubules) and functional (loss of cytochrome C, decrease in NADPH activity) alterations [7, 13, 16, 19] (Fig. 28.2). A recent study investigated tubular functions in 13 adolescent and adult MMA patients who did not previously receive kidney and/or liver transplantation [20]. The authors confirmed the high prevalence of CKD (54% had mGFR below 60 mL/min/1.73 m^2) but they failed to demonstrate tubular involvement. No patient had complete proximal tubular syndrome. Only one patient had biological signs suggestive of incomplete proximal tubulopathy with increased β2-microglobulin excretion and renal loss of magnesium [20].

As all patients with isolated MMA, even in the moderate forms, are considered to be at risk of developing chronic kidney disease (CKD), renal function should be closely monitored. There is a risk of developing progressive kidney failure, requiring renal replacement therapy and kidney transplantation. The estimated glomerular filtration rate (eGFR) based on serum creatinine levels

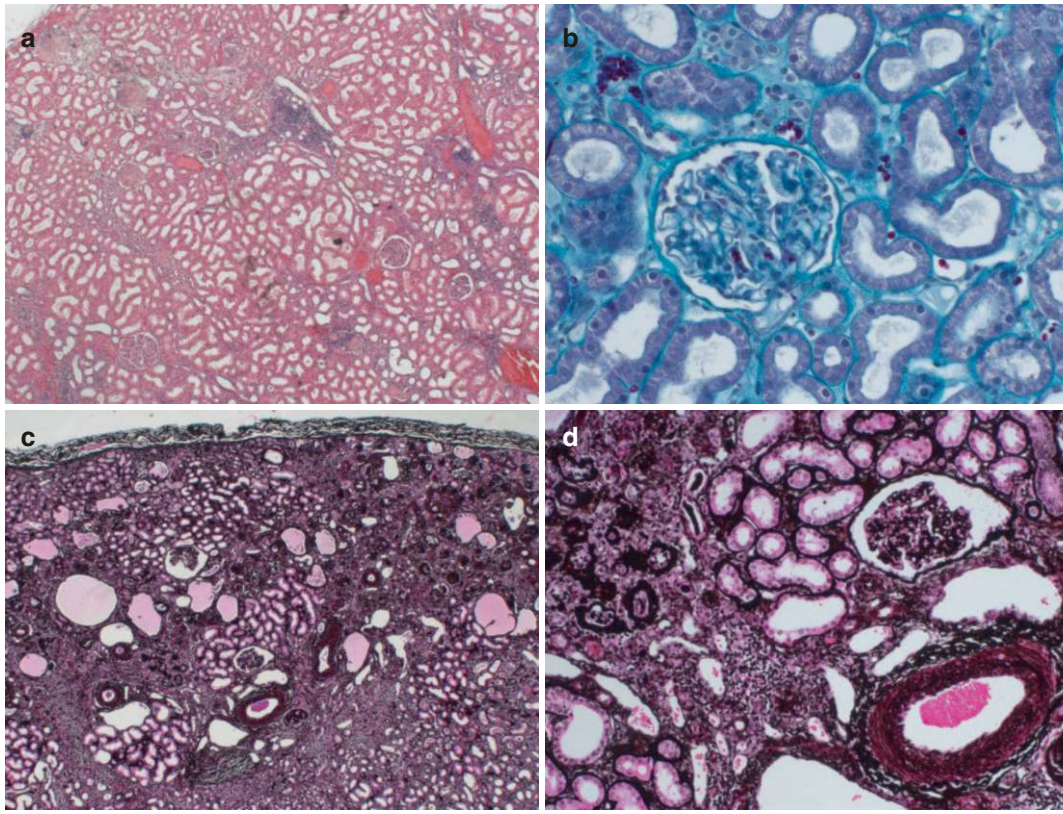

Fig. 28.2 Methylmalonic acidemia (MMA) renal biopsy. Two nephrectomy specimen procured at the time of transplantation in children with MMA at different stages of chronic kidney disease. The first specimen (**a** and **b**) shows non-specific mild tubular atrophy with interstitial fibrosis (IF/TA) and moderate inflammation within fibrotic areas (**a**) (HES staining, ×250). (**b**) Glomeruli are unremarkable and proximal tubules shows vacuoles in epithelial cells (Masson Trichrome, ×500). The second specimen (**c** and **d**) shows severe IF/TA with ischemic glomeruli (**c**) and tubular dilatations (Jones staining, ×250). Arteries display thickening of the media (**d**) (Jones staining, ×500). (Picture from M Rabant and MC Gubler)

may overestimate the actual GFR due to the low muscle mass and protein intake of patients [20]. Therefore, it is recommended to measure the GFR using "gold standard" techniques such as the inulin or iohexol clearances, when therapeutic decisions such as dialysis or transplantation are discussed.

The cumulative urinary excretion of methylmalonic acid over time (measured in repeated urine samples) correlates with the risk of CKD [5]. However, as kidney function declines, urinary methylmalonic acid is no longer a reliable marker and must be replaced by measurement of plasma methylmalonic acid. Standard medical management and follow-up of CKD follows the general therapeutic principles established in patients without inborn errors of metabolism, including monitoring of blood pressure, electrolytes, prevention and management of anemia, growth and bone disease. The experience with nephroprotective measures in the paediatric population has not been extensively studied.

In PA, a few cases of kidney failure have been reported [21].

Conservative Treatment

Isolated Methylmalonic Acidemias

The classical treatment consists of protein restricted diet (limited intake of precursor amino acids), which has to be tailored to the patients' needs and carefully monitored. L-carnitine (100 mg/kg/day) is applied to restore carnitine levels and CoA levels, bind and eliminate propionyl-CoA molecules, which are assumed to be responsible for some of the toxic metabolite effects in MMA [4]. Hydroxocobalamin is a powerful therapeutic tool in responsive patients; therefore this option has to be carefully evaluated [6]. In the recent guideline, a protocol for patients' monitoring has been proposed (Table 28.3) [4].

Table 28.3 Suggested monitoring in isolated methylmalonic acidemia and propionic acidemia according to guideline (adapted from [4])

Assessment	Frequency
Metabolic follow-up	
NH3, blood gas, lactate	Each clinic visit
Quantitative plasma amino acids (3–4 h of fasting prior to sample collection)	3–6 monthly
Methylmalonic acid in plasma (and urine if available)	3–6 monthly
Acylcarnitine profile in dried blood or plasma (propionylcarnitine and free carnitine)	3–6 monthly
Diet and nutritional status	
Diet history	Each clinic visit
Growth (weight, length or height, head circumference)	Each clinic visit
Full clinical examination	Each clinic visit
Albumin, total protein	6-monthly
Bone health (Ca, P, ALP, Mg, PTH, 25-OH vitamin D in blood; Ca, P in urine)	12-monthly
Full blood count, ferritin, folic acid, vitamin B12	12-monthly
Long-term complications	
Neurological examination with assessment of developmental milestones	Each clinic visit
Kidney function (serum creatinine, electrolytes, cystatin C, uric acid; urinary electrolytes and protein loss; GFR)	6-monthly
Pancreas function (lipase, pancreatic amylase)	6-monthly
Cardiac assessment (ECG, echocardiography)	12-monthly
Formal developmental/cognitive assessment	When clinically indicated
EEG, cerebral MRI	When clinically indicated
Ophthalmologic assessment	12-monthly
Formal hearing test	When clinically indicated

Combined Methylmalonic Acidurias

Experience on treatment mostly derives from cblC patients, the most common disorder. Treatment aims at normalizing plasma methionine and methylmalonate levels and reducing plasma total homocysteine. In severe cases levels of total homocysteine cannot be normalized, but levels between 40 and 60 μmol/L can be reached [3].

Treatment consists of hydroxocobalamine parenterally and betaine [3]. This treatment reduces homocysteine and methylmalonate levels and prevents metabolic crisis, but visual and cognitive impairment may not improve [3, 22].

Kidney and Liver Transplantation

The long-term outcome of MMA remains poor with medical treatment. Organ transplantation is an alternative, especially in case of renal failure but also as an enzyme replacement therapy. However, it remains unanswered exactly which patients should be transplanted. Liver transplantation (LT), kidney transplantation (KT), or combined liver and kidney transplantation (LKT) have been proposed for renal failure or as an enzyme replacement therapy in case of frequent metabolic decompensations, but also to prevent long-term complications [23]. Several reports emphasized the improved quality of life after LT [23].

The metabolic results after LKT are dramatically better than after KT, reducing protein restriction and improving quality of life. However, it is associated with an increased frequency of adverse events. Global patient survival after transplantation is calculated at 86–87% [23, 24], similar to non-transplanted patients and to patients receiving transplantation for other indications [24]. Mortality risk is highest within 14 days after transplantation. To decrease the mortality risk, it is recommended to ensure a stable metabolic state at time of transplantation and to have transplantation performed by an experienced transplantation team [24]. Some patients experience post-LKT neurological disorders, mainly reported in Mut0 type MMA [23, 24]. This might be due to calcineurin inhibitor toxicity [25].

Early LT may be considered to prevent years of protein deprivation and MMA toxicity and to delay the need for KT. LKT should be proposed when the measured GFR is lower than 60 mL/min/1.73 m^2 [23]. However, an isolated KT can be individually discussed.

Lysinuric Protein Intolerance

Lysinuric protein intolerance or cationic aminoaciduria is a rare autosomal recessive disorder. Affected children come to medical attention soon after weaning with failure to thrive and episodes of altered consciousness caused by hyperammonemia. This clinical picture is similar to urea cycle disorders, which are an important differential diagnosis. The disease may also present with chronic digestive symptoms and failure to thrive. Hepatosplenomegaly is often present [26]. Later, patients develop hematologic complications and bone marrow abnormalities reminding of lymphohistiocytosis or biological macrophage activation syndrome. This is accompanied by immunologic abnormalities and auto-immune manifestation. The respiratory system may also be involved by pulmonary alveolar proteinosis, which is a severe life-threatening complication.

The defect in the transporter leads to a characteristic pattern in urine amino acids, which show elevated concentrations of arginine, lysine and ornithine and low levels of these amino acids in plasma. Orotic acid in urine may also be elevated. Classically ferritin and LDH levels are elevated in plasma. Molecular genetic analysis of the *SLC7A7* gene is used to confirm the diagnosis, but there is no clear genotype-phenotype correlation [26].

Kidney Involvement

Renal involvement is described in LPI patients with both tubular and glomerular abnormalities [27]. In the first large clinical series describing kidney involvement in LPI, 74% of patients presented with proteinuria, 38% with microscopic or macroscopic hematuria and 38% with renal failure [28]. Patients may progress to ESKD [26–28]. Severe anemia and increased bleeding may be observed in these patients [28].

The majority of patients with kidney involvement have tubular dysfunction [27–29]. The most common observation is nephrocalcinosis and chronic tubulointerstitial nephritis [27, 30]. This

is probably due to the accumulation of calcium phosphate in the kidney secondary to hypercalciuria and possibly to proximal tubular acidosis [27]. Hyperechogenic kidneys may be observed by renal ultrasound. Fanconi syndrome has been reported in two independent cases [31, 32].

Glomerular involvement is quite variable. Mesangial thickening can be observed [27]. Focal glomerulosclerosis, mesangial, membranous and lupus-like proliferative glomerulonephritis can also be associated with LPI [33–36]. Another striking observation is the finding of amyloidosis in the liver and in kidneys of some patients.

Treatment

To maintain metabolic control age-adapted dietary protein restriction is applied and patients have to be carefully monitored for nutritional deficiencies. Citrulline is supplemented and ammonia scavenging drugs, which are used in other urea cycle disorders, are also applied [37].

Kidney Transplantation

The disease does not prohibit treatment by transplantation. Better metabolic control is observed after transplantation.

Fabry Disease

Fabry disease is an X-linked lysosomal storage disorder caused by mutations in *GAL*, the gene that encodes the lysosomal enzyme α-galactosidase A, leading to deficient activity of this enzyme. The disease is characterized by a progressive accumulation of globotriaosylceramide (Gb-3) and related glycosphingolipids in the plasma and different cell types. Male individuals are primarily affected, but female heterozygotes may display moderate or severe disease, which is likely related to the pattern of X-chromosome inactivation [38]. The disease can be divided into a severe, classical phenotype, most often seen in men without residual enzyme activity, and a generally milder non-classical phenotype. Patients with classical Fabry disease initially present with characteristic Fabry disease symptoms, such as neuropathic pain, cornea verticillata, and angiokeratoma.

Once suspected, men are diagnosed with Fabry disease if enzyme activity is below 35% of the mean and gene sequencing. The gold standard of diagnosis for females is α -Gal gene sequencing only.

The Gb3 degradation product, globotriaosylsphingosine (lysoGb3), is currently used in disease screening, but also in the determination of pathogenicity of a mutation. LysoGb3 has also been accepted as an accurate marker of disease activity [39].

Fabry Disease in Children and Adolescents

Children may present with characteristic neuropathic pain, which may lead to the diagnosis. Overt kidney involvement is rare in children, but renal histologic lesions can be demonstrated in children even before the onset of overt proteinuria and CKD [40, 41]. The natural history of Fabry nephropathy has not yet been thoroughly assessed in children [42]. Initially, glomerular hyperfiltration may mask impairment of kidney function [43]. Patients may present with microalbuminuria and proteinuria during the second or third decades, and CKD has been scarcely reported in adolescents [40–42, 44, 45].

Renal Biopsy

Renal biopsy may be performed for diagnosis in case of presentation with glomerular disease without extrarenal manifestation or for therapeutic discussion. On renal biopsy, vacuolization of podocytes and epithelial cells is a

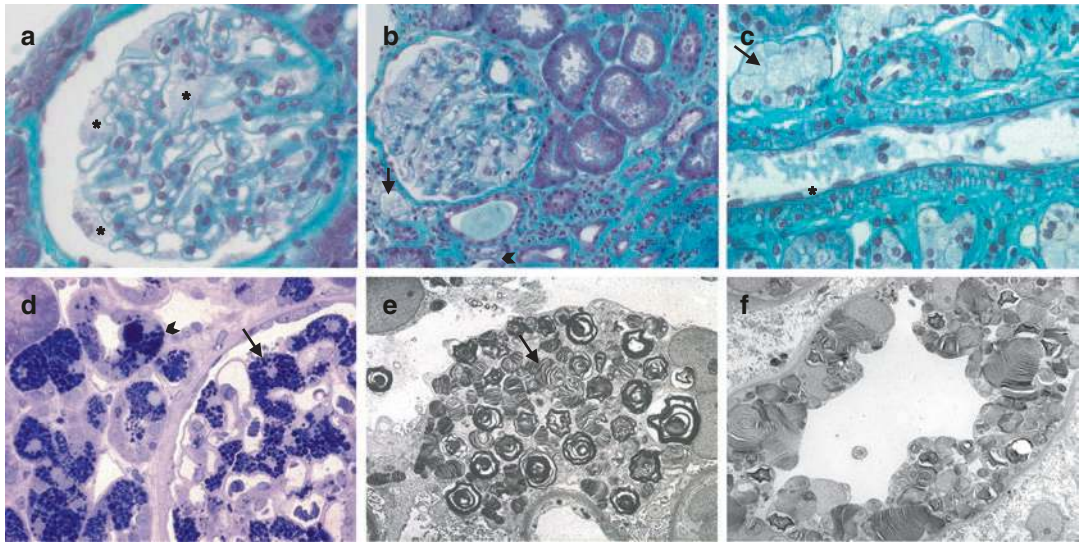

Fig. 28.3 Fabry disease renal biopsy. (**a**) Glomerulus with typical vacuolizations of podocytes (star) (Masson Trichrome ×400). (**b**) Masson Trichrome (×200) showing tubular inclusions (arrow) in distal tubules as well as peritubular capillaries inclusions (short arrow). (**c**) Vascular section showing endothelial cells inclusions (star) associated with tubules inclusions (arrow) (Masson Trichrome ×400). (**d**) Toluidine blue-stained semi-thin section showing darkly stained round inclusions in podocytes (arrow) and distal tubular cells (short arrow). (**e** and **f**) Electron microscopy showing glycosphingolipid inclusions shaped as multilamellated myelin figures in podocytes (**e**) and tubular cells (**f**). (Picture from M Rabant and MC Gubler)

characteristic histologic finding (Fig. 28.3) [46]. Tubular as well as peritubular capillaries inclusions, and endothelial cells inclusions are also observed. By electron microscopy, glycosphingolipid inclusions shaped as multilamellated myelin are found in podocytes (Fig. 28.3). Mesangial expansion, segmental and global glomerulosclerosis, tubular atrophy and interstitial fibrosis are also seen, even in early stages of the disease.

Long Term Follow-Up: Renal and Extra-Renal Complications

Long–term disease manifestations include hypertrophic cardiomyopathy, cardiac rhythm disturbances, progressive renal failure, and stroke. Non-classical Fabry disease, also referred to as late-onset or atypical Fabry disease, is characterized by a more variable disease course, in which patients are generally less severely affected and disease manifestations may be limited to a single organ.

Therapy

Treatment of Fabry disease consists of enzyme replacement therapy or chaperone molecule and adjunctive treatment, including angiotensin converting enzyme inhibitors or angiotensin receptor blockers, and analgesics. Studies have shown that enzyme therapy can delay but not always prevent some of the clinical complications of the disease. Enzyme therapy has been shown to provide the greatest benefit to patients if started early on. Antibody formation possibly also contributes to reduced therapy effect. Migalastat is a small-molecule chaperone which facilitates enzyme trafficking to lysosomes in certain mutant enzymes and can be administered orally [47, 48].

Glycogen Storage Disease (GSD) Type 1a and 1b

Glycogen Storage disease type 1 is caused by a mutation of the *G6PC* gene (GSD 1a) or *SLC37A4* gene (GSD 1b) leading to two distinct clinical subtypes. The first manifestations mostly leading to further medical work-up are hypoglycemic episodes occurring at the age of 3–6 months 3–4 h after feeding, hepatomegaly and failure to thrive. The laboratory findings (combination of hypoglycemia, metabolic acidosis, hyperuricemia, elevated lactate and triglycerides) are suggestive. The diagnosis is confirmed by molecular genetics. In GSD 1b additional neutropenia and leucocyte dysfunction render the patients susceptible to bacterial infections.

In patients with GSD I, several renal complications have been reported. Enlargement of the kidneys is the earliest finding, caused by accumulation of glycogen in the kidneys. Because of hyperuricemia, uric acid lithiasis may occur. These complications can be prevented by an optimal metabolic control with diet and by xanthine oxidase inhibitor. Another cause of lithiasis may be the decreased urinary citrate excretion together with an increased urinary calcium excretion in GSD I patients. Proximal tubular dysfunction has also been described in patients with GSD I. Hyperphosphaturia and loss of bicarbonate in urine may lead to tubular acidosis. The main renal complication is glomerular hyperfiltration and persistent proteinuria. Renal biopsies performed in three GSD I patients with persistent proteinuria showed focal segmental glomerulosclerosis [49]. These findings suggest an etiology of glomerular hyperfiltration and proteinuria similar to diabetic nephropathy.

The treatment aims at avoiding hypoglycemia by frequent carbohydrate intake. Optimal metabolic control has a renoprotective effect on the development of microalbuminuria and proteinuria. Treatment with an angiotensin converting enzyme inhibitor significantly decreases the GFR in GSD I patients with glomerular hyperfiltration and reduces proteinuria [50].

In GSD 1b bone marrow stimulation by G-CSF is often necessary [51].

Primary Hyperoxaluria

29

Bodo B. Beck, Cristina Martin-Higueras, and Bernd Hoppe

Introduction

The **primary hyperoxalurias** (PH) are a group of rare disorders in hepatic glyoxylate metabolism that result in excessive endogenous oxalate generation, their biochemical hallmark [1–4]. The PH's *per se* are not renal diseases, but inborn errors of metabolism that usually first manifest within the kidney and genitourinary tract as recurrent urolithiasis and/or nephrocalcinosis (Fig. 29.1).

Currently, three distinctive types of PH are known. They were termed PH type 1 to 3 in the order of their identification. All are inherited in an autosomal-recessive mode and each type is caused by a single enzymatic defect in the hepatic glyoxylate metabolism that induces overproduction of oxalate [1, 2]. The level of urinary oxalate excretion describing the primary range is commonly defined as greater ≥1 mmol/1.73 m^2/day (normal is <0.5 mmol/1.73 m^2/day) (Tables 29.1 and 29.2).

PH type 1 (PH1) is the most frequent and most devastating PH subtype that regularly leads to end stage kidney disease (ESKD) from infancy to late adulthood. PH type 2 (PH2), which is much less frequent in Europe and North America, bears a considerable risk of chronic kidney disease (CKD) (50%) and ESKD (25%) in adulthood [6]. The third type of PH (PH3) is the second most common and, according to recent literature, also shows a certain risk of CKD (20% of patients ≥CKD stage 2), while ESKD has been reported in few patients [2–4, 7–10]. While PH is rare, idiopathic calcium-oxalate urolithiasis is a frequent condition that bears in comparison only a modest risk of renal impairment. However, patients with severe secondary hyperoxaluria, especially those with Crohn's disease and status post ileocecal resection, are also prone to CKD and subsequently ESKD [11].

Humans, like all mammals, cannot metabolize oxalate. Whatever amount of oxalate is produced in the organism (physiologically or at increased levels in states of primary hyperoxaluria) or absorbed from the gastrointestinal tract (physio-

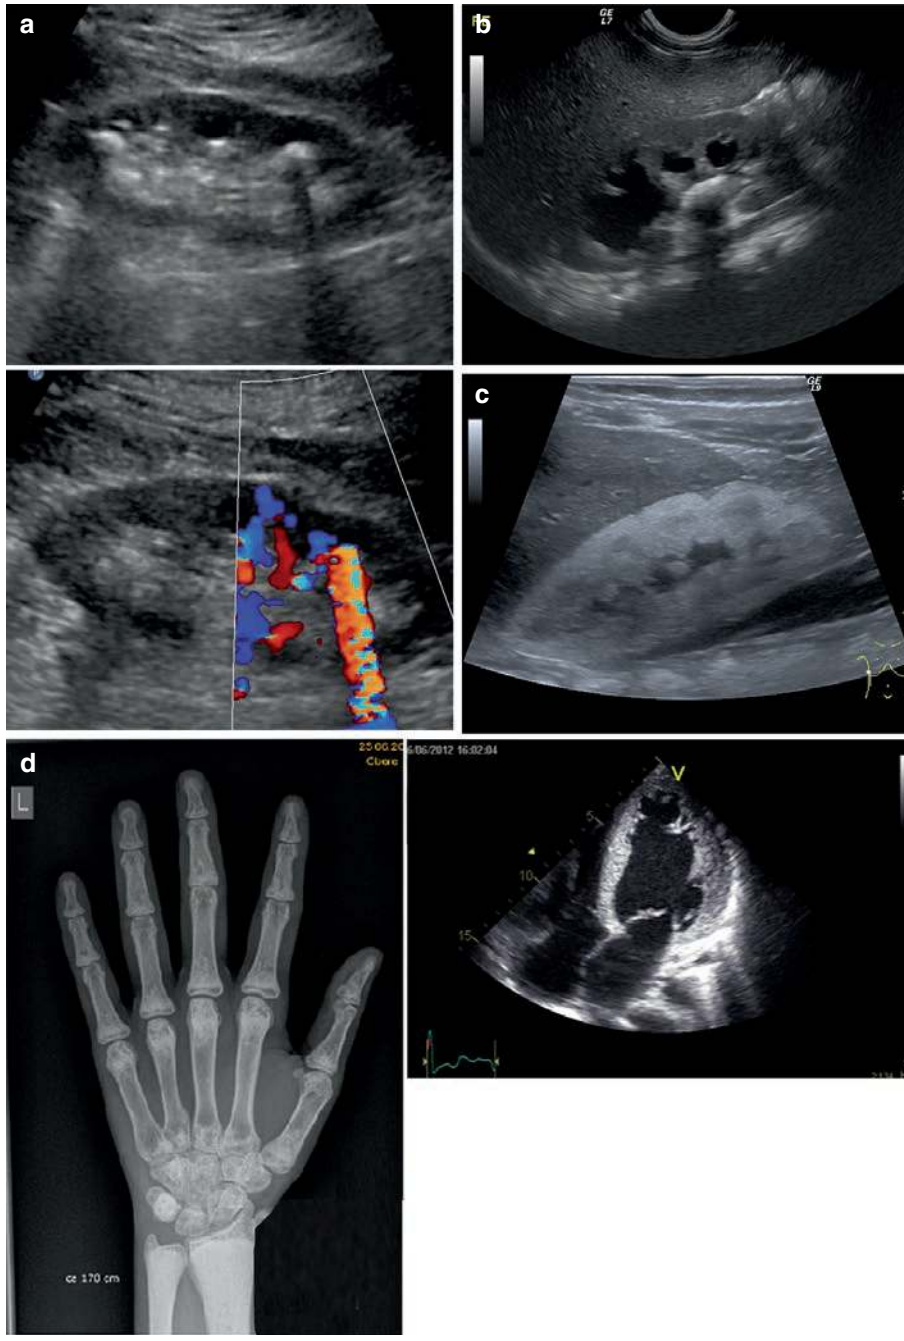

Fig. 29.1 Hallmarks of the primary hyperoxalurias. (**a**) Multiple kidney stones (with positive twinkling sign) in a 21-year-old patient with primary hyperoxaluria type 1 and recurrent stone passages. Stable kidney function with hyperhydration, vitamin B6 and alkaline citrate medication (eGFR = 80.9 mL/min). (**b**) Staghorn calculus in a 7-month-old boy with primary hyperoxaluria type 3. Repeated stone passages in the following months, now, aged 6 years, one not growing stone in the right kidney, no further stones passage. (**c**) Generalized nephrocalcinosis in a 16-month-old girl with primary hyperoxaluria type 1. (**d**) Oxalate osteopathy and cardiac manifestation of systemic oxalosis in a 24-year-old female PH1 patient. Renal replacement therapy since 5 years, plasma oxalate levels >100 μmol/L before hemodialysis. Extreme hyperechogenicity of left ventricular mass depicting severe calcium-oxalate deposition

Table 29.1 Synopsis of clinical features and characteristics of PH1–3

PH type	Clinical presentation	ESKD risk	Infantile oxalosis	Systemic oxalosis	Clinical remission
1	UL, NC, UTI, hematuria, failure to thrive	>50–100%	10–20% of cases	+++ in case of advanced CKD/ESKD	None
2	UL, UTI, hematuria NC↓	ca. 25%	Not reported	+ reported	None
3	UL, UTI, hematuria NC↓↓ is reported	CKD <20%, ESKD reported	Not reported	(+) uncommon	Stones also in adulthood

UL Urolithiasis, *NC* nephrocalcinosis (NC↓ indicates less frequent plus less severe NC in PH2; NC↓↓ indicates that (severe) nephrocalcinosis is a rare finding in PH3), *UTI* Urinary tract infection, *CCR* complete clinical remission, *ESKD* end-stage renal disease

Table 29.2 Synopsis of biochemical features in PH1–3

PH type	Degree of hyperoxaluria	Concomitant/ intermittent hypercalciuria	L-glycerate excretion	HOG/ DHG/4OHGlu excretion	Persistence of hyperoxaluria	Glycolate excretion
1	+++	−−− (rare)	−−− (normal)	−− (normal)	+++ (HO)	+++ (high)
2	++	−−− (rare)	+++ (high)	−−− (normal)	+++ (HO)	−− (normal)
3	++	Rare	−−− (normal)	+++ (high)[a]	++ (HO; 80% cases)	−− (normal)

HOG 4 Hydroxy -2- oxoglutarate, *HO* Hyperoxaluria

[a] It was recently shown by Pitt at all that individuals with PH3 excreted increased levels of HOG (2,4 dihydroxyglutarate, DHG, the reduced form of HOG) and 4-hydroxyglutamate (4OHGlu) the immediate HOG precursor [5]

logically or at increased levels in conditions associated with secondary forms of hyperoxaluria) has to be excreted via the kidneys in order to avoid the potentially deleterious accumulation of this metabolic end product [1]. Oxalic acid is found in virtually all dietary products in variable quantities depending on the source and processing of the product. Particularly high amounts can be found in some leafy green vegetables and legumes (beetroot, rhubarb, spinach, black tea, black chocolate, peanuts, sweat potatoes etc.) [12]. The oxalate content of a balanced Western diet constitutes in general no major medical issue unless in conditions prone to secondary hyperoxaluria (SH) such as malabsorption states in inflammatory bowel disease, short bowel syndrome, cystic fibrosis, celiac disease and many more [11, 13]. SH can also result from selective overconsumption of oxalate rich food or intoxications with precursor compounds (e.g. ascorbic acid, ethylene-glycol, glycolate, hydroxyproline) that are further metabolized into oxalate [14].

PH (rare, usually not amenable to dietary restrictions) must be differentiated from SH (more frequent and diverse, potentially/partially treatable by dietary restriction of glyoxylate precursors) for diagnostic and therapeutic reasons, which can sometimes be challenging [15]. Here, 24-h urine collections under different dietary regimens (low oxalate and high oxalate diets) can help to better distinguish PH from SH [16].

In principle, the main physiologic route of excretion via the kidneys allows the excretion of large quantities of this metabolic end-product. However, the poor solubility of oxalate and the concentration of the urine along the tubular system factually limit the amount of calcium oxalate that can be excreted without causing harm to the kidney [1, 2]. In primary or secondary hyperoxaluria oxalate levels are increased to 1.5-fold to >10-fold the upper level of normal, which may lead to the precipitation of insoluble calcium oxalate (CaOx) salts in the tubular lumen and interstitial tissue [17]. Interstitial deposition of CaOx induces a strong inflammatory reaction that leads to a progressive decline in kidney function and finally ESKD [18, 19].

Once renal function has declined below a certain glomerular filtration rate (GFR) threshold of approximately 30–40 mL/min/1.73 m^2, continuous systemic accumulation of oxalate occurs. This is indicated by a rise in plasma oxalate concentration (POx; normal <7.4 μmol/L, depending on the analytical method) [20] that can vastly

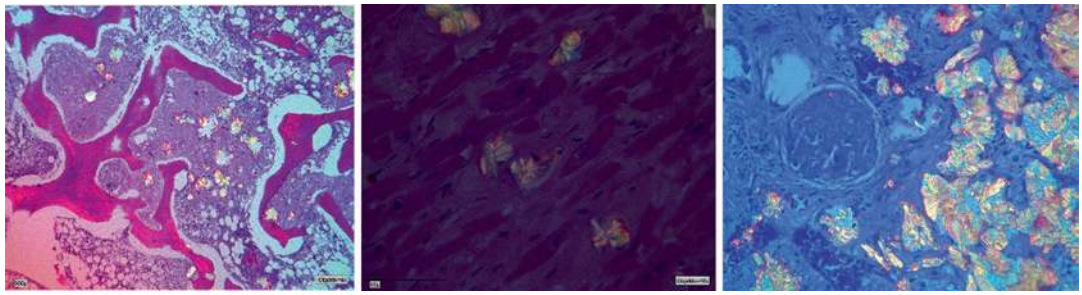

Fig. 29.2 Systemic oxalosis in a female PH type 1 patient with end stage renal failure since 3 years, chronic hemodialysis treatment and delayed diagnosis until skin biopsy revealed massive calcium-oxalate crystal deposition at age 33 years. Here, birefringent calcium-oxalate crystals are shown in polarized microscopy (from left) in bone marrow (leading to treatment resistant anemia), heart (leading to arrhythmias), and kidney (leading to end stage renal failure [21, 22]). Patient died due to severe systemic oxalosis shortly after diagnosis. It is to mention, that diagnosis was primarily not considered although her sister had received a combined liver-kidney transplantation because of PH1

exceed plasma saturation (about 30 μmol/L) and lead to a second phase of severe multisystem injury characterized by CaOx deposition in virtually all tissues (bone, retina, myocardium, vessel walls, skin etc.), termed systemic oxalosis (Figs. 29.1 and 29.2) [1, 2, 23]. Particularly bone deposition can be massive, which results in debilitating pain and fractures, as well as treatment resistant anemia. After successful kidney transplantation large amounts of oxalate can be mobilized from the bone compartment, which can pose a serious threat to the kidney graft [1, 2]. Severe systemic oxalosis in a strict sense is mainly observed in PH1, but it also has been reported in a few individuals with PH2 [6, 24]. So far it has not been reported for PH3, but this group is less well studied regarding the long-term consequences of hyperoxaluria and risk for CKD.

Interestingly, in non-PH ESKD patients a substantial contribution of elevated POx to the pro-inflammatory state and increased cardiovascular risk of the latter population has recently been suggested [23, 25]. In view of the vascular consequences of longstanding hyperoxalemia in PH1, further research addressing the role of POx for cardiovascular outcomes in the general ESKD population appears warranted.

A novel therapeutic concept is based on RNA interference (RNAi). This alternative approach focuses on depleting the messenger RNA of key enzymes in hepatic glyoxylate metabolism that are responsible for generating oxalate precursors or substrate for the defective AGT. The first approved RNAi drug is Lumasiran (Oxlumo©), which silences liver-specific glycolate-oxidase (gene symbol *HAO1*). Depletion of glycolate oxidase mRNA results in a reduction of glyoxylate in the peroxisomal compartment. Another RNAi therapeutic, Nedosiran, targets the liver-specific isoform of L-lactate dehydrogenase (LDHA) and therefore blocks the final step of oxalate production in the liver.

Epidemiology of Primary Hyperoxaluria

The PHs are a spectrum of rare, but most likely underreported diseases, as evident by the high rate of late diagnosis in PH1 in many countries. The true prevalence of PH1–3 is unknown. The estimated prevalence of PH1, the most commonly diagnosed PH form worldwide, is 1 to 3 cases per million population and the incidence rate is approximately 1 case per 100,000 live births in Europe and North America [26–33]. Extrapolation from the allelic frequencies of pathogenic PH1–3 sequence variants found in gene bank data yields much higher prevalence estimates for all primary hyperoxaluria subtypes than reported in the registries. For example, the allelic frequency of the most prevalent patho-

genic PH3 variants would predict about 2000 patients in Germany (estimated prevalence ca. 1:40 000), which is about 20 times the number currently identified throughout Europe (n = 95, in the latest report on PH3 by the OxalEurope registry) [10]. The low number of adult patients identified with PH3 points towards a markedly reduced penetrance and/or high rate of clinical remission with age in this incompletely understood form.

PH1 accounts for roughly 1% of childhood ESKD in many industrialized countries with a low rate of consanguineous marriages. A higher prevalence is observed in countries in which parental consanguinity is more common. PH1 is reported as the cause of pediatric ESKD in up to 10% of cases in some Middle Eastern and North African countries [34, 35]. The two largest PH registries (OxalEurope and the Rare Kidney Stone Consortium (RKSC)) have identified >1500 patients with proven type 1 disease [28, 30].

Most data discussed in this chapter is derived from populations of European ancestry. It should be kept in mind that the distribution of PH types, causative mutations and their allelic frequency might vary widely among different populations.

Primary Hyperoxaluria Type 1

Biology and Molecular Basis

The first clinical description of PH1 is attributed to the French physician Lepoutre who in 1925 reported extensive CaOx crystal tissue depositions in the kidney of an infant [36]. Later, the biochemical hallmark of massive oxalate excretion in the urine was monitored by various methods that became more and more refined over time [37], but it took until 1986 for Danpure and Watts to discover deficiency of hepatic alanine-glyoxylate aminotransferase (AGT) as the cause of PH1 [38]. Shortly afterwards the cloning of the corresponding *AGXT* gene (OMIM 604285) allowed the identification of the first causative mutations [39]. Those landmark discoveries paved the way to the development of routine molecular diagnostic testing and led to a rational transplantation strategy for PH1.

PH1 (OMIM 259900) is caused by absent (nonsense/frameshift mutations, large deletions), deficient (missense/splice site mutations) or mistargeted activity (specific missense mutations) of liver-specific, pyridoxal dependent alanine:glyoxylate aminotransferase (AGT) [40, 41]. AGT catalyzes the transamination of the immediate oxalate precursor glyoxylate to glycine in the peroxisomal compartment. In the absence of catalytically active AGT in the peroxisome glyoxylate is converted to oxalate and glycolate via the cytoplasmatic lactate dehydrogenase A (LDHA). A synopsis of hepatic glyoxylate metabolism is given in Fig. 29.3.

The single copy *AGXT* gene is located on chromosome 2p37.3. Its genomic sequence consists of 11 exons spanning ~10 kb, resulting in a 1.7 kb cDNA with an open reading frame of 1176 base pairs. The gene product AGT is a homo-dimeric protein exclusively expressed in human hepatocytes, each 43 kDa subunit containing 392 amino acids and holding one molecule of pyridoxal-phosphate as cofactor [42]. The large N-terminal domain contains most of the catalytic active site, the cofactor binding site, and the dimerization interface. The smaller C-terminal domain contains the atypical peroxisomal targeting sequence (PTS1, LysLysLeu) and a presumed ancillary sequence, PTS1A, required for proper peroxisomal transport [43]. The crystal structure of normal AGT has been solved and provided valuable knowledge of AGT folding and how specific mutations and polymorphisms effect protein folding, dimerization and catalytic activity [44].

At least 220 causative mutations of all types have been reported throughout the *AGXT* gene [2]. Approximately 50% of the identified changes are missense mutations, including the most frequent mutation in Caucasians, p.G170R, and other recurring mutations (p.I224T, p.F152I). Hence, a substantial fraction of patients should carry at least one missense variant. Those point mutations will generally not result in protein truncation with total absence of AGT, but rather predispose to local changes in the polypeptide

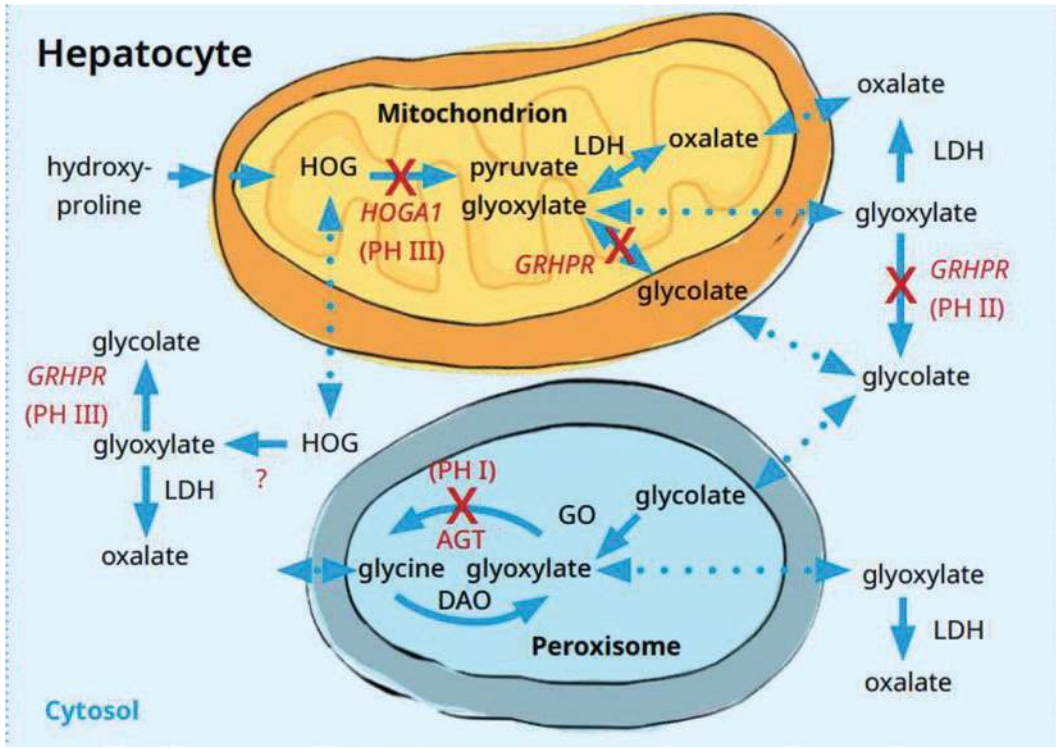

Fig. 29.3 Currently known disturbances in oxalate metabolism. *AGT* alanine:glyoxylate aminotransferase, *GRHPR* glyoxylate reductase/hydroxypyruvate reductase, *HOG* hydroxy-2-oxo-glutarate, *HOGA* hydroxy-2-oxo-glutarate aldolase, *LDH* lactate dehydrogenase, *PH (1–3)* primary hyperoxaluria, *GO* glycolyate oxidase, *DAO* diamino-oxidase, *PLP* pyridoxal phosphate

chain that will affect its enzymatic activity and/or stability. Moreover, as most mutations are not localized within the active or binding sites of the enzyme but rather interfere with protein folding and dimerization, potentially salvageable residual activity could be expected for the majority of (non-consanguineous) patients displaying at least one misfolding mutation. Missense point mutations impair AGT enzymatic function by: (1) abrogating the catalytic activity (rare), (2) forming insoluble AGT aggregates or impaired AGT homodimers, (3) disrupting peroxisomal import or iv) a combination of all [39].

In Caucasians the *AGXT* gene contains a number of common variants forming two main haplotypes, named AGT major allele (80% frequency) and AGT minor allele (20% frequency). In Asia the minor allele frequency is much lower, around 2% [40]. The two haplotypes differ in a number of polymorphisms occurring on the minor allele, within which a single base-pair change on position c.32 C>T (p.P11L) is the functionally most significant one. The leucine variant on position 11 (p.11L) influences the function of AGT in several ways. It reduces AGT activity by 30–50%, impairs dimerization of AGT subunits, and introduces a weak mitochondrial mistargeting sequence to the protein leading to dislocation of about 5% of the enzyme to the mitochondria. These changes are insufficient to cause a PH1 phenotype [39].

The most frequent causative mutation, c.508G>A (p.G170R), occurs at an allelic frequency of 25–40% among Caucasians, always on the background of the minor allele (p.G170R-Mi). This mutation is associated with aberrant localization of AGT within the mitochondria instead of peroxisomal targeting. AGT mistargeting is

caused by the synergistic interaction between the p.P11L polymorphism and the p.G170R mutation. This phenomenon is attributed to the principal difference between mitochondrial and peroxisomal protein-import machineries [45]. While peroxisomes import their matrix enzymes in a folded and even oligomerized conformation [46], mitochondria-targeted proteins are associated with chaperones which maintain them in a translocation-competent unfolded conformation. The unfolded mutant protein unmasks the N-terminal mitochondrial targeting sequence encoded by the p.P11L polymorphism, leading to its translocation into the mitochondrial matrix. Further folding of the mutated AGT is facilitated by means of mitochondrial chaperones, resulting in the formation of active dimeric molecules. Despite being essentially active, mitochondrial AGT cannot prevent oxalate overproduction [47]. In addition to p.G170R, the recurrent mutations p.I244T, p.F152I, and p.G41R also result in mitochondrial mistargeting [48].

The frameshift mutation c.33dupC (formerly known as c33_34insC; pK12Qfs*156) leads to a protein truncation and is the most common mutation found on the major allele (~12% allelic frequency in Caucasians) [41]. This variant is commonly found in patients suffering from infantile oxalosis.

Another frequently encountered missense mutation, c.731T>C (p.I244T, 6–9% allelic frequency), is especially common in patients from Spanish-African descent. Since it represents the causative mutation in about 90% of PH1 patients from the Canary Islands it is believed to result from a founder effect in this population [49, 50].

Besides aberrant compartmentalization, protein aggregation, accelerated degradation and other mechanisms contribute to AGT deficiency [51, 52]. The p.G41R, p.F152I, p.G170R, and p.I244T variants are all soluble and catalytically active in the absence of the p.P11L polymorphism, whereas in its presence all lead to protein destabilization and aggregation. Since the dimer structure can be stabilized by the interaction with pyridoxal phosphate (PLP, a vitamin B6 component), some of these missense mutations (p.G170R, p.F152I) have been associated with variable pyridoxine-responsiveness in patients. Responsiveness to vitamin B6 therapy may be affected via improved protein stability, activity and peroxisomal import. Renal survival is prolonged in patients with biallelic B6 responsive mutations, best documented for the group of p.G170R homozygotes. The latter group has a more favorable long-term outcome and many p.G170R homozygotes can be managed with isolated kidney transplantation in case of ESKD. However, early ESKD and infantile oxalosis can even occur in p.G170R homozygotes and patients with other missense mutations which are rated beneficial on molecular grounds. There is no established genotype-phenotype correlation for other important clinical aspects like onset of disease or degree of hyperoxaluria [53–55].

Chemical and physical actors that assist protein folding may decrease the negative effect of AGT missense mutants [21]. Further to the effects of vitamin B6, some *in vitro* evidence supports beneficial effects of amino-oxy-acetic acid (inhibitor), chemical chaperons (betaine, glycerol, DMSO, trimethylamine oxide and phenylbutyric acid), low temperature and pH. From this extended list, only vitamin B6 is an accepted therapeutic agent and even for this treatment only a single controlled small prospective clinical trial has been performed [56]. Therefore, therapeutic recommendations mostly rely on case reports, small retrospective case series and *in vitro* data [57].

Clinical Spectrum

Apart from being the most frequent type, PH1 is of particular importance as ESKD is the typical long-term outcome for this group.

The typical clinical presentation includes (recurrent/familial) calcium-oxalate urolithiasis and/or nephrocalcinosis, hematuria, urinary tract infection, and (chronic) renal failure (Fig. 29.1). Clinical presentation is highly variable and encompasses fulminant infantile oxalosis with

diffuse nephrocalcinosis (white kidneys) and failure to thrive within the first year of life, occasional stone formation at adult age, as well as elderly adult patients presenting with isolated renal failure without any past medical history compatible with metabolic stone disease. While the disease can first manifest at any age, median age of manifestation is 6 years. About 10–20% of the cohort will experience ESKD within the first few years of life, the condition termed infantile oxalosis [1, 2].

Contrary to the common misconception that monogenic diseases should result in a rather uniform and childhood onset presentation this is not the case in PH1 as in many Mendelian disorders[1, 2, 53]. PH1 shows marked inter- and intra-familial phenotype variability despite identical genotypes [21, 56].

With advanced renal insufficiency and the failure to excrete oxalic acid, the disease turns from a kidney and urinary tract limited phenotype into a potentially lethal multi-systemic condition [57–61]. In case of ESKD, plasma oxalate (Pox) levels will exceed the supersaturation threshold for calcium oxalate. Pox levels typically are >80–200 μmol/L pre-dialysis, with calcium oxalate crystal precipitation occurring at Pox >30 μmol/L [23]. This inevitably results in systemic deposition of calcium-oxalate salts (oxalosis) in virtually all tissues, with a predilection of retina (most often in the infantile cases) [24], myocardium, vessel walls, skin, bone, bone marrow and the central nervous system (Figs. 29.1 and 29.2) [21]. Systemic oxalosis has devastating consequences that include cardiomyopathy, cardiac conduction disturbances/heart block, vasculopathy, treatment resistant anemia, oxalate osteopathy resulting in debilitating bone and joint deformation and pain, retinopathy, skin infection and if untreated untimely death.

The multitude and systemic nature of symptoms can obscure a correct diagnosis for years [62, 63]. About 20–35% of adults with PH1 in developed countries are diagnosed only when having reached ESKD or even after kidney graft failure [28–31].

Primary Hyperoxaluria Type 2

Biology and Molecular Basis

PH2 (OMIM 260000) is a result of deficient glyoxylate reductase/hydroxypyruvate reductase (GRHPR) enzyme activity [64, 65]. *GRHPR* was first cloned from a human liver library in 1999.

The single copy *GRHPR* gene (OMIM 604296) located on chromosome 9p13.2 is the only gene to result in PH2. Its genomic sequence consists of 9 exons spanning ca. 14 kb, resulting in a 1.2 kb cDNA with an open reading frame of 984 base-pairs. The gene product is a 328 amino acid protein with a molecular weight of 35.4 kDa. The normal protein forms a homodimer that, unlike AGT, shows widespread tissue expression in cytoplasm and mitochondria outside the liver, indicating a role in metabolism. GRHPR, like LDH, utilizes pyridine nucleotides (NADPH, NADH) as cofactors. GRHPR has a 100-fold higher affinity towards NADPH than for NADH, which strongly favors the reaction from hydroxypyruvate to D-glycerate in the cytosol [66]. Under physiologic conditions cellular glyoxylate is mainly restricted to the mitochondria and peroxisomes [47, 67]. Flux between the two compartments is provided by mitochondrial GRHPR (glyoxylate → glycolate) and reverse oxidation (glycolate → glyoxylate) by peroxisomal glycolate oxidase (GO). This largely prevents glyoxylate from being converted to oxalate. If present in the cytosol glyoxylate forms the substrate for 3 reactions catalyzed by the enzymes lactate dehydrogenase A (LDHA) and GRHPR: i) GRHPR catalyzes the reduction to glycolate using NADPH and NADH as cofactors; ii) in the presence of NAD^+ oxidation to oxalate by LDHA; or reduction to glycolate with NADH as cofactor [68]. The competition between glyoxylate oxidation (LDH) versus reduction (GRHPR) is largely determined by the NAD^+/NADPH ratio and the LDHA/GRHPR ratio available in the cytosol, which if determined by sheer quantities alone would strongly favor oxidation [47, 68]. Fortunately, the GRHPR route of mitochondrial

conversion of glyoxylate to glycolate and subsequent peroxisomal transamination to glycine seems to be largely preferred over oxidation by cytosolic LDHA in physiologic states.

In PH2 hepatic glyoxylate metabolism is predominantly affected and results in increased amounts of cytosolic glyoxylate and hydroxypyruvate, now available for conversion by (LDHA) to both oxalate and L-glyceric acid (L-glycerate, Fig. 29.3) [69, 70]. Excessive amounts of both metabolites are excreted by the kidney that led to the initial description of PH2 as "L-glyceric aciduria" [71].

To date, 48 causative mutations have been identified in patients with PH2. While the c.103delG (p.D35Tfs*11) frameshift mutation is predominant in Caucasians with an allelic frequency between 30 to 50%, the mis-splicing variant c.403_404+2delAAGT is the primary mutation found in individuals of Asian descent. Interestingly all identified causative *GRHPR* mutations including the missense variants are functionally null alleles resulting in loss of protein expression and/or of catalytic activity [65].

Clinical Spectrum

At least in Europe and North America, PH2 appears to be much less frequent than PH1 (<10% of PH patients), although it cannot be excluded that PH2, due a less severe clinical course, is more underdiagnosed than PH1 (Table 29.1). With increasing awareness and the availability of genetic screening this entity might be recognized more often in the future.

The disease typically manifests in childhood and presentation can overlap largely with PH1 (recurrent urolithiasis, hematuria, UTI etc.), but nephrocalcinosis is less commonly seen. An asymptomatic clinical course for years or late stone disease does not preclude a diagnosis of PH2 [72, 73]. In our experience, ESKD in PH2 is often found in patients who underwent unilateral nephrectomy in childhood in the absence of a clear diagnosis.

In general, infantile oxalosis is not regularly observed in PH2. However, systemic oxalosis has been reported, and CKD or ESKD occurs more frequently with this type than previously thought [6, 72]. Once ESKD is reached there is some risk of systemic oxalosis. One adult patient with PH2 developed cardiomyopathy while on hemodialysis [74–77]. Retinal deposits were found in another PH2 patient with ESKD [24].

Apart from hyperoxaluria, elevated urinary L-glyceric acid excretion is a characteristic feature in most patients with this type [71, 72, 78], although cases with genetically proven PH2 and normal urinary L-glyceric acid excretion are known, one of those was published [78].

The scarcity of PH2 makes any prognostic and therapeutic recommendations difficult. A recent report on long term outcomes of PH2 did not observe a genotype-phenotype correlation. The significant rate of CKD and ESKD and the necessity of combined liver kidney transplantation in some PH2 patients indicate that PH2 may be a more problematic clinical condition than initially anticipated.

Primary Hyperoxaluria Type 3

Biology and Molecular Basis

PH3 (OMIM 613616) was first associated with mutations in the *HOGA1* gene (4-hydroxy-2-oxoglutarate aldolase) on chromosome 10q24.1 in 2010 [3]. The gene product catalyzes the final step of mitochondrial hydroxyproline metabolism from 4-hydroxy-2-oxoglutarate to glyoxylate and pyruvate (Fig. 29.3) [3, 47, 79]. To date at least 50 different mutations in *HOGA1* (OMIM 613597) have been identified that cause loss of enzymatic activity in liver and kidney tissue [3, 4, 7, 80]. The enzymatic block leads to accumulation of the glyoxylate precursor 4-hydroxy-2-oxoglutarate (HOG), its reduced form 2,4 dihydroxyglutarate (DHG) and the HOG precursor 4-hydroxyglutamate (4OHGlu). The latter was recently proposed as a new potential biomarker for PH3 [5, 47]. Next to oxalate all three of the latter compounds can be found at elevated levels in the urine and liver tissue samples, but not in plasma, of PH3 patients [5,

47, 81]. The precise mechanisms underlying hyperoxaluria are not fully understood, but the following model has been proposed: In non-PH3 states almost all HOG is converted to glyoxylate which is in turn reduced to glycolate by mitochondrial GRHPR (see PH2 paragraph above). In HOGA1-deficiency, accumulation of HOG (reduced HOG and 4OHGlu) leads to leakage/transport from the mitochondrial compartment into the cytosol. Cytosolic HOG, its reduced form, and 4OHGlu are partially excreted in the urine; to some extent HOG is converted into the reactive oxalate precursor glyoxylate by a yet to be identified HOG aldolase. This aldolase, potentially N-acetylneuraminate lyase, is an enzyme with high homology to HOGA1 [5, 47]. Another factor that may contribute to increased oxalate generation could be the reported inhibition of GRHPR, the cytosolic counterpart of LDH, by excess HOG [81].

Currently 50 causative mutations have been identified in patients with PH3. While the splicing mutation c.700+5G>T constitutes the most frequent mutation in patients from European descent (AF 45%), the in frame deletion c.944-46delAGG (p.Glu135del) is the most frequently encountered in patients of Askenazi Jewish descent, and the splicing mutation c.834+1G>T mutation is commonly found in Chinese patients. So far, no relevant genotype-phenotype correlation could be established for PH3 [10].

Further unraveling of the metabolic consequences in PH3 is of paramount importance for our understanding in general as they may lead to the discovery of novel therapeutic options not restricted to PH3. Hydroxyproline turnover is almost exclusively derived from dietary collagen intake and endogenous metabolism of collagen. Modulation of hydroxyproline metabolism either by dietary measures or pharmacological interventions may become feasible in the future. Subsequent detailed studies will help to further clarify the impact of nutrition and dietary interventions for the spectrum of hyperoxaluria and associated stone disease [15, 82].

Clinical Spectrum

PH3 seems to be more frequent than PH2 in some populations and according to the allelic frequency of pathogenic mutations in large gene banks (about 15% of PH patients in the German PH registry; high carrier rate in the Ashkenazi Jewish population). The scarcity of adult patients identified with symptomatic PH3 suggests a reduced penetrance and possibly an increasing rate of clinical and/or biochemical remission with age. The latter is a matter of controversy, which to resolve will require the identification and phenotyping of more adult individuals with biallelic mutations.

Based on the limited available data PH3 represents the least severe form of primary hyperoxaluria, but is not a benign condition [3, 4, 7, 80]. The most severe clinical phenotype of PH3 is observed in infancy and early childhood, with recurrent kidney stones and the necessity of repeated stone removal procedures. However, new stones may still be formed at adult age. Approximately 20% of PH3 patients will develop chronic kidney disease [10].

Previous biochemical findings of persisting hypercalciuria and intermittent hyperuricosuria have been questioned by new studies [5]. Compared to PH1, in which urinary citrate excretion is clearly subnormal at diagnosis, normal citrate excretion has been found in PH3 patients even before treatment was inititated [10].

Diagnosis and Differential Diagnosis

General Remarks and Clinical Diagnosis

Any child presenting with a calcium oxalate stone, (progressive) nephrocalcinosis or renal failure of unknown cause should be evaluated for primary hyperoxaluria [1, 2, 13, 83] (Tables 29.1 and 29.2). The same applies to adult recurrent

stone formers with or without renal impairment. Non-PH1 renal failure per se produces a multitude of symptoms not confined to the kidney (e.g. osteopathy, anemia, cardiovascular disease). However, in patients on chronic dialysis without an established diagnosis, especially those who do deteriorate on an adequate dialysis regimen and/or those who display features of a presumed collagenosis, autoimmune disorder, or vasculopathy, it is prudent to rule out PH1. Pathologists should be explicitly asked to look for potential calcium oxalate deposition (birefringent crystals under polarized light) in all patients undergoing kidney biopsy for unexpected and/or early graft dysfunction [2, 21].

Biochemical Screening and Diagnosis

Repeated measurement of oxalate excretion in 24-h urine collections (UOx) constitutes an excellent screening tool for detection of PH1–3 as long as renal function is within normal limits (Table 29.2). Unfortunately oxalate determination is not routinely available in many clinical laboratories, which often leads to its omission from screens. Urinary screening should be performed on repeated samples as incomplete collection, shorter sampling intervals than 24 h, diurnal variation (up to 15–20%) [84], and active stone growth may lead to false positive or false negative findings [2, 21, 85]. When oxalate/creatinine ratio in spot urine samples must be used, i.e. in infants and toddlers, interpretation requires repeated sampling, the use of age-related reference values, and extra caution with regard to interpretation of findings. A low urinary creatinine concentration frequently leads to falsely elevated molar ratios. Especially in preterm babies higher ratios are common, in particular under parenteral nutrition containing amino acids [13].

All other glyoxylate metabolites should also be determined in urine samples from patients with suspected hyperoxaluria, as this already allows a differentiation of PH subtype. Glycolate is elevated in urine and plasma in patients with PH1, L-glyceric acid in urine from patients with PH2 and HOG, DHG and 4OHGlu in patients with PH3. If these laboratory parameters are available, the diagnosis of PH and the subclassification of the PH subtype can be made already on biochemical grounds and later proofed by genetics. In this setting, personalized genetic testing will provide definitive diagnostic confirmation. PH can be differentiated from SH by collecting urines under different dietary conditions (high vs. low oxalate contents) [16].

Although the absolute amount of oxalate excretion allows a reasonable statistical discrimination between the three groups, biochemical subtyping at the individual patient level is compromised by intra-individual variation of oxalate excretion [21]. In patients with advanced chronic kidney disease (glomerular filtration rate, GFR < 30 mL/min*1.73 m^2) urinary oxalate excretion might be well within normal limits due to reduced glomerular filtration. As CKD progresses towards ESKD, urinary oxalate measurement becomes even less useful or even impossible and determination of Pox becomes more important, which has no diagnostic role in early CKD stages. Pox levels remain within the normal range (< 10 μmol/L) or increase only slightly for a long period of time, but correlate inversely with decreasing GFR at higher grades of CKD. Marked elevations of both Pox (to >80 μmol/L) and glycolate prior to dialysis are commonly observed and may give a high index of suspicion to a diagnosis of PH1, while selective hyperoxalemia occurs in PH2 and PH3 [86, 87]. While the specificity of elevated Pox as a diagnostic marker of PH is limited by the global accumulation of oxalate in ESKD patients irrespective of the underlying disease, Pox values are typically much lower (30–50 μmol/L) and rarely exceed the 80 μmol/L threshold in non-PH patients [23].

Confirmation of Diagnosis by Genetic Testing

A clinically and biochemically based diagnosis of PH1–3 always requires confirmation by a definite test, which today is done by targeted or NGS based mutational analysis of the three causative

Table 29.3 Synopsis of most common genetic findings in PH1–3

PH type	Gene (exon)	Min. no of identified causative mutations	Frequent/founder mutations	AF	Reported cases for PH type
1	***AGXT*** (11)	220	c.508G>A (p.R170G-Mi)[a] c.33dupC (p.K12Qfs*156-Ma)[a] c.731T>C (p.I244T- Mi/(Ma))[b]	~25–40%[a] ~10–12%[a] ~7–9%[b] (>90%[CI])	>>>1000
2	***GRHPR*** (9)	50	c.103delG (p.D35Tfs*11)[a] c.403_404+2 delAAGT (missplicing)[c]	~37–60%[a] ~16%[c]	>100
3	***HOGA1*** (7)	50	c.700+5 G>T (missplicing)[a] c.944_946delAGG (p.E315del)[d]	~50%[a] >90%[d]	>>100

Mi AGT minor allele, *Ma AGT* major allele; Mi/(Ma) indicates that c.731C>T occurs both with the minor and major allele, but is mostly segregating in cis with the minor allele

Mutations are given according to allelic frequency =AF, in different populations: [a]Caucasians, [b]Spain/North Africa [CI]Canary Islands, [c]Asians, [d]Ashkenazi Jewish

genes: *AGXT*, *GRHPR,* and *HOGA1* (Table 29.3). Genetic testing can be considered the gold standard for diagnosis since it provides fast and reliable distinction of the precise PH type. Exact genotype information is clinically relevant since some missense mutations in the *AGXT* gene are more likely to respond to a specific medication (vitamin B6 treatment) and correlate with better long-term renal survival. Moreover, genotype data will become even more important with the personalized medicine approaches that are being developed or may become available in the future [53–55, 83, 88, 89].

Clinical and biochemical data can be used to prioritize and guide stepwise genetic analysis in order to make the molecular analysis even faster and more cost effective (Fig. 29.3 and Table 29.4).

In case sequencing only identifies a single causative mutation in heterozygous state in line with a high clinical suspicion of PH, copy number variations (CNV; larger heterozygous deletions/amplifications) should be considered. CNVs cannot be detected by Sanger sequencing. NGS based bioinformatic CNV detection is available but less sensitive than multiplex ligation-dependent probe amplification (MLPA), the gold standard for CNV detection. a commercial MLPA assay (MLPA; MRC Holland) allows simultaneous detection of abnormal CNVs in *AGXT* and *GRHPR* [90]. However, CNVs seem to be very rare in primary hyperoxaluria (<1%) [91].

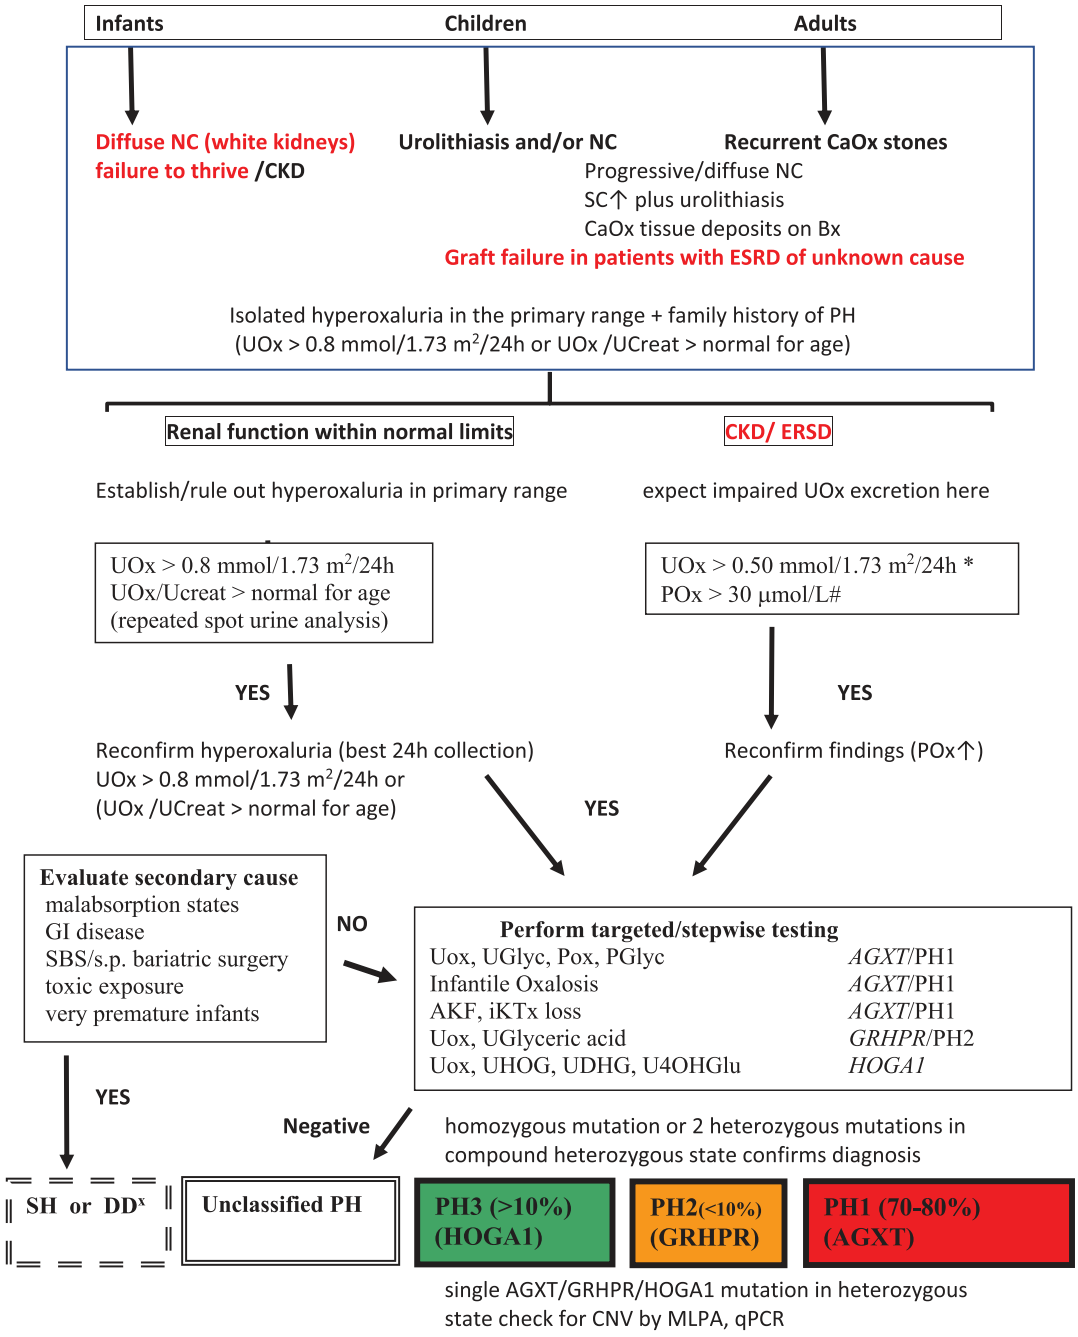
Historically, enzyme activity/expression used to be assayed by liver biopsy to confirm the diagnosis. This invasive and elaborate procedure has been abandoned and replaced by genetic screening.

Differential Diagnosis and Secondary Hyperoxaluria

In principle, a wide spectrum of disorders resulting in recurrent urolithiasis with calcium oxalate stones, nephrocalcinosis and/or CKD/ESKD can mimic primary hyperoxaluria. Careful clinical and biochemical assessment including repeated measurement of urinary oxalate excretion is effective in excluding most relevant differential diagnoses, at least in patients with normal kidney function (Table 29.4).

PH needs to be differentiated from secondary forms of hyperoxaluria (SH), where dietary or toxic exposure to oxalate or its precursors (hydroxyproline, ascorbic acid) leads to increased adsorption from the gastrointestinal tract [13]. In contrast to SH, patients with PH show oxalate absorption within the normal range (often <5–10% [15]). Oxalate excretion is usually <1 mmol/1.73 m^2/day in SH, but in some cases maybe as high as in patients with PH [11]. However, secondary causes attributable to gastrointestinal disease, which are usually characterized by fat malabsorption (e.g. inflammatory bowel diseases (IBD), cystic fibrosis, status post bariatric surgery, short bowel syndrome (SBS)) can lead to constant hyperoxaluria due to

Table 29.4 Diagnostic algorithm for the evaluation of primary hyperoxaluria



NC nephrocalcinosis, *CKD* chronic kidney disease, *SC* serum creatinine, *CaOx* calciumoxalate, *UOx* urinary oxalate excretion, *creat* creatinine, *ESKD* end stage renal disease, *POx* plasma oxalate, *GI* gastro intestinal, *SBS* short bowel syndrome, *NRF* normal renal function, *SH* secondary hyperoxaluria, *LBx* liver biopsy, *AGT* alanine:glyoxylate aminotransferase, *GRHPR* glyoxylate reducatase/hydroxypyruvate reductase, *HOGA1* hydroxyl-oxo-glutarate aldolase 1, *HOG* Hydroxy-oxo-glutarate

enhanced absorption of oxalate from the gastrointestinal tract and in exceptional cases may ultimately result in ESKD. In severe cases of ESKD from SBS or IBD, systemic oxalosis states similar to that seen in PH1 can occur [11].

Three 24-h urine oxalate collections should be performed under varying dietary conditions to obtain first evidence on whether hyperoxaluria may be primary or secondary. Patients collect 24-h urines under diets with normal, low and high oxalate content. Patients without hyperoxaluria and those with the typical pattern of secondary hyperoxaluria (low UOx under low Ox diet, high UOx under high Ox diet) are easy to diagnose [16].

Genetic Counselling in PH

Since all three types of PH are inherited in autosomal recessive manner, siblings of an affected individual have an *a priori* chance of 25% to be affected, a 25% chance of being unaffected and not a carrier, and a 50% chance of being an asymptomatic carrier of the familial mutation. All heterozygous carriers are asymptomatic with regards to primary hyperoxaluria, although heterozygosity for *HOGA1* mutations has been claimed to be a potential risk factor for calcium oxalate stone disease in a single report [4]. Since heterozygous carriers of an *AGXT*/*GRHPR*/*HOGA1* mutation are asymptomatic with respect to primary hyperoxaluria, they are acceptable liver and/or kidney donors.

In principle, prenatal testing is possible by DNA analysis from fetal cells (amniotic fluid, chorionic villus) and carrier testing for at-risk family members by testing in peripheral blood if the causative mutation(s) have been identified. Requests for prenatal testing (PD) in PH2 and particular for PH3, conditions that do not cause childhood ESKD and do not affect the intellectual capabilities, are uncommon. Preimplantation genetic diagnosis (PID) is a valuable alternative for families considering prenatal diagnosis for the purpose of pregnancy termination in PH1. With regards to family members at risk, it is recommended not to disclose PH1–3 carrier status to asymptomatic minors.

Treatment

Current Treatment Options

Conservative Treatment

Fluid Intake

Hyperhydration is the backbone of conservative treatment for stone disease in general and this is particularly true for all types of primary hyperoxaluria. High fluid intake (>3 liters per 1.73 m^2 per day) is essential. In infants and toddlers this is frequently problematic, so placement of a gastrostomy tube should be considered that will also ensure adequate fluid administration during nighttime. Situations of fluid losses (fever, diarrhea/vomiting, urinary tract infections etc.) or with compromised oral hydration (status post-surgery) have to be anticipated and there should be a low threshold to hospitalizing for intravenous fluid supplementation.

Dietary Considerations

At least in patients with PH1 and PH2 only a small proportion of the oxalate excreted in the urine is derived from the gut, so dietary oxalate restriction is of limited benefit and generally not recommended [15]. Conversely, restriction of oxalate intake is a necessity in SH. Patients with PH1 and PH2 absorb even less oxalate than healthy individuals, with a low fraction of dietary oxalate excreted in the urine (<5%) [15]. This phenomenon may be due to a concentration dependent flux (higher plasma, lower intestinal oxalate concentration) of oxalate into the intestinal lumen [92, 93]. However, it is reasonable to avoid large amounts of nutrients rich in oxalate and an excessive intake of ascorbic acid (vitamin C, oxalate precursor) and vitamin D (to avoid an increase in calcium excretion).

Calcium intake must not be restricted as this maneuver is likely to result in higher oxalate absorption from the gut because less intestinal calcium will lead to more free, absorbable oxalate [14, 15].

In PH3 the situation might be more complex since catabolism of 4-hydroxyproline derived from collagen turnover and dietary sources

results in significant glyoxylate and oxalate generation, which links the PH spectrum to the gastrointestinal tract, sometimes referred to as the "gut-kidney axis" [15].

Vitamin B6

A treatment option specific to PH1 is the oral administration of vitamin B6. The vitamin B6 component pyridoxal-phosphate (PLP) is the cofactor of all body transaminases and hence also of the AGT enzyme deficient in PH1. PLP was first described in 1961 by McLaurin and colleagues as a treatment option in two patients with PH1, long before AGT deficiency was known to be the cause of the disease [94]. Pharmacological doses of PLP supposedly help 30–50% of patients with PH1 with residual AGT activity to reduce or even normalize endogenous oxalate production [95–97]. Treated patients progressed to ESKD later and were older at the time of death [32, 98].

However, current evidence is mostly based on case series, single case reports and retrospective trials, while prospective trials are still pending [99–104]. There is an ongoing debate about the mechanisms of action and response patterns [105–107]. Some authors even concluded that pyridoxine treatment is not efficient in reducing oxalate excretion [108, 109]. The only prospective B6 treatment study showed that in about 50% of PH1 patients, urine oxalate excretion was reduced by >30% [88]. However, complete normalization of UOx was not observed, not even in patients with a homozygous p.G170R mutation. Also, no correlation was found between serum B6 levels and the reduction of urinary oxalate excretion [88].

Vitamin B6 comprises six compounds (vitamers) with vitamin B6 activity: pyridoxine, pyridoxal, pyridoxamine, and the activated phosphate esters pyridoxine 5' phosphate, pyridoxal 5'-phosphate and pyridoxamine 5'-phosphate [88]. Vitamin B6 is usually administered as pyridoxine-hydrochloride and resorption in the jejunum is passive. In the liver, vitamin B6 vitamers are enzymatically interconverted, and finally deliver pyridoxal 5'-phosphate, the active form that interacts with AGT [110].

As explained in detailed above, in PH1 AGT is misfolded or mistargeted to the mitochondria due to missense mutations in *AGXT* [111]. There are different hypotheses how the vitamin B6 ester PLP might reduce endogenous oxalate production and UOx excretion. Possible mechanisms include an increase in AGT expression, AGT enzyme activity, or, most likely, facilitated targeting of AGT into the peroxisomes [112]. All mechanisms would lead to an increased metabolic efficiency of AGT. Since mutant AGT protein is not as stable as wild type AGT, stabilizing compounds such as PLP acting as a pharmacological chaperone might lead to re-stabilization of the AGT protein with an increase of enzymatic function [113].

The responsiveness to vitamin B6 treatment depends on the underlying mutation. Mutations which lead to residues at the active site directly interacting with PLP (e.g. p.W108R, p.S158L and p.D183N) are considered to be associated with PLP responsiveness [114]. In addition, missense mutations that result in misfolding and impaired import (e.g. p.G170R or p.F152I) are also likely to benefit from PLP [34, 115, 116]. as confirmed in a prospective study [117]. Responsiveness was, however, not seen in all patients and there also was intrafamilial heterogeneity in response to B6 despite the same genotype [88].

Notably, pyridoxine absorption and metabolism has not been studied *in vivo*, so efficacy of B6 may not only depend on the *AGXT* genotype, but also be affected by individual variation in absorption and metabolism of Vitamin B6.

Responsiveness is currently defined by a decrease in urinary oxalate excretion after a test period of a minimum of 3 months at maximum dose [1, 88]. It is recommended to administer vitamin B6 (pyridoxine) in all patients with proven PH1, starting at a dose of 5 mg/kg per day and not exceeding 20 mg/kg per day, aiming to decrease urine oxalate excretion by >30% [88, 118]. If responsive, patients should remain on medication even if commencing dialysis [56, 103, 116]. In case of suspected infantile oxalosis, PLP should be given immediately as renal failure can sometimes be reversed in patients with a susceptible genotype (e.g. p.G170R homozygotes) (Fig. 29.4).

From a mechanistic point of view, one would expect the effect of RNAi treatment (which

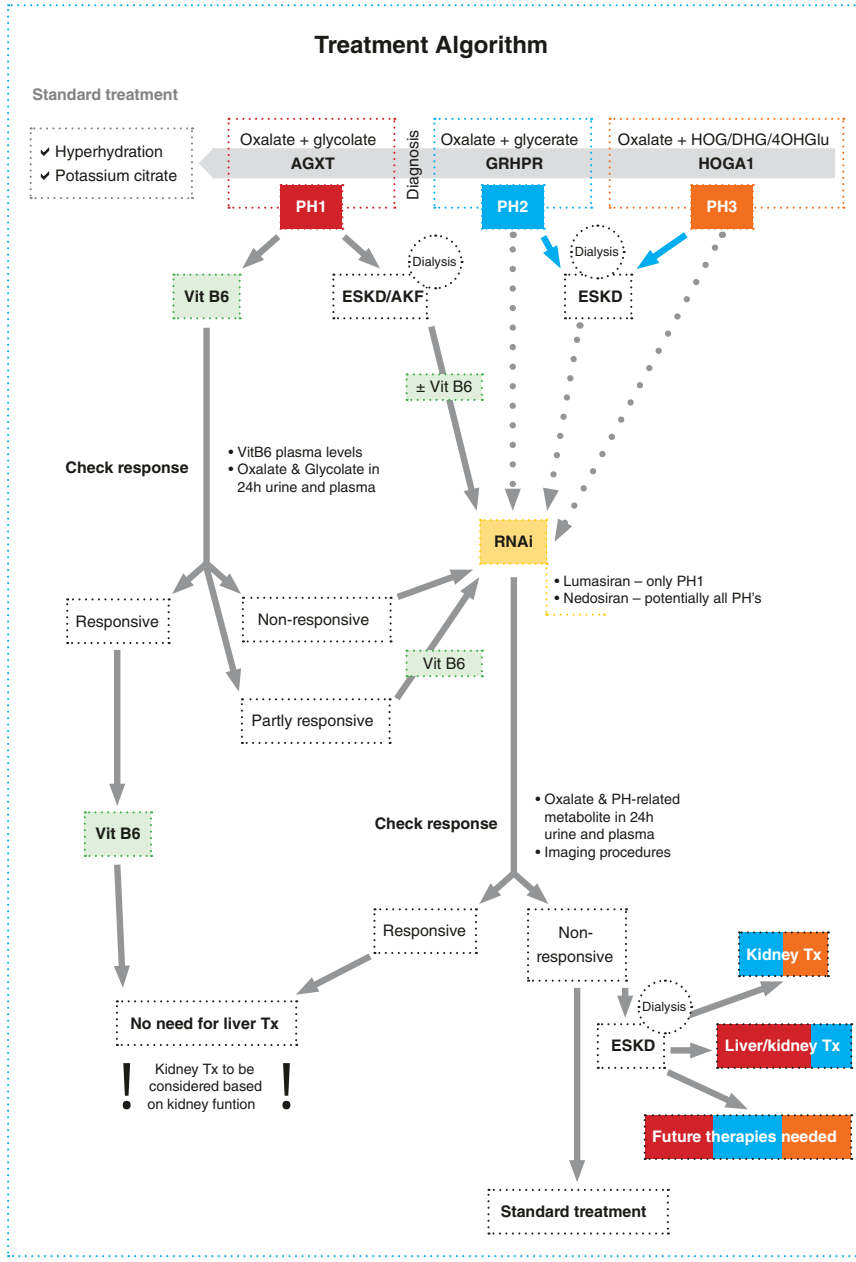


Fig. 29.4 Treatment algorithm in patients with the primary hyperoxalurias implementing the new RNAi interference (RNAi) treatment option. All patients should receive hyperhydration and alkaline citrate medication at start of treatment. In patients with primary hyperoxaluria type 1 (PH1), vitamin B6 (Vit B6) response has to be checked primarily before considering RNAi medication. In those patients who only show partial or no responsiveness to Vit B6, treatment decision is challenging and must be personalized by clinical follow up, quality of life and socio-economic evaluation. No liver Tx is needed in patients with adequate Vit B6 or RNAi response as indicated by normalized or nearly normalized urinary oxalate excretion. In patients with PH2&3 there currently is no RNAi treatment available. *PH1–3* primary hyperoxaluria types 1–3, *ESKD* end stage kidney disease, *AKF* acute kidney failure, *Tx* transplantation, *sqm* square meter, *Vit B6* vitamin B6

depletes oxalate precursors/substrates) to be independent of the effect of vitamin B6 treatment (which partially restores proper targeting of AGT to the peroxisome), so synergistic benefits could be expected from combining RNAi and vitamin B6 in patients with susceptible missense genotypes, e.g. partly B6 responsive patients (Fig. 29.4).

Side effects are rarely seen and even at higher dosages sensory neurotoxicity is uncommon according to investigator brochures and retrospective case series [95] (Table 29.2).

RNA Interference Therapeutics

RNA interference (RNAi) therapeutics are a revolutionary new approach to the treatment of PH. RNAi compounds work at the level of messenger RNA (mRNA) translation. These synthetic small double-stranded RNA molecules (small interfering RNA, siRNA) bind to a cytoplasmic protein complex (RNA-induced silencing complex, RISC), which specifically degrades the targeted mRNA and thus prevents translation into the corresponding protein [119–121]. This renders placing false information at the site that normally produces an enzymatic protein involved in oxalate metabolism (in the liver). If this is not produced, oxalate production in the liver can be significantly reduced or even completely blocked.

A first RNAi drug, Oxlumo® (Lumasiran, Alnylam Pharmaceuticals, USA), has recently been approved and can be prescribed since January 2021 [122]. Oxlumo® targets the mRNA of glycolate oxidase (GO) and, thus, prevents its translation in patients with PH1. This reduces the production of glyoxylate (i.e. the precursor to oxalate) and hence also oxalate production. Subcutaneous administration in animals showed reduction of urinary oxalate excretion by 98% [119, 120]. In healthy volunteers, Oxlumo® blocked about 80% of the corresponding mRNA without relevant side effects. In PH1 patients, urinary oxalate excretion is reduced by an average of 65% [122]. The downregulation of glycolate oxidase leads to an increased production and urinary excretion of the supposedly non-toxic compound glycolate. In patients with >20 kg body weight Oxlumo® is injected subcutaneously at a dosage of 3 mg/kg at monthly intervals for the first four injections, followed by quarterly injections. Smaller children are started on 6 mg/kg per month for the first 4 dosages, followed by 3 mg/kg monthly in children <10 kg and 6 mg/kg quarterly in patients with 10–20 kg body weight.

Another RNAi medication, Nedosiran® (Dicerna Pharmaceuticals/NovoNordisk, USA/Denmark) interferes with the final step towards oxalate production, the translation of liver-specific lactate dehydrogenase A (LDHA), preventing the conversion of glyoxylate to oxalate in all three types of PH [123]. Its efficacy in reducing urinary oxalate excretion has been demonstrated in animal models [124]. In a pilot study with long-term follow-up a significant decrease in urinary oxalate excretion, up to normalization, was achieved [119]. Nedosiran® is also injected subcutaneously, at a fixed dose of 170 mg per month in adults >50 kg and 136 mg in those <50 kg, and corrected to body weight in children (3.5 mg/kg). In a recent pivotal study Nedosiran® achieved equivalent reduction of urinary oxalate excretion in patients with PH1 as Oxlumo® [119, 123]. However, the expected positive results were not reached in patients with PH2.

The recent advent of RNAi therapeutics for clinical use mark a new era in the treatment of PH. Although long-term outcome data are not yet available, these drugs promise to allow better preservation of renal function and even prevention of progression to ESKD and systemic oxalosis at excellent tolerability. The major drawback of RNAi based drugs is their very high cost.

Oxalate Degrading Bacteria

The human intestine is physiologically colonized by oxalate degrading bacteria. Among these is *Oxalobacter formigenes*, an obligate anaerobic microbe residing primarily in the intestines of vertebrate animals [125]. This bacterium is unique among oxalate-degrading organisms as it has become totally dependent on oxalate for energy metabolism [125]. During the past three

decades compelling evidence has been gathered that the intestine plays an important role in oxalate homeostasis in states of health and disease and that *Oxalobacter formigenes* exerts a symbiotic relationship regarding the regulation of oxalic acid absorption in the gut [92, 93]. In various animal models of primary and secondary hyperoxaluria it was demonstrated that endogenous oxalate can be eliminated by *Oxalobacter* colonization of the intestinal tract [116, 126, 127]. Such treatment also showed efficacy in two pilot clinical trials with orally administered *Oxalobacter formigenes*, as paste or capsule, in PH patients with normal renal function or in ESKD [128, 129]. UOx or POx levels decreased significantly during 4 weeks of *Oxalobacter formigenes* administration, confirming the findings in the animal models [116, 126]. Significant reduction of POx was also observed in a phase 2 study with PH1 patients on chronic renal replacement therapy [128]. However, these results were not reproduced in two subsequent phase III trials [130]. A double blind multicenter trial was recently finalized but did not reach the primary endpoint, so the manufacturer stopped the developing process. A potential reason for the disappointing results in humans may be an inefficient delivery of the drug to the colon. Alternatively, the human gut flora may be deranged and microbial interplay be severely hampered by administration of *Oxalobacter* at excessive doses [130]. It is also possible that difficulties of the production process, with a less active *Oxalobacter* preparation used in the latter studies, might explain the findings [127].

Other Medication

Like in all other kidney stone formers, an increased excretion of urinary stone inhibitory parameters is regarded as an important measure. Both, alkaline citrate and orthophosphate treatment increases urinary pH (pH values above 7.5 should be avoided to prevent precipitation of calcium-phosphate crystals) and urinary citrate excretion. With the increase in citrate excretion, urinary calcium to oxalate binding is reduced, but also the urinary calcium excretion *per se* can be reduced by approximately 30% [131, 132].

Dialysis

No blood purification modality sufficiently removes the endogenously overproduced oxalate [58, 133–135]. Not even daily hemodialysis, nor its combination with peritoneal dialysis achieves a negative oxalate balance [135]. Body oxalate accumulation increases rapidly in dialyzed children and cannot prevent systemic oxalosis from taking its disastrous course. Hence, the period of dialysis prior to transplantation should be kept as short as possible. Since oxalate, a small hydrophilic molecule, is rapidly cleared by hemodialysis, frequent relatively short hemodialysis sessions, e.g. 5–6 times a week for 3 h, are more efficient than extended less frequent dialysis protocols [133, 134]. High-flux filters have a slight advantage in oxalate elimination [133]. Post dialysis POx should be well below <30 μmol/L, the cutoff value for plasma CaOx supersaturation [23]. A rapid POx rebound occurs after hemodialysis, making nocturnal peritoneal dialysis a valuable option for further oxalate elimination [135]. However, intense dialysis protocols are also fraught with higher technical complication rates [133]. Also, dialysis prescription should keep the families' quality of life in mind.

Transplantation Strategies

The transplant procedure is different for either form of PH, with no specific procedures for transplantation reported so far in PH type 3 patients. Liver transplantation cures the enzyme defect in PH1 and hence, pre-emptive liver transplantation and sequential or combined liver/kidney transplantation are possible procedures. However, due to the extreme clinical heterogeneity of PH1 even within families and in patients with the same genotype, individualized transplantation strategies are necessary [57, 61].

Combined liver/kidney transplantation is the method of choice in patients with ESKD and in vitamin B6 unresponsive patients without severe systemic oxalosis. Patient and liver allograft survival following combined liver and kidney transplantation were 80% and 72% at 5 years, respectively in European registry data [21, 57]. Pre-emptive liver transplantation might be an option in patients with a more rapid decline in kidney function [136], but timing of that procedure is difficult due to the variability of the disease course. Due to mobilization and renal elimination of systemically deposited oxalate, kidney function may still deteriorate after preemptive liver transplantation and kidney transplantation may still become necessary [57, 61]. In patients with infantile oxalosis, sequential liver and kidney transplantation is sometimes reasonable for technical/anatomical reasons [57]. In patients with severe systemic oxalosis sequential transplantation should also be considered to avoid prompt recurrence of oxalosis within the kidney graft.

Isolated kidney transplantation was generally not recommended in PH1. There is substantial evidence that PH1 patients with isolated kidney transplantation develop renal and systemic oxalate deposition [76, 77]. Allograft oxalosis clearly limits the duration of graft function: Following isolated kidney transplantation, graft survival rates were only 46%, 28%, and 14% at 1, 3, and 5 years in PH patients, as compared to 95%, 90%, and 85% in non-PH patients [21]. By contrast, urinary and plasma oxalate normalize following combined liver and kidney transplantation. Isolated kidney transplantation might be considered in elderly patients with late onset of ESKD and a pyridoxin-sensitive genotype [137, 138]. Also, a recent report from the OxalEurope registry suggested that isolated kidney transplantation in patients with pyridoxine sensitive genotypes treated with vitamin B6 may be equivalent in long term outcome to combined transplantation procedures [139].

The advent of the RNAi therapies opens the option to reduce oxalate overproduction pharmacologically, potentially removing the need for curative liver transplantation in patients with PH1. However, it is currently still too early to say how many patients can eventually be spared liver transplantation in the long run by RNAi therapy, comparable to those patients being sensitive to vitamin B6 medication and reduce their urinary oxalate excretion to merely normal. Long-term follow-up data will be required to address whether liver transplantation will really become obsolete and ESKD can be prevented by this therapy. Our current approach is shown in Fig. 29.4.

In the rare patients with PH2 who reached ESKD, isolated kidney transplantation has mostly been performed since the clinical picture clearly is less severe than in PH1 and liver transplantation does not truly eliminate oxalate overproduction. Although the currently followed very small group of PH2 patients with a kidney transplant show good overall graft survival, patients with oxalate related graft dysfunction, which appeared earlier than chronic rejection induced graft failure, have been described [27]. In a few PH2 cases even combined liver kidney transplantation was found to be necessary [140].

Conclusions and Outlook

The primary hyperoxalurias are challenging diseases. Diagnosis is still frequently delayed despite the availability of genetic screening as a rapid diagnostic tool. Any urolithiasis in a child should prompt an investigation of the underlying cause to treat adeuqately and not only with symptomatic empiric therapy and/or repeated stone removal procedures. This also applies to adult patients with multiple or recurrent kidney stones. The relevance of an early diagnosis for improved long-term outcomes has markedly increased with the advent of RNAi therapeutics as another effective therapy of PH1 aside vitamin B6. It may be now possible to largely prevent the hitherto dismal course of the disease, preserve kidney function and avoid liver transplantation as a curative therapy.

Further curative treatment approaches are under development. Gene therapy might be considered in patients with PH1, as new, safe and highly liver-selective vectors are becoming available which would deliver the targeted gene into the liver cells. In *AGXT* deficient mice it has already been demonstrated that PH1 can be cured with such a therapy [141]. Currently, new vector technologies are being developed since a singular gene therapy might not be sufficient in PH patients as more or less all hepatocytes must be transfected. Multiple administrations will induce immune reactions of the host, which may limit the tolerability of the procedure [142]. Induced pluripotent stem cell-derived hepatocytes, which have first been used experimentally to model human metabolic liver diseases [143], can now be generated from blood leukocytes and dermal fibroblasts of PH1 patients (hiPSC) [144, 145]. In the future, such cells could be gene-edited and used for autologous hepatocyte-like cell transplantation [146] if a proliferative advantage of the hISPC over native diseased hepatocytes can be achieved. Gene editing of the *HAO1* gene by Crispr-Cas9 has already been applied in the animal model [147].

Cystinosis

30

Elena Levtchenko, Leo Monnens, and Aude Servais

Introduction

Cystinosis is an autosomal recessive disorder characterized by an accumulation of the amino acid cystine in lysosomes throughout the body. The responsible gene *CTNS* is located on the short arm of the chromosome 17 (p13) and encodes the lysosomal cystine carrier cystinosin [1, 2]. Lysosomal cystine accumulation is the hallmark of the disease.

Depending on the age of presentation and the degree of disease severity, three clinical forms of cystinosis are distinguished:

- Nephropathic infantile form (MIM #219800), which is the most frequent and the most severe form of the disease
- Nephropathic juvenile form (MIM #219900); synonyms: intermediate cystinosis, late-onset form, adolescent form
- Non-nephropathic adult form (MIM #219750); synonyms: benign non-nephropathic cystinosis, ocular non-nephropathic cystinosis

All three forms of the disease are caused by mutations in the *CTNS* gene and have phenotypic overlap. Unless specified otherwise, this chapter focuses on infantile nephropathic cystinosis which affects ~95% of the patients.

Historical Aspects

Cystinosis was first described as a clinical entity by the chemist Abderhalden in 1903 [3] and recognized as a main cause of generalized proximal tubulopathy, called de Toni-Debré-Fanconi syndrome in the late 1940s/early 1950s [4–6]. Real progress in the investigation of cystinosis started when amino acid chromatographic analysis allowed measuring elevated cystine concentrations in tissues of cystinotic patients [7, 8]. In the

1980s it was demonstrated that cystine was stored within the lysosomes due to the impairment of cystine transport across the lysosomal membrane [9, 10]. The availability of renal transplantation and treatment with the amino thiol cysteamine dramatically improved the prognosis of cystinosis patients allowing them to survive into adulthood [11, 12]. Cloning the *CTNS* gene in 1998 was pivotal for understanding the genetic basis of the disease and performing genetic counseling of the families [1]. Moreover, the *CTNS* gene discovery opened a new chapter in studying the disease pathogenesis and searching for novel molecular therapies [13].

Epidemiology

The estimated incidence of cystinosis is 1 in 100,000–200,000 live births [2] with clustering reported in some populations [14–16]. Cystinosis affects all races, with specific hotspot mutations reported in different nations [16, 17].

Males and females are equally affected. Overall cystinosis patients account for approximately 1–2% of the pediatric end-stage renal failure population or 0.85/million of age related population [18, 19].

Genetics

Mutation Spectrum

Cystinosis is caused by mutations in the *CTNS* gene, which has been identified by positional cloning strategy [1]. *CTNS* maps to 17p13.2 (Fig. 30.1a) [1] and encodes a 367 amino acid protein, cystinosin, with a 7-transmembrane domain structure which is highly glycosylated at the N-terminus [21] (Fig. 30.1b). Cystinosin contains 2 lysosomal-targeting sequences, one situ-

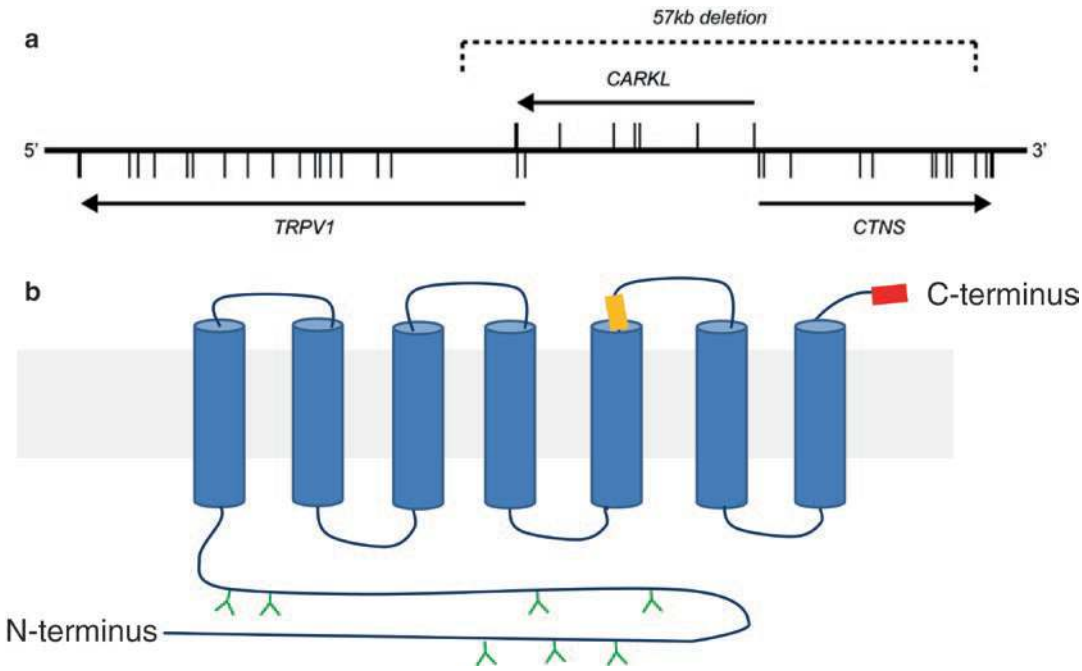

Fig. 30.1 Molecular basis of cystinosis. (**a**) The *CTNS* gene is mapped at chromosome 17p13.2 and is composed of 12 exons, with the open reading frame starting in exon 3. The *CTNS* shares promoter sequence with the *CARKL* gene. Common 57 kb deletion is the most prevalent mutation in the Northern-European population which affects *CTNS*, *CARKL* and the first two non-coding exons of the adjacent *TRPV1* gene (Used with permission of The American Physiological Society from Wilmer et al. [20]); (**b**) *CTNS* encodes lysosomal membrane protein cystinosin with seven transmembrane domain structure. Cystinosin contains two lysosomal-targeting sequences: GYDQL at C-terminus (red box), and YFPQA—in the fifth inter-transmembrane domain loop (yellow box). Y—predicted glycosylation sites

ated in its C-terminus, a tyrosine-based motif (GYDQL) and the second (YFPQA) in the fifth inter-transmembrane domain (TM) loop [21].

Mutations in *CTNS* have been detected in all three clinical forms of cystinosis, demonstrating that these forms are allelic [1, 22, 23]. The most common anomaly is a large 57 kb deletion spanning the first nine exons and a part of exon 10 of the *CTNS* gene, the upstream 5-prime region that encodes the *CARKL* (carbohydrate kinase-like) gene, and the first two noncoding exons of the *TRPV1* gene [1, 24–26]. *CARKL* encodes the enzyme sedoheptulokinase [26] and *TRPV1* encodes the protein transient receptor potential one [27]. Patients with the homozygous 57 kb deletion have increased sedoheptulose levels in tissues, serum and urine [26, 28], but no clinical disorders related to CARKL deficiency has been reported so far. Decreased sensitivity to capsaicin and altered sensation of heat due to strongly reduced activity of TRPV1 channel may account for the reported sensory alterations and thermoregulatory deficits (such as impaired sweating) in patients carrying homozygous 57 kb deletion [27]. The common 57 kb deletion can be detected by FISH analysis, by a rapid PCR assay with the 57 kb deletion breakpoint primer sets, or by MLPA [29–31]. While being frequent in the Northern-European population, the 57 kb deletion is rare in Southern Europe and in patients originating from other ethnical groups [16].

Over 140 other mutations in *CTNS* have been reported, which include small deletions, insertions, nonsense, missense, splicing mutations, mutations in the promoter region or small genomic rearrangements (uniparental disomy on chromosome 17) [1, 16, 22, 25, 30–34].

In a recently published European cohort, 33% of patients were homozygous and 23% were heterozygous for the 57 kb deletion, and 45% had other pathogenic variants of the *CTNS* gene [35]. Missense variants, splicing variants and out-of-frame deletions were the other most frequent types of mutations. If standard analysis using PCR technique and Sanger sequencing fails to demonstrate *CTNS* mutations in patients with the clinical diagnosis of cystinosis, the *CTNS* gene transcripts analysis for detection of exon-skipping mutations should be performed [34]. Maternal heterodisomy should be suspected when no mutation is found in the father and can be detected using analysis of microsatellite markers on chromosome 17 [33].

Genotype: Phenotype Correlations

In infantile forms, individuals have severe mutations in both alleles, leading to the complete loss of cystinosin function. No differences in kidney survival and severity of the extra-renal disease between patients that inherited the 57 kb deletion in homozygous or in heterozygous state and patients with other severe pathogenic *CTNS* variants were found [35–37]. In contrast, point mutations in the *CTNS* gene that do not disrupt the open reading frame of cystinosin are more commonly associated with the late-onset phenotype and generally affect the inter-transmembrane loops or the N-terminal region [22, 23, 38–42]. In the late-onset form, patients are usually homozygous for mild mutations or compound heterozygous for a mild mutation and a severe mutation [22]. Mild mutations impair, but do not completely abolish cystine transport [43]. Moreover, the level of transport inhibition often correlates with the severity of symptoms. Some tissues might be spared in benign cystinosis due to tissue-specific splicing factors mitigating the effect of splice-site mutations in renal tissue by favoring the expression of residual normal message [23, 42, 43]. Mutations in the promoter region have also been described in patients with ocular cystinosis [25]. In addition, contrasting to almost 100% detection rate in infantile cystinosis, *CTNS* mutations are not found in all patients in late-onset forms [39, 41]. Mutations in the non-coding regions of the *CTNS*, such as the regulatory regions, may also be involved in these patients.

Pathogenesis

Following the seminal studies by Schneider et al. [7, 8], electron microscopy of lymph nodes of patients with cystinosis first suggested that cystine accumulation occurs in lysosomes [44]. The lysosomal localization of cystine was later confirmed in cystinotic leucocytes [45]. Subsequently, kinetic studies of cystine clearance from lysosomes of cystinotic leucocytes and fibroblasts provided evidence that impaired lysosomal cystine efflux represents the primary defect causing cystine accumulation in cystinosis [9, 10, 46].

The discovery of the gene defective in cystinosis allowed the functional characterization of the gene product cystinosin as a proton-driven lysosomal cystine carrier [47]. A transcript variant of the *CTNS* originating from alternative splicing of exon 12, which replaces the lysosomal targeting motif GYDQL at the C-terminus by a longer amino acid sequence (termed CTNS-LKG based on the sequence of the three last amino acids leucine (L), lysine (K), glycine (G)) shows expression in the plasma membrane, in lysosomes, in the endoplasmatic reticulum, in the Golgi apparatus, and in small intracellular vesicles [48]. In most tissues, CTNS-LKG represents 5–20% of *CTNS* transcripts with the highest expression level found in the testes [49].

The source of lysosomal cystine *in vivo* is uncertain. Because kidney proximal tubules are the first affected cells of the body, it has been suggested that the endocytosis of disulfide-reach plasma proteins with subsequent hydrolysis in lysosomes can lead to extensive cystine accumulation and early damage of proximal tubular cells. Blocking megalin-driven endocytosis in a mouse model of cystinosis substantially decreased crystal formation and prevented proximal tubular atrophy, providing a proof-of-concept that the megalin pathway can be a potential therapeutic target [50]. On the other hand, inhibiting the lysosomal membrane cysteine transporter MFSD12 responsible for the import of cytosolic cysteine to the lysosomal lumen substantially decreases lysosomal cystine accumulation in fibroblasts from patients in cystinosis, pointing that cytosolic cysteine is an important source of lysosomal cystine [51].

ATP Depletion

Prior to the development of the knockout mouse model, cystine-loaded proximal tubules were used to study renal pathogenesis in cystinosis [52, 53]. Whether cystinosis causes a direct alteration of mitochondrial ATP generation remains controversial [54–56]. While studies in skin fibroblasts and immortalized proximal tubular cells derived from cystinosis patients showed overall normal ATP generating capacity and unaltered activity of Na-K ATPase [57–60], decreased mitochondrial levels of cyclic-AMP, reduced complex I and V activity and altered mitochondrial morphology and dynamics were demonstrated and point to altered mitochondrial function [61, 62] (Fig. 30.2).

Increased Apoptosis

Another pathologic mechanism involved in cystinosis is an altered regulation of cell survival and death due to enhanced apoptosis.The rate of apoptosis is increased in fibroblasts and proximal tubular cells of patients with nephropathic cystinosis compared to normal cells [63, 64].

Enhanced apoptosis has been postulated to cause the specific atrophy of renal proximal convoluted tubules adjacent to glomeruli (“swan-neck” deformity), that has been demonstrated in cystinotic kidney biopsies starting from sixth month of age [65, 66]. Transcripts of pro-apoptotic caspase 1, caspase 4 and caspase 12 are increased in cystinotic tissues, with significant increase in caspase 3 activity being demonstrated in proximal tubular cells of cystinosis mouse model [67].

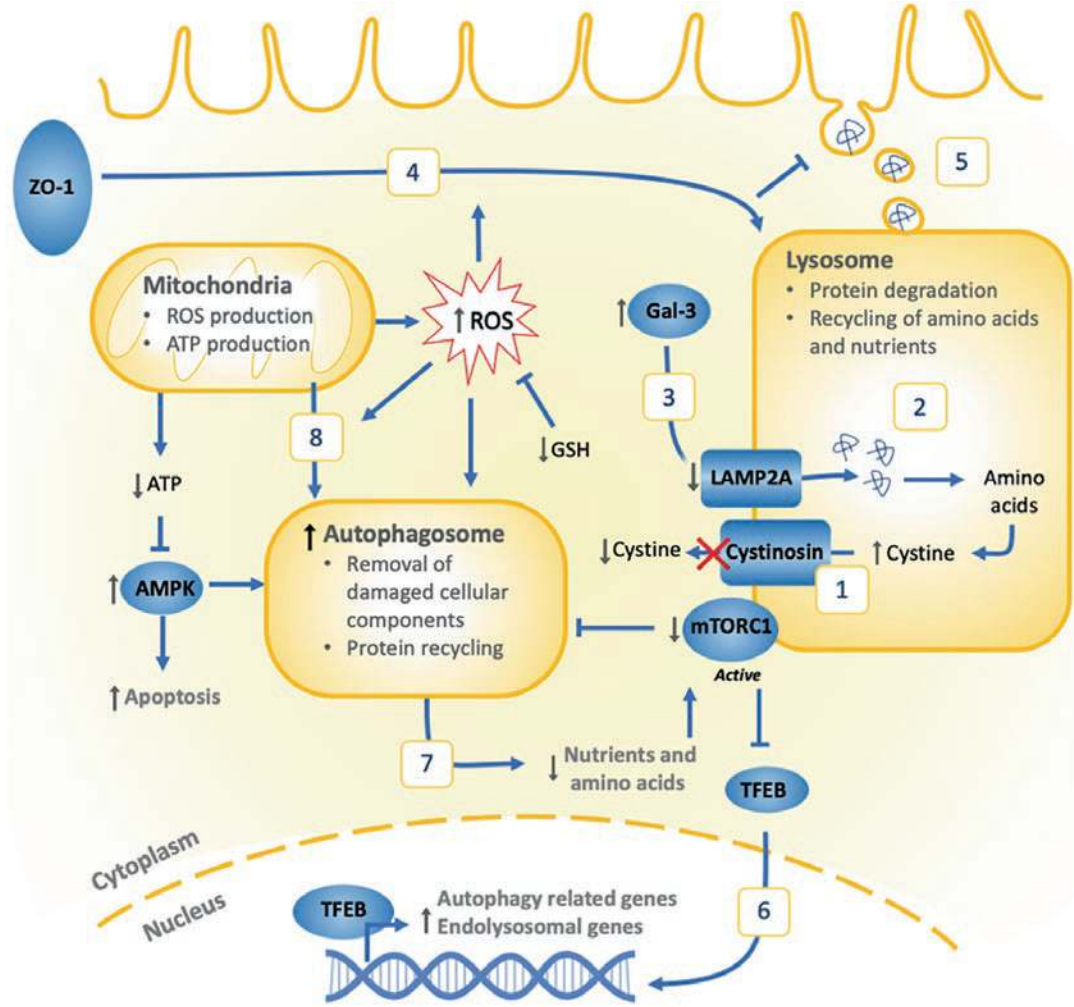

Fig. 30.2 Simplified scheme of the current knowledge on pathogenesis of cystinosis. (1) Dysfunctional cystinosin leads to the accumulation of cystine within the lumen of the lysosome. (2) Reduced protein degradation due to defective lysosomal enzyme activation. (3) Reduced chaperone-mediated autophagy leads to galectin-3 overexpression and has been associated with chronic kidney disease progression. (4) Phosphorylation of tight junction adapter protein ZO-1 results in its misrouting to endolysosomal compartments and disruption of tight junction integrity. (5) Disruption of tight junctions leads to epithelial dysfunction and dedifferentiation, repressing apical endocytic receptors and megalin/cubilin-mediated endocytosis. (6) Increased TFEB nuclear translocation by inhibiting mTOR activates transcription of autophagy related genes and can reduce cystine accumulation via increased exocytosis. (7) Reduced autophagic flux and degradation. (8) Abnormal mitophagy can lead to increased oxidative stress, further promoting epithelial dysfunction, dedifferentiation, and apoptosis. *AMPK* 5′ adenosine monophosphate-activated protein kinase, *ATP* adenosine triphosphate, *GSH* glutathione, *Gal-3* galectin-3, *LAMP2A* lysosome-associated membrane protein 2A, *mTORC1* mammalian target of rapamycin complex 1, *ROS* reactive oxygen species, *TFEB* transcription factor EB, *ZO-1* zonula occludens 1. Altered Redox Homeostasis and Increased Oxidative Stress

Multiple studies have demonstrated that cystinosis cells are prone to oxidative stress and that the mitigation of oxidative stress is an important therapeutic target in cystinosis [68]. Cystine is composed of two molecules of cysteine and the cysteine/cystine couple represents one of the major cell thiol/disulfide systems involved in the regulation of the cell redox state. In the cytosole cystine is reduced to cysteine through electron transfer from the other major cell thiol/disulfide systems, mainly free and oxidized glutathione (GSH/GSSG) [69]. Altered GSH metabolism has been demonstrated in cystinosis cells with decreased GSH levels [58, 70], decreased GSH/GSSG ratio or inability to upregulate GSH synthesis upon oxidative stress [71]. These alterations might be a direct consequence of cystinosin dysfunction as cystinosin expression is regulated by the intracellular Cys/CySS redox state [72]. On top, mitochondrial dysfunction and altered autophagy of damaged mitochondria have been shown to increase the generation of reactive oxidative species (ROS) which can further exhaust the cellular anti-oxidative capacity and lead to cell damage [73]. Reducing lysosomal cystine accumulation with cysteamine interferes with this cascade, increases cellular glutathione levels, attenuates oxidative stress and decreases the rate of apoptosis promoting cell survival in cystinosis [60, 63, 64].

Altered Vesicle Trafficking and Cell Signaling

The fact that renal Fanconi syndrome is not fully responsive to cysteamine treatment suggested that not all cellular mechanisms of cystinosis are due to cystine accumulation and pointed to potential other functions of cystinosin [20, 68]. This hypothesis was substantiated by recent studies demonstrating that the absence of cystinosin led to alterations of cellular trafficking mechanisms, impaired cell signaling and autophagy (Fig. 30.2).

Altered vesicle movements with a predominance of slow moving lysosomes was found in murine and human cystinotic proximal tubular cells, accompanied by decreased expression of the small GTPase Rab27a [74]. In addition, altered autophagic flux was demonstrated in human cystinotic fibroblasts, proximal tubular cells and in patient kidney biopsies [75, 76].

Proximal tubular cells of the *ctns* $^{-/-}$ mouse showed signs of dedifferentiation with decreased expression of the endocytotic receptors megalin and cubilin and elevated expression of zonula occludens-1 (ZO-1)-associated nucleic acid-binding transcription factor (ZONAB) and proliferation markers PCNA and cyclin D1 characteristic of immature proximal tubular cells [77]. In line with the development of the "swan-neck" lesion demonstrated in human cystinotic kidneys [65], the first segment of proximal convoluted tubules in the *ctns* $^{-/-}$ mice was first affected with lesions gradually progressing towards more distal parts of the proximal tubule [78]. Increased oxidative stress might be a link between cystinosin dysfunction and altered endocytosis as it stimulates Gα12/Src-mediated phosphorylation of tight junction protein ZO-1 and triggers a signaling cascade involving ZO-1-associated Y-box factor ZONAB, which leads to dedifferentiation of proximal tubular cells, cell proliferation and transport defects [73]. It is still a working model without explanation for decreased transport for glucose, phosphate and other small solutes.

Altered mammalian target of rapamycin (mTOR) signaling might be another potential therapeutic target in cystinosis, unrelated to cystine accumulation. While an interaction between cystinosin and Vacuolar H+—ATPase-Ragulator-Rag complex controlling mTOR has been demonstrated [79], studies of mTOR activity in cystinosis cells provided inconsistent results [80, 81]. Nevertheless, inhibiting mTOR activity by everolimus reduced the number of large lysosomes, decreases apoptosis, and activates autoph-

agy in kidney organoids derived from *CTNS*-deficient human induced pluripotent stem cells [82]. The expression of transcription factor EB (TFEB), which inhibits mTOR activity, is reduced in cystinosis proximal tubular cells, and overexpressing TFEB improves the altered cellular phenotype [83]. Inhibiting mTOR stimulates nuclear transplocation of TFEB and can reduced cellular cystine accumulation by increasing exocytosis of cystine loaded lysosomes [68] (Fig. 30.2).

A drug-repositioning strategy combined with high-throughput screening showed that the flavonoid luteolin improves the lysosome-mediated degradation of the autophagy cargoes, restores lysosomal distribution, and stimulates endocytosis in cystinotic proximal tubular cells, opening a new therapeutic prospective in cystinosis [84].

Mechanism of Chronic Interstitial Damage

The progression of cystinotic nephropathy is characterized by the development of diffuse tubulo-interstitial lesions and fibrosis. Cystinosis is also associated with early podocyte dysfunction characterized by excessive losses of podocytes into urine and the development of glomerular proteinuria [81].

Reabsorption of excessively filtered proteins may contribute to the renal interstitial injury in analogy to other proteinuric conditions by stimulating local inflammatory response [85, 86]. Furthermore, higher circulating levels of pro-inflammatory interleukin-1β and interleukin-18 were attributed to inflammasome activation by cystine crystals [87]. Macrophage activation in the kidney is likely to contribute to the development of interstitial renal damage caused by cystine accumulation. Furthermore, studies have demonstrated an additional new role for cystinosin in inflammation through its interaction with the lectin and β-galactoside-binding protein family 21 galectin-3 (Gal-3), enhancing macrophage infiltration and CKD progression [88] (Fig. 30.2).

Clinical Presentation

Kidney Disease

Infantile nephropathic cystinosis is the most frequent cause of inherited renal Fanconi syndrome in childhood. The dysfunction of different proximal tubular transporters develops gradually after birth with aminoaciduria being present already during the first month of life [89]. Full-blown renal Fanconi syndrome characterized by excessive urinary excretion of amino acids, phosphate, bicarbonate, glucose, sodium, potassium, low molecular weight proteins and other solutes, handled in renal proximal tubules is usually present by the age of 6 months. Clinically, patients are asymptomatic at birth and develop normally until 3–6 months, when they manifest with failure to thrive, vomiting, constipation, polyuria and excessive thirst, periods of dehydration and sometimes rickets [90, 91]. Growth retardation in case of late diagnosis may reach −4 SD [90]. Renal loss of sodium and potassium can result in hyponatremia and hypokalemia, which may be life threatening. Hypouricemia, decreased plasma carnitine and medullary nephrocalcinosis related to increased calcium excretion are also observed [92, 93]. Total protein excretion can reach several grams per day and contains both low molecular weight proteins, albumin and high molecular weight proteins [85].

In untreated patients glomerular filtration declines gradually and progresses towards kidney failure before the age of 10 years [94, 95]. At start of kidney replacement therapy patients with cystinosis have better blood pressure control and lower serum phosphate levels compared to patients with end stage kidney disease (ESKD) due to other causes because of still ongoing renal Fanconi syndrome with polyuria and urinary sodium and phosphate losses [96].

Renal Pathology

The age at which the first morphological changes appear in the kidneys of patients with cystinosis

is unknown. No significant renal changes were observed in the fetus [97]. Serial renal biopsies in two cystinotic patients demonstrated that the typical "swan-neck" deformity of proximal convoluted tubules appeared only after 6 months of life [65]. In a large series of kidney specimens, the most striking feature were the marked irregularities of renal tubular cells with the presence of flat cells with focal disappearance of the brush border and very large cells with a prominent and hyperchromatic cytoplasm (Fig. 30.3a) [97, 98]. Glomeruli can appear normal but most contain peculiar giant multinucleated podocytes (Fig. 30.3a) [85]. Podocyte foot process effacement seen in other proteinuric disorders is also present in cystinosis (Fig. 30.3b) [85]. Cystine crystals located in the lysosomes or in cytoplasm are seen mostly within interstitial cells and rarely within podocytes [97]. Patients with late-onset or juvenile cystinosis can demonstrate focal and segmental glomerular sclerosis (FSGS) undistinguishable from idiopathic FSGS [39].

The deterioration of kidney function is accompanied by progressive tubulo-interstitial lesions, including interstitial fibrosis, tubular atrophy and marked arteriolar thickening. The progressive glomerular damage, leading to increasing albuminuria and hematuria, consists of segmental or global collapse of the capillary tuft, accumulation of mesangial matrix material, and, observed by electron microscopy, irregular thickening of glomerular basement membrane [97].

In transplanted kidneys cystine crystals, sometimes seen at graft biopsy, have no clinical relevance as they are present in the host mononuclear cells [99].

Kidney Transplantation

Kidney transplantation is the best therapeutic option for ESKD in young patients [100]. In pediatric cohorts, the outcome of kidney transplantation in patients with cystinosis is generally better than that of other patients undergoing transplantation [96, 101–103]. In adults, a similar rate of graft survival at 5 and 10 years among patients with cystinosis and control patients has been reported [104]. Furthermore, long term graft survival is higher in patients with cystinosis compared to controls by multivariate analysis. Proximal tubular disease does not occur in the transplanted kidney because the metabolic disorder is not present in the engrafted kidney. However, retention of a native kidney can result in the persistence of renal tubular Fanconi syndrome. Renal transplantation does not correct the systemic meta-

bolic defect of cystinosis and cystine continues to accumulate in most organs and may lead to late systemic complications.

Patients with cystinosis are at risk of developing post-transplant diabetes. However, the risk of diabetes is not increased compared with control patients [104]. Immunosuppressive maintenance treatment regimens should be equivalent between patients with or without cystinosis.

Extra-renal Involvement

Ocular Impairment

Accumulation of cystine crystals occurs in all ocular structures, including the cornea, the conjunctiva, the iris and the retina causing symptoms of photophobia, blepharospasm and other complications. The corneal crystals, pathognomonic of the disorder, are absent at birth, but generally may be visible on ophthalmological investigation from around 16 months of age in most patients with cystinosis (Fig. 30.4a). If untreated, patients develop increasingly severe photophobia, refractory blepharospasm, peripheral corneal neovascularisation and band keratopathy, eventually progressing to involvement of the posterior segment of the eye with hypopigmentary mottling of the retinal pigment epithelium, glaucoma and visual impairment [105–107].

Novel techniques such as *in vivo* confocal microscopy and anterior segment optical coherence tomography of the cornea allow not only to visualize corneal cystine crystals with high sensitivity, but also to quantify the crystals and the

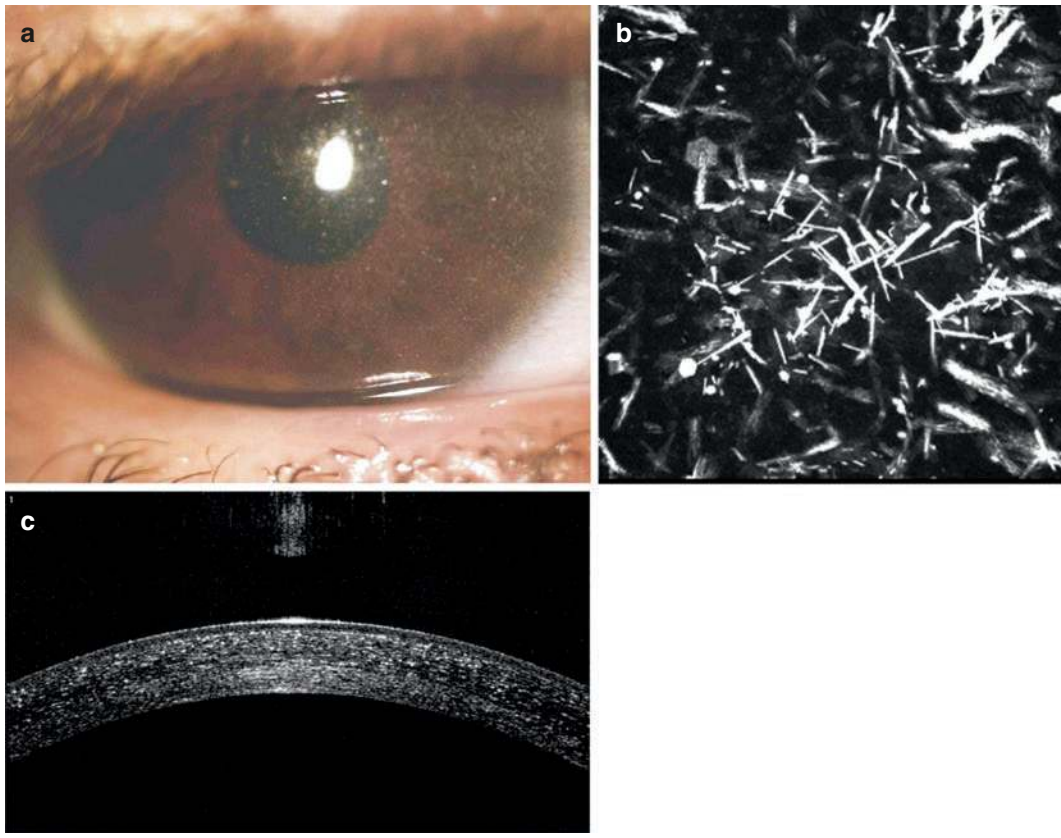

Fig. 30.4 Eye examination of cystinosis. (**a**) Slit-lamp photography of corneal cystine crystals. Corneal crystals typically appear as needle-shaped and highly reflective. (**b**) *In vivo* confocal microscopy images of crystals detected in the cornea stroma. thickness of the cornea, improving the longitudinal monitoring of the patients (Fig. 30.4b). The prevalence of anterior segment complications increases with age [108].

Growth Impairment

Growth retardation is severe in untreated cystinosis compared to other patients with renal failure [96, 109]. In historical cohorts of patients not treated with cysteamine, only very few patients attained an adult height >150 cm [110]. The causes of growth retardation are multi-factorial and encompass poor nutrition, metabolic disturbances due to renal Fanconi syndrome, rickets, renal function impairment and possibly a direct effect of cystinosis on the bone formation.

Significantly improved linear growth is associated with early use of cysteamine [12, 35, 111]. However, cysteamine does not induce catch-up growth in children who are already growth retarded [111, 112]. Growth hormone treatment is indicated in patients in whom adequate feeding, good metabolic control and cysteamine treatment fail to normalize growth even if renal function is still not severely compromised [108]. Most of the catch-up growth occurs during the first 3 years of treatment [108]. Long-term GH treatment improves final height to a range of −2.6 to −2 SD in the majority of patients [112, 113].

Endocrine Impairment

The continuing accumulation of cystine crystals leads to the impairment of endocrine organs. Cystine accumulation in thyroid follicular cells causes fibrosis, atrophy and dysfunction of the thyroid gland.

Thyroid impairment starts with a compensated hypothyroidism defined by a high TSH but a free T4 still in the normal range, followed by a confirmed hypothyroidism with clinical symptoms [114]. Hypothyroidism has been found in more than 70% of adult patients In historical cystinosis cohorts [36, 37]. Treatment requires thyroxine supplementation.

Cystine also accumulates in the bêta cells of the islets of Langerhans with massive crystal deposits in the pancreas and complete architectural disorganisation. Glucose intolerance is characterized by a slow, progressive loss of insulin secretion and C-peptide production [115]. Hypothyroidism and diabetes are less frequent and delayed when cysteamine has been administered early [36, 37, 107].

While puberty generally proceeds normally in females, it is delayed in males, who may show primary hypogonadism and do not always complete pubertal development [116]. Testosterone treatment allows puberty but does not prevent infertility. Azoospermia is present in almost all males with infantile cytinosis, even in those treated with cysteamine started from early age and maintaining normal hormonal tests, and is caused by obstruction at the level of epididymis [117, 118]. Testicular fibrosis without germinal dysplasia and with sufficient spermatogenesis is observed [117]. One successful conception induced by a cystinosis male has been reported through assisted reproductive technology [13]. Several females with cystinosis have given birth [119, 120].

Central Nervous System and Muscle Impairment

Although rare, central nervous system complications have been described in adults with cystinosis [107, 121–124]. In these patients, the occurrence of central neurological complications did not correlate with other extra-renal complications of cystinosis, but their frequency correlated with patient age in untreated patients. Cystine is increased in all parts of the brain, especially in basal ganglia and in the arterial walls.

Two forms were observed: a cystinosis encephalopathy [121, 124, 125] and stroke-like episodes. Clinical encephalopathy often started with cerebellar signs and/or motor difficulties, mainly of the lower limbs. Decrease of oral expression was also characteristic [121, 124, 125]. Motor coordination difficulties and muscular hypotonia were initially recognized and then

corroborated with more recent studies of motor performance [126–128]. The other form of central nervous system complications resembled stroke-like episodes with coma and hemiplegia or milder symptoms. These symptoms may still be observed in adult patients, in particular with poor adherence to treatment [129]. Idiopathic intracranial hypertension has also been described, associated with headaches, or without clinical manifestation, and might be revealed during a routine ophthalmic examination [121, 124, 130].

By computed tomography (CT) scan or magnetic resonance imaging (MRI), cortical atrophy is observed in all patients with central nervous system symptoms [121, 124]. Cerebral atrophy is also reported in patients without gross central nervous system clinical abnormalities [129, 131] and in patients with minor alterations in cognitive performance, particularly those with impairment of visual memory [132]. Gahl et al. observed a 22% incidence of cerebral calcifications in a large retrospective cohort of cystinosis patients, but this was not confirmed in a more recent cohort [129, 133].

Neuro-imaging studies by MRI showed selective changes in cerebral white matter early during the development [134]. Children with cystinosis evidenced diminutions in mean fractional anisotropy and corresponding elevation in mean diffusivity in component areas of the dorsal visual pathway. In adults, a neuro-imaging study showed a significant grey matter decrease in the middle frontal gyrus compared with healthy controls and a significant negative correlation between the cystine blood level and rest cerebral blood flow was observed in the right superior frontal gyrus, a region associated with executive function [129].

Cystine also accumulates in muscular tissue and distal myopathy is found in 50–70% of patients in historical cohorts. Hand muscles are mostly initially affected (Fig. 30.5) [36, 37, 133]. In addition Vester et al. demonstrated electrophysiological signs of myopathy in patients with cystinosis without obvious weakness [135]. This distal myopathy also results in an extra-parenchymal pattern of restrictive lung disease with inspiratory and expiratory dysfunction in adults who have not received long-term cystine depletion [136]. Gahl et al. have shown that pulmonary dysfunction decreased in frequency and severity with time on cysteamine therapy, but very few patients had been treated for more than 20 years [133]. Dysphagia and swallowing difficulties for solid food appear to develop with age in nearly all patients with cystinosis [137, 138]. In a historical cohort severity increased with the number of years without cysteamine therapy. Swallowing dysfunction in cystinosis correlates with the presence of muscle atrophy and presents a risk of fatal aspiration or aspiration pneumonia.

Fig. 30.5 Hand muscle atrophy in a 18-year-old cystinosis patient

Intelligence and School Performance

Clinical studies have shown that patients have generally normal intelligence but may have mild neurocognitive abnormalities [127, 128, 139], with specific impairments in the processing of visual information. Relative weakness was found in visual motor, visual spatial and visual memory skills, and may be associated with academic difficulties, primarily in arithmetic. A fine-motor coordination deficit in children and adolescents with cystinosis has also been documented [126].

Gastro-intestinal Disease

Cystine excessively accumulates in the stomach and in the intestine of cystinosis patients [140].

However, nausea and vomiting are mostly caused by cysteamine treatment due to increased gastric acid secretion [141].

Hepatosplenic complications have become rare with the routine use of cysteamine [36, 37]. Liver enlargement with normal synthetic function was a frequent finding in historical cohorts, while hepatic fibrosis with portal hypertension and hypersplenism, eventually causing bleeding problems, and cholestatic liver disease due to nodular hyperplasia can still be observed. Electron microscopy showed extensive cystine crystal accumulation in Kŭppfer cells [110, 142, 143].

Bone Disease

Bone impairment is also described in patients with cystinosis. International recommendations concerning the management of cystinosis associated bone disease have been published in 2019 [144]. Even though the exact pathophysiology of bone impairment remains unclear, at least five distinct but complementary entities can explain it: consequences of renal Fanconi syndrome, malnutrition and copper deficiency, hormonal disturbances, myopathy, and intrinsic bone defects [144, 145]. Bone complications have a significant impact on patients' quality of life due to an increased frequency of bone pain, deformations and fractures occurring in late teenage and early adulthood [146–148].

Other Clinical Features

Diminished skin, hair and iris pigmentation is frequently observed in cystinosis patients and is explained by reduced melanin synthesis [149]. Impaired sweating has been reported in some patients. Premature skin aging is a typical feature in adult patients [150, 151].

Cystine crystals are found in the bone marrow of the patients, but has usually they have few consequences for the hematopoiesis, although some patients with bi-or pancytopenia have been reported [152, 153].

Cystinosis in Adults

Renal transplantation has transformed cystinosis from a fatal pediatric disease into a multisystem adult disease. The series of patients described in the 1990s revealed a high rate of mortality and morbidity. The main causes of death occurring before 35 years of age were aspiration, pseudobulbar palsy and uremia. The most incapacitating morbidities included blindness or severely impaired vision, and swallowing difficulties due to myopathy [122]. The long-term prognosis of patients has been substantially improved during the past two decades due to the administration of cysteamine with reduced morbidity and mortality rates [107, 133, 154], especially in patients in whom cysteamine was started before the age of 5 years [36, 37]. Transition from pediatric to adult care providers remains an area of concern due to the generally lacking expertise of internists-nephrologists with this ultra-rare disorder with historically rare survival into adulthood. Good communication between pediatric and internists-nephrologists is required to guarantee the continuation of adequate medical care [155, 156]. Management of systemic disease involvement is mandatory and requires a multi-disciplinary team.

Late Onset and Ocular Forms of Cystinosis

Less severe clinical forms of cystinosis account for less than 5% of all patients. Patients with the nephropathic late-onset form (MIM #219900) manifest with a spectrum of symptoms, varying from a milder proximal tubulopathy to apparent nephrotic syndrome, focal segmental histological lesions and generally have a slower rate of renal disease progression [2, 39, 41, 157, 158]. Cystine crystals accumulate also in the cornea and are diagnostic. In terms of the age at presentation there is probably a continuum between the infantile and the late-onset forms; however, most of the described patients were older than 10 years. Extra-renal organs may also be affected in these patients and progression towards end stage kidney disease may also occur.

Ocular non-nephropathic cystinosis (MIM #219750) affects the cornea with cystine crystal deposits causing photophobia. The kidneys, retina and other organs are clinically spared in these patients, but they do have elevated cystine leukocyte content and cystine crystals in bone marrow [23, 159]. The co-existence of the ocular form with late-onset nephropathy in the same family has been reported, warranting monitoring of kidney function in patients with ocular cystinosis [39].

Diagnosis

The diagnosis of cystinosis has to be suspected in all infants and children presenting with renal Fanconi syndrome. Other inherited and acquired forms of Fanconi syndrome should be excluded. Urine dipstick usually shows low specific gravity, overt glucosuria and mild albuminuria. Serum creatinine is generally normal in young children, unless patients are dehydrated [2].

The diagnosis is based on the measurement of elevated white blood cell (WBC) cystine levels. The isolation of polymorphonuclear (PMN) leukocytes is recommended for WBC cystine determination because cystine preferentially accumulates in this type of blood cells and not in the lymphocytes [160, 161]. It is important at a younger age when lymphocytes are the predominant cells type (up to about 60% of WBC) until the age of 5–7 years when neutrophils predominate. As leukocyte isolation and cystine measurement (by either high performance liquid chromatography or tandem mass spectrometry) require specific expertise, this analysis should only be performed in specifically certified laboratories. Cystine values in healthy individuals, heterozygous subjects, patients at diagnosis and under cysteamine therapy are provided in Table 30.1. The detection of corneal cystine crystals is pathognomonic for the diagnosis in patients above the age of 1.5 years. Molecular analysis of the *CTNS* gene should be performed for confirming the diagnosis and genetic counselling of the families [162]. Including cystinosis in the list of diseases to be detected via neonatal screening programs using next generation sequencing (NGS) in on the research agenda in many countries. The feasibility of this approach and the benefit for the patients' prognosis has been demonstrated [163, 164] (Fig. 30.6).

Table 30.1 Reference values for intracellular cystine

Healthy subjects	
PMN leukocytes	0.04–0.16 nmol cystine/mg protein [a]
Mixed Leukocytes	0.05–0.17 nmol cystine/mg protein [a]
Fibroblasts	0.0–0.23 nmol cystine/mg protein [a]
Patients at diagnosis	
PMN leukocytes	>2 nmol cystine/mg protein
Heterozygotes	
PMN leukocytes	0.14–0.57 nmol cystine/mg protein
Patients under cysteamine therapy	
PMN leukocytes	<1 nmol cystine/mg protein

[a]Values are provided by Laboratory of Genetic and Metabolic diseases, Radboud University Nijmegen Medical Centre, The Netherlands and presented as Percentile 5 and 95

Cystine is frequently expressed as nmol ½ cystine per mg protein. Conversion factor ½ cystine/mg protein = 2× cystine/mg protein

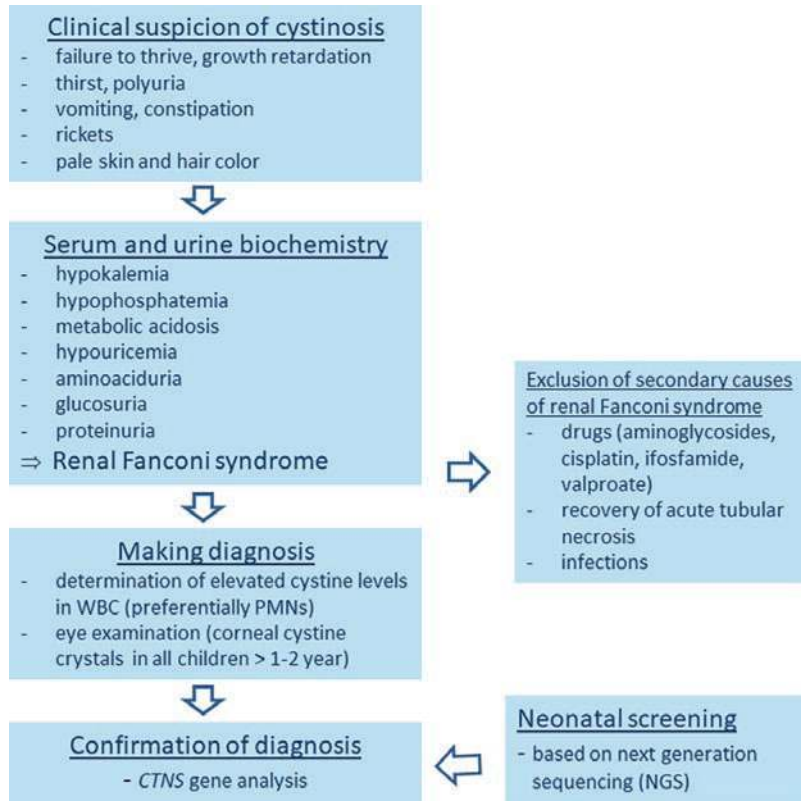

Fig. 30.6 Proposed diagnosis algorithm for cystinosis. Other genetic, metabolic and secondary causes of renal Fanconi syndrome should be excluded (see Chap. 32 for differential diagnosis of renal Fanconi syndrome)

Treatment

Treatment of cystinosis includes adequate feeding, the symptomatic replacement of substances lost into urine due to renal Fanconi syndrome, hormone replacement therapy and specific cystine lowering therapy with cysteamine. Kidney replacement therapy in cystinosis patients reaching ESKD is not different compared with other underlying diseases and is beyond the scope of this chapter. Both hemodialysis and peritoneal dialysis can be successfully applied.

Feeding Recommendations

Early gastric tube placement should be considered in all children who have poor appetite or frequent vomiting [165]. Gastric tubes also facilitate administration of oral medications and fluid. Patients with frequent vomiting and gastroesophageal reflux may respond to proton pump inhibitor therapy [166]. Overall, children should receive at least 100% of the recommended dietary allowance (RDA) for their age; however, no current evidence indicates that any higher caloric intake is useful. The composition of the diet should be balanced and should include salt and fluid supplementation.

Symptomatic Therapy of Renal Fanconi Syndrome

Patients with cystinosis should have free access to water and toilet privilege, because of pronounced polyuria and polydipsia. Prolonged exposure to heat and sun should be avoided because to photophobia, and the risk of dehydration and heat stroke due to impaired sweating.

Symptomatic therapy aims to maintain fluid and electrolyte balance, to prevent rickets and to

Table 30.2 Symptomatic therapy of renal Fanconi syndrome in cystinosis

Drugs [a]	Doses
Sodium potassium citrate	
Suspension (Na 50 g = 1.2 mmol/mL, K 55 g = 1.1 mmol/mL, Citrate 33.5 g = 2.3 mmol/mL, sir Simplex ad 500 mL)	2–10 mmol K/kg/day, divided in 4 doses
Potassium citrate	
Powder (100 mg: K 37 mg = 1 mmol, Citric Acid 62 mg = 0.3 mmol)	2–10 mmol K/kg/day, divided in 4 doses
Sodium bicarbonate	
Suspension 8.4% (Na 1 mmol/mL, bicarbonate 1 mmol/mL)	2–15 mmol/kg/day, divided in 4 doses
Powder (100 mg: Na 27 mg = 1.2 mmol, bicarbonate 73 mg = 1.2 mmol)	
Potasium phosphate	
Suspension (K dihydrophosphate/K_2 hydrophosphate) 7.5 g, aqua ad 100 mL (K 39 mg = 1 mmol/ml, phosphate 18 mg = 0.6 mmol/mL	0.6–2 mmol phosphate/kg/day, divided in 4 doses
Powder (100 mg: K 52 mg = 1.3 mmol, phosphate 23 mg = 0.6 mmol)	
L-carnitine	
Suspension 100 mg/mL	20–30 mg/kg/day, divided in 3 doses
Tablets 330 mg	
Indomethacin	
Suspension 5 mg/mL	0.5–3 mg/kg/day, divided in 2–3 doses
Vitamin D	
1 alpha-hydroxycholecalciferol	0.5–2 μg/day in one dose

improve growth. An overview of frequently prescribed drugs is shown in Table 30.2. Excessive administration of phosphate, 1,25-dihydroxycholecalciferol and bicarbonate is not indicated as it may aggravate nephrocalcinosis and stimulate renal stone formation [93]. A decrease of the renal function requires adaptation of the doses.

The aim of symptomatic therapy is to maintain serum potassium levels >3 mmol/L, serum bicarbonate level 22–25 mmol/L, serum phosphate level 0.8–1.6 mmol/L with normal for age levels of alkaline phosphatases. The administration of high doses of phosphate and vitamin D can increase nephrocalcinosis. Blood for electrolyte measurements should preferentially be drawn before the next dose of electrolyte supplements as their levels fluctuate substantially during 24 h. Carnitine replacement normalizes plasma and muscular carnitine levels; however, it is not established whether carnitine administration results in improved muscular performance [167, 168]. The recommended dose of 50 mg/kg causes changes in plasma acetylcarnitine and several short and medium-chain acylcarnitines indicating oversupplementation [169]. In patients with muscular complaints lower doses of carnitine (20–30 mg/kg) might be considered, but no clinical evidence supports carnitine supplementation in all patients.

Maintaining fluid and electrolyte balance in young patients can be challenging and can be improved by the administration of indomethacin [170]. Indomethacin is a non-selective inhibitor of cyclooxygenase (Cox). The Cox-1 and Cox-2 metabolites have a direct effect on salt and water transport along the nephron. Indomethacin increases NaCl reabsorption in the medullary ascending limb and in the collecting duct and augments the antidiuretic effect of the antidiuretic hormone. These effects compensate for the proximal tubular losses [170].

The inhibition of renin-angiotensin-aldosterone system (RAAS) decreases albuminuria [171] and might improve renal function survival [112]; however, this class of drugs should be used with caution, because of the risk of hypotension and renal function decline in patients having extracellular volume and salt depletion. Concomitant administration of RAAS inhibitors and indomethacin is contra-indicated to avoid acute kidney injury. Of note, in a large European cohort of cystinosis patients no beneficial effect of RAAS inhibitors on kidney function survival could be demonstrated [35]. Long-term administration of indomethacin didn't have a detrimental effect on the kidney function [35].

Hormone Replacement Therapy

Treatment with recombinant GH improves growth in children with cystinosis, allowing them

to catch-up and to maintain normal growth velocity [13]. Hence, GH therapy should be considered in children with cystinosis and subnormal growth rates even in the presence of a still normal glomerular filtration rate [109]. Levothyroxine is indicated in patients with hypothyroidism, as is insulin in case of diabetes. Testosterone supplementation should be considered in male patients with hypogonadism.

Specific Treatment with Cysteamine

Cysteamine, first introduced for the treatment of cystinosis in 1976 [172] and approved for clinical use in the 1990s, is still the only available treatment that efficiently decreases lysosomal cystine accumulation [173]. Inside lysosomes the drug reacts with cystine and breaks it into cysteine and cysteamine-cysteine mixed disulfide that can exit the lysosome via transporters other than the defective cystinosin (Fig. 30.7). Cysteamine therapy has fundamentally transformed the prognosis of the disease. In patients born between 1970 and 2000, early initiation of cysteamine delayed end stage renal disease by ~6 to 10 years [35, 36, 96, 112]. In well-treated patients in whom cysteamine was administered before the age of 2 years, renal Fanconi syndrome could be attenuated and renal function remained preserved until young adult age [36, 112, 174]. Cysteamine treatment has beneficial effects also on extra-renal symp-

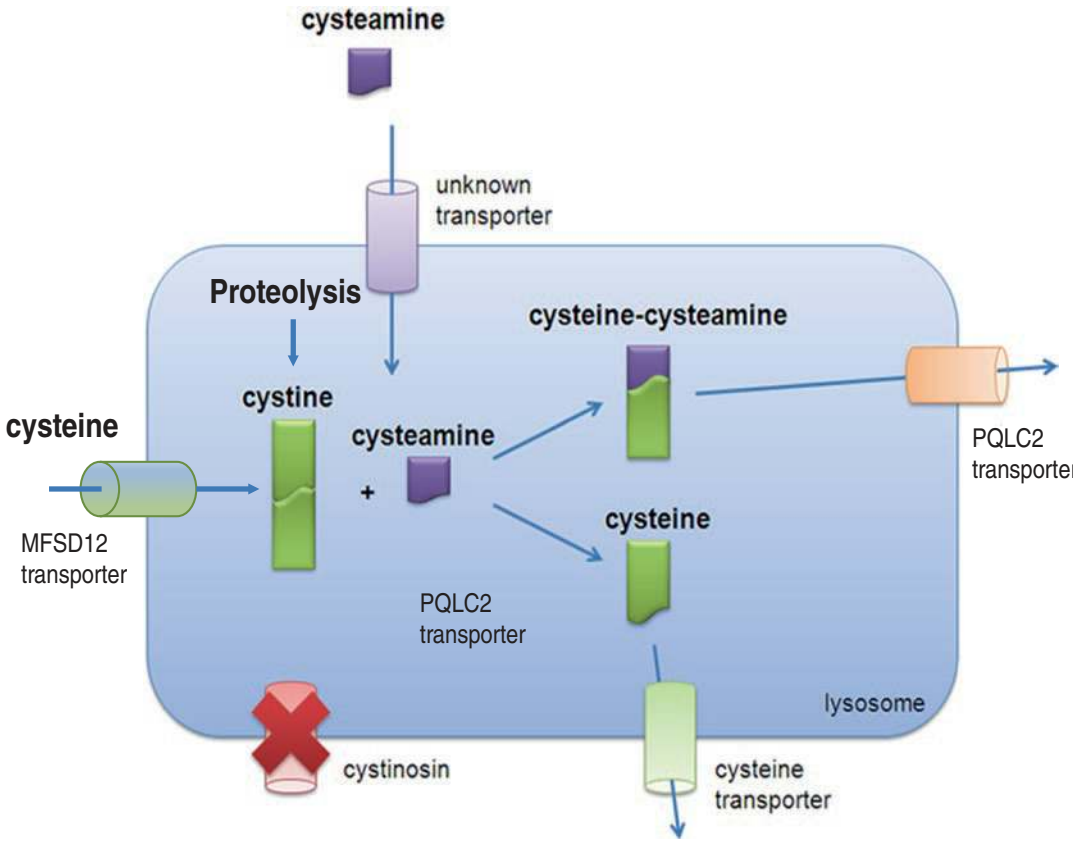

Fig. 30.7 Schematic drawing of cysteamine action in cystinotic cells. Cysteamine can enter the lysosome trough an unknown transporter. Once inside the lysosome it breaks the disulfide bond in cystine, leading to the formation of cysteine and a cysteamine-cysteine disulfide which can leave the lysosome trough the cysteine and PQLC2 transporters respectively. Lysosomal cystine is formed by the proteolytic degradation of proteins and by oxidation of cytosolic cysteine which enters lysosomes via MFSD12 transporter [51] (Used with permission of Elsevier from Besouw et al. [173])

toms of cystinosis with decreased frequencies of hypothyroidism, diabetes, myopathy, pulmonary dysfunction, swallowing difficulties, and death [36, 133, 154, 155, 175, 176]. The drug also prevents the development of visual loss due to retinopathy [105, 177].

The most widely used cysteamine salt, cysteamine bitartrate, is available as an immediate release (Cystagon®) and as a delayed release (Procysbi®) preparations. Cystagon® has to be administered every 6 h including the night period [178]. Procysbi® is a micro-spheronized enteric-coated cysteamine bitartrate with an improved pharmacokinetic profile, allowing twice daily dosing. Non-inferiority of the effect of the delayed release formulation compared to immediate-release cysteamine on WBC cystine levels has been demonstrated [179, 180]. The recommended daily dose of cysteamine is 1.3 g/m^2 of cysteamine base (or 2 g/day in patients older than 12 years). The maximum cysteamine dose should not exceed 1.95 g/m^2/day. To avoid the development of side-effects cysteamine has to be started at ~1/6 of the target dose and gradually increased over 6–8 weeks. Patients using delayed release formulation show better adherence to treatment compared with immediate release preparation ([181], see below)

WBC cystine levels are used as a biomarker to monitor the effectiveness of cystine depletion; the upper limit of asymptomatic heterozygous carries (<1 nmol ½ cystine/mg protein) is usually considered as an indication for adequate cysteamine dosing (Table 30.1). WBC cystine levels have to be measured 6 h after last dose of immediate-release cysteamine or ideally 30 min after last dose for delayed-release cysteamine, however, a pre-dose sampling is frequently performed in routine practice.

The most commonly reported side effects comprise gastro-intestinal complaints, for which the concomitant use of proton pump inhibitors is advised [141, 166] although reducing the acidity of the stomach will influence the pharmacokinetics of Procysbi®. Gastrointestinal tolerability may be improved with the slow-release cysteamine formulation [179].

Cysteamine causes disagreeable breath and sweat odor due to the conversion of cysteamine to methanethiol and dimethylsulphide [182]. This side effect may lead to significant psychosocial issues, which sometimes limit the long-term compliance with the medication especially during adolescence [181, 183].

Three cystinosis patients with lupus nephritis while receiving cysteamine were reported [173]. Eight cystinosis patients, mostly treated with high cysteamine doses, developed skin adverse events, consisting of vascular proliferative lesions on the stretchable skin surfaces, striae and severe bone and muscular pains (Fig. 30.8a, b) [184]. An abnormal morphology of dermal collagen fibers was found on EM in these patients and suggested to be caused by copper deficiency due to urinary losses that could inhibit collagen cross-linking (Fig. 30.8b) [185].

Animal studies showed an increased risk for intrauterine death, intrauterine growth retardation and fetal malformations (especially cleft palate and kyphosis) in pregnant rats given high cysteamine doses of 100 and 150 mg/kg [186]. While human teratogenicity information is lacking, FDA classified cysteamine as a category C drug based on the animal data. It is advised in female cystinosis patients to stop cysteamine administration at the diagnosis of pregnancy until the baby is born, although one normal pregnancy in a cystinosis female receiving 900 mg cysteamine per day has been reported [187].

Cysteamine Eye Drops

Corneal cystine accumulation is resistant to oral cysteamine and must be treated by topical administration of cysteamine eye drops, which dissolve corneal cystine crystals and alleviate symptoms at all ages [105, 188]. Cysteamine collyrium containing 0.55% cysteamine base needs to be administered six to ten times daily [188]. A commercial 0.44% cysteamine ophthalmic solution (Cystaran®, Sigma-Tau Pharmaceuticals, Gaithersburg, MD, USA) has been approved for clinical use in the US and should be administered 6–12 times per day. In this formulation, cyste-

Fig. 30.8 Cutaneous signs of cysteamine toxicity. (**a**) Upper row: Bruise-like lesion at the elbow at early stage (left) and in regression (after the decrease of cysteamine dose) (right). Lower row: the lesion above lumbar vertebrae in regression, the skin is becoming loose and wrinkly (left); skin striae at the stretchable surface of the knee (right). (**b**) Skin biopsy from the elbow lesion. Left: light microscopy, anti-CD34 immuno-staining, original magnification ×20. Plump CD34-positive endothelial cells line numerous vascular structures, some of them completely developed and others with immature features. The CD34− negative sweat gland epithelium serves as negative control. Right: electron microscopy. Variability of collegan fibre caliber: focal diameter increase (arrows) (Used with permission of Elsevier from Besouw et al. [184])

amine oxidises at room temperature, necessitating cold storage. Another topical 0.55% cysteamine gel formulation (Cystadrops® Recordati Rare Diseases, Puteaux, France) for less frequent (three to four times) daily administration has been proven to be safe, efficacious and tolerable [189, 190]. The chemical stability of the formulation was improved, allowing the 0.55% cysteamine drops to be kept at room temperature for up to 7 days after opening, although refrigeration is still required for long-term storage. Eye drop administration can cause eye burning due to the low pH of the solution, especially in patients with corneal erosions. Using hydrating eye drops prior to cysteamine might improve discomfort related to cysteamine eye drop administration.

Prognosis and Future Treatments

The overall prognosis in patients with cystinosis has dramatically improved during the past decades due to the availability of renal replacement therapy and wide use of cysteamine therapy starting from the 1990s. The oldest patients with infantile cystinosis are reaching now their 50th and sometimes 60th birthday.

Although cysteamine treatment has substantially improved the prognosis of cystinosis patients, the drug offers no cure of the disease. Therefore continued efforts are undertaken to develop more definitive therapies. In a mouse model of cystinosis, allogeneic hematopoietic stem cell (HSC) transplantation significantly reduced cystine tissue content in all tested organs (by 70% in the kidney) and resulted in long-term preservation of kidney function [191, 192]. HSCs differentiate into tissue-resident macrophages forming tunneling nanotubes transferring cystinosin-bearing lysosomes into CTNS-deficient cells, even crossing tubular basement membrane. More recently, autologous HSC transplantation after *ex vivo* lentiviral *CTNS* gene transduction and subsequent injection has proven to be efficient in cystinosis mice [193]. Allogenic full HLA-matched HSC transplantation in one cystinosis patient resulted a temporary stabilization of the kidney function and demonstrated *de novo* expression of wild type cystinosin in different tissues of the recipient. The procedure, however, was complicated by therapy-resistant graft-versus-host disease with fatal outcome [194]. A clinical trial evaluating the safety and efficiency of autologous HSC transplantation after *ex vivo* gene therapy in humans is ongoing (https://clinicaltrials.gov/ct2/show/NCT03897361).

Novel pharmacological therapies targeting cystine accumulation and/or other altered pathways in cystinosis cells are currently at different stages of development and have been reviewed elsewehere [68]. It can be expected that during the next decade early diagnosis of cystinosis in pre-symptomatic patients via neonatal screening based on NGS and administration of novel thera-

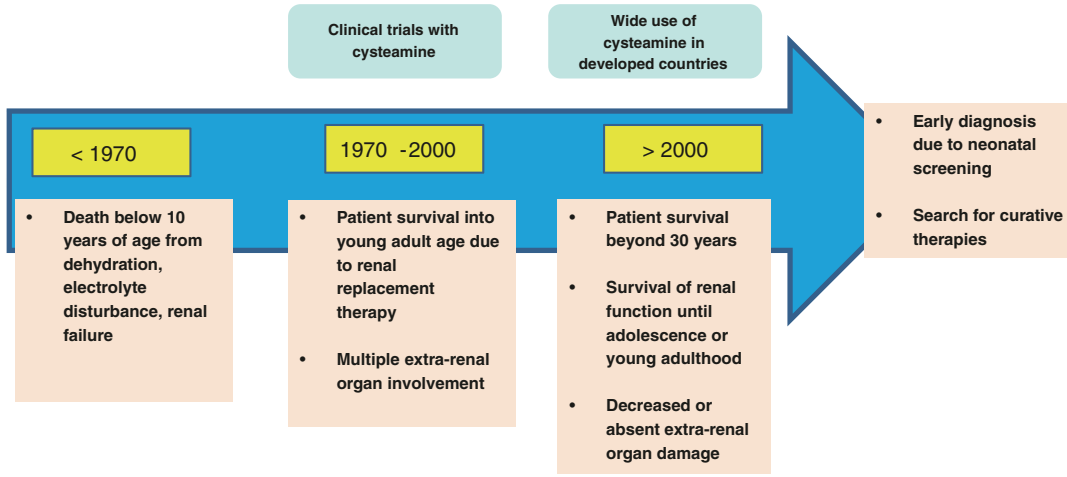

Fig. 30.9 Improved prognosis of nephropathic cystinosis. The overall prognosis of patients with cystinosis has substantially improved by the availability of renal replacement therapy allowing patients to survive into young adult age, and by wide use of cysteamine treatment prolonging renal function survival and protecting extra-renal organs. Early diagnosis in pre-symptomatic patients and the administration of novel therapies will further improve patients' survival and quality of life

pies will further improve patients survival and quality of life (Fig. 30.9).

The Kidney in Sickle Cell Disease

31

Jeffrey Lebensburger and Cristin Kaspar

Sickle cell disease (SCD) is the most common inherited red blood cell disorder in the United States, impacting approximately 100,000 Americans and 1 in 365 African American births [1]. SCD is most prevalent in sub-Saharan Africa due to its protective inheritance against malaria. About 1000 children are born in Africa each day with SCD [2]. Some Hispanic and Indian populations have also been identified with up to 40% of residents having at least one sickle gene mutation.

The sickle cell mutation causes a hydrophobic valine to replace a hydrophilic glutamic acid in the sixth amino acid position of the β-globin protein. This mutation allows polymerization of hemoglobin S in the deoxyhemoglobin state. Two inherited β-globin sickle cell mutations result in the diagnosis of hemoglobin SS (HbSS). Different mutations in one of the β-globin subunits cause other forms of SCD. These include mutations that lead to no beta globin synthesis (β0 thalassemia) or minimal globin synthesis (β+ thalassemia) as well as other mutations, including hemoglobin C (HbC). The most prevalent, severe forms of SCD are HbSS and hemoglobin Sβ0 (HbSβ0) thalassemia; these genotypes are referred to as sickle cell anemia (SCA) and occur in about 70% of SCD patients. Other genotypes usually have less severe disease, and include hemoglobin Sβ+ (HbSβ+) thalassemia and hemoglobin SC (HbSC).

Sickle cell trait, which occurs in 1 in 13 African Americans, has been studied for its association with progressive kidney disease in adults, hematuria, renal papillary necrosis, and pyelonephritis during pregnancy. Sickle cell trait is associated with the rare cancer, renal medullary carcinoma. Patients with sickle cell trait do not have a significant pediatric clinical disease course due to the protective effect of one normal β-globin gene. Therefore, patients with sickle cell trait do not have SCD and, aside from counseling, do not receive follow-up care by a pediatric hematologist.

Hyposthenuria, Renal Papillary Necrosis, and Nocturnal Enuresis

Hyposthenuria

Pathophysiology: The development of hyposthenuria and renal papillary necrosis begin with sickling of the red blood cells in the vasa recta, leading to marked vascular changes. Necropsy studies have demonstrated almost complete destruction of the vasa recta and medullary

capillaries in patients with SCA as compared to a reduced number of vasa recta in patients with sickle cell trait and HbSC disease [3]. These findings may be related to the impact of the hyperosmolar environment of the kidney on red cell rheology. In vitro models have demonstrated that sickle red blood cells exposed to even mildly hypertonic environments (sodium levels of 141 mEq/L) experience a delay in transit time, an increase in red cell rigidity and an increase in red cell adherence to vascular walls [4]. The renal medulla is an extremely hypertonic, hyperosmotic environment (800–1200 mOsm/kg) relative to the milder in vitro environments studied, which likely contributes to the more pronounced pathophysiologic changes seen in vivo. In addition, the renal medulla is a relatively hypoxic environment. Sickle red blood cells are stable in normoxia, but hemoglobin S begins to polymerize during the hypoxic state. Finally, acidic environments promote sickling of RBCs. Therefore, the combination of hypertonicity, hypoxia, and the acidotic environment in the renal medulla causes sickling of red blood cells within the vasa recta, with subsequent ischemic and reperfusion injury.

Epidemiology: A diminished urine concentrating ability is a well-established complication in patients with SCD [5–8]. The prevalence of hyposthenuria increases with disease severity (SCA > HbSC disease > sickle cell trait) [9, 10]. Urine concentration defects are first noted in infants and toddlers with SCA. In the baseline analysis of the BABY HUG study of children with SCA, only 30% of infants concentrated their urine >500 mOsm/kg, and only 13% of infants concentrated their urine >2 times their serum osmolality [11]. Of note, infants whose urine osmolality was >500 mOsm/kg after fluid deprivation had higher mean fetal hemoglobin concentrations, and the urine osmolality correlated with glomerular filtration rate (GFR).

Treatment: The BABY HUG study treated infants with 24 months of hydroxyurea, which increases fetal hemoglobin, versus placebo. While treatment with hydroxyurea for 24 months did not affect GFR, it did result in a significantly higher mean urine osmolality (495 mOsm/kg hydroxyurea vs. 452 mOsm/kg placebo) and a higher percentage of infants with a urine osmolality >500 mOsm/kg after fluid deprivation [12]. Murine models also suggest that a higher percentage of fetal hemoglobin and higher hemoglobin levels are associated with less severe concentrating defects [13]. Thus, hydroxyurea may decrease the urine concentrating defect early in life in SCA patients. Chronic transfusion therapy may also improve hyposthenuria [5, 6, 14]. However, preventing hyposthenuria is not an indication for initiating chronic transfusion; it is restricted to patients with increased risk of a poor central nervous system outcome or a very severe clinical course.

Interventions to prevent hyposthenuria should be initiated early in life. Red blood cell transfusions before the age of 10 years are effective in reversing hyposthenuria, but this reversibility was lost when initiated after the first decade [3, 5]. In a study of HbSC patients with a mean age of 11 years, hydroxyurea treatment for 12 months did not improve urinary concentrating ability [15]. This contrasts with the BABY HUG study and suggests loss of reversibility in older children.

Renal Papillary Necrosis

Another complication resulting from destruction of the renal vasculature is renal papillary necrosis. The pathophysiology is likely due to the renal medullary environment that promotes a higher level of sickling of red blood cells. It is believed that occlusion of the blood supply causes ischemia-induced necrosis of the renal medulla and papillae. This necrosis initiates subclinical and clinical hematuria. Pathology studies in SCD patients identified papillary necrosis in about one-third, most often located in the tips of the papillae [16]. Hematuria is secondary to changes in the permeability of the vasculature that allows red cell leakage into the collecting system.

Epidemiology: In radiologic studies, 30–75% of SCD patients have evidence of papillary necrosis [17–19]. Studies in Africa suggest 2% of

patients will develop symptomatic renal papillary necrosis [20]. Risk factors for renal papillary necrosis are female sex, older age, more severe anemia and hypertension. Renal papillary necrosis is more common in the left kidney.

Diagnosis: While renal papillary necrosis is a common etiology of hematuria in pediatric patients with SCD, a standard diagnostic workup for hematuria should be performed on initial presentation. Since hemoglobinuria may cause a positive urine dipstick result, microscopic evaluation of the urine is necessary to confirm hematuria. SCD patients should also have a complete blood count (CBC) and creatinine to identify acute changes in hemoglobin and kidney function. Patients should be queried regarding other acute symptoms of SCD, prior history of hematuria, and medication use.

Several diagnostic imaging techniques can be considered in the initial evaluation of hematuria in a SCD patient. Ultrasound, which does not require contrast and is readily available, will identify hydronephrosis, and may provide evidence for a kidney stone as a cause of hematuria. A renal mass suggesting renal medullary carcinoma is more often identified in patients with sickle cell trait than SCA [21]. Findings on ultrasound suggestive of renal papillary necrosis include filling defects and necrosed papillae in cavities [22]. However, ultrasound is not the optimal imaging for identifying renal papillary necrosis. Most patients require a contrast evaluation, including intravenous urography, retrograde pyelography, or CT with contrast [23]. Intravenous urography and retrograde pyelography have less radiation exposure than CT [23]. Findings on a contrast study will often demonstrate filling defects of the renal calyx, including deformities of the renal papillae (hooks, spurs) and a blunted calyx [22].

Treatment: Some cases of hematuria due to papillary necrosis will be mild, painless, and self-resolve; other cases may require therapy. There are no guidelines addressing the efficacy of supportive care or when patients should be admitted to the hospital for care. Treatment may include intravenous (IV) fluids, analgesia, bedrest, alkalization, and low-dose aminocaproic acid [24, 25]. Patients who develop severe anemia require transfusion. Surgical interventions such as papillary tamponade, shunt placement, or nephrectomy are rarely indicated unless a pediatric patient is experiencing severe, persistent, life-threatening hemorrhage [16, 26].

The goal of fluid therapy is to ensure adequate hydration and to maintain high urine output. For mild cases, aggressive oral hydration as an outpatient is sufficient. For more severe cases, IV fluids can be prescribed in either outpatient day hospital settings or inpatient units. Patients can be administered fluids at maintenance to 1.5 times maintenance with or without a loop diuretic to further ensure adequate urinary output [27]. Since acidosis promotes sickling, adding base to the IV fluids to create a more alkaline environment to reduce sickling is theoretically appealing; however, there are no trials demonstrating benefit in SCD patients with papillary necrosis [28]. Bedrest may reduce the risk for dislodging of clots. Clinicians should closely monitor for the development of respiratory symptoms or fluid overload in patients receiving higher rates of IVF and/or suggested bedrest. Analgesia is used in patients with painful hematuria. If patients presenting with painless hematuria progress to painful hematuria, additional imaging may be required to evaluate new obstructive disease due to blood clots. Low dose aminocaproic acid at 20–50 mg/kg IV or po every 8 or 12 h has been used in severe cases as well as lower maintenance oral dosing [24, 25, 29]. SCD is a hypercoagulable state so close monitoring for new clot formation or ureteral obstruction should occur when using aminocaproic acid. Transfusion therapy can improve the anemia and reduce the concentration of sickle red blood cells, which should reduce sickling. In very severe cases, exchange transfusion may be used to significantly reduce the concentration of sickle cells, often to a sickle cell concentration of less than 30%. Reducing the sickle cell concentration may not treat the acute complication, but may allow more rapid recovery and prevent early recurrence of another renal injury.

Nocturnal Enuresis

Epidemiology: Primary nocturnal enuresis (PNE) is bedwetting that occurs in an individual who has never been dry at night, and is usually not associated with daytime wetting symptoms. PNE affects approximately 15% of children aged 5 years in the general population, and spontaneously remits at a rate of 15% per year [30]. The prevalence of PNE in SCD is much higher; children with SCD aged 14–17 years old were five times more likely to have PNE than controls [31–35]. Similar to the general population, PNE is more common in males, younger children and children with a positive family history of PNE [31–35]. Children with SCA and PNE are more likely to have sleep-disordered breathing [36]. In a study of 8-year-old Jamaican children, the prevalence of enuresis was 52% for boys and 38% for girls with HbSS disease, and 10% for boys and 20% for girls with HbSC disease. The prevalence of PNE in HbSS disease was significantly more common than HbSC disease or controls, but there was no significant difference between HbSC disease and controls. There was no significant difference by sex [37].

Risk Factors: PNE in HbSS disease has been attributed to hyposthenuria and polyuria. However, in a study comparing HbSS patients with and without enuresis, there was no difference in urinary concentrating ability or overnight urine volume [38]. However, the bladder capacity corrected to body surface area was lower, and the ratio of overnight urine volume divided by bladder capacity was higher in enuretic compared to non-enuretic children. A high prevalence of daytime symptoms of overactive bladder was also present in those with nocturnal enuresis and SCA [34]. These results suggest that hyposthenuria-induced polyuria may not be the primary cause of PNE in HbSS disease. In addition to urinary tract pathology, an association has been identified between sleep disordered breathing and PNE [36].

Therapy: Several pharmacological and behavioral therapies have been identified to treat patients with PNE in the general populations [39]. However, there are no controlled trials demonstrating benefit in children with SCD. One prospective study of 10 patients with SCD treated with desmopressin reported improvement in six patients [32]. Hence, the evidence for pharmacologic treatment is inadequate, and thus the focus of therapy is watchful waiting and bed-wetting alarms in some patients [40].

Albuminuria

Epidemiology: Fifty to seventy percent of adults with SCA have albuminuria in large cross-sectional studies [41–43]. Children with SCD develop albuminuria around 5–10 years of age and the prevalence increases throughout adolescence. The reported prevalence of albuminuria in cross-sectional pediatric SCA studies is 20–40% [44–46]. There is a need for longitudinal data on the natural history of the progression of kidney disease and development of end-stage kidney disease (ESKD) among pediatric patients with albuminuria as they transition into adulthood [47].

Pathology: Patients with SCA develop albuminuria due to either direct glomerular injury or impaired tubular reabsorption of albumin. In adults with SCD, glomerular complications include glomerular hypertrophy, focal segmental glomerulosclerosis, and membranoproliferative glomerulonephritis [48]. Kidney pathologic data was reported from 36 pediatric patients that underwent renal biopsy for proteinuria or low estimated GFR (eGFR) [49]. The majority had glomerular hypertrophy. In addition, the majority of the biopsies had mesangial hypercellularity and/or increased mesangial matrix. All patients in this cohort with mesangial hypercellularity, had proteinuria, including 88% with nephrotic range proteinuria. Eleven of the 36 patients had focal segmental glomerulosclerosis, six of the 11 also had global sclerosis. Five patients had membranoproliferative glomerulonephritis. On electron microscopy, more than 50% of biopsies had podocyte effacement, and a quarter had mesangial deposits. This study supports the importance of nephrology evaluation of children with SCD and significant proteinuria or decreased GFR.

Impaired tubular reabsorption of albumin may also contribute to albuminuria independent of glomerular disease in patients with SCA. Some albumin is normally filtered at the glomerulus and then reabsorbed by receptor-mediated endocytosis by megalin and cubilin in the proximal tubule [50]. However, internalization of albumin is subject to competition from many other proteins. Importantly in SCD, hemoglobin dimers can also be reabsorbed in the proximal tubule. In preclinical models, the addition of oxyhemoglobin to proximal tubule cells significantly reduced albumin uptake [51]. As SCD patients have daily variations in the amount of hemolysis consequent hemoglobinuria, it is plausible that albuminuria may vary depending on the amount of hemolysis. Studies have demonstrated that a single urine sample with albuminuria may not represent persistent albuminuria [47, 52]. While free hemoglobin or heme reuptake may lead to non-glomerular albuminuria, the uptake of free heme by the proximal tubule may induce pathologic changes and kidney disease progression, as described in the section on acute kidney injury.

Risk factors: Older age is a risk factor for albuminuria in SCD [43, 47]. Inheritance of two apolipoprotein L1 (APOL1) risk alleles, which are common in people of African descent, is associated with increased risk of albuminuria and CKD in SCD [53, 54]. Albuminuria in SCD patients with two APOL1 risk alleles begins in the first decade of life [44]. Serum hemoglobin is inversely related to risk of albuminuria [45, 55–57]. Patients with severe anemia in their second year of life are more likely to develop albuminuria earlier in life [45]. There is inconsistent data on the association of albuminuria with leukocytosis, hemolytic markers (lactate dehydrogenase), and blood pressure [46, 58–61].

Similar to diabetes, hyperfiltration is a risk factor for albuminuria in SCD. In cross-sectional studies, there are conflicting results on the association of eGFR with albuminuria [55, 62, 63]. A large, prospective, pediatric cohort evaluated the impact of hyperfiltration on progression of albuminuria; patients with hyperfiltration in the first decade of life were more likely to develop albuminuria at an earlier age [64]. Patients that developed albuminuria had a significant increase in eGFR prior to developing albuminuria while patients without albuminuria did not experience a significant rise in eGFR during the first decade of life. Adult data also suggests that hyperfiltration is associated with albuminuria [65].

Diagnosis: The National Heart, Lung, and Blood Institute (NHLBI) guidelines recommend screening for albuminuria by age 10 years, with annual screening thereafter [66]. Patients with a positive screening result should have a first morning test for albuminuria (albumin/creatinine ratio [ACR] >30 mg/g), with referral to a kidney specialist if positive. If a first morning void is not available or feasible, scheduling patients for an early morning appointment to obtain a second morning void may be of benefit. This second urine measurement is important as patients with SCD experience intermittent albuminuria, but may not have persistent albuminuria. About 25–50% of SCA patients with ACR <100 mg/g do not have persistent albuminuria; patients with ACR >100 mg/g are more likely to have persistent albuminuria [47, 67].

Albuminuria can begin prior to 10 years of age; therefore, some centers may begin screening for albuminuria earlier than 10 years of age [44, 64]. This is especially relevant in patients with two APOL1 risk alleles since almost 25% of these patients with SCD develop albuminuria prior to age 10 years.

The presence of severe albuminuria (ACR >300 mg/g) in SCD is less likely in pediatric patients than adults. As severe albuminuria is a rare complication in children with SCA, patients presenting with severe albuminuria require a complete diagnostic workup for proteinuria.

Treatment: The therapeutic approach in patients with SCD and albuminuria focuses on traditional modifiers of SCD and interventions to reduce hyperfiltration.

SCD Modifying Therapies: All patients with SCA should be offered hydroxyurea, a daily oral therapy, starting at 9 months of age regardless of clinical complications [66]. Therefore, patients that have progressed to albuminuria should be encouraged to begin hydroxyurea or improve adherence if nonadherence is present.

Hydroxyurea induces fetal hemoglobin, raises hemoglobin, and reduces hemolysis and inflammation. The dose of hydroxyurea may be increased to 35 mg/kg in children to allow for maximal effect without reducing the absolute neutrophil count below 1000–2000/μL [68]. Patients on hydroxyurea have reduced hospitalizations, pain events, and episodes of acute chest syndrome; this may provide downstream renoprotective effect [69]. Pediatric patients on hydroxyurea with higher fetal hemoglobin levels have a lower prevalence of albuminuria [70]. As hydroxyurea improves anemia and reduces hemolysis, biologic plausibility suggests that early use of hydroxyurea should decrease glomerular hyperperfusion and reduce free hemoglobin exposure to proximal tubule cells; however, randomized controlled data demonstrating this benefit is lacking. Longitudinal adult studies have demonstrated some benefit of hydroxyurea when started prior to the development of severe albuminuria [71].

Chronic transfusion therapy is a proven therapy to reduce progressive SCD and treat acute SCD complications. By performing chronic monthly transfusion therapy, patients are maintained with a very low sickle cell concentration, often to a lower percentage of sickle cells than patients with sickle cell trait. Chronic transfusion protocols have demonstrated a clear benefit to prevent a first or second stroke in patients at risk. The use of transfusion therapy would likely benefit pediatric patients with albuminuria or other renal complications, but using chronic transfusion for this indication has not been systematically studied for benefit or cost-effectiveness in large studies [72]. One complication of chronic transfusion is the development of iron overload. After 10–12 transfusions, many patients will be started on iron chelation, which can have nephrotoxic effects [73].

A few SCD modifying therapies have been recently approved by the Food and Drug Administration (FDA), but these approvals were not based on a renal indication. Crizanlizumab is a P-selectin inhibitor administered intravenously monthly that can prolong the time to the next pain event in patients with 2–10 pain events annually [74]. It is currently being studied for renoprotective effects (NCT04053764). Voxelotor is a daily oral medication that increases the oxygen affinity of sickle red blood cells. This increased oxygen affinity reduces sickling of red blood cells and was FDA approved for its ability to raise hemoglobin [75]. As a medication that reduces hemoglobinuria and likely reduces heme exposure in the kidneys, this therapy may have renoprotective effects and is being studied in adults with high risk for CKD (NCT04335721). Finally, L-glutamine received FDA approval for the reduction in painful events among pediatric and adult patients with two or more painful events in the last year [76]. L-glutamine may protect SCD patients by reducing oxidative stress through an increase in the availability of glutathione. Future studies will need to be performed to determine the effect of glutamine on renal endpoints.

Angiotensin Blockade: Based on the benefit of angiotensin converting enzyme inhibitors (ACEI) and angiotensin receptor blockers (ARBs) in patients with diabetes to reduce proteinuria and lower intraglomerular pressure, SCD patients with albuminuria may be started on these medications. The American Society of Hematology (ASH) Guidelines for the management of SCD includes an evidence-based review of ACEI/ARBs in patients with albuminuria [77]. Based on a low certainty in the evidence, the guideline panel decided to "suggest" the use of ACEI/ARBs for albuminuria rather than "recommend" it for albuminuria. One randomized controlled trial and several observational studies that suggested benefit were evaluated [78]. The methodologic experts and guideline panel members determined from these studies that 63% of patients who received ACEI showed improvement in albuminuria; the panel also identified that 100% of 30 patients who received ARBs had improved albuminuria at some point during the treatment [77–82]. Patients started on ACEI/ARBs should be reassessed in one week and then serially for changes in GFR and serum potassium. In addition, these medications should be held during acute illness, planned IV contrast administration, or prior to surgery or other procedures.

Endothelin Receptor Antagonist: Endothelin receptor A (ETA) is responsible for vasoconstriction, inflammation, and adhesion. Endothelin B receptor mediates nitric oxide (NO) production and vasodilation. It is likely that specific blockade of the ETA receptor could improve renal and SCD outcomes as compared to dual blockade. Murine sickle cell data showed a benefit after 10 weeks of ETA receptor blockade, as compared to a combined ETA/B antagonist, in reducing plasma ET-1 levels, urinary protein and albumin excretion and maintaining a stable GFR [83]. In adults with SCA, a phase I double blind study of ETA antagonist ambrisentan has been completed [84]. The data suggests a potential benefit for albuminuria and improved microvascular function.

Glomerular Filtration Rate

Epidemiology: Patients with SCD experience hyperfiltration early in life. Infants enrolled in a randomized trial underwent measured GFR (mGFR) at around one year of age and again at study exit 2 years later. At one year of age, participants had a normal mGFR; 2 years later, the mGFR had increased by a mean of 20 mL/min/1.73 m^2 to 146 mL/min/1.73 m^2 [69]. This increase in GFR occurs throughout early life and cross-sectional studies have identified that around 40–80% of SCD patients will develop hyperfiltration [12, 46, 58, 85]. After this early rise in GFR, pediatric patients likely experience a plateau in GFR around 6–12 years of age before they begin a decline in GFR [58, 64]. Some pediatric patients will progress to a GFR <90 mL/min/1.73 m^2; these patients should be evaluated to investigate non-SCD related causes of CKD [62, 86].

Risk Factors: Many cross-sectional studies have identified potential associations with GFR. Data is conflicting for the role of anemia, leukocytosis, blood pressure, male sex, and LDH [12, 58, 85, 87]. A few studies have explored the association of uric acid and GFR in SCD; these studies suggest that uric acid may be an early marker of risk for GFR decline [88–90]. As discussed in the albuminuria section, several studies have identified a link between hyperfiltration (elevated GFR) and albuminuria.

Treatment: Treatment approaches to prevent hyperfiltration or glomerular injury have not been fully explored. Treatment of infants with hydroxyurea for 2 years did not prevent the increase in eGFR or reduce the number of participants who developed hyperfiltration [12]. In contrast, some older participants started on hydroxyurea experience a decrease in eGFR that was associated with change in fetal hemoglobin and LDH [91]. The studies of angiotensin targeted therapies often focused on albuminuria as the primary outcome; however, some of these studies have also reported the impact of treatment on change in GFR. In a well-designed study of enalapril in adults, treatment for 2 weeks did not change the mean GFR, effective renal plasma flow, or filtration fraction [80]. Two studies using losartan therapy for 6 months or 1 year also did not identify a change in GFR while on treatment [92, 93].

One concern in clinical care and conducting research to evaluate eGFR or change in eGFR in patients with SCA is that the equations used to estimate GFR in children and adults have low precision and accuracy [12, 94–96]. In addition to the concern for the bias in a single eGFR measurement, individual patients do not demonstrate concordance between eGFR and mGFR in longitudinal studies [96]. Therefore, clinicians and researchers need to evaluate GFR changes at several time points to reduce these inaccuracies. Formulas using either cystatin C alone or cystatin C and creatinine may have the best precision and accuracy among the current formulas. A current study is attempting to develop novel eGFR equations for children and adult participants with SCA (NCT 04380610). A second concern is that after a period of hyperfiltration in early childhood, a decline in eGFR occurs. Several studies have evaluated the change in eGFR after an intervention or in the evaluation of risk factors. A rapid decline in eGFR in adults is associated with higher morbidity and mortality [97–99]. However, shorter-term longitudinal pediatric studies of patients with baseline hyperfiltration

struggle to determine whether a decline in eGFR during the study is related to an improvement in renal function back to baseline, the beginning of a progressive decline in renal function to CKD, or regression to the mean among participants with higher eGFR at one time point. Long-term pediatric research is vital to determine whether a change in eGFR represents a benefit or risk.

Progressive CKD, End-Stage Kidney Disease, and Mortality

It is important to monitor pediatric patients with SCA for progression from glomerular hypertrophy with elevated GFR to CKD with decreased GFR due to sclerosis and fibrosis [80]. CKD in SCA is an independent risk factor for early death [100]. The management of CKD in SCD is similar to other patients with CKD, including control of hypertension and proteinuria with an ACEI or ARB. Currently, there are no FDA-approved medications for the specific treatment of sickle cell nephropathy.

Renal Replacement Therapy: The average age of initiation of renal replacement therapy (RRT) in SCD patients is 40–45 years [101–103]. Patients with SCD are currently a small minority of U.S. dialysis patients, but this population is expected to grow as overall life expectancy improves [104]. A longitudinal cohort study of SCA patients published in 1991 reported that the median survival of patients requiring dialysis was a mere 4 years [105]. In a more contemporary study (2005–2009), the hazard ratio for mortality among SCD patients with ESKD was 2.8 (95% CI 2.31–3.38) compared to those without SCD as the primary cause of renal failure, and 26.3% of incident SCD ESKD patients died within the first year of dialysis [101].

SCD patients are less likely than other ESKD patients to have a functioning arteriovenous fistula at the time of hemodialysis initiation, an important quality metric tied to improved RRT survival [103]. SCD patients on RRT experience greater rates of bacteremia and sepsis, atrial flutter and fibrillation, congestive heart failure exacerbations, and major hemorrhage than other ESKD patients [103]. SCD patients on RRT have more RBC transfusions than other RRT patients. SCD patients not receiving erythropoietin stimulating agents (ESAs) have the highest transfusion burden, while those treated with ESAs and hydroxyurea have the lowest transfusion burden [103]. The 2019 ASH guidelines recommend that hydroxyurea and ESAs be used in combination to promote fetal hemoglobin production. Clinicians should use a lower hemoglobin threshold (<10 g/dL) when prescribing this combination therapy as higher hemoglobin levels, especially with higher HbS percentage, may be associated with increased SCD complications [77].

Renal Transplantation: For those with advanced CKD, the ASH evidenced-based guidelines suggests referral for renal transplant. As SCD is associated with chronic inflammation, the guidelines suggest judicious use of corticosteroids in post-transplant protocols due to the risk for vaso-occlusive pain with the increase in WBCs that accompanies steroid use [77]. Referral rates for transplantation for SCA patients are lower than other ESKD patients, even after adjusting for covariates [102]. One potential explanation for this disparity may be related to historical data reporting high rates of complication and poor graft survival in SCD patients. An analysis of the U.S. Renal Data System data from 1984–1996 showed that SCA patients and other renal transplant recipients have similar 1-year cadaveric graft survival [106]. Recipients had higher rates of 3-year graft loss (RR 1.60) and a significantly higher adjusted mortality rate at 1 year (RR 2.95) and 3 years (RR 2.82) compared to non-SCA transplant recipients [106]. However, more recent data (2000–2011 compared to 1988–1999) showed that 6-year survival among SCA recipients improved in the more recent era compared to the early era (78% versus 55.7%, $p < 0.001$) [107]. While the 6-year patient survival was still significantly lower than non-SCA recipients (HR for mortality 2.03, 95% CI 1.31–3.16), it was equal to that of black diabetic transplant recipients [107].

An additional concern that may hinder referral for renal transplantation is the perceived risk of alloimmunization if blood transfusion is required

in anemic SCD transplant recipients. It is not surprising, given the lifetime exposure to RBC transfusions, that a greater proportion of SCA renal transplant recipients had allosensitization, with panel reactive antibodies >20% [107]. One retrospective multicenter study compared the proportion of *de novo* donor specific antibodies (DSAs) and graft survival among SCD renal transplant recipients who received regular automated exchange blood transfusions (EBT) pre or post renal transplant versus those who did not receive regular EBT [108]. Goals for EBT were to maintain hemoglobin >9 g/dL, to reduce HbS to <30%, and to reduce sickling-related complications. The median number of red blood cell units transfused per year was 37 and 8 in the EBT and non-EBT group, respectively. Overall, patient survival, graft survival, and graft function were superior in those who were on EBT, and the proportion of patients who developed *de novo* DSAs was not different (20% and 21%) between the groups. In addition, the incidence of rejection was lower in those on EBT (28% vs 54%). These data, while limited by sample size, indicate that blood transfusions peri-transplant are effective, safe and lead to improved outcomes in the SCA renal transplant population.

SCA patients with advanced CKD should therefore be counseled on the shortened graft survival and increased complication rates expected after transplantation, but should not be restricted from renal transplant access. Moreover, they should receive blood transfusions as needed pre or post transplantation.

Acute Kidney Injury

Patients with SCD may be at increased risk for acute kidney injury (AKI) due to high use of nephrotoxic medications and hemolysis causing proximal tubule injury from free heme and hemoglobin exposure [51, 109]. Acute pain events are a leading cause of hospitalization in children with SCD and repeated acute pain events can progress to chronic pain. Aggressive and early pain management is important, and many centers utilize individualized pain plans for home and during hospitalizations [110]. These pain plans often include non-steroidal anti-inflammatory medications (NSAIDs) during home pain events and inpatient IV ketorolac as adjunctive therapy to opioids [111–113]. The 2014 NIH guidelines provide a moderate recommendation for the use of NSAIDs for mild to moderate pain in the absence of contraindications [110]. The 2019 ASH guidelines suggest a short course of NSAIDs in addition to opioids for acute pain management based on a low certainty of evidence [113]. The ASH guidelines remark that patients with known risk for renal toxicity should be identified as the mild potential benefit to NSAIDs for pain may not outweigh the risks associated with NSAID use. One concern with these guidelines is that pediatric patients may utilize a significant amount NSAIDs without appropriate monitoring of kidney function or fluid intake. Rarely, a single dose of ketorolac in the absence of volume depletion may precipitate irreversible renal failure [114].

In addition to acute pain events, infections may lead to use of nephrotoxic medications in SCD patients, who are increased risk for infection with pneumococcus and other encapsulated bacteria [115–117]. Patients may receive vancomycin or other nephrotoxic antibiotics for acute chest syndrome, fever, sepsis, or skin infections. It is important to consider the pros and cons of nephrotoxic medications given the potential long-term exposure and underlying risk of developing sickle cell nephropathy; monitoring of kidney function is needed when patients with SCD are at risk of AKI from nephrotoxins, volume depletion or infection.

When pediatric SCD patients are admitted for pain events or acute chest syndrome, AKI, when defined as an increase in creatinine occurs in 10–20% [118–120]. Risk factors for AKI in these studies include ketorolac exposure and an acute drop in hemoglobin, which probably reflects increased hemolysis and tubular exposure to free heme and hemoglobin. In another study using coding data, 1.4% of hospitalized SCD patients develop AKI, with risk factors including HbSS genotype, older age and greater number of total hospitalizations [121].

Adult studies of SCD patients demonstrate a higher incidence of AKI during hospitalization than described in children [122]. In a prospective study of adult SCD patients observed for a median of 5.5 years, 46% developed AKI [122]. Patients with AKI were older, had lower hemoglobin levels, higher white blood cell counts, and higher use of vancomycin. Moreover, genetic variants of heme catabolism (HMOX1) were independently associated with the development of AKI. Finally, adults with AKI were likely to develop CKD sooner, with the highest risk associated with more severe AKI.

Tubular Abnormalities and Acidification Defects

Along with defects in urinary concentrating ability (see above), SCD patients have well-described defects in other tubular functions, including urinary acidification and potassium excretion. SCA patients have an incomplete distal renal tubular acidosis as evidenced by decreased urine acidification in response to a systemic acid load [10, 123]. In one study, 42% of adult SCA patients had a metabolic acidosis [124]. Defects in acid excretion are associated with poor outcomes. In one adult study, the lowest tertile of urinary ammonia excretion increased the risk of ESKD [125]. Acidification of the urine was impaired in 52% of adults SCD patients, and was associated with older age, higher serum uric acid, increased hemolysis, lower eGFR, and lower serum bicarbonate [121]. Poor urinary ammonium excretion, as a measure of acid excretion, is associated with poor urinary concentrating ability [121].

SCA patients also have impaired potassium excretion [126]. In this study, patients had a normal renin-aldosterone axis and normal GFR, but had impaired potassium excretion, urine acidification and urinary concentrating ability, indicating that a severe distal tubular dysfunction is present in SCA patients despite preservation of glomerular function.

In one study of 24 children without decreased GFR, 75% had hyperphosphatemia, but serum calcium was normal [127]. Seventy-nine percent of participants had elevated FGF-23 levels, which is the expected physiologic response to hyperphosphatemia and would be expected to increase renal phosphate excretion. However, patients had evidence of impaired phosphate excretion, suggesting t that SCA patients have a proximal tubular resistance to FGF-23 before evidence of GFR decline.

Hypertension

A meta-analysis conducted for the 2014 NHLBI guidelines demonstrated that patients with HbSS genotype have lower diastolic and systolic blood pressures than healthy children. A large cohort study developed 90th percentile curves for children with SCD [128]. Hence, it may be appropriate to use SCD-specific blood pressure (BP) tables when evaluating BP in children with SCD.

There is an association in SCD patients between elevated BP and higher hemoglobin values [128, 129]. Hypertension in SCD patients has been associated with increased risk of acute stroke, although causality has not been established [128, 130]. Finally, data suggests that there is a direct correlation between higher blood pressure and increased mortality [128].

SCD patients have a high prevalence of masked hypertension and "white coat" hypertension in studies using 24-h ambulatory blood pressure monitoring (ABPM). Patients with SCA have only moderate concordance between in-clinic blood pressure and ABPM, with 25–33% having masked hypertension and 60% having white coat hypertension [61, 90, 131–133]. This may explain why some studies of in-clinic BP did not find a correlation between albuminuria and hypertension while there was an association when using ABPM [90, 132, 133]. Hence, since ABPM is the gold standard for measurement of BP, it is especially important to follow the American Academy of Pediatrics Guidelines and perform ABPM prior to initiation of antihypertensive treatment in SCD patients. Screening for masked hypertension may be appropriate in children with SCD and evidence of kidney disease. Patients identified with nocturnal

hypertension or abnormal nocturnal dipping may have an increased risk for more rapid annual decline in GFR, albuminuria, and silent cerebral infarcts [61, 90, 131–133].

The ASH evidence-based guidelines for the management of SCD patients recommends a lower BP goal (<130/80) than the usual goal in adults without additional co-morbidities (<140/90) [77]. This strong recommendation was based on a moderate certainty in the evidence. The guidelines did not address BP management in children, and thus there are no recommendations to have a lower BP goal in SCD patients than in healthy children. Hence, BP management in children with SCD should follow the guidelines for healthy children.

Diabetic Kidney Disease

32

Allison B. Dart

Introduction to Diabetic Kidney Disease

While diabetic nephropathy is the most common cause of end-stage kidney disease (ESKD) in adults in many countries [1, 2], it has become increasingly relevant to children and adolescents. Traditionally, the chronic kidney disease (CKD) associated with diabetes in adults has been termed diabetic nephropathy in both type 1 and type 2 subtypes. As the clinical phenotype of kidney complications associated with diabetes has broadened, the term diabetic kidney disease (DKD) is increasingly utilized. It has been defined as CKD, with diabetes being partially involved in the pathogenesis of the kidney disease. DKD in adults can include diabetic nephropathy, ischemic nephropathy, hypertensive nephrosclerosis, and non-diabetic kidney disease, with multiple entities possible in the same patient [3]. In general, the natural history of DKD is similar in adult type 1 and type 2 diabetes populations. In children, the natural history and pathology of kidney complications in the diabetes subtypes is quite different. Currently, DKD is used to describe the kidney complications in all youth with diabetes. Important differences in DKD associated with youth onset type 1 and type 2 diabetes will be outlined in each section. This chapter will outline the clinical risk factors, natural history, pathology, and treatment of DKD.

Epidemiology of Diabetes in Children

Youth onset diabetes, defined as disease onset prior to 18 years of age, is an important clinical problem in children and adolescents, with an increasing incidence of both type 1 and type 2 diabetes in the last 20 years [4, 5]. While type 1 diabetes is the most common endocrine condition in children, the proportion of children with type 2 is increasing, especially in disadvantaged populations and minority ethnic groups, including children of African, Arab, Asian, Hispanic, and Indigenous descent [6]. The increasing prevalence of obesity in children is an important cause; however, most important are the social determinants of health such as poverty, colonization and systemic racism that are driving the increased risk of chronic disease in disadvantaged populations [7, 8].

The unadjusted estimated incidence of type 1 diabetes and type 2 diabetes in the United States (US) between 2002–2003 and 2011–2012 increased annually by 1.4% and 7.1%, respectively [9]. Overall, 87% of youth with diabetes in North America have type 1 diabetes [10], but type 2 diabetes accounts for up to 50% of cases in some clinical settings [11]. The incidence of type 1 diabetes is now 1–3 per 100,000 per year in South America, China and other Asian countries; 10–20 per 100,000 in South European countries and the US; and 30–60 per 100,000 in Scandinavia [12, 13]. In North America, the prevalence of type 2 diabetes is 12.5 cases per 100,000 and the prevalence of diabetes in youth overall is now up to 0.8% [14, 15].

Clinical Risk Factors for Diabetic Kidney Disease

The most well-characterized and clinically important risk factors for DKD are glycemic control and hypertension. Additional risk factors include hyperlipidemia, smoking, duration of diabetes, and post-pubertal status. More common in youth with type 2 diabetes are risk factors for non-diabetic kidney disease, such as in-utero exposure to diabetes and obesity, which affect nephron endowment, and an increased risk of immune-mediated kidney disease, such as IgA nephropathy, in Indigenous and Asian populations [16, 17].

Hyperglycemia is a consistent and important determinant of renal injury. The Diabetes Control and Complications Trial (DCCT) [18] and the UK Prospective Diabetes Study (UKPDS) [19] evaluated intensive glycemic control vs. conventional regimens and provided clear evidence that optimized glycemic control was associated with improved long-term kidney health. In the DCCT study, the 9-year risk of microalbuminuria was reduced by 34% and macroalbuminuria by 56% in the intensive therapy group when compared with standard therapy. The intensive therapy group also had improved long-term outcomes with respect to estimated glomerular filtration rate (eGFR) [20].

However, target glycemic control is often very difficult to achieve in adolescents. Many observational studies have reported hemoglobin A1c (HbA1c) levels well above the recommended <7% [21, 22]. There are important psychological factors related to adolescence that make adherence to the complex care regimens of diabetes management unattainable. There is also increasing recognition of mental health co-morbidities that both affect adolescents ability to self-manage their chronic disease [23].

Hypertension has also been consistently identified as an important modifiable risk factor for DKD in type 1 diabetes [24]. Youth onset type 2 diabetes studies that included 24 h ABPM data also support the importance of this clinical risk factor [25, 26]. Additional risk factors include duration of diabetes, and post-pubertal status [27]. Hyperlipidemia and smoking have also been associated with an increased risk of albuminuria [28, 29]. Obesity is common in youth with type 2 diabetes; however, it has not independently been shown to increase the risk of DKD early in the disease course [30].

Natural History

The natural history of DKD has 5 stages: glomerular hyperfiltration with a period of subclinical morphological changes; onset of albuminuria; progressive increases in albumin excretion; declining GFR; and ultimately ESKD (Table 32.1). The period of glomerular hyperfiltration is fairly consistent, but its pathogenicity is controversial [31]. Following this period, albuminuria starts to manifest, which once consistent, is considered the first clinical marker of DKD [3]. Historically, thresholds for microalbuminuria, and macroalbuminuria were described, but these thresholds are no longer recommended; albuminuria should be evaluated as a continuous outcome.

Traditionally, DKD developed in 25–35% of patients with type 1 diabetes, but typically manifested 10–20 years after diagnosis [32]. In modern adolescent cohorts, persistent albuminuria occurs in 0.7–9.2% of youth with type 1 diabetes

Table 32.1 Typical stages of diabetic kidney disease

	Clinical feature	Typical timeline after diagnosis
Hyperfiltration	eGFR >140 mL/min/1.73 m^2	0–<5 years
Albuminuria (Incipient Nephropathy)	UAE 30–300 mg/day ACR > 30 mg/g	5–15 years
Progressive albuminuria (Overt Nephropathy)	Increasing UAE >300 mg/day Declining eGFR	10–20 years
Progressive nephropathy (Chronic Kidney Disease)	Declining eGFR	15–25 years
End Stage Kidney Disease	eGFR <15 mL/min/1.73 m^2	>20 years

UAE Urinary Albumin Excretion, *ACR* Albumin:Creatinine Ratio, *eGFR* estimated Glomerular Filtration Rate

[29, 33] and 5.1–30.5% of youth with type 2 diabetes [25, 34]. Indigenous youth are at particularly high risk of early onset albuminuria and progression of CKD [30, 34–36]. This may reflect the important impact of developmental risk factors in this population. Autopsy studies have identified larger and fewer glomeruli in Indigenous adults, especially in individuals exposed to diabetes in pregnancy [37] and living in remote locations [38].

DKD is generally slowly progressive, typically taking 5 years to progress through each stage, with a decrease in GFR manifesting after many years of progressive albuminuria. GFR generally starts to decrease after more severe albuminuria has developed. Early in the course, the GFR decreases by 1–2 mL/min/1.73 m^2/year, but this can accelerate to 5–10 mL/min/1.73 m^2/year subsequently [3]. Once more severe albuminuria has developed, rates of progression are very high (cumulative risk of ESKD are 24.4%, 43% and 52% at 5, 10 and 15 years) [39].

With modern therapy, however, rates of ESKD have improved. Long-term, 30-year follow-up from the DCCT trial has shown nephropathy in only 9% of the trial cohort 30 years after diagnosis, and only 2% require kidney replacement therapy [40]. Similarly, a Swedish study reported a rate of persistent albuminuria of only 8.9% at 25 years, presumed to be secondary to improvement in glycemic control [41]. Studies in which glycemic control remains suboptimal continue to show high rates of kidney complications [42].

Rates of progression in youth with type 2 diabetes are much higher. Long-term follow-up of Indigenous youth from Canada and Australia with type 2 diabetes have shown rates of ESKD up to 50% [30, 43]. The modern type 2 diabetes cohorts are only now reaching young adulthood; therefore, more knowledge regarding eGFR trajectories in this population will be available [44, 45].

Ultimately, individuals with type 1 [46] and type 2 [47] diabetes that develop kidney disease are at increased risk of mortality; hence, prevention and delay of progression of kidney disease are very important.

Pathophysiology

The mechanisms proposed to contribute to hyperfiltration in diabetes include up-regulation of sodium-glucose cotransporter-2 (SGLT-2) in the proximal tubule due to the higher load of glucose. Up-regulation of SGLT-2, which co-transports sodium and glucose back into the circulation, decreases distal sodium delivery to the macula densa, thereby promoting renin release, and thus over-activation of the renin-angiotensin-aldosterone system (RAAS) [48]. Glomerular hypertrophy also leads to an increased filtration surface area. Additionally, abnormal vascular control decreases afferent glomerular arteriolar resistance and increases efferent glomerular resistance, ultimately causing an increase in renal blood flow [49].

Metabolic factors are also important, including advanced glycation end products (AGEs), which are thought to increase production of reactive oxygen species; stimulate intracellular molecules such as protein kinase C and NF-kB; and activate growth factors, including TGF-B and vascular endothelial growth factor. These factors, along with hemodynamic changes, contribute to podocyte injury, oxidative stress, inflammation and, ultimately, fibrosis.

Exacerbating factors in youth with type 2 diabetes may include a decreased functional nephron mass, as well as a higher prevalence of immune-mediated glomerular diseases [16]. Adults with diabetes may have hypertensive nephrosclerosis or ischemic nephropathy from atherosclerotic changes, either overlapping with traditional DKD or on their own.

Biomarkers

Albuminuria is the most established biomarker of early kidney disease, but there is a subset of patients that develop progressive CKD in the absence of proteinuria [50, 51]. This suggests that albuminuria may not identify all patients with DKD. There are several potential additional biomarkers that are predictive of progressive kidney disease. These include uric acid, tumor necrosis factor receptors, markers of oxidative stress and profibrotic cytokines [52], but their role in clinical practice is not defined.

Pathology

The typical pathological changes in DKD include mesangial matrix expansion, glomerular basement membrane thickening, diffuse or nodular glomerulosclerosis, and ultimately tubulointerstitial inflammation and fibrosis (Fig. 32.1). Biopsy studies in youth with type 1 diabetes between 1.5 and 5 years after diabetes onset show early pathological changes [53–55].

Pathologic classification of diabetic nephropathy has been divided into four hierarchical glomerular lesions [56]. Class I is defined by isolated glomerular basement membrane thickening and only mild changes on light microscopy. Class II includes mild (IIa) and severe (IIb) mesangial expansion. Class III includes nodular sclerosis (Kimmelstiel-Wilson lesions) in at least one glomerulus. Class IV, advanced diabetic glomerulosclerosis, includes glomerulosclerosis in more that 50% of glomeruli, along with lesions from Classes I-III. Interstitial and vascular lesions including interstitial fibrosis and tubular atrophy (IFTA) and arteriolar hyalinosis and arteriosclerosis develop concomitantly.

Biopsy findings in youth with type 2 diabetes often occur early in the disease course, but have frequently shown features other than typical diabetic nephropathy [57]. In Canadian First Nation children with type 2 diabetes, histologic changes included enlarged glomeruli; focal, mild hyaline arteriolosclerosis; and focal and mild glomerular basement membrane thickening (Fig. 32.2). Additional findings included immune complex deposition, and focal segmental or global glomerulosclerosis [57]. Most adults with type 2 diabetes exhibit typical DKD [58]; however, the prevalence of non-diabetic kidney disease varies (3–82.9%), with IgA nephropathy being a common finding, occurring in 3–59% of biopsies in a meta-analysis [17].

Kidney biopsy may therefore be indicated if a patient's course is not following the expected natural history of DKD in order to identify alternative causes of albuminuria or decreased eGFR. Non-diabetic kidney is more likely in patients with diabetes if there is nephrotic range proteinuria with a disease duration of <5 years; persistent hematuria suggestive of an immune-mediated process; rapidly progressive proteinuria or renal insufficiency; or a family history of non-diabetic kidney disease, [3] and may be an indication for kidney biopsy. The absence of retinopathy has been utilized as a criterion for biopsy is adult populations, but the association between retinopathy and DKD in youth with type 2 diabetes is unknown.

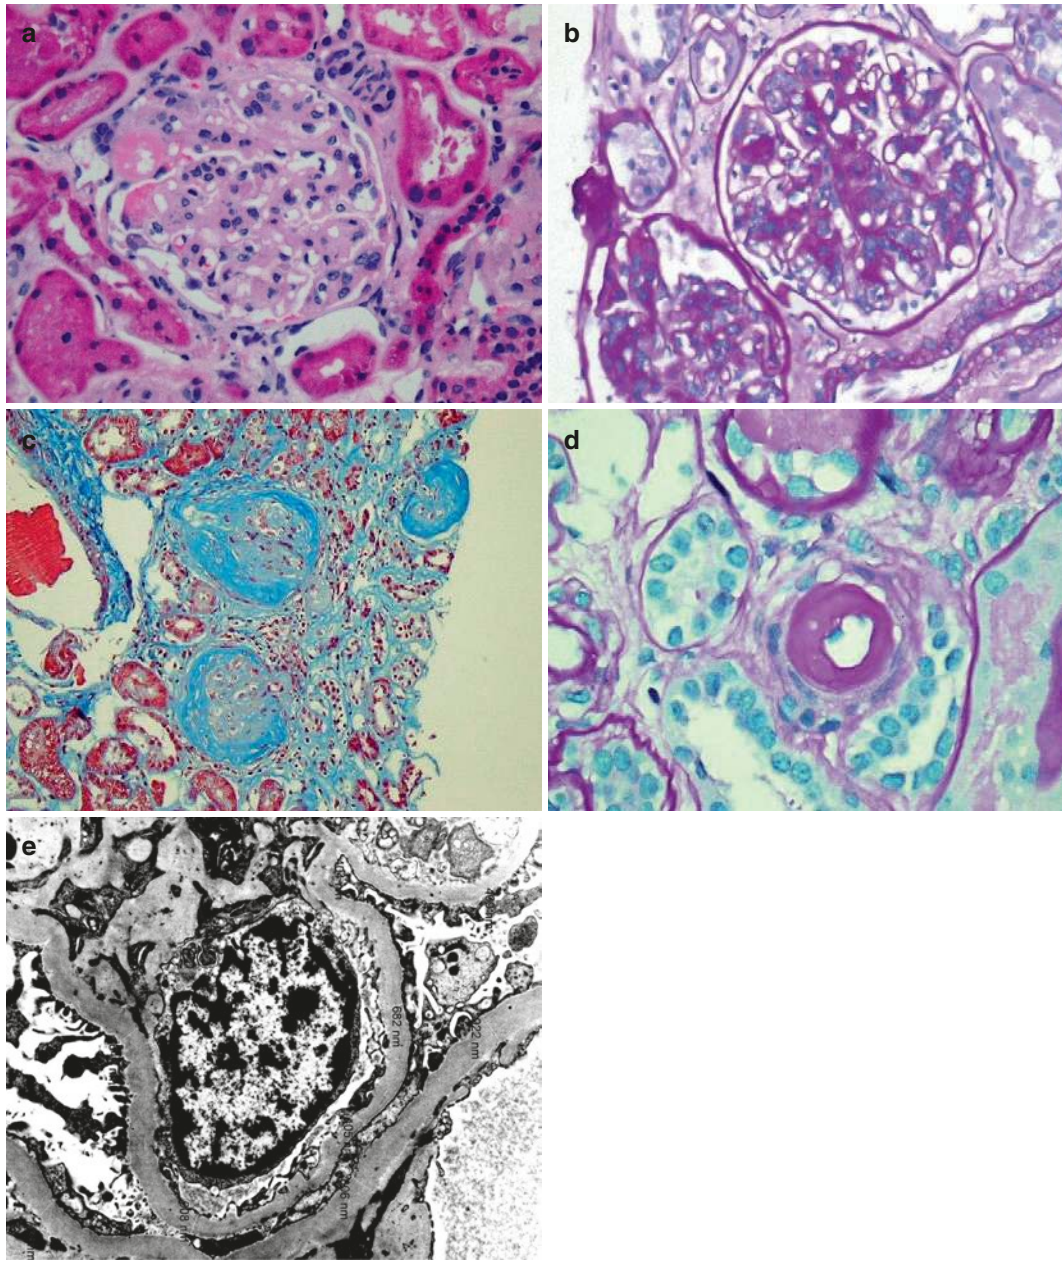

Fig. 32.1 Kidney pathology in an adolescent with type 1 diabetes for 10 years with poor glycemic control showing characteristic features of diabetic kidney disease. (**a**) Hematoxylin + Eosin [H+E] stain showing diffuse diabetic glomerulosclerosis with mesangial matrix expansion and secondary focal segmental glomerulosclerosis and hyalinosis. (**b**) Periodic acid-Schiff [PAS] stain showing moderate mesangial matrix expansion. (**c**) Trichrome stain showing three globally sclerosed glomeruli and associated severe tubular atrophy and interstitial fibrosis. (**d**) PAS stain showing nodular hyaline arteriolosclerosis. (**e**) Electron micrograph showing diffuse glomerular basement membrane thickening (>600 nm) and patchy epithelial cell foot process effacement. (*Images courtesy of Dr. Ian Gibson, University of Manitoba*)

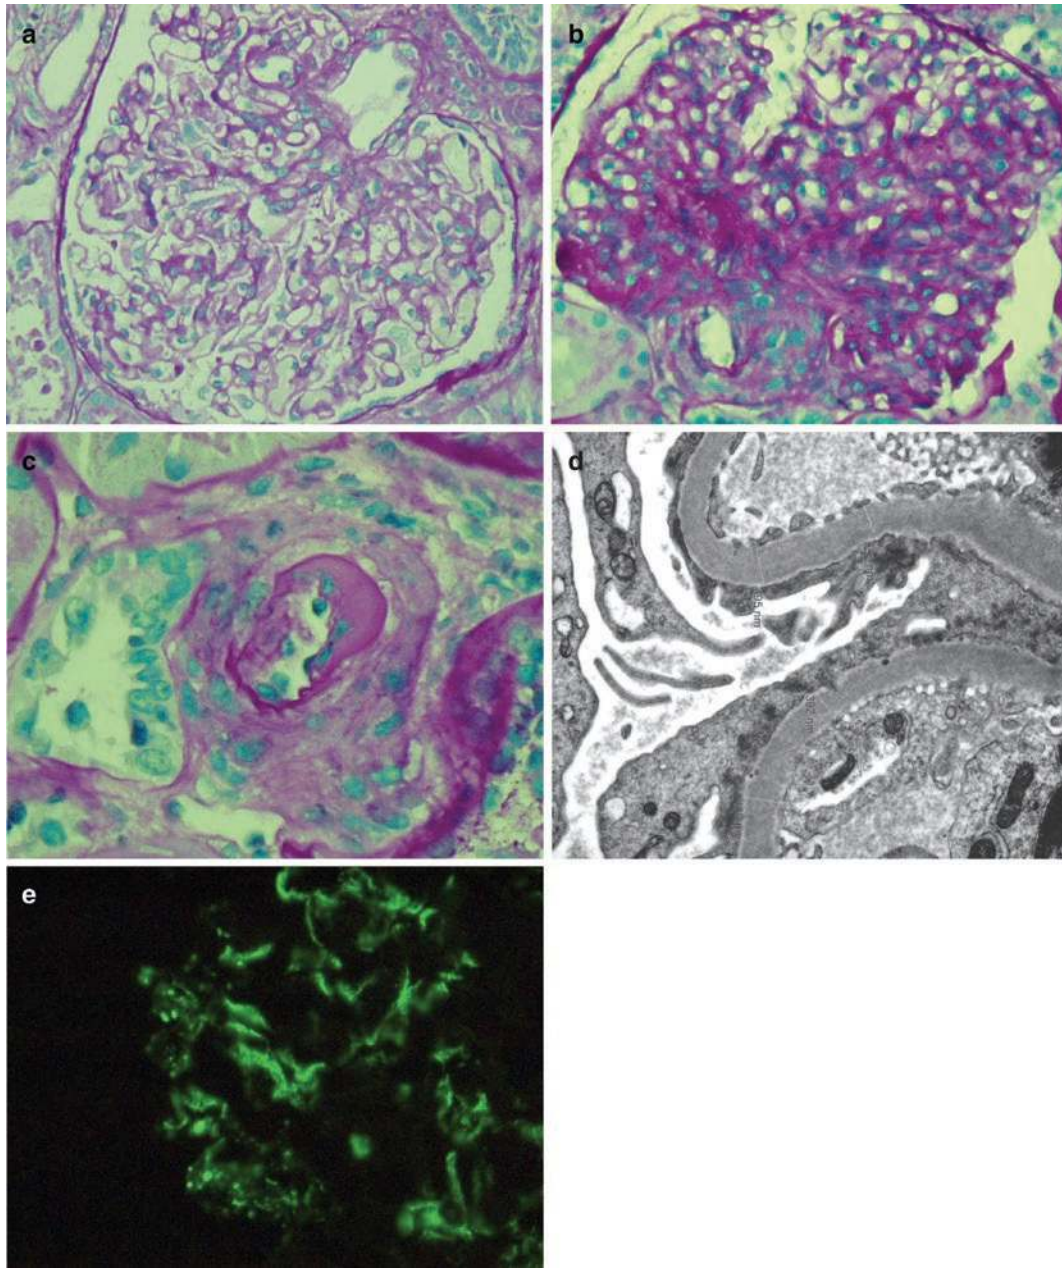

Fig. 32.2 Kidney pathology in a youth with type 2 diabetes and albuminuria. (**a**–**c**) Light microscopy (Periodic acid-Schiff stain), (**d**) Electron microscopy. (**e**) Immunofluorescence. Findings include (**a**) Glomerular hypertrophy; (**b**) Hilar focal segmental glomerulosclerosis; (**c**) Nodular arteriolar hyalinosis; (**d**) Early diffuse diabetic glomerulosclerosis with glomerular basement membrane thickening up to 500 nm; (**e**) Mesangial staining for IgA indicating co-existent non-proliferative IgA nephropathy. (*Images courtesy of Dr. Ian Gibson, University of Manitoba*)

Screening and Monitoring

Albuminuria

Yearly screening for albuminuria is recommended when patients with type 1 diabetes are at least 11 years of age and have had 5 years of diabetes [59] and at diagnosis for youth with type 2 diabetes [60]. Random urines are acceptable as initial screening tests. However, a first morning urine or overnight urine collection is required to confirm the diagnosis of non-orthostatic albuminuria if the random sample is abnormal [2]. The confirmation of persistent albuminuria also requires albuminuria in 2/3 samples at least 1 month apart over a 6-month time period [61]. Thresholds for albuminuria differ slightly across consensus guidelines. The Diabetes Canada urine albumin:creatinine ratio (ACR) threshold for albuminuria is >2 mg/mmol in adults with DKD (equivalent to a 24 h albumin excretion >30 mg/day) [3]; the American Diabetes Association utilizes an ACR threshold of 30 mg/g (3.39 mg/mmol); and the International Society for Pediatric and Adolescent Diabetes ACR threshold is >3.5 mg/mmol for males and >2.5 mg/mmol for females. KDIGO utilizes an ACR threshold of >3 mg/mmol [61]. Limitations of this test are false positives due to the high prevalence of orthostatic proteinuria in adolescents and intercurrent illness causing transient albuminuria. In addition, reduction in kidney function in the absence of albuminuria occurs in a subset of patients with DKD [62].

Glomerular Filtration Rate

Annual measurement of creatinine to determine the eGFR is also recommended, although the best equation for estimating eGFR in this population is unknown. As many youth have hyperfiltration, elevated eGFRs are quite common. For youth with type 1 diabetes, options for eGFR include the CKiD equation [63], with or without the addition cystatin C, or other cystatin C based equations if cystatin C is available [64]. Equations utilized in the youth onset type 2 diabetes population include the Zappitelli equation [65, 66] and the iCARE study equation, which was developed and validated in an Indigenous population in Canada [67]. All existing formulas have limitations, and therefore should be interpreted with caution.

Blood Pressure

Blood pressure should be measured at each healthcare encounter. Based on the American Academy of Pediatrics clinical practice guidelines, blood pressure is considered elevated at a threshold of >90th percentile for age, sex and height or >120/80 in adolescents >13 years of age. Hypertension is defined as >95th percentile for age, sex and height or>130/80 in adolescents >13 years of age. In addition, routine performance of 24-h ambulatory blood pressure is strongly recommended in children with diabetes to assess hypertension severity and to evaluate circadian blood pressure patterns [68].

Lipids

Screening for dyslipidemia is recommended after stabilization of hyperglycemia in children with type 1 diabetes after age 11. As fasting lipid profiles are not always feasible, non-fasting screening is acceptable. If abnormal, a fasting sample should be obtained [69].

Treatment

Preventive strategies should be considered early in the disease course of diabetes. Intervention during childhood and adolescence prevents or delays complications [70]. Specific treatment targets for DKD include glycemic and blood pres-

sure control. Optimization of glycemic control is critical for preventing or delaying albuminuria and progression in youth with both types of diabetes. The target HbA1c and blood pressure is the same for both types of diabetes: HbA1c <7% and the blood pressure <90th percentile for age, sex and height or <130/80 in adolescents >13 years.

Blood Sugar Control

Treatment with insulin is required in youth with type 1 diabetes. Pharmacologic therapy approved for youth with type 2 diabetes includes insulin or metformin [60]. Efforts to address lifestyle related risk factors for diabetes, especially in patients with type 2 diabetes, include healthy eating, with a diet high in vegetables, fruits, whole grains, fiber, legumes, plant-based proteins, unsaturated fats, and nuts, with few processed meats, refined carbohydrates and sweetened beverages; light and vigorous exercise; and adequate sleep quality and quantity [60]. Specific recommendations include 60 min of daily moderate-to-vigorous physical activity, screen time limited to no more than 2 h per day, limiting sitting, and time spent indoors [71]. Team-based, multidisciplinary care, including nutrition specialists, to support patients with these recommendations is critical. In addition, the screening and treatment of mental health co-morbidities is essential [25, 72]. It is important, however, to provide counselling to patients that is non-judgmental, and considers the social context of the individual, the impact of food insecurity [73] and access to safe places to be active [74]. Many youth with type 2 diabetes confront stigma, which can significantly add to the challenges of managing a chronic disease [75]. Healthcare providers have a responsibility to educate themselves about systemic barriers that families confront, and to focus less on individual behavior strategies and blame.

Smoking Cessation

Implementation of strategies to promote smoking prevention or cessation is also important [76].

Lipid Management

The intervention for hyperlipidemia depends on the severity of the problem. An LDL cholesterol >2.6 mmol/L warrants a low fat diet and increased exercise. An LDL >3.4 mmol/L is the threshold for initiation of a statin in children over age 10, with a target of <2.6 mmol/L [69].

Hypertension Management

The first line medications for the treatment of hypertension and albuminuria are RAAS inhibitors, including angiotensin-converting enzyme inhibitors (ACEi) and angiotensin receptor blockers (ARBs). Many intervention studies in adults have documented decreased progression of albuminuria and attenuated decline of GFR with these therapies [77, 78]. These drugs are safe and effective in children with CKD [79]. The AdDIT trial, which randomized youth with type 1 diabetes in the upper tertile of ACR to an ACEi, a statin or both, did not identify a significant effect on albuminuria progression over 2–4 years [33]. Hence, initiation of these medications prior to the onset of hypertension or albuminuria is not recommended.

Combinations of ACEs and ARBs have been associated with safety concerns, including increased risk of acute kidney injury and hyperkalemia [80], and are therefore not recommended. Side effects of ACEi include hyperkalemia, cough, and a decrease in eGFR. They should be avoided if eGFR <30 mL/min/1.73 m^2. Monitoring of serum creatinine and potassium is indicated within 2 weeks of starting the medication. In addition, due to the potential teratogenicity in pregnancy, pre-conception counselling in postmenarchal girls is essential [81].

Novel Therapies

SGLT2 inhibitor trials, including The Canagliflozin and Renal Events in Diabetes with Established Nephropathy Clinical Evaluation (CREDENCE) trial, have demonstrated improved

glycemic control, weight loss, and renal protection in adults with type 2 diabetes [82]. Randomized trials which include adolescents with type 2 diabetes are ongoing. These drugs are associated with an increased risk of euglycemic diabetic ketoacidosis; therefore, they likely warrant significant caution in adolescents. Guidelines now consider SGLT2 inhibitors standard of care for adults with type 2 diabetes [83]. They have the potential to significantly delay DKD progression in adolescents if safety is demonstrated.

Glucagon-like peptide-1 agonists have been studied and approved by the United States Food and Drug Administration in children and adolescents with type 2 diabetes [84]. The potential kidney benefits, beyond glycemic control, are not fully understood. Newer studies are also focusing on AGE inhibitors, metabolic memory resulting from epigenetic changes from hyperglycemia, and incretin-related drugs for their effects on renal outcomes [85] (Table 32.2).

Table 32.2 Screening, risk factors and treatment of diabetic kidney disease in youth with type 1 and type 2 diabetes

	Type 1 diabetes	Type 2 diabetes
Timing of screening	11 years with 2–5 years diabetes duration	At diagnosis
Screening method	Random urine for albumin:creatinine ratio annually Serum creatinine and/or Cystatin C for calculation of eGFR annually	
Follow-up screening	If random urine ACR 30mg/g to align or 3mg/mmol then collect 2–3 first am urine samples over the next 6 months, at least 1 month apart	
Risk factors	Hyperglycemia Hypertension Lipid abnormalities Smoking Duration of diabetes Post-pubertal status	Hyperglycemia Hypertension Minority ethnicity Socioeconomic factors
Treatment	Diet and exercise, smoking cessation Angiotensin converting enzyme inhibitors or angiotensin receptor blockers for persistent urine ACR 30mg/g or 3mg/mmol and/or blood pressure >130/80	
Targets	HbA1c <7% Blood pressure <130/80 >13 years or <90th percentile for age, sex, height <13 years	
Treatment considerations	Multidisciplinary teams Mental health assessment and treatment	

eGFR estimated glomerular filtration rate, *ACR* albumin:creatinine ratio, *HbA1c* glycosylated hemoglobin A1c

Hemostasis

Hemostasis constitutes a physiologic response of the human body to injury regulated by the dynamic equilibrium between pro-coagulant and natural anticoagulant mechanisms. An inherited and/or acquired defect in any of those pro- or anticoagulant forces may "tip the clotting balance", resulting in either bleeding or excessive hypercoagulability.

Endothelial cells are one of the major components of the hemostatic system, covering the vascular structures and having a primordial anticoagulant role when the body is in a steady state. However, after an endothelial injury occurs, a process entitled primary hemostasis ensues, where platelets play a major role towards thrombus formation particularly under high shear stress forces (e.g., arterial circulatory component). Secondly, in conjunction with the now activated platelets and their newly exposed negatively charged phospholipid (PL) membranes, the coagulation factors that are circulating in a non-active state are activated in sequence to promote the formation of an insoluble thrombus, which will ultimately anchor the platelet plug to the newly formed wound site, preventing excessive bleeding. The steps summarized above are part of the accepted model that integrates the hemostatic response, entitled the "cellular model" of the coagulation cascade [1]. The mechanisms of the second wave, called secondary hemostasis, are counterbalanced by the progressively increased activation of natural anticoagulant pathways, which will ultimately tailor down the formation of insoluble thrombus in an attempt to restrain its growth to the wound site. Additionally, the fibrinolytic system will also help contain the newly formed thrombus to the wound site by promoting a local thrombolytic effect to digest thrombus formed in excess (Fig. 33.1). Moreover, non-coagulation components in blood, such as red blood cells (RBC) and white blood cells (WBC), also have a contributory role in the hemostatic system. Understanding normal hemostasis is helpful and necessary to explain the pathophysiology of hemorrhage and thrombosis in patients with renal diseases.

Primary Hemostasis

Vessel Wall

When a vessel wall is damaged, many different pro-coagulant components of the hemostatic system are activated to generate a clot (i.e., thrombus). The release of cytokines leading to vasoconstriction and activation of the local endothelial cells occurs immediately after injury. This process is a result of the neurogenic reflex when endothelin, a vasoconstrictive agent, is released from endothelial cells in a process that sustains hemostasis for an initial short period of time [2]. Additionally, serotonin, a substance which is released from dense granules of activated platelets, and thromboxane A2 (TXA2), a derivative of platelet membrane PL metabolism, stimulate smooth muscles of the vessel wall and augment the process of vasoconstriction [3].

Endothelium

Endothelial cells have a great influence on hemostasis because of their interaction with all parts of the hemostatic system. Endothelial cells produce several important substances directly or indirectly related to the hemostatic processes: [2, 3]

- Vasoactive substances
  - Nitric oxide (NO) and prostacyclin (PGI2), which are both potent vasodilators.
  - Heparan sulfates, a group of "heparin-like" compounds that prevent the initiation phase of the coagulation cascade.
- Pro-coagulant activation
  - Von Willebrand factor (VWF).
  - Coagulation cascade: tissue factor (TF) and factor VIII (FVIII).
- Anticoagulation mechanisms

(a) Natural anticoagulant pathways
  - Protein C (PC)
  - Protein S (PS)
  - Thrombomodulin (TM)
  - Endothelial PC receptor (EPCR).
  - Tissue factor pathway inhibitor (TFPI).

(b) Fibrinolytic system
  - Tissue-type plasminogen activator (t-PA)
  - Urinary type plasminogen activator (u-PA).
  - Plasminogen activator inhibitor type 1 (PAI-1).

In addition, the disruption of endothelial cells at the site of vascular injury exposes subendothelial matrix, which is an activator of platelets and of the coagulation system [3–5].

Platelets

Platelets are disc-like, anucleated cells generated by megakaryocytes in the bone marrow that have a major role in primary hemostasis. After the exposure of subendothelial matrix, circulating platelets adhere to the injured site in a process called "platelet adhesion." This first step of platelet activation results from the interaction between several glycoprotein (GP) complexes expressed by the platelet surface (e.g., GP Ib/IX/V, GP Ia/IIa and GP VI), with the subendothelial matrix. For instance, the complex named GP Ib/IX/V interacts with VWF under high shear conditions as the VWF molecule unfolds, exposing the domains which will bind to the GP complex expressed by the platelet membrane, promoting the platelet to vessel wall interaction that leads to adherence of platelets to subendothelial matrix. In addition, GP Ia/IIa and GP VI adhere directly to collagen fibers in subendothelial matrix [5, 6].

After platelet adhesion, platelet activation occurs rapidly. During this process, the many pro-coagulant substances contained within platelet granules are released, including calcium (Ca^{++}) and ADP from dense granules, FV, FXI, FXIII, VWF, platelet factor-4 (PF4) and other substances from alpha granules, all ultimately leading to further activation of other platelets. During this second step of platelet activation, platelets also change their shapes by remodeling their platelet cytoskeleton, to fully spread with pseudopodia and expose important platelet membrane PL, phosphatidylserine and phosphatidylethanolamine [4]. This process further increases the amount of activated platelet surface area, which is necessary for the next step of secondary hemostasis [4, 7].

The major platelet GP activated during this step is GP IIb/IIIa, which works with fibrinogen under low shear flow and VWF under high shear flow to promote platelet-platelet interactions, also known as platelet aggregation. Several agonists, such as ADP, collagen, arachidonic acid and thrombin at the damaged vessel wall, also play a role on specific receptors in this process [4, 5].

Secondary Hemostasis

The secondary hemostatic wave combines serial proteolytic reactions to activate coagulation proteins (i.e., coagulation factors), culminating in the formation of an insoluble fibrin clot (Fig. 33.1). Postulated in 1964, the original waterfall cascade model of coagulation is still helpful to explain the in vitro phenomenon evaluated by screening coagulation tests, namely the prothrombin time (PT) for the extrinsic pathway and the activated partial thromboplastin time (APTT) for the intrinsic pathway of the coagulation cascade [7, 8]. Coagulation factors are most often synthesized in the liver, and can be classified by their functions into a few distinct groups as follows: contact factors (include prekallikrein, high-molecular-weight kininogen, FXII and FXI), extrinsic tenase complex (comprises TF and activated FVIIa), intrinsic tenase complex (consists of both FVIIIa and FIXa), prothrombinase complex (includes FXa and FVa), thrombin (FIIa) (activates fibrinogen and FXIII, which stabilizes fibrin), and fibrinogen and factor XIII (FXIII), which work together to form a fibrin clot.

Anticoagulation System

There are three major systems of proteins that counteract the coagulation system by inactivating coagulation proteins.

(a) *Antithrombin* (AT; formerly known as ATIII) inhibits mainly FIIa and FXa. In addition, it also inactivates FIXa, FXIa and FXIIa. The liver synthesizes AT, which potentiates unfractionated heparin anticoagulant power by 1000-fold.
(b) *TFPI* inactivates the extrinsic tenase complex. TFPI is released from endothelial cells and platelets.
(c) *PC*, *PS and TM* work together to inhibit FVa and FVIIIa. After being released from endothelium and activated by thrombin, TM combines with TM receptor and EPCR to form a complex with PC. Then activated PC (APC) is released from the complex and works with PS to inhibit target factors. Both PC and PS are vitamin K-dependent enzymes and synthesized by the liver [2–7].

Fibrinolytic System

The fibrinolytic system is a complex system that lyses or "digests" fibrinogen and non-cross linked and cross-linked fibrin. There are many proteins involved in the fibrinolytic system [9] and these include:

(a) *Plasminogen*, *t- PA and u- PA* work together to lyse a clot.
(b) *α 2 - antiplasmin* (*α 2–AP*) is synthesized in the liver and inactivates plasmin by forming a 1:1 ratio complex.
(c) *α 2 - macroglobulin* (*α 2–M*) is a four-polypeptide protease that can inhibit plasmin and tPA.
(d) *Thrombin-activatable fibrinolytic inhibitor* (*TAFI*) is synthesized by the liver and activated by thrombin and plasmin. It inhibits fibrinolysis by cleaving some parts of fibrin, which prevent fibrin degradation by plasmin.

The final products of fibrinolysis are called fibrin degradation products (FDP), which consist of different-sized lysed fibrin-derived fragments. One of the FDP- laboratory tests, which is commonly used in clinical practice, is called D-dimer.

Other Components

(a) *Red Blood Cells* (*RBCs*): in normal blood flow conditions, RBCs circulate in the central part of the flow within vessels while platelets flow along the vessel wall [4]. This blood rheology facilitates platelets reaching injured sites quicker. Patients with decreased red cell mass lose this mechanism, potentially having impaired platelet function. Nonetheless, hemolytic anemias may cause a hypercoagulable state leading to an increased risk for thromboembolic events (TEs) by other mechanisms [10].
(b) *White Blood Cells* (*WBCs*): an extremely high number of WBC causes hyperviscosity of the blood and can result in thromboembolism in leukemic patients. In addition, monocytes can be activated and express TF in some specific conditions, contributing to thrombus formation [11].
(c) *Neutrophil Extracellular Traps (NETs):* an original defense mechanism by neutrophils and leukocytes to extrude their DNA and protein components (e.g., histones) to trap and kill pathogenic microorganisms, which can lead to pathogenic thrombosis [12].

Age-Appropriate Development of Hemostasis (Developmental Hemostasis)

Hemostasis evolves from the fetal period, starting at 10 weeks of gestational age.

Primary Hemostasis

(a) Vessel wall and endothelial cells: increased levels of glycosaminoglycans in the vessel

walls of neonates promote antithrombotic property by working with AT, while increased levels of VWF and large VWF multimers from endothelial cells counteract this effect [13].

(b) Platelets: there is no difference in platelet numbers between healthy neonates and children. Conversely, the platelet count in preterm neonates can be lower than term neonates due to several factors. Platelets in full-term neonates express a lower quantity of specific receptors on the platelet surface. The response to several agonists may also be less pronounced in comparison to the response found in adult platelets. However, these observations suggestive of a likely platelet function defect in neonates is counterbalanced by a higher red cell mass, mean corpuscular volume (MCV), higher circulating VWF level and a higher proportion of large VWF multimers [14].

Secondary Hemostasis

At birth, the levels of vitamin K-dependent factors (prothrombin, FVII, FIX and FX), contact factors and FV are lower than in adults. In contrast, FVIII, VWF and TF levels are higher than in adults during the first 6 months of life, subsequently decreasing [15–18]. The levels of fibrinogen and FXIII are similar from birth to adulthood [15, 17, 18]. However, a study of endogenous thrombin potential (ETP) showed almost two-times higher levels in adults compared to children less than 5 years of age [18].

Anticoagulation System

At birth, the levels of AT and TFPI are lower than circulating adult levels. The same finding applies for PC and PS [15, 17, 18]. PS gradually increases to adult levels at 6 months of age; whereas, for PC circulating levels reach adult values only after 11 years of age [16].

Thrombolytic System

The levels of plasmin, PAI-1 and α_2-AP are lower at birth than in adults. In contrast, t-PA and α_2-M are much higher at birth than in adults. Most of the fibrinolytic proteins reach adult levels within 5 days of life, except plasminogen, which increases to adult levels at 6 months of age, and α_2-M, which is still elevated until the second to third decade of life. The level of u-PA measured in neonates remains controversial [8, 15].

Ultimately, healthy neonates and infants do not bleed spontaneously when challenged during birth despite their distinct platelet-related laboratory testing results. Likewise, despite having lower circulating levels of many of the natural anticoagulant pathways, neonates, infants, and children have an incidence of thrombosis that is much lower than the one reported in adults [19]. Moreover, venous thrombotic events in neonates and infants are almost invariably provoked. This contrast between laboratory and clinical findings highlights some of the limitations of current laboratory testing, as well as the yet unraveled aspects of developmental hemostasis.

Bleeding in Renal Disease

Uremic Coagulopathy

The association between uremia and bleeding was first described in 1764 by GB Morgagni. In 1836, Richard Bright published on 100 cases of patients with albuminous urine and also noted the connection between purpura and uremia. The observation that bleeding in uremic patients occurs despite having normal clotting factors led to the supposition that the primary abnormality must be within the platelet system [20]. Despite many theories and suppositions, the exact etiology of uremic coagulopathy remains poorly understood.

Clinical Manifestations

The occurrence of bleeding in uremia is twofold higher in those with chronic kidney disease (CKD) and has been widely reported [20–22]. This includes potential bleeding in many locations, including the skin and mucosa, the gastrointestinal tract, the retroperitoneum, ocular tissues, genitourinary system, and intracranial. There are potential risks of bleeding during surgery or post-operatively and from venipuncture and renal biopsy sites. Pleural and pericardial hemorrhagic effusions have also been described. Most of these reports have been in the adult population with only a few scattered reports of increased bleeding risk in uremic children [20]. Whether the adult risks of bleeding can be extrapolated to children is a question that is still unanswered, given the developmental hemostatic differences.

Pathogenesis

The levels and function of coagulation factors are normal in patients with CKD [23]. From these data, it is assumed that platelet dysfunction is primarily responsible for the increased bleeding risk due to uremia. When placed into normal plasma, uremic platelets demonstrate normal function, implying that causative factors are present in the surrounding uremic plasma. However, research has found that there are both intrinsic and extrinsic platelet abnormalities that result in the uremic coagulopathy.

Intrinsic Platelet Abnormalities

In CKD and uremia, the content of ADP and serotonin is reduced in the platelet granules. This is felt to be either an acquired storage pool defect or a defect in secretory mechanisms [23]. Cyclic adenosine monophosphate (cAMP) has been reported to be increased in CKD, which can affect the mobilization of calcium in response to stimulus and, ultimately, platelet activation. It may be through an imbalance among ADP, serotonin and cAMP that results in platelet activation defects. Other defects include low levels of GP Ib/V/IX in association with elevated levels of glycocalicin, a proteolytic byproduct released by GP Ib/V/IX when damaged on the platelet surface [24]. Thromboxane A2 levels, generated from free arachidonic acid, are also low in uremia and result in poor platelet adhesion and aggregation [25].

Platelet contractility defects may be another factor contributing to platelet dysfunction by reducing its mobility and secretory capacity [26]. In uremic states, platelets have deficient cytoskeletal proteins, such as α-actin and tropomyosin, with the abnormalities becoming more pronounced after activation by thrombin.

Platelet: Vessel Wall Abnormalities

Levels of VWF and fibrinogen are normal in uremic states [22, 23]. There is normal surface expression of the platelet receptor GP Ib/V/IX, although the total levels of GP Ib/V/IX have been found to be suboptimal [24]. It has also been shown that there is impaired binding of VWF to GP 1b/V/IX and that this results in lower levels of TXA2 and ADP, both necessary to stabilize hemostatic plugs [27]. Another noted abnormality is reduced binding capacity of VWF and fibrinogen to GP IIb/IIIa, resulting in reduced platelet adhesion to injured endothelium. This may be secondary to receptor blockade by fibrinogen, or through substances that are dialyzable, as dialysis improves this anomaly.

Other extrinsic factors that might come into play include platelets and prostaglandins [28–30]. Anemia in CKD may influence platelet function through changes in laminar blood flow, as previously noted. A reduction in hematocrit can change platelet travel from where it is normally at the periphery of a blood vessel to the central part where erythrocytes traverse. Reduced contact with vessel wall results in stimulation of platelet ADP release and activation of PGI-1, which reduces platelet activity. Prostaglandin-I2 (PGI2) is a vasodilator released by endothelial cells and inhibits platelet function through its action on adenylyl cyclase and its modulating effects on cAMP and calcium mobilization within platelets. Although several studies have shown increased production of PGI2 in

endothelium of uremic models, blockage of PGI2 production does not result in improved coagulation, thereby suggesting that there are other factors that are involved in platelet dysfunction in renal failure. Vasoactive substances like nitric oxide are increased in CKD, which can further inhibit platelet function.

Circulating uremic toxins may also play a role in uremic coagulopathy. Substances such as urea, creatinine, phenol, phenolic acids and guanidinosuccinic acid (GSA) have all been investigated for their potential effects on platelet function [24]. GSA inhibits the second wave of ADP-induced platelet aggregation. This is further supported by the observation that dialysis can partially correct these defects.

Finally, platelet number and volume are both reduced in uremia [30]. Platelet numbers are lower in uremia when compared to healthy controls, although they are rarely less than 80×10^9/L. The reduction in platelet volume can further reduce the amount of circulating platelet mass, resulting in ineffectual platelet contact with injured endothelium.

Treatment

Treatment for uremic coagulopathy in the past was based on its ability to normalize the prolonged bleeding time (BT) observed in uremic patients. However, BT has no in vivo correlation with risk of bleeding, so that treatment should only be directed towards active cases of bleeding in the setting of uremia. There is also limited evidence that prophylactic treatment reduces the bleeding risk [31]. Treatment should therefore be utilized if there is active bleeding and includes dialysis, erythropoietin, desmopressin (DDAVP), estrogens, and cryoprecipitate [27, 28, 32–34]. DDAVP should be the first line of therapy in a bleeding uremic patient [27]. Discussion here will focus around the use of DDAVP in settings where there is a significant history of clinical bleeding.

DDAVP was first utilized for its anti-diuretic properties until it was discovered in the 1970s to have hemostatic properties [35]. Infusions of DDAVP increase VWF, factor VIII coagulant activity, ristocetin co-factor and tissue plasminogen activator. The rise of coagulation factors is rapid, likely related to release of endogenous reserves rather than new synthesis. DDAVP may also promote the glycoprotein transmembrane proteins, including VWF and GP IIb/IIIa.

Administration of DDAVP:

- Administered via intravenous, subcutaneous, or intranasal routes.
- The maximal effect on clotting factor levels occurs at 30 min, lasting up to 6 h, with an intravenous dose of 0.3 μg/kg (to a maximum of 20 μg/dose infused in 20–50 mL of normal saline over 15–30 min).
- With subcutaneous dosing, the levels peak at 1–2 h.
- For intranasal administration, a dose of 300 μg is comparable to 0.2 μg/kg intravenous dose. Use one single spray in one nostril (150 μg) if <12 years/50 kg; 1 puff per nostril (300 μg) if ≥12 years/50 kg.
- Tachyphylaxis occurs after the first dose due to depletion of FVIII and vWF endothelial stores.
- Adverse effects of DDAVP include facial flushing, headache, hypotension, tachycardia, water retention, hyponatremia and seizures (uncommon but higher incidence in children less than 5 years of age). Hypotonic solutions should be administered with caution in children who have received DDAVP.
- DDAVP should not be used in children <3 years, or in cases of polydipsia, unstable angina, or congestive heart failure because of its antidiuretic effects.

Conjugated estrogens improve the BT in uremia by increasing platelet responsiveness [32]. There have been no reports of its use in children, although adult studies recommend a dosage of 0.6 mg/kg/day given intravenously daily for 4–5 days. Effects start within 6 h and can last for up to 2 weeks after an intravenous course. It can also be given as an oral dose, but the effect is shorter, lasting up to 5 days. Side effects include hypertension, fluid retention and raised liver transaminases.

Cryoprecipitate is rich in factor VIII, vWF, fibrinogen and factor XIII, but has the risks of blood borne infections and anaphylaxis [36].

Clotting in Renal Disease

Thrombotic Manifestations of Nephrotic Syndrome

Epidemiology

Nephrotic syndrome (NS) is a hypercoagulable state with a predisposition to the development of thromboembolic events [37–42]. With effective treatments for inducing remission, thromboembolism (TE) is much less common now in children as compared to adults with an overall incidence of 3% versus 25%, respectively [43–46]. TE seems to be more likely in adolescents [46], in children with congenital NS (incidence around 10%) [47, 48], and in secondary NS, such as NS associated with vasculitis (incidence around 17%) [46]. Membranous nephropathy or a histologically similar process (e.g. class V SLE nephritis) seems to confer the highest risk, where the incidence of TE approaches that seen in adults (25%) [46]. A correlation between infection and TE has also been observed [49].

Venous TE (VTE) is the predominate form of thromboembolic disease in children with NS, accounting for 97% of the cases in a large, retrospective study [46]. In that study, arterial disease was encountered in only 0.3% of subjects. Commonly affected areas for VTE include: deep venous system within the lower limbs, inferior vena cava, renal vein, hepatic veins, and sagittal and transverse sinovenous vessels. Arterial thromboses can involve any artery, including femoral, mesenteric and intracardiac [39, 41, 46]. Finally, TE tend to occur early in the course of the disease (usually <3 months from onset) [38].

Pathogenesis

The prothrombotic tendencies in nephrotic patients have been attributed to a number of factors including state of hydration and hyperviscosity, imbalance between clotting factors and thrombophilic proteins, increase in platelets and platelet activation, abnormalities of the fibrinolytic system and use of medications [38, 40].

Antithrombin (AT; formerly known as ATIII) is an endogenous anticoagulant that was first documented to be low in NS in 1976, with confirmation in subsequent studies [37–39]. In these studies, AT had a strong correlation with plasma albumin levels and a negative correlation with urinary protein excretion, suggesting that one of the mechanisms resulting in low AT levels is due to its loss in the urine [50]. Subsequent remission of the nephrotic syndrome results in normalization of AT levels. Data on other *in vivo* anticoagulants have not been conclusive, although the majority of studies suggest that PC, PS, and tissue factor pathway inhibitor are all elevated during acute nephrotic relapses, but functionality may be reduced [37, 42, 51–53]. This might exert a protective effect against thrombosis and might explain why children have fewer thromboembolic events than adults with NS.

Platelets have been found to be higher in number and more active in children with NS. Studies suggest improved platelet availability due to their higher numbers and increased exposure of the normally albumin-bound arachidonic acid leading to thromboxane A2 activation and subsequent platelet aggregation [42, 54]. Hyperlipidemia may also promote platelet aggregation, based on the simple observation that treatment with lipid lowering agents decreases platelet hyperaggregability in NS [55].

The fibrinolytic system is also speculated to influence the risk of thromboembolic events in NS. Lower levels of plasminogen and tissue-type plasminogen activator (tPA) results in diminished fibrinolytic activity. This may be accentuated by hypoalbuminemia since albumin is a cofactor for binding plasminogen to fibrin [37, 42, 46, 56].

The use of corticosteroids has been reported to be associated with hypercoagulability [57, 58]. Mechanisms responsible include increase in coagulation factors and reduction in fibrinolysis.

Finally, children with congenital nephrotic syndrome are at higher risk of TE, which may be explained in part by a disease-specific pathophysiology. In addition, they are unlikely to achieve NS remission and are thus hyperco-

agulable for a longer time-frame, and they more often require the use of a central venous catheter (CVC), which is a well-known risk factor for TE.

Prevention and Treatment

Non-pharmacologic strategies to limit the risk of VTE include regular ambulation, adequate hydration, and avoidance of CVCs whenever possible [59].

The use of prophylactic anticoagulation to prevent TE in children with NS is controversial, due in part to the lack of randomized trials to determine the efficacy and safety of such an approach [60]. Despite the lack of robust evidence, some authors have suggested prophylactic strategies for children based on risk factors, severity markers, or coagulation abnormalities. Among these strategies, some authors have recommended aspirin prophylaxis in some circumstances [59, 61, 62]. Others propose AT replacement by administration of AT concentrates [40, 63].

Once TE has developed, clinical management is similar to that utilized in patients without NS, starting with heparinization [64]. In this case (i.e., severe AT deficiency), treatment with AT concentrate may be necessary as heparinoids are dependent on AT for their mechanism of action. However, the optimal target level of AT to achieve an adequate anticoagulant effect in children with NS is unclear. Both plasma-derived and recombinant AT are clinically available [65].

Renal Vein Thrombosis

Although renal vein thrombosis (RVT) is the most common non-catheter related thrombosis in the newborn period, few long-term outcome studies have been carried out [66–71]. Most RVTs present in the first month, with 70% presenting in the first week of life. It affects twice as many males and there is a left sided predominance. The clinical features of RVT are variable and include hematuria, oliguria-anuria, hypertension, decreased renal function, palpable flank mass and thrombocytopenia. Doppler ultrasound may show a decrease in amplitude or absence of venous signal, abnormal flow patterns in a number of renal venous branches or evidence of venous collateral development. The etiology of RVT in most cases is unknown. There is speculation about decreased levels of naturally occurring anticoagulants and fibrinolytic compounds leading to the thrombotic event [71]. Risk factors reported for the development of RVT include prematurity, maternal diabetes mellitus (either type 1 or gestational), pathologic states associated with thrombosis (e.g., shock, dehydration, perinatal asphyxia, polycythemia, cyanotic heart disease), sepsis, umbilical venous catheterization, conjoined twins, and inherited prothrombotic abnormalities [69, 72, 73]. However, the prevalence of these disorders has not been studied in a cohort of patients with neonatal RVT.

The sequelae of RVT reported in the literature include death (5%), glomerular disease (3–100%), tubular dysfunction (9–47%), hypertension (9–100%), and evidence of renal scarring or atrophy (27–100) [66–71]. Performance of multicentre, randomized clinical trials is required to investigate the safety and efficacy of treatment for RVT and to determine the long-term outcomes.

Renal Artery Thrombosis

In neonates, renal artery thrombosis (RAT) occurs as a result of umbilical arterial cannulation, with a low incidence of symptomatic cases (1–3%) [74]. In older children, RAT is most commonly associated with renal transplant and occurs at the site of vascular anastomosis. It has also been reported in patients placed on ventricular assist devices [75].

Risk factors for RAT in kidney transplant recipients include cadaver donor source, pre-transplant peritoneal dialysis, more than five pre-transplant blood transfusions, cold ischemia time >24 h, type of immunosuppression, and prior renal transplant [76–79]. There are no studies on the treatment of RAT determining the safety and efficacy of embolectomy, fibrinolysis

or anticoagulation. If RAT associated with renal transplant is diagnosed, embolectomy or fibrinolytic/anticoagulation therapy should be considered in the absence of contraindications (bleeding) to attempt to save the graft [80].

Renal Vascular Thrombosis in Renal Transplantation

Graft failure secondary to renal vascular thrombosis in the most recent report of NAPRTCS is noted to be high at 10.7% in the transplant era of 2008–2017 [81].

Different from RAT predisposing factors, risk factors for renal vascular thrombosis include underlying renal disease, pre-existing thrombotic history, abnormal anatomy, young donor, recipient age (<5 years) and donor-recipient size mismatch [76, 82–85]. Thrombophilia may also be a potential risk factor for thrombosis and early graft loss, but conclusions are not definitive [86, 87]. Therefore, some programs screen all patients for genetic and acquired thrombophilic disorders before transplantation, while others selectively screen high risk patients, such as those with a personal or family history of thrombosis.

Outcomes of graft thrombosis are not favorable and preventative strategies are crucial, including a proper history and identification of risk factors for thrombosis. Evidence for routine heparinization of all patients post-transplantation is not conclusive. Some authors suggest selective heparinization only for higher risk groups, such as small patients (<20 kg) or those with confirmed inherited thrombophilia [87–93]. The type and duration of anticoagulation prophylaxis to prevent thrombosis is also unclear. Some centres use unfractionated heparin while others use low molecular weight heparin, sometimes followed by aspirin, for various durations of time [87, 91, 92]. The effect of using anticoagulation prophylaxis on the incidence of thrombosis and graft survival in the pediatric population is unknown. Any potential benefits of heparin must be closely balanced with the risks of bleeding, which was shown to be increased in some groups using that approach [87, 90, 91].

Hemolytic Uremic Syndrome and Coagulation

Although hemolytic uremic syndrome (HUS) is reviewed in detail elsewhere (Chaps. 24 and 25), because HUS is a pro-coagulant state, it is pertinent to review this feature of the disease here. The HUS triad of hemolytic anemia, thrombocytopenia and renal involvement underscore the primary abnormality with this entity, which is related to a procoagulant state initiated by endothelial injury [72]. In the presence of Shiga toxin, up-regulation occurs of the chemokine stromal cell-derived factor-1 (SDF-1), which is found in kidney, spleen, lung, liver, brain, heart, and muscle. This chemokine activates a pathway that enhances platelet activation induced by thrombin, thereby resulting in platelet aggregation [73, 94]. Shiga toxin also inhibits prostacyclin production and increase thromboxane A2 release from endothelial cells, thereby favoring platelet aggregation. Inhibition of SDF-1 normalized platelets in vivo and prevented formation of platelet strings [95].

The procoagulant state of HUS is evidenced by the formation of microthrombi throughout the systemic circulation. Subclinical thrombogenesis occurs prior to the clinical onset of HUS, with elevation of markers of thrombin activation (increase in prothrombin fragments 1 + 2 and thrombin-antithrombin complexes) [73]. In the normal state, levels of thrombin activation markers are negligible. Tissue factor (TF), expressed on mononuclear and endothelial cells and an initiator of the coagulation cascade leading to thrombin generation, has been found to be upregulated by Shiga toxin. Blockade of thrombin activity with lepirudin prevented lethal Shiga toxin effects in greyhounds, suggesting that Shiga toxin may mediate injury via thrombin activation.

The thrombocytopenia in HUS is also intertwined in this process and is due to a consumptive process with platelet deposition in the microthrombi [94]. The platelets are activated with degranulation as evidenced by reduction in intracellular levels of β-thromboglobulin and impaired aggregation in vitro. Other evidence of

platelet activation includes increase in platelet microparticles and platelet derived factors including platelet factor-4, β-thromboglobulin, and P-selectin. The resultant effect is the formation of platelet aggregates through binding of fibrinogen leading to thrombus formation.

Fibrinolysis has been suggested to be depressed in the setting of HUS, adding to the prothrombotic state [73, 94]. However, studies are conflicting as to whether indications of depressed fibrinolysis, such as elevated levels of plasminogen activator inhibitor type 1 (PAI-1), support this finding [95].

Finally, other evidence of vascular and complement activation includes increases terminal complement complex, *Fas*-ligand and soluble *Fas*, interleukin-1 receptor antagonist, transforming growth factor, platelet activating factor, degraded VWF multimers and numerous plasma factors as previously noted [95–97]. All of these changes support an enhanced thrombogenic state.

Diagnosis of Thromboembolism

Deep vein thrombosis (DVT) and pulmonary embolism (PE) are the two major categories of venous thrombotic events (VTE), both notably prevalent in the adult population [98]. In the USA, approximately 160,000–240,000 cases of DVT are diagnosed every year [99]. In children, VTE was initially thought to be extremely rare. International pediatric thrombosis registries were instrumental in changing this perception by characterizing the higher prevalence of VTE in hospitalized pediatric patients. Moreover, registries described peaks of thrombotic events during infancy and adolescence [100]. Pediatric VTE is commonly associated with several different underlying conditions (e.g., congenital heart defects, cancer, systemic lupus erythematosus), as well as treatment-related prothrombotic risk factors (e.g., CVCs, steroids, asparaginase). In comparison to adults, unprovoked VTE is uncommon in children. VTE occurs in 1:200 individuals admitted to pediatric tertiary care facilities [101, 102].

Importantly, thrombotic events in children are also associated with a significant thrombus-related morbidity and mortality, and affect children with a variety of underlying conditions [103]. For example, patients with nephrotic syndrome are at increased risk of developing DVT, particularly RVT and PE [50, 104]. RVT can be associated with several clinical complications including chronic renal tubular dysfunction and hypertension [105], whereas PE has an associated mortality rate of approximately 9% [106]. Therefore, prompt investigation of children, either under clinical suspicion or at risk for VTE development, is vital to decrease VTE-related short and long-term complications.

DVT can present with symptoms such as pain or swelling of the affected limb [107]. However, thrombotic events in children are commonly not accompanied by signs and symptoms, given that they are usually secondary to the placement of a CVC [108]. In those instances, their clinical presentation usually occurs in a sub-acute manner, when partial obstruction of the venous territory caused by the CVC and thrombus is counterbalanced by collateral vessel development. Moreover, CVC-related DVT in children is very prevalent in the upper venous system, where the mild findings of limb swelling can also be interpreted as line-related infection, leading to under-recognition of those events. Hence, to diagnose VTE in children imaging studies are required. A summary of the various imaging modalities used for the diagnosis of VTE in children is listed in Table 33.1.

The most common radiological modality utilized to diagnose DVT, the ultrasound Doppler (USD), is very sensitive for the detection of lower limb DVT. However, this imaging modality is not as sensitive for the diagnosis of upper limb DVT in children, especially for events located within the intrathoracic territory, as USD relies on vessel compressibility to confirm the presence of an intraluminal thrombus [109]. Therefore, a composite of USD and venogram has been suggested as the best way to diagnose upper extremity DVT in children. The role of computerized tomography (CT) and magnetic

Table 33.1 Summary of imaging studies for diagnosis of TE

Types of TE	Imaging	Advantages	Disadvantages
Deep vein thrombosis of limbs [95, 107–110]	Venography	Gold standard, ability to quantify venous obstruction and identify collateral veins	Invasive procedure, technical experience, cost, contrast media-related side effects, exposure to radiation, inter-radiologist interpretation discrepancy (up to 16%)
	Doppler ultrasound sensitivity 94% and specificity 98% (adults)	Noninvasive procedure, readily available, possible for bedside evaluation	Inter-variation between operators, difficulty to test in patients with obesity, edema, trauma, burns and casts, less sensitive for upper limb DVT especially for intrathoracic vessels
	CT venography sensitivity 100% and specificity 96% (adults)	Minimally invasive procedure, less radiation exposure, well tolerated contrast media	High technical demand, cost, not readily available, radiation and contrast exposure
	MR venography sensitivity 100% and specificity 96–100% (adults)	Minimally invasive procedure, well tolerated contrast media	High technical demands, cost, not readily available, requirement for anesthesia in young children
Pulmonary embolism [98, 107–111]	Pulmonary angiography	Gold standard	Same as venography for DVT of limbs; mortality of ~1% in adults
	Ventilation/perfusion (V/Q) scan sensitivity 31% and specificity 97% for high-probability scan (adults)	Less radiation exposure	Not convenient for young children due to the requirement of cooperation of patients
	CT pulmonary angiography sensitivity 69% and specificity 69% (adults)	Same as CT venography for DVT of limbs	Same as CT venography for DVT of limbs
	MR pulmonary angiography sensitivity 78% and specificity 99% (adults)	Same as MR venography for DVT of limbs	Same as MR venography for DVT of limbs
	Echocardiography for RV free wall hypokinesis sensitivity 77% and specificity 94% (adults)	Same as ultrasound for DVT of limbs	Unable to detect mild degree of PE, same as ultrasound for DVT of limbs
Renal vein thrombosis [107, 108, 111, 112]	Ultrasound high sensitivity	Same as ultrasound for DVT of limbs	Inter-variation between operators, bowel gas obscuring abdominal findings
	CT venography sensitivity almost 100% and specificity almost 100% (adults)	Findings not affected by bowel gas, same as CT venography for DVT of limbs	Same as CT venography for DVT of limbs
	MR venography sensitivity 94–96% and specificity 100% (adults)	Findings not affected by bowel gas, same as MR venography for DVT of limbs	Same as MR venography for DVT of limbs
Portal vein thrombosis [107, 108, 113–115]	Doppler ultrasound sensitivity 70–90%, specificity 99% and negative predictive value 98% (adults)	Same as ultrasound for DVT of limbs	Same as ultrasound of renal vein thrombosis
	CT venography	Able to show varices and hepatic parenchyma, same as CT venography for renal vein thrombosis	Same as CT venography for DVT of limbs
	MR venography	Able to show varices and hepatic parenchyma, same as MR venography for renal vein thrombosis	Same as MR venography for DVT of limbs

CT computerized tomography, *DVT* deep vein thrombosis, *MR* magnetic resonance
Data from: Young [107] and Monagle [108]

resonance imaging to diagnose upper extremity DVT in children is evolving.

Besides imaging studies, laboratory biomarkers have also been used in the diagnosis of adults with VTE. Most commonly, a normal D-dimer is used to rule out thrombotic events. To further improve the use of D-dimer testing, clinical predictive rules were instituted. They stratify patients into low, moderate or high clinical suspicion groups, which further improve the positive and negative pre-imaging predictive values of D-dimer.

The sensitivity of D-dimer for the diagnosis of VTE in adult patients is around 90% [116] and the specificity around 49–78% [117, 118]. For example, a normal D-dimer may have a negative predictive value as high as 99% to exclude VTE in patients who have a low pretest clinical likelihood [118]. Conversely, the low specificity of D-dimer testing for the diagnosis of VTE may be due to the fact that D-dimer levels are usually influenced by several factors, particularly underlying diseases such as recent major surgery, trauma, cancer, pregnancy, disseminated intravascular coagulation and end-stage liver disease [119, 120].

The three most comprehensive pediatric studies to date have shown disappointing results regarding the performance of D-dimer testing as a diagnostic tool for DVT in children. A retrospective chart evaluated children with suspected VTE that had D-dimer testing done within 72 h of imaging. The researchers identified 33 patients; 26 diagnosed with acute VTE, 6 unchanged chronic VTE, and 1 without VTE. D-dimer levels were significantly higher in patients with acute VTE compared to the remaining patients (77% sensitivity; 71% specificity) [121]. Conversely, another study evaluated 132 patients referred for CT pulmonary angiography to rule out PE: 88% of the patients with PE and 87% of those without PE had a positive D-dimer result, thus showing that D-dimer positivity did not show a significant relationship with the presence of PE [122]. The third study examined the role of the Wells score, which has been validated for the stratification of adults at risk for PE, as a potential tool to risk stratify children investigated for PE. The Wells score used in combination with D-dimer testing did not differentiate children with or without PE [123], illustrating that pediatric-specific tools will be required to improve the use of D-dimer.

Thrombophilia Work Up

Thrombus formation results from a dynamic balance between pro- and anticoagulant forces; more specifically, from several different pro- and anticoagulant factors involved in the generation or inhibition of thrombin formation.

Thrombophilia refers to conditions, either inherited or acquired, that increase the risk of thrombus formation. Patients identified with an inherited or acquired thrombophilia may be predisposed to sustain a thrombotic event. However, having one isolated thrombophilia trait rarely leads to an immediate VTE.

A little more than a decade ago, the International Society on Thrombosis and Haemostasis (ISTH) published a position statement suggesting that thrombophilia investigation should occur in a stratified manner in all pediatric patients with an objectively documented VTE. However, the epidemiology of VTE in children has evolved, demonstrating that underlying conditions and/or acquired risk factors other than thrombophilia are usually present in children with VTE, rendering the role of thrombophilia as a potential causal risk factor less relevant [124].

We now understand that laboratory investigation of a child with a recently diagnosed with VTE is rarely justified. Moreover, acute VTE may also affect the circulating levels of many of the natural anticoagulant factors [e.g., PC, PS, AT], adding to the reasoning of why thrombophilia evaluation should not be performed at the time of initial VTE diagnosis [124]. Furthermore, except in extremely rare instances, thrombophilia work-up results do not change the choice of antithrombotic intensity or duration [125, 126]. Those rare instances include newborns with purpura fulminans, as its recognition requires prompt PC or PS replacement in addition to anticoagulation [125]. Similarly, children with unprovoked VTE, who may have higher recurrence rates than provoked VTE, particularly if associated with lupus anticoagulant antibodies, PC, PS or AT

Table 33.2 The summary of thrombophilic risks in children

Thrombophilic risks	Prevalence in the general population [129]	OR (95% CI) for first onset VTE in children [128]	OR (95% CI) for recurrent VTE in children [128]	Acquired conditions related to abnormal thrombophilic tests [124]
Congenital thrombophilic risks				
Antithrombin deficiency—AT activity[a]	0.02%	8.73 (3.12–24.42)	3.37 (1.57–7.20)	Acute thrombosis, nephrotic syndrome, complex congenital heart disease, L-asparaginase therapy, liver disease, heparin therapy
Protein C deficiency—PC activity[a]	0.2%	7.75 (4.48–13.38)	2.53 (1.30–4.92)	Acute thrombosis, nephrotic syndrome, complex congenital heart disease, liver disease, warfarin therapy
Protein S deficiency—total and free PS antigen[a]	0.03–0.3%	5.77 (3.07–10.85)	3.76 (1.57–7.20)	Acute thrombosis, nephrotic syndrome, complex congenital heart disease, liver disease, warfarin therapy, inflammation, pregnancy
Factor V Leiden (G1691A)—genetic test[a]	3–7%	3.56 (2.57–4.93)	0.77 (0.40–1.45)	–
Prothrombin G20210A—genetic test[a]	0.7–4%	2.63 (1.61–4.29)	2.15 (1.12–4.10)	–
Lipoprotein (a)[a]	–	4.50 (3.19–6.35)	0.84 (0.50–1.40)	Inflammation, nephrotic syndrome
Acquired thrombophilic risks				
Antiphospholipid antibodies (persistent)[b] [33]—lupus anticoagulant[a]—anticardiolipin antibodies[a]—anti beta-2 glycoprotein I antibodies [33]	1–8% 5% 3.4%	4.9 (2.20–10.90)	–	Infection

[a]Level I laboratory testing for thrombophilia in pediatric patients on behalf of the Subcommittee for Perinatal and Pediatric Thrombosis of the Scientific and Standardization Committee of the International Society on Thrombosis and Haemostasis (ISTH) [130]

[b]Persistent means that at least one of the three tests were positive twice with at least 12 weeks between the repeated testing

deficiencies [127], may also benefit from an initial laboratory work-up [125].

The results of a meta-analysis enumerating the thrombotic risk for first onset and recurrent VTE of the most common thrombophilia traits in children [127, 128] are summarized in Table 33.2.

Treatment

When a patient is diagnosed with VTE, treatment with antithrombotic agents, including antiplatelet, anticoagulant or thrombolytic agents is usually considered. The goal of using anticoagulant drugs is to prevent progression of acute TE, whereas in thrombolytic therapy the goal is to lyse the thrombus in cases where the patient has a life-, limb-, or organ-threatening condition.

The guidelines of antithrombotic treatment in children published by the American College of Chest Physician [125], the British Committee for Standard in Haematology [126], and the American Society of Hematology [131] are the main available references regarding anticoagulant therapy in children. However, most recommendations are not based on randomized controlled trials due to the limitation in the number of studies in children. The following text summarizes those recommendations regarding the most commonly used agents.

Unfractionated heparin (*UFH*) *or heparin* is a glycosaminoglycan which forms a complex with AT, enhancing the inhibitory effect of AT against both activated factors X (FXa) and factor II (FIIa, e.g., thrombin) [132]. Moreover, this complex can also inhibit FIXa, FXIa and FXIIa [133]. Due to higher volume of distribution and physiologically low AT in infants [125, 126], the dose of heparin required for anticoagulation in infants is higher than the one required in children aged more than 1 year (Table 33.3). The anticoagulant effects of heparin can be monitored by the activated partial thromboplastin time (aPTT) or the anti-FXa assay [127]. Because of its short half-life, around 30 min in children, heparin is rapidly cleared from the body after discontinuation and its effect can be fully reversed by protamine sulfate [134].

Low molecular weight heparin (*LMWH*) is derived from unfractionated heparin after it is chemically fragmented into smaller molecular sizes. Whereas UFH contains polysaccharide chains from 5 to 40 kDa with at least 18 repeats of pentasaccharide sequences that bind to AT, conferring on the molecule its most potent anticoagulant effects (e.g., protease activity inhibition of activated coagulation FII (thrombin) and FX [anti-IIa and anti-Xa inhibition]), LMWH has chains with an average molecular weight between 4 and 5 kDa that still contain enough pentasaccharide sequences to retain anti-IIa and anti-Xa activity, depending on the LMWH length [132]. Overall, because of its reduced molecular size, LMWH inhibits FXa more effectively than thrombin. Similar to what occurs with unfractionated heparin, the dose requirements for LMWH are also age-dependent (Tables 33.4 and 33.5). Infants younger than 2 months need higher doses than older children. Because the kidney excretes LMWH, patients who have decreased

Table 33.3 Unfractionated heparin dosing

Loading dose: 50–75 units/kg, IV, over 10 min					
Maintenance dose:	≤1 year of age: 28 units/kg/h >1 year of age: 20 units/kg/h				
aPTT (s)	Anti-Xa (units/mL)	Bolus (units/kg)	HOLD (min)	Rate change	Repeat aPTT
<50	<0.1	50	0	Increase 10%	4 h
50–59	0.1–0.34	0	0	Increase 10%	4 h
60–85	0.35–0.7	0	0	0	24 h
86–95	0.71–0.89	0	0	Decrease 10%	4 h
96–120	0.9–1.20	0	30	Decrease 10%	4 h
>120	>1.20	0	60	Decrease 10%	4 h

Table 33.4 Low molecular weight heparin (enoxaparin) dosing

	Age ≤ 2 months	Age > 2 months–18 years
Initial treatment dose	1.75 mg/kg/dose SC q12h	1 mg/kg/dose SC q 12 h
Initial prophylactic dose	0.75 mg/kg/dose SC q12h or 1.5 mg/kg/dose SC q24h	0.5 mg/kg/dose SC q12h or 1 mg/kg/dose SC q24h

Table 33.5 Low molecular weight heparin (enoxaparin) adjustment

Anti-Xa (units/kg)	HOLD	Dose change	Repeat anti-Xa
<0.35	No	Increase 25%	4 h post next dose
0.35–0.49	No	Increase 10%	4 h post next dose
0.5–1.0	No	0	1×/week; 4 h post morning dose
1.01–1.5	No	Decrease 20%	4 h post morning dose
1.6–2.0	3 h	Decrease 30%	Trough level prior to next dose; and then 4 h post morning dose
>2.0	Yes (until level < 0.5)	Decrease 40%	Trough level prior to next dose, until Level < 0.5, and then 4 h post Morning dose

kidney function should be monitored with the anti-FXa assay carefully to prevent drug retention [132]. While there are several formulations of LMWH available, enoxaparin is the one most commonly used. Unlike heparin, LMWH is only partially reversed by protamine sulfate [134].

Warfarin is an oral vitamin-K antagonist that inhibits the carboxylation of the vitamin K-dependent FII, FVII, FIX and FX by blocking the activity of the enzyme vitamin K epoxide reductase complex subunit 1 (VKORC1) in the vitamin K cycle [135]. Therefore, the production of carboxylated factors, which are the active forms of these coagulation proteins, is depleted. The effect of warfarin can be reversed by vitamin K. To date, oral vitamin K inhibitors constitute the main class of oral anticoagulants widely used in children (Table 33.6). However, there are limitations for using warfarin in children: the drug level, which is monitored by international normalization ratio (INR), can be affected by many foods and other drugs; it takes a longer time than heparin or LMWH for patients to reach a therapeutic drug level; no liquid preparation is available; and its use is not recommended in infants [125, 126].

A summary of conventional anticoagulation in children is shown in Table 33.7.

Table 33.6 Warfarin loading doses (days 2–4)

	0.2 mg/kg PO, daily; maximum 5 mg	
Loading dose	0.1 mg/kg; with liver dysfunction, Fontan procedure, or severe renal impairment	
INR	1.1–1.3	Repeat initial loading dose
INR	1.4–3.0	50% of initial loading dose
INR	3.1–3.5	25% of initial loading dose
INR	>3.5	Hold until INR <3.5, then restart at 50% less than previous dose

Table 33.7 Conventional anticoagulant in children

	Heparin	Enoxaparin	Warfarin
Route of administration	Intravenous	Subcutaneous	Oral
Treatment dose	Bolus 75–100 units/kg/dose then: Age less than 1 year: 28 units/kg/dose Age 1 year and more: 20 units/kg/dose	Age less than 2 months: 1.75 mg/kg/dose Age 2 months and more: 1 mg/kg/dose	0.2 mg/kg/dose
Administration interval for treatment dose	Bolus followed by continuous infusion	Every 12 h	Once daily
Target range	Anti-FXa for heparin 0.35–0.70 U/mL APTT which correlates to anti-FXa at therapeutic level	Anti-FXa for enoxaparin 0.5–1.0 U/mL	INR 2.0–3.0
Half-life	30 min	6 h	42 h
Anti-thrombin dependence	Yes	Yes	No
Antidote	Protamine	Protamine (partial)	Vitamin K
Elimination	Renal	Renal	Liver
Bleeding risk	1.5–24%	0.8–5% (major bleeding)	0.05–12.2%/year (major bleeding)
Other complications	Heparin-induced thrombocytopenia (HIT) (0.3–1.0%) Osteoporosis (rare)	No report of HIT and osteoporosis in children	Warfarin- induced skin necrosis (0.01–0.1%) Hair loss (rare) Tracheal calcification (rare)

Table 33.8 Anticoagulation duration in children

VTE type	Neonates	Infants	Childhood	Level of evidence
CNS	0–6 months	0–6 months	3–12 months	2C
Non-CNS				
Provoked[a], symptomatic	6 weeks–3 months	6 weeks–3 months	3 months	2C
Unprovoked, symptomatic	6–12 months	6–12 months	6–12 months	2C

VTE venous thromboembolism, *CNS* central nervous system
Data from Monagle [80] and Monagle [64]
[a]Provoked includes central venous catheter (CVC)-related events. In those instances, if the CVC remains *in situ* after the end of anticoagulation, prophylaxis until the catheter is removed is recommended (please, see Table 33.4 for doses)

Adults with provoked VTE are treated for 3 months, while anticoagulation in unprovoked VTE is typically indefinite [136–138]. In children, anticoagulation duration is summarized in Table 33.8

Heparin-induced thrombocytopenia (HIT) is a clinical-laboratory entity where an immunological response against heparin and platelet factor-4 creates a hypercoagulable state. HIT is suspected when patients who receive heparin develop thrombocytopenia within 5–10 days after heparin treatment accompanied by a new episode or progression of TE.

Three additional major groups of anticoagulants are used in current adult practice with a high clinical suspicion of HIT: direct thrombin inhibitors (DTI, parenteral: bivalirudin and argatroban), indirect FXa inhibitor (parenteral: fondaparinux), and a direct FXa inhibitor (parenteral: danaparoid).

Bivalirudin, argatroban, and danaparoid can be used for children requiring hemodialysis who develop HIT, but most dosing recommendations have been extrapolated from the adult literature. There are only a few studies including children on hemodialysis or continuous renal replacement therapy with HIT [139–144]. The available pediatric doses that have been reported derive mostly from children undergoing surgery under cardiopulmonary bypass (CPB) who had also been diagnosed with HIT [145–150]. Of note, bivalirudin or argatroban can be monitored by the activated partial thromboplastin time (aPTT), which can be confounded in patients with disseminated intravascular coagulation (DIC), liver dysfunction, or a lupus anticoagulant. In such instances, danaparoid or fondaparinux may be preferred [151–154]. The summary of parenteral anticoagulants available for treatment of HIT in children requiring hemodialysis is shown in Table 33.9.

New oral anticoagulants (NOAC), or direct oral anticoagulants (DOAC), including the DTI dabigatran etexilate and the direct anti-Xa inhibitors apixaban, betrixaban, edoxaban, and rivaroxaban, have been approved in adult patients. Recently, rivaroxaban has also been approved by the Food and Drug Administration and Health Canada for the treatment of acute VTE in children, and dabigatran has been approved by the European Medicines Agency. A summary of the NOAC/DOAC under investigation in children is listed in Table 33.10.

Thrombolytic therapy is used when immediate thrombus lysis is required, such as life-, limb- or organ threatening scenarios. Pulmonary embolism accompanied by hypotension (massive PE), extensive or progressive DVT of a lower limb, bilateral RVT, or failure of treatment with conventional anticoagulants are examples of pediatric cases when this therapy should be considered [155, 156]. Tissue plasminogen activator (tPA) has been the drug of choice in children [155] and is the recommended agent by the American College of Chest Physician, the British Committee for Standard in Haematology [125, 126], and the American Society of Hematology to be used for thrombolytic therapy in neonates and children. However, the risk of major bleeding can be as high as 11–18% and intracerebral hemorrhage has been reported in up to 1.5% of pediatric patients who receive this therapy. Therefore, some patients might not be ideal candidates for this type of treatment. Contraindications for thrombolytic therapy

Table 33.9 Anticoagulants that can be used for treatment of HIT in children requiring hemodialysis

	Fondaparinux	Bivalirudin [145, 147, 148]	Argatroban [145, 148–150]	Danaparoid [144, 145]
Route of administration	Subcutaneous	Intravenous	Intravenous	Intravenous
Treatment dose	0.1 mg/kg/dose, x1, and reassess subsequent doses based on anti-Xa levels	Loading dose 0.5–1.0 mg/kg, then continuous infusion 2.5 mg/kg/h	Loading dose 75–250 μg/kg, then continuous infusion with 0.1–24 μg/kg/min (average dose 1–5 μg/kg/min)	1000 U plus 30 U/kg in patients aged <10 years and 1500 plus 30 U/kg in patients aged 10–17 years, then subsequent dose adjusted by anti-Xa
Half-life	17–21 h	25–34 min	39–60 min	Approximately 25 h
Target range	0.5–1 U/mL peak level 3 h post-dose	ACT >200–400 s or APTT ratio 1.5–2 times of baseline	ACT >200–400 s or APTT ratio 1.5–2 times of baseline	Anti-Xa <0.3 U/mL pre-dialysis If anti-Xa 0.3–0.5 U/mL, then decrease dose by 250 U If anti-Xa >0.5 U/mL, then hold next dose
Elimination	Renal	Intravascular proteolysis	Liver	Renal
Antidote	None	None	None	None

Renal clearance (unchanged)	80%	36%	27%	50%	11%
PGP substrate	Yes	Yes	Yes	Yes	Yes
CYP3A4 substrate	No	Yes (~18%)	Yes (~25%)	No (<4%)	No (<1%)
Administration considerations	Do not open capsules; swallow whole	Administer with a meal (or up to 2 h after)	N/A	N/A	Administer with food
Usual effect on coagulation parameters at therapeutic doses	Increased dilute thrombin time and often increased aPTT. May increase PT	Increased anti-Xa and often increased PT. May increase aPTT	Increased anti-Xa. May increase PT and aPTT	Increased anti-Xa and PT. May increase aPTT	Increased anti-Xa. May increase PT and aPTT
Reversal agent	Idarucizumab (no published pediatric data; study ongoing). Partially removed by dialysis.	Prothrombin complex concentrate (limited pediatric data) or andexanet alfa (no pediatric data)	Prothrombin complex concentrate (very limited pediatric data) or andexanet alfa (no pediatric data)	Prothrombin complex concentrate (very limited pediatric data) or andexanet alfa (no pediatric data)	Prothrombin complex concentrate (very limited pediatric data) or andexanet alfa (no pediatric data)

include any type of previous operation within 10 days prior to therapy, severe asphyxia within 7 days prior to therapy, an invasive procedure within 3 days of therapy, seizures within 48 h of therapy, preterm newborns with gestational age less than 32 weeks and patients who are bleeding and are unable to maintain a platelet count >50–100 × 10^9/L and fibrinogen >1.0 g/L [155, 156].

There are two methods to administer thrombolytic therapy in children: systemic thrombolysis and catheter-directed thrombolysis. Two types of dosage of systemic thrombolysis have been published in children: high dose tPA, with doses ranging between 0.1 and 0.6 mg/kg/h for 6 h, and low dose tPA, with doses ranging between 0.01 and 0.06 mg/kg/h for 4–48 h. Even though lower doses have been claimed to have a lower incidence of therapy-associated bleeding [155, 156], the American College of Chest Physician recommends a dose of 0.5 mg/kg/h for 6 h [126].

For catheter-directed tPA therapy, there have been no randomized trials and very few prospective pediatric series in children [157]. Even though the risk of major bleeding is potentially smaller and the efficacy higher in patients who are treated with this modality (dose reduction of tPA to 0.015–0.2 mg/kg/h), there have been no comparisons regarding efficacy and safety in children [155, 156]. Currently, the use of catheter-directed thrombolysis in children depends on center availability, local protocol, and level of complexity of care delivered.

In summary, in the last decade, there has been tremendous progress in the recognition and care of children affected by VTE, which includes children with underlying renal conditions.

Conclusion

Children with renal disease may have disordered hemostasis, resulting in a risk of either bleeding or clotting. Normal hemostasis in children must be understood by the clinician in order to determine whether, in a child with renal disease, therapeutic intervention to prevent abnormal bleeding or clotting is prudent. Unfortunately, there are few properly designed studies in children with renal disease providing guidelines for best practice relating to diagnosis and treatment of disordered hemostasis.

Acknowledgments We would like to acknowledge the past contributions of the late Dr. Patricia Massicotte and Mary Bauman for their work in the original chapter published in the first edition, for which some of the content was utilized for this current chapter.

Differential Diagnosis and Management of Fluid, Electrolyte and Acid-Base Disorders

Giacomo D. Simonetti, Sebastiano A. G. Lava, Gregorio P. Milani, and Mario G. Bianchetti

Introduction

In this chapter, the disturbances of fluid, electrolyte and acid-base balance will be addressed in different subchapters that deal with water, salt, K^+, acid-base, Ca^{++}, Mg^{++}, and phosphate. This traditional presentation is didactically relevant. It is worth mentioning, however, that more than one disturbance in fluid, electrolyte and acid-base homeostasis often concurrently occurs in the same subject.

Overall, the etiology of fluid, electrolyte and acid-base disorders is straightforward, since the most commonly occurring causes are easily recognized on clinical grounds. In some cases, however, the cause is not readily apparent, and a comprehensive systematic approach is recommended. The diagnostic approach to initially unexplained "isolated" disturbances involving the fluid, electrolyte and the acid-base balance should include both very careful history and clinical examination as well as the concurrent assessment of an extended "electrolyte spectrum". In the setting of initially unclassified and apparently "isolated" disturbances involving the fluid, electrolyte and acid-base balance, the concomitant measurement in blood of pH, pCO_2, HCO_3^-, Na^+, K^+, Cl^-, Ca^{++} (either total or ionized), Mg^{++}, inorganic phosphate, alkaline phosphatase, total protein level (or albumin), uric acid, urea and creatinine is advised.

Water and Salt

Introduction

Body Fluid Compartments

Water accounts for ≈50–75% of the body mass. The most significant determinants of the wide range in water content are age and gender: (a) the

F. Schaefer, L. A. Greenbaum (eds.), *Pediatric Kidney Disease*,
https://doi.org/10.1007/978-3-031-11665-0_34

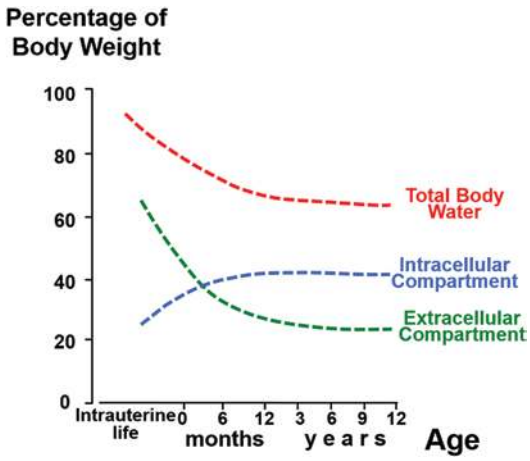

Fig. 34.1 Influence of age on the subdivision of total body water, intracellular fluid and extracellular fluid. For clinical purposes, "the rule of 3" is suggested: (1) total body water makes up 2/3 of the body mass; (2) the intracellular compartment contains 2/3 of the total body water; (3) the extracellular compartment is further subdivided into the interstitial and the intravascular compartments (blood volume), which contain 2/3 and 1/3 of the extracellular fluid, respectively

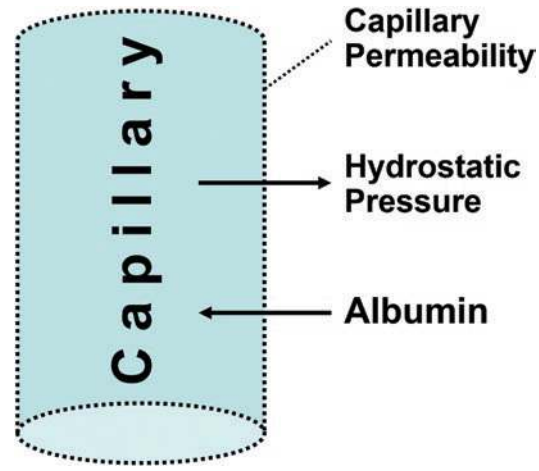

Fig. 34.2 Distribution of ultrafiltrate across the capillary membrane. The barrel-shaped structure represents a capillary. A high hydrostatic pressure or increased capillary permeability causes fluid to leave the vascular space. By contrast, an increased intravascular albumin concentration (and, therefore, an increased oncotic pressure) causes fluid to enter the vascular space

water content of a newborn, an adolescent and an elderly man are ≈75, ≈60 and ≈50%; (b) after puberty males generally have 2–10% higher water content than females (Fig. 34.1). The intracellular compartment contains about two-third of the total body water and the remaining is held in the extracellular compartment. The solute composition of the intracellular and extracellular fluid differs considerably because the sodium pump (=Na^+-K^+-ATPase) maintains K^+ in a primarily intracellular and Na^+ in a primarily extracellular location. Consequently, K^+ largely determines the intracellular and Na^+ the extracellular compartment [1–4]. The extracellular compartment is further subdivided into the interstitial and the total intravascular compartments (total blood volume), which contain ≈2/3 and ≈1/3 of the extracellular fluid [1–4], respectively (the transcellular fluid compartment, which comprises the digestive, cerebrospinal, intraocular, pleural, peritoneal and synovial fluids, will not be further addressed in this review).

The size of the total intravascular compartment is determined by the overall size of the extracellular fluid compartment and by the Starling forces. Three major forces control the distribution of fluids across the capillary membrane (Fig. 34.2): (a) the hydrostatic pressure, which causes fluids to leave the vascular space, and; (b) the higher concentration of proteins in the intravascular compartment as compared with that in interstitial fluid, which causes fluids to enter the vascular space. This force, which is called oncotic pressure, is due both to the concentration gradient of albumin (blood proteins other than albumin account for 50% of the weight of proteins in blood but only for 25% of the oncotic pressure) as well to the fact that albumin is anionic and therefore attracts cations (largely Na^+) into the vascular compartment (Gibbs-Donnan effect). (c) Capillary permeability, which is a further modulator of the distribution of fluids across the capillary membrane (and can be increased, for example, during inflammatory states like infection, post-operatively or in the context of an idiopathic capillary leak syndrome).

Recent data suggest that an extrarenal system might also contribute to sodium homeostasis. Sodium might be stored on negatively charged glycosaminoglycans in the skin interstitium,

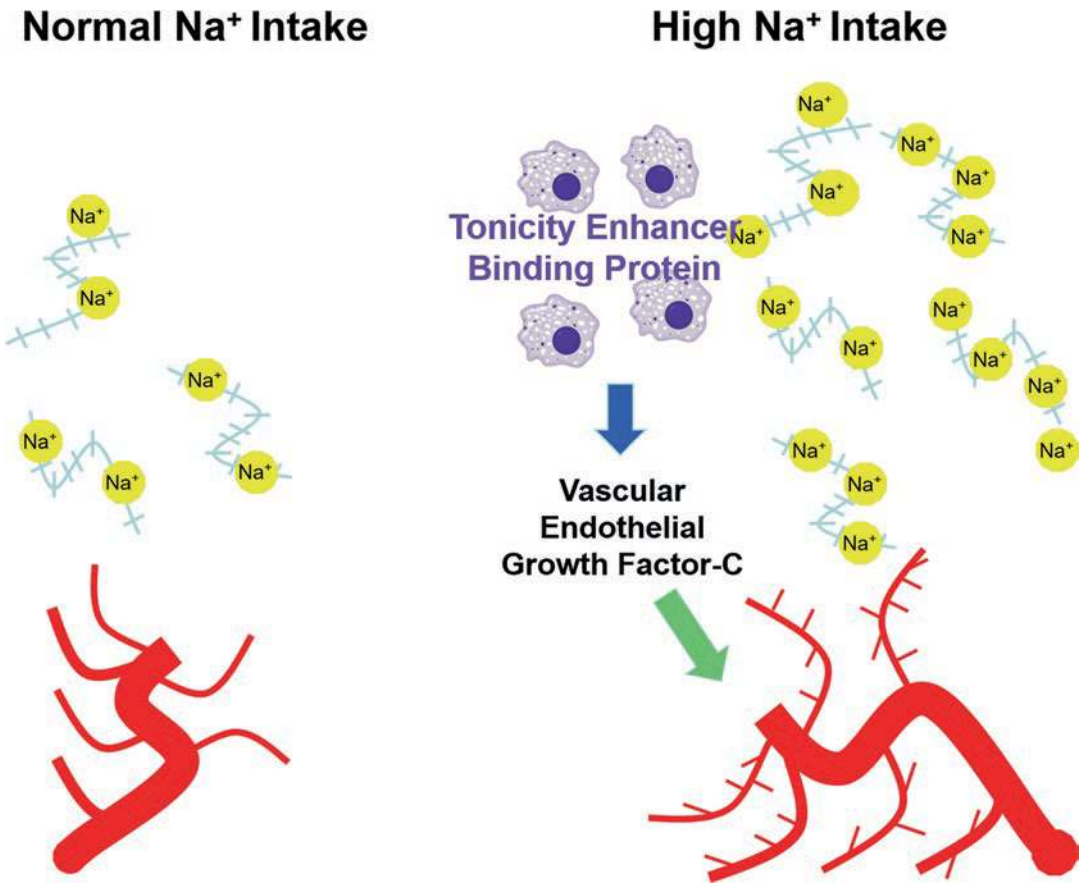

Fig. 34.3 Sodium is stored on negatively charged glycosaminoglycans in the skin interstitium. Excess sodium modulates lymphangiogenesis, and osmotically inactive sodium accumulates in the skin interstitium, binding proteoglycans. Excess sodium recruits macrophages, and subsequently activates within subcutaneous macrophages (cells with blue nucleus) a transcription factor, tonicity-enhanced binding protein, which in turn induces the production of the angiogenic protein vascular endothelial growth factor-C. Vascular endothelial growth factor-C stimulates lymphatic vessel (red) growth and creates a new fluid compartment, which buffers the increased body sodium (yellow) and ameliorates the tendency to excess body fluid linked with excess salt intake [5–7]

becoming osmotically inactive [5]. The skin interstitium might therefore represent a sort of fluid-buffering system, able to store sodium without commensurate water retention and potentially limiting accumulation of excess body fluid following high salt intake (Fig. 34.3) [6, 7].

Effective Circulating Volume

The total intravascular compartment is subdivided into the effective (≈ arterial) and the ineffective (≈ venous) compartment. Effective circulating volume denotes the part of the total intravascular compartment that is in the arterial system and is effectively perfusing the tissues. The effective circulating volume is biologically more relevant than the total intravascular (respectively the ineffective) compartment and usually varies directly with the extracellular fluid volume. As a result, the regulation of extracellular fluid balance (by alterations in urinary Na^+ excretion) and the maintenance of the effective circulating volume are intimately related. Na^+ loading will tend to produce volume expansion, whereas Na^+-loss (e.g., due to vomiting, diarrhea, or diuretic therapy) to volume depletion. The body responds to changes in effective circulating volume in two steps: (a) the change is sensed by the volume receptors that are located in the cardio-

pulmonary circulation, in the carotid sinuses and aortic arch, and in the kidney; (b) these receptors activate effectors that restore normovolemia by varying vascular resistance, cardiac output, and renal water and salt excretion. In brief, the non-renal receptors primarily govern the activity of the sympathetic nervous system and natriuretic peptides, whereas the renal receptors affect volume balance by modulating the renin-angiotensin II-aldosterone system [1–4].

In some settings the effective circulating volume is independent of the extracellular fluid volume. For example, among patients with heart failure the extracellular fluid volume is increased but these patients are effectively volume depleted due to the low volume of blood pumped by the heart [1–4].

Blood Osmolality: Measurement of Sodium

Osmolality is the concentration of all solutes in a given weight of water (the similar concept of osmolarity denotes the concentration of all of the solutes in a given volume of water). The total (or true) blood osmolality is equal to the sum of the osmolalities of the individual solutes in blood. Most osmoles in blood are Na^+ salts, with lesser contributions from other ions, glucose, and urea. However, under normal circumstances, the osmotic effect of the ions in blood can usually be estimated as two times the Na^+ concentration. *Blood osmolality* (in mosm/kg H_2O) can be measured directly (via determination of freezing point depression) or estimated from circulating Na^+, glucose and urea (in mmol/L[1]) as follows [3, 4, 8–12]:

$$\left(Na^+ \times 2\right) + \text{glucose} + \text{urea}$$

The *effective blood osmolality*, known colloquially as blood tonicity, is a further clinically significant entity, which denotes the concentration of solutes impermeable to cell membranes (Na^+, glucose, mannitol) and are therefore restricted to the extracellular compartment (osmoreceptors sense effective blood osmolality rather than the total blood osmolality). These solutes are effective because they create osmotic pressure gradients across cell membranes leading to movement of water from the intracellular to the extracellular compartment. Solutes that are permeable to cell membranes (urea, ethanol, methanol) are ineffective solutes because they do not generate osmotic pressure gradients across cell membranes and therefore are not associated with such water shifts. Glucose is a unique solute because, at normal concentrations in blood, it is actively taken up by cells and therefore acts as an ineffective solute, but under conditions of impaired cellular uptake (like diabetes mellitus) it becomes an effective extracellular solute.

Since no direct measurement of effective blood osmolality (which is biologically more important than the total or true blood osmolality) is possible, the following equations are used to calculate this entity [3, 4, 8–12]:

$$\left(Na^+ \times 2\right) + \text{glucose}$$

$$\text{measured total blood osmolality} - \text{urea}$$

Plasma normally consists of about 93% water and 7% solids (proteins and lipids). Electrolytes are dissolved exclusively in the water portion of plasma. Blood Na^+ (normal range between 135 and 145 mmol/L) can be determined either by indirect or direct potentiometry. The two techniques show good agreement as long as protein and lipid concentrations are normal. However, while assessed by indirect potentiometry in diluted samples, increased protein or lipid concentrations result in spuriously low Na^+ (pseudo-hyponatraemia) whereas decreased protein or lipid concentrations result in spuriously high Na^+ (pseudo-hypernatraemia). A spuriously normal Na^+ value (pseudonormonatraemia) might also occur [13]. Direct potentiometry measures Na^+ in undlitued samples and avoids this problem. Therefore, it is the currently recommended technique [14].

Flame photometry, the traditional assay for circulating Na^+, measures the concentration of Na^+ per unit volume of solution, with a normal

[1]To obtain glucose in mmol/L divide glucose in mg/dL by 18. To obtain urea in mmol/L divide urea nitrogen in mg/dL by 2.8 or urea in mg/dL by 6.0.

range between 135 and 145 mmol/L. In fact, Na^+ is dissolved in plasma water, which accounts for 93% of the total volume of plasma. Ion selective electrodes, that have replaced flame photometry in most laboratories, determine the activity of Na^+ in plasma water, which ranges between 145 and 155 mmol/L (that, multiplied by 0.93, gives the traditional range of 135–145 mmol/L). For convenience, laboratories routinely apply a correction factor so that the reported values still correspond to the traditional normal range of 135–145 mmol/L. A kind of "pseudohyponatremia" caused by expansion of the non-aqueous phase of plasma—for example, due to hyperlipidemia or paraproteinemia—is no longer seen because determination by selective electrodes in undiluted samples is not affected by this (the recommended name for this quantity is ionized sodium). Although, strictly speaking, a Na^+ concentration outside the range of 135–145 mmol/L denotes dysnatremia, clinically relevant hypo- or hypernatremia is mostly defined as a concentration outside the range of 130–150 mmol/L [3, 4].

Dehydration and Extracellular Fluid Volume Depletion

Although dehydration[2] semantically and in general usage means loss of water, in physiology and medicine the term denotes both a loss of water and salt. Depending on the type of pathophysiologic process, water and salts (primarily Na^+Cl^-) may be lost in physiologic proportion or lost disparately, with each type producing a somewhat different clinical picture, designated as normotonic (mostly isonatremic), hypertonic (mostly hypernatremic), or hypotonic (always hyponatremic) dehydration. Dehydration develops when fluids are lost from the extracellular space at a rate exceeding intake. The most common sites for extracellular fluid loss are (1) the intestinal tract (diarrhea, vomiting, or bleeding), (2) the skin (fever, excessive sweating or burns), and (3) the urine (osmotic diuresis, diuretic therapy, diabetes insipidus, or salt losing renal tubular disorders). More rarely, dehydration results from prolonged inadequate intake without excessive losses [3, 4, 8–12].

The risk for dehydration is high in children and especially infants for the following causes: (a) infants and children are more susceptible to infectious diarrhea and vomiting than adults; (b) there is a higher proportional turnover of body fluids in infants compared to adults (it is estimated that the daily fluid intake and outgo, as a proportion of extracellular fluid, is in infancy more than three times that of an adult, Fig. 34.4); (c) young children do not communicate their need for fluids or do not independently access fluids to replenish volume losses.

Dehydration reduces the effective circulating volume, therefore impairing tissue perfusion. If not rapidly corrected, ischemic end-organ damage occurs.

Three groups of symptoms and signs occur in dehydration: (a) those related to the manner in which fluids loss occurs (including diarrhea, vomiting or polyuria); (b) those related to the electrolyte and acid-base imbalances that sometimes accompany dehydration; and (c) those directly due to dehydration. The following discussion will focus on the third group.

When assessing a child with a tendency towards dehydration, the clinician needs to address the degree of extracellular fluid volume depletion. More rarely the clinician will address the laboratory testing and the type of fluid lost (extracellular or intracellular fluid).

Degree of Dehydration

It is crucial to correctly assess the degree of dehydration since severe extracellular fluid volume depletion calls for rapid isotonic fluid resuscita-

[2]The terms dehydration and extracellular fluid volume depletion are mostly used interchangeably. However, these terms denote conditions resulting from different types of fluid losses. Volume depletion refers to any condition in which the effective circulating volume is reduced. It is produced by salt and water losses (as with vomiting, diarrhea, diuretics, bleeding, or third space sequestration). Strict sense dehydration refers to water loss alone. The clinical manifestation of dehydration is often hypernatremia. The elevation in serum Na^+ concentration, and therefore effective blood osmolality, pulls water out of the cells into the extracellular fluid. However, much of the literature does not distinguish between the two terms.

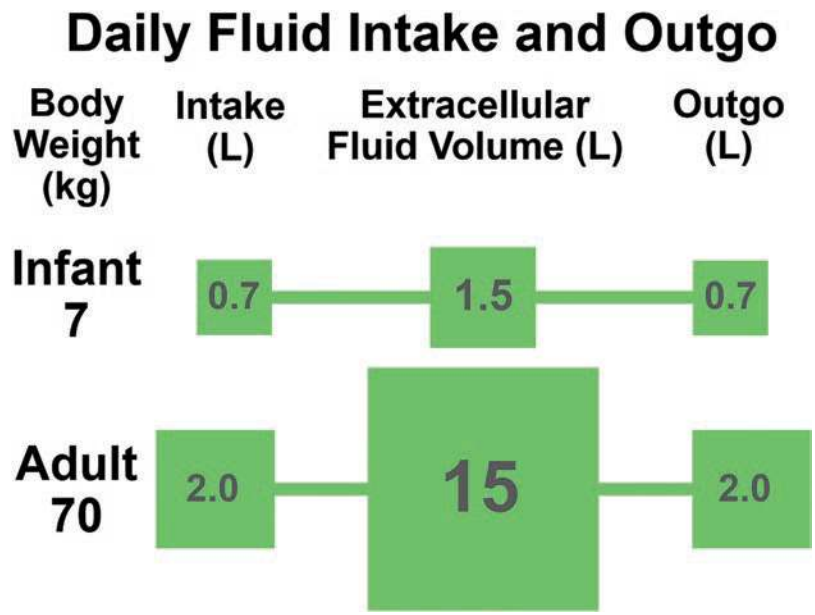

Fig. 34.4 Fluid turnover in infancy and adulthood. There is a proportionally greater turnover of fluids and solutes in infants and children as compared with adults. The figure depicts fluid intake, extracellular fluid volume and fluid outgo (diuresis and perspiratio insensibilis) in a healthy 6-month-old infant weighing 7.0 kg (input represents ≈50% of extracellular fluid volume) and in a healthy adult weighing 70 kg (input represents ≈15% of extracellular fluid volume)

tion. Dehydration is most objectively measured as an acute change in weight from baseline (acute loss of body weight reflects the loss of fluid, not lean body mass; thus, a 1.3 kg weight loss reflects the loss of 1.3 liters of fluid). In most cases, however, an accurate recent weight is unavailable.

As a result, a pertinent history and a number of findings on physical examination are used to help assess dehydration. The signs and symptoms of dehydration include static (reduced general appearance, dry mucous membranes, reduced skin turgor, sunken eyes and fontanelle, colder extremities) and dynamic signs (delayed capillary refill, deep respiration with or without increased respiratory rate, tachycardia, weak peripheral pulses, reduced blood pressure, reduced urine output, reduced or absent tears' production). Skin turgor, sometimes referred to as skin elasticity, is a sign commonly used to assess the degree of hydration (the skin on the back of the hand, lower arm, or abdomen is grasped between two fingers, held for a few seconds and then released: skin with normal turgor snaps rapidly back to its normal position but skin with decreased turgor remains elevated and returns slowly to its normal position). However, decreased skin turgor is a late sign in dehydration that is associated with moderate or, more frequently, severe dehydration. Like decreased skin turgor, arterial hypotension is a late sign in hypovolemia (in children with minimal to mild dehydration blood pressure is often slightly increased).

Several attempts have been made to determine a measure of dehydration by using combinations of clinical findings. In children ≤4 years of age with a diagnosis of acute diarrhea or vomiting, four clinical items ((a) general appearance, (b) eyes, (c) mucous membranes, (d) tears), which may be summed up to a total score ranging from 0 to 8, accurately estimate dehydration (Table 34.1) [15].

Laboratory Testing and the Type of Fluid Lost

Laboratory testing can confirm the presence of dehydration. The *fractional clearance of* Na^+ (which measures the amount of filtered Na^+ that is excreted in the urine)

$$\frac{\text{Urinary } Na^+ \times \text{Circulating creatinine}}{\text{Circulating } Na^+ \times \text{Urinary creatinine}}$$

is $<0.5 \times 10^{-2}$ (or <0.5%) and the *urine spot* Na^+ *concentration* <30 mmol/L (unless the disease underlying dehydration is renal).

Furthermore, in dehydration, the urine is concentrated with an *osmolality* >450 mosm/kg

Table 34.1 "4-item 8-point rating scale" clinical dehydration scale. The score consists of 4 clinical items, which may be summed for a total score ranging from 0 to 8. The final 3 categories are no or minimal dehydration (<3%; score of 0), mild dehydration (≥3% to <6% dehydration; score of 1–4), and moderate to severe dehydration (≥6% dehydration; score of 5–8)

	Score		
Characteristic	0	1	2
General appearance	Normal	Thirsty, restless or lethargic but irritable when touched	Drowsy, limp, cold, or sweathy; comatose or not
Eyes	Normal	Slightly sunken	Very sunken
Mucous membranes (tongue)	Moist	Sticky	Dry
Tears	Tears	Decreased tears	Absent tears

H_2O. The urinary concentration is measured with an osmometer or fairly estimated, in the absence of proteinuria and glucosuria, from the specific gravity, as determined by refractometry (dipstick assessment of specific gravity is unreliable), as follows:

$$(\text{specific gravity} - 1000) \times 40$$

Furthermore, laboratory testing can detect associated electrolyte and acid-base abnormalities but determination of circulating electrolytes and acid-base balance is typically limited to children requiring intravenous fluids. These children are more severely volume depleted and are therefore at greater risk for dyselectrolytemias. Laboratory testing is less useful for assessing the degree of volume depletion.

- *Bicarbonatemia* ≤17.0 mmol/L is considered by some a useful laboratory test to assess dehydration.
- The *blood urea* level might be a further good biochemical marker of dehydration because it reflects both the decreased glomerular filtration rate and the enhanced Na^+ and water reabsorption in the proximal tubule. Unfortunately, this test is of limited usefulness since it can be increased by other factors such as bleeding or tissue breakdown (on the other side the rise can be minimized by a concomitant decrease in protein intake).
- The *serum* Na^+ concentration varies with the relative loss of solute to water. Changes in Na^+ concentration play a pivotal role in determining the type of fluid depletion (Fig. 34.5):
  - Hyponatremic (and hypotonic) dehydration: Here, hyponatremia reflects net solute loss in excess of water loss. This does not occur directly, as fluid losses such as diarrhea are not hypertonic. Usually solute and water are lost in proportion, but water is taken in and retained in the context of hypovolemia-induced secretion of antidiuretic hormone. Since body water shifts from extracellular fluid to cells under these circumstances, and since signs of dehydration mostly depend on effective intravascular volume and tissue perfusion, signs of dehydration easily become profound.
  - Normonatremic (and isotonic) dehydration: in this setting, solute is lost in proportion to water loss.
  - Hypernatremic (and hypertonic) dehydration: this setting reflects water loss in excess of solute loss. Since body water shifts from intracellular to extracellular fluid under these circumstances, these children have less signs of dehydration for any given amount of fluid loss than do children with normonatremic (or normotonic) dehydration and especially those with hyponatremic dehydration. Clinical assessment can therefore underestimate the degree of dehydration in these children.
- *Bioimpedance devices* can also be helpful in determing hydration status in children as they measure fluid deficit in relation to extracellular water content or body weight, or consider absolute resistance [16].

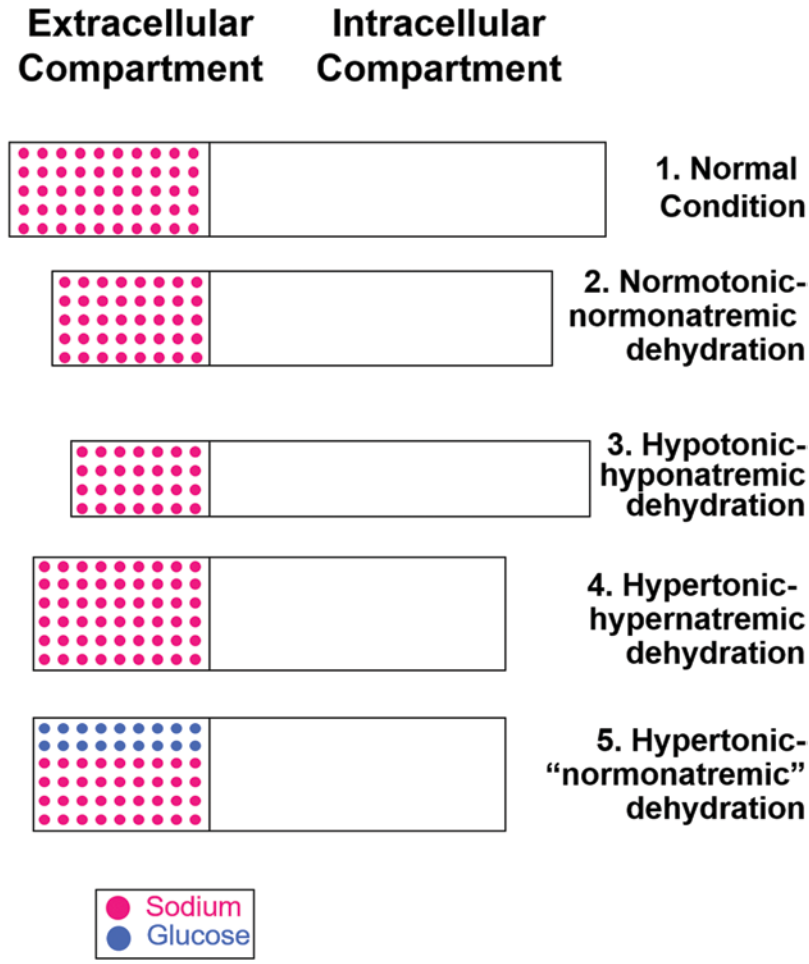

Fig. 34.5 Extracellular and intracellular compartments in children with dehydration. Normally, the extracellular compartment makes up approximately 20% and the intracellular 40% of the body weight (panel 1 of the figure). The second, third and fourth panels depict the relationship between extracellular and intracellular compartment in three children with dehydration in the context of an acute diarrheal disease: dehydration is normotonic-normonatremic in the first (panel 2), hypotonic-hyponatremic (mainly extracellular fluid losses) in the second (panel 3), and hypernatremic (mainly intracellular fluid losses) in the third child (panel 4). The lower panel depicts the relationship between extracellular and intracellular compartment (mainly intracellular fluid losses) in a child with dehydration in the context of diabetic ketoacidosis (hypertonic-"normonatremic" dehydration; the brackets indicate that in the context of diabetic ketoacidosis the concentration of circulating sodium is normal or even reduced). In each panel the red circles denote sodium and blue circles impermeable solutes that do not move freely across cell membranes (in the present example glucose). For reasons of simplicity, no symbols are given for potassium, the main intracellular cation

Dysnatremia

Consequences, Symptoms and Diagnostic Work Up

Under normal conditions, blood Na^+ concentration is maintained within the narrow range of 135–145 mmol/L despite great variations in water and salt intake. Na^+ and its accompanying anions Cl^- and HCO_3^- account for 90% of the extracellular effective osmolality. The main determinant of the Na^+ concentration is the plasma water content, itself determined by water intake (thirst or habit), "insensible" losses (such as metabolic water, sweat and respiration), and urinary dilution. The last of these is under most circumstances crucial and predominantly determined by anti-diuretic hormone. In response to this hormone, concentrated urine is produced. Dysnatremias produce central nervous system dysfunction. While hyponatremia may induce brain swelling, hypernatremia may induce brain shrinkage, yet the clinical features elicited by opposite changes in tonicity are remarkably similar [3, 4, 8–12].

Hyponatremia

Introduction

Hyoponatremia is classified (Fig. 34.6) according to the extracellular fluid volume status, as either "hypovolemic" (= depletional) or "normo-hypervolemic" (= dilutional). Vasopressin is released both in children with low effective circulating volume, the most common cause of hyponatremia in everyday clinical practice, as well as

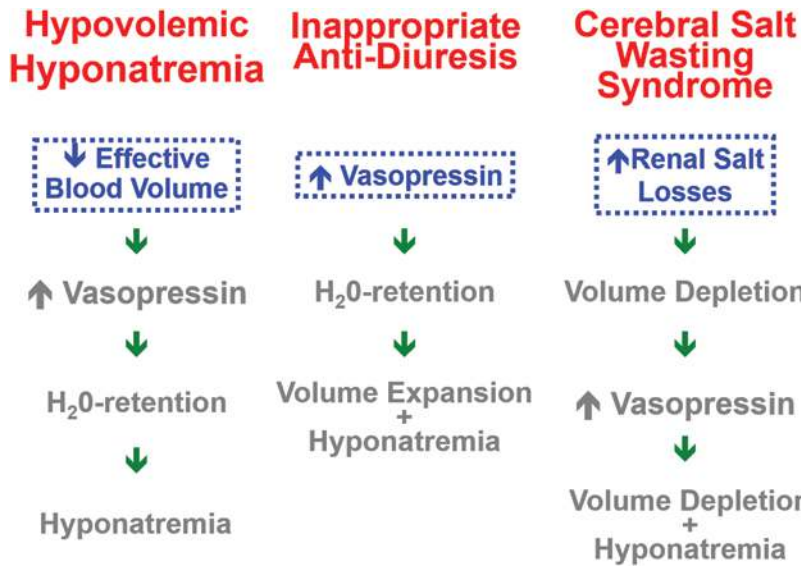

Fig. 34.6 Extracellular fluid volume status in children with hyponatremia. Hyoponatremia is classified according to the extracellular fluid volume status, as either hypovolemic (= depletional) or normo-hypervolemic (= dilutional). In most cases (left panel) hyponatremia results from a low effective arterial blood volume and is termed hypovolemic hyponatremia (the term appropriate anti-diuresis is sometimes used in this circumstance). The true syndrome of inappropriate anti-diuresis results from persistently high levels of vasopressin or, more rarely, activation of its renal receptor (middle panel). Cerebral salt-wasting syndrome is a further form of hyponatremia that sometimes develops in patients with intracranial disorders (right panel). In this condition, renal salt-wasting is the primary defect, which is followed by volume depletion leading to a secondary rise in vasopressin

in those with normo-hypervolemic hyponatremia. In hypovolemic hyponatremia, vasopressin release is triggered by the low effective arterial blood volume (this condition is also referred to as 'syndrome of appropriate anti-diuresis'). In dilutional hyponatremia, the primary defect is a euvolemic, inappropriate increase in circulating vasopressin levels (this condition is also termed 'syndrome of inappropriate anti-diuresis').

Assessing the cause of hyponatremia may be straightforward if an obvious cause is present (for example in the setting of vomiting or diarrhea) or in the presence of a clinically evident extracellular fluid volume depletion [3, 4, 8, 11, 12]. Sometimes, however, assessing the volume status and distinguishing hypovolemic from normo-hypervolemic hyponatremia may not be straightforward. In such cases, the urine spot Na^+ and the fractional Na^+ clearance are helpful, as patients with dilutional hyponatremia have a urinary Na^+ >30 mmol/L (and fractional Na^+ clearance >0.5%), whereas those with extracellular fluid volume depletion (unless the source is renal) will have a urinary Na^+ <30 mmol/L (and fractional Na^+ clearance <0.5%). Since effective blood osmolality is mostly low in hyponatremia, and urine is less than maximally dilute (inappropriately concentrated), blood and urine osmolalities, although usually measured, are rarely discriminant.

A decrease in Na^+ concentration and effective blood osmolality causes movement of water into brain cells and results in cellular swelling and raised intracranial pressure. Nausea and malaise are typically seen when the Na^+ level acutely falls <125–130 mmol/L. Headache, lethargy, restlessness, and disorientation follow, as its concentration falls <115–120 mmol/L. With severe and rapidly evolving hyponatremia, seizures, coma, permanent brain damage, respiratory arrest, brain stem herniation, and death may occur. In more gradually evolving hyponatremia, the brain self regulates to prevent swelling over hours to days by transport of, firstly, Na^+, Cl^-, and K^+ and, later, solutes like glutamate, taurine, myoinositol, and glutamine from intracellular to extracellular compartments. This induces water loss and ameliorates brain swelling, and hence leads to few symptoms in subacute and chronic hyponatremia.

Evaluating the Cause

In normovolemic subjects, the primary defense against developing hyponatremia is the ability to dilute urine and excrete free-water [3, 4, 8, 11, 12]. Rarely is excess ingestion of free-water alone the cause of hyponatremia. It is also rare to develop hyponatremia from excess urinary Na^+ losses in the absence of free-water ingestion. In order for hyponatremia to develop, both a relative excess of free-water as well as an underlying condition that impairs the ability to excrete free-water are typically required. Renal water handling is primarily under the control of vasopressin, which is released from the posterior pituitary and impairs water diuresis (hence the synonymous name "anti-diuretic hormone") by increasing the permeability to water in the collecting tubule.

There are osmotic, hemodynamic and non-hemodynamic stimuli for release of vasopressin. In most cases, hyponatremia develops when the body attempts to preserve the extracellular fluid volume at the expense of circulating Na^+ (therefore, a hemodynamic stimulus for vasopressin production overrides an inhibitory effect of hyponatremia). However, there are further stimuli for production of vasopressin in hospitalized children that make virtually any hospitalized patient at risk for hyponatremia (Table 34.2).

Some specific causes of hypotonic hyponatremia deserve further discussion.

- **Hospital-acquired hyponatremia** is most often seen in the postoperative period or in association with a reduced effective circulating volume.
- Postoperative hyponatremia is a serious problem in children, which sometimes is caused by a combination of nonosmotic stimuli for release of anti-diuretic hormone, such as pain, nausea, stress, narcotics, and edema-forming conditions. Subclinical depletion of the effec-

Table 34.2 Causes of hypotonic hyponatremia in childhood

Hypovolemic	Normovolemic (or hypervolemic)
Intestinal salt loss – Diarrheal dehydration – Vomiting, gastric suction – Fistulae – Laxative abuse	*Increased body water* – Parenteral hypotonic solutions – Exercise-associated hyponatremia – Habitual (and psychogenic) polydipsia
Transcutaneous salt loss – Cystic fibrosis – Endurance sport	*Non osmolar release of antidiuretic hormones*[a] – Cardiac failure – Sever liver disease (mostly cirrhosis) – Nephrotic syndrome – Glucocorticoid deficiency – Drugs causing renal water retention – [Hypothyroidism][b]
Renal sodium loss – Mineralocorticoid deficiency (or resistance) – Diuretics – Salt wasting renal failure – Salt wasting tubulopathies (including Bartter syndromes) – Gitelman syndrome, and De Toni-Debré–Fanconi syndrome) – Cerebral salt wasting	*Syndrome of inappropriate anti-diuresis* – Classic syndrome of inappropriate secretion of antidiuretic – hormone – Hereditary nephrogenic inappropriate antidiuresis
Perioperative (e.g.: preoperative fasting, vomiting, third space losses)	*Reduced renal water loss* – Chronic renal failure – Oliguric acute renal failure

[a] Effective arterial blood volume mostly reduced
[b] Evidence supporting this association is rather poor

tive blood volume and administration of hypotonic fluids are currently considered the most important causes of postoperative hyponatremia.

– More rarely, hospital-acquired hyponatremia is seen in association with the syndrome of inappropriate anti-diuresis, which is caused either by elevated activity of vasopressin or, less commonly, by hyperfunction of its renal (= V2) receptor, independently of increased effective blood osmolality and hemodynamic stimulus (i.e.: reduced effective circulating volume). It is currently assumed that this condition results not only from dilution of the blood by free-water but also from inappropriate natriuresis. The syndrome of inappropriate anti-diuresis (Fig. 34.6) should be suspended in any child with hyponatremic hypotonia, a urine osmolality >100 mosmol/kg H_2O, a normal fractional Na^+ clearance (>0.5%), low normal or reduced uric acid level, low blood urea level and normal acid-base and K^+ balance.
– The longstanding assumption that hypontremia associated with meningitis or respiratory infections is caused by inappropriate antidiuresis is not substantiated by reports that adequately assessed the volume status. On the other hand, dysnatremia is frequently observed in many other community-acquired infections. Hyponatremia develops in approximately 50% of acute moderate gastroenteritis cases, often associated with metabolic acidosis and potassium disturbances. Up to 60% of infants with bronchiolitis tend to develop an isolated hyponatremia, while 70% of infants with pyelonephritis might develop hyponatremia. In these patients, metabolic acidosis and hyperkalemia are also often present, suggesting silent renal resistance to aldosterone [17].
– **Desmopressin**, a synthetic analogue of the natural anti-diuretic hormone, is used in central diabetes insipidus, in some bleeding disorders, in diagnostic urine concentration testing and especially in primary nocturnal enuresis with nocturnal polyuria. Desmopressin is generally regarded as a safe drug and adverse effects are uncommon. Nonetheless, hyponatremic water intoxication leading to convulsions has been reported as a rare side effect of desmopressin therapy in enuretic children. This complication mostly develops in subjects managed with the intranasal formulation ≤14 days after starting the medication, following excess fluid intake and during intercurrent illnesses (Table 34.3) [18].

Table 34.3 Drug-induced hyponatremia

Diuretics (thiazides more commonly than loop diuretics)
Drugs blocking the renin-angiotensin-aldosterone system (converting enzyme inhibitors, sartans or renin inhibitors)
Antidiuretic drugs
• ↑ **water permeability of the renal collecting tubule:** arginine-vasopressin, vasopressin analogues like desmopressin and oxytocin
• ↑ **antidiuretic hormone release,** ↑ **antidiuretic hormone action:** carbamazepine, lamotrigine, valproate, barbiturates, antidiabetic drugs (chlorpropamide, tolbutamide), clofibrate, colchicine, nicotine, vincristine, cyclophosphamide
• ↓ **synthesis of prostaglandins:** nonsteroidal anti-inflammatory drugs including salicylates, paracetamol
• **Mechanism unknown:** haloperidol, tricyclic antidepressants, selective serotonin-reuptake inhibitors, monoamine oxidase inhibitors, narcotics like morphine

– Male infants have been described with hyponatremia and laboratory features consistent with release of vasopressin but who had no measurable circulating levels of this hormone. This rare condition results from gain-of-function mutations of the X-linked receptor gene that mediates the renal response to vasopressin, resulting in persistent activation of the receptor. The condition, which has been termed **hereditary nephrogenic syndrome of inappropriate anti-diuresis**, represents a kind of mirror image of the X-linked nephrogenic diabetes insipidus, the result of loss-of-function genetic defects in the aforementioned renal receptor.
– **Cerebral salt wasting syndrome** is a peculiar form of depletional hyponatremia that sometimes occurs in patients with cerebral disease (Fig. 34.6). It mimics the syndrome of inappropriate anti-diuresis, except that salt-wasting is the primary defect with the ensuing volume depletion leading to a secondary release of vasopressin. Salt wasting of central origin might result from increased secretion of a natriuretic peptide with subsequent suppression of aldosterone synthesis. The distinction between cerebral salt wasting and inappropriate activity of vasopressin is not always simple since the true volume status is sometimes difficult to ascertain.
– **Endurance athletes** sometimes replace their diluted but Na^+-containing sweat losses with excessive amounts of severely hypotonic solutions: the net effect is a reduction in the circulating Na^+ level. The effect is likely compounded by a reduced renal function during exercise (such individuals may also be taking non-steroidal anti-inflammatory drugs, which can impair the excretion of free water).
– A tendency towards low normal blood Na^+ level is sometimes seen in children who drink excessively and present with polyuria and polydipsia. Usually the problem is simply one of habit, particularly in infants who are attached to a bottle (= **habitual polydipsia**). In childhood, polydipsia is rarely a symptom of significant psychopathology (= **psychogenic polydipsia**).
– Diuretics (thiazides more frequently than loop diuretics) and **drugs** that block the renin-angiotensin-aldosterone system (converting enzyme inhibitors, sartans or direct renin inhibitors) make up a common cause of hyponatremia (Table 34.3). More rarely, other drugs sometimes cause renal retention of fluids and therefore dilutional hyponatremia.

Hypernatremia

Introduction

Hypernatremia (Na^+ >145 mmol/L) reflects a net water loss or a hypertonic Na^+ gain, with inevitable hypertonicity [3, 4, 8–10]. Severe symptoms are usually evident only with acute and large increases in Na^+ concentration ≥160 mmol/L. Importantly, the sensation of thirst protecting against the tendency towards hypernatemia is absent or reduced in patients with altered mental status or with hypothalamic lesions and in infancy.

The cause of hypernatremia is almost always evident from the history. Determination of urine osmolality in relation to the effective blood osmolality and the urine Na^+ concentration helps

if the cause is unclear. Patients with diabetes insipidus present with polyuria and polydipsia (and not hypernatremia unless thirst sensation is impaired). Central diabetes insipidus and nephrogenic diabetes insipidus may be differentiated by the response to water deprivation (failure to concentrate urine) followed by desmopressin, causing concentration of urine uniquely in patients with central diabetes insipidus.

Non-specific symptoms such as anorexia, muscle weakness, restlessness, nausea, and vomiting tend to occur early. More serious signs follow, with altered mental status, lethargy, irritability, stupor, or coma. Acute brain shrinkage can induce vascular rupture, with cerebral bleeding and subarachnoid hemorrhage.

Evaluating the Cause

Two mechanisms protect against developing hypernatremia or increased effective blood osmolality: the ability to release vasopressin (and therefore to concentrate urine) and a powerful thirst mechanism. Release of vasopressin occurs when the effective blood osmolality exceeds 275–280 mosmol/kg H_2O and results in maximally concentrated urine when the effective blood osmolality exceeds 290–295 mosmol/kg H_2O. Thirst, the second line of defense, provides a further protection against hypernatremia and increased effective osmolality. If the thirst mechanism is intact and there is unrestricted access to free-water, it is rare to develop sustained hypernatremia from either excess Na^+ ingestion or a renal concentrating defect (Table 34.4).

Hypernatremia is primarily a hospital-acquired condition occurring in children who have restricted access to fluids. Most children with hypernatremia are debilitated by an acute or chronic disease, have neurological impairment, are critically ill or are born premature. Hypernatremia in the intensive care setting is common as these children are typically either intubated or moribund, and often are fluid restricted, receive large amounts of Na^+ as blood products or have renal concentrating defects from diuretics or renal dysfunction. The majority of hypernatremia results from the failure to administer sufficient free-water to children who are unable to care for themselves and have restricted access to fluids.

Two special causes of hypernatremia deserve some further discussion.

- A frequent cause of hypernatremia in the outpatient setting is currently **breastfeeding-associated hypernatremia**, which should more properly be labeled "not-enough-breastfeeding-associated hypernatremia" [19]. This condition occurs between days 7 and 15 in otherwise healthy term or near-term newborns of first-time mothers who are exclusively breast-fed. In all cases feeding had been

Table 34.4 Causes of hypernatremia in childhood

Hypovolemic	Normovolemic	Hypervolemic
Inadequate intake – Breast feeding hypernatremia – Poor access to water – Altered thirst perception (uncosciousness, mental impairment) **Intestinal salt loss** (diarrheal dehydration) **Renal water and salt loss** – Postobstructive polyuria – Diuretics – Diabetes insipidus (either primary or, more rarely, secondary[a]) – Medullary renal damage	**Hypodypsia** (essential hypernatremia) **Hyperventilation** **Fever**	**Inappropriate intravenous fluids** (e.g.: hypertonic saline, $NaHCO_3$) **Salt poisoning** (accidental, deliberate) **Primary aldosteronism** (and other conditions that cause low-renin hypertension)

[a] Secondary nephrogenic diabetes insipidus may develop as a complication of inherited renal diseases such as nephropathic cystinosis, Bartter and Gitelman syndromes and nephronophthisis

difficult to establish and the volume of milk ingested was likely to have been low. The underlying problem is water deficiency: Na^+ concentration raises predominantly as a result of low volume intake and a loss of water, demonstrating that inadequate feeding is the cause of hypernatremic dehydration. Monitoring postnatal weight loss provides an objective assessment of the adequacy of nutritional intake allowing targeted support to those infants who fail to thrive or demonstrate excessive weight loss (≥10% of birth weight).
– Diarrhea or vomiting are a further reason of hypernatremia in the outpatient setting, but are much less common than in the past, presumably due to the advent of low solute infant formulas and the increased use and availability of oral rehydration solutions.

Management

The discussion will exclusively focus on some features of parenteral hydration, and the management of hyponatremia with V2 anti-diuretic hormone receptor antagonists [3, 4, 8–12].

Maintenance and Perioperative Fluids

Intravenous maintenance fluids are designed to provide water and electrolyte requirements in a fasting patient. The prescription for intravenous maintenance fluids was originally described by Holliday (Table 34.5), who rationalized a daily H_2O requirement of 1700–1800 mL/m^2 body surface area and the addition of 3 and 2 mmol/kg body weight of Na^+ and K^+ respectively (approximating the electrolyte requirements and urinary excretion in healthy infants). This is the basis for the traditional recommendation that hypotonic intravenous maintenance solutions are ideal for children. This approach has subsequently been questioned because of the potential for these hypotonic solutions to cause hyponatremia. Surgical patients appear as the subgroup of children with the highest risk to develop severe hyponatremia with the use of hypotonic intravenous solutions, likely because they tend to be hypovolemic. Furthermore, traditional maintenance fluid recommendations may be much greater than actual water needs in children at risk of hyponatremia.

Most authors currently suggest (Table 34.5) that hyponatremia should be prevented by (a) using isotonic (usually normal saline, which contains NaCl 9 g/L) or near isotonic (usually Ringer's lactate) solutions and (b) reducing by ≈20% the daily volume of maintenance fluid to 1400–1500 mL/m^2 body surface area. Considering the potential for hypoglycemia in infancy, ringer's lactate or normal saline in 5% glucose in water (which contains glucose 50 g/L) is considered the safest fluid composition for most children.

Table 34.5 Intravenous maintenance fluids designed to provide water and electrolyte requirements in a fasting patient. Both the recommendation originally described by Holliday and the most recent recommendation are given. The addition of KCl 2 mmol/kg body weight is also recommended

	Holliday's recommendation	Current suggestion
Solution	5% dextrose in water supplemented with NaCl 3 mmol/kg body weight daily	Isotonic saline in 5% dextrose in water
Amount (mL/m^2 body surface area[a] daily)	1700–1800	1400–1500
Clinical practice	100 mL/kg body weight for a child weighing less than 10 kg[b] + 50 mL/kg for each additional kg up to 20 kg + 20–[25] mL/kg for each kg in excess of 20 kg	80 mL/kg body weight for a child weighing less than 10 kg[b] + 40 mL/kg for each additional kg up to 20 kg + 15–[20] mL/kg for each kg in excess of 20 kg

[a] The Mosteller's formula may be used to calculated the body surface area (in m^2): $\sqrt{\frac{\text{height (cm)} \times \text{body weight (kg)}}{3600}}$

[b] In children weighing ≤5.0 kg the daily parenteral water requirement is 120 mL/kg body weight

Dehydration

Oral rehydration therapy is currently the treatment of choice for children with minimal, mild or moderate dehydration due to diarrheal diseases. However, in the practice of pediatric emergency medicine, mainly because of rapidity, intravenous rehydration is a commonly used intervention for these children.

Treatment approaches to parenteral rehydration in the hospitalized child vary. There are numerous ways to estimate the degree of dehydration (the "4-item 8-point rating scale" is currently widely recommended; Table 34.1), to calculate fluid and electrolyte deficits, and to deliver the deficits to the patient. For many years, the recommendation was to accomplish 100% (or even less) replacement of the volume deficit during the first 24 h of treatment. More recently, the aim of treatment has generally been to accomplish a more rapid full repletion within ≤6 h. In many children with mild to moderate dehydration, especially those resistant to initial oral rehydration therapy, and in children with severe dehydration, we currently administer intravenous isotonic (or near isotonic) crystalloid solutions such as normal saline or lactate Ringer's as repeated boluses of 10–20 mL/kg body weight (administered over 20–60 min).

In children with diarrhea or vomiting, reduced carbohydrate intake leads to free fatty acid breakdown, excess ketones, and an increased likelihood of continued nausea and vomiting. Consequently, some authorities have suggested the use of a glucose containing normal solution (mostly the lactate Ringer's in 5% glucose in water), which will stimulate insulin release, reduce free fatty acid breakdown, and therefore reduce treatment failure due to persisting nausea and vomiting (owing to hyperketonemia) [20].

The child with hypovolemic circulatory shock presents with (a) increased heart rate and weak peripheral pulses, (b) cold, pale and diaphoretic skin, and (c) delayed capillary refill. The initial management recommended by the American Academy of Pediatrics includes the administration of a high concentration of O_2 (ensuring that 100% of the available arterial hemoglobin is oxygenated). Common errors in the child with hypovolemic circulatory shock secondary to a diarrheal disease are delayed or inadequate (i.e. with hypotonic crystalloid solution) fluid resuscitation.

Children with hypernatremic dehydration are also hydrated parenterally with isotonic crystalloid solutions until diagnosis of the dyselectrolytemia, followed by slightly hypotonic solutions (e.g.: half-saline) in order to slowly correct the circulating Na^+ concentration (abruptly correcting hypernatremia using a Na^+ free glucose solution creates an increased risk of brain edema; Fig. 34.7). In acute dysnatremic dehydration, Na^+ should be corrected slowly at a rate not exceeding 0.5 mmol/L per hour (or more than by 12 mmol/L per day). Subacute or chronic hypernatremia should be corrected even more slowly.

Hydration in Infectious Diseases Associated with a Tendency Towards Hyponatremia

Fluid restriction has been widely advocated in the initial management of infectious diseases such as meningitis, pneumonia or bronchiolitis, which are often associated with a low Na^+ level. However, there is no evidence that fluid restriction is useful. Furthermore, hyponatremia results from appropriate, volume-dependent antidiuresis in these disease conditions. In clinical practice, initial restoration of the intravascular space with an isotonic crystalloid followed by isotonic maintenance fluids 1400–1500 mL/m^2 body surface area per day (Table 34.5, right panel) are currently advised. In cases presenting with overt hyponatremia, frequent monitoring of electrolytes is also required with adjustments to be made according to laboratory findings.

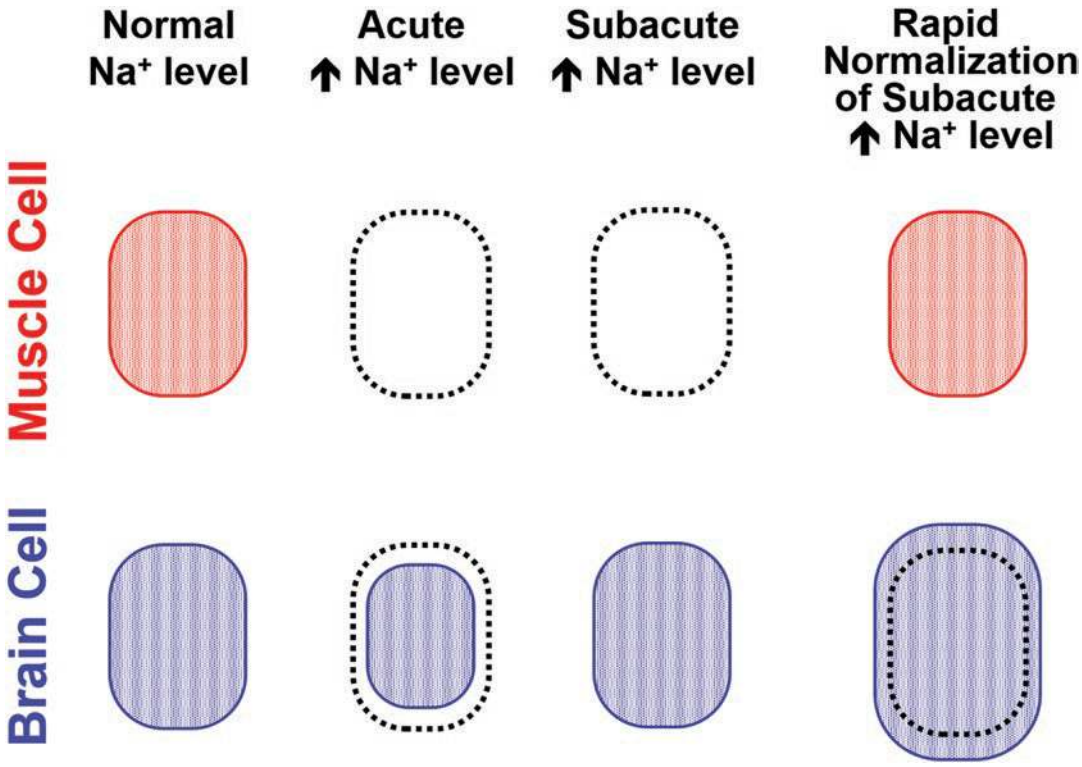

Fig. 34.7 Cell volume in acute or subacute hypernatremia and after rapid correction of hypernatremia. When hypernatemia develops acutely, all cells are reduced in size (the degree of cell volume reduction reflects the degree of hypernatremia). When hypernatremia is present for 36–48 h or more (= subacute hypernatremia), cell volume reduction persists in most cells, including muscle cells (upper panel). However, brain cells and red blood cells tend to restore their normal cell volume (lower panel). A rapid normalization of sodium level in children affected with subacute or chronic hypernatremia pathologically increases the volume of brain cells (and red blood cells). Swelling of cells, which does not have serious consequences when it occurs in most organs, may have damaging consequences when it occurs in the brain (lower panel, right)

Hyponatremia

Chronic normovolemic (or hypervolemic) hyponatremia is usually managed either by restricting water intake or by giving salt. An alternative may be the use of nonpeptide vasopressin receptor antagonists. There are three receptors for vasopressin: the $V1_a$ receptors that mediate vasoconstriction, the $V1_b$ receptors that mediate adrenocorticotropin release, and the V2 receptors that mediate the anti-diuretic response. Vaptans, oral V2 receptor antagonists, have been approved for the management of normovolemic and hypervolemic hyponatremia: these agents produce a selective water diuresis (without affecting Na^+ and K^+ excretion) that raises the circulating Na^+ level. Only limited information is currently available with these agents in childhood.

Vaptans do not correct hyponatremia in patients affected by nephrogenic syndrome of inappropriate childhood anti-diuresis. In these patients, a way to enhance water excretion is the oral administration of urea (dosage in adults: 30 g per day). This regimen, which may be effective because it causes simultaneously water diuresis and renal Na^+ retention, is well tolerated, and has been used chronically in pediatric outpatients.

Potassium

Balance

Most (98%) of the K^+ in the body (40–50 mmol/kg) is within cells. The maintenance of distribution of K^+ across cells is largely dependent on the activity of the sodium pump (= Na^+-K^+-ATPase). In healthy humans, the extracellular K^+ concentration is maintained between 3.5 and 5.0 mmol/L. K^+ balance, like that of other ions, is a function of intake and urinary excretion. In adults, the daily K^+ intake averages 0.5–2 mmol/kg body weight (Fig. 34.8). The homeostasis goal of the adult is to remain in zero K^+ balance. Thus, ≈90–95% of the typical daily intake of 1 mmol/kg is ultimately eliminated from the body in the urine (the residual 5–10% is lost through the stool). Infants maintain a positive K^+ balance (the estimated requirement for growth is 1.2 mmol/day during the first 3 months of life, 0.8 mmol/day up to 1 year and 0.4 mmol/day thereafter). The net accretion of K^+ ensures the availability of adequate substrate for incorporation into cells newly formed during periods of somatic growth. Postnatal growth is associated with an increase in total body K^+ from ≈8 mmol/cm body height at birth to >14 mmol/cm body height by 18 years of age. The rate of accretion of body K^+ per kg body weight in the infant is more rapid than in the older child, reflecting both an increase in cell number and K^+ concentration, at least in skeletal muscle, with advancing age [21–23].

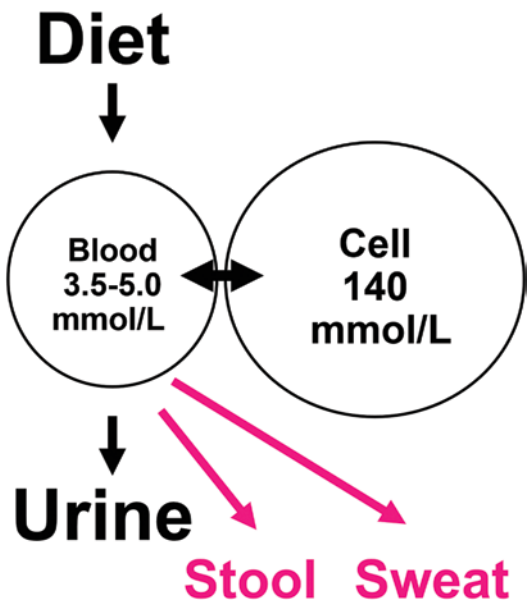

Fig. 34.8 Major factors governing the homeostasis of potassium. Most of the potassium in the body resides within cells. The maintenance of distribution of potassium across cells is largely dependent on the activity of the sodium pump. Potassium balance, like that of other ions, is a function of intake and urinary excretion. Since only small amounts of potassium are normally lost in the sweat and in the stool, they are depicted in a different color. However, substantial intestinal potassium and therefore potassium depletion can be seen with vomiting, diarrhea or other intestinal disease conditions or when sweat production is chronically increased

Regulation of Circulating Potassium

Circulating K^+ concentration is regulated by the total body K^+ content, which depends upon (a) the external balance, i.e. the difference between intake and excretion in the urine, feces and sweat, and (b) the internal balance, which represents the relative distribution of K^+ between the intracellular and the extracellular spaces [21–23].

External (≈ Renal) Potassium Homeostasis

Virtually all regulation of urinary K^+ excretion and therefore of external K^+ homeostasis occurs in the **renal cortical collecting tubule**. Indeed, almost all of the filtered K^+ is reabsorbed in the proximal tubule and the loop of Henle, so that <10% of the filtered load is delivered to the cortical collecting tubule. This tubular segment adjusts the external homeostasis of K^+ by modulating its secretion.

- The major physiologic regulators of K^+ secretion within the cortical collecting tubule are "hyperkalemia" and aldosterone, which act in concert to promote the tubular secretion and therefore the urinary excretion of this ion.
- Increasing the flow rate traversing the cortical collecting tubule is a further factor that may increase the K^+ excretion. This response is most prominent in the presence of hyperkale-

mia, since the concurrent elevations in aldosterone and circulating K^+ concentration produce a high level of K^+ secretion within the cortical collecting tubule.

Internal Potassium Homeostasis

The main modulators of the distribution of K^+ between the intracellular and the extracellular spaces are insulin, the sympathetic nervous system (via β_2-adrenergic receptors) and the acid-base balance.

Prenatal and Neonatal Potassium Balance

During fetal life K^+ is actively transported across the placenta from the mother to the fetus (indeed, the fetal K^+ concentration is maintained at levels ≥5.0 mmol/L even in the face of maternal K^+ deficiency). The tendency to retain K^+ early in postnatal life is reflected by the observation that infants, especially premature newborns, tend to have higher circulating K^+ levels than children. Furthermore, in infancy the ability to increase urinary K^+ excretion is blunted (see: non-oliguric hyperkalaemia of the premature infant).

Symptoms, Signs, and Consequences of Hypokalemia and Hyperkalemia

Excess or deficient K^+ in the extracellular space impairs cardiovascular, neuromuscular, renal and endocrine-metabolic body functions [21, 22]. The most dangerous clinical consequence of these dyselectrolytemias is the predisposition to life-threatening cardiac arrhythmias. The manifestations of hypokalemia are outlined in Table 34.6, those of hyperkalemia in Table 34.7.

The severity of hypokalemic manifestations is proportionate to the degree and duration of hypokalemia and symptoms generally do not become manifest until the K^+ concentration is below 2.5–3.0 mmol/L. Hypokalemia causes characteristic

Table 34.6 Body functions impaired by hypokalemia

• Cardiovascular abnormalities
Cardiac arrhythmias (premature atrial and ventricular beats, sinus bradycardia, paroxysmal atrial or junctional tachycardia, atrioventricular block, and ventricular tachycardia or fibrillation)
Increased systemic vascular resistance
• Neuromuscular disturbances
Skeletal muscle weakness (usually beginning with the lower extremities and progressing to the trunk and upper extremities; sometimes involvement of the respiratory muscles)
Muscle cramps, rhabdomyolysis
Smooth muscle dysfunction (intestinal and urinary system)
• Renal effects
Decreased urinary concentrating ability (decreased expression of the antidiuretic hormone-sensitive water channel aquaporin-2)
Increased renal ammonium production (and therefore ↑ generation of HCO_3)
Hypokalemic nephropathy[a] (interstitial fibrosis, tubular atrophy, cyst formation in the renal medulla)
• Endocrine and metabolic effects
Negative nitrogen balance (causing growth retardation)
Glucose intolerance (with tendency towards diabetes mellitus)
Decreased aldosterone release (direct adrenal action), increased renin secretion
Hepatic encephalopathy (in susceptible individuals)

[a] Following prolonged hypokalemia

Table 34.7 Body functions impaired by hyperkalemia

• Cardiovascular abnormalities
Cardiac arrhythmias (ventricular fibrillation or standstill are the most severe consequences)
Reduced systemic vascular resistance
• Neuromuscular disturbances
Skeletal muscle weakness (usually beginning with the lower extremities and progressing to the trunk and upper extremities; rarely involvement of the respiratory muscles)
Smooth muscle dysfunction (intestinal and urinary system)
• Renal effects
Reduced renal ammonium production (and therefore reduced generation of HCO_3)
• Endocrine and metabolic effects
Increased aldosterone release (direct adrenal action), reduced renin secretion

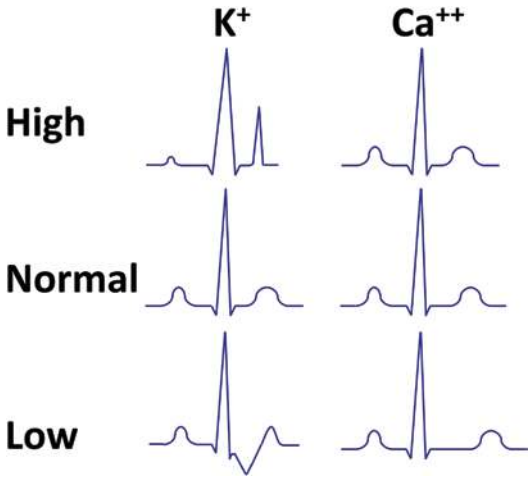

Fig. 34.9 Diagram illustrating some electrocardiographic consequences of hyperkalemia, hypokalemia, hypercalcemia and hypocalcemia. The electrocardiographic changes of hyperkalemia include tall and "peaked" T waves, PR prolongation, QRS widening and, at very high K^+ concentrations, ventricular arrhythmias (not shown). Hypokalemia produces a decreased amplitude of the T wave, a depression of the ST segment and an increased amplitude of U waves, which occur at the end of the T wave. Hypercalcemia manifests with a shortened, hypocalcemia with a prolonged QTc interval

electrocardiographic changes (Fig. 34.9): depression of the ST segment, a decreased amplitude of the T wave, and an increased amplitude of U waves which occur at the end of the T wave.

There are very few symptoms or signs of hyperkalemia, and these tend to occur only with very high levels. Symptoms generally do not become manifest until the K^+ concentration exceeds 7.0 mmol/L, unless the rise in concentration has been very rapid. Hyperkalemia produces the following elecrocardiographic changes: peaked T wave with shortened QT interval is the first change, followed by progressive lengthening of the PR interval and QRS duration. The severity of hyperkalemia is classified as follows: (a) mild: K^+ between 5.1 and 6.0 mmol/L and absent or equivocal electrocardiographic changes; (b) moderate: K^+ between 6.1 and 7.0 mmol/L and definite eletrocardiographic changes in reploarization ("peaked" T waves); (c) severe: K^+ ≥7.1 mmol/L and severe definite eletrocardiographic changes including atrial standstill, advanced atrio-ventricular heart block, QRS widening or ventricular arrhythmia (usually associated with weakness of skeletal muscles). The electrocardiographic signs of hyperkalemia are given in Fig. 34.9.

Evaluating the Causes of Hypokalemia and Hyperkalemia ("Diagnostic Tests")

The following tests have been developed to evaluate and distinguish the various causes of hypo- or hyperkalemia in childhood [21–23].

(a) The **t**rans**t**ubular **K+** concentration **g**radient, colloquially referred to as TTKG, measures the K^+ secretion within the cortical collecting tubule and represents an estimate of the aldosterone activity. This parameter can be easily calculated assuming (a) that the urine osmolality at the end of the cortical collecting tubule is similar to that of blood, and (b) that no K^+ secretion or reabsorption takes place in the medullary collecting tubule. If these assumptions are accurate, then the K^+ concentration in the final urine will rise above that in the cortical collecting tubule due to reabsorption of water in the medullary collecting duct. This effect can be accounted for by dividing the urine K^+ concentration by the ratio of the urine to blood osmolality. If, for example, this ratio is 2, then 50% of the water leaving the cortical collecting tubule has been reabsorbed in the medulla, thereby doubling the luminal K^+ concentration. This parameter is calculated as follows:

$$\frac{\text{Urinary } K^+ \,/\, \text{Urinary Osmolality}}{\text{Blood Osmolality} \,/\, \text{Circulating } K^+}$$

Blood osmolality (in mosm/kg) can be measured with an osmometer or very reasonably estimated from circulating Na^+, glucose, and urea (in mmol/L) as follows: (Na^+ × 2) + glucose + urea. On the other hand, urinary osmolality (in mmol/kg H_2O) can be measured with an osmometer or esti-

mated, in the absence of proteinuria and glucosuria, from the specific gravity, as determined by refractometry, as follows: (specific gravity − 1000) × 40.

(b) The fractional clearance of K^+ (which measures the amount of filtered K^+ that is excreted in the urine)

$$\frac{\text{Urinary } K^+ \times \text{Circulating Creatinine}}{\text{Circulatory } K^+ \times \text{Urinary Creatinine}}$$

and the molar urinary potassium/creatinine ratio (mol/mol)

$$\frac{\text{Urinary } K^+}{\text{Urinary Creatinine}}$$

are two further frequently used tests, which are strongly correlated.

(c) The fractional clearance of Cl^- (which measures the amount of filtered Cl^- that is excreted in the urine)

$$\frac{\text{Urinary } Cl^- \times \text{Circulating Creatinine}}{\text{Circulating } Cl^- \times \text{Urinary Creatinine}}$$

and especially the molar urinary chloride/creatinine ratio (mol/mol; see above)

$$\frac{\text{Urinary } Cl^-}{\text{Urinary Creatinine}}$$

are two further, closely correlated tests that have been suggested.

The molar urinary potassium/creatinine and the urinary chloride/creatinine indices are based on a near-constant creatinine excretion rate and consequently have a limited significance in patients with a very low body mass index.

(d) The 24-h K^+-excretion is a further useful diagnostic test. The use of this traditional diagnostic test is not generally advised considering that 24-h urine collections are troublesome and difficult to obtain (and often imprecise) in children who are not hospitalized, are not practical in a medical emergency, and almost impossible without invasive techniques such as bladder catheterization in infants.

In our experience, the following three "urinary tests" are useful to distinguish the various causes of hypokalemia and hyperkalemia:

- In normotensive children with hypokalemia the transtubular K^+ gradient and the urinary potassium/creatinine ratio (and perhaps the fractional clearance of K^+) easily help distinguish hypokalemia due to a short-term shift of the ion into cells (transtubular K^+ gradient <2.5; urinary potassium/creatinine <2.5 mol/mol) from hypokalemia resulting from a deficit of this ion, including renal K^+ losing conditions and hypokalemia complicating intestinal diseases (in patients experiencing diarrhea, secondary hyperaldosteronism caused by circulating volume depletion leads to an increased urine K^+ excretion).
- In normotensive children with hypokalemia and metabolic alkalosis the urinary excretion of Cl^- helps distinguish renal (urinary chloride/creatinine ratio >10 mol/mol) from non-renal causes (urinary chloride/creatinine ratio <10 mol/mol), as explained in the subchapter metabolic alkalosis.
- It has sometimes been incorrectly assumed that, when hypokalemia occurs in the context of non-renal conditions, the fractional clearance of K^+, the molar urinary potassium/creatinine ratio and the 24 h K^+-excretion are very low, allowing discrimination of non-renal and renal conditions. However, in most children with non-renal hypokalemia extracellular volume depletion is present also, leading to secondary activation of the renin-angiotensin II-aldosterone system, and therefore to an increased urinary K^+ excretion. As a consequence, the urinary K^+ excretion sometimes does not discriminate between non-renal and renal conditions associated with hypokalemia.

- In hyperkalemia the molar urinary potassium/creatinine ratio and the transtubular K^+ gradient help distinguish impaired from unimpaired urinary K^+ excretion. In subjects with unimpaired urinary K^+ excretion the molar urinary potassium/creatinine ratio is expected to be >20 mol/mol, the transtubular K^+ gradient >7.

Hypokalemia

The clinician evaluating a child with hypokalemia (<3.5 mmol/L) should consider five groups of causes [21–26]: (a) spurious hypokalemia; (b) redistribution; (c) true K^+ depletion due to non-renal (mostly intestinal) conditions; (d) true K^+ depletion due to renal conditions; and (e) hypokalemia associated with an expanded "effective" circulating volume and therefore with systemic hypertension due to enhanced mineralocorticoid activity (Table 34.8).

The total K^+ stores are reduced only in subjects with hypokalemia due to non-renal or renal conditions. On the other side, the body K^+ content is normal in children with spurious hypokalemia, in those with an increased shift of K^+ into cells and in those with hypokalemia associated with an expanded "effective" circulating volume.

Table 34.8 Causes of hypokalemia

• **Spurious hypokalemia** (cells take up potassium after blood has been drawn)
• **Hypokalemia associated with normal or low blood pressure**
– **Increased shift of potassium into cells (total body K^+ content normal)**
Activation of β_2-adrenergic receptors
Endogenous: stress, hypothermia
Exogenous: β_2-adrenergic agonists (e.g.: albuterol), xanthines
Hormones
Insulin
Endogenous: anabolism (e.g.: refeeding syndrome)
Exogenous: treatment of diabetic ketoacidosis
Aldosterone (possibly)
Alkalosis (metabolic)
Rare causes
Hypokalemic periodic paralysis
Congenital (autosomal dominant inheritance)
Complicating thyrotoxicosis (particularly in Chinese males)
Barium-induced hypokalemia, acute chloroquine intoxication
Maturation of red cell precursors after treatment of megaloblastic anemia with vitamin B_{12} or folic acid
Paraneoplastic hypokalemia secondary to increased cell synthesis in acute myeloid leukemia[a]
– **True potassium depletion (= total K^+ body content reduced)**
Extrarenal "conditions"
Prolonged poor potassium intake, protein-energy malnutrition
Gastrointestinal conditions
Gastric (associated with alkalosis): Vomiting, nasogastric suction
Small bowel
Associated with acidosis: biliary drainage, intestinal fistula, malabsorption, diarrhea (including diarrhea associated with AIDS), radiation enteropathy
Associated with alkalosis: Congenital chloride diarrhea
Large bowel
Associated with acidosis: uretero-sigmoidoscopy
Acid-base balance unpredictable: bowel cleansing agents, laxatives, clay ingestion, potassium binding resin ingestion
Sweating, full thickness burns

(continued)

Table 34.8 (continued)

Cystic fibrosis
Dialysis
Renal "conditions"
Interstitial nephritis, post-obstructive diuresis, recovery from acute renal failure
With metabolic acidosis: renal tubular acidosis (type I or II), carbonic anhydrase inhibitors (e.g.: acetazolamide and topiramate), amphotericin B, outdated tetracyclines
With metabolic alkalosis
Inherited conditions: Bartter syndromes, Gitelman syndrome and related syndromes
Acquired conditions: normotensive primary aldosteronism**,** loop and thiazide diuretics, high dose antibiotics (penicillin, naficillin, ampicillin, carbenicillin, ticarcillin), magnesium depletion
Acid-base balance unpredictable: cetuximab
• **Hypokalemia associated with high blood pressure (often linked with metabolic alkalosis; total K^+ body content normal)**
Low renin: primary aldosteronism (either hyperplasia or adenoma), apparent mineralocorticoid excess (= defect in 11-β-hydroxysteroid-dehydrogenase), Liddle syndrome (congenitally increased function of the collecting tubule sodium channels), dexamethasone-responsive aldosteronism (synthesis of aldosterone promoted not only by renin but also by adrenocorticotropin), congenital adrenal hyperplasia (11-β-hydroxylase or 17-α-hydroxylase deficiency), Cushing disease, exogenous mineralocorticoids, licorice-ingestion (= 11-β-hydroxysteroid-dehydrogenase blockade)
Normal or high renin: renal artery stenosis, malignant hypertension, renin producing tumor

[a] The pathogenic mechanism includes also hyperkaluresis due to activation of the renin-angiotensin II system

Occasionally, metabolically active cells (in the blood sample) take up K^+ after blood has been drawn and before it has been tested in the laboratory. This condition, which has been called **spurious hypokalemia**, has been noted in patients with acute myeloid leukemia associated with a very high white blood cell count and in hot weather. The problem of spurious hypokalemia, which is much less common than spurious hyperkalaemia, can be avoided if plasma (or serum) is rapidly separated from the cells or if the blood is stored at 4 °C.

Normal total body K^+ content with hypokalemia results from an **increased shift of this ion into cells**. Metabolic alkalosis, increased endogenous secretion or exogenous administration of insulin, sympathetic activation and exogenous administration of β_2-adrenergic receptors are the main causes of hypokalemia caused by cellular uptake of K^+. Hypokalemic periodic paralysis is an uncommon form of hypokalemia resulting from an increased shift of K^+ into cells, which is characterized by recurrent episodes of hypokalemia (associated with hypophosphatemia and mild hypomagnesemia) and muscular weakness or paralysis that occurs primarily in males of Asian descent. The hypokalemic episodes are precipitated by rest after exercise, a carbohydrate meal or the administration of insulin or β-adrenergic agonists.

The K^+ stores may be depleted when **dietary K^+ is very low** and therefore fails to counterbalance the obligatory K^+ losses and, in infancy and childhood, the required K^+ accretion. Since the kidney is able to lower K^+ excretion to very low figures in the presence of K^+ depletion, decreased intake alone will cause hypokalemia only in rare cases. However, it contributes to the severity of K^+ depletion when another problem is superimposed. Under normal circumstances the net fluid loss from the skin and the gastrointestinal tract is small, therefore preventing the development of K^+ depletion. Sometimes, however, in cases such as prolonged exertion in hot, dry environment, in cystic fibrosis (in these patients sweat contains large amounts of Na^+, K^+ and Cl^-), and especially in the context of various gastrointestinal conditions (Table 34.8) K^+ loss occurs. In most of these cases extracellular volume depletion is present also, leading to secondary activation of the renin-angiotensin II-aldosterone system, and further worsening the K^+ deficiency. It has even been noted that in some patients with diarrheal states, an increased urinary K^+ excretion plays a more important role than intestinal losses in the development of K^+ deficiency. Hypokalemia is mostly

associated with metabolic alkalosis after poor dietary K^+ intake, in the context of "upper" gastrointestinal conditions or in conditions associated with increased sweating and with acidosis in "lower" gastrointestinal conditions. Finally, **renal K^+ losses** occur either associated with acidosis or, more frequently, with alkalosis.

Excessive mineralocorticoid activity is the main cause of hypokalemia associated with metabolic alkalosis and arterial hypertension. The underlying mechanism will be discussed elsewhere.

Clinical Work Up

The clue to the diagnosis of spurious hypokalemia is a normal electrocardiogram without the characteristic changes (Fig. 34.9). Considering that the great majority of children with true hypokalemia have either a gastrointestinal condition or take drugs associated with renal K^+ wasting, the causes of hypokalemia can almost always be discerned clinically. When the data obtained from the clinical history fail to establish a presumptive diagnosis, the following simple steps are suggested:

- Repeated measurement of blood pressure;
- Concurrent determination of the acid-base balance, Na^+, Cl^-, Ca^{++}, Mg^{++}, inorganic phosphate, alkaline phosphatase, uric acid, and especially urea and creatinine;
- In normotensive subjects the molar urinary potassium/creatinine ratio distinguishes hypokalemia due to a short-term shift of K^+ into cells (ratio <2.5 mol/mol) from hypokalemia resulting from a deficit of the ion;
- In normotensive subjects with hypokalemia and metabolic alkalosis the urinary chloride/creatinine ratio discriminates renal (ratio >10 mol/mol) from non-renal causes (ratio <10 mol/mol).

Management

Considering the numerous origins of hypokalemia, this section will focus exclusively on the urgency and the mode of substitution in patients with normotensive hypokalemia [24–26].

- The urgency for substitution is dictated by following factors: (a) Conditions that increase the likelihood of dangerous cardiac arrhythmias (and/or concurrent cardiac pathologies reducing the hemodynamic tolerance of arrhythmias); (b) The possibility that K^+ will shift into cells (e.g.: during recovery from diabetic ketoacidosis); (c) Severe muscle weakness in a child who must intensively hyperventilate because of metabolic acidosis, (d) Magnitude of the ongoing K^+ losses (e.g.: during severe diarrhea); and (e) Degree of hypokalemia.
- Potassium preparations
  - Potassium chloride: preferred in metabolic alkalosis due to diuretic therapy or vomiting;
  - Potassium citrate or potassium bicarbonate: prescribed in hypokalemia and metabolic acidosis (typically renal tubular acidosis);
  - Potassium phosphate: administered in the recovery from diabetic ketoacidosis, in subjects at risk of refeeding syndrome and during total parenteral nutrition.
- The concurrent intravenous administration of K^+Cl^- with glucose or bicarbonate is not advised in patients with severe hypokalemia, because glucose and bicarbonate cause a shift of K^+ into cells and transiently reduce circulating K^+ concentration.
- Route of administration. The safest way to administer K^+ is by mouth. Intestinal conditions that limit intake or absorption of K^+, severe hypokalemia (<2.5 mmol/L), characteristic electrocardiogram abnormalities (with or without cardiac arrhythmias) or respiratory muscle weakness and an anticipated shift of K^+ into cells mandate intravenous substitution.
- Intravenous K^+Cl^-
  - Bolus of K^+Cl^- is recommended exclusively in very severe degree of hypokalemia and abnormal electrocardiogram. The aim will be to raise K^+ to 3.0 mmol/L in

1–2 min.[3] The amount of intravenous K^+Cl^- (in mmol) will be chosen from measured K^+ (in mmol/L) and body weight (in kg) using the formula: (3.0 − measured K^+) × body weight × 0.04. Following this bolus, the rate of infusion of K^+ should be reduced to 0.015 mmol/kg body weight per minute, and measurement of K^+ concentration should be repeated each 5–10 min.

N.B.: The K^+Cl^- supplementation should be minimal if hypokalemia is due exclusively to an abnormal distribution of the K^+ stores (e.g.: exogenous administration of β_2-adrenergic receptors or hypokalemic periodic paralysis).

- In conditions demanding intravenous K^+ but without any acute emergency the rate of infused K^+ should not exceed 0.5–1.0 mmol/kg body weight hourly. Furthermore the K^+ concentration in intravenous solutions should be less than 40 mmol/L for use in peripheral veins because higher concentrations lead to local discomfort, venous spasm and sclerosis.
- Parenteral supplemental K^+ administration is the most common cause of severe hyperkalemia. Consequently, the safest route to give K^+ is by mouth. A traditional approach to minimizing hypokalemia is to ensure adequate dietary K^+ intake (unfortunately the K^+ contained in foods that have a high K^+ content is almost entirely coupled with phosphate rather than with Cl^- and therefore is not effective in repairing K^+-loss associated with Cl^--depletion, including use of diuretics, vomiting or nasogastric drainage). In most circumstances, oral replacement with K^+Cl^- (1–3 mmol/kg body weight daily in divided doses) is effective in correcting hypokalemia.

[3]The basis for this decision is as follows: the total blood volume approximates 7% of body weight (this volume circulates each minute, cardiac output being at least 70 mL/min/kg body weight) and plasma volume 60% of blood volume, i.e. approximately 4% of body weight. Consequently a 50.0-kg adolescent with a very severe hypokalemia of 1.5 mmol/L will be given (3.0–1.5) × 50 × 0.04 = 3.0 mmol of K^+Cl^- in 1–2 min. Considering that infused K^+ will mix with interstitial fluid (approximately 3–4 times the plasma volume) before reaching cell membrane, there will be a much smaller increase in K^+ concentration near cell membranes.

Hyperkalemia

The clinician evaluating a child with hyperkalemia (>5.5 mmol/L) will initially consider the possible diagnosis of **spurious hyperkalemia** (Table 34.9) [21–23, 27–29]. The term refers to those conditions in which the elevation in the measured K^+ is due to K^+ movement out of the cells during or after the blood specimen has been drawn. The major cause of this common problem is mechanical trauma during venipuncture, resulting in the release of K^+ from red cells and a characteristic reddish tint of the serum (or plasma) due to the release of hemoglobin. A normal electrocardiogram without the characteristic signs (Fig. 34.9) is the initial clue to this diagnosis.

In very rare instances, however, red serum (or red plasma) represents severe intravascular hemolysis rather than a hemolyzed specimen.

Furthermore, spurious hyperkalemia can also occur in hereditary spherocytosis and in familial pseudohyperkalemia, a rare autosomal dominant disorder recognized as a laboratory artifact. In the circulation, the Na^+ and K^+ content of red cells is normal. However, the measured plasma or serum K^+ concentration is elevated because of an abnormally high rate of efflux of K^+ from the red cells when the temperature is lowered below 22 °C. The in vitro K^+ efflux can be reversed by incubation at 37 °C.

K^+ also moves out of white cells and platelets after clotting has occurred. Thus, the serum K^+ concentration normally exceeds the true value in the plasma by 0.1–0.5 mmol/L. Although in normal individuals this difference is clinically insignificant, the measured serum K^+ concentration may be as high as 9 mmol/L in patients with marked leukocytosis or thrombocytosis. Spurious hyperkalemia is suspected whenever there is no apparent cause for the elevation in the serum K^+ concentration in an asymptomatic patient.

True hyperkalemia (Table 34.9) occurs rarely in healthy subjects, because cellular and urinary adaptations prevent substantial extracel-

Table 34.9 Causes of hyperkalemia (drugs associated with hyperkalemia appear in Table 34.10)

• **Spurious hyperkalemia** (potassium movement out of the cells during or after blood has been drawn)
– Mechanical trauma during venipuncture
– Hereditary spherocytosis
– Familial pseudohyperkalemia
• **True hyperkalemia**
– **Increased potassium load**[a]
– **Increased shift of potassium out of cells**
Normal anion gap metabolic acidosis
Insulin deficiency
Extracellular hypertonicity
Increased tissue catabolism (severe hemolysis, rhabdomyolysis, tumor lysis syndrome, immediately after cardiac surgery)
Severe exercise
Familial hyperkalemic periodic paralysis (= Gamstorp disease)
Hyperkalaemia of the premature infant
– **Impaired renal potassium excretion**
Global renal failure: acute or chronic
Hyperreninemic hypoaldosteronism: adrenal insufficiency (= Addison disease), salt-losing congenital adrenal hyperplasia (21-hydroxylase deficiency)
Hyporeninemic hypoaldosteronism: idiopathic, complicating acute glomerulonephritis or mild-to-moderate renal failure)
Pseudohypoaldosteronism
Type 1 (cortical collecting tubule)
Primary
Autosomal recessive[b]: reduced sodium channel activity
Autosomal dominant: mutations in the gene for the mineralocorticoid receptor, phenotype mild and transient
Secondary: complicating obstructive uropathy (with or without urinary tract infection), systemic lupus erythematosus, sickle cell disease, renal transplantation, renal amyloidosis
Type 2 (= Familial hyperkalemic hypertension or Gordon syndrome[c])

[a] Not a cause of hyperkalemia, unless very acute (and important) or occurring in subjects with impaired potassium excretion (due, for example, to underlying kidney disease)
[b] Autosomal recessive pseudohypoaldosteronism type 1 is opposite to Liddle syndrome
[c] The clinical phenotype of Gordon syndrome is opposite to Gitelman syndrome

lular K^+ accumulation. Furthermore, the efficiency of K^+ handling is increased if K^+ intake is enhanced, thereby tolerating what might be a fatal K^+ load. These observations lead to the following conclusions concerning the development of hyperkalemia:

(a) **Increasing K^+ load** is not a cause of hyperkalemia, unless very acute or occurring in a patient with impaired urinary K^+ excretion. In special conditions, acute hyperkalemia can be induced (primarily in infants because of their small size) by the intravenous administration of unusual large doses of K^+ or the use of stored blood for transfusions.
(b) The net **release of K^+ from the cells** can cause a transient elevation in the circulating K^+ concentration (in the presence of normal or even low total body K^+ stores). Four causes of hyperkalemia resulting from release of the ion from cells will be discussed: (a) extracellular hypertonicity; (b) tumor lysis syndrome; (c) hyperkalemic familial periodic paralysis; and d. non-oliguric hyperkalaemia of the premature infant.

An *elevated extracellular tonicity* results in water movement from the cells into the extracellular fluid. This is linked with K^+ movement out of the cells by two mechanisms. First, the loss of water raises the intracellular K^+ level, creating a gradient for passive K^+ exit. Second, the friction forces between water and solute result in K^+ being carried along with water. Hypertonicity-induced hyperkalemia occurs in

hyperglycemia, in hypernatremia, and following administration of mannitol.

The phenotype of acute *tumor lysis syndrome* is opposite to refeeding syndrome. The term denotes the metabolic abnormalities that occur either spontaneously or immediately after initiation of cytotoxic therapy in neoplastic disorders. The findings include hyperuricemia, hyperkalemia, hyperphosphatemia, hypocalcemia (due to precipitation of calcium phosphate), and acute renal failure. The syndrome has been noted in children with a tumor characterized by rapid cell turnover such as lymphomas (particularly non-Hodgkin lymphoma) and some leukemias.

Hyperkalemic familial periodic paralysis, or Gamstorp disease, is a rare inherited autosomal dominant disease that causes patients to experience episodes of flaccid weakness[4] associated with increased K^+ levels. In this syndrome, hyperkalemia occurs with increased K^+ intake, cold weather, exercise or at rest. The attacks of paralysis, however, are not always linked with hyperkalemia.

Non-oliguric hyperkalemia (>6.5 mmol/L) of the premature infant is a common and serious condition. The features are a rapid rise of K^+ concentration to excessively high values at 24 h after birth, a tendency towards cardiac arrhythmia, and occurrence only within 72 h after birth exclusively in premature infants. This peculiar condition mainly results from a K^+ loss from the intra- into the extracellular space. Moreover, renal K^+ excretion that is dependent on both glomerular filtration rate and urinary output is slightly decreased in this setting. Finally, aldosterone unresponsiveness, rather than a decreased concentration of aldosterone, also contributes to the degree of hyperkalemia. However, since there is no significant K^+ intake during the first days of life of premature infants, even total absence of renal K^+ excretion cannot increase K^+ concentration, if there is no intra- to extracellular K^+ shift.

(c) Persistent hyperkalemia requires an **impaired urinary K^+ excretion** (the total body K^+ stores are increased in this condition). Two factors modulate renal K^+ homeostasis in the cortical collecting tubule: "hyperkalemia" and aldosterone, which act in concert to promote the tubular secretion and therefore the excretion of K^+, and the flow rate traversing the cortical collecting tubule. Consequently, a decreased aldosterone release or effect or a decreased renal tubular flow rate are the major conditions impairing urinary K^+ excretion.

- *Reduced aldosterone secretion or effect*: Any cause of decreased aldosterone release or effect can diminish the efficiency of K^+ secretion and lead to hyperkalemia. The ensuing tendency towards hyperkalemia directly stimulates K^+ secretion, partially overcoming the relative absence of aldosterone. The net effect is that the rise in the K^+ concentration is generally small in patients with normal renal function, but can be clinically important in the presence of underlying renal insufficiency or with multiple insults.
- *Decreased renal tubular flow rate*: The ability to maintain K^+ excretion at near normal levels is habitually preserved in advanced renal disease as long as both aldosterone secretion and distal flow are maintained. Thus, hyperkalemia generally develops in oliguria or in the presence of an additional problem including high K^+ diet, increased tissue breakdown or reduced aldosterone bioactivity. Impaired cell uptake of K^+ also contributes to the development of hyperkalemia in advanced renal failure. Decreased distal tubular flow rate due to marked effective volume depletion, as in heart failure or "salt-losing" nephropathy, can also induce hyperkalemia.
- Acute and chronic renal failure, the most recognized causes of impaired urinary K^+ excretion, will be discussed elsewhere (See Chaps. 51 and 58). Hyperkalemia

[4]Please note that hyperkalemic skeletal muscle paralysis results from hyperkalemia of any cause, rather than this rare inherited disorder.

and a tendency towards hyponatremia and metabolic acidosis characteristically occur in children with hyperreninemic hypoaldosteronism (including classic congenital adrenal hyperplasia), hyporeninemic hypoaldosteronism, and end-organ resistance to aldosterone, mostly referred to as pseudohypoaldosteronism. In North-America, Japan, and most European countries neonatal screening (measurement of 17-hydroxy-hydroxyprogesterone in filter paper blood) identifies children affected by classic congenital adrenal hyperplasia due to 21-hydroxylase deficiency before salt-losing crises with hyperkalemia develop. Consequently, in these countries classic congenital adrenal hyperplasia is nowadays an uncommon cause of hyperkalemia. In our experience, secondary type 1 pseudohypoaldosteronism is, together with advanced renal failure, a common cause of true hyperkalemia, at least in infancy. Secondary type 1 pseudohypoaldosteronism develops in infants with urinary tract infections, in infants (but not older children) with urinary tract anomalies (either obstructive or vesicoureteral reflux), and especially in infants with both urinary tract infections and urinary tract anomalies [30].

– Finally, the syndrome of (acquired) *hyporeninemic hypoaldosteronism*, which is characterized by mild hyperkalemia and metabolic acidosis, is due to diminished renin release and, subsequently, decreased angiotensin II and aldosterone production. The syndrome, which mostly occurs in subjects with mild renal failure, has been first reported in subjects with overt diabetic kidney disease and has been occasionally noted in children with acute glomerulonephritis or mild-to-moderate chronic renal failure.
– Prescribed medications, over-the-counter drugs, and nutritional supplements may disrupt K^+ balance and promote the development of hyperkalemia, as shown in Table 34.10. Although most of these prod-

Table 34.10 Drugs that have been associated with hyperkalemia

Medication	Mechanism of action
Increased K^+ input	K^+ ingestion or infusion
K^+ supplements (and salt substitutes)	
Nutritional and herbal supplements	
Stored packed red blood cells	
Potassium containing penicillins	
Transcellular K^+ shifts	
β-adrenergic receptor antagonists	↓ β_2-driven K^+ uptake
Intravenous amino acids (Lysine, Arginine, Aminocaproic acid)	↑ K^+ release from cells
Succinylcholine	Depolarized cell membranes
Digoxin intoxication	↓ Na^+-pump
Impaired renal excretion	
Potassium sparing diuretics	
Spironolactone, eplerenone	Aldosterone antagonists
Triamterene, amiloride	Na^+ channels blocked (collecting tubule)
Trimethoprim[a], pentamidine	Na^+ channels blocked (collecting tubule)
Nonsteroidal anti-inflammatory drugs	↓ Aldosterone synthesis, ↓ glomerular filtration rate, ↓ renal blood flow
Blockers of the renin-angiotensin II-aldosterone system (converting enzyme inhibitors, angiotensin II-antagonists, renin inhibitors)	↓ Aldosterone synthesis
Heparins (both unfractionated and low molecular weight heparins)	↓ Aldosterone synthesis
Calcineurin inhibitors (e.g.: cyclosporineand tacrolimus)	↓ Aldosterone synthesis, ↓ Na^+-pump, ↓ K^+-channels

[a] Including cotrimoxazole, the fixed combination of trimethoprim with sulfomethoxazole

ucts are well tolerated, drug-induced hyperkalemia may develop in subjects with underlying renal impairment or other abnormalities in K^+ handling or with concurrent, combined use of multiple drugs potentially inducing hyperkalemia. Their hyperkalemic action is less evident in children than in elderly subjects.

Clinical Work Up

The clue to the diagnosis of spurious hyperkalemia, the most common cause of elevated K^+ levels in clinically asymptomatic infants and children, is a normal electrocardiogram without the characteristic changes.

Considering that the great majority of children with true hyperkalemia have renal failure (either acute or chronic), secondary type 1 pseudohypoaldosteronism or take drugs that can cause hyperkalemia, the cause of hyperkaemia can mostly be discerned clinically. When the data obtained from the clinical history fail to establish a presumptive diagnosis, the following simple steps are suggested [21–23, 27–29]:

- Repeated measurement of blood pressure;
- Concurrent determination of the acid-base balance, Na^+, Cl^-, Ca^{++}, Mg^{++}, inorganic phosphate, alkaline phosphatase, uric acid, and especially urea and creatinine;
- In subjects with true hyperkalemia unrelated to an impaired urinary K^+ excretion, the expected molar urinary potassium/creatinine ratio is >20 mol/mol and the transtubular potassium gradient >10.

Management

Because many conditions account for true hyperkalemia, there is no universal therapy for this dyselectrolytemia. The following measures deserve consideration upon recognition of hyperkalemia with increased total body K^+ stores: (a) Interruption of excessive dietary K^+ intake; (b) Discontinuation of drugs that may cause hyperkalemia; (c) Increasing renal K^+ excretion (for this purpose children without end-stage renal failure or physical signs of fluid overload must have substantial salt intake[5] via oral or parenteral routes; the use of a loop diuretic, less frequently a thiazide diuretic, also increases renal K^+ excretion); (d) Increasing gastrointestinal K^+ excretion using cation exchange resins; and (e) Institution of dialysis in children with end-stage renal failure.

Emergencies: Because of the serious deleterious cardiac effects, severe hyperkalemia (≥7.1 mmol/L) with electrocardiographic abnormalities requires emergency intervention. The following measures, which are listed according to their rapidity of action, have been recommended:

(a) Intravenous Ca^{++}, which directly antagonizes the membrane actions of hyperkalemia;
(b) Intravenous insulin (and glucose), which lowers extracellular K^+ level by driving K^+ into cells;
(c) Intravenous or nebulised $ß_2$-adrenergic agonists, which, like insulin, drive K^+ into cells; and
(d) Intravenous $NaHCO_3$, which results in H^+ ion release from cells (as part of the buffering reaction), a change that is accompanied by K^+ movement into cells to preserve electroneutrality.

Available data indicate (1) that nebulized (or inhaled) albuterol, a $ß_2$-adrenergic agonist, or intravenous insulin (and glucose) are the best supported recommendations; (2) that their combination may be more effective than either alone; (3) that although there are no properly conducted studies assessing the efficacy of Ca^{++}, there remains little doubt of its effectiveness in treating or preventing arrhythmias; and (4) that evidence for the use of intravenous $NaHCO_3$ is equivocal. For practical purposes, the emergency interventions given in Table 34.11 are advised.

[5] A low salt intake and extracellular fluid volume depletion are the most commonly observed contributing factors in the development of hyperkalemia in children with renal failure. In patients with a salt-retaining disease, proper management is achieved by avoiding severe restriction of dietary salt while concurrently administering diuretics.

Table 34.11 Currently recommended emergency intervention for severe hyperkalemia (≥7.1 mmol/L) with electrocardiogram abnormalities. Albuterol and intravenous glucose (with insulin) lowers extracellular potassium level by driving potassium into cells, while calcium directly antagonizes the membrane actions of hyperkalemia but does not modify extracellular potassium concentration. None of the recommended emergency interventions modifies the total body potassium content

Medication	Dosage	Onset (min)	Length of effect (h)	Comments—Cautions
Nebulized albuterol	10–20 mg (diluted in 4 mL of saline) over 10 min	15–30	4–6	May increase heart rate
Intravenous albuterol	10 μg/kg body weight over 15 min	15–30	4–6	May increase heart rate
Glucose and insulin	Glucose 0.5–1.0 g/kg body weight and insulin 0.1 U/kg body weight intravenously over 15 min	15–30	4–6	Tendency towards hypoglycemia (monitor blood glucose level)
Intravenous calcium	20–50 mg/kg body weight over 1–3 min	Immediate	½–1	Does not lower potassium level

Acid-Base Balance

Introduction

Maintenance of acid-base balance within narrow limits (i.e. pH 7.00–7.30 within the cell depending on the cell type and tissue of origin and pH 7.35–7.45 in extracellular fluids) is a crucial function of the living organism, largely because of its effects on body proteins. The "pCO2-HCO_3^--pH"-based approach, popularized by Relman and Schwartz in the 1960s, relies upon the definition of pH in blood as a function of the ratio between the partial pressure of carbon dioxide (pCO_2; mmHg or kPa) and the bicarbonate (HCO_3^-; mmol/L or meq/L) concentration, as indicated by the (simplified) Henderson-Hasselbalch equation [31, 32]:

$$pH = pK + \frac{HCO_3^-}{pCO_2}$$

Arterial blood is the standard sample for the determination of acid-base balance but arterial blood sampling, which can be painful, is often unavailable in childhood. In this age group, acid-base balance is mostly assessed in arterialized capillary blood samples (from the finger pulp following hand warming during ≥10 min or the earlobe following spreading the lobe with a vasodilating cream during ≥10 min) or in venous blood samples. Normal values for peripheral venous blood differ from those of arterial blood due to the uptake and buffering of metabolically produced CO_2 in the capillary circulation. If a tourniquet is used to facilitate phlebotomy, it should be released about one minute before blood is drawn to avoid changes induced by ischemia. The peripheral venous pH range is ≈0.02–0.04 pH units lower than in arterial blood, the pCO_2 ≈3–8 mmHg higher and the HCO_3^- concentration ≈1–2 mmol/L lower. Automated blood gas analyzers measure pH and pCO_2, while the HCO_3^- concentration is calculated from the Henderson-Hasselbalch equation. Most currently available blood gas analyzers determine circulating L-lactate as well (the assay does not detect D-lactate). Abnormalities of blood pH result from a deviation in circulating bicarbonate (HCO_3^-; mmol/L) or in partial pressure of carbon dioxide (pCO_2; mmHg[6]). There are four primary disturbances of acid-base balance (Fig. 34.10). Since alveolar ventilation regulates pCO_2, any disturbance in pH that results from a primary change in pCO_2 is called respiratory acid-base disorder: retention of CO_2 leads to a reduction in pH (<7.35) called respiratory acidosis, a fall in pCO_2 leads to a rise in pH (>7.45) called respiratory alkalosis. On the other side, primary changes in the concentration of HCO_3^- are called metabolic acid-base disorders: a primary reduction in

[6]To obtain SI units (kPa) divide by 7.5.

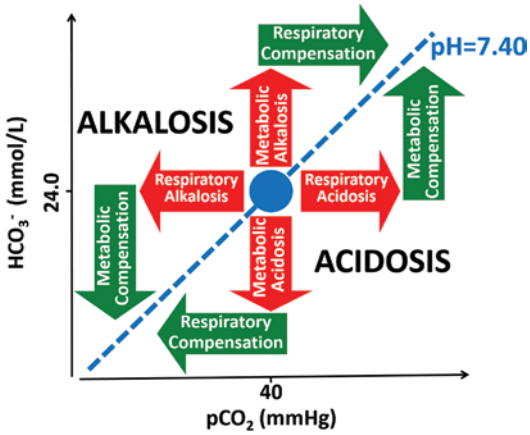

Fig. 34.10 Common sense diagram depicting the four primary disturbances of acid-base balance with the expected compensation. There are four primary disturbances (red arrows) of acid-base balance. Since ventilation modulates pCO_2, any disturbance in pH that results from a primary change in pCO_2 is called respiratory acid-base disorder: retention of CO_2 leads to a reduction in pH (<7.35) called respiratory acidosis, while a fall in pCO_2 leads to a rise in pH (>7.45) called respiratory alkalosis. On the other side, primary changes in the HCO_3^- concentration are called metabolic acid-base disorders: a primary reduction in HCO_3^- is termed metabolic acidosis and a primary increase in HCO_3^- is called metabolic alkalosis. Since blood pH is determined by the ratio between HCO_3^- and pCO_2, and not either one alone, primary respiratory (primary changes in pCO_2) disturbances invoke compensatory metabolic (secondary changes in HCO_3^-) responses (green arrows), and primary metabolic (primary changes in HCO_3^-) disturbances elicit compensatory respiratory (secondary changes in pCO_2) responses (green arrows)

HCO_3^- is termed metabolic acidosis and a primary increase in HCO_3^- is called metabolic alkalosis.

Blood pH is determined by the ratio between HCO_3^- and pCO_2, not either one alone. Thus, primary respiratory disturbances (primary changes in pCO_2) invoke compensatory metabolic responses (secondary changes in HCO_3^-), and primary metabolic disturbances (primary changes in HCO_3^-) elicit compensatory respiratory responses (secondary changes in pCO_2). For instance, metabolic acidosis due to an increase in endogenous acids (e.g., ketoacidosis) lowers extracellular fluid HCO_3^- and decreases extracellular pH. This stimulates the medullary chemoreceptors to increase the ventilation in an attempt to return the ratio of HCO_3^- to pCO_2, and thus pH, towards normal. The physiologic metabolic and respiratory compensations to simple primary acid-base disturbances can be guessed from the relationships displayed in Table 34.12.

"Base excess" and "standard HCO_3^-" are *in vitro* generated parameters of the acid-base balance that are of little value and often even misleading [31, 32].

Systemic Effects of Metabolic Acid-Base Abnormalities

The systemic effects of acid-base abnormalities will be briefly addressed below [31, 32].

Respiratory System

Primary metabolic acid-base balance disturbances (primary changes in HCO_3^-) elicit compensatory respiratory responses (secondary changes in pCO_2). Metabolic acidosis (=primary reduction in HCO_3^-) stimulates the ventilation to correct the ratio of HCO_3^- to pCO_2, and thus pH, towards normal (Fig. 34.10). The rise in ventilation occurs within minutes but may take several hours to reach its fullest expression. The increase is more the result of increased tidal volume than respiratory rate. This degree of hyperventilation, called Kussmaul respiration, may cause some dyspnea and be appreciated on physical examination. In a child with simple metabolic acidosis, the pCO_2 is expected to decrease by 1.3 mmHg for each mmol per liter decrease in HCO_3^- (Table 34.12), reaching a minimum of 10–15 mmHg. Thus, a patient with metabolic acidosis and HCO_3^- of 16.0 mmol/L would be expected to have a pCO_2 of ≈30 mmHg, i.e. between 27 and 33 mmHg. Values for pCO_2 <27 or >33 mmHg define a mixed disturbance (metabolic acidosis and respiratory alkalosis or metabolic acidosis and respiratory acidosis, respectively).

Primary metabolic alkalosis (= primary increase in HCO_3^-) may lead to compensatory hypoventilation and consequent CO_2 retention. Uncomplicated metabolic alkalosis is usually not associated with profound alveolar hypoventilation. Metabolic alkalosis should be repaired

Table 34.12 Predicted compensations to simple primary acid-base disturbances

Disorder	Primary change	Compensatory response
Metabolic acidosis	↓ HCO_3^-	↓ pCO_2 by 1.3[a] mmHg for ↓ 1.0 mmol/L[b] in HCO_3^-
Metabolic Alkalosis	↑ HCO_3^-	↑ pCO_2 by 0.6[a] mmHg for ↑ 1.0 mmol/L[b] in HCO_3^-
Respiratory Acidosis	↑ pCO_2	
Acute		↑ 1.0 mmol/L[c] in HCO_3^- for ↑ 10 mmHg[d] in pCO_2
Chronic		↑ 3.5 mmol/L[c] in HCO_3^- for ↑ 10 mmHg[d] in pCO_2
Respiratory Alkalosis	↓ pCO_2	
Acute		↓ 2.0 mmol/L[c] in HCO_3^- for ↓ 10 mmHg[d] in pCO_2
Chronic		↓ 5.0 mmol/L[c] in HCO_3^- for ↓ 10 mmHg[d] in pCO_2

[a] Range approximately ±3 mmHg
[b] From 25 mmol/L
[c] Range approximately ±2.0 mmol/L
[d] From 40 mmHg

before surgery (e.g.: before pyloromyotomy in infantile hypertrophic pyloric stenosis) because this acid-base abnormality predisposes to respiratory depression in the immediate postoperative course.

Potassium Balance

There are major interactions between the internal K^+ balance and acute metabolic acid-base changes. In patients with normal anion gap metabolic acidosis the excess hydrogen ions are buffered in the cell and electroneutrality is maintained by movements of intracellular K^+ into the extracellular fluid. Interestingly, metabolic acidosis is much less likely to raise the extracellular K^+ concentration in patients with high anion gap acidosis like L-lactate acidosis or ketoacidosis. The underlying mechanisms are briefly explained in Fig. 34.11 (upper panel). For similar reasons, some tendency towards hypokalemia is noted in metabolic alkalosis (Fig. 34.11, lower panel). Respiratory acidosis and alkalosis do not significantly modulate K^+ balance.

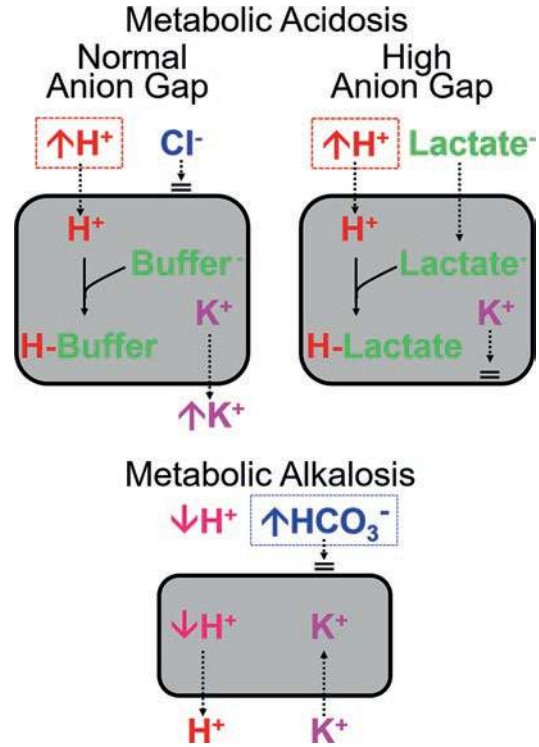

Fig. 34.11 Effect of metabolic acidosis or alkalosis on circulating potassium level. Both in normal (= hyperchloremic) and high (= normochloremic) anion gap metabolic acidosis some extracellular H^+ shifts into the intracellular fluid volume (the squares denote the cell membrane). In normal anion gap (left upper panel) metabolic acidosis, Cl^- remains largely in the extracellular fluid volume. On the contrary, in high anion gap (right upper panel) metabolic acidosis (e.g.: L-lactate acidosis) some organic anions enter the intracellular fluid. Hence, a tendency towards hyperkalemia, the consequence of a shift of K^+ from the intracellular to the extracellular fluid volume, occurs almost exclusively in normal anion gap metabolic acidosis only. Please note that hyperkalemia is followed by a stimulated aldosterone release and results in the urinary excretion of the extra K^+. No tendency towards hyperkalemia occurs in respiratory acidosis. In metabolic alkalosis (lower panel) some intracellular H^+ shifts into the extracellular fluid volume. Hence, a tendency towards hypokalemia, the consequence of a shift of K^+ from the extracellular to the intracellular fluid volume, occurs. No tendency towards hypokalemia occurs in respiratory alkalosis

Ca^{++} (and Mg^{++}) Balance

Acid-base disorders affect circulating Ca^{++}, Mg^{++}, inorganic phosphate, and K^+. Acidemia increases calcium phosphate dissociation, increasing free (ionized) Ca^{++}. Acidemia also allows greater dis-

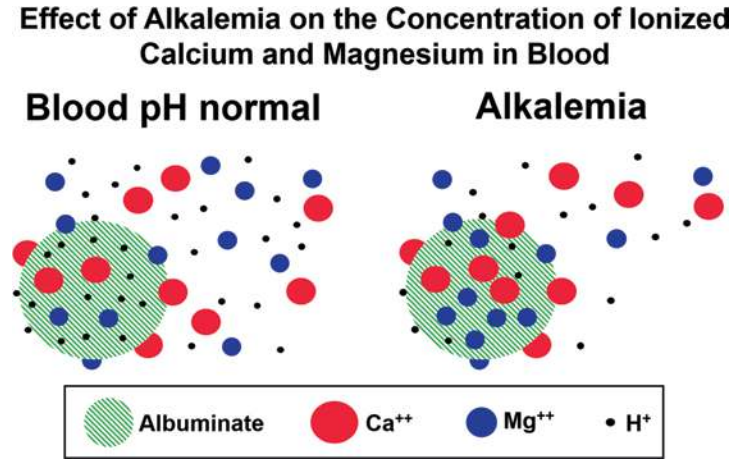

Fig. 34.12 Effect of Alkalemia on the concentration of ionized calcium and magnesium in blood. In the context of alkalemia (e.g.: hyperventilation) blood H^+ concentration decreases. As a consequence, freely ionized calcium and magnesium concentrations decrease. The opposite is observed in the context of acidemia

sociation of Ca^{++} and Mg++ from plasma protein. The effect of acidosis on Ca^{++} salt dissociation extends to the bone. Alkalemia might increase calcium phosphate precipitation and lowers ionized Ca^{++} and Mg^{++} (the underlying mechanisms are explained in Fig. 34.12).

Hemoglobin Oxygen Affinity

Blood pH alters hemoglobin oxygen binding and tissue oxygen delivery. Acidemia decreases hemoglobin oxygen affinity, shifts the oxygen dissociation curve "to the right" and increases tissue delivery of oxygen (Bohr effect). On the contrary, alkalemia shifts the curve to the left, increasing the oxygen binding to hemoglobin and tending to decrease tissue delivery.

Cardiovascular System

Acidemia impairs cardiovascular function in four ways: (a) it depresses vascular tone; (b) it alters the release of, and the response to, catecholamines; (c) it depresses myocardial contractility inducing diastolic dysfunction; and (d) it induces arrhythmias (in mild to moderate acidemia, increased catecholamines produce sinus tachycardia; when acidemia is severe, vagal activity increases and bradycardia ensues; there is also an increased risk of ventricular fibrillation). Alkalemia exerts fewer effects on the cardiovascular system. The predominant clinical problem is an increase in myocardial irritability. Alkalemia reduces the free Ca^{++} and Mg^{++} inside the cell and out, and most alkalemic patients are also hypokalemic. Changes in both ions contribute to the increased potential for arrhythmias.

Alkalemia has significant effects on vascular tone in the cerebral circulation: hypocarbia constricts the cerebral vasculature as indicated by the fact that subjects with respiratory alkalosis develop lightheadedness and lack of mental acuity, but coma does not occur.

Central Nervous System

Acidosis and alkalosis impair central and peripheral nervous system function. Alkalemia increases seizure activity. If pH is $\geq$7.60, seizures may occur in the absence of an underlying epileptic diathesis. Acidosis depresses the central nervous system (this most frequently occurs in respiratory acidosis). Early signs of impairment include tremors, myoclonic jerks, and clonic movement disorders. At pH $\leq$7.10, there is generalized depression of neuronal excitability. Central effects of severe hypercarbia include lethargy and stupor at pCO_2 60 mmHg or more, coma occurs at pCO_2 $\geq$90 mmHg. Metabolic acidosis causes central nervous system depression less commonly. Fewer than 10% of diabetics with ketoacidosis develop coma (hyperosmolarity and the presence of acetoacetate may be more important than acidosis per se).

Metabolism

A final aspect of acid-base pathophysiology is the effect of pH on metabolism. The most often

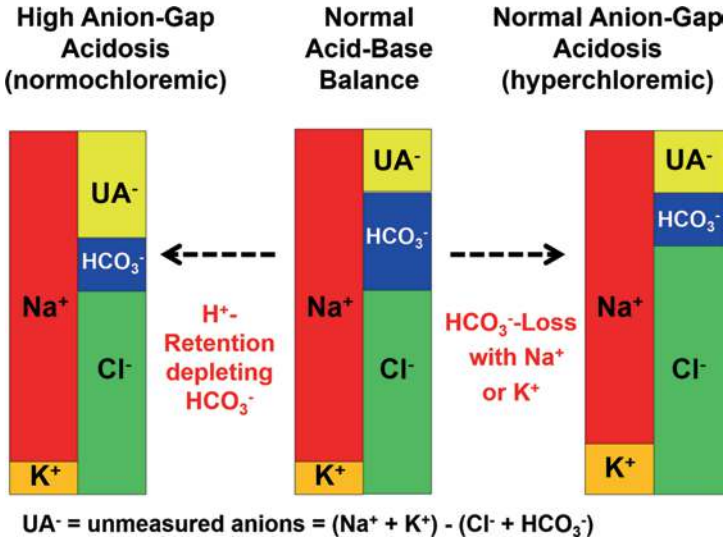

Fig. 34.13 High anion gap (= normochloremic) and normal anion gap (= hyperchloremic) metabolic acidosis. Calculation of the blood anion gap, the difference between the major measured cations (Na^+ and K^+; mmol/L) and the major measured anions (HCO_3^- and Cl^-; mmol/L), is a crucial laboratory diagnostic tool in patients with metabolic acidosis. The blood anion gap separates two major types of metabolic acidosis. High anion gap (= normochloremic) metabolic acidosis results from retention of fixed acids, which deplete HCO_3^- stores by releasing their protons (most cases develop following excessive endogenous or exogenous acid load). Most cases of normal anion gap (= hyperchloremic) metabolic acidosis result from an intestinal or a renal loss of HCO_3^- (accompanied either by Na^+ or K^+). The figure also emphasizes the tendency towards hyperkalemia (the result of a K^+-shift from the intracellular to the extracellular fluid volume) in normal anion gap (hyperchloremic) metabolic acidosis (as explained in Fig. 34.11)

cited example of pH control of enzyme activity is the pH regulation of phosphofructokinase, which catalyzes a rate-controlling step in carbohydrate metabolism. Glycolysis terminates in lactic and pyruvic acid; and accumulation of these acids reduces pH. This is but one example of pH feedback. Most enzymes operate most effectively at a specific optimum pH. As pH varies from the optimum, enzyme activity changes. The integrated response of the individual enzyme alterations may serve to maintain or restore normal pH.

Metabolic Acidosis

Primary hypobicarbonatemia and, therefore, metabolic acidosis mostly occurs when endogenous acids are produced faster than they can be excreted, when HCO_3^- is lost from the body, or when exogenous acids are administered [31–35].

The main laboratory tool in metabolic acidosis is the calculation of the blood anion gap (Fig. 34.13), the difference between the major measured cations (Na^+ and K^+; mmol/L) and the major measured anions (bicarbonate and Cl^-; mmol/L) by means of the equation:

$$AG = \left(Na^+ + K^+\right) - \left(Cl^- + HCO_3^-\right)$$

Because electroneutrality must be maintained, the anion gap results from the difference between the unmeasured anions (primarily albumin, which is largely responsible for the normal anion gap, but also phosphate, sulfate, and organic anions such as lactate) and the remaining cations (Ca^{++} and Mg^{++}).

The calculation of blood anion gap (reference: ≤18 mmol/L[7]) allows separation of the two major types of metabolic acidosis: one type has an increased anion gap (>18 mmol/L; high anion

[7]The blood anion gap sometimes does not include the blood concentration of K^+: $Na^+ - (HCO_3^- + Cl^-)$. The approximate upper value of this anion gap is lower by 4 mmol/L: 14 mmol/L.

Table 34.13 Causes of metabolic acidosis

• **Metabolic acidosis with increased anion gap**
– Excessive acid load
Endogenous sources of acid (due to abnormal metabolism of substrates)
Ketoacidosis (largely β-hydroxybutyric acid)
Congenital organic acidemias (e.g.: methylmalonic acidemia and propionic acidemia)
L-lactate acidosis
Type A (impaired tissue oxygenation; e.g.: sepsis, hypovolemia, cardiac failure)
Type B (altered metabolism of L-lactate with normal tissue oxygenation in the context of a mitochondrial impairment)
Inherited metabolic diseases: either altered production of glucose from lactate or altered degradation of pyruvate derived from pyruvate
Thiamine deficiency
Drugs (e.g.: biguanides, antiretroviral agents)
Toxins (e.g.: ethanol)
Chronic diseases (mostly hepatic)
Overproduction of organic acids in the gastrointestinal tract (D-lactate)
Conversion of alcohols (methanol, ethylene glycol) to acids and poisonous aldehydes
– Defective renal excretion of acids due to generalized renal failure ("uremic acidosis")
• **Metabolic acidosis with normal anion gap**
– Losses of bicarbonate (HCO_3^-)
Intestinal: diarrhea, surgical drainage of the intestinal tract, gastrointestinal fistulas resulting in losses of fluid rich in HCO_3^-, patients whose ureters have been attached to the intestinal tract (the alkali of intestinal secretion is lost by titration with acid urine)
Urinary: carbonic anhydrase inhibitors (e.g.: acetazolamide), proximal renal tubular acidosis (= type 2)
– Failure to replenish HCO_3^- stores depleted by the daily production of fixed acids
Distal renal tubular acidosis (either classic, also called type 1, or type 4)
Diminished mineralocorticoid (or glucocorticoid) activity (adrenal insufficiency, selective hypoaldosteronism, aldosterone resistance)
Administration of potassium sparing diuretics (spironolactone, eplerenone, amiloride, triamterene)
– Exogenous infusions
Amino acids like L-arginine and L-lysine (during parenteral nutrition)
HCl or NH_4Cl
– Rapid administration of normal saline solution (= "dilutional" metabolic acidosis)

gap metabolic acidosis) and the other does not (normal anion gap metabolic acidosis or hyperchloremic metabolic acidosis), as shown in Fig. 34.13 and Table 34.13.

High Anion Gap Metabolic Acidosis

The HCO_3^- deficit observed in high anion gap metabolic acidosis results from retention of fixed acids, which deplete HCO_3^- stores by releasing their protons. Two mechanisms lead to this form of metabolic acidosis (Fig. 34.13 and Table 34.13): (a) excessive acid load (endogenous or exogenous) overwhelming the normal capacity to decompose or excrete the acid; and (b) diminished capacity to excrete the normal load of fixed acids in the context of renal failure.

In health, the blood anion gap is predominantly due to the net negative charge of albumin. Abnormally low serum albumin levels influence acid-base interpretation as calculated by the anion gap. For example, in a patient with increased production of endogenous acids, elevation of the anion gap may be masked by concurrent hypoalbuminemia. In this condition the anion gap corrected for albumin may be calculated by means of the following formula (albumin in g/L):

$$\left(Na^+ + K^+\right) - \left(Cl^- + HCO_3^-\right) + \frac{1}{4}\left(40 - \text{Albumin}\right)$$

Considering that many currently available blood gas analyzers determine circulating L-lactate, the determination of the albumin and lactate corrected anion gap has been recently suggested (upper reference: 15 mmol/L):

$$\left(Na^{+}+K^{+}\right)-\left(Cl^{-}+HCO_3^{-}+\text{Lactate}\right)+\frac{1}{4}\left(40-\text{Albumin}\right)$$

Normal Anion Gap Metabolic Acidosis (= "Hyperchloremic")

This form of metabolic acidosis develops (Fig. 34.13 and Table 34.13): (a) from a primary loss of HCO_3^-, (b) from the failure to replenish HCO_3^- stores depleted by the daily production of fixed acids (H^+: 1–3 mmol/kg body weight) in subjects with normal glomerular filtration rate, or (c) from the administration of exogenous acids (including the rapid administration of large volumes of normal saline solution and other Cl^- rich fluids).

The following factors account for the metabolic acidosis that is observed after administration of normal saline solution, which is called "dilutional" (or "chloride overload") acidosis: (a) Volume expansion, which results from infusion of normal saline, reduces the renal threshold for HCO_3^- leading to bicarbonaturia; (b) The infusion of normal saline with a Na^+ level almost identical to that of blood results in a relatively stable Na^+ level in blood. By contrast, the concentration of Cl^- in the infused solution, which is much higher than that of normal blood, leads to progressive hyperchloremia and hypobicarbonatemia.

Urine Net Charge

The kidney prevents the development of metabolic acidosis by modulating the HCO_3^- concentration in blood. This is done by (a) preventing loss of large amounts of filtered HCO_3^- (primarily a task of the proximal tubule, which may reclaim the filtered HCO_3^-) and (b) generating HCO_3^- (primarily a task of the distal tubule). The main mechanism by which the distal tubule generates HCO_3^- is the conversion of glutamine to NH_4^+, which is excreted in the urine, plus HCO_3^-, which is added to the blood. As a consequence, the urinary NH_4^+ excretion reflects the renal HCO_3^- generation, and the renal NH_4^+ excretion can be equated with HCO_3^- regeneration on a 1:1 basis. In a child with normal anion gap metabolic acidosis and normal renal mechanisms of acidification a very low urinary concentration of HCO_3^- and, more importantly, a large concentration of NH_4^+ will result. The measurement of these parameters, which is complicated by the need to avoid significant changes in urine composition after voiding,[8] is usually unavailable in clinical practice. In the context of metabolic acidosis, a urinary pH significantly <6.2 indicates a very low urinary concentration of HCO_3^- and argues against an altered renal mechanism of urinary acidification. Furthermore, and more importantly, the crucial concept of urinary net charge or urine anion gap[9] (which results from urinary Na^+, K^+ and Cl^-) was developed as an indirect assessment of urinary NH_4^+ concentration. Usually, because ammonium (an unmeasured cation) accompanies Cl^- in the context of metabolic acidosis, the concentration of Cl^- should be greater than the sum of Na^+ and K^+, and the net charge negative ($Na^+ + K^+ < Cl^-$). A positive net charge ($Na^+ + K^+ > Cl^-$) indicates impaired ammonium secretion and, therefore, impaired distal acidification of renal tubule. For instance, in the aforementioned context of metabolic acidosis with normal renal mechanisms of acidification (e.g. a child with normal anion gap metabolic acidosis

[8] The changes are due to bacterial overgrowth, especially at room temperature, as well as to open exposure to the atmosphere, which produces gas loss.

[9] The term urine anion gap is a misnomer for what should have been named urine cation gap.

Table 34.14 Indirect assessment of urinary excretion of NH_4^+ by means of the urinary net charge in subjects with normal anion gap metabolic acidosis

Distal acidification of the renal tubule	Urinary NH_4^+	Urinary net charge
Normal	↑ NH_4^+	$Na^+ + K^+ < Cl^-$
Impaired	↓ NH_4^+	$Na^+ + K^+ > Cl^-$[a]

[a] The urine osmolal charge is a more precise estimate of the urinary NH_4^+ concentration in this setting: $\frac{\text{Measured Osmolality} - \left[2 \times (\text{Na} + \text{K}) + \text{Urea} + \text{Glucose}\right]}{2}$

due to mild diarrhea) the enhanced urinary NH_4^+ excretion will result in a large urinary level of urinary NH_4Cl and consequently the measured urinary cations (= $Na^+ + K^+$) will have a concentration lower than that of the measured anion Cl^-: $Na^+ + K^+ < Cl^-$. On the contrary, in a child with an impaired renal acidification, the urine net charge will be as follows: $Na^+ + K^+ > Cl^-$ (Table 34.14).

When the urine net charge is positive ($Na^+ + K^+ > Cl^-$) and it is unclear whether increased excretion of unmeasured anions is responsible, the urinary NH_4^+ concentration can be estimated from calculation of the urine osmolal gap (Table 34.14). This calculation requires measurement of the urine osmolality (in mosm/kg) and the urine Na^+, K^+, urea, and, if the dipstick is positive, glucose concentrations[10] (in mmol/L). In the context of metabolic acidosis, an estimated urinary NH_4^+ concentration of <20 mmol/L indicates an impaired NH_4^+ excretion.

Metabolic Acidosis During the First Months of Life

During the first months of life bicarbonatemia is lower by 2–4 mmol/L than in older children, and it is even lower in preterm infants. This is the consequence of a lower renal threshold for bicarbonate. In addition, in preterm infants and in growing children the daily production of H^+ is higher by 50–100% than that noted in adults (this is mainly explained by the fact that the growing skeleton releases 20 mmol of H^+ for each 1 g of Ca^{++} that is incorporated). The clinical implications of these data are that, as compared with older children, newborns and infants have a relatively limited capacity to compensate for hypobicarbonatemia. In this age, the tendency towards metabolic acidosis is compensated for by the large intake of milk, whose alkali content is high. Infants are therefore more prone to develop metabolic acidosis in conditions associated with a decreased milk intake.

Symptoms, Signs, Consequences

The signs and symptoms of acute metabolic acidosis include (1) high respiratory rate (in young children and infants, the increase in depth of respiration, as observed in classic Kussmaul type deep breathing, may not be as apparent as in adults and the response to metabolic acidosis may be tachypnea alone); (2) abdominal pain and vomiting; (3) irritability and lethargy.

The gastrointestinal absorption and excretion of dietary base plays a major role in acid-base homeostasis in infants in whom the predominantly milk-based diet supplies a considerable amount of alkali. Infants are therefore more vulnerable to developing metabolic acidosis in illnesses associated with decreased milk intake.

Since an excessive chronic acid burden interferes with Ca^{++} deposition in the bone and Ca^{++} intestinal absorption, metabolic acidosis of any form can impair growth in children. Other signs and symptoms are abdominal pain, vomiting, irritability, lethargy, seizures and coma. However, the latter manifestations are primarily due to the underlying disease (e.g.: organic acidemias or hyperosmolality in diabetic ketoacidosis) and not primarily to the acidosis itself.

Clinical Work Up

The causes of metabolic acidosis, which appear in Table 34.13, can almost always be discerned clinically. A careful history and physical exami-

[10] The obtain urea and glucose in mmol/L divide blood urea nitrogen (in mg/dL) by 2.8 and glucose (in mg/dL) by 18.

nation and the determination of the blood anion gap direct an accurate evaluation. For the initial diagnostic approach to metabolic acidosis of unknown origin, the following initial steps are taken [31–35]:

- Confirm the diagnosis of metabolic acidosis
- Confirm that the respiratory response is appropriate
- Distinguish high from normal anion gap metabolic acidosis:
  - Normal anion gap: consider intestinal loss of HCO_3^-
  - High anion gap: assess urinary ketones, blood glucose and blood L-lactate

The major causes of high anion gap acidosis are L-lactate acidosis, which results from impaired tissue oxygenation (type A acidosis) or from an altered metabolism of L-lactate with normal tissue oxygenation in the context of a mitochondrial impairment (type B acidosis), diabetic ketoacidosis, which mainly results from the accumulation of ß-hydroxybutyrate, and "uremic" metabolic acidosis, which is characterized by the accumulation of phosphate, sulfate, and organic anions.

In children, normal anion gap metabolic acidosis mostly results from intestinal bicarbonate losses due to diarrhea. Renal bicarbonate wasting is much less common. In children with normal anion gap acidosis but without history of diarrhea, the concurrent determination of urinary Na^+, K^+, Cl^- will provide information on the renal mechanisms of acidification.

Sometimes there is overlap between the causes of a normal and high anion gap metabolic acidosis. Diarrhea, for example, is most often associated with a normal anion gap. However, severe diarrhea and hypovolemia can result in an increase in the anion gap due to hypoperfusion-induced lactic acidosis and starvation ketosis.

Management

The management of metabolic acidosis includes the following four points:

- Emergency measures:
  - Avoidance of further production of H^+ including measures to ensure a proper airway, adequate peripheral perfusion and O_2 delivery. For instance, in a child with type A L-lactate acidosis in the context of severe dehydration, delivery of O_2 and the rapid administration of normal saline will regenerate adenosine triphosphate. On the other hand, in a child with accidental methanol intoxication the administration of ethanol might stop the production of toxins leading to acidosis.
  - Increasing pH level by lowering the pCO_2, ensuring an adequate degree of hyperventilation, if necessary by mechanical ventilation.
- Correction of the underlying condition. For example, the administration of insulin, in addition to normal saline, in diabetic ketoacidosis.
- Administration of $NaHCO_3$. The use of $NaHCO_3$ is controversial, considering the possible benefits ((a) metabolic advantage of faster glycolysis with better availability of adenosine triphopsphate in vital organs; (b) improved cardiac action) and the risks ((a) extracellular fluid volume expansion; (b) tendency towards hypernatremia; (c) development of hypokalemia and hypocalcemia; (d) worsening of intracellular acidosis). The following guidelines have been suggested for administration of $NaHCO_3$:
  - Diabetic ketoacidosis: $NaHCO_3$ should be considered when hyperkalemia persists despite insulin therapy, when acidemia worsens despite insulin therapy (suggesting insulin resistance as a result of acidemia) and perhaps when HCO_3^- is <5.0 mmol/L. We are very reluctant to use bicarbonate in diabetic ketoacidosis because the administration of $NaHCO_3$ is a risk factor for cerebral edema.
  - Type A L-lactate metabolic acidosis: In this form of acidosis the primary effort should be directed at improving delivery of O_2. $NaHCO_3$ should be given when HCO_3^- is <5.0 mmol/L.

– Since the "HCO_3^- space" is ≈0.5 L/kg body weight the dose of $NaHCO_3$ in severe metabolic acidosis may be calculated from body weight (in kg), current blood HCO_3^-, and desired blood HCO_3^- (both in mmol/L), using the equation:

$$\text{Body weight} \times 0.5\left(\text{desired } HCO_3^- - \text{current } HCO_3^-\right)$$

– Hence, a child weighing 20.0 kg with a severe hypobicarbonatemia of 3.5 mmol/L will be given 40 mmol of $NaHCO_3$ over several minutes (i.e. 2.0 mmol/kg body weight) if the "desired" blood HCO_3^- level is 7.5 mmol/L. In most cases, however, the initial dosage of $NaHCO_3$ is 1.0 mmol/kg body weight, a dosage that is expected to increase blood HCO_3^- by 2.0 mmol/L.

- Correction of metabolic acidosis tends to decrease circulating K^+ level. Hence, one must avoid a severe degree of hypokalemia when $NaHCO_3$ is given. K^+ depletion and metabolic acidosis are associated in three settings: classic distal renal tubular acidosis, acute diarrheal disease and diabetic ketoacidosis, as shown in Table 34.15. The management of renal tubular acidosis will be discussed in the chapter "Renal tubular acidosis", that of uremic acidosis in the sections discussing renal replacement therapy.

Table 34.15 Conditions associating metabolic acidosis and potassium depletion

Condition	Basis of potassium depletion
Classic distal renal tubular acidosis	Renal loss
Diarrhea	Intestinal and renal (secondary hyperaldosteronism due to circulating volume depletion) loss
Diabetic ketoacidosis	Renal loss (osmotic diuresis)[a], cellular shift following insulin therapy

[a] Circulating potassium is often initially normal in diabetic ketoacidosis

Metabolic Alkalosis

Primary hyperbicarbonatemia and, therefore, alkalemia, are the hallmarks of metabolic alkalosis [31, 32, 36, 37]. In this peculiar acid-base disorder (Table 34.16) hyperbicarbonatemia, alkalemia and the compensatory hypoventilation (resulting in a rise of the pCO_2) are almost always associated with hypokalemia (see: systemic effects of acid-base abnormalities).

With the constraints of electroneutrality, the ways to add HCO_3^- to extracellular space are loss of the anion Cl^- or retention of Na^+. Hence circulating HCO_3^- may be raised either (1) associated with a normal or contracted "effective" circulating volume (blood pressure normal or low) or with (2) an expanded "effective" circulating volume (blood pressure increased).

- **Metabolic alkalosis associated with normal or contracted "effective" circulating volume (= "unaccompanied" Cl^- deficiency syndrome or normotensive hypokalemic metabolic alkalosis) = chloride depletion metabolic alkalosis**
- In this clinical-laboratory entity Cl^- is lost from the extracellular space "not accompanied" by the major cations Na^+ and K^+ but "accompanied" by H^+ or NH_4^+. Since a loss of H^+ or NH_4^+ is equivalent to a gain of HCO_3^-, the final effect is loss of Cl^- and gain of HCO_3^-.
- Two further steps complete the development of metabolic alkalosis:
  – "Extra" HCO_3^-, which is filtered by the kidney, is mostly reabsorbed and only a little HCO_3^- is excreted.

Table 34.16 Causes of metabolic alkalosis (linked with hypokalemia)

• Associated with normal (or contracted) "effective" circulating volume (and therefore with normal or even low blood pressure)
(a) Nonrenal causes (low urine chloride excretion: chloride/creatinine <10 mol/mol)
Intestinal causes
Low dietary chloride intake (e.g.: soybean formula with a low chloride content in infancy, "tea and toast diet")
Loss of gastric secretions (vomiting, nasogastric suction)
Posthypercapnia
Congenital chloridodiarrhea (uncommon), villous adenoma (uncommon)
Cutaneous cause
Cystic fibrosis
Excessive sweating (uncommon, associated with low dietary chloride intake)
"Posthypercapnia" (= posthypercapnic alkalosis)
Refeeding syndrome
Transient neonatal metabolic alkalosis in infants of mothers affected by chloride deficiency (eating disorders associated with chloride deficiency, Bartter syndromes, Gitelman syndrome)
(b) Renal causes (high urine chloride excretion: chloride/creatinine >10 mol/mol)
Primary chloride losing tubulopathies (Bartter syndromes, Gitelman syndrome)
Secondary chloride losing tubulopathies (some cases of chronic cisplatin tubulopathy)
Current diuretic use (including surreptitious use)[a]
• Associated with an expanded "effective" circulating volume (and therefore with high blood pressure)
Enhanced mineralocorticoid activity
Primary aldosteronism (either hyperplasia or adenoma)
Apparent mineralocorticoid excess (= defect in 11-β-hydroxysteroid-dehydrogenase), Liddle syndrome (congenitally increased function of the collecting tubule sodium channels), dexamethasone-responsive aldosteronism (synthesis of aldosterone promoted not only by renin but also by adrenocorticotropin), congenital adrenal hyperplasia (11-β-hydroxylase or 17-α-hydroxylase deficiency), Cushing disease
Secondary hyperaldosteronism (including renal artery stenosis, malignant hypertension, and renin producing tumor)
Exogenous mineralocorticoids, licorice-ingestion (= 11-β-hydroxysteroid-dehydrogenase blockade)
Reduced renal function plus a source of HCO_3^-: alkali ingestion, ingestion of ion-exchange resin plus nonreabsorbable alkali

[a] The urinary chloride excretion is low in subjects with remote use of diuretics

  - Contraction of the circulating volume activates the renin-angiotensin II-aldosterone system resulting in urinary K^+ excretion, which further aggravates hyperbicarbonatemia.
- Secondary hyperaldosteronism resulting in urinary K^+ excretion is the main cause of hypokalemia that accompanies this form of metabolic alkalosis.
- This clinical-laboratory entity, termed in the past volume contraction hypokalemic alkalosis, is currently termed Cl^- depletion hypokalemic alkalosis because balance and clearance studies indicate that Cl^- repletion in the face of persisting alkali loading, volume contraction, and K^+ and Na^+ depletion repairs alkalosis. During the first months of life metabolic alkalosis is often not associated with hypokalemia (alternatively it is associated with mild hypokalemia) because the ability of the kidney to excrete K^+ is reduced early in life.
- Maternal Cl^- depletion, deficient Cl^- intake, gastrointestinal Cl^- losses, cutaneous Cl^- losses in the setting of cystic fibrosis, diuretics and renal tubular disturbances are the most important causes of normotensive hypokalemic metabolic alkalosis (Table 34.16). The urinary excretion of chloride is low in patients with non-renal and normal or high in subjects with renal causes of this peculiar form of metabolic alkalosis. In our experience the determination of the molar urinary chloride/

creatinine ratio in spot urine samples from patients with normotensive metabolic alkalosis distinguishes between renal (urinary chloride/creatinine ratio largely >10 mol/mol) and non-renal causes (urinary chloride/creatinine ratio <10 mol/mol). In clinical practice this simple parameter is useful in patients in whom the etiology of metabolic alkalosis with normal or low normal blood pressure is not obtainable from the history. Please note that the urinary chloride/creatinine ratio is also usually >10 mol/mol in patients with metabolic alkalosis associated with expanded effective circulating volume (see below).

- **Posthypercapnic alkalosis (= "posthypercapnia").** Chronic respiratory acidosis is associated with a compensatory hyperbicarbonatemia. In those patients with a tendency towards a contracted circulating volume when pCO_2 falls to normal, there will be a stimulus for persistently increased HCO_3^- levels and hypokalemia. In addition, a rapid correction of chronic respiratory acidosis (e.g.: mechanical ventilation) results in an acute rise in cerebral pH that can produce serious neurologic sequelae or even death. Consequently, pCO_2 should be lowered slowly and carefully in chronic hypercapnia.
- **Metabolic alkalosis associated with an expanded "effective" circulating volume (= hypertensive metabolic alkalosis)**
- The second way to add HCO_3^- to the circulating volume and preserving electroneutrality is to retain HCO_3^- along with Na^+, therefore expanding the extracellular fluid volume and increasing blood pressure. Obviously, to retain extra Na^+ (along with HCO_3^-), "permission" of the kidney is required.
- The mechanisms for renal retention of Na^+ and HCO_3^- include either (1) an enhanced reabsorption of filtered HCO_3^- or (2) a reduced glomerular filtration rate plus a source of HCO_3^- (e.g.: the ingestion of large amounts of milk and the absorbable antacid $CaCO_3$).
- Excessive mineralocorticoid activity is the main cause of metabolic alkalosis associated with hypokalemia and expanded circulating volume. The corresponding causes appear in Table 34.16.

Symptoms, Signs, Consequences

There are no specific diagnostic symptoms or signs of metabolic alkalosis [23, 31, 32, 36, 37]. Physical examination may reveal neuromuscolar irritability, such as tetany or hyperactive reflexes. These signs will be more pronounced if hypocalcemia is an accompanying feature, since the ionized Ca^{++} concentration decreases as pH rises. The symptoms and signs of accompanying hypokalemia have been discussed above.

It is recognized that in children with both normal (or contracted) and expanded circulating volume and metabolic alkalosis the assessment of the fluid volume status by physical examination and history may be quite inaccurate. This assumption is supported by the experience in infantile hypertrophic pyloric stenosis where the clinical assessment of the fluid volume status may be quite inaccurate, and the severity of metabolic alkalosis helps to define the amount of fluid replacement required.

Management

The most frequent causes of hypokalemic metabolic alkalosis associated with a normal or contracted "effective" circulating volume include intestinal (mostly gastric) or cutaneous fluid losses, and excessive diuretic therapy. These forms of metabolic alkalosis are termed "chloride responsive", because they are reversed by the oral or intravenous administration of Na^+Cl^-, K^+Cl^- and water. Many institutions hydrate infants with hypertrophic pyloric stenosis with a "near isotonic" parenteral solution containing glucose 5% (= 50 g/L), Na^+Cl^- 80–90 mmol/L and K^+Cl^- 20–30 mmol/L until correction of the acid-base and K^+ balance. The initial parenteral repair consists of a normal saline solution at least in chil-

dren with both hypokalemic alkalosis and rather severe hyponatremia (≤120 mmol/L).

Occasionally, severe metabolic alkalosis is additionally treated with (1) a carbonic anhydrase inhibitor like acetazolamide, which induces bicarbonaturia accompanied by Na^+- and K^+-losses, (2) with NH_4Cl, or (3) with HCl (through a central venous line). Finally, hemodialysis (or hemofiltration) with a low dialysate HCO_3^- in association with saline infusion has been advised for the treatment of severe metabolic alkalosis in advanced kidney disease.

In "chloride responsive" metabolic alkalosis the oral administration of K+ with any anion other than Cl^- (e.g.: citrate) prevents the correction of alkalosis.

Respiratory Acid-Base Disturbances

These acid-base disorders will not be discussed in this textbook of clinical nephrology with the exception of Table 34.17, which depicts the main causes.

Table 34.17 Causes of respiratory acidosis (hypoventilation) and alkalosis (hyperventilation)

• Respiratory acidosis (hypoventilation)
– Central nervous system (patient will not breathe!)
Cerebral
Posthypoxic brain damage
Cerebral trauma
Intracranial disease
Psychotropic drugs
Brain stem
Brain stem herniation
Encephalitis
Central sleep apnea
Severe metabolic alkalosis
Sedative or narcotic drugs
Upper airway reflexes
Bulbar palsy
Anterior horn cell lesion (including Guillan-Barré and poliomyelitis)
Disruption of airway
– Peripheral disorders (patient cannot breathe)
Respiratory muscle disease
Myasthenia, Guillain-Barré syndrome, myopathy, muscular dystrophy
Muscle fatigue or paralysis (including hypokalemic paralysis)
Airway and pulmonary disease
Interstitial lung disease (including lung fibrosis)
Obstructive disease (including upper airway obstruction, asthma, bronchiolitis, cystic fibrosis)
Obstructive sleep apnea
Obesity, kyphoscoliosis
• Respiratory alkalosis (hyperventilation)
– Hypoxia: intrinsic pulmonary disease, high altitude, congestive heart failure, cyanotic congenital heart disease
– Pulmonary receptor stimulation: pneumonia, asthma, interstitial lung disease, pulmonary edema, pulmonary thromboembolism
– Drugs: salicylates, nikethamide, catecholamines, theophylline, progesterone
– Central nervous disorders: subarachnoid hemorrhage, Cheyne-Stokes respiration, primary hyperventilation syndrome
– Miscellaneous: panic attacks with hyperventilation (rare before puberty), fever, sepsis, recovery from metabolic acidosis

Calcium

Balance

A 70 kg man contains one kg of Ca^{++} (= 25 mol), 99% of which resides in the skeleton in the form of hydroxyapatite and 1% of which is found in soft tissues and the extracellular space. Since Ca^{++} plays a crucial role in neuromuscular function, blood coagulation, and intracellular signaling, circulating Ca^{++} concentrations are maintained within a tight physiologic range. The Ca^{++} (and phosphate) homeostasis involves intestinal, bone, and renal function. Regulation of intestinal function is important because, in contrast to the complete absorption of dietary Na^{+}, K^{+} and Cl^{-}, that of Ca^{++} (like Mg^{++} and phosphate) is incomplete. This limitation is due both to the requirement for vitamin D and to the formation of insoluble salts in the intestinal lumen, such as calcium phosphate, calcium oxalate, and magnesium phosphate.

A normal adult ingests ≈1000 mg (= 25 mmol) of Ca^{++} per day, of which ≈40–50% may be absorbed. However, 300 mg (approximately 8 mmol) of Ca^{++} from digestive secretions is lost in the stool, resulting in the net absorption of no more than 10 to 20%. In the steady state, this amount of Ca^{++} is excreted in the urine. Within the blood Ca^{++}, ≈40% is bound to albumin, 15% is complexed with citrate, sulfate, or phosphate, and 45% exists as the physiologically important ionized form [38–40].

Considering that a large proportion of circulating Ca^{++} is bound to albumin, the determination of albumin (or the direct measurement of ionized Ca^{++}) is essential to the diagnosis of true hypocalcemia or hypercalcemia. The so-called Payne's formula [38–41] may be used for correction of total calcium to account for albumin binding:

$$\text{Adjusted } Ca^{2+}\left[\text{mmol / L}\right] = \text{measured } Ca^{2+}\left[\text{mmol / L}\right] + \frac{40 - \text{albumin}\left[\text{g / L}\right]}{40}$$

Although only a small fraction of the total body Ca^{++} is located in the plasma, it is the blood level of ionized Ca^{++} that is under control of calciotropic hormones:

(a) **vitamin D**,
(b) **parathyroid hormone** and
(c) the **Ca^{++}-sensing receptor**. This receptor, which is found on the cell surface of tissues such as the parathyroid gland, kidney, and bone, detects hypocalcemia and leads to enhanced secretion of parathyroid hormone. Summarizing the process briefly, a fall in circulating Ca^{++} in normal subjects leads to a compensatory increase in parathyroid hormone secretion, which returns the Ca^{++} level to normal by two major actions: increased Ca^{++} release from bone and stimulated production of 1,25-dihydroxyvitamin D, the active metabolite of vitamin D, resulting in an increase in intestinal Ca^{++} absorption [38–40].
(d) **Parathyroid hormone related peptide** is a further calciotropic hormone with the following identified actions: (1) During pregnancy, Ca^{++} is transferred from the maternal circulation to the fetus by a pump regulated by this hormone; (2) Parathyroid hormone related peptide levels are elevated during lactation and contribute substantially to the movement of Ca^{++} from the maternal skeleton to the mammary glands; (3) Finally, this peptide is involved in the pathogenesis of hypercalcemia of malignancies [38–40].

Hypocalcemia

Non-neonatal Hypocalcemia

Symptoms and Signs

Symptoms and signs of hypocalcemia, which is often asymptomatic, result from neuromuscular, ocular, ectodermal, dental, gastrointestinal, car-

diovascular, skeletal or endocrine dysfunctions, and are related to the severity and chronicity of the hypocalcemia (Table 34.18). Hypocalcemia manifests with a prolonged QT interval on standard electrocardiogram (Fig. 34.9). However, some signs and symptoms are unique to chronic

Table 34.18 Clinical signs and symptoms of hypocalcemia

• **Neuromuscular**
– **Tetany**
sensory dysfunction: circumoral and acral paresthesias
muscular dysfunction
Stiffness, myalgia, muscle spasms and cramps
Forced adduction of the thumb, flexion of the metacarpophalangeal joints and wrists, and extension of the fingers
Laryngismus stridulus (spasm of respiratory muscles and of glottis causing dyspnea)
Autonomic dysfunction: diaphoresis, bronchospasm, biliary colic
Trousseau sign: inflation of a sphygmomanometer above systolic blood pressure for 3–4 min induces a carpal spasm
Chvostek sign: ipsilateral tapping of the facial nerve just anterior to the ear followed by contraction of the facial muscles (the complete sign is contraction of corner of the mouth, the nose and the eye; contraction of the corner of the mouth alone often occurs in normal subjects)
– **Myopathy:** generalized muscle weakness and wasting with normal creatine kinase (myopathy represents more a feature of vitamin D deficiency than hypocalcemia per se; elevated parathyroid hormone level or hypophosphatemia may contribute to the myopathy)
– **Extrapyramidal disorders:** Bradykinetic movement disorders, sometimes dystonia, hemiballismus, choreoathetosis, oculogyric crises
– **Convulsions** (generalized or partial)
– **Mental retardation**, **psychosis**
• **Ocular**
– Cataract (rarely keratoconjunctivitis)
– Papilledema (often associated with benign intracranial hypertension; rarely optic neuritis is present)
• **Ectodermal** (especially in the context of severe, chronic hypocalcemia)
– Dry scaly skin
– Hyperpigmentation, dermatitis, eczema, and psoriasis
– Course, brittle, and sparse hair with patchy alopecia
– Brittle nails, with characteristic transverse grooves
– Candidiasis: usually as a component of **A**utoimmune **P**oly**E**ndocrinopathy-**C**andidiasis-**E**ctodermal **D**ystrophy (= APECED-association)
• **Dental** (dental hypoplasia, failure of tooth eruption, defective enamel and root formation, and abraded carious teeth)
• **Gastrointestinal**
– Loose stools (steatorrhea due to impaired pancreatic secretion)
– Gastric achlorhydria
• **Cardiovascular**
– Systemic hypotension, decreased myocardial function, congestive heart failure
– Prolonged QTc interval on standard electrocardiogram with tendency towards cardiac arrhythmias (clinically relevant if hypocalcemia is associated with hypokalemia and hypomagnesemia)
• **Skeletal**
– Rachitic findings
Delayed closure of the fontanelles
Parietal and frontal bossing
Craniotabes
Rachitic rosary: enlargement of the costochondral junction visible as beeding along the anterolateral aspects of the chest
Harrison sulcus caused by the muscular pull of the diaphragmatic attachments to the lower ribs

(continued)

Table 34.18 (continued)

Enlargement and bowing of the distal radius, ulna, tibia and fibula
Progressive lateral bowing of the femur and tibia
– Children with hypoparathyroidism: increased bone mineral density, osteosclerosis and thickening of the calvarium
– Children with pseudohypoparathyroidism: Albright's hereditary osteodystrophy, osteitis fibrosa cystica (due to normal skeletal responsiveness to parathyroid hormone)
• **Endocrine manifestations**
– Impaired insulin release
– Hypothyroidism, prolactin deficiency, and ovarian failure associated with polyglandular autoimmune syndromes

hypoparathyroidism and not hypocalcemia: these include candidiasis and dysmorphic changes in **A**utoimmune **P**oly **E**ndocrinopathy-**C**andidiasis-**E**ctodermal **D**ystrophy (= APECED-association). Among the symptoms of hypocalcemia, tetany, papilledema and seizures may occur in patients who develop hypocalcemia acutely. By comparison, ectodermal and dental changes, cataracts, basal ganglia calcification, and extrapyramidal disorders are features of chronic hypocalcemia and are common in hypoparathyroidism [38–40, 42].

Causes

Deficiency or impaired function of (a) parathyroid hormone, (b) vitamin D or (c) Ca^{++}-sensing receptor are major causes of reduced blood level of ionized Ca^{++}. Because bone Ca^{++} stores are so large, the major reason for hypocalcemia is decreased bone resorption. Sometimes acute events such as hyperphosphatemia, can produce hypocalcemia even though the regulatory systems are intact. The main causes of hypocalcaemia include vitamin D deficiency, Ca^{++} deficiency, impaired vitamin D metabolism, impaired parathyroid hormone action (secondary to end organ resistance), reduced production of parathyroid hormone, and abnormal Ca^{++}-sensing receptor or impaired renal function (Table 34.19).

Diagnostic Work Up

Hypocalcemia is a rather common clinical problem, the cause of which can very often be determined from the history (as with a breast-fed infant not receiving any supplementation of vitamin D presenting with non-febrile generalized convulsions, enlargement of the costochondral junction along the anterolateral aspects of the chest and enlargement of the wrist). In some cases, however, the underlying condition is not readily apparent. A detailed history documenting diet, lifestyle, family, and drug history, as well as development and hearing is important. The examination should include an assessment of skin, nails, teeth, and the skeleton, as well as the cardiovascular system. A comprehensive range of investigations should be performed at baseline, which have been divided into first and second line (Table 34.20). The objective of assessing urine Ca^{++} excretion is to establish whether the molar urine calcium/creatinine is inappropriately high in the presence of hypocalcemia. Reference values for urine calcium/creatinine ratio in young children are not well defined and will vary according to factors such as diet. The upper limits of normal urine Ca^{++} excretion in healthy children appear in the footnote of Table 34.20. Renal phosphate handling may be abnormal despite a blood phosphate within the quoted laboratory normal range, and should be assessed in more detail by determining the tubular maximum reabsorption threshold of phosphate (see phosphate).

Checking biochemistry of the parents and possibly siblings is crucial when inherited diseases such as hypocalcaemic hypercalciuria and hypophosphataemic rickets are suspected. It is also important to measure maternal Ca^{++} and vitamin D levels in the case of hypocalcaemia in infancy because of the link with maternal vitamin D deficiency and hyperparathyroidism. Maternal hyperparathyroidism is linked with adverse preg-

Table 34.19 Causes of hypocalcemia in infants and children

Parathyroid hormone level low
• **Abnormal production of parathyroid hormone**
– Magnesium deficiency[a]
– Following neck surgery
– Hypoparathyroidism (autosomal recessive, autosomal dominant, or X-linked)
– Di George anomaly (= 22q11 deletions), 10p13 deletion, Hall-Hittner or CHARGE-association (=Coloboma, Heart anomaly, Choanal Atresia, mental Retardation, Genital hypoplasia, and Ear anomalies), HDR-association (= Hypoparathyroidism, Deafness, Renal dysplasia)
– **A**utoimmune **P**oly**E**ndocrinopathy-**C**andidiasis-**E**ctodermal **D**ystrophy (= APECED-association)
– Infiltrative lesions such as Wilson's disease and thalassemia
– Mitochondrial diseases (e.g. Kearns Sayre syndrome)
• **Altered "set point"** (calcium sensing receptor activating mutations)
Intact parathyroid hormone level high
• **Hypovitaminosis D, calcium deficiency, impaired vitamin D metabolism**
– **Hypovitaminosis D**
Reduced vitamin D intake or production in the skin
Decreased intestinal absorption (e.g. celiac disease and cystic fibrosis)
– **Calcium deficiency**
– **Impaired vitamin D "metabolism"**
Severe liver disease
Drugs that "inactivate" vitamin D: anticonvulsants (phenobarbital, phenytoin, carbamazepine, oxcarbazepine), antimicrobials (isoniazid and rifampicin), antiretroviral drugs
Enzyme deficiency: defects of the 1-α-hydroxylase gene (= vitamin D dependent rickets type I)
End organ resistance to vitamin D (= vitamin D dependent rickets type II)
• **Signaling defects: pseudohypoparathyroidisms**
• **Renal failure, osteopetrosis, excessive fluoride intake**

[a] Severe chronic magnesium deficiency (≤0.45 mmol/L) causes hypocalcaemia by impairing parathyroid hormone secretion as well as parathyroid hormone action

Table 34.20 First and second line investigations in childhood hypocalcemia when the cause cannot be determined from the history and clinical examination

First line investigations	Second line investigations
• **Blood values**	
Phosphate[a], Magnesium	Autoantibody screen
Alkaline Phosphatase	Parental (and siblings)
Sodium, Potassium, Bicarbonate, Creatinine	Maternal Vitamin D_3-status
Intact Parathyroid Hormone	1,25-hydroxy vitamin D3
25-Hydroxyvitamin D_3 (= calcidiol)	Genetic studies (e.g. 22q11 deletion)
• **Urinary values**	
Urinalysis (for glucose, protein and pH)	
Calcium[a], Phosphate[b], Creatinine	
• **Imaging**	
Hand and wrist radiograph	Renal ultrasound
	Skull radiograph

[a] The upper limit of normal for urine calcium/creatinine in healthy children is 2.20 mol/mol (or 0.81 mg/mg) in infants aged 6–12 months, 1.50 mol/mol (or 0.56 mg/mg) in infants aged 13–24 months, 1.40 mol/mol (or 0.50 mg/mg) in infants aged 25–36 months, 1.10 mol/mol (or 0.41 mg/mg) in children aged 3–5 years, 0.80 mol/mol (or 0.30 mg/mg) in children aged 5–7 years and 0.70 mol/mol (or 0.25 mg/mg) in older children

[b] Calculate the maximal tubular reabsorption of phosphate as indicated in the section on phosphate

nancy outcome and causes transient hypocalcemia in the newborn because the fetal parathyroids are suppressed following exposure to high Ca^{++} levels in utero. An autoantibody screen including adrenal, parathyroid, smooth muscle and microsomal antibodies is useful in cases of isolated hypoparathyroidism and where APECED-association is suspected. Renal ultrasound scan looking for evidence of nephrocalcinosis or renal dysplasia is also often advised.

The biochemical picture of hypocalcemia can be categorized according to the presence of undetectable, normal or high levels of circulating parathyroid hormone, an approach that reflects the underlying pathophysiology [42].

- Undetectable or low levels of this hormone in the hypocalcemic child suggest hypoparathyroidism (Table 34.19). Aplasia or hypoplasia of the parathyroids is most commonly due to the DiGeorge syndrome associated with deletion of chromosome 22q11. In this syndrome, the characteristic clinical signs of the so called "CATCH-22" might be noticed: Cardiac malformations (especially conotruncal anomalies

like tetralogy of Fallot, truncus arteriosus communis or interrupted aortic arch), Abnormal facies, Thymic aplasia, Cleft palate and Hypocalcemia/Hypoparathyroidism). A similar phenotype including hypoparathyroidism has also been associated with deletions of chromosome 10p, while the HDR-association (**H**ypoparathyroidism, **D**eafness, and **R**enal dysplasia) is due to defects in the GATA3 gene. Defects in the parathyroid hormone gene are rare. Diseases such as APECED can present with hypoparathyroidism in the absence of the two other major manifestations, which are candidiasis and adrenal failure. There should be a high index of suspicion for this disease in all cases of hypoparathyroidism presenting in children older than 4 years. Children with APECED may have other "minor" features such as malabsorption, gallstones, hepatitis, dysplastic nails and teeth. Screening should be considered in the siblings of affected individuals. Mitochondrial disease is a rare cause of hypoparathyroidism but is not usually an isolated finding.

- Detectable parathyroid hormone values (low-normal or normal) in an asymptomatic individual raise the possibility of hypocalcemic hypercalciuria, an abnormality of the Ca^{++}-sensing receptor which can be assessed in more detail by determining urinary Ca^{++} excretion. This parameter is typically low in longstanding hypoparathyroidism, and a relatively high urine Ca^{++} excretion (molar urinary calcium/creatinine ratio $\geq$0.30) suggests hypocalcemic hypercalciuria. This abnormality is due to activating mutations of the Ca^{++}-sensing receptor with downshift of the setpoint for Ca^{++} responsive parathyroid hormone release. Mg^{++} levels are low in this disorder because the Ca^{++}-sensing receptor also detects this cation. Interestingly, the biochemical picture of hypocalcemic hypercalciuria sometimes resembles Bartter syndromes and includes hypokalemia and hyperbicarbonatemia.
- If blood creatinine is normal, thereby excluding renal insufficiency, then increased parathyroid hormone levels point towards a diagnosis of rickets[11] or pseudohypoparathyroidism. Vitamin D deficiency is still prevalent in the Western world. High-risk groups include families, where the maternal and child diet may be low in Ca^{++} and vitamin D and where exposure to sunlight can be limited. The diagnosis of Fanconi-De Toni-Debré syndrome should be considered in any hypocalcemic child with persistent glycosuria, phosphaturia, and acidosis. Pseudohypoparathyroidism is a heterogeneous disorder that results from signaling defects of the cell surface receptors. Patients may become hypocalcemic despite a compensatory increase in parathyroid hormone concentration, and may have other endocrine problems, such as primary hypothyroidism and hypogonadism that are also manifestations of an abnormal signaling mechanism. Some patients are overweight and mentally retarded.

Neonatal Hypocalcemia

Hypocalcemia is a common metabolic problem in newborns. During pregnancy, Ca^{++} is transferred from the maternal circulation to the fetus by a pump regulated by parathyroid hormone-related peptide. This process results in higher blood Ca^{++} in the fetus than in the mother and leads to fetal hypercalcemia, with total Ca^{++} level of ≈2.50–2.75 mmol/L in umbilical cord blood [38–40, 42].

The cessation of placental transfer of Ca^{++} at birth is followed by a fall in total blood Ca^{++} concentration to ≈2.00–2.25 mmol/L and ionized Ca^{++} to ≈1.10–1.35 mmol/L at 24 h. Ca^{++} subsequently rises, reaching levels seen in older children and adults by 2 weeks of age.

The definition of hypocalcemia depends upon birth weight: (a) in term infants or premature infants >1.50 kg birth weight, hypocalcemia is defined as a total Ca^{++} concentration <2.00 mmol/L or a ionized fraction <1.10 mmol/L; (b) premature infants with birth weight <1.50 kg are hypocalcemic if they have a total Ca^{++} concentration <1.75 mmol/L or a ionized fraction of <1.00 mmol/L [38–40, 42].

[11] In hypophosphataemic rickets, circulating parathyroid hormone and calcium are usually normal.

Symptoms and Signs

Neonatal hypocalcemia is usually asymptomatic. Among those who become symptomatic, the characteristic sign is increased neuromuscular irritability. Such infants are jittery and often have muscle jerking. Generalized or partial clonic seizures can occur. Rare presentations include inspiratory stridor caused by laryngospasm, wheezing caused by bronchospasm or vomiting possibly resulting from pylorospasm [38–40, 42].

Causes

The causes of neonatal hypocalcemia are classified by the timing of onset. Hypocalcemia is considered to be early when it occurs in the first 2–3 days after birth.

Early Neonatal Hypocalcemia

Early hypocalcemia is an exaggeration of the normal decline in Ca^{++} concentration after birth. It occurs commonly in premature infants, in infants of diabetic mothers, and after perinatal asphyxia or intrauterine growth restriction.

- Prematurity: One-third of premature infants and the majority of very-low-birth-weight infants develop hypocalcemia during the first 2 days after birth. Multiple factors contribute to the fall. They include hypoalbuminemia and factors that lower both total and ionized Ca^{++}, such as reduced intake of Ca^{++} because of low intake of milk, possible impaired response to parathyroid hormone, increased calcitonin and increased urinary Ca^{++} losses.
- Infants of diabetic mothers: Hypocalcemia occurs in 10–20% of infants of diabetic mothers. The lowest concentration typically occurs between 24 and 72 h after birth and often is associated with hyperphosphatemia. Hypocalcemia is caused by lower parathyroid hormone concentrations after birth in this condition compared to normal infants. Hypoparathyroidism is likely related to intrauterine hypercalcemia suppressing the fetal parathyroid glands. Concurrent hypomagnesemia is a further contributing factor.
- Birth asphyxia: Infants with birth asphyxia frequently have hypocalcemia and hyperphosphatemia. Possible mechanisms include increased phosphate load caused by tissue catabolism, decreased intake due to delayed initiation of feedings, renal insufficiency, acidosis, and increased serum calcitonin concentration.
- Intrauterine growth restriction: Hypocalcemia occurs with increased frequency in infants with intrauterine growth restriction. The mechanism is thought to involve decreased transfer of Ca^{++} across the placenta.

Late Neonatal Hypocalcemia

Late hypocalcemia develops after the second or third day after birth. It typically occurs at the end of the first week.

- Hypoparathyroidism: Hypoparathyroidism associated with excess phosphorus intake is the most common cause of late neonatal hypocalcemia. Hypoparathyroidism often occurs as part of a syndrome, including DiGeorge syndrome or, more rarely, mitochondrial cytopathies.
- Maternal hyperparathyroidism: Infants born to mothers with hyperparathyroidism frequently have hypocalcemia. The mechanism is related to increased transplacental Ca^{++} transport caused by maternal hypercalcemia, which results in excessive fetal hypercalcemia that inhibits fetal and neonatal parathyroid secretion. Affected infants typically develop increased neuromuscular irritability in the first 3 weeks after birth, but they can present later.
- Hypomagnesemia: Hypomagnesemia causes resistance to parathyroid hormone and impairs its secretion, both of which can result in hypocalcemia. The most common etiology in newborns is transient hypomagnesemia, although rare disorders of intestinal or renal tubular Mg^{++} transport can occur.
- Other causes: Critically ill or premature infants are exposed to many therapeutic interventions that may cause transient hypocalcemia including bicarbonate infusion resulting

in metabolic alkalosis, transfusion with citrated blood or infusion of lipids leading to formation of Ca^{++} complexes and decreased ionized Ca^{++}. Finally, mild hypocalcemia has been associated with phototherapy. Other rare causes include acute renal failure of any cause, usually associated with hyperphosphatemia, any disorder of vitamin D metabolism and rotavirus infections.

- High phosphate intake: Intake of excess phosphate is an historically important cause of late hypocalcemia that was seen in term infants fed bovine milk or a formula with a high phosphorus concentration. It has been postulated that the high phosphorus levels antagonize parathyroid hormone or may produce increased Ca^{++} and phosphorus deposition in bones. Symptomatic infants typically present with tetany or seizures at 5–10 days of age. Severe hyperphosphatemia and hypocalcemia also can be caused by phosphate enemas.

Hypercalcemia

Signs and Symptoms

Hypercalcemia is more difficult to diagnose than hypocalcemia because of the nonspecific nature of symptoms and signs (Table 34.21). Hypercalcemia manifests with a shortened QT interval on electrocardiogram (Fig. 34.9). Major symptoms include sekeletal pain, fatigue, anorexia, nausea and vomiting, and particularly important are polyuria and polydipsia. Changes in behavior and frank psychiatric disorders may also be a result of hypercalcemia. The extent of symptoms and signs is a function of both the degree of hypercalcemia and the rate of onset of the elevation in the blood concentration. Thus, a rather severe hypercalcemia of 3.50 mmol/L is asymptomatic when it develops chronically, while an acute rise to these values may cause marked changes in sensorium. It is worthy of mention, however, that symptoms and signs associated with hypercalcemia may be due to the elevation in the Ca^{++} concentration but also to the underlying disease [38–40, 43, 44].

Table 34.21 Symptoms and signs of hypercalcemia

• **General**
– Weakness
– Depression
– Anorexia
• **Central nervous system**
– Impaired concentration
– Increased sleep requirement
– Altered state of consciousness
– Mental retardation
– Polydypsia (and polyuria)
• **Muscular:** weakness
• **Ocular**
– Palpebral calcification
– Band keratopathy
– Conjunctival calcification
• **Dermal:** Pruritus and skin calcifications
• **Gastrointestinal**
– Constipation
– Anorexia, nausea, vomiting
– Pancreatitis
– Peptic ulcer
• **Cardiovascular**
– Shortened QTc interval on standard electrocardiogram[a]
– Arterial hypertension
• **Skeletal: joint pains (pseudogout)**
• **Renal dysfunction**
– Altered urinary concentration ability with polyuria and polydypsia
– Nephrolithiasis, nephrocalcinosis, renal failure
– Distal renal tubular acidosis

[a] without any major tendency towards cardiac arrhythmias

Causes

Hypercalcemia results when the entry of Ca^{++} into the circulation exceeds the excretion of Ca^{++} into the urine or deposition in bone. Since the major sources of Ca^{++} are the bone and the intestinal tract, hypercalcemia mostly results from increased bone resorption or from increased intestinal absorption. In some cases, however, multiple sites are involved in the development of hypercalcemia. The great majority of adult patients with elevated Ca^{++} level will be found to have either **primary hyperparathyroidism** or **malignancy** (this form of hypercalcemia is thought in many instances to be caused by secretion of parathyroid hormone related peptide), although the differential diagnosis is much longer. For these other causes of hypercalcemia,

which include **vitamin D (or A) intoxication**, **sarcoidosis**, **tuberculosis**, some **fungal infections**, **thyreotoxicosis**, **Addison's disease**, milk-alkali syndrome (= **calcium-alkali syndrome**) related to the prescription of Ca^{++}, absorbable alkali and vitamin D supplements, treatment with **thiazides** or **lithium** carbonate, **familial hypocalciuric hypercalcemia**, **prolonged immobilization** in subjects with high skeletal turnover (including adolescents) and the recovery phase of **rhabdomyolysis**, the use of the mnemonic VITAMINS TRAPS (Table 34.22) has been suggested. Children present with hypercalcemia less frequently than adults, but the

Table 34.22 Causes of hypercalcemia (please note that some causes of hypercalcemia are given twice)

• **Classical causes (Mnemonic VITAMINS TRAP)**
– **V**itamin D and vitamin A
– **I**mmobilization
– **T**hyrotoxicosis
– **A**ddison's disease
– **M**ilk-alkali syndrome (= calcium-alkali syndrome)
– **I**nflammatory disorders (granulomatous diseases with excessive production of calcitriol)
– **N**eoplastic-related disease[a]
– **S**arcoidosis
– **T**hiazides[b] and other drugs
– **R**habdomyolysis (recovery phase)
– **AIDS**
– **P**arathyroid disease[a] (including familial hypocalciuric hypercalcemia), **p**arenteral nutrition
• **Hypercalcemia associated with elevated calcitriol (1,25-dihydroxyvitamin D_3)**
– Sarcoidosis
– Acute granulomatous pneumonia, lipoid pneumonia
– Tuberculosis (and other mycobacterial infections)
– Wegener's granulomatosis
– Crohn's disease
– Hepatic granulomatosis
– Talc and silicone granulomatosis
– Cat scratch disease
– Neonatal subcutaneous fat necrosis
• **Hypercalcemia associated with elevated parathyroid hormone related peptide**
– Hypercalcemia of malignancy
– Some benign tumors (ovary, kidney, pheochromcytoma)
– Systemic lupus erythematosus
– HIV-associated lymphadenopathy
– Massive mammary hyperplasia
– During late pregnancy and lactation in hypoparathyroidism
• **Drugs associated with the development of hypercalcemia**
– **Common:** calcium, vitamin D, vitamin A, lithium, thiazides[b] (e.g.: hydrochlorothiazide, chlortalidone)
– **Less common:** omeprazole, theophyllin (toxic doses), recombinant growth hormone, foscarnet, hepatitis B vaccination, manganese toxicity
• **Rare causes of hypercalcemia with an unknown underlying mechanism**
– Infections: nocardiosis, brucellosis, cytomegaloviric infection (in AIDS), berylliosis
– Juvenile idiopathic arthritis
– Advanced chronic liver disease
• **Rare causes of hypercalcemia in infancy and young children**
– Reduced function of the calcium-sensing receptor
Deactivating mutations
Heterozygous: Familial hypocalciuric hypercalcemia

(continued)

Table 34.22 (continued)

Homozygous: Severe neonatal hyperparathyroidism
Autoantibodies directed at the calcium-sensing receptor
– Congenital hypoparathyroidism
– Idiopathic infantile hypercalcemia
– Jansens metaphyseal chondrodysplasia[c]
– Williams-Beuren syndrome
– Down syndrome
– Hypophosphatasia
– Congenital lactase deficiency
– Phosphate depletion in severe prematurity
– Renal tubular acidosis
– Primary hyperoxaluria
– Neonatal subcutaneous fat necrosis

[a] Malignancy and primary hyperparathyroidism account for 80–90% of cases of hypercalcemia in adulthood
[b] Although thiazides are frequently cited as a cause of hypercalcemia, it is more usual that they bring mild pre-existing hypercalcemia to light
[c] Consequence of a constitutive activation of the parathyroid hormone receptor

causes that are common in adults are also common in children. Young children and infants, however, present with hypercalcemia in association with some rather rare conditions seen almost exclusively in that population. **Idiopathic infantile hypercalcemia** is characterized by an increased sensitivity to vitamin D. It is the consequence of loss of function mutations in the gene that encodes the enzymatic system responsible for the inactivation of 25-hydroxyvitamin D, resulting in its decreased conversion into inactive metabolites [38–40, 43, 44]. Hypothermia treatment for neonatal asphyxia can sometimes lead to neonatal subcutaneous fat necrosis and consequentely hypercalcemia by elevated calcitriol (Table 34.22).

Diagnostic Work Up

The causes of hypercalcemia are often discerned clinically. Clinical history (calcium-alkali syndrome, which replaces the traditional term of milk-alkali syndrome, is currently a cause of hypercalcemia that results from the widespread use of over-the-counter Ca^{++} and vitamin D supplements), physical examination and rather simple laboratory data (circulating phosphate and creatinine; urinary Ca^{++}, phosphate and creatinine) and chest x-ray (looking for sarcoidosis) provide the correct diagnosis in many cases.

– **Step 1: Assess clinical and simple laboratory data**
– Clinical history and physical examination are useful in establishing the diagnosis of hypercalcemia induced by immobilization, medication or thyreotoxicosis, and the diagnosis of "syndromic" hypercalcemia, including Williams-Beuren syndrome, Down syndrome and Jansens metaphyseal chondrodysplasia. Measurement of the serum phosphate concentration and urinary Ca^{++} excretion also may be helpful in selected cases: hyperparathyroidism and the humoral hypercalcemia of malignancy induced by secretion of parathyroid hormone related peptide often present with hypophosphatemia resulting from inhibition of renal proximal tubular phosphate reabsorption. In comparison, the serum phosphate concentration is normal or elevated in granulomatous diseases, vitamin D intoxication, immobilization, thyrotoxicosis and metastatic bone disease. Calciuria is usually raised or high-normal in hyperparathyroidism and hypercalcemia of malignancy. Two conditions lead to relative hypocalciuria: thiazides, which directly enhance active reabsorption of Ca^{++} in the distal tubule, and familial hypocalciuric hypercalcemia, in which the fractional excretion of Ca^{++} is often <1.0% (further clues to

the possible presence of this disorder are a family history of hypercalcemia and few if any hypercalcemic symptoms).

– **Step 2: analyze parathyroid hormone level**
– An elevated parathyroid hormone concentration indicates the presence of primary hyperparathyroidism or a patient taking lithium. 10–20% of patients with primary hyperparathyroidism have a parathyroid hormone concentration in the upper end of the normal range: such a "normal" level, which indicates that the secretion is not suppressed, is virtually diagnostic of primary hyperparathyroidism, since it is still inappropriately high considering the presence of hypercalcemia. A low or low-normal parathyroid hormone level is consistent with all other non-parathyroid hormone-induced causes of hypercalcemia.
– **Step 3: Analyze vitamin D metabolites**
– The levels of vitamin D metabolites 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D are assessed if there is no obvious malignancy and parathyroid hormone levels are not elevated. An elevated 25-hydroxyvitamin D is indicative of either vitamin D intoxication or idiopathic infantile hypercalcemia. On the other hand, increased 1,25-dihydroxyvitamin D may be induced by direct intake of this metabolite or non-renal production in granulomatous diseases or lymphoma.

Management

The degree of hypercalcemia and the rate of rise of Ca^{++} level habitually determine symptoms and urgency of treatment [42, 43]:

– asymptomatic or mildly symptomatic hypercalcemia (total Ca^{++} <3.00 mmol/L) does not require immediate treatment. Similarly, Ca^{++} of 3.00–3.50 mmol/L is often well-tolerated chronically, and may not require urgent treatment (however, an acute rise to these concentrations may cause marked sensorium changes, which require more urgent measures).
– Total Ca^{++} concentration >3.50 mmol/L requires immediate treatment, regardless of symptoms.

The nonsurgical management of childhood hypercalcemia includes following points:

(a) Avoidance of the cause. For example, removal of exogenous vitamin D and Ca^{++} in children with vitamin D intoxication, calcium-alkali syndrome or idiopathic infantile hypercalcemia.
(b) Specific management. Steroids inhibit the effects of vitamin D and are particularly effective in hypercalcemia secondary to granulomatous diseases. The bisphosphonates, which inhibit skeletal Ca^{++} release, are effective in hypercalcemia that results from excessive bone resorption of any cause (including among others hypercalcemia of malignancy, hypercalcemia associated with neonatal subcutaneous fat necrosis and vitamin D intoxication). Pharmacologic doses of calcitonin reduce the Ca^{++} levels by decreasing bone resorption. The effect of calcitonin, which is limited to the first 48 h, is most beneficial in subjects with total Ca^{++} >3.50 mmol/L when combined with a bisphosphonate and administration of saline.
(c) Normal saline, administered at a rapid rate (initially 2800–3000 mL/m^2 body surface area daily), corrects possible volume depletion due to hypercalcemia-induced renal salt wasting and promotes renal Ca^{++} excretion. The loop diuretic furosemide is no longer recommended with the exception of cases with volume overload.

Magnesium

Balance

A 70 kg man contains ≈1 mole of Mg^{++}. About half of it is present in bone tissue, the other half in soft tissue, whereas no more than 1–2% of the total body Mg^{++} is present in extracellular fluids. Intracellular Mg^{++} serves as cofactor for many enzymes that produce and store energy via hydrolysis of adenosine triphosphate [40, 45, 46].

In healthy humans the total circulating Mg^{++} concentration is maintained within narrow limits

and ranges between 0.75 and 1.00 mmol/L.[12] Approximately 1/4 of circulating Mg^{++} is bound to albumin. For the remaining 3/4 of circulating Mg^{++} ≈10% is complexed to inorganic phosphate, citrate and other compounds, while 90% (≈2/3 of total circulating Mg^{++}) is in the form of free ion.

Mg^{++} balance, like that of other ions, is a function of intake and urinary excretion. In adults the daily Mg^{++} intake averages 0.23–0.28 mmol/kg (5.6–6.8 mg/kg) body weight. About 1/3 of this Mg^{++} is absorbed. In healthy adults there is no net gain or loss of Mg^{++} from bone so that balance is achieved by the urinary excretion of the absorbed 0.06–0.08 mmol/kg (1.5–1.9 mg/kg) body weight.

Only 15–25% of filtered Mg^{++} is reabsorbed in the proximal tubule and 5–10% in the distal tubule. The major site of Mg^{++} transport is the thick ascending limb of the loop of Henle where 60–70% of the filtered load is reabsorbed [40, 45, 46].

With negative Mg^{++} balance, the initial loss comes primarily from the extracellular fluid (equilibration with bone stores begins after several weeks). Thus, circulating Mg^{++} falls rapidly with negative Mg^{++} balance, leading to a conspicuous decrease in Mg^{++} excretion unless urinary Mg^{++} wasting is present. The fractional clearance of Mg^{++}, which is 3–5% in healthy subjects ingesting a normal diet, can fall to <0.5% with Mg^{++} depletion due to non-renal losses. This parameter is calculated from the following equation:

$$\frac{\text{Urinary}\,Mg^{++} \times \text{Circulating Creatinine}}{\text{Circulating}\,Mg^{++} \times \text{Urinary Creatinine}}$$

There is no protection against hypermagnesemia with loss of renal function. In this setting, high intake leads to extracellular Mg^{++} retention.

[12] Circulating magnesium levels can be reported in mmol/L, meq/L, mg/dL or mg/L. The valence of magnesium is 2 and its molecular mass 24.3 g/mol; therefore 0.50 mmol/L is equivalent to 1.00 meq/L, 1.22 mg/dL and 12.2 mg/L.

Hypomagnesemia

Hypomagnesemia, which is not rare, results either from intestinal (including dietary insufficiency) or renal losses (Table 34.23). In the presence of hypomagnesemia, the healthy kidney lowers Mg^{++} excretion to very low values. Hence, the diagnosis of hypomagnesemia caused by intestinal Mg^{++} losses (or low dietary Mg^{++} intake) is established by the demonstration of low urinary excretion of Mg^{++}. Conversely the diagnosis of hypomagnesemia caused by renal losses is established by the demonstration of inappropriately high (= "normal") urinary Mg^{++} excretion [40, 45, 46].

Table 34.23 Causes of hypomagnesemia

Decreased magnesium intake and intestinal losses
– Dietary deprivation
– Small bowel disorders, including acute or chronic diarrhea, malabsorption and steatorrhea, and small bowel bypass surgery
– Acute pancreatitis
– Paunier disease[a] (= hypomagnesemia with secondary hypocalcemia)
– Chronic management with proton-pump inhibitors
Renal losses
– Primary renal magnesium wasting diseases
– Drugs
Loop and thiazide-type diuretics
Drugs other than diuretics (aminoglycoside antibiotics, amphotericin B, cisplatin, pentamidine, cyclosporine, tacrolimus, foscarnet, cetuximab[b])
– Volume expansion
– Hypercalcemia
– Miscellaneous: recovery from acute tubular necrosis, following renal transplantation and during a postobstructive diuresis
Further causes
– Alcohol
– Refeeding syndrome
– Diabetes mellitus
– Following surgery
– "Hungry bone syndrome" following parathyroidectomy for hyperparathyroidism
Neonatal hypomagnesemia
– Maternal hypomagnesemia (including maternal diabetes mellitus)
– Intrauterine growth retardation

[a] Often combined with impaired renal magnesium conservation

[b] A monoclonal antibody against the epithelial growth factor receptor

Decreased Intake, Poor Intestinal Absorption or Intestinal Loss

Intestinal secretory losses, which contain some Mg^{++}, are continuous and not regulated. Although the obligatory losses are not large, marked dietary deprivation can lead to progressive Mg^{++} depletion. Mg^{++} loss will also occur when the intestinal secretions are incompletely reabsorbed as with most disorders of the small bowel, including acute or chronic diarrhea, malabsorption and steatorrhea, and small bowel bypass surgery. Prolonged use of proton pump inhibitors is an increasingly recognized cause of hypomagnesemia (these drugs interfere with the transport of this ion across the intestinal wall) [47]. Hypomagnesemia can also be seen in acute pancreatitis (saponification of Mg^{++} and Ca^{++} in necrotic fat is the underlying mechanism). Paunier disease or hypomagnesemia with secondary hypocalcemia is a very rare defect of intestinal Mg^{++} resorption (usually combined with impaired renal Mg^{++} conservation), which presents early in infancy with hypocalcemia responsive to Mg^{++} administration. The disease is caused by a loss of function mutation in an ion channel of the transient receptor potential gene family called TRPM6 [45, 46].

Renal Losses

Urinary Mg^{++} losses can be induced by different mechanisms.

Primary renal Mg^{++} wasting: these disorders are discussed in Chap. 37.

Drugs: Both loop and thiazide diuretics can inhibit net Mg^{++} reabsorption, while the K^+-sparing diuretics may lower excretion of Mg^{++}. The degree of hypomagnesemia induced by the loop and thiazide diuretics is generally mild, in part because the associated volume contraction will tend to increase proximal Na^+, water, and Mg^{++} reabsorption. Many further drugs can also produce urinary Mg^{++} wasting, as depicted in Table 34.23.

Volume expansion: Expansion of the extracellular fluid volume can decrease passive Mg^{++} transport. Mild hypomagnesemia may ensue if this is sustained.

Hypercalcemia: Ca^{++} and Mg^{++} seem to compete for transport in the thick ascending limb of the loop of Henle. The increased filtered Ca^{++} load in hypercalcemic states will deliver more Ca^{++} to the loop; the ensuing rise in Ca^{++} reabsorption will diminish that of Mg^{++}.

Miscellaneous: Mg^{++} wasting can be seen as part of the tubular dysfunction seen with recovery from acute tubular necrosis, following renal transplantation and during a postobstructive diuresis.

Alcohol: Excessive urinary excretion of Mg^{++} is common in alcoholic patients. Dietary deficiency, acute pancreatitis, diarrhea and refeeding also contribute to hypomagnesemia in these patients.

Further Causes

- Hypomagnesemia, together with hypophosphatemia, hypokalemia and increasing extracellular fluid volume, occurs in the context of refeeding syndrome (See: hypophosphatemia).
- Hypomagnesemia sometimes occurs in diabetes mellitus and is related in part to the degree of hyperglycemia.
- Hypomagnesemia can be seen following surgery, at least in part due to chelation by circulating free fatty acids.
- Hypomagnesemia can occur as part of the "hungry bone" syndrome in which there is increased Mg^{++} uptake by renewing bone following parathyroidectomy (for hyperparathyroidism).
- Hypomagnesemia is often encountered in cystic fibrosis patients with advanced disease, although sweat Mg^{++} concentration is normal in these patients. The causes are multiple, including aminoglycoside toxicity inducing renal magnesium-wasting and impaired intestinal magnesium balance. Interestingly, magnesium supplementation may lead to an improvement in respiratory muscle strength and mucolytic activity [48].

Neonatal Hypomagnesemia

Like in older children, in newborns hypomagnesemia may result from decreased Mg^{++} intake,

intestinal losses or renal losses. However, two peculiar causes of neonatal hypomagnesemia deserve consideration: (1) maternal hypomagnesemia and (2) intrauterine growth retardation.

- **Maternal hypomagnesemia:** Neonatal hypomagnesemia secondary to maternal hypomagnesemia is a recognized feature of maternal diabetes mellitus. However, maternal hypomagnesemia from any cause has been associated with neonatal hypomagnesemia.
- **Intrauterine growth retardation:** Hypomagnesemia sometimes occurs in infants whose birth weight is small in relation to their gestational age.

Symptoms, Signs, Consequences

Mg^{++} depletion is often associated with two biochemical abnormalities: (1) hypokalemia and (2) hypocalcemia. As a result, it is often difficult to ascribe specific manifestations solely to hypomagnesemia. The typical signs and symptoms of Mg^{++} depletion include tetany, positive Chvostek, Trousseau and Lust signs (the Lust sign, also called peroneal sign, is the dorsal extension and abduction of the foot, which is elicited by tapping the peroneal nerve on the lateral aspect of the fibula), or generalized convulsions. Generalized weakness and anorexia sometimes also occur. In addition, Mg^{++} depletion can induce ventricular arrhythmias, particularly during myocardial ischemia or cardiopulmonary bypass [40, 45, 46].

Hypokalemia

Hypokalemia, mostly accompanied by metabolic alkalosis, is common in hypomagnesemia. This association is in part due to underlying disorders that cause both Mg^{++} and K^+ loss, such as diuretic therapy and diarrhea. There is also evidence that concomitant Mg^{++} depletion aggravates hypokalemia and renders it refractory to treatment by potassium because Mg^{++} depletion increases distal K^+ secretion, as depicted in Fig. 34.14 [45, 46].

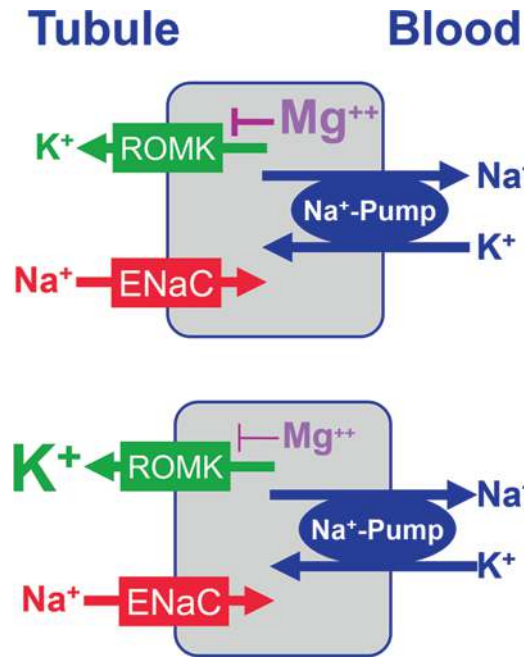

Fig. 34.14 Renal mechanism underlying hypokalemia in Mg^{++} depletion. In the distal nephron K^+ is taken up into cells across the basolateral membrane via Na^+ pump (blue oval) and secreted into luminal fluid via the apical ROMK K^+ channels (green rectangle). Na^+ is reabsorbed via epithelial Na^+ channels (ENaC, red rectangle). Intracellular Mg^{++} inhibits the ROMK K^+ channels and decreases K^+-secretion (upper panel). A decrease in intracellular Mg^{++} releases the Mg^{++}-mediated inhibition of ROMK K^+ channels, increases K^+-secretion (lower panel) and results in hypokalemia that is refractory to treatment by K^+. ROMK denotes renal outer medullary K^+ channel

Hypocalcemia

Hypocalcemia is the classical consequence of severe hypomagnesemia ($\leq$0.50 mmol/L). The following factors account for this tendency [40, 45, 46]:

- Inappropriately low circulating **parathyroid hormone** secretion.
- Inappropriately low **1,25-dihydroxyvitamin D**, the active metabolite of vitamin D.
- Bone resistance to **parathyroid hormone** (hypomagnesemia interferes with G protein activation in response to parathyroid hormone, thereby minimizing the stimulation of adenylate cyclase).

Repletion

Repletion of Mg^{++} is controversial in asymptomatic (mostly mild) hypomagnesemia. Oral repletion using lactate, oxide, pidolate or chloride salts is usually preferred. Because of the laxative effect of oral Mg^{++}, the amounts administered must be tailored to the individual patients (0.30 mmol/kg body weight of Mg^{++} per day in divided doses results in diarrhea in ≈10% of patients). The parenteral route is preferred in critically ill patients but the exact dosage is poorly understood. For true emergencies (e.g. generalized convulsions or ventricular arrhythmias) Mg^{++} is administered (either as sulphate or as chloride) intravenously over 1–2 min in a dosage of 0.15–0.20 mmol/kg body weight[13] (repeated if no response 5–10 min later). In subjects with moderate to severe but rather oligosymptomatic Mg^{++} deficiency, the mentioned dose is given over 4–6 h until circulating Mg^{++} returns to normal.

Inorganic Phosphate

Balance

In a 70 kg man, the body phosphate content amounts to ≈1% of the body weight, or 700 g, of which 85% is contained in the bone tissue and teeth, 14% in the soft tissues, and the remaining 1% in extracellular fluids [49].

In the blood, phosphate is found both as organic as well as inorganic salt but clinical laboratories measure the inorganic form. Of the circulating inorganic phosphate, ≈10% is bound to proteins, 5% is complexed with Ca^{++}, Mg^{++} or Na^{+} and 85% exists as ionized phosphate. The normal blood concentration of inorganic phosphate is highest during the neonatal period and early childhood and declines thereafter (Table 34.24) because infants and children retain phosphate avidly. There is a mean diurnal variation in concentration of phosphate of ≈0.20 mmol/L (≈0.6 mg/dL) with a nadir at 11.00 h, subsequently rising to a plateau at 16.00 h and peaking in the early night.

Table 34.24 Fasting values for circulating inorganic phosphate, fractional phosphate excretion and maximal tubular phosphate reabsorption in infancy and childhood

Age	Blood inorganic phosphate, mmol/L[a]	Fractional phosphate excretion, 10^{-2}	Maximal tubular reabsorption of phosphate, mmol/L[a]
0–3 months	1.62–2.40	11.9–38.7	1.02–2.00
4–6 months	1.78–2.21	3.50–34.9	1.27–1.88
6–12 months	1.38–2.15	10.3–20.0	1.13–1.86
1–2 years	1.32–1.93	5.50–23.3	1.05–1.74
3–4 years	1.02–1.92	≤18.4	0.90–1.78
5–6 years	1.13–1.73	0.60–15.0	1.02–1.62
7–8 years	1.06–1.80	≤16.8	0.98–1.64
9–10 years	1.13–1.70	1.80–14.1	1.00–1.58
11–12 years	1.04–1.79	1.80–12.1	0.97–1.65
13–15 years	0.97–1.80	≤12.6	0.91–1.68

[a] To obtain traditional units (mg/dL) multiply by 3.1

The average diet of a 70 kg man provides 800–1500 mg phosphate daily. As much as 2/3 of the dietary phosphate is absorbed in the gut but intestinal secretion, mainly in saliva and bile acids, adds 200 mg of phosphate into the intestinal lumen daily. Under steady-state conditions, the kidney is the most important modulator of the blood phosphate level, ensuring that urinary phosphate output is equivalent to the net phosphate absorption from the intestine. Phosphate is freely filtered across the glomerulus, and 80–90% of the phosphate is reabsorbed by the renal tubules (mostly in the proximal tubule) in subjects aged 6 months or more (Table 34.24). The renal tubular handling of phosphate is best expressed as fractional excretion of phosphate or, more precisely, as maximal tubular reabsorption of phosphate, which clarifies the relationship between circulating phosphate and urinary phosphate excretion. The fractional clearance of phosphate, the tubular phosphate reabsorption and the maximal tubular phosphate reabsorption are easily calculated, following an overnight fast, from plasma (P_{Ph}) and urinary (U_{Ph}) phosphate, and plasma (P_{Cr}) and urinary (U_{Cr}) creatinine, as follows [50]:

$$\text{Fractional excretion} = \frac{\mathbf{U_{Ph}} \times \mathbf{P_{Cr}}}{\mathbf{P_{Ph}} \times \mathbf{U_{Cr}}}$$

[13] Approximately 3.5–4.5 mg/kg body weight of elemental magnesium.

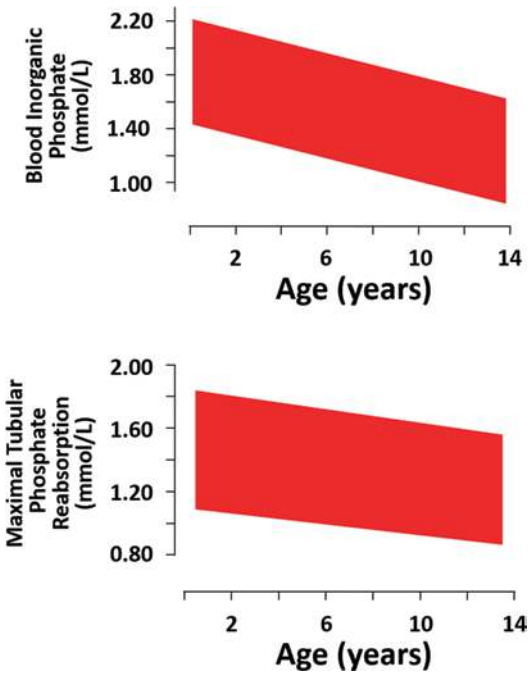

Fig. 34.15 Influence of age on fasting blood inorganic phosphate and maximal tubular reabsorption of phosphate. Blood inorganic phosphate and maximal tubular reabsorption of phosphate measured in infants, children and adolescents [50]

$$\text{Tubular phosphate reabsoption} = 1 - \frac{\mathbf{U_{Ph}} \times \mathbf{P_{Cr}}}{\mathbf{P_{Ph}} \times \mathbf{U_{Cr}}}$$

$$\text{Maximal reabsoption} = \mathbf{P_{Ph}} - \left(\frac{\mathbf{U_{Ph}} \times \mathbf{P_{Cr}}}{\mathbf{U_{Cr}}} \right)$$

The reference values [50] for the fractional excretion of phosphate and the maximal tubular reabsorption of phosphate are age dependent and appear in Table 34.24 and Fig. 34.15.

Three groups of hormonal factors regulate phosphate homeostasis [49]:

(a) **1,25-dihydroxyvitamin D** stimulates the intestinal phosphate absorption;
(b) **Parathyroid hormone** decreases the renal tubular reabsorption and causes phosphaturia;
(c) **"Phosphatonins"** are phosphaturic factors other than parathyroid hormone. **Fibroblast growth factor 23** (FGF-23) is currently considered the most important phosphatonin. FGF-23 is secreted by osteocytes and osteoblasts in response to phosphate loading or increased serum $1,25(OH)_2D_3$ levels and mainly targets the kidney in order to regulate the reabsorption of phosphate, the production and catabolism of 1,25-dihydroxyvitamin D and the expression of α-Klotho, an FGF-23 co-receptor and anti-ageing hormone.

Hypophosphatemia

Hypophosphatemia does not necessarily mean phosphate depletion since it can occur in the presence of a low, normal, or high total body phosphate. On the other hand, phosphate depletion may exist with normal, low, or elevated levels of blood phosphate [51, 52].

The normal phosphate level in adolescents and adults ranges between 0.97 and 1.80 mmol/L (2.9–5.4 mg/dL). In this age group, hypophosphatemia is arbitrarily divided into moderate cases (phosphate 0.32–0.65 mmol/L or 0.96–1.95 mg/dL) and severe cases (phosphate <0.32 mmol/L or <0.96 mg/dL). There are three major mechanisms by which hypophosphatemia can occur: (1) low dietary intake or poor intestinal absorption, (2) internal redistribution, and (3) increased urinary loss. In patients with hypophosphatemia caused by decreased intestinal absorption or internal redistribution the fractional excretion of phosphate and the maximal tubular reabsorption of phosphate are normal (Table 34.25). On the contrary, these parameters are low or inappropriately normal in patients with increased urinary losses [51–53].

Low Dietary Intake or Poor Intestinal Absorption

Given the fact that phosphate is ubiquitous in foods, the development of deficiency would be anticipated only in severe cases of malnutrition or in very-low-birth weight infants at the time of rapid postnatal growth. If phosphate restriction is severe and prolonged, or if intestinal absorption is reduced by the chronic use of phosphate binders, then the constantly reduced intestinal delivery may induce phosphate depletion.

Table 34.25 Causes of hypophosphatemia

• **With normal maximal tubular phosphate reabsorption and fractional excretion of phosphate**
– Low dietary intake or poor intestinal absorption
Low dietary intake: severe malnutrition, very-low-birthweight infants
Poor absorption: steatorrhea, chronic diarrhea, use of phosphate binders
– Internal redistribution
Refeeding syndrome in malnutrition (including diabetic ketoacidosis treated with insulin)
Respiratory alkalosis
Hungry bone syndrome after parathyroidectomy
• **With increased fractional excretion of phosphate**
– Hyperparathyroidism
– De Toni-Debré–Fanconi syndrome (= general impairment of the proximal tubule)[a]
– Gitelman syndrome and Bartter syndromes[b]
– Hypophosphatemic rickets[c]
– After kidney transplant (= posttransplant hypophosphatemia)

[a] Various drugs may cause an incomplete or, more rarely, a complete form of De Toni-Debré–Fanconi syndrome with hypophosphatemia including paracetamol poisoning, and treatment with ifosfamide, valproic acid, the iron chelator deferasirox or $ß_2$-adrenoreceptors (e.g.: albuterol)

[b] Hypophosphatemia is rather mild in these post-proximal tubular disorders

[c] At least in part explained by increased activity of fibroblast growth factor 23

Internal Redistribution

In the majority of cases, an acute shift in phosphate from the extracellular to the intracellular compartment is primarily responsible for lowering phosphatemia. The most frequent cause is refeeding syndrome, a recognized and potentially fatal condition that occurs when previously malnourished patients are fed. The fluid and electrolyte abnormalities noted in the refeeding syndrome and those noted in severe diabetic ketoacidosis following the administration of insulin therapy are similar.

Patients who are malnourished develop a total body depletion of phosphate, Mg^{++} and K^{+}. Nonetheless, their blood levels are maintained by redistribution from the intracellular space. The delivery of glucose as part of a feeding strategy causes a huge increase in the circulating insulin level that induces a rapid uptake of glucose, K^{+}, phosphate and Mg^{++} into cells. The blood concentration of these metabolites falls dramatically. In addition, the body begins to retain fluid, and the extracellular space expands. Although hypophosphatemia is the predominant feature of the syndrome, rapid falls in K^{+} and Mg^{++} levels, together with some tendency towards metabolic alkalosis, predispose to cardiac arrhythmias, while extracellular space expansion can precipitate acute heart failure in patients with cardiovascular disease. The most effective way to treat refeeding syndrome is to be aware of it. One should start feeding slowly and aggressively supplement and monitor phosphate, K^{+} and Mg^{++} for 4 days after feeding is started.

Another cause of hypophosphatemia in hospitalized patients is respiratory alkalosis. Severe hyperventilation can be seen in patients with anxiety, pain, sepsis, and in patients during mechanical ventilation. The fall in carbon dioxide will result in a similar change in the cells because carbon dioxide readily diffuses across cell membranes. The elevated pH stimulates the glycolysis, leading to an accelerated production of phosphorylated metabolites and a rapid shift of phosphate into the cells.

The hungry bone syndrome, characterized by massive deposition of Ca^{++} and phosphate in the bone, can occur after parathyroidectomy for long-standing hyperparathyroidism (both primary and secondary).

Urinary Loss

1. In hyperparathyroidism, both primary and secondary, there is an increased urinary loss of phosphate.
2. Fanconi-De Toni-Debré syndrome is characterized by a general impairment of the proximal tubule leading to urinary loss of compounds normally reabsorbed by the proximal tubule. It results in hypophosphatemia, glucosuria, hyperaminoaciduria, uricosuria, and hyperbicarbonaturia (causing renal tubular acidosis).
3. The urinary phosphate excretion is also increased in patients with hereditary hypophosphatemic rickets and tumor-induced osteomalacia and rickets, as discussed in Chap. 55.

4. Recent data demonstrate a mild tendency towards urinary loss of phosphate in Gitelman and Bartter syndromes [54].
5. Following kidney transplant, hypophosphatemia has been described in the absence of both hyperparathyroidism and other signs of proximal tubule dysfunction.

Symptoms, Signs, Consequences

Phosphate depletion can cause a variety of symptoms and signs [49, 51–53]. Two major mechanisms are responsible for these symptoms: (a) decrease in intracellular adenosine triphosphate, and (b) in diphosphoglycerate. In adults, hypophosphatemia is symptomatic when the phosphate level is <0.35 mmol/L. Hypophosphatemia may be asymptomatic under certain clinical situations: patients recovering from diabetic ketoacidosis and patients with prolonged hyperventilation are usually asymptomatic because often there is not real phosphate depletion. The clinical features of phosphate depletion appear in Table 34.26.

Management

Hypophosphatemia does not automatically mean that phosphate replacement is indicated. To determine whether treatment is indicated, it is necessary to establish the cause of the hypophosphatemia, in which the history and the clinical setting are important. The identification and treatment of the primary cause usually leads to normalization of the circulating phosphate level. As an example, the hypophosphatemia found in patients with diabetic ketoacidosis will usually correct spontaneously with normal dietary intake. However, replacement therapy is needed in patients with hypophosphatemia in combination with evidence of renal or gastrointestinal phosphate loss, the presence of underlying risk factors, and particularly if there are the clinical manifestations described above [53].

The safest mode of therapy is oral. Cow's milk is a good phosphate source: it contains 1 g (32 mmol) elemental phosphate per liter. Alternatively, oral preparations in the form of sodium phosphate or potassium phosphate can be used. The average adult patient requires 1–2 g (32–64 mmol) phosphate per day for 7–10 days to replenish body stores. An important side effect of oral supplementation is diarrhea.

Intravenous phosphate, usually 2.5–5.0 mg/kg (0.08–0.16 mmol/kg) over 6 h is given in symptomatic patients, who cannot take milk or tablets. More aggressive repletion with phosphate has been advocated but the magnitude of the response is unpredictable (close monitoring of phosphate level is crucial). Side effects of intravenous phosphate repletion are hypocalcemia, metastatic calcification, hyperkalemia associated with K^+-containing supplements, volume excess, hypernatremia, metabolic acidosis, and hyperphosphatemia.

Burosumab, a fully human monoclonal antibody against FGF-23, is used for the treatment of hereditary hypophosphatemic rickets. The drug has demonstrated superior efficacy in correcting hypophosphatemia and clinical symptoms compared to conventional therapy consisting of oral phosphate and active vitamin D (Chap. 55).

Table 34.26 Symptoms, signs and consequences of phosphate depletion

• Skeletal muscle and bone: proximal myopathy, rhabdomyolysis[a]
• Cardiovascular system: impaired myocardial contractility
• Respiratory system: respiratory failure (and failed weaning)
• Neurological system: paresthesias, tremors, seizures, features resembling Guillain-Barré syndrome or Wernicke encephalopathy
• Hematological system: hemolysis, impaired granulocyte chemotaxis and phagocytosis causing Gram-negative sepsis, altered platelet function and thrombocytopenia

[a] In patients with rhabdomyolysis, hypophosphatemia can be masked by the release of phosphate from the injured muscle

Hyperphosphatemia

Spurious or artefactual hyperphosphatemia has been observed if hemolysis occurs during the collection or processing of blood samples. Spurious hyperphosphatemia due to interference with analytical methods occurs in patients with

hyperglobulinemia, hyperlipidemia or hyperbilirubinemia and following contamination with heparinized saline from indwelling catheters or in subjects receiving liposomal amphotericin [55]. True hyperphosphatemia indicates either an increased phosphate load or a decreased renal phosphate excretion, as shown in Table 34.27. High dietary ingestion of phosphate alone rarely causes hyperphosphatemia with the exception of newborns and infants fed cow's milk, whose phosphate content is six times greater than human milk [49].

Table 34.27 Causes of hyperphosphatemia

• **Artifactual or spurious**
• **Increased phosphate load (with normal fractional excretion of phosphate and normal maximal tubular phosphate reabsorption)**
– High dietary intake or increased intestinal absorption
Newborns and infants fed cow's milk (rather than breast milk or adapted formula milk)
Parenteral administration of phosphate salts
Large amounts of phosphate-containing laxatives, phosphate enemas[a]
Vitamin D intoxication
– Internal redistribution
Tumor lysis syndrome (before treatment and after initiation of cytotoxic therapy)
Rhabdomyolysis
Lactic and ketoacidosis (or severe hyperglycemia alone)[b], including severe dehydration in the context of acute diarrhea
• **Decreased renal phosphate excretion**
– Reduced renal function (either acute or chronic)
– Increased renal tubular phosphate reabsorption (= decreased fractional phosphate excretion and increased maximal tubular phosphate reabsorption)
Hypoparathyroidism (and pseudohypoparathyroidism)
Acromegaly
Drugs: growth hormone, bisphosphonates, dipyridamole
Idiopathic childhood nephrotic syndrome
Familial hyperphosphatemic tumoral calcinosis

[a] The danger of hyperphosphatemia secondary to phosphate enema is especially high in children less than 2 years of age

[b] Metabolic acidosis blunts glycolysis and therefore cellular phosphate utilization. In addition, tissue hypoxia or insulin deficiency also play a crucial role

Acutely or chronically impaired renal function plays at least a partial role in most instances of hyperphosphatemia, including physiologically low glomerular filtration rate to explain the inability of the neonate to eliminate excess phosphate, mild renal insufficiency (due to volume contraction secondary to diarrhea) in subjects ingesting large amounts of phosphate-containing laxatives or mild to moderate tubulointerstitial injury secondary to intrarenal accumulation of uric acid in tumor lysis syndrome (see "hyperkalemia").

Familial hyperphosphatemic tumoral calcinosis is a recessive disorder characterized by hyperphosphatemia due to an increased maximal tubular phosphate reabsorption. Affected subjects present with extra-articular soft tissue deposition of calcium phosphate. This very rare disease (a kind of mirror image of some forms of hypophosphatemic rickets) results from inactivating mutations that lead to deficiency of circulating fibrolast growth factor 23 [49].

35 Renal Fanconi Syndromes and Other Proximal Tubular Disorders

Detlef Bockenhauer and Robert Kleta

Introduction

Fanconi first described the concept that defective renal proximal tubule reabsorption of solutes might contribute to "non-nephrotic glycosuric dwarfing with hypophosphataemic rickets in early childhood" [1]. Rickets and albuminuria secondary to kidney disease was described some 50 years previously but attributed to a disorder of adolescence [2]. Fanconi's first case presented at 3 months with rickets and recurrent fevers. She had glycosuria and albuminuria and progressed to terminal renal failure by 5 years of age. At autopsy the renal tubule cells appeared filled with crystals, which were thought to be cystine. In subsequent reports, Debré, de Toni and Fanconi all described series of children with rickets, glycosuria and albuminuria [3–5]. In acknowledgment of this pioneering work, we now refer to this symptom constellation as Fanconi-Debre-de Toni syndrome, or just short as "renal Fanconi syndrome" (RFS). The presentation, course and outcome of the described children, however, varied markedly. This reflects that RFS is not a uniform entity, but a diagnosis of proximal tubular dysfunction, which can be due to a variety of different causes (see Tables 35.1 and 35.2). RFS can be isolated or in the context of multiorgan disorders, congenital or acquired, transient or permanent, associated with progression to end-stage kidney disease (ESKD) or with stable kidney function throughout. Moreover, it can differ in the extent and severity of tubular dysfunction. Severe and generalized proximal tubular dysfunction is seen in cystinosis whilst many children with e.g. Dent disease or Lowe syndrome may have no clinically significant disturbance of phosphate and bicarbonate transport [39]. Indeed, there is some debate at what point proximal tubular dysfunction can be called RFS [40].

Here, we use the term RFS to include disorders with dysfunction of multiple proximal tubular pathways, but recognize that not every transport system need be affected. This clinical and biochemical heterogeneity is likely to arise from the multiple mechanisms involved in proximal tubular transport, reflecting not only the bulk of solute and water reabsorption but also the reuptake of proteins, amino acids, vitamins, cytokines and many other substances. RFS do not therefore have a common and single pathogenetic basis but reflect the interplay of a number of different biochemical processes. Identification of the underlying etiology is therefore of utmost importance, as it informs management and prognosis.

Table 35.1 Congenital causes of renal Fanconi Syndrome (RFS) by age of onset. (Adapted from [6])

Onset	Disorder	Associated features	Diagnostic test
Neonatal	Galactosemia	Liver dysfunction, jaundice, encephalopathy, sepsis	Red cell galactose 1-phosphate uridyl transferase
	Mitochondrial disorders	Usually multisystem dysfunction (brain, muscle, liver, heart)	Lactate/pyruvate (plasma lactate may be normal due to urinary losses), muscle enzymology
	Tyrosinemia	Poor growth, hepatic enlargement and dysfunction	Plasma amino acids, urine organic acids (succinylacetone)
Infancy	Fructosemia	Rapid onset after fructose ingestion, vomiting, hypoglycemia, hepatomegaly	Hepatic fructose-1-phosphate aldolase B
	Cystinosis	Poor growth, vomiting, rickets ± corneal cystine crystals	Leukocyte cystine concentration, molecular diagnosis (*CTNS*)
	Fanconi Bickel syndrome	Failure to thrive, hepatomegaly, hypoglycemia rickets, severe glycosuria, galactosuria	molecular diagnosis (*GLUT2*)
	Lowe's syndrome	Males (X-linked), cataracts, hypotonia, developmental delay	Clinical and molecular diagnosis (*OCRL*)
	RFS—GATM	Autosomal dominant, RFS recognisable in infancy, usually "mild" RFS, advanced CKD in adulthood	molecular diagnosis (*GATM*)
	RFS—EHHADH	Autosomal dominant, RFS recognisable in infancy, no progressive CKD	molecular diagnosis (*EHHADH*)
Childhood	Cystinosis	see above	
	Dent disease	Males (X-linked), hypercalciuria, nephrocalcinosis	Molecular diagnosis (*CLCN5, OCRL*)
	Wilson's disease	Hepatic & neurological disease, Kayser-Fleischer rings	Copper, coeruloplasmin, molecular diagnosis (*ATP7B*)

Fumaric acid [25]
Suramin [26]
Paraquat [27]
L-Lysine [28]
Renal disorders
Tubulointerstitial nephritis [29]
Membranous nephropathy with anti-tubular basement antibodies [30–38]

Clinical Features

The presenting clinical features of RFS in childhood are usually failure-to-thrive and rickets, although patients with RFS in the context of a systemic disorder may first be identified via the extra-renal manifestations, such as the cataracts in Lowe syndrome, or myopathy in mitochondrial cytopathies.

The failure-to-thrive is presumably due to the high-volume losses, with patients preoccupied with drinking, rather than caloric intake. Some patients exhibit features of a secondary nephrogenic diabetes insipidus, further compounding the water losses from impaired proximal reabsorption [41, 42].

Rickets is the consequence of renal phosphate losses (see below), as well as impaired proximal hydroxylation of vitamin D. The critical step in the formation of active Vitamin D (i.e. 1,25 OH-cholecalciferol) is mitochondrial 1α-hydroxylation in the proximal tubule. For this to occur, cholecalciferol, bound to its car-

rier vitamin D-binding protein (a low-molecular weight protein) needs to be reabsorbed from the tubular lumen, a process impaired in RFS [43].

Biochemical Abnormalities

Excessive urinary levels of a wide range of solutes and substances normally reabsorbed in the proximal tubule are the biochemical hallmarks of RFS.

Proteinuria

Proteinuria **in RFS** is made up of albumin, low molecular weight proteins and tubular enzymes, such as retinol binding protein (RBP), α-1 microglobulin, β-2 microglobulin, N-acetylglucoseaminidase, alanine aminopeptidase. The urinary level of these very sensitive markers of proximal tubular dysfunction is markedly elevated, especially if RBP is assayed [44, 45]. Albuminuria can be highly variable in RFS, but is typically below nephrotic range proteinuria [46]. In a family with autosomal dominant isolated RFS without apparent glomerular dysfunction the total amount was roughly 1g per day in affected adults [47]. This is consistent with some estimates of the amount of filtered albumin, which would usually undergo tubular reabsorption, at 0.4–1 g albumin per 1.73 m^2 per day [48, 49]. However, more recent estimates suggest that the amount of filtered albumin may actually be much higher, reaching several grams per day [50]. Indeed, there are multiple reports of patients with genetically defined defects in proximal tubular protein reabsorption, such as pathogenic variants in *OCRL*, *CLCN5* or *CUBN*, excreting several grams of protein in the urine per day [51–53]. Whether this amount of albuminuria is solely tubular or does reflect secondary glomerular damage remains controversial [54]. Interestingly, patients with proximal tubular disorders, even when they have nephrotic range proteinuria, typically have normal levels of plasma albumin and do not exhibit oedema [53]. Thus, the total amount of protein loss in RFS can be variable, reflecting the degree of impairment of reabsorption and potential concomitant glomerular dysfunction.

It is important to remember that urine dipsticks primarily detect larger proteins including albumin and thus can miss the mostly low-molecular weight proteinuria of RFS. Tubular proteinuria may be seen in some forms of nephrotic syndrome, likely reflecting associated tubulointerstitial damage [55, 56].

Aminoaciduria

The aminoaciduria seen in RFS is generalized and its pattern is influenced by plasma values, so that in rare situations of severe protein malnutrition, aminoaciduria as analyzed on thin-layer chromatography, may be recorded as “normal” or “mild” [44]. Quantitative analysis in urine and plasma by ion-exchange chromatography should be used to determine the degree and specific nature of aminoaciduria.

Organic Aciduria

Organic acids, including citrate and uric acid, are also exclusively reabsorbed in the proximal tubule and excretion is thus increased in RFS [57]. Consequently, patients with RFS typically have hyperuricosuria with hypouricemia, as well as hypercitraturia [58]. Moreover, transport of drugs, such as probenecid, furosemide or penicillin, can be affected, potentially altering pharmacokinetics [59]. The increased excretion of lactate can lead to normalization of plasma lactate levels in mitochondrial cytopathies, resulting in another potential diagnostic pitfall [60].

Glycosuria

Renal glycosuria in RFS reflects the impaired proximal tubular ability for glucose reabsorption, so that glycosuria occurs with normal blood glucose levels. As RFS is typically associated with marked polyuria, the urinary glucose concentration may be less than the 5 mmol/L and thus missed by dipstick measurement [39]. Formal

laboratory measurement, ideally of a 24-h urine collection, should thus be used to detect and quantify glycosuria. Normally, less than 1.5 mmol (300 mg)/day/1.73 m^2 are excreted [61], but this can increase to several grams daily with defects in proximal tubular reabsorption [62].

Renal Tubular Acidosis

Since the proximal tubule is the key site for bicarbonate reabsorption, bicarbonaturia is a typical feature of RFS with consequent metabolic acidosis (see also Chap. 35). The degree to which the threshold for reabsorption is reduced is variable, according to the underlying cause of RFS. In severe acidosis, filtered bicarbonate is reduced to a level below the threshold for proximal reabsorption and urine pH falls below 5.3 if distal acidification is intact. The hyperchloremic metabolic acidosis contributes to loss of skeletal calcium and consequent hypercalciuria. Unfortunately, treatment with alkali supplementation is complicated by the ongoing proximal losses, as soon as the plasma bicarbonate level rises above the threshold capacity for reabsorption. Frequent daily dosing of alkali supplementation can help to sustain bicarbonate levels in the normal range, or at least closer to it.

Phosphaturia

Renal phosphate wasting with secondary hypophosphatemia is another hallmark of proximal tubular dysfunction, leading to rickets or bone disease. Urine phosphate handling is usually assessed as the tubular reabsorption (TRP), the complement to the fractional excretion of phosphate (FEP). Thus, it is calculated as: TRP [%] = 100 − FEP [%]. Usually, a TRP >70% is considered normal, however this can be misleading. If the plasma phosphate level is decreased, the filtered load of phosphate may be close to or below the threshold of tubular phosphate reabsorption and TRP can therefore be misleadingly "normal". To account for the filtered load, urinary phosphate excretion can be assessed using the tubular threshold concentration for phosphate excretion, corrected for glomerular filtration rate (TmP/GFR) [63]. It is calculated as follows: TmP/GFR = (Phosphate plasma − Phosphate urine/Creatinine urine × Creatinine plasma). Normal values are age-dependent and listed in Table 35.3.

Table 35.3 Normal age-specific values for TmP/GFR (derived from [64–66])

Age	mmol/L
<1 month	1.48–3.43
1–3 months	1.48–3.30
4–6 months	1.15–2.60
7 months–2 years	1.10–2.70
2–4 years	1.04–2.79
4–6 years	1.05–2.60
6–8 years	1.26–2.35
8–10 years	1.10–2.31
10–12 years	1.15–2.58
12–15 years	1.18–2.09
>15 years	0.80–1.35

Hypercalciuria

Approximately 70% of filtered calcium is reabsorbed in the proximal tubule and, consequently hypercalciuria is another characteristic of RFS. It is further compounded by the acidosis-mediated calcium release from bone (see above). Nephrocalcinosis and stone formation can ensue, but interestingly is rather uncommon. Presumably, the polyuria inherent in RFS is protective against these complications, as may be the increased luminal concentration of citrate (see organic aciduria, above) [67].

Hypokalemia

Potassium, like almost all other electrolytes, is predominantly reabsorbed in the proximal tubule, making hypokalemia another typical feature. It can further be compounded by hyperaldosteronism if electrolyte and fluid losses result in volume contraction [68–70].

Other Substances

Carnitine is reabsorbed in the proximal tubule and is therefore lost in excess in RFS. Low plasma carnitine concentrations have been reported in children with cystinosis and tyrosinemia [71, 72] leading to plasma and muscle deficiencies of carnitine, which could contribute to the myopathy in these disorders. Moreover, losses of vitamins, carrier proteins and chemokines have all been described in RFS [46, 73].

Pathogenesis

The variation in etiology, manifestations and severity of RFS make it unlikely that there is a single common pathogenetic mechanism. Most studies of the pathogenesis have, of necessity, focused on one biochemical pathway. However, *in vivo*, it is more likely that a number of interlinked biochemical processes are disrupted in a variable manner.

Disruption of Energy Production

The high transport activity of the proximal tubule requires a large amount of energy. Thus, disruption of the energy supply is an obvious etiology of RFS. Consequently, it is not surprising that RFS is a frequent complication of mitochondrial cytopathies [60]. In fact, most inherited primary forms of RFS that have been genetically solved to date appear to be associated with mitochondrial dysfunction [74–76] (see below: Primary renal Fanconi syndromes).

Mitochondrial dysfunction has also been implicated in the development of RFS in cystinosis (see Chap. 30). Similar studies have been undertaken in models of tyrosinemia, which is associated with excessive accumulation of succinylacetone (SA). SA reduced sodium-dependent uptake of sugar and amino acids across rat brush border membranes [77] and intra-peritoneal injection of SA to rats led to development of RFS [78]. SA inhibits sodium-dependent phosphate transport by brush border membrane vesicles, decreases ATP production and inhibits mitochondrial respiration [79]. Administration of maleic acid, used to create an animal model of RFS, causes a reduction in ATP and phosphate concentrations, NaK ATPase activity and coenzyme A [80].

Glutathione Depletion

Historically, another line of investigation has looked into the role of glutathione (GSH) in the pathogenesis of RFS. GSH has a number of key cellular roles including post-translational protein modification, xenobiotic detoxification and it acts as a major antioxidant. Some such studies have mainly focused on cystinosis (Chap. 30), yet deficiency of GSH has also been implicated in other forms of the RFS. Ifosfamide toxicity, which leads to RFS, may be mediated by its interaction with γ-glutamyl transpeptidase, a precursor of GSH synthesis, and by hepatic metabolism to chloroacetaldehyde [81]. Incubation of chloroacetaldehyde with isolated human renal proximal tubules was associated with depletion of GSH, coenzyme A, acetyl-coenzyme A and ATP [82]. Wistar rats injected with ifosfamide develop RFS, associated with GSH depletion which is attenuated by treatment with melatonin [82]. Addition of ochratoxin A, the presumed toxin causing RFS in Balkan Endemic Nephropathy, to rat proximal tubular cells causes an elevation of reactive oxygen species and depletion of cellular GSH [83]. However, other data suggest that specific renal proximal tubular uptake and metabolism of ifosfamide is causative for the side effect of RFS [84].

Reduced Activity of Cotransporters

Increased solute excretion in RFS could result from reduced expression or activity of sodium-coupled cotransporters, which mediate proximal tubular reabsorption. In the animal model of maleic acid induced RFS, decreased *Slc34a1* mRNA expression and consequent reduced NaPi2a protein were observed [85].

Mice lacking hepatocyte nuclear factor 1 alpha (HNF1α), a transcription factor expressed in liver, pancreas, kidney and intestine, develop RFS, abnormal bile metabolism and diabetes [86]. HNF1α −/− mice had reduced expression of sodium-coupled transporters for glucose (SGLT2) and phosphate (NaPi1 and NaPi4) but normal levels of NaPi2a, the major phosphate transporter [87]. In addition, one primary form of proximal tubular dysfunction (see below: Primary renal Fanconi syndromes) is associated with a homozygous mutation in *SLC34A1* [88].

Disruption of the Endocytic Pathway (Megalin/Cubilin)

An important task of the proximal tubule is to reabsorb filtered proteins, including peptide hormones, as well as small carrier proteins binding fat-soluble vitamins and trace elements. Therefore, by reabsorbing filtered proteins the proximal tubule actively participates in the homeostasis of hormones, trace elements and vitamins. In addition, some lipoproteins, such as apolipoprotein A-I and A-IV are also reabsorbed in the proximal tubule [89]. Reabsorption of the vast majority of filtered proteins is mediated by two endocytic receptors: megalin and cubilin (reviewed in [90, 91]). These receptors contain several protein-binding domains and protrude from the microvilli, which make up the brush border of the proximal tubule, into the tubular lumen. Once a protein is attached, the receptor-ligand complex moves towards the base of the microvilli into clathrin-coated pits, which then bud off into the cytoplasm to form endosomes (see Fig. 35.1). Subsequently, the receptors are recycled back to the membrane to mediate further uptake. The fate of the protein ligands is different: most are degraded by acid hydrolysis after fusion of the endosome to a lysosome, while others, such as vitamins, are released back into the blood circulation across the basolateral membrane. In this fashion, the megalin/cubilin complex assumes a role in the regulation of several hormonal pathways, the importance of which becomes apparent, when considering, for instance, calcium-regulation: Megalin competes with the PTH receptor for the binding of filtered PTH and renders it non-functional by endocytosis and subsequent delivery to a lysosome for degradation [93]. In contrast, megalin/cubilin facilitates activation of Vitamin D by binding of filtered 25-OH vitamin D-Vitamin D binding protein and thus allowing uptake into the proximal tubule cell and activation by 1α-hydroxylase [43, 94].

Megalin is a large transmembrane protein belonging to the family of low-density lipoprotein receptors and was originally identified as the target of antibodies causing Heymann nephritis in rats [95]. It is expressed in epithelial cells of a variety of other tissues active in endocytosis [92]. Megalin-deficient mice mostly die in utero, but those that survive indeed show Fanconi-type low-molecular weight proteinuria, confirming the central role of megalin in endocytosis in the proximal tubule [96]. Interestingly, mutations in *LRP2*, the gene encoding megalin, were identified as the cause of Donnai-Barrow syndrome [97]. Donnai-Barrow syndrome is characterized by facial and ocular anomalies, sensorineural hearing loss and proteinuria. However, whilst these patients have, as expected, low-molecular weight proteinuria, there is no generalized proximal tubular dysfunction [98].

Cubilin is a peripheral membrane protein and is dependent on megalin to initiate endocytosis after ligand binding. These two proteins are co-expressed in proximal tubule and along the endocytic pathway and work in tandem to mediate protein uptake [90, 91]. Cubilin is otherwise known as the intrinsic factor-vitamin B12 receptor [99]. Loss-of-function mutations are associated with juvenile megaloblastic anemia or Imerslund-Graesbeck disease [100, 101]. The anemia is caused by deficient intestinal endocytosis of intrinsic factor-vitamin B12. In addition, some of these patients also have a selective low-molecular weight proteinuria that identifies those proteins requiring cubilin for endocytosis, such as albumin, transferrin, immunoglobulin light chains and α1- and β2-microglobulin [102]. Yet, as with Megalin, mutations in Cubilin are not associated with complete RFS.

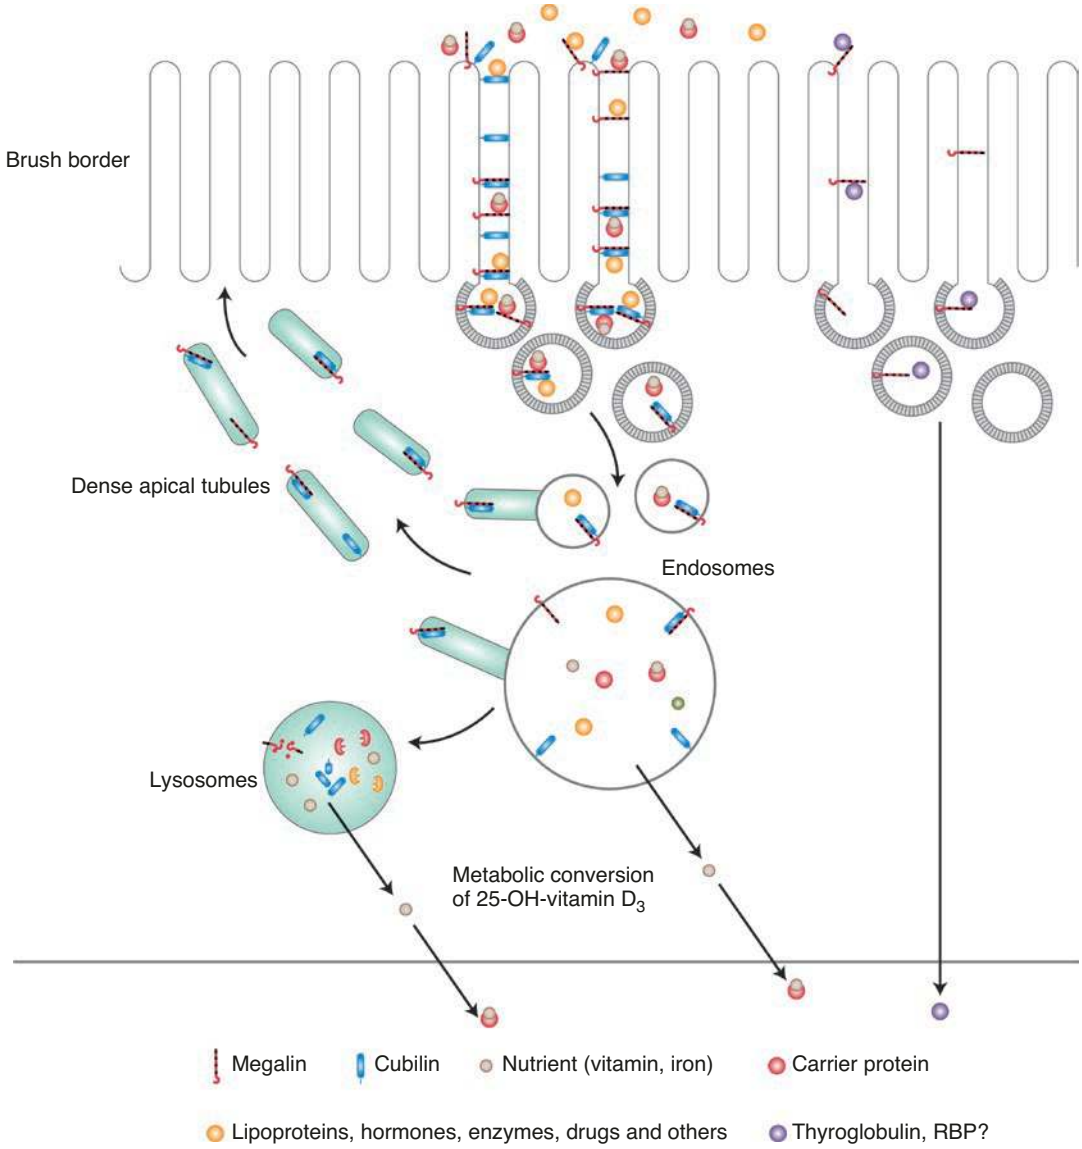

Fig. 35.1 Role of Megalin and Cubilin in proximal tubular transport. The receptors Megalin and Cubilin stick out from the brush border into the lumen of the proximal tubule. Once bound to a ligand (such as LMWP, nutrients etc.), the complex is endocytosed and ligand and receptor are separated by the low pH in the endosomes. The receptors are subsequently recycled to the membrane. (From [92])

Decreased expression of both megalin and cubilin at the brush border has been described in a mouse model of Dent disease [103]. Decreased levels of megalin have also been found in the urine of patients with Dent disease and Lowe syndrome, suggesting defective trafficking of the receptors as a mechanism of the low-molecular weight proteinuria seen in affected patients [104, 105]. The loss of vitamins, hormones and trace elements associated with endocytic dysfunction may explain some of the clinical heterogeneity seen in RFS.

Primary Renal Fanconi Syndromes

Sometimes, RFS appears in patients without an identified cause. The majority of these primary or idiopathic cases occur in adulthood, but some have also been reported in children [106]. A small number of cases occur in families and different modes of inheritance have been reported [47, 107–111]. Amongst the families with autosomal-dominant inheritance two distinct forms are recognized: (1) RFS with progressive chronic kidney disease (OMIM 134600), which is related to mutations in *GATM* [75] and (2) RFS with preserved GFR into advanced age (OMIM 615605) [88]. *GATM* encodes arginine-glycine amidinotransferase, an enzyme involved in creatine synthesis and recessive mutations are associated with a neurological disorder, cerebral creatine deficiency (OMIM 612718). However, the dominant mutations associated with RFS do not cause creatine deficiency and affected patients have no associated neurological manifestations. Instead, these dominant mutations cause linear aggregates of GATM in mitochondria, which are visible on electron microscopy in biopsy specimen. These aggregates appear to affect mitochondrial fission with consequent elongation of mitochondria, enhanced reactive oxygen species production and activation of the inflammasome, which in turn, is thought to contribute to tubulointerstitial fibrosis and progressive chronic kidney disease [75].

In RFS with preserved GFR so far only one specific dominant mutation in *EHHADH* has been identified (c.7G>A). *EHHADH* encodes a peroxisomal enzyme involved in fatty acid oxidation and, similar to *GATM*, this mutation does not lead to enzyme deficiency. Instead, the variant creates a novel mitochondrial targeting motif, leading to misrouting of the enzyme from the peroxisome to the mitochondria, where it interferes with fatty acid oxidation [74, 112]. While EHHADH is expressed in all organ systems, clinical manifestations appear restricted to the proximal tubule only, highlighting the dependence of the proximal tubule on mitochondrial fatty acid oxidation, rather than glucose metabolism [74, 112–114].

Another dominantly inherited form of RFS is associated with impaired insulin secretion (initially hyperinsulinism, later maturity onset diabetes in the young, OMIM 616026) and due to a specific missense mutation in *HNF4A* (p.Arg85Trp, also annotated as p.Arg63Trp or p.Arg76Trp, depending on reference sequence), encoding a transcription factor expressed in liver, pancreas and kidney [115, 116]. Interestingly, other dominant mutations in *HNF4A* are only associated with impaired insulin secretion, but not RFS. The exact mechanisms of how this particular mutations causes RFS are unclear, but impaired phosphorylation with subsequent changes in localization of HNF4A has been reported [76].

An autosomal recessive form of an incomplete RFS in two siblings has been attributed to a specific mutation in the phosphate transporter NaPi2a (*SLC34A1*), an in-frame 21bp duplication g.2061_2081dup; p.I154_V160dup [88]. It is yet to be clarified, how exactly this specific defect in proximal tubular phosphate transport causes a more generalized proximal tubular dysfunction, especially when considering that recessive mutations in *SLC34A1* have since been identified as the cause of a different disorder, infantile hypercalcaemia [117]. Interestingly, the specific mutation initially linked to proximal tubular dysfunction was subsequently linked also to infantile hypercalcaemia [118].

Treatment of these primary forms is symptomatic and in those with kidney failure, transplantation is an option.

Secondary Forms of Inherited Renal Fanconi Syndromes

Cystinosis

Nephropathic cystinosis, the most common cause of RFS in children, is covered in Chap. 30.

Tyrosinemia

The tyrosinemias are a group of disorders affecting the metabolism of tyrosine. The most severe one is tyrosinemia type 1, due to a defect in the enzyme fumarylacetoacetate hydrolase. Severity of clinical symptoms is variable but typically includes hepatic dysfunction with progression to cirrhosis and risk of hepatic cancer, as well as a porphyria-like neuropathy. In addition, patients can develop a severe RFS and chronic renal impairment may eventually ensue. The enzymatic defect in tyrosinemia leads to an accumulation of succinylacetone, which is thought to cause the symptoms. In experimental models succinylacetone inhibits transport in the proximal tubule, potentially by inhibition of mitochondrial function [77–79]. In addition, it inhibits porphobilinogen synthetase, which may explain the porphyria-like neuropathy [119]. Further evidence for the pathogenic role of succinylacetone comes from the discovery that blockade of tyrosine metabolism further upstream effectively remedies the symptoms of tyrosinemia: mice deleted for the gene encoding fumarylacetoacetate hydrolase die in the neonatal period, but are rescued by the additional deletion of the 4-OH-phenylpyruvate dioxygenase (HPD) gene (the basis for tyrosinemia type 3) which prevents the accumulation of succinylacetone [120]. Similarly, administration of nitisinone, a blocker of HPD effectively prevents and even reverses the symptoms of tyrosinemia in the vast majority of patients [121]. Consequently, nitisinone is now the first line therapy for tyrosinemia together with a tyrosine- and phenylalanine-restricted diet [122]. In the roughly 10% of patients where this fails, liver transplantation is an option. However, even though transplantation corrects the enzymatic defect in the liver, elevated levels of succinylacetone are still found in the urine of these patients and some of them have persisting tubular defects [123, 124].

Mitochondrial Cytopathies

The proximal tubule has a high energy requirement in order to reabsorb the bulk of filtered solutes. Cellular energy is provided in the form of ATP, produced by the respiratory chain in mitochondria. Therefore, proximal tubular cells are rich in mitochondria and it is not surprising that the proximal tubule is particularly susceptible to mitochondrial dysfunction. Indeed, RFS is the most common renal manifestation of mitochondrial cytopathies [60]. The clinical manifestations of mitochondrial disorders are highly variable, but those with RFS typically have severe multi-organ involvement and present during infancy [60]. Neuromuscular manifestations usually predominate and the prognosis is often poor. Mitochondrial DNA mutations are inherited through the maternal line, as mitochondria derive from the maternal egg. An egg contains several mitochondria, each carrying their own DNA. Mutations in mitochondrial DNA can therefore be present in some mitochondria, but not in others within the same cell, a state termed heteroplasmy. Depending on the number of mitochondria with mutations passed on during cell division the ratio of mutated to healthy mitochondria can be highly variable within different tissues and cells, which may explain some of the clinical variability [125]. However, the majority of genes encoding the respiratory chain enzymes are encoded in the nuclear genome and mutations in these genes are typically inherited in autosomal-recessive fashion and affect all mitochondria uniformly.

An initial investigation in suspected mitochondrial cytopathies is typically to determine the ratio of lactate to pyruvate in the serum. However, in patients with RFS, this ratio is often normal, due to the grossly increased loss of organic acids in the urine [60]. Therefore, measurement of activity of respiratory chain enzymes should be performed in those patients with high suspicion of a mitochondrial cytopathy. Renal

histology is typically non-specific, showing tubular damage, but may show giant mitochondria [126, 127]. Some forms of mitochondrial cytopathies can be improved by supplementation with certain vitamins, especially those with a deficiency in the coenzyme Q10 [128]. Otherwise, no definitive treatment exists and management is only supportive for the renal manifestations.

Fanconi-Bickel-Syndrome

Fanconi-Bickel-syndrome is a rare autosomal-recessive glycogen-storage disease, caused by mutations in the gene *SLC2A2* encoding the glucose transporter GLUT2 [62, 129]. Patients typically present in infancy with hepatomegaly, failure-to-thrive and renal Fanconi-syndrome with excessive glucosuria [130]. GLUT2 is expressed in liver, intestine, pancreatic β-cells and proximal tubule cells. In hepatocytes, the transporter facilitates glucose uptake, as well as release. The impaired release leads to hepatomegaly and hypoglycemia during fasting, while the defective uptake causes post-prandial hyperglycemia. In the pancreas, it leads to impaired glucose sensing and insulin release [130, 131]. In the kidney, GLUT2 localizes to the basolateral membrane of the proximal tubule, easily explaining the excessive glucosuria, which has been reported to exceed 300 g per day [132] The RFS is less well understood, but may be due to impaired mitochondrial function [133]. Interestingly, *GLUT2*-deleted mice reproduce the hepatic and pancreatic phenotype and also have glucosuria, but RFS has not been reported [131]. The mouse model is therefore not helpful in understanding the mechanisms responsible for the RFS.

Mutations in *SLC2A2* associated with Fanconi-Bickel are typically severe, expected to completely abrogate GLUT2 function, although mutations with a milder phenotype with only mild glycosuria and LMWP have recently been described [134]. Interestingly, some heterozygous carriers of *SLC2A2* mutations can have isolated renal glucosuria and some milder recessive mutations, associated only with glucosuria and LMWP have also been described [134, 135].

Treatment consists of frequent feedings of slowly absorbed carbohydrates, as well as replacement of renal losses of water and solutes [136].

Fructose Intolerance

Fructose intolerance is due to a deficiency in the enzyme fructose-1-phosphate aldolase B, also simply called aldolase. Affected infants typically become symptomatic at weaning, with the introduction of fructose-containing food, such as fruits and vegetables. Patients develop nausea, vomiting and diarrhea and can progress to hypoglycemia, convulsions and shock. Proximal tubule dysfunction develops and is most obvious in the form of a renal tubular acidosis, which is compounded by accumulation of lactic acid in the blood. The mechanism of cellular dysfunction is thought to be intracellular phosphate depletion due to phosphorylation of accumulating fructose. Phosphate is required for the generation of the cellular fuel ATP [137]. Moreover, a direct association between aldolase and the vacuolar proton pump V-H^+-ATPase has been shown [138]. This pump is involved in bicarbonate reabsorption in the proximal tubule, as well as acid secretion in the distal tubule and an inhibition by defective aldolase may explain the pronounced acidosis seen in patients. Treatment consists of a fructose-free diet, which completely reverses the renal symptoms.

Galactosemia

A reversible and incomplete form of proximal tubular dysfunction can be seen in infants with classical galactosemia, an autosomal-recessive disorder due to loss-of-function of the enzyme galactose-1-phosphate uridyl transferase [139]. This is a key enzyme for the conversion of galactose to glucose. Affected infants typically present with failure-to-thrive and develop vomiting, diar-

rhea and jaundice after ingestion of galactose-containing feeds. Untreated, hepatomegaly with progression to cirrhosis, cataracts and mental retardation develop. Renal manifestation are aminoaciduria, albuminuria, acidosis and galactosuria, the latter due to the elevated blood galactose levels [140]. The mechanism of tubular dysfunction is unclear, but may be related to intracellular depletion of free phosphate, due to phosphorylation of the accumulating galactose.

The diagnosis is made by increased blood galactose levels and confirmed by demonstration of enzyme deficiency. Importantly, the RFS is completely reversible with treatment, which is the elimination of galactose from the diet.

ARC-Syndrome

The combination of arthrogryposis, renal dysfunction and cholestasis constitutes a rare autosomal recessive disorder, due to mutations in genes encoding vacuolar sorting protein involved in intracellular transport, including *VPS33B and VIPAR* [141, 142]. Affected neonates are identified by their contractures, conjugated hyperbilirubinemia and severe failure to thrive. In addition, giant platelets with a bleeding diathesis are observed. Renal manifestations include severe proximal tubular dysfunction, but nephrocalcinosis, nephrogenic diabetes insipidus and dysplasia have also been described [143]. No specific treatment exists and the prognosis is poor with patients typically dying in their first year of life [141, 143–146]. However, milder forms have been described [147].

Membranous Nephropathy with Anti-proximal Tubule Basement Membrane Antibodies

Several reports exist about an association between membranous nephropathy and RFS [30–38, 148]. In most cases, antibodies have been found directed against the basement membrane of the proximal tubule. In some cases, pulmonary symptoms associated with anti-alveolar basement membrane antibodies are also present [34]. Most likely the antibodies are directed against an antigen expressed in the glomerulus, as well, explaining the combination of glomerular and proximal tubular dysfunction. In two families the syndrome has been linked to a region on the X-chromosome, but no gene has yet been identified [36].

Dent Disease

Clinical Features

Dent disease is an X-linked recessive proximal tubulopathy, characterized by low-molecular weight proteinuria (LMWP) and hypercalciuria with nephrocalcinosis and nephrolithiasis, as well as progressive renal failure [149]. Patients may also have aminoaciduria, glucosuria and phosphaturia, consistent with generalized proximal tubular dysfunction. It was first described as hypercalciuric rickets by Dent and Friedman [150]. Clinical manifestations can vary enormously and once an underlying gene, *CLCN5*, was identified in 1996, it was realized that mutations in the same gene also caused related tubulopathies, previously thought to be distinct, namely X-linked recessive nephrolithiasis and Japanese idiopathic low-molecular-weight proteinuria [151–157]. Patients typically manifest with complications of hypercalciuria, such as hematuria, nephrocalcinosis or stones. Progression to ESKD is rare in childhood. Women very rarely can be affected, probably due to skewed X-chromosome inactivation [158]. The diagnosis is made by the presence of hypercalciuria and low-molecular weight proteinuria (see above: proteinuria) and typically a family history on the maternal side. Renal histology is non-specific, showing features of interstitial nephritis and calcium deposits and is thus not useful in establishing the diagnosis.

Genetics

The first gene identified to underlie Dent disease was *CLCN5*, encoding a proton-chloride antiporter expressed in the proximal tubule and especially on late endosomes and lysosomes [151]. Mutations in this gene are identified in approximately 60% of patients with a clinical diagnosis of Dent disease. A second gene, *OCRL*, encoding a phosphatidylinositol 4,5-bisphosphate 5-phosphatase (PIP_2-5-phosphatase), was identified later and mutations in this gene are found in approximately 15% of patients [159]. These patients are often referred to as having Dent2 disease, to distinguish them from CLCN5-based Dent disease. In the remaining approximately 25% of patients, no mutation in either gene is found, indicating that other genes may be responsible.

The identification of *OCRL* underlying Dent disease was surprising, as this gene also underlies Lowe syndrome, which besides renal proximal tubular dysfunction includes cataracts and developmental delay (see below). A genotype-phenotype effect has been hypothesized, as frameshift, splice site and nonsense mutations in *OCRL* causing Dent disease all cluster in exons 1–7, whereas those associated with Lowe syndrome mostly localize to the exons further downstream [160]. Use of potential alternate start codons in exons 7 and 8, which maintain the *OCRL* frame and, presumably, some functionality, could explain the milder phenotype in Dent disease. However, this hypothesis cannot explain, why some missense mutations in OCRL are associated with multiorgan disease (the Lowe phenotype) in some patients and predominant kidney involvement (the Dent phenotype) in others [160].

Pathophysiology

Whilst the identification of underlying genes has provided great insights, the pathogenesis of Dent disease is still incompletely understood. *CLCN5* clearly plays an important part in endocytosis in the proximal tubule. It is highly expressed in endosomes and lysosomes, where it co-localizes with endocytosed proteins [103]. *CLCN5* is likely to provide an electric shunt in the lysosome that neutralizes the electrical gradient otherwise created by the H^+-ATPase, to allow its efficient operation. However, *CLCN5* is not a voltage-gated chloride channel, as initially described, but in fact a Cl^-/H^+ antiporter, which thus would remove protons from the lysosomal lumen [161, 162]. However, the net effect of CLCN5 function still appears to favor lysosomal acidification, as loss of function of *CLCN5* has been shown to impair this process in mice and also in cultured human proximal tubular cells *in vitro* [103, 163]. Initially, the LMWP was thought to be a consequence of the impaired lysosomal function, but there is evidence for a role of CLCN5 beyond the lysosome. CLCN5 is also expressed at the apical surface of proximal tubule cells, where it is important in the assembly of the endocytic complex containing megalin and cubilin (see above) [104, 164–166]. Indeed, megalin and cubilin expression at the brush border is dramatically reduced in *CLCN5*-deleted mice, as is the excretion of megalin in the urine in Dent patients and the mouse model [104, 105]. Therefore, the proteinuria seen in this disease likely reflects impaired receptor-mediated endocytosis [163]. This is consistent also with the involvement of OCRL in endocytosis (see Lowe syndrome, below). Indeed, the renal phenotype of Lowe syndrome strongly resembles that of Dent disease [39] and proteomic analysis of the urine of patients with Dent disease shows a similar pattern as in Lowe syndrome, suggesting that *CLCN5* and *OCRL* may participate in similar endocytic pathways [167]. Potentially, in patients with Dent2 disease, other PIP_2-5-phosphatases can compensate for the loss of *OCRL* except with respect to endocytosis and hypercalciuria. Redundancy in PIP_2-5-phosphatases is suggested by the fact that *OCRL*-deleted mice do not show any clinical phenotype [168]. Interestingly, children with Dent2 disease frequently have some extra-renal manifestations in the form of elevated plasma levels of LDH and CK and poorer growth [169]. In addition, mild developmental delay is noted

in some patients and it has been suggested that Dent2 disease is just a milder form of Lowe syndrome [170].

The hypercalciuria of Dent disease is poorly understood. One hypothesis is based on altered endocytosis of PTH and vitamin D-binding protein and a subsequently altered balance of calciotropic hormones [171]. Others propose a more direct role of CLCN5 in calcium handling by the kidney and bone [172, 173]. This discrepancy may in part be due to the fact that there are two different mouse strains with deleted *CLCN5* function, one of which has LMWP but no hypercalciuria [103].

Treatment

Treatment is mainly symptomatic and includes a large fluid intake to dilute urinary calcium and 1-α-OH vitamin D supplementation, to normalize PTH levels, so as to treat or prevent rickets. This needs to be monitored carefully, as excessive supplementation would worsen the hypercalciuria. Citrate supplementation has been helpful in a mouse model of the disease [174]. Thiazide diuretics have been shown to reduce calcium excretion at least in the short term and thus reduce the stone-forming risk in Dent disease [175] but are sometimes poorly tolerated. The reduction in urinary calcium excretion by thiazides in this disorder is surprising, as thiazides are thought to enhance calcium reabsorption in the proximal tubule, the segment affected in these patients [176].

Lowe Syndrome

Clinical Features

Lowe syndrome (oculo-cerebro-renal syndrome) was first described in 1952 as a clinical entity comprising "organic aciduria, decreased renal ammonia production, hydrophthalmus and mental retardation" [177]. Severity of symptoms varies, but in its complete form, patients are profoundly hypotonic with absent reflexes, have severe mental impairment, congenital cataracts, glaucoma and RFS [178, 179]. There is often a delay in establishing the diagnosis and the renal manifestations can be minimal in early years but gross LMWP is characteristic [44]. Most patients first present to the ophthalmologist due to congenital cataracts [180–182]. Interestingly, individual patients with pathogenic variants in *OCRL* and brain and kidney involvement, but without cataracts, have been described recently, further blurring the distinction between Dent2 disease and Lowe syndrome [160, 183, 184].

Motor development is typically delayed and most patients do not achieve independent walking before 3 years of age. Mental impairment can be very variable, but in one study most patients had IQ measured around 50, yet with 25% in the normal range (>70). Seizures have been reported in about a third of patients [185]. Brain imaging, if performed, may show white matter changes, cerebral atrophy or periventricular cysts [186–188]. Behavioral abnormalities in the form of temper tantrums, negativism and obsessive behavior are another typical feature that can be extremely difficult for the families [189, 190].

The renal phenotype, as discussed above, is predominated by LMWP and hypercalciuria, but can involve more generalized proximal dysfunction, such as a metabolic acidosis and phosphate wasting [39]. Hypercalciuria is presumably due to impaired proximal reabsorption, but may be compounded by increased intestinal absorption, which OCRL may be involved in regulating [191]. Associated with the hypercalciuria is nephrocalcinosis/lithiasis with is seen in about two thirds of Lowe patients.

Renal histology is non-specific, showing some distortion of proximal tubular architecture and later also glomerular changes [192]. Most patients exhibit a slow progression of renal insufficiency with ESKD typically reported during the fourth and fifth decade of life [193, 194]. Using the Schwartz-Haycock formula with usual k-values substantially overestimates the GFR in children with Lowe syndrome from serum creatinine when compared to formal GFR measurements, probably due to the low muscle mass of these patients [39].

In addition to the manifestations in eyes, brain and kidneys, other clinical symptoms can occur. These include:

- platelet dysfunction with increased bleeding risk [195]
- a debilitating arthropathy [196]
- growth failure [178], which is independent of GFR [170]
- skeletal abnormalities, such as kyphosis, scoliosis, joint hypermobility and hip dislocation [197]. Some of these features may be secondary to the neurological features, such as the muscular hypotonia
- dental abnormalities, such as eruption and dental cysts [198]
- dermal cysts [199]

Genetics

The gene underlying Lowe syndrome was cloned in 1992 and named OCRL [200].

Mutations are identified in approximately 80–90% of cases suspected of Lowe syndrome and in one study roughly one third of these occurred de novo [160]. About two thirds of mutations in patients diagnosed with Lowe syndrome are nonsense, frameshift and splice site changes, the remainder missense plus a few gross deletions. The presence of lens opacities has been suggested to identify female mutation carriers, although the reported sensitivity is variable [44, 181, 201–204].

Pathophysiology

Since identification of the underlying gene, much progress has been made towards understanding the pathophysiology. The OCRL protein contains several functional domains, including PIP_2-5-phosphatase located in the Golgi apparatus. Impairment of this phosphatase function results in elevated cellular levels of PIP_2. PIP_2 levels affect vesicle trafficking at the Golgi [205] and may also account for alterations in the actin cytoskeleton seen in fibroblasts from patients with Lowe's syndrome [206], resulting in altered endosomal membrane trafficking [207] (Fig. 35.2). Besides, the phosphatase domain, the

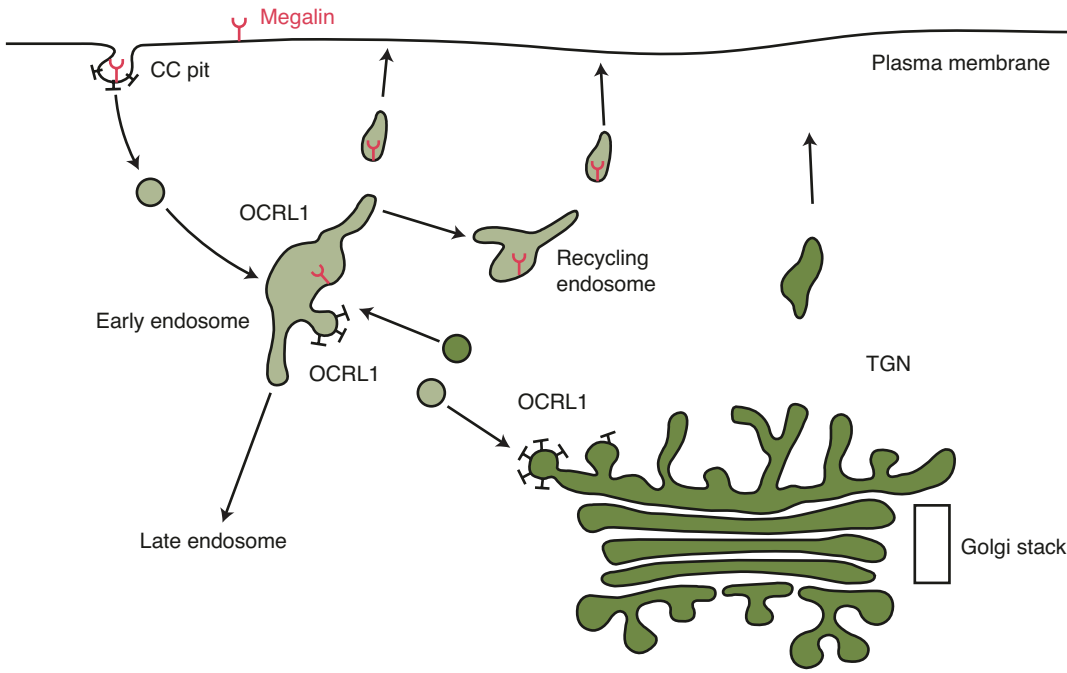

Fig. 35.2 Role of OCRL in regulation of traffic between apical membrane, endosomes and the trans-Golgi network. OCRL is present in clathrin-coated pits (CC) on the apical membrane of proximal tubular epithelial cells, early endosomes and the trans-Golgi network (TGN). (Adapted from [208])

OCRL protein also contains several other domains that are important for endosomal trafficking via protein-protein interactions, including an N-terminal PH (pleckstrin homology) domain, an ASH (ASPM-SPD2-Hydin) domain, and a C-terminal RhoGAP (Rho GTPase activating) domain [209]. Missense mutations within the RhoGAP domain were identified in some patients with Lowe syndrome, highlighting its importance for OCRL function [210].

Beyond the role in endocytosis, intracellular trafficking and regulation of the actin skeleton, OCRL has also been implicated in a wide range of cellular processes, including cell migration, cell polarity, cell-cell interaction, cytokinesis, mitochondrial function and cilia formation. Indeed, it has been suggested that Lowe syndrome could be considered a mitochondrial cytopathy [211] or, more recently, a ciliopathy [212]. It remains to be determined, to what degree these multiple mechanisms are clinically relevant and contribute to the variable phenotype associated with OCRL mutations.

Treatment

There is no specific treatment of Lowe syndrome and thus, management is symptomatic. Supplementation of electrolytes, alkali and vitamin D is based on biochemistries, and vitamin D is usually needed in 1-α- hydroxylated forms. Oversupplementation could worsen the hypercalciuria, so monitoring parathyroid hormone (PTH) and calcium levels is advised. Nutritional support with tube feeding may be helpful in the more severely affected patients.

The bleeding diathesis from the platelet dysfunction may be ameliorated with tranexamic acid and this should be considered prior to elective surgeries.

Cataract surgery is usually performed in the first year of life, but vision is nevertheless typically impaired and rarely better than 20/70 [213]. Anti-epileptic drugs can help in those patients suffering from recurrent seizures [187].

Acquired RFS

Many exogenous causes of RFS have been reported and are listed in Table 35.2. The mechanism of tubular damage is often unclear, although mitochondrial dysfunction has been implicated in some forms (see below).

Treatment, aside from supportive measures, is always the removal of the offending agent, which typically reverses the symptoms. Except for those compounds, where blood levels can be measured (such as lead or aminoglycosides), no specific diagnostic tests exist. Thus, the diagnosis is typically made through suspicion of an exogenous cause and its subsequent removal.

Chemotherapeutic Agents

Ifosfamide is the chemotherapeutic agent most commonly associated with RFS, which is seen in up to 10% of patients. Risk factors include total dose, reduced renal mass, young age or the combination with other nephrotoxic agents, such as cisplatin [214–218]. Symptoms typically reverse within weeks after cessation of the drug, but in some cases persist for several years and chronic impaired kidney function is possible [219, 220]. A mechanism has been proposed implicating specific ifosfamide uptake and metabolization in the proximal tubular cells [84].

Antibiotics and Antiretrovirals

Aminoglycosides are well known for their nephrotoxic side effects. In a small percentage of patients, they can also induce RFS. In fact, aminoaciduria has been proposed as a highly sensitive marker for aminoglycoside-induced renal injury, at least in the rat model [221]. The mechanism of damage is thought to be mitochondrial dysfunction: aminoglycosides target bacterial ribosomes where they induce faulty protein synthesis and since mitochondrial ribosomes bear structural resemblances to those of bacteria, they

are vulnerable to the toxicity [222]. The risk appears to be related to the dosage and length of treatment and symptoms typically reverse after cessation of the drug (reviewed in [223]).

With the advent of retroviral treatment, tenofovir has become an increasingly common cause of RFS, although rarely seen in children as risk factors for tenofovir toxicity include older age, pre-existing kidney disease and low body mass [11, 224]. The exact mechanism is unclear, but histology, if obtained, typically shows dysmorphic mitochondria [224].

Treatment

Specific therapy of RFSs depends on the underlying cause. The renal features of galactosemia and hereditary fructose intolerance are reversed by appropriate dietary therapy. Removal of the causative toxin or drug usually ameliorates the tubulopathy although some drugs (e.g. ifosfamide) can cause long-term dysfunction. Nitisinone (NTBC (2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione)), reverses the RFS in tyrosinemia (see above). Otherwise, treatment of RFS is mainly supportive. In severe cases, rehydration initially with 0.9% saline and careful electrolyte correction is necessary and can be hazardous if not monitored and managed by experts. Historically, fatalities occurred during rehydration with glucose-containing solutions, which exacerbated the profound hypokalemia. Rapid correction of acidosis can precipitate hypocalcemic seizures, exacerbated by the "hungry bone" phenomenon [225]. Once stabilized, large amounts of alkali (3–20 mmol/kg/day) are often needed to maintain acid-base homeostasis. As so often in tubular disorders, the more supplementation is given, the higher the filtered load and consequently, the more is lost in the urine. Smaller, but frequent dosing can help to maintain more consistent plasma levels and to reduce urinary losses from brief spikes in filtered load, associated with intermittent large doses, as well as side effects, such as diarrhoea. Alkali supplementation is typically prescribed in the form of sodium or potassium bicarbonate or citrate, or as a compound preparation. Supplements of sodium chloride may also be needed. For some children, provision of all the above supplements fails to correct the biochemical disturbances and growth failure persists. Indomethacin or an alternative non-steroidal anti-inflammatory agent may be helpful in such cases [226]. Carnitine supplements have been used to correct the plasma and muscle carnitine deficiencies that can occur due to renal losses. Hypophosphataemic rickets is treated with phosphate supplementation and 1-α-calcidol or calcitriol.

Basic Principles of Ion Transport in the TAL and the Early DCT

With respect to their role in sodium reabsorption, the TAL and early DCT form a functional unit that separates tubular sodium chloride from water. Compared to sodium reabsorption in the other nephron segments, which occurs via sodium hydrogen exchange or by sodium channels in the proximal nephron and in the ASDN, respectively, TAL and early DCT sodium transport is accomplished primarily by the active reabsorption of sodium together with chloride from the tubular fluid. These nephron segments are relatively water-tight and thus prevent osmotically driven absorptive flow of water. About 30% of the total sodium load provided by glomerular filtration is absorbed along the TAL and—via counter current multiplication—contribute to medullary interstitial hypertonicity. TAL sodium reabsorption thus not only accounts for the—in quantitative terms—most important mechanism of sodium retention (apart from the proximal nephron, which reabsorbs about 60% of the filtered sodium load), but also generates the osmotic driving force for water reabsorption along the CD. For this reason, disturbances in TAL salt reabsorption result in both salt-wasting and severely reduced urinary concentrating capacity (i.e. water loss). In contrast, DCT mediated salt reabsorption accounts for only about 5% of the filtered sodium load and does not contribute to the urinary concentrating mechanisms. Impaired DCT salt reabsorption therefore does not interfere with urinary concentrating capability, although the accompanying saluresis indirectly increases renal water excretion even with normal urine osmolalities.

Transepithelial sodium chloride reabsorption in the TAL and DCT is driven by secondary active transport processes that depend on a low intracellular sodium concentration maintained by active extrusion of sodium by the basolateral sodium-potassium-ATPase (sodium pump). By far the majority of TAL sodium reabsorption depends upon the operation of the furosemide-sensitive sodium-potassium-chloride cotransporter (NKCC2) with about half of the sodium taking the transcellular route and half taking a paracellular route by cation-selective intercellular pathways (Fig. 36.1a). Potassium that enters the TAL cell by sodium-potassium-chloride cotransport (1 potassium ion being transported with 1 sodium and 2 chloride ions) recycles back to the tubular urine through KCNJ1 (ROMK).

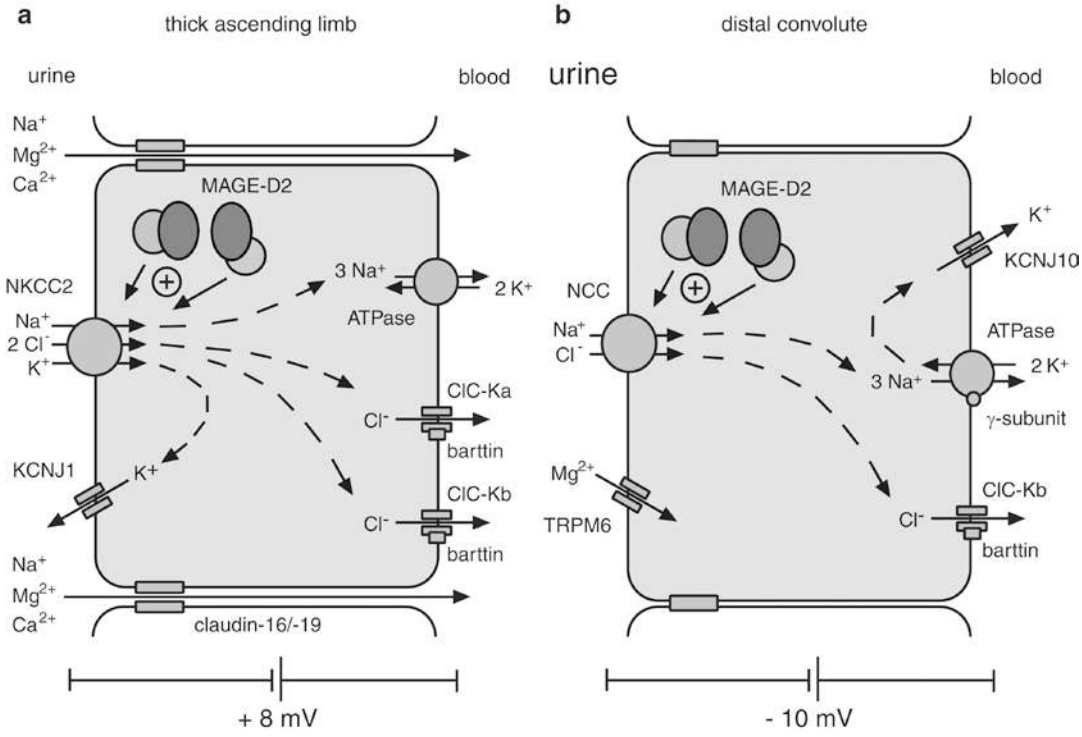

Fig. 36.1 Mechanisms of sodium reabsorption along the distal nephron. The key transport proteins and ion channels are shown for the thick ascending limb (**a**) and the distal convolute (**b**), for details please see text

This not only guarantees proper activity of NKCC2-mediated transport along the entire length of the TAL by replenishment of urinary potassium that otherwise would rapidly decrease along the TAL through reabsorption by NKCC2. Even more important, luminal potassium secretion in addition establishes a lumen-positive transepithelial voltage gradient that provides—in terms of energy recovery—a low-priced driving force for paracellular transport of cations like sodium, calcium, and magnesium. The essential functions of the TAL thus not only include the reabsorption of sodium chloride but also that of magnesium and calcium. Noteworthy, all of the TAL chloride reabsorption occurs by the transcellular route. Overall parity of sodium (with ~50% transcellular and ~50% paracellular) and chloride (100% transcellular) reabsorption is due to the stoichiometry of the apical NKCC2 cotransporter that transports two chloride ions for each sodium ion (Fig. 36.1a).

Taken together, the initial step of transcellular sodium chloride and paracellular sodium transport across the TAL epithelium critically depends on the proper activity of NKCC2 and KCNJ1.

In contrast to the TAL, sodium chloride reabsorption in the DCT occurs almost exclusively by the transcellular route (Fig. 36.1b). Luminal sodium chloride uptake is mediated by the electroneutral thiazide-sensitive sodium chloride cotransporter NCC that is structurally related to the NKCC2 protein, but transports 1 sodium ion together with 1 chloride ion without potassium. A relevant apical potassium conductance seems not to exist in early DCT cells, that instead express TRPM6 cation channels that permit apical magnesium entry. Inhibition of NCC transport by long term administration of thiazides or by genetic ablation in animal models has been shown to reduce the number of DCT cells, which might explain impaired renal magnesium reabsorption with consequent hypomagnesemia

observed in human diseases caused by impaired NCC mediated transport.

DCT and TAL cells differ with respect to the apical entry step for sodium chloride, however, as mentioned above, basolateral sodium release in both cell types is accounted for by the sodium pump. Moreover, epithelial cells in TAL and early DCT share similar pathways for basolateral chloride exit. In both cell types two highly homologous ClC-K type chloride channel proteins (ClC-Ka and ClC-Kb) associate with their beta subunit barttin to form a basolateral chloride conductance, which accounts for the release of the majority of reabsorbed chloride ions (Fig. 36.1a, b).

Taken together, NCC mediates early DCT cell sodium chloride uptake and ClC-K channels in association with barttin account for basolateral chloride release.

In the transition zone between the TAL and DCT a plaque of closely packed epithelial cells morphologically different from TAL- and DCT-cells forms the *macula densa*. Together with closely adjacent extraglomerular mesangial cells and granular cells of the afferent arterioles appendant to the same nephron, these specialized tubular cells assemble the juxtaglomerular apparatus. *Macula densa* cells serve an important function in coupling renal hemodynamics with tubular reabsorption in that they monitor the sodium chloride concentration of the tubular fluid. Via paracrine signalling molecules like prostaglandin E_2 (PGE_2), ATP, adenosin, and NO, the *macula densa* provides a feed-back mechanism, which adapts glomerular filtration to tubular reabsorption (tubuloglomerular feedback, TGF). In case of an increased sodium chloride concentration at the *macula densa* the TGF induces afferent arteriole vasoconstriction and decreases renin release, whereas a decreased *macula densa* sodium chloride concentration dilates the afferent arteriole and increases renin release. To sense the tubular sodium chloride concentration the *macula densa* takes advantage of essentially the same repertoire of transport proteins as found in salt-reabsorbing TAL cells. Via apical sodium chloride uptake (NKCC2 and KCNJ1) and basolateral chloride release (ClC-K and barttin) changes in luminal sodium chloride concentration are translated in alterations of basolateral transmembrane voltage. This again results from recycling of potassium into the tubular lumen, which guarantees an asymmetric - hence electrogenic - transcellular transport of sodium chloride, which results in basolateral membrane depolarization. This in turn regulates among other processes voltage-sensitive calcium entry, which triggers a series of intracellular signalling events eventually resulting in the release of the above mentioned paracrine signals. Owing to these combined functions in transepithelial transport and sensing of tubular sodium chloride, impaired activity of one of the participating proteins not only results in salt-wasting due to reduced TAL salt-reabsorbing capacity, but also abrogates the TGF as an important safety valve, which otherwise would reduce the filtered sodium chloride load by decreasing glomerular filtration. In fact, blinding of the *macula densa* for the tubular sodium chloride concentration with resultant disinhibition of glomerular filtration might constitute the single most important mechanism underlying the severe salt-wasting observed in impaired TAL salt transport.

Taken together, NKCC2, KCNJ1, ClC-K chloride channels, and barttin participate in the salt sensing-mechanism of the *macula densa*. Impaired function of one of these proteins affects the TGF and prevents adjustment of glomerular filtration with tubular salt-reabsorbing capacity, which further aggravates renal salt wasting [1].

Hypokalemic Salt-Wasting Tubular Disorders

With the exception of the medullary collecting duct that is primarily responsible for the reabsorption of water, reabsorption of sodium chloride from the glomerular filtrate at least in quantitative terms constitutes the key function of all nephron segments. Given the normal daily amount of 170 liters of glomerular filtrate produced by adult kidneys, at a normal plasma

sodium concentration of 140 mmol/L and plasma chloride concentration of 105 mmol/L the filtered load of sodium and chloride per 24 h amounts to 23.8 mols (about 550 g) and 17.9 mols (about 630 g), respectively. Healthy kidneys manage the reabsorption of more than 99% of the filtered load, with about 60% by the proximal tubule, 30% by the TAL, 5% by the early DCT, and the remainder by the aldosterone-sensitive distal nephron (ASDN). Impairment of sodium transport in any of these nephron segments causes a permanent reduction in extracellular fluid volume, which in turn causes compensatory activation of sodium conserving mechanisms, i.e. stimulation of renin secretion and aldosterone synthesis. Accordingly, with intact ASDN function, the primary symptoms of renal salt-wasting like hypovolemia with tendency for reduced arterial blood pressure mix with those of secondary hyperaldosteronism, which increases ASDN sodium retention at the expense of an increased potassium excretion eventually resulting in hypokalemia. In case of renal salt-wasting, hypokalemia thus indicates proper function of the ASDN and points to the involvement of nephron segments upstream to the ASDN.

As mentioned above, sodium reabsorption along the TAL and early DCT is coupled to the reabsorption of chloride. Sodium-wasting caused by defects in these nephron segments hence is accompanied by decreased reabsorption of chloride. Unlike sodium, which at least partially may be recovered by increased reabsorption along the ASDN, chloride irretrievably gets lost with the urine. Accordingly, the urinary chloride-loss exceeds that of sodium and for the sake of electroneutrality has to be balanced by other cations like ammonium or potassium. Loss of ammonium, the main carrier of protons in the urine, results in metabolic alkalosis, potassium loss in addition aggravates hypokalemia caused by secondary hyperaldosteronism. For this reason, hypochloremia with metabolic alkalosis, in addition to severe hypokalemia characterizes salt-wasting due to defects along the TAL and early DCT.

Finally, sodium reabsorption along the proximal tubule via the sodium proton exchanger and the carboanhydrase is indirectly coupled to the reabsorption of bicarbonate. Proximal tubular salt-wasting thus—in addition to hypokalemia—is accompanied by urinary loss of bicarbonate resulting in hyperchloremic metabolic acidosis.

Taken together, in the state of renal salt-wasting the determination of plasma potassium, chloride, and bicarbonate concentrations allows for the rapid assessment of the affected nephron segment. Of note, in this context the determination of the plasma sodium concentration is not very helpful, since changes in plasma sodium—the more or less exclusive extracellular cation accounting for plasma osmolality—reflects disturbances in the osmoregulation (i.e. water balance) rather than in the regulation of sodium balance.

Apart from more general disturbances of proximal tubular function which among other transport processes affect proximal tubular sodium reabsorption (as seen in Fanconi syndrome), no hereditary defects specifically affecting the proximal tubular sodium proton exchanger have been described in humans. By contrast, several genetic defects affect sodium chloride transport along the TAL and DCT and will be the focus of the following section.

Renal Salt-Wasting with Hypokalemia and Hypochloremic Metabolic Alkalosis

Historical Overview and Nomenclature

In 1957, two pediatricians described an infant with congenital hypokalemic alkalosis, failure to thrive, dehydration, and hyposthenuria, who finally died at the age of 7.5 months [2]. Some years later, two patients with normotensive hyperaldosteronism, hyperplasia of the juxtaglomerular apparatus, metabolic alkalosis and severe renal potassium wasting were characterized by the endocrinologist Frederic Bartter [3]. Other features of this syndrome were increased activity of the renin-angiotensin system and a relative

vascular resistance to the pressor effect of exogeneously applied angiotensin II. Following these original reports, hundreds of such Bartter syndrome (BS) cases have been described. While all shared the findings of hypokalemia and hypochloremic alkalosis, patients differed with respect to age of onset, severity of symptoms, degree of growth retardation, urinary concentration capacity, magnitude of urinary excretion of potassium and prostaglandins, presence of hypomagnesemia, and extents of urinary calcium excretion.

Gitelman and colleagues pointed to the susceptibility to carpopedal spasms and tetany in three BS cases [4]. Tetany was attributed to low plasma magnesium levels secondary to impaired renal conservation of magnesium. Further examination of these patients in addition revealed low urinary calcium excretion [5]. Consequently, the association of hypocalciuria with renal magnesium-wasting was regarded as a hallmark to separate the then defined Gitelman syndrome (GS) from other forms of BS [6]. Interestingly, both patients in Bartter's original report displayed positive Chvostek's sign and carpopedal spasms. Indeed, in a review of the original observations described by Bartter et al., one of the coauthors conceded that the majority of patients seen by both endocrinologists perfectly matched the later description of Gitelman [7].

Phenotypic homogeneity of BS was challenged even more seriously when the pediatricians Fanconi and McCredie described high urinary calcium excretion and medullary nephrocalcinosis in preterm infants initially suspected of having BS [8, 9]. Descriptions of this variant in the literature became more frequent in the 1980s, most likely because advances in neonatal medicine resulted in higher survival rates of extremely preterm born babies. The neonatologist Ohlsson finally described the antenatal history with maternal polyhydramnios, which likely predisposed to premature birth [10]. Immediately after birth, profound polyuria puts such patients at great risk for life-threatening dehydration. Contraction of the extracellular fluid (ECF) volume is accompanied by markedly elevated renal and extrarenal prostaglandin E_2 (PGE_2) production. Treatment with prostaglandin synthesis inhibitors effectively reduced polyuria, ameliorated hypokalemia, and improved growth [11, 12]. Another variant of this severe, prenatal-onset salt-wasting disorder was first described in a Bedouin family. It differs from the above mentioned antenatal variant of BS by the presence of sensorineural deafness, absence of medullary nephrocalcinosis, and slowly deteriorating renal function [13]. The last variant that has been described is X-linked transient antenatal BS. This disorder is of peculiar interest because at onset the clinical course is very severe and still many patients die from complications. Interestingly, the disease phenotype is self-limited and clinical symptoms disappear within a few weeks to months of life [14].

Taken together, renal salt-wasting syndromes associated with hypokalemia and hypochloremic metabolic alkalosis (frequently subsumed as "Bartter syndrome" in a broader sense) present with marked clinical variability. Severe, early onset forms (**antenatal Bartter syndrome, aBS**) with symptoms directly arising from profound salt-wasting with extracellular volume depletion contrast with milder late onset forms primarily characterized by the features of secondary hyperaldosteronism (**Gitelman syndrome, GS**). In between these two extremes, the Bartter syndrome *sensu stricto* (**classic Bartter syndrome, cBS**) presents as a disorder of intermediate severity. Variable extents of extracellular volume depletion and secondary electrolyte disturbances contribute to a rather variable disease phenotype, which in its extremes may mimic aBS or GS.

This classification based on clinical criteria was enriched by clarification of the underlying *genetic* defects, of which all but one follow an autosomal recessive mode of inheritance. As disclosed by molecular genetic analyses, aBS results from disturbed salt reabsorption along the TAL due to defects either in NKCC2 [15], KCNJ1 (ROMK) [16], Barttin [17], or both ClC-Ka and ClC-Kb [18]. X-linked transient aBS is caused by mutations in MAGE-D2, a chaperone-like molecule affecting the expression of NKCC2 and NCC during fetal life [14]. The cBS is caused by dysfunction of ClC-Kb [19], which impairs salt transport to some extent along the TAL and in

particular along the DCT. A pure defect of salt reabsorption in the DCT due to dysfunction of NCC finally results in GS [20].

Given the significant clinical overlap within the different subtypes of BS and also with GS, it is more and more accepted to describe the subtypes by the underlying genetic abnormality (Table 36.1). According to this molecular genetic classification, Bartter syndrome type 1 **(BS1)** refers to a defect in NKCC2 (gene name *SLC12A1*), **BS2** in KCNJ1 (*KCNJ1*), **BS3** in ClC-Kb (*CLCNKB*), **BS4a** in Barttin (*BSND*), **BS4b** to a digenic defect in ClC-Ka and ClC-Kb, and **BS5** in MAGE-D2. Previously patients with a Bartter-like phenotype with gain of function mutations in the calcium sensing receptor (CaSR) have been described [21, 22] and sometimes referred to as BS5, but this designation has been abandoned in accordance with the current OMIM nomenclature. **GS**, owing to disturbed NCC (*SLC12A3*) function, was not included in this classification despite its apparent relatedness to this group of disorders.

Another facet of the clinical and genetic heterogeneity of inherited renal salt wasting disorders unsurfaced in 2009, when a new autosomal recessive clinical syndrome characterized by epilepsy, ataxia, sensorineural deafness and renal salt wasting with or without mental retardation was described under the acronyms EAST or SeSAME syndrome [23, 24]. **EAST/SeSAME** syndrome is caused by loss-of-function mutations in the *KCNJ10* gene encoding the inwardly-rectifying potassium channel KCNJ10 (Kir4.1). The renal tubular defect disturbs the reabsorption of sodium chloride in the DCT and thus symptoms closely resemble GS with hypokalemic alkalosis, hypomagnesemia and hypocalciuria.

Taken together, renal salt-wasting with hypokalemia and hypochloremic metabolic alkalosis becomes manifest in three clinically defined syndromes: BS, GS, and EAST syndrome.

Genetic Disorders with Hypokalemic Salt-Wasting

Bartter Syndrome Type 1 (BS1)

Disruption of sodium chloride reabsorption in the TAL due to inactivating mutations of the *SLC12A1* gene which encodes NKCC2 causes BS1, a severe disorder with onset *in utero*. Within the second trimester, fetal polyuria leads to progressive maternal polyhydramnios. Untreated, premature delivery occurs around 32 weeks of gestation. The most striking abnormality of the newborns is profound polyuria. With adequate fluid replacement, daily urinary outputs can easily exceed half of the body weight of the newborn (>20 mL/kg/h). Despite ECF volume contraction and presence of high AVP levels, urine osmolality hardly approaches that of plasma, indicating a severe renal concentrating defect. Salt reabsorption along the TAL segment is also critical for urine dilution, which explains that urine osmolality on the other hand typically does not decrease below 160 mosmol/kg. Some preserved ability to dilute urine might be explained by an adaptive increase of salt reabsorption in the DCT which functions as the most distal portion of the diluting segment. This moderate hyposthenuria clearly separates NKCC2-deficient patients from polyuric patients with nephrogenic diabetes insipidus, who typically display urine osmolalities below 100 mosmol/kg.

Within the first months of life, nearly all patients develop medullary nephrocalcinosis in parallel with persistently high urinary calcium excretion. Remarkably, conservation of magnesium is not affected to a similar extent and

NKCC2-deficient patients usually do not develop hypomagnesemia. This is even more surprising given that mutations in either *CLDN16* or *CLDN19* which both encode tight junction proteins that mediate paracellular transport of divalent cations along the TAL, invariably cause both hypercalciuria and hypermagnesiuria with subsequent hypomagnesemia [25, 26]. With respect to magnesium transport, the difference between both disorders might be explained by an upregulation of magnesium reabsorption parallel to a compensatory increase of sodium chloride reabsorption in DCT cells in case of a NKCC2 defect [27].

Bartter Syndrome Type 2 (BS2)

Patients with mutations in the *KCNJ1* gene encoding the ATP-sensitive inwardly rectifying potassium channel KCNJ1 (ROMK) similarly show a history of maternal polyhydramnios, prematurity with a median age of gestation of 33 weeks, vasopressin-insensitive polyuria, isosthenuria, and hypercalciuria with secondary nephrocalcinosis. As in the case of NKCC2 dysfunction, the severity of the symptoms argues for a complete defect of sodium chloride reabsorption along the TAL. The mechanism of RAAS activation is virtually identical to that proposed for NKCC2-deficient patients. However, despite the presence of high plasma aldosterone levels, KCNJ1-deficient patients exhibit transient hyperkalemia in the first days of life [28]. The simultaneous appearance of hyperkalemia and hyponatremia resembles the clinical picture of mineralocorticoid-deficiency (which however shows low aldosterone levels) or that of pseudohypoaldosteronism type I (PHA-I; high aldosterone levels). Indeed, several published cases of PHA-I turned out to be misdiagnosed and subsequent genetic analysis revealed KCNJ1 mutations as the underlying defect [29]. The severity of initial hyperkalemia decreases with gestational age [30]. Hyperkalemia may be attributed to the additional role of KCNJ1 in the cortical collecting duct (CCD) where it participates in the process of potassium secretion. Although less pronounced as compared to NKCC2-deficiency, the majority of KCNJ1-deficient patients develop hypokalemia in the later course of the disease. The transient nature of hyperkalemia may be explained by the upregulation of alternative pathways for potassium secretion in the CCD.

Bartter Syndrome Type 3 (BS3)

BS3, previously often designated as "classic Bartter syndrome", is caused by mutations in *CLCNKB* (encoding the basolateral chloride channel ClC-Kb). This subtype of BS is characterized by a very high clinical variability which might be partly explained by an alternative chloride extrusion pathway in the basolateral membrane of TAL cells, namely ClC-Ka. Several studies have indicated that the clinical variability is not related to a certain type of mutation [31, 32]. Even the most deleterious mutation, which implies the absence of the complete *CLCNKB* gene and which affects nearly 50% of patients, can cause varying degrees of disease severity. Features of tubular dysfunction distal from the TAL predominate, suggesting a major role of ClC-Kb along the DCT. Although TAL salt transport can be impaired to a variable extent, its function is never completely perturbed.

With respect to renal function, the neonatal period in ClC-Kb-deficient patients usually passes without major problems. Maternal polyhydramnios is observed in only one fourth of the patients and usually is mild. Accordingly, duration of pregnancy is not substantially shortened. More than half of the patients are diagnosed within the first year of life. Symptoms at initial presentation include failure to thrive, dehydration, muscular hypotonia, and lethargy. Laboratory examination typically reveals low plasma chloride concentrations (down to 60 mmol/L), decreased plasma sodium concentration, and severe hypokalemic alkalosis. At first presentation, electrolyte derangement is usually more pronounced as compared to the other variants of BS. However, because renal salt wasting progresses slowly and polyuria may be absent, medical consultation may be delayed. Plasma renin activity is greatly increased, whereas plasma aldosterone concentration is only slightly elevated. This discrepancy might be attributed to negative feed-back regulation of aldosterone

incretion by hypokalemia and alkalosis. Therefore, normal or slightly elevated aldosterone levels under conditions of profound hypokalemic alkalosis are in fact inappropriately low.

Urinary concentrating ability is preserved at least to a certain extent and a number of patients with BS3 achieve urinary osmolalities above 700 mosmol/kg in morning urine samples. Because renal medullary interstitial hypertonicity is critically dependent on sodium chloride reabsorption in the TAL, the ability to concentrate urine above 700 mosmol/kg indicates nearly intact TAL function despite of ClC-Kb deficiency. Moreover, the integrity of TAL function is also reflected by the finding that hypercalciuria is not a typical feature of ClC-Kb dysfunction and—if present—occurs only temporarily. The majority of patients exhibit normal or even low urinary calcium excretion. Accordingly, medullary nephrocalcinosis—a hallmark of pure TAL dysfunction—is rare. The plasma magnesium concentration gradually decreases over time owing to impaired renal magnesium conservation, as is observed in other forms of abnormal DCT function. Accordingly, several ClC-Kb deficient patients exhibit both hypomagnesemia and hypocalciuria, a constellation which usually is thought to be highly indicative for an NCC-defect. ClC-Kb deficiency thus may mimic GS.

Bartter Syndrome Type 4a (BS4a)

In 2001, a new player in the process of salt reabsorption along the TAL and DCT was identified—the ClC-K channel beta-subunit barttin—following the discovery of molecular defects in *BSND* in patients with a very rare variant of BS with sensorineural deafness [17]. Because Barttin had no homology to any known protein, its physiologic function remained unclear until its role as an essential beta-subunit of the ClC-K channels was demonstrated [33, 34].

Two ClC-K isoforms of the ClC family of chloride channels are highly expressed along the distal nephron, with ClC-Ka being primarily expressed in the thin ascending limb and decreasing expression levels along the adjacent distal nephron. Its close homologue, ClC-Kb, is predominantly expressed in the DCT. Along the TAL, both channel isoforms are equally expressed. Barttin, which is found in all ClC-K expressing nephron segments, is essential for proper ClC-K channel function in that it facilitates the transport of ClC-K channels to the cell surface and modulates biophysical properties of the assembled channel complex.

In affected individuals, the Barttin defect seems to completely disrupt chloride exit across the basolateral membrane in TAL as well as DCT cells. Accordingly, patients display the severest salt-wasting kidney disorder described so far. As with defects of NKCC2 and KCNJ1, the first symptom of a Barttin defect is maternal polyhydramnios due to fetal polyuria beginning at approximately 22 weeks of gestation. Again, polyhydramnios accounts for preterm labor and extreme prematurity. Postnatally, patients are at high risk of volume depletion. Plasma chloride levels fall to approximately 80 mmol/l, a further decrease usually can be avoided by close laboratory monitoring and rapid intervention. Polyuria again is resistant to vasopressin and urine osmolalities range between 200 and 400 mOsmol/kg.

Unlike patients with loss-of-function mutations in KCNJ1 and NKCC2, Barttin-deficient patients exhibit only transitory hypercalciuria [35]. Medullary nephrocalcinosis is absent, yet progressive renal failure is common with histologic signs of pronounced tissue damage like glomerular sclerosis, tubular atrophy, and mononuclear infiltration. The mechanisms underlying the deterioration of renal function are not yet understood. The lack of hypercalciuria, however, may be explained by disturbed sodium chloride reabsorption along the DCT. Isolated DCT dysfunction as seen in GS (see below) or after long-term inhibition of NCC-mediated transport by thiazides is known to induce hypocalciuria. This effect might counter-balance the hypercalciuric effect of TAL-dysfunction in case of a combined impairment of salt reabsorption along the TAL and DCT. In contrast to calcium, the renal conservation of magnesium is impaired, leading to hypomagnesemia. This might be explained by the disruption of both magnesium reabsorption pathways, the paracellular one in the TAL and the transcellular one in the DCT, respectively.

Barttin defects are invariably associated with sensorineurinal deafness. Elucidation of the

pathogenesis of this rare disorder has provided a deeper insight into the mechanisms of potassium rich endolymph secretion in the inner ear: Marginal cells of the *stria vascularis* contribute to the endolymph formation by apical potassium secretion. Transcellular potassium transport is mediated by the furosemide-sensitive Na-K-2Cl-cotransporter type 1 (NKCC1) ensuring basolateral potassium entry into the marginal cells. Voltage-dependent potassium channels mediate apical potassium secretion into the endolymph. Proper function of NKCC1 requires basolateral recycling of chloride. Deafness associated with Barttin defects suggests that this recycling is enabled by the ClC-K/barttin channel complex.

A Digenic Disorder: Bartter Syndrome Type 4b (BS4b)

The concept of the physiologic role of Barttin as a common beta-subunit of ClC-K channels was substantiated by the description of patients harbouring inactivating mutations in both the ClC-Ka and ClC-Kb chloride channels, respectively [18]. The clinical symptoms resulting from this digenic disease are indistinguishable from those of Barttin-deficient patients. This observation not only proves the concept of the functional interaction of Barttin with both ClC-K isoforms but also excludes important other functions of Barttin not related to ClC-K channel interaction.

X-Linked Transient Bartter Syndrome (BS5)

Transient forms of antenatal BS have been first described in the 1990s [36, 37]. The clinical course is characterized by early development of severe polyhydramnios, high prenatal mortality and excessive neonatal salt wasting in the surviving infants. This disease condition is mainly observed in male infants and surprisingly the disease manifestations spontaneously resolve within a few weeks to several months of life. Mutations in *MAGED2* encoding the melanoma-associated antigen-D2 have been identified to underly the disorder [14]. As expected for an X-linked disease, transient BS (BS5) is almost exclusively observed in boys. Only two female infants have been described to date [38]. Functional data indicate that MAGED2 regulates the expression of NKCC2 and NCC, especially during fetal life. Because of the transient character of the disease, it is of crucial importance to establish the exact diagnosis in order to avoid therapies such as NSAIDs which are no longer necessary by nature of the disease.

Gitelman Syndrome (GS)

DCT epithelia contain two cell types: early DCT cells (DCT1) which express the thiazide-sensitive sodium chloride cotransporter (NCC) as its predominant apical sodium entry pathway, and further distal residing late DCT cells (DCT2), which express the epithelial sodium channel (ENaC) as the main pathway for apical sodium reabsorption. Both sodium entry pathways are inducible by aldosterone. Early DCT and late DCT cells probably also differ with respect to their function in divalent cation transport.

Genetic defects in *SLC12A3* encoding NCC result in only mild renal salt wasting. Initial presentation frequently occurs at school age or later with the characteristic symptoms being muscular weakness, cramps, and fatigue. Whereas a history of salt craving is common, urinary concentrating ability typically is preserved. Laboratory examination shows a typical constellation of metabolic alkalosis, low normal chloride levels, hypokalemia, and hypomagnesemia, urine analysis shows hypocalciuria. Family studies revealed that electrolyte imbalances are present from infancy, although most of the affected infants displayed no obvious clinical signs. Of note, the combination of hypokalemia and hypomagnesemia exerts an exceptionally unfavorable effect on cardiac excitability, which puts these patients at high risk for cardiac arrhythmia.

The pathognomonic feature of GS is the dissociation of renal calcium and magnesium handling, with low urinary calcium and high urinary magnesium levels. Subsequent hypomagnesemia causes neuromuscular irritability and tetany. Decreased renal calcium elimination together with magnesium deficiency favors deposition of mineral calcium as demonstrated by increased bone density as well as chondrocalcinosis. Although the combination of hypomagnesemia and hypocalciuria is typical for GS, it is neither a specific nor universal finding. Clinical observa-

tions in GS patients disclosed intra- and inter-individual variations in urinary calcium concentrations which can be attributed to gender, age-related conditions of bone metabolism, intake of magnesium supplements, changes in diuresis and urinary osmolality, respectively. Likewise, hypomagnesemia might not be present from the beginning. Because less than one percent of total body magnesium is circulating in the blood, renal magnesium loss can be balanced temporarily by magnesium release from bone and muscle stores as well as by an increase of intestinal magnesium reabsorption. Accordingly, the strict definition of hypomagnesemia with coincident hypocalciuria in order to separate GS from BS3 appears arbitrary.

The mechanisms compromising distal magnesium reabsorption and favoring reabsorption of calcium are not yet completely understood. The occasional co-existence of hypomagnesemia and hypocalciuria in ClC-Kb deficient patients indicates that this phenomenon is not restricted to NCC defects but is rather a consequence of impaired transcellular sodium chloride reabsorption along the early DCT. It is tempting to speculate, that with a functional defect of early DCT cells, which in addition to sodium chloride normally reabsorb magnesium by apical TRPM6 magnesium channels, these cells are replaced by late DCT cells, which reabsorb sodium via ENaC channels and calcium via epithelial calcium channels (TRPV5). Accordingly, reabsorption of magnesium would decrease and that of calcium increase. Moreover, other phenomena like for example the redistribution of renal tubular sodium chloride reabsorption to more proximal nephron segments (proximal tubule and TAL) might contribute to alterations in renal calcium and magnesium handling.

EAST/SeSAME Syndrome

In 2009, a newly described autosomal recessive clinical syndrome characterized by epilepsy, ataxia, sensorineural deafness and renal salt wasting with/without mental retardation was described under the acronyms EAST or SeSAME syndrome [23, 24]. EAST/SeSAME syndrome is caused by loss of function mutations in the *KCNJ10* gene encoding the inwardly-rectifying potassium channel KCNJ10 (Kir4.1). The expression pattern of KCNJ10 fits the disease phenotype with high expression levels in brain, the stria vascularis of the inner ear, and in the distal nephron, especially in the DCT. Here, KCNJ10 is localized at the basolateral membrane of DCT cells where it is thought to function in collaboration with the Na^+K^+-ATPase as it might allow for a recycling of potassium ions entering the tubular cells in countermove for the extruded sodium [24]. Loss of KCNJ10 function most likely leads to a depolarization of the basolateral membrane and thereby to a reduction of the driving force for basolateral anion channels as well as sodium-coupled exchangers. By this mechanism, KCNJ10 defects could also affect the putative Na^+/Mg^{2+} exchanger and possibly explain the magnesium wasting observed in EAST/SeSAME syndrome. Moreover, it could be demonstrated that lack of KCNJ10 decreases basolateral chloride conductance and results in a diminished expression of NCC in the apical membrane [39]. These results could explain the salt loss observed in EAST/SeSAME patients. Interestingly, the renal phenotype of KCNJ10 knockout mice had not been thoroughly studied until the description of the human disease [40]. However, the reevaluation of KCNJ10 knockout mice clearly demonstrated renal salt wasting leading to significant growth retardation [23].

Patients usually present early in infancy with generalized tonic-clonic seizures, speech and motor delay, as well as severe ataxia leading to an inability to walk, intention tremor, and dysdiadochokinesis. In addition they exhibit a severe hearing impairment. Renal salt wasting may develop or be recognized only later during the course of the disease [41]. Closely resembling GS, the renal phenotype includes the combination of hypokalemic alkalosis, hypomagnesemia and hypocalciuria.

A summary of the most important clinical features and the ordinary age of disease manifestation is given in Table 36.2.

Table 36.2 Main clinical and biochemical characteristics of different renal salt wasting disorders

	BS1	BS2	BS3	BS4a BS4b	BS5	GS	EAST/SeSAME
Age at onset	Prenatally	Prenatally	0–5 years	Prenatally	Prenatally	>5 years	Infancy
Polyhydramnios	Severe	Severe	Absent-mild	Severe	Very severe	Absent	Absent
Leading symptoms	Polyuria Hypochloremia Alkalosis Hypokalemia	Polyuria Hypochloremia Alkalosis Transient neonatal hyperkalemia	Hypokalemia Hypochloremia Alkalosis Failure to thrive	Polyuria Hypochloremia Alkalosis Hypokalemia	Polyuria Hypochloremia Alkalosis Hypokalemia	Hypokalemia Alkalosis Hypomagnesemia	Hypokalemia Alkalosis Hypomagnesemia
Calcium excretion	High	High	Variable	Variable	High	Low	Low
Nephrocalcinosis	Very frequent	Very frequent	Rare, mild	Rare, mild	Rare, mild	Rare, mild	Rare, mild
Other findings			Mild Hypomagnesemia	Deafness Risk for CKD Risk of ESKD	Large for gestational age Transient disease	Growth retardation Chondrocalcinosis	Ataxia Deafness Seizures Mental retardation

CKD chronic kidney disease, *ESKD* end stage kidney disease

Treatment

As with other hereditary diseases the desirable correction of the primary genetic defects is not yet feasible. In the case of salt-wasting kidney disorders, however, the correction of secondary phenomena like increased renal prostaglandin synthesis or disturbed electrolyte homeostasis have been part of treatment virtually from the first description of the diseases. To the present, the cornerstones in the treatment of renal salt-wasting are non-steroidal anti-inflammatory drugs (NSAID) and long-term salt and electrolyte substitution [1].

In all subtypes of BS inhibition of renal and systemic prostaglandin synthesis leads to reduced urinary prostaglandin E_2 (PGE_2) excretion, dramatically decreases polyuria, converts hyposthenuria to isosthenuria, reduces hypercalciuria, and stimulates catch up growth [11, 12, 30]. Maintenance of euvolemia in the immediate postnatal period by meticulous replacement of renal fluid and salt loss is of central importance before starting NSAID therapy, which might precipitate acute renal failure if extracellular volume is depleted. There is long standing experience with the unselective cyclooxygenase (COX) inhibitor indomethacin which is started at 0.05 mg/kg per day and may be gradually increased to 1.5 mg/kg per day according to its effects on urinary output, renal PGE_2-synthesis and blood aldosterone levels. However, the potential benefit of indomethacin in preterm infants and neonates should be weighed against potential risks of severe gastrointestinal complications, i.e. ulcers, perforation and necrotizing enterocolitis [42, 43]. In particular, indomethacin therapy of newborns with KCNJ1 defects (BS2) may be complicated by oliguric renal failure and severe hyperkalemia. At any age, KCNJ1-deficient patients are particularly sensitive to indomethacin, with doses well below 1mg/kg/day being sufficient to maintain normal plasma potassium levels.

Gastrointestinal side effects (gastritis and peptic ulcers) are also the main drawbacks of longterm indomethacin therapy. These might be reduced by the use of COX-2 specific inhibitors (e.g. celecoxib), which show a comparable effect on renal salt wasting but adversely affect blood pressure [44]. A convincing explanation for these unsurpassed effects of NSAIDs is still missing although a reduction of glomerular filtration and blockage of an aberrant tubulo-glomerular feedback certainly are important contributors. Despite these beneficial effects of NSAIDs, lifelong substitution of potassium chloride usually is required to prevent life-threatening episodes of hypokalemia. Additional potassium supplementation is more often required for NKCC2-deficient (BS1) than KCNJ1-deficient (BS2) patients [1, 30]. In single patients, treatment with a potassium-sparing diuretic (i.e. spironolactone) has been shown to effectively increase serum potassium levels. Also ACE inhibitors have been used in a few patients with success but should be used with caution because ACE inhibitors could impair the compensatory mechanisms for sodium reabsorption in the more distal nephron. Thiazides should not be used to reduce hypercalciuria, since they interfere with compensatory mechanisms in the DCT and further aggravate salt and fluid losses.

Patients with BSND (BS4) are managed primarily with intravenous fluids in neonatal intensive care units. In contrast to other forms of BS, and despite high levels of urinary PGE_2, the effect of indomethacin on growth and correction of electrolyte disorders is rather poor [35, 45]. Hypokalemic metabolic alkalosis persists despite high doses of sodium chloride and potassium chloride supplementation [35]. In a single patient, combined therapy with indomethacin and captopril was needed to discontinue intravenous fluids and improve weight gain [46]. A pre-emptive nephrectomy for refractory electrolyte and fluid losses and persistent failure to thrive, followed by peritoneal dialysis and successful renal transplantation has been reported in a 1-year-old child with BS4 [47].

Patients with cBS (BS3) are typically treated with NSAIDs. Indomethacin is the most frequently used drug, usually started within the first years of life at doses ranging from 1 to 2.5 mg/kg/day. Potassium supplementation (usually KCl, 1–3 mmol/kg/day) is mandatory in BS3, as hypo-

kalemia is often severe at presentation and is not fully corrected by indomethacin. If potassium chloride alone fails to correct hypokalemia, then addition of spironolactone (1–1.5 mg/kg/day) may be considered. ACE-inhibitors should be given with caution because of the risk of hypotension. Magnesium supplementation should be added when hypomagnesemia is present, but the correction is typically difficult [30].

In patients with GS, unrestricted salt intake as well as magnesium and potassium supplementations are the main therapeutic measures. Magnesium supplementation should be considered first, since magnesium repletion will facilitate potassium repletion and reduce the risk of tetany and other complications related to hypomagnesemia [48, 49]. All types of magnesium salts are effective, but their bioavailability is variable. Magnesium chloride, magnesium lactate and magnesium aspartate show higher bioavailability [48]. Magnesium chloride is recommended since it will also correct the urinary loss of chloride. The dose of magnesium must be adjusted individually in 3–4 daily administrations, with diarrhea being the limiting factor. In addition to magnesium, high doses of oral potassium chloride supplements are necessary in the majority of patients with GS [50]. Importantly, magnesium and potassium supplementation results in catchup growth [51, 52]. Spironolactone or amiloride can be useful, both to increase serum potassium levels in patients resistant to potassium chloride supplements and to treat magnesium depletion that is worsened by elevated aldosterone levels [53]. Both drugs should be started cautiously to avoid hypotension. Patients should be encouraged not to deny their usual salt craving, particularly if they practice regular physical activity. Following the pathophysiology with salt loss distal to the *macula densa* and thus not involving disturbances of the tubuloglomerular feeback, prostaglandin inhibitors are less frequently used in GS, since urinary PGE_2 levels are usually normal. However, in a recent controlled, randomized crossover study, Blanchard et al. demonstrated that indomethacin in GS effectively increases potassium levels. In this study, it was even more effective than amiloride or eplerenone [54]. Considering the occurrence of prolonged QT interval in up to 50% GS patients [55, 56], QT-prolonging medications should be used with caution.

Although GS adversely affects the quality of life [57], information about the long-term outcome of these patients are lacking. Renal function and growth appear to be normal, provided lifelong supplementation. Progression to renal failure is extremely rare in GS: only 2 patients with GS who developed end-stage renal disease have been reported [58, 59].

For further details, please see two recent expert consensus statements summarizing the current knowledge on diagnosis and management of BS and GS [60, 61].

Disorders of Calcium and Magnesium Metabolism

37

Karl Peter Schlingmann and Martin Konrad

Calcium Physiology

Approximately one kilogram of the adult human body consists of elemental Ca^{2+}, of which 99% are bound in bone. The extracellular fluid contains only ~1000 mg of Ca^{2+}. Following national boards of nutrition, a daily uptake of 1000–1200 mg of elemental Ca^{2+} with a normal diet is recommended [1]. The intestine reabsorbs approximately 25–33% of the nutritional Ca^{2+} content [2]. In the kidney, ~800 mg of Ca^{2+} are filtered per day in the glomeruli of which 99% are reabsorbed along the renal tubule. Only ~10 mg (~0.1 mg/kg/day) are excreted with the urine. In plasma, ~50% of Ca^{2+} is present in the free ionized form, ~35% is protein-bound, and ~15% is complexed to bicarbonate, citrate or phosphate. The physiological range for blood Ca^{2+} equals 1.1–1.35 mmol/L for free, ionized Ca^{2+} and 2.2–2.6 mmol/L for total Ca^{2+} (in the presence of physiological whole protein levels) [3]. Only the free, ionized fraction is responsible for the biological Ca^{2+} effects.

The blood Ca^{2+} level is kept within a narrow physiological range by the concerted action of endocrine systems controlling intestinal Ca^{2+} uptake, renal Ca^{2+} excretion, and Ca^{2+} transport in bone and soft tissues. These comprise the parathyroid gland, active 1,25-$(OH)_2$-vitamin D_3, and the bone-derived phosphaturic hormone FGF-23 [4]. All three systems are tightly linked and influence each other's activity. Parathyroid hormone (PTH) increases intestinal Ca^{2+} absorption and Ca^{2+} release from bone, it promotes renal Ca^{2+} reabsorption while stimulating renal phosphate excretion. In contrast, active 1,25-$(OH)_2$-vitamin D_3 promotes intestinal Ca^{2+} and phosphate absorption as well as renal Ca^{2+} and phosphate conservation thereby ensuring sufficient Ca^{2+} and phosphate supply for bone mineralization. Finally, FGF-23 together with its co-factor klotho increases renal phosphate excretion by inhibiting proximal tubular phosphate reabsorption, but also negatively regulates active 1,25-$(OH)_2$-vitamin D_3 by inhibiting its activation and promoting its degradation [5]. The common aim of this endocrine interplay is to keep extracellular Ca^{2+} levels constant while supplying sufficient amounts of Ca^{2+} for soft tissues and bone mineralization.

At the glomerulus, the ionized fraction of serum Ca^{2+} is freely filtered. The majority of filtered Ca^{2+} (60–70%) is reabsorbed in the proximal tubule (Fig. 37.1) [6]. Classically, Ca^{2+} transport in the proximal tubule is considered to occur via the paracellular pathway driven by active transcellular Na^+ reabsorption and paracellular water flow [7]. Apical uptake of Na^+ into the

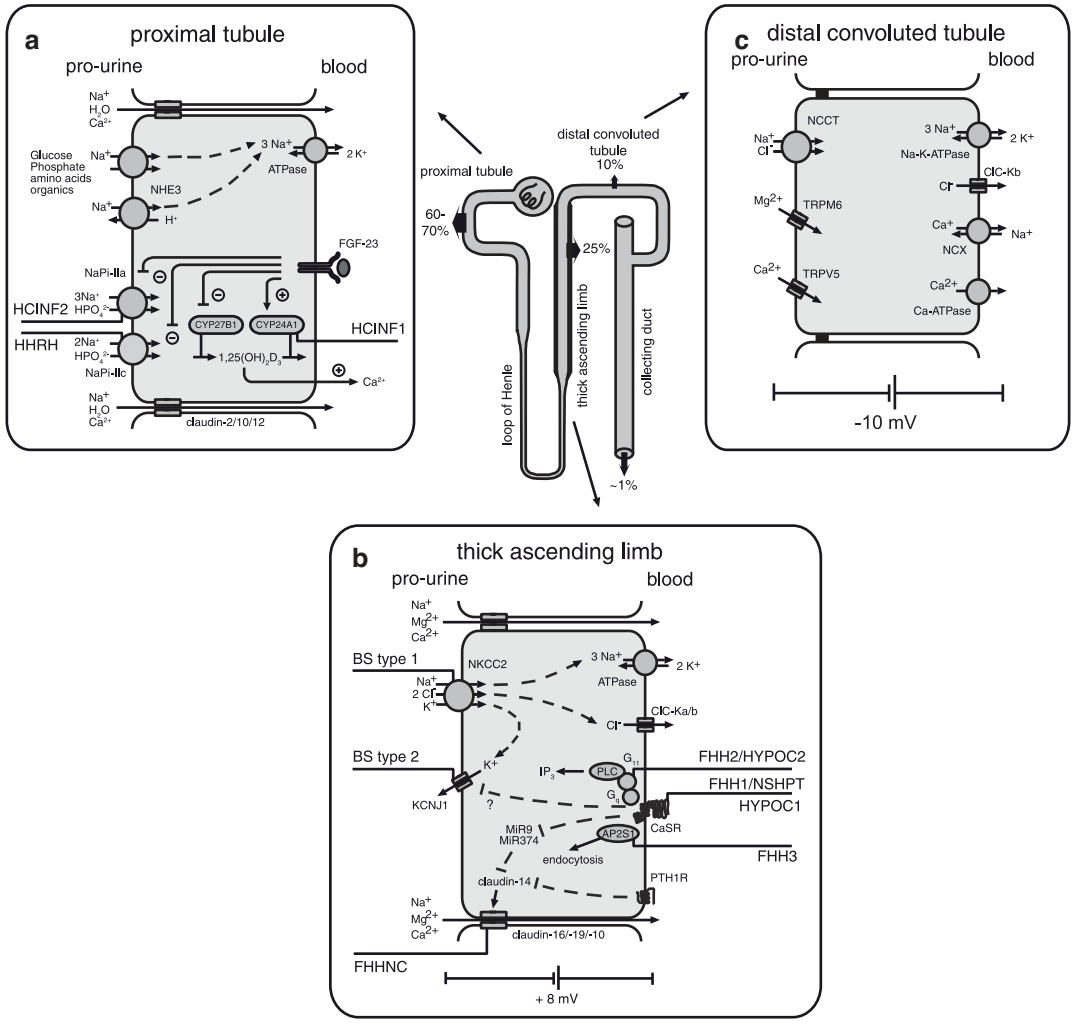

Fig. 37.1 Ca^{2+} reabsorption along the kidney tubule. (**a**) In the proximal tubule (PT), Ca^{2+} is reabsorbed via a paracellular pathway through tight junctions containing claudin-2. Also, the enzymes responsible for vitamin D activation, 1a-hydroxylase (CYP27B1), and vitamin D inactivation, 24-hydroxylase (*CYP24A1*), are expressed in PT cells and functionally linked to PO_4^{3-} reabsorption via NaPi-IIa (*SLC34A1*) and NaPi-IIc (*SLC34A3*). (**b**) In the thick ascending limb (TAL), Ca^{2+} is reabsorbed together with Mg^{2+} through paracellular tight junctions composed by claudin-16 and -19. This process is negatively regulated by basolateral Ca^{2+}-sensing receptor (CaSR) and PTH. Mutations in the CaSR and its associated proteins lead to mirror-like changes in calcium metabolism. (**c**) In the distal convoluted tubule (DCT), Ca^{2+} is actively reabsorbed via the transcellular pathway involving an apical entry through TRPV5 and a basolateral exit via Ca^{2+}-ATPase and Na^+/Ca^{2+}-exchanger (NCX). Hereditary defects affecting tubular Ca^{2+} reabsorption are indicated

proximal tubular cell is achieved via the Na^+/H^+-exchanger NHE3 (*SLC9A3*) followed by basolateral extrusion via Na^+/K^+-ATPase [8]. The paracellular space in the proximal tubule has a high permeability for ions and water that is conferred by tight junctions composed of claudin-2, claudin-10, and claudin-12 [9, 10]. Interestingly, recent data also indicate transcellular Ca^{2+} transport in the proximal tubule involving apically expressed Ca^{2+}-sensing receptor (CaSR) and the Ca^{2+}-permeable ion channel TRPC3 (transient receptor potential family C member 3) [11].

Around 25% of filtered Ca^{2+} is reabsorbed in the thick ascending limb (TAL) of the loop of

Henle. Here, Ca^{2+} transport is passive and paracellular in nature and occurs together with magnesium (Fig. 37.1). It is driven by a lumen-positive transepithelial voltage generated by active transcellular salt reabsorption. Next to changes in transcellular NaCl reabsorption, the permeability and cation selectivity of the paracellular pathway play a critical role in determining Ca^{2+} and Mg^{2+} reabsorption. Paracellular tight junctions in the TAL are composed of a complex set of claudin proteins conferring different properties: Claudin-16 and claudin-19 facilitate paracellular Ca^{2+} and Mg^{2+} transport, but also influence Na^+ permeability while sealing the paracellular space for Cl^- [12]. Furthermore, paracellular movement of Ca^{2+} and Mg^{2+} is modified by claudin-10 which is thought to form a paracellular Na^+ pore [13]. Paracellular Ca^{2+} and Mg^{2+} transport in the TAL is regulated by a complex network involving claudin-14 as well as the CaSR and PTH receptor, both expressed at the basolateral membrane [14–16]. Claudin-14 interacts with claudin-16 and diminishes paracellular cation permeability in vitro. Under physiologic conditions, the expression of claudin-14 is suppressed via a microRNA pathway [17]. By activation of the CaSR, extracellular Ca^{2+} is able to relieve this suppression and to induce claudin-14 expression, thus inhibiting paracellular divalent cation reabsorption [15]. The CaSR is a G-protein-coupled receptor that stimulates phospholipase C through G-proteins G_q and G_{11} resulting in the production of inositol 1,4,5-trisphosphate. This in turn leads to a reduction in PTH secretion from the parathyroid gland as well as increased urinary Ca^{2+} and Mg^{2+} excretion rates [18]. Finally, claudin-14 expression and therefore paracellular cation transport are also directly regulated by PTH via basolaterally expressed PTH-receptor PTH1R [16].

The distal convoluted tubule (DCT) only reabsorbs a small proportion of filtered Ca^{2+} (10–15%), however, as for Mg^{2+}, the DCT determines the final urinary excretion as there is no Ca^{2+} reabsorption beyond this segment. Transcellular Ca^{2+} reabsorption in the DCT is a sequential process of three steps: apical entry into the epithelial cell through Ca^{2+}-permeable ion channels (TRPV5), binding to calbindin-D_{28k} for diffusion through the cytoplasm, and basolateral exit through either a Ca^{2+}-ATPase (PMCA1b, *ATP2B1*), or a Na^+/Ca^{2+}-exchanger (NCX1, *SLC8A1*) [19]. Transcellular Ca^{2+} reabsorption in the DCT is critically influenced by PTH and active 1,25-OH_2-vit D_3 that regulate the expression levels of all the mentioned transport proteins [20]. In addition, Ca^{2+} (as well as Mg^{2+}) handling in the DCT appears to depend on dietary K^+ and the rate of active transcellular salt reabsorption [21, 22].

Disturbances of Calcium Homeostasis

Disturbances in Ca^{2+} metabolism comprise states of Ca^{2+} deficiency as well as Ca^{2+} excess usually detected in the form of hypo- or hypercalcemia. Whereas hypocalcemia represents a more common finding and is usually apparent by typical clinical signs and symptoms, hypercalcemia in infancy and childhood is a rare event and may remain unrecognized as clinical symptoms are rather unspecific. An overview on symptoms, causes, and the diagnostic work-up of pediatric hypocalcemia and hypercalcemia is provided in Chap. 31. Here, we focus on hereditary disorders of Ca^{2+} metabolism. These typically manifest with characteristic changes in serum and urine Ca^{2+} levels. As for acquired disorders of Ca^{2+} homeostasis, the diagnostic work-up, next to the parallel measurement of serum and urine electrolytes and creatinine, comprises the determination of parathyroid hormone (PTH) and vitamin D metabolites.

Hypercalciuria

The assessment of urinary Ca^{2+} excretion rates provides important information on alterations of renal Ca^{2+} conservation. Reference values for urinary Ca^{2+} excretion rates in infants and children are provided in Table 37.1 [23]. An increased urinary Ca^{2+} excretion may either reflect a primary disturbance in renal calcium handling or may reflect changes in renal Ca^{2+} handling in order to

Table 37.1 Reference ranges for urinary calcium excretion in children

	Urinary Ca/Crea mg/mg (mol/mol)	
Age (years)	5th percentile	95th percentile
0–1	0.03 (0.09)	0.81 (2.2)
1–2	0.03 (0.07)	0.56 (1.5)
2–3	0.02 (0.06)	0.50 (1.4)
3–5	0.02 (0.05)	0.41 (1.1)
5–7	0.01 (0.04)	0.30 (0.8)
7–10	0.01 (0.04)	0.25 (0.7)
10–14	0.01 (0.04)	0.24 (0.7)
14–17	0.01 (0.04)	0.24 (0.7)

compensate for disturbances in body Ca^{2+} homeostasis or its hormonal regulation.

Hypercalciuria is the most common risk factor for nephrocalcinosis and stone formation in children [24]. The etiology is assumed to be multifactorial with a complex interaction of environmental and genetic factors. Still, despite an increased knowledge in the underlying genetic causes, the majority of patients are classified as having idiopathic hypercalciuria. A detailed overview on hypercalciuria and its role in the etiology of nephrocalcinosis and kidney stone disease is also provided in Chap. 44 "Renal Calculi".

In the past two decades, genetic studies have identified variants in an increasing number of genes involved in tubular Ca^{2+} reabsorption in patients with hypercalciuria, nephrocalcinosis and kidney stone disease. Classic examples of disturbed renal tubular calcium (and magnesium) reabsorption are hereditary defects in the tight junction proteins claudin-16 and -19 in patients with FHHNC (HOMG3, HOMG5), as well as activating and inactivating mutations in the CaSR producing mirror images of disturbed calcium homeostasis (ADH1, FHH1, NSHPT) (see below).

Disorders affecting proximal tubular Ca^{2+} reabsorption comprise Dent's disease (DENT1, DENT2) and Lowe syndrome (see Chaps. 32 and 44). Both disorders affect endosomal function in proximal tubular epithelial cells resulting in a complex dysfunction characterized by tubular proteinuria, hypercalciuria, renal Fanconi syndrome, and progressive renal failure [25, 26].

Next to different metabolic disorders affecting proximal tubular function leading to renal Fanconi syndrome (see Table 37.2), Fanconi-Bickel syndrome due to mutations in *SLC2A2* [27] is another generalized defect of proximal tubular function with hypercalciuria. Moreover, an isolated renal phenotype without hepatic symptoms and disturbance in glucose metabolism has been described in families with bi-allelic *SLC2A2* mutations [28].

Detailed descriptions of differential diagnoses for hereditary renal Fanconi syndrome and proximal tubulopathies are also provided in Chap. 32.

Hereditary defects of proximal tubular phosphate reabsorption and vitamin D degradation are discussed below (section "Hypercalcemia").

A recent study directly implicated defective paracellular Ca^{2+} reabsorption in the proximal tubule in the pathogenesis of hypercalciuria and renal calcifications since deletion of claudin-2 in mice resulted in hypercalciuria and renal calcifications [29]. The same study also identified a potentially pathogenic heterozygous variant in *CLDN2* in a family with multiple members affected by kidney stones and associated common genetic variants near the *CLDN2* locus with kidney stone risk [29]. No primary defects in transcellular Ca^{2+} reabsorption in the DCT have been linked to monogenic human disease to date. Deletion of the epithelial Ca^{2+} channel TRPV5 in mice resulted in severe hypercalciuria, compensatory intestinal hyperabsorption of Ca^{2+}, and reduced bone thickness [30]. A TRPV5 missense mutation was identified in a mouse model with dominant hypercalciuria [31]. In contrast, homozygous knock-out of basolateral NCX1 (SLC8A1) and PMCA1b (ATP2B1) in mice is embryonically lethal [32, 33].

Finally, hypercalciuria is observed in other renal tubular disorders including Bartter syndrome (see Chap. 33) and renal tubular acidosis (see Chap. 36).

Table 37.2 Monogenic disorders associated with hypercalciuria

Proximal tubule	**OMIM #**	**Inheritance**	**Gene**	**Protein**
Dent's disease type 1	300009	XLR	*CLCN5*	ClC-5 chloride channel
Dent disease type 2/Lowe syndrome	309000	XLR	*OCRL*	Inositol-polyphosphate-5-phosphatase
Nephropathic cystinosis	219800	AR	*CTNS*	Cystinosin cystine transporter
Tyrosinemia 1	276700	AR	*FAH*	Fumarylacetoacetate hydrolase
Fanconi renotubular syndrome 3	615605	AD	*EHHADH*	Enoyl-CoA-hydratase
Fanconi renotubular syndrome with MODY	600281	AD	*HNF4A*	Hepatocyte nuclear factor 4α
Fanconi-Bickel syndrome	227810	AR	*SLC2A2*	GLUT2 glucose transporter
Infantile hypercalcemia 1 (HCINF1), nephrocalcinosis, calcium nephrolithiasis	143880	AR, AD	*CYP24A1*	25-OH-vitamin D_3-24-hydroxylase
Infantile hypercalcemia 2 (HCINF2), nephrocalcinosis, calcium nephrolithiasis	616963	AR, AD	*SLC34A1*	Na-Po_4 co-transporter NaPi-IIa
Hypophosphatemic rickets with hypercalciuria (HHRH), nephrocalcinosis, calcium nephrolithiasis	241530	AR, AD	*SLC34A3*	Na-Po_4 co-transporter NaPi-IIc
Thick ascending limb	**OMIM #**	**Inheritance**	**Gene**	**Protein**
Bartter syndrome type 1	601678	AR	*SLC12A1*	NKCC2 co-transporter
Bartter syndrome type 2	241200	AR	*KCNJ1*	ROMK potassium channel
Bartter syndrome type 3	607364	AR	*CLCNKB*	ClC-Kb chloride channel
Bartter syndrome type 4a	602522	AR	*BSND*	Barttin subunit
Bartter syndrome type 4b	613090	DR	*CLCNKA/B*	ClC-Ka/ClC-Kb chloride channels
Bartter syndrome type 5	300971	XLR	*MAGED2*	MAGE-D2
Familial hypomagnesemia with hypercalciuria/nephrocalcinosis (FHHNC)(HOMG3)	248250	AR	*CLDN16*	Claudin-16 (paracellin-1), tight junction protein
Familial hypomagnesemia with hypercalciuria/nephrocalcinosis (FHHNC) and severe ocular involvement (HOMG5)	248190	AR	*CLDN19*	Claudin-19, tight junction protein
Autosomal dominant hypoparathyroidism 1 (ADH1)	601198	AD	*CASR*	CaSR, Ca^{2+}/Mg^{2+} sensing receptor
Autosomal dominant hypoparathyroidism 2 (ADH2)	615361	AD	*GNA11*	G-protein α-11
Collecting duct (CD)	**OMIM #**	**Inheritance**	**Gene**	**Protein**
dRTA 1 dRTA 4	179800 611590	AD AR	*SLC4A1*	AE1 anion echanger
dRTA 2 with progressive sensorineural deafness	267300	AR	*ATP6V1B1*	H^+-ATPase subunit B1
dRTA with/without sensorineural deafness	602722	AR	*ATP6V0A4*	H^+-ATPase subunit A4
dRTA with early onset sensorineural deafness	600791	AR	*FOXI1*	Forkhead box I1 transcription factor

Hypocalcemia

A detailed description of clinical symptoms and signs of hypocalcemia is provided in Chap. 31 (see Table 30.18). Following the approach outlined there (Table 30.19), the etiology of Ca^{2+} deficiency and hypocalcemia can be categorized according to the serum level of PTH [34]. Low levels of PTH indicate primary dysfunction of the parathyroid gland with impaired or absent PTH

production or release. Hereditary disorders involving abnormal parathyroid gland function include **primary hypoparathyroidism** due to mutations in the *PTH* gene (**isolated familial hypoparathyroidism 1**, OMIM #146200), due to **Di George syndrome** caused by microdeletions on chromosome 22q11 (OMIM #188400), or due to **HDR syndrome** (hypoparathyroidism, sensorineural deafness, renal dysplasia, OMIM #146255) caused by mutations in the transcription factor GATA3.

However, inappropriately low or normal levels of PTH may also point to an activating mutation in the *CASR* gene encoding the Ca^{2+} sensing receptor (CaSR) or in the *GNA11* gene encoding the accessory G-protein G-alpha-11 causing **autosomal-dominant hypocalcemia type 1 and 2**, respectively (ADH1, ADH2). These entities will be discussed in more detail below. ADH1 might be differentiated from the above mentioned disorders by determination of urinary Ca^{2+} excretion: In contrast to low urinary Ca^{2+} excretion found in primary forms of parathyroid dysfunction, urinary Ca^{2+} excretion is inappropriately high in face of hypocalcemia in patients with ADH1.

Elevated levels of PTH in the presence of normal renal function are also found in **acquired Ca^{2+}- and vitamin D-deficient rickets**. Whereas hypocalcemia might also be an associated finding in **renal Fanconi syndrome**, it is rather uncommon in other disorders of the proximal tubule such as hypophosphatemic rickets, Dent's disease or Lowe syndrome. These disorders are discussed in detail in Chaps. 32 and 44.

Pseudohypoparathyroidism represents a heterogeneous group of rare hereditary disorders with the common feature of PTH end-organ resistance and hypocalcemia despite elevated serum PTH levels (PHP1A OMIM #103580; PHP1B, OMIM #612462; PHP1C, OMIM #203330). Different (epi)genetic defects have been discovered as underlying causes, including loss of function mutations in the *GNAS* gene encoding the Gs-alpha isoform or methylation defects of the *GNAS* gene locus [35].

Autosomal Dominant Hypocalcemia

The extracellular **Ca^{2+}-sensing receptor (CaSR)** plays an essential role in Ca^{2+} and Mg^{2+} homeostasis by modulating PTH secretion and by directly regulating the rate of Ca^{2+} and Mg^{2+} reabsorption in the kidney [36]. The CaSR, a dimeric cell-surface protein of the G-protein receptor family, has a large extracellular domain that can bind extracellular Ca^{2+} at multiple sites [37]. Activation of the CaSR induces G_q and $G_{alpha\text{-}11}$ dependent phospholipase C signaling [18, 38], resulting in an inhibition of PTH release from the parathyroid gland and of renal tubular Ca^{2+} absorption. The function of the CaSR is inhibited by non-competitive binding of PO_4^{3-} to anion binding sites at the extracellular domain, leading to increased PTH secretion from the parathyroid gland [39]. Ca^{2+} sensing is also influenced by the level of CaSR surface expression. The CaSR is internalized from the plasma membrane by clathrin-mediated endocytosis. A central component of these clathrin-coated vesicles (CCVs) is the adaptor protein 2 (AP2) that forms a heterotetrameric complexes of α, β, μ, and σ (*AP2S1*) subunits [40]. Several diseases associated with both activating and inactivating mutations in the *CASR* gene, *GNA11*, and *AP2S1* have been described.

In the kidney, the CaSR is expression and basolateral localized in TAL, DCT, and intercalated cells of the cortical collecting duct (CCD) [41]. In addition, the CaSR is expressed in the apical membrane of the collecting duct as a putative sensor of urine Ca^{2+} levels [42]. Here, by adjusting aquaporin-2 expression, the CaSR is thought to adjust water diuresis to Ca^{2+} load, minimizing the risk of stone formation in the face of an increased urine Ca^{2+} excretion [43].

Autosomal dominant hypocalcemia 1 (ADH1) is caused by activating mutations in the *CASR* gene. Affected individuals typically manifest during childhood with seizures or carpopedal spasms. Laboratory evaluation reveals the typical combination of hypocalcemia and low PTH levels. Serum Ca^{2+} levels are usually in a range of 6–7 mg/

dL. In addition, many patients also exhibit moderate hypomagnesemia [44, 45]. Patients are often given the incorrect diagnosis of primary hypoparathyroidism on the basis of inappropriately low PTH levels. As indicated above, the differential diagnosis can be established by determination of urinary Ca^{2+} excretion which is low in primary hypoparathyroidism but usually increased in ADH1 patients. The differentiation of ADH from primary hypoparathyroidism is of particular importance because treatment with active vitamin D in ADH may result in a dramatic increase in hypercalciuria with subsequent nephrocalcinosis and impairment of renal function. Therefore, therapy with active vitamin D or Ca^{2+} supplementation should be reserved for symptomatic patients with the aim to maintain serum Ca^{2+} levels just sufficient for the relief of symptoms [45].

Activating *CASR* mutations lead to a lower setpoint of the receptor or an increased affinity for extracellular Ca^{2+} and Mg^{2+}. This inadequate activation by physiological extracellular Ca^{2+} and Mg^{2+} levels results in a diminished PTH secretion in the parathyroid gland as well as a decreased reabsorption of both divalent cations in the TAL. A severe degree of hypocalcemia and hypomagnesemia is observed in patients with complete activation of the CaSR at physiologic serum Ca^{2+} and Mg^{2+} concentrations who may also exhibit a Bartter-like phenotype [46]. In these patients, CaSR activation inhibits TAL-mediated salt and divalent cation reabsorption to an extent that cannot be compensated in more distal nephron segments [46].

Genetic heterogeneity in autosomal-dominant hypocalcemia (**ADH2**) was demonstrated by the discovery of heterozygous missense mutations in *GNA11* encoding the accessory G-protein $G_{alpha\text{-}11}$ of the CaSR [47, 48].

Hypercalcemia

Clinical Findings

In contrast to hypocalcemia, hypercalcemia represents a rather uncommon finding in infancy and childhood but requires prompt diagnostic work-up and targeted therapy [49, 50]. Hypercalcemia is defined as ionized Ca^{2+} above 1.35 mmol/L, usually with concomitant elevation of total serum Ca^{2+} levels above 2.7 mmol/L. While most children with a mild degree of hypercalcemia remain asymptomatic, more severe hypercalcemia can lead to a serious clinical disease pattern that may even be life-threatening, especially in infants. Symptoms of hypercalcemia include failure to thrive, weight loss, dehydration, fever, muscular hypotonia, constipation, irritability, lethargy, and disturbed consciousness. Cardiovascular findings may comprise bradycardia, shortened QT interval, and arterial hypertension (Table 37.3).

An impairment of renal function by volume contraction can further limit renal Ca^{2+} elimination and therefore aggravate hypercalcemia. On the other hand, the increase of renal Ca^{2+} excretion in hypercalcemic conditions is a risk factor for the development of nephrocalcinosis and kidney stone formation.

Table 37.3 Symptoms of acute hypercalcemia

Neurology
Muscle weakness
Irritability/confusion
Somnolence, stupor, coma
Abnormal behaviour
Headache
Gastrointestinal tract
Loss of appetite
Nausea/vomiting
Constipation
Abdominal cramping
Pancreatitis
Kidneys and urinary tract
Polyuria/polydipsia
Dehydratation
Nephrocalcinosis
Nephro-/urolithiasis
Musculoskeletal system
Bone pain
Ectopic calcifications
Heart/cardiovascular system
Shortened QT interval
Cardiac arrhythmia
Arterial hypertension

Diagnostic Workup

The assessment of past medical history should comprise medications including over-the-counter vitamin preparations and family history with a focus on disturbances in Ca^{2+} metabolism, renal disease and urolithiasis.

The etiology of hypercalcemia in children and especially infants significantly differs from that in adulthood where primary hyperparathyroidism and malignancy represent the most common underlying causes [51]. Especially in infants, rare hereditary disorders should be considered in the differential diagnosis [49].

The diagnostic work-up requires comprehensive laboratory testing including molecular genetics. Next to the parallel measurement of serum and urine electrolytes, the determination of PTH and vitamin D metabolites represents the most important element. Potential diagnostic parameters are summarized in Table 37.4.

Inappropriately normal or elevated levels of PTH point to a primary defect in the parathyroid gland (Fig. 37.2). Next to primary hyperparathyroidism, which is extremely rare in infancy and childhood, hypercalcemia with elevated PTH might be caused by a hereditary disorder of the CaSR or associated proteins. In contrast to dominant activating CaSR mutations as present in ADH1 (see above), inactivating CaSR mutations may be present in either heterozygous or homozygous/compound-heterozygous state leading to Familial Hypocalciuric Hypercalcemia 1 (FHH1) and Neonatal Severe Hyperparathyroidism (NSHPT), respectively (see below). Genetic heterogeneity in FHH was demonstrated in 2013 by discovery of heterozygous mutations in *GNA11* (FHH2) and *AP2S1* (FHH3) [40, 47].

Table 37.4 Evaluation of hypercalcemia in children

Laboratory tests	
Blood	Ionized and total calcium
	Sodium, potassium, chloride, magnesium, phosphate
	Renal function tests
	Alkaline phosphatase
	Blood gases
	Intact parathyroid hormone (iPTH)
	Vitamin D metabolites (25-OH-D_3, 1,25-$(OH)_2$-D_3)
	Optional: PTH-related peptide (PTHrP)
	Vitamin A
	Angiotensin converting enzyme (ACE)
	FISH (Williams-Beuren-Syndrom)
Urine	Calcium
	Sodium, potassium, chloride, magnesium, phosphate
	Creatinine
	->Ca^{2+}/Crea ratio and tubular phosphate reabsorption (TRP)
Imaging studies	
	Ultrasound examination of kidneys and urinary tract
	Optional:
	X-ray studies (long bones, thorax)
	Ultrasound of parathyroid glands

In face of an appropriate suppression of PTH, vitamin D metabolites should be evaluated. The determination of 25-OH-vitamin D_3 primarily helps to exclude overt vitamin D intoxication. While cut-off values vary in the literature, levels above 200 ng/mL are usually considered toxic [52]. Next, serum levels of active 1,25-$(OH)_2$-vitamin D_3 are of critical importance for further diagnostic considerations (Fig. 37.2). Elevated levels are not only observed in vitamin D poisoning, but also in disorders with extra-renal expression of 1α-hydroxylase including granulomatous disease or subcutaneous fat necrosis. In these disorders, 1α-hydroxylase (CYP27B1) is expressed by monocytes and, in contrast to renal tissue, not regulated by serum Ca^{2+}, PO_4^{3-}, PTH, and 1,25-$(OH)_2$-vitamin D_3. Finally, in hypercalcemic individuals with high levels of active 1,25-$(OH)_2$-vitamin D_3, hereditary disorders of vitamin D metabolism or renal phosphate handling should be considered (see below).

Treatment

Acute therapeutic measures in hypercalcemic patients primarily aim at the lowering of serum Ca^{2+} levels into the reference range resulting in a rapid relief of clinical symptoms. For this purpose, different pharmacologic approaches have been considered (Table 37.5).

Even before clarification of the underlying etiology, vitamin D supplements need to be

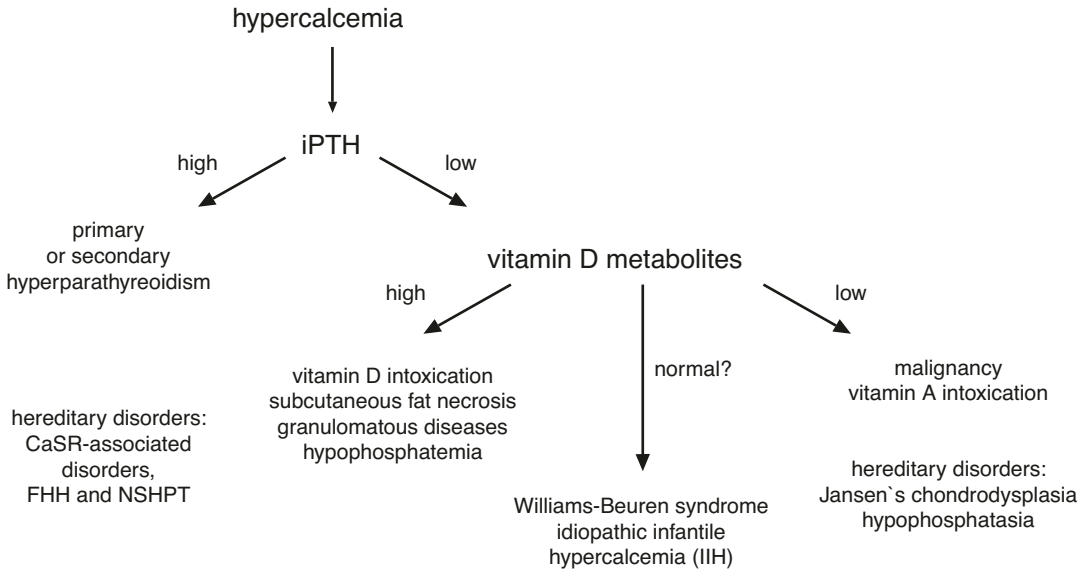

Fig. 37.2 Diagnostic approach in hypercalcemia in childhood. Central diagnostic steps are the determination of parathyroid hormone (PTH) and vitamin D-metabolites. Following this diagnostic approach, three major entities can be discerned: PTH-dependent hypercalcemia as present in primary hyperparathyroidism and in disorders due to inactivating mutation of the CaSR, vitamin D-induced hypercalcemia including idiopathic infantile hypercalcemia, and hypercalcemia due to third causes including also hypophosphatasia

Table 37.5 Therapy of hypercalcemia in children

General measures
Stop of vitamin D supplementation
Ca^{2+} restriction in enteral and parenteral nutrition
Specific measures
Promotion of renal Ca^{2+} excretion
– Furosemide 0.5–1 mg per kg body weight q6h
Inhibition of enteral Ca^{2+} absorption/inhibition of vitamin D-conversion
– Glucocorticoids, i.e. methylprednisolone ~1 mg/kg q.6h
– Na^{+}-cellulose phosphate
Inhibition of Ca^{2+} release from bone
– Bisphosphonates, i.e. pamidronate 0.5–1 mg/kg over 4–6 h
– Calcitonin 4–8 IU/kg body weight
Inhibition of vitamin D-activation by 1α-hydroxylase
– Imidazole derivates, i.e. ketoconazole 3–9 mg per kg body weight per day
Hemodialysis/hemofiltration

stopped and, if appropriate, a low-Ca^{2+} diet should be implemented. Vigorous rehydration, usually performed via the intravenous route, is a key therapeutic strategy in hypercalcemia independent of etiology. Quantities up to twice the daily fluid requirements have been described. Pharmacological treatment includes measures to decrease Ca^{2+} absorption from the intestine, to promote renal Ca^{2+} excretion, and to inhibit Ca^{2+} release from bone. To increase renal Ca^{2+} elimination loop diuretics that inhibit paracellular Ca^{2+} reabsorption in the TAL (such as furosemide) are widely used. A fast and effective approach to inhibit enteral Ca^{2+} absorption is the administration of glucocorticoids, i.e. prednisolone. Next to this intestinal effect, glucocorticoids also inhibit the conversion of 25-OH-vitamin D_3 into active 1,25-$(OH)_2$-vitamin D_3, an effect that is of special importance in vitamin D-mediated hypercalcemia. Sodium cellulose phosphate (SCP) is a non-absorbable cation exchange resin used for the removal of excess Ca^{2+} from the body [53]. It was initially used in patients with so-called absorptive hypercalciuria in order to decrease renal Ca^{2+} excretion and prevent stone formation [54]. In the acute phase of hypercalcemia calcitonin may be used because of its prompt and pronounced effect on serum Ca^{2+} levels, however, its therapeutic usefulness is limited by its short duration of action due to the develop-

ment of end organ resistance. In the presence of intermediate to severe symptomatic hypercalcemia, bisphosphonates such as pamidronate may be used [55]. If bisphosphonate therapy is considered, it is important to have the diagnostic work-up completed in advance to avoid misinterpretation of diagnostic tests for PTH and vitamin D metabolites. A class of drugs that are specifically used in vitamin D-mediated hypercalcemia are imidazole derivates, such as ketoconazole [56]. Next to their antifungal effect these compounds also inhibit mammalian cytochrome P450 enzymes. Via inhibition of 1α-hydroxylase (CYP27B1) they are able to effectively lower serum levels of active 1,25-$(OH)_2$-vitamin D_3 and consecutively normalize serum Ca^{2+} levels. In individual patients with extremely high serum Ca^{2+} levels hemofiltration and hemodialysis have been applied sucessfully [57].

Hypercalcemia with Inappropriately High PTH

Familial Hypocalciuric Hypercalcemia/ Neonatal Severe Hyperparathyroidism

Familial hypocalciuric hypercalcemia 1 (FHH1) and **neonatal severe hyperparathyroidism** (NSHPT) result from inactivating mutations of the CaSR present in either mono-allelic or bi-allelic state, respectively [58]. Genetic heterogeneity has been described in FHH with heterozygous variants in *GNA11* (**FHH2**) encoding accessory G-protein $G_{\alpha 11}$ of the CaSR and in *AP2S1* (**FHH3**) encoding adaptor protein σ1 involved in CaSR recycling from the plasma membrane [40, 47]. Therefore, all three subtypes of FHH share the pathophysiology of a decreased CaSR-mediated Ca^{2+} sensing. FHH patients typically present with mild to moderate hypercalcemia, accompanied by few if any symptoms, and often do not require treatment. However, the occurrence of pancreatitis and chondrocalcinosis has been described [59]. Urinary Ca^{2+} and Mg^{2+} excretion rates are markedly reduced and serum PTH levels are inappropriately high. In addition, affected individuals also show mild hypermagnesemia [60].

In contrast to FHH, patients with **NSHPT** with two mutant CaSR alleles usually present in early infancy with polyuria and dehydration due to severe symptomatic hypercalcemia (Table 37.9). Unrecognized and untreated, hyperparathyroidism and hypercalcemia result in skeletal deformities, extraosseous calcifications, and also severe neurodevelopmental deficit. Early treatment with partial to total parathyroidectomy therefore seems to be essential for outcome [61]. Serum PO_4^{3-} levels are typically low due to increased iPTH levels. Data on serum Mg^{2+} in NSHPT is sparse and contradictory [62]. However, elevations to levels around 50% above the reference range have been reported.

Hypercalcemia with Suppressed PTH and Inappropriately High 1,25-$(OH)_2$-Vitamin D_3

Idiopathic Infantile Hypercalcemia

Idiopathic Infantile Hypercalcemia (IIH) was first decribed in the 1950s after an endemic occurrence in the United Kingdom (UK) [63, 64]. Affected infants present with typical symptoms of severe hypercalcemia. Concomitant hypercalciuria typically leads to the development of early nephrocalcinosis (Table 37.9). The laboratory analysis reveals serum Ca^{2+} levels up to 5 mmol/L. Intact PTH is suppressed while levels of active 1,25-$(OH)_2$-vitamin D_3 are usually elevated or in the upper normal range. A role of exogenously administered vitamin D was suspected early on [65–67]. Some children exhibited a complex phenotype that became later known as the Williams Beuren syndrome [68, 69]. However, most hypercalcemic infants did not have syndromic features and were considered to be affected by a milder variant of the syndrome that was termed idiopathic infantile hypercalcemia (IIH) [63, 64].

The pathophysiology of IIH remained elusive until the discovery of loss-of-function mutations in the vitamin D catabolizing enzyme

25-OH-vitamin D_3-24-hydroxylase (CYP24A1) [70]. CYP24A1 is responsible for several sequential degradation steps that convert active 1,25-$(OH)_2$-vitamin D_3 into water soluble calcitroic acid [71, 72]. Loss-of-function mutations of *CYP24A1* lead to an accumulation and increased action of active 1,25-$(OH)_2$-vitamin D_3. Functional studies in vitro demonstrated a complete loss of enzyme function for most of the identified *CYP24A1* mutations [70]. In addition to the genetic analysis of the *CYP24A1* gene, the determination of 24-hydroxylated vitamin D metabolites by liquid chromatography/mass spectrometry (LC/MS) represents a quick and reliable test in the diagnosis of the disease [73].

The critical role of the cumulative dose of exogenous vitamin D is underscored by the following observations: Under the most commonly used dose of 500 IU vitamin D_3 per day, symptoms usually develop after several months. Higher doses of supplemental vitamin D most likely lead to an increased incidence of the disease in infancy and an earlier manifestation. Regimens using oral bolus doses of up to 600.000 IU provoke symptoms of acute vitamin D toxicity in infants with CYP24A1 deficiency while being tolerated well by healthy individuals [74]. Finally, omitting vitamin D supplementation in a genetically affected infant due to symptomatic disease in the older sibling prevented hypercalcemic episodes and the development of nephrocalcinosis [70].

After diagnosis of symptomatic hypercalcemia with inappropriately high levels of 1,25-$(OH)_2$-vitamin D_3, vitamin D prophylaxis is usually stopped and a low-Ca^{2+} diet might be instituted. The restriction of dietary Ca^{2+} has to be carefully monitored as it might lead to a defective mineralization of bone as well as an increased intestinal absorption of oxalate with subsequent risk of stone formation. Next to these immediate therapeutic measures, vigorous intravenous rehydration and a repertoire of strategies to reduce serum Ca^{2+} levels as described above are used (Table 37.5).

Currently, it remains an unanswered question, why many of the affected individuals after acute treatment in infancy do not show recurrence of symptomatic hypercalcemia during later life. Potentially, compensatory mechanisms, i.e. a down-regulation of 1α-hydroxylase (CYP27B1) are able to prevent an excessive activation of vitamin D. Laboratory parameters, i.e. suppressed PTH and inappropriately high values of 1,25-$(OH)_2$-vitamin D_3, are detectable for a long time during follow-up. However, nephrocalcinosis persists and together with recurrent nephrolithiasis might result in an impairment of renal function. Interestingly, since the initial description of *CYP24A1* mutations, several groups identified *CYP24A1* mutations also in adult patients with mild hypercalcemia, nephrocalcinosis, and recurrent kidney stone disease [75–77].

Genetic heterogeneity in IH was demonstrated by discovery of recessive mutations in *SLC34A1* encoding proximal-tubular sodium-phosphate co-transporter NaPi-IIa [78]. Patients with NaPi-IIa defects share phenotypic and biochemical features of patients with *CYP24A1* mutations but hypercalcemia is usually milder. In addition, they exhibit phosphate depletion and hypophosphatemia. The pathophysiology involves primary renal phosphate wasting, phosphate depletion, and suppression of the phosphaturic hormone FGF-23. FGF-23, next to its role in proximal-tubular phosphate reabsorption, negatively regulates vitamin D metabolism by inhibiting 1α-hydroxylase (*CYP27B1*) and promoting the degradation of active 1,25-$(OH)_2$-vitamin D_3 by 24-hydroxylase (*CYP24A1*) [78].

In addition to acute therapeutic measures also applied in patients with *CYP24A1* defects, hypercalcemic patients potentially benefit from PO_4^{3-} supplementation in order to control Ca^{2+} metabolism.

A significant subset of patients with NaPi-IIa defects may also be diagnosed with isolated early nephrocalcinosis or present later in childhood or adolescence with nephrolithiasis [79]. Of note, prenatally diagnosed renal calcifications due to *SLC34A1* mutations have even been described as a differential diagnosis for fetal hyperechogenic kidneys [80].

Very similar biochemical changes as in NaPi-IIa deficiency have also been reported in patients with *SLC34A3* defects encoding the

closely related proximal-tubular sodium-phosphate co-transporter NaPi-IIc [81]. Mutations in *SLC34A3* have initially been described in patients with **hypophosphatemic rickets with hypercalciuria** (HHRH) [82, 83]. Whereas a clinical manifestation with hypercalcemia in infancy has not been reported yet in a patient with *SLC34A3* defect, patients with bi-allelicas well as mono-allelic *SLC34A3* mutations appear to commonly present with nephrocalcinosis and/or kidney stones [81]. As individuals with CYP24A1 defects, patients with NaPi-IIa and NaPI-IIc defects are at risk to develop chronic renal failure [84].

Magnesium Physiology

Mg^{2+} is the second most abundant intracellular cation in the body. As a cofactor for many enzymes, it is involved in energy metabolism and protein and nucleic acid synthesis. It also plays a critical role in the modulation of membrane transporters and in signal transduction. Under physiologic conditions, serum Mg^{2+} levels are maintained at almost constant values. Homeostasis depends on the balance between intestinal absorption and renal excretion. Mg^{2+} deficiency can result from reduced dietary intake, intestinal malabsorption or renal loss. The control of body Mg^{2+} homeostasis is primarily accomplished in the kidney tubules.

The daily dietary intake of Mg^{2+} varies substantially. Within physiologic ranges, diminished Mg^{2+} intake is balanced by enhanced Mg^{2+} absorption in the intestine and reduced renal excretion. These transport processes are regulated by metabolic and hormonal influences [85, 86]. The principal site of Mg^{2+} absorption is the small intestine, with smaller amounts being absorbed in the colon. Intestinal Mg^{2+} absorption occurs via two different pathways: a saturable active transcellular transport and a nonsaturable paracellular passive transport (Fig. 37.3a) [86, 87]. Saturation kinetics of the transcellular transport system are explained by the limited transport capacity of active transport. At low intraluminal concentrations Mg^{2+} is absorbed primarily via the active transcellular route and with rising concentrations via the paracellular pathway, yielding a curvilinear function for total absorption (Fig. 37.3b).

In the kidney, approximately 80% of total serum Mg^{2+} is filtered in the glomeruli, of which more than 95% is reabsorbed along the nephron. Mg^{2+} reabsorption differs in quantity and kinetics depending on the different nephron segments. 15–20% are reabsorbed in the proximal tubule of the adult kidney. Interestingly, the premature kidney of the newborn is able to reabsorb up to 70% of the filtered Mg^{2+} in this nephron segment [88].

From early childhood onward, the majority of Mg^{2+} (around 70%) is reabsorbed in the loop of Henle, especially in the cortical TAL. Transport in this segment is passive and paracellular, driven by the lumen-positive transepithelial voltage (Fig. 37.4a). Although only 5–10% of the filtered Mg^{2+} is reabsorbed in the distal convoluted tubule (DCT), this is the part of the nephron where the fine adjustment of renal excretion is accomplished. The reabsorption rate in the DCT defines the final urinary Mg^{2+} excretion as there is no significant uptake of Mg^{2+} in the collecting duct. Mg^{2+} transport in this part of the nephron is an active transcellular process (Fig. 37.4b). The apical entry into DCT cells is mediated by a specific and regulated Mg^{2+} channel driven by a favorable transmembrane voltage [89]. The mechanism of basolateral transport into the interstitium is unknown. Here, Mg^{2+} has to be extruded against an unfavourable electrochemical gradient. Most physiologic studies favor a Na^{+}-dependent exchange mechanism [90]. Mg^{2+} entry into DCT cells appears to be the rate-limiting step and the site of regulation. Finally, 3–5% of the filtered Mg^{2+} is excreted in the urine.

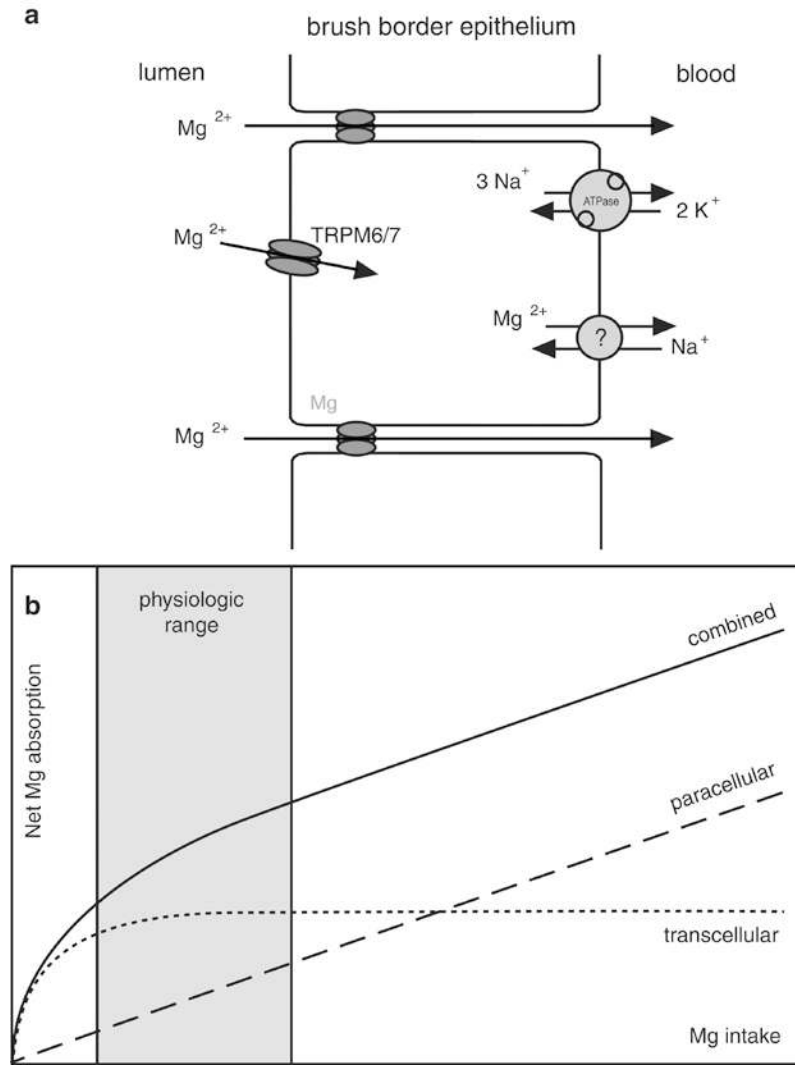

Fig. 37.3 Intestinal Mg^{2+} reabsorption. (**a**) Model of intestinal Mg^{2+} absorption via two independent pathways: passive absorption via the paracellular pathway and active, transcellular transport consisting of an apical entry through a putative Mg^{2+} channel and a basolateral exit mediated by a putative Na^+–coupled exchange. (**b**) Kinetics of intestinal Mg^{2+} absorption in humans. Paracellular transport linearly rising with intraluminal concentrations (dotted line) and saturable active transcellular transport (dashed line) together yield a curvilinear function for net Mg^{2+} absorption (solid line)

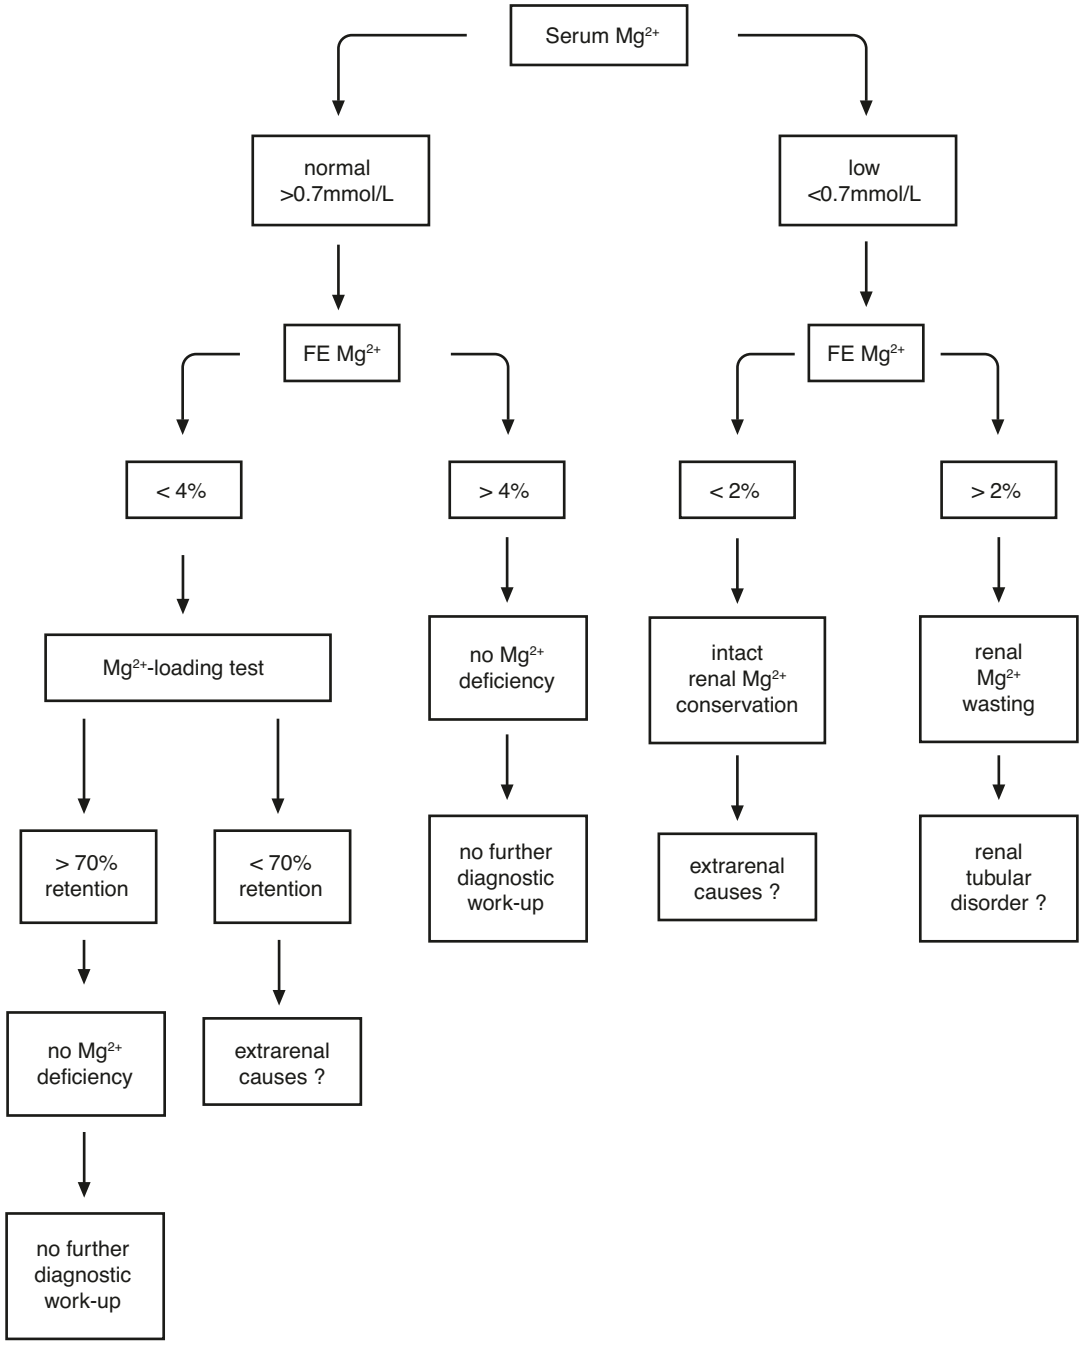

Fig. 37.4 Diagnostic workup in patients with suspected magnesium deficiency. In face of hypomagnesemia, the determination of urinary Mg^{2+} excretion allows for a distinction between renal Mg^{2+} wasting and extrarenal losses. In normomagnesemic individualswith low urinary magnesium excretions, an increased retention of Mg^{2+} in the Mg^{2+}-loading test might indicate Mg^{2+} deficiency. This test, however, requires an intact renal Mg^{2+} conservation process

Magnesium Depletion

Mg^{2+} depletion usually occurs secondarily to another disease process or to a therapeutic agent. Some disorders that can be associated with Mg^{2+} depletion are summarized in Table 37.6 [91]. Mg^{2+} may be lost via the gastrointestinal tract, either by excessive loss of secreted fluids or impaired absorption of both dietary and endogenous Mg^{2+}. Mg^{2+} depletion is common in patients with acute or chronic diarrhea. Malabsorption syndromes such as celiac disease may also result in Mg^{2+} deficiency. Also, acute severe pancreatitis may be associated with hypomagnesemia.

Excessive excretion of Mg^{2+} into the urine is another cause of Mg^{2+} depletion. Renal Mg^{2+} excretion is proportional to tubular fluid flow as well as to Na^+ and Ca^{2+} excretion. Therefore, both chronic intravenous fluid therapy with Na^+-containing fluids and disorders in which there is extracellular volume expansion may result in Mg^{2+} depletion. Hypercalcemia and hypercalciuria have been shown to decrease renal Mg^{2+} reabsorption and are probably the cause of excessive renal Mg^{2+} excretion and hypomagnesemia observed in many hypercalcemic states. A large variety of pharmacological agents also cause renal Mg^{2+} wasting and Mg^{2+} depletion (see below). Various renal diseases, e.g. chronic pyelonephritis or post-obstructive nephropathy may also be accompanied by Mg^{2+} losses.

During infancy and childhood, a substantial proportion of patients receiving medical attention for signs of hypomagnesemia are affected by inherited renal disorders associated with Mg^{2+} wasting. In these disorders, hypomagnesemia may either be the leading symptom or may be part of a complex phenotype resulting from tubular dysfunction. Finally, Mg^{2+} wasting may be caused by endocrine disorders, e.g. by hyperparathyroidism because of the hypercalcemia or within the context of a SIADH state. In SIADH, Mg^{2+} losses are explained by the volume expansion.

Table 37.6 Main causes of magnesium deficiency

Gastrointestinal loss
Prolonged nasogastric suction/vomiting
Acute and chronic diarrhea
Malabsorption syndromes (e.g., celiac disease)
Extensive bowel resection
Intestinal and biliary fistulas
Acute hemorrhagic pancreatitis
Renal loss
Chronic parenteral fluid therapy
Osmotic diuresis (e.g. due to presence of glucose in diabetes mellitus)
Hypercalcemia
Drugs (e.g. diuretics, aminoglycosides, calcineurin inhibitors)
Alcohol
Metabolic acidosis
Renal diseases
– Chronic pyelonephritis, interstitial nephritis, and glomerulonephritis
– Polyuria after acute renal failure
– Post-obstructive nephropathy
– Renal tubular acidosis
– After kidney transplantation
Inherited tubular diseases
Endocrine disorders
– Hyperparathyroidism
– Hyperthyroidism
– Hyperaldosteronism
Syndrome of inappropriate secretion of antidiuretic hormone (SIADH)

Manifestations of Hypomagnesemia

Mg^{2+} deficiency and hypomagnesemia often remain asymptomatic. Clinical symptoms are mostly not very specific and Mg^{2+} deficiency is frequently associated with other electrolyte abnormalities. The biochemical and physiologic manifestations of severe Mg^{2+} depletion are summarized in Table 37.7.

Hypokalemia

A common accompanying feature of Mg^{2+} depletion is hypokalemia [91]. During Mg^{2+} depletion, there is loss of K^+ from the cell with intracellular K^+ depletion, which is enhanced due to the inability of the kidney to conserve K^+. Attempts to replete the K^+ deficit with K^+ therapy alone may not be successful without simultaneous Mg^{2+}

Table 37.7 Major manifestations of magnesium depletion

Biochemical
Hypokalemia
Excessive renal potassium excretion
Decreased intracellular potassium
Hypocalcemia
Impaired parathyroid hormone (PTH) secretion
Renal and skeletal resistance to PTH
Resistance to vitamin D
Neuromuscular
Positive Chvostek's and Trousseau's sign
Spontaneous carpal-pedal spasm
Seizures
Vertigo, ataxia, nystagmus, athetoid and chorioform movements
Muscular weakness, tremor, fasciculation and wasting
Psychiatric: depression, psychosis
Cardiovascular
Electrocardiographic abnormalities
Prolonged PR- and QT-intervals
U-waves
Cardiac arrhythmia
Atrial tachycardia, fibrillations
"Torsades de pointes"
Gastrointestinal
Nausea, vomiting
Anorexia

supplementation. K^+ depletion may contribute to the electrocardiographic findings and cardiac arrhythmias observed in $Mg^{2}+$ deficiency. Secondary K^+ depletion in the presence of Mg^{2+} deficiency must be differentiated from renal tubular disorders mainly affecting the distal convoluted tubule (DCT) that lead to combined losses of both cations, such as Gitelman syndrome (see below).

Hypocalcemia

Hypocalcemia is a common finding in moderate to severe Mg^{2+} depletion and may be a major contributing factor to the increased neuromuscular excitability often present in Mg^{2+}-depleted patients. The pathogenesis of hypocalcemia is multifactorial. Impaired parathyroid hormone (PTH) secretion appears to be a major factor in hypomagnesemia-induced hypocalcemia. Serum PTH concentrations are usually low in these patients, and Mg^{2+} administration will immediately stimulate PTH secretion. Patients with hypocalcemia due to Mg^{2+} depletion also exhibit both renal and skeletal resistance to exogenously administered PTH, as manifested by subnormal urinary cyclic AMP (cAMP) and phosphate excretion and a diminished calcemic response. All these effects are reversed following several days of Mg^{2+} therapy. The paradoxical inhibition of PTH secretion in patients with severe hypomagnesemia was already described in the 1970s [92]. Later, the failure of the parathyroid gland to synthesize and secrete PTH was attributed to a defect in G-protein signaling within parathyroid cells [93]. As a functional consequence, the intracellular signaling pathways responsible for Ca^{2+}-sensing Receptor (CaSR)-mediated inhibition of PTH secretion are enhanced including the generation of inositol phosphates and the inhibition of cAMP. Because cAMP is also an important second messenger mediating PTH effects in kidney and bone, it was also postulated that there may be a defect in adenylate cyclase function as Mg^{2+} is both an essential part of the substrate (Mg-ATP) as well as an important co-factor for catalytic activity [94].

Vitamin D metabolism and action may also be abnormal in hypocalcemic Mg^{2+}-deficient patients. Resistance to vitamin D therapy has been reported in such cases. This resistance may be due to impaired metabolism of vitamin D because plasma concentrations of 1,25-dihydroxyvitamin D_3 are low. Because PTH is a major stimulator of 1,25-dihydroxyvitamin D_3 synthesis, the decrease in PTH secretion observed in hypomagnesemia and hypocalcemia may also be a cause of the impaired metabolism of vitamin D.

Neuromuscular Manifestations

Neuromuscular hyperexcitability may be the prominent complaint of patients with Mg^{2+} deficiency. Tetany and muscle cramps may be present. Generalized seizures may also occur. Other neuromuscular signs may include dizziness, dis-

equilibrium, muscular tremor, wasting, and weakness [91]. Although hypocalcemia often contributes to the neurologic signs, hypomagnesemia without hypocalcemia has also been reported to result in neuromuscular hyperexcitability.

Cardiovascular Manifestations

Mg^{2+} depletion may also result in electrocardiographic abnormalities as well as in cardiac arrhythmias [95], which may be manifested by tachycardia, premature beats, or a totally irregular cardiac rhythm (fibrillation). Cardiac arrhythmia is also known to occur during K^+ depletion; therefore, the effect of Mg^{2+} deficiency on K^+ loss may be a contributing factor (see section on Gitelman syndrome below) [91].

Clinical Assessment of Magnesium Deficiency

Although Mg^{2+} is an abundant cation in the body, more than 99% of it are located either intracellularly or in bone. The less than 1% of total Mg^{2+} present in the body fluids is the most easily accessible compartment for clinical testing, and the total serum Mg^{2+} concentration is the most widely used measure of Mg^{2+} status, although its limitations in reflecting Mg^{2+} deficiency are well recognized [96]. The reference range for normal total serum Mg^{2+} concentration is a subject of ongoing debate, but concentrations of 0.7–1.1 mmol/L are widely accepted. Because the measurement of serum Mg^{2+} concentration does not necessarily reflect the true total body Mg^{2+} content, it has been suggested that measurement of ionized serum Mg^{2+} or intracellular Mg^{2+} concentrations might provide more precise information on Mg^{2+} status. However, the relevance of such measurements to body Mg^{2+} stores has been questioned because the ionized serum Mg^{2+} and intracellular Mg^{2+} did not correlate with tissue Mg^{2+} and the correlation with the results of Mg^{2+} retention tests was contradictory [97–99].

Hypomagnesemia develops late in the course of Mg^{2+} deficiency and intracellular Mg^{2+} depletion may be present despite normal serum Mg^{2+} levels. Due to the kidney's ability to sensitively adapt its Mg^{2+} transport rate to imminent deficiency, the urinary Mg^{2+} excretion rate is important in the assessment of the Mg^{2+} status. In hypomagnesemic patients, urinary Mg^{2+} excretion rates help to discern renal Mg^{2+} wasting from extrarenal losses. In the presence of hypomagnesemia, the 24-h Mg^{2+} excretion is expected to decrease below 1 mmol [100]. Mg^{2+}/creatinine ratios and fractional Mg^{2+} excretions have also been advocated as indicators of evolving Mg^{2+} deficiency [101, 102]. However, the interpretation of these results seems to be limited due to intra- and inter-individual variability [103, 104].

In patients at risk for Mg^{2+} deficiency but with normal serum Mg^{2+} levels, the Mg^{2+} status can be further evaluated by determining the amount of Mg^{2+} excreted in the urine following an intravenous infusion of Mg^{2+}. This procedure has been described as "parenteral Mg^{2+} loading test" and is still the gold standard for the evaluation of the body Mg^{2+} status [96, 98]. Normal subjects excrete at least 80% of an intravenous Mg^{2+} load within 24 h, whereas patients with Mg^{2+} deficiency excrete much less. The Mg^{2+} loading test, however, requires normal renal handling of Mg^{2+}.

Hereditary Disorders of Mg^{2+} Handling

Recent advances in molecular genetics of hereditary hypomagnesemia substantiated the role of a variety of genes and their encoded proteins in human epithelial Mg^{2+} transport (Table 37.8). The knowledge of underlying genetic defects helps to distinguish different clinical subtypes of hereditary disorders of Mg^{2+} homeostasis.

By careful clinical observation and additional biochemical parameters, the different disease entities can already be distinguished clinically and biochemically in many cases, even if there might be a considerable overlap in phenotypic characteristics (Table 37.9).

Table 37.8 Inherited disorders of renal Ca^{2+} and Mg^{2+} handling

Thick ascending limb (TAL)	**OMIM #**	**Inheritance**	**Gene**	**Protein**
Autosomal dominant hypoparathyroidism 1 (ADH1)	601198	AD	*CASR*	CaSR, Ca^{2+}/Mg^{2+} sensing receptor
Autosomal dominant hypoparathyroidism 2 (ADH2)	615361	AD	*GNA11*	G-protein α-11
Familial hypocalciuric hypercalcemia 1 (FHH1)	145980	AD	*CASR*	CaSR, Ca^{2+}/Mg^{2+} sensing receptor
Familial hypocalciuric hypercalcemia 2 (FHH2)	145981	AD	*GNA11*	G-protein α-11
Familial hypocalciuric hypercalcemia 3 (FHH3)	600740	AD	*AP2S1*	Adaptor protein 2 σ-subunit
Neonatal severe hyperparathyroidism (NSHPT)	239200	AR	*CASR*	CaSR, Ca^{2+}/Mg^{2+} sensing receptor
Familial hypomagnesemia with hypercalciuria/ nephrocalcinosis (FHHNC) (HOMG3)	248250	AR	*CLDN16*	Claudin-16, tight junction protein
Familial hypomagnesemia with hypercalciuria/ nephrocalcinosis (FHHNC) and severe ocular involvement (HOMG5)	248190	AR	*CLDN19*	Claudin-19, tight junction protein
Hypohidrosis, electrolyte imbalance, lacrimal gland dysfunction, ichthyosis, and xerodermia (HELIX)	617671	AR	*CLDN10*	Claudin-10, tight junction protein
Distal convoluted tubule (DCT)	**OMIM #**	**Inheritance**	**Gene**	**Protein**
Gitelman syndrome (GS)	263800	AR	*SLC12A3*	NCC, NaCl cotransporter
EAST/SeSAME syndrome	612780	AR	*KCNJ10*	KCNJ10, basolateral potassium channel
Hypomagnesemia with secondary hypocalcemia (HSH) (HOMG1)	602014	AR	*TRPM6*	TRPM6, ion channel subunit
Hypomagnesemia, seizures, and mental retardation 2 (HOMGSMR2)	618314	AD	*ATP1A1*	α1-subunit of the Na^+-K^+-ATPase
Isolated dominant hypomagnesemia (IDH) (HOMG2)	154020	AD	*FXYD2*	γ-subunit of the Na^+-K^+-ATPase
Hypomagnesemia, episodic ataxia/myokymia syndrome	160120	AD	*KCNA1*	Kv1.1, apical potassium channel
Isolated recessive hypomagnesemia (IRH)(HOMG4)	611718	AR	*EGF*	Pro-EGF (epidermal growth factor)
Hypomagnesemia, seizures, and mental retardation 1 (HOMGSMR1)	616418	AR, AD	*CNNM2*	CNNM2, Cyclin M2
HNF1α nephropathy	137920	AD	*HNF1B*	HNF1beta, transcription factor
Transient neonatal hyperphenylalaninemia	264070	AR	*PCBD1*	PCBD1, tetrahydrobioterin metabolism
Hypomagnesemia/metabolic syndrome	500005	mito	*MTTI*	Mitochondrial tRNA (Isoleucin)

Table 37.9 Clinical and biochemical characteristics of inherited Ca^{2+} and Mg^{2+} disorders

Disorder	Age at onset	Serum Mg^{2+}	Serum Ca^{2+}	Serum K^{+}	Blood pH	Urine Mg^{2+}	Urine Ca^{2+}	Nephro-calcinosis	Renal stones
Autosomal dominant hypoparathyroidism (ADH)	Infancy	↓	↓	N	N or ↑	↑	↑–↑↑	Yes[a]	Yes[a]
Familial hypocalciuric hypercalcemia (FHH)	Often asymptomatic	N to ↑	↑	N	N	↓	↓	No	?

[a] Frequent complication under therapy with Ca^{2+} and vitamin D

Familial Hypomagnesemia with Hypercalciuria and Nephrocalcinosis

Familial hypomagnesemia with hypercalciuria and nephrocalcinosis (**FHHNC**) is an autosomal recessive disorder caused by mutations in two members of the claudin gene family which encode the tight junction proteins claudin-16 and claudin-19 [105, 106]. More than 150 patients have been reported to date, allowing a comprehensive characterization of the clinical spectrum [107–111]. Due to excessive renal Mg^{2+} and Ca^{2+} wasting, affected individuals almost uniformly develop the characteristic triad of hypomagnesemia, hypercalciuria, and nephrocalcinosis that gave the disease its name. Additional biochemical abnormalities include elevated PTH levels before the onset of chronic renal failure, hypocitraturia, and hyperuricemia. The majority of patients clinically present during early childhood with recurrent urinary tract infections, polyuria/polydipsia, nephrolithiasis, and/or failure to thrive. Clinical symptoms of severe hypomagnesemia such as seizures and muscular tetany are less common. The clinical course of FHHNC patients is complicated by the development of chronic renal failure (CRF) early in life. A considerable number of patients exhibit a marked decline in GFR (<60 mL/min per 1.73 m^2) already at the time of diagnosis and about one third of patients develops ESRD during adolescence. Hypomagnesemia may completely disappear with the decline of GFR due to a reduction in filtered Mg^{2+} that limits urinary Mg^{2+} losses. Whereas the renal phenotype is almost identical in carriers of *CLDN16* and *CLDN19* mutations, ocular involvement including severe myopia, nystagmus, or macular coloboma are observed only in patients with *CLDN19* mutations [106, 107, 109, 110].

Claudins are crucial components of tight junctions and the individual composition of tight junctions strands with different claudin members confers the characteristic properties of different epithelia regarding paracellular permeability and/or transepithelial resistance. Within the tight junction barrier, claudins positioned on neigbouring cells are thought to form charge-selective pores.

Claudin-16 and claudin-19 colocalize at tight junctions of the TAL [106]. Tight-junction strands in this part of the renal tubule also express other members of the claudin family including claudin-3, claudin-10 and claudin-18. These other claudins maintain the barrier function of the tight junction complex also in the absence of claudin-16 and -19, however, claudin-16 and -19 depleted tight junctions display a loss in cation permselectivity [112]. Mice deficient in Claudin-16 or claudin-19 also exhibit increased renal Na^+ and K^+ losses in addition to impaired renal Mg^{2+} and Ca^{2+} handling [113].

The majority of *CLDN16* and *CLDN19* mutations reported in FHHNC are missense mutations affecting the transmembrane domains and the extracellular loops with a particular clustering in the first extracellular loop. Within this domain, patients originating from Germany or Eastern European countries exhibit a common mutation (p.L151F) due to a founder effect [108].

Progressive renal failure in FHHNC is thought to be a consequence of massive urinary Ca^{2+} wasting and nephrocalcinosis. Individuals with bi-allelic loss-of-function mutations in *CLDN16* exhibit a younger age at manifestation and a more rapid renal function loss compared to patients with at least one allele with residual claudin-16 function [114]. Of note, first degree relatives of FHHNC patients appear to have a high incidence of hypercalciuria, nephrolithiasis and/or nephrocalcinosis [107, 108]. Moreover, a tendency towards mild hypomagnesemia has been observed in these heterozygous family members [115]. Thus, one might speculate that *CLDN16* mutations could be involved in idiopathic hypercalciuric stone formation. Finally, a homozygous *CLDN16* mutation (p.T303R) affecting the C-terminal PDZ domain has been identified in two families with isolated hypercalciuria and nephrocalcinosis without abnormalities in renal Mg^{2+} handling [116]. Notably, hypercalciuria disappeared during follow-up and urinary Ca^{2+} levels reached normal values beyond puberty.

In addition to oral Mg^{2+} supplementation, **therapy** aims at a reduction of Ca^{2+} excretion in order to prevent the progression of nephrocalcinosis and stone formation because the degree of renal calcifications has been correlated with progression of chronic renal failure [107]. In a short term study, thiazides effectively reduced urinary Ca^{2+} excretion in FHHNC patients [117]. However, these therapeutic strategies have not been shown yet to significantly influence the progression of renal failure. Supportive therapy is important for the protection of kidney function and should include provision of sufficient fluids and effective treatment of stone formation and bacterial colonization. As expected, renal transplantation is performed without evidence of recurrence of the disease because the primary defect resides in the kidney.

Gitelman Syndrome

Gitelman syndrome (GS) is the most frequent inherited salt wasting disorder with an estimated prevalence of approximately 1:40.000 [118]. It is caused by mutations in the *SLC12A3* gene coding for the thiazide-sensitive NaCl- cotransporter, NCC [119]. The NCC is exclusively expressed at the apical membrane of the DCT where it reabsorbs approximately 5–10% of the filtered NaCl (Fig. 37.5). The cardinal biochemical features of GS are persistent hypokalemia and metabolic alkalosis together with hypomagnesemia and hypocalciuria [120, 121]. Hundreds of GS patients have been reported to date, allowing for a thorough clinical description of the phenotype as well as for an extensive analysis of the mutational spectrum in the *SLC12A3* gene [122–126].

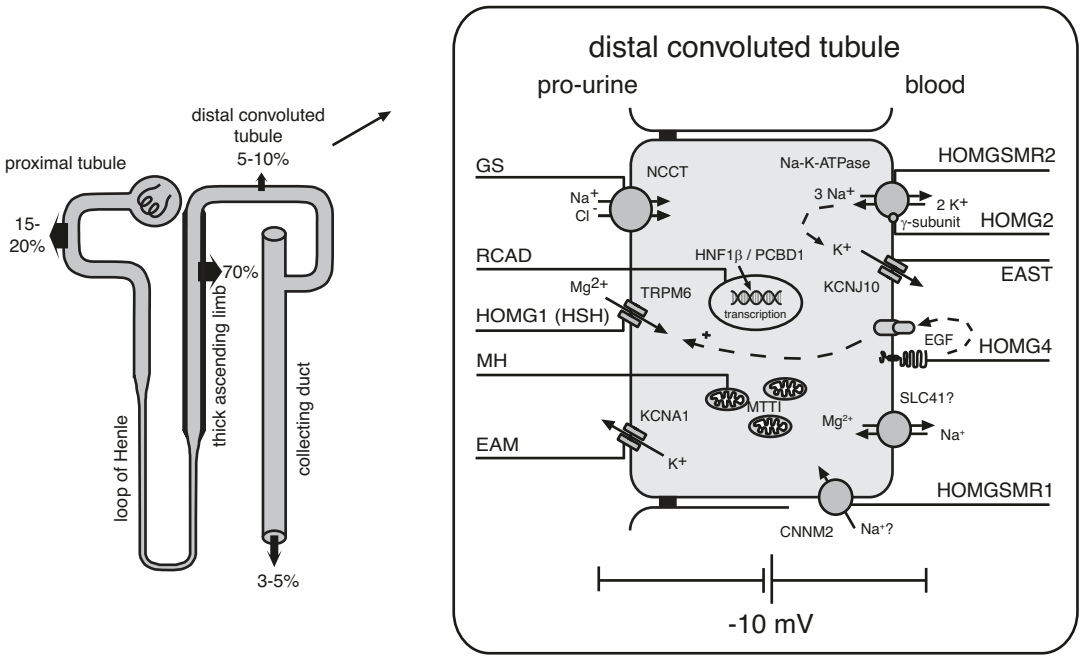

Fig. 37.5 Mg^{2+} reabsorption in the distal convoluted tubule. Mg^{2+} is actively reabsorbed via the transcellular pathway involving an apical entry step through a Mg^{2+}-permeable ion channel (TRPM6) and a basolateral exit, presumably mediated by a Na^+-coupled exchange mechanism. Mg^{2+} reabsorption in the DCT is dependent on transcellular salt reabsorption via NCC, basolateral Na^+/K^+-ATPase activity, and K^+ recycling. It is regulated by basolateral EGF and the putative Mg^{2+} sensor CNNM2. Furthermore, Mg^{2+} transport rates are influenced by cellular energy metabolism (mitochondrial function) and expression levels of transport proteins (regulated by HNF1B). The respective hereditary defects are indicated

A consensus and guidance document concerning the diagnostic criteria, clinical workup, genetic testing, treatment, and long-term follow-up of patients with GS was recently published to which the reader should refer if diagnosing or treating a GS patient [127].

The initial presentation of GS most frequently occurs at school age or later with the characteristic symptoms being muscular weakness, cramps, and fatigue [128]. However, severe manifestations with early onset of disease, growth retardation, chondrocalcinosis, tetany, rhabdomyolysis, seizures, or ventricular arrhythmia have been reported [122, 129]. On the other hand, patients are frequently diagnosed accidentally while searching medical consultation for unrelated reasons, because of growth retardation, constipation or enuresis. A thorough past medical history of such patients commonly reveals long-standing salt craving [122]. Typically, urinary concentrating ability is not affected. Laboratory examination shows the characteristic constellation of metabolic alkalosis, low-normal Cl^- levels, hypokalemia, and hypomagnesemia; urine analysis reveals hypocalciuria [130]. Family studies demonstrated electrolyte imbalances present since infancy despite the absence of obvious clinical signs and symptoms in the affected infant [131].

Of note, the combination of hypokalemia and hypomagnesemia exerts an exceptionally unfavorable effect on cardiac excitability, which puts these patients at high risk for cardiac arrhythmia [132, 133]. Therefore, next to appropriate potassium and magnesium supplementation, the recognition of other possible triggering mechanisms as well as the avoidance of drugs that aggravate K^+ and Mg^{2+} depletion or prolong the QT-interval appears to be critical. Respective tables of drugs that should be avoided are available online (www.crediblemeds.org).

The pathognomonic feature of Gitelman syndrome is the dissociation of renal Ca^{2+} and Mg^{2+} handling, with low urinary Ca^{2+} and high urinary Mg^{2+} levels. Subsequent hypomagnesemia causes neuromuscular irritability and tetany. Decreased renal Ca^{2+} elimination together with Mg^{2+} deficiency favors deposition of mineral Ca^{2+} as demonstrated by increased bone density as well as chondrocalcinosis [134].

Although the combination of hypomagnesemia and hypocalciuria is typical for NCC deficiency, this finding is neither specific nor universal. Clinical observations in NCC deficient patients disclosed intra- and inter-individual variations in urinary Ca^{2+} concentrations which can be attributed to gender, age-related conditions of bone metabolism, intake of Mg^{2+} supplements, changes in diuresis and urinary osmolality, respectively. Likewise, hypomagnesemia might not be present from the beginning. Renal Mg^{2+} loss can be balanced temporarily by Mg^{2+} release from bone and muscle stores as well as by an increase of intestinal Mg^{2+} reabsorption. The mechanisms compromising distal Mg^{2+} reabsorption and favoring reabsorption of Ca^{2+} are not yet completely understood.

In contrast to TAL defects, disturbed salt reabsorption along the DCT does not affect the tubulo-glomerular feedback and thus is not associated with increased renal prostaglandin synthesis [135]. Accordingly, NSAIDs are of little benefit in Gitelman syndrome. Substitution of KCl and Mg^{2+} is therefore of prime importance in the treatment of this disorder. As pointed out above, avoidance of factors which in addition to hypokalemia and hypomagnesemia might affect cardiac excitability (in particular QT-time prolonging drugs) is mandatory to prevent life-threatening cardiac arrhythmia.

EAST/SeSAME Syndrome

A clinical syndrome with autosomal recessive inheritance combining epilepsy, ataxia, sensorineural deafness and renal salt wasting with/without mental retardation was first described in 2009 under the acronyms EAST or SeSAME syndrome [136, 137]. Patients usually present early in infancy with generalized tonic–clonic seizures, speech and motor delay, as well as ataxia leading to an inability to walk, intention tremor, and dysdiadochokinesis. In addition, they exhibit a variable degree of hearing impairment [138]. The

neurological features and hearing impairment are usually non-progressive [139]. Renal salt wasting is often recognized later during the course of the disease. Closely resembling GS, the renal phenotype includes the combination of hypokalemic alkalosis, hypomagnesemia and hypocalciuria.

EAST/SeSAME syndrome is caused by loss-of-function mutations in the *KCNJ10* gene encoding the inwardly-rectifying K^+-channel KCNJ10 (Kir4.1) [136, 137]. The expression pattern of KCNJ10 fits to the disease phenotype with highest expression in brain, the stria vascularis of the inner ear, and in the distal nephron, especially in the DCT (Fig. 37.5). Here, KCNJ10 is localized at the basolateral membrane of DCT cells and supposed to function in collaboration with Na^+-K^+-ATPase as it might allow for a recycling of K^+ ions entering the tubular cells in countermove for the extruded Na^+ [137]. Loss of KCNJ10 function most likely leads to a depolarization of the basolateral membrane and thereby to a reduction of the driving force for basolateral anion channels as well as sodium-coupled exchangers. By this mechanism, KCNJ10 defects might also affect the putative Na^+/Mg^{2+} exchanger and possibly explain the Mg^{2+} wasting observed in EAST/SeSAME syndrome.

As in patients with Gitelman syndrome, medical treatment of EAST/SeSAME patients regarding the renal phenotype mainly comprises potassium and magnesium supplementation. In individual adult patients, persistent hypokalemia despite supplementation has been treated with spironolactone in order to prevent frequent hospitalisations [140]. Seizures typically respond well to initial anti-epileptic treatment but may recur at later age. Finally, ataxia remains a major debilitating disease feature.

Hypomagnesemia with Secondary Hypocalcemia

Hypomagnesemia with secondary hypocalcemia (HSH) is a rare recessive disorder that manifests in early infancy with generalized seizures or other symptoms of increased neuromuscular excitability [141]. Biochemical abnormalities include extremely low serum Mg^{2+} (about 0.2 mmol/L) and low serum Ca^{2+} levels. Hypocalcemia is thought to result from an impaired synthesis and/or release of PTH in the presence of severe hypomagnesemia [92]. The failure of the parathyroid gland to synthesize and secrete parathyroid hormone has been attributed to a defect in g-protein signalling within parathyroid cells required for CaSR-mediated stimulation of PTH release [93].

Transport studies in HSH patients pointed to a primary defect in intestinal Mg^{2+} absorption [142, 143]. However, in some patients an additional renal leak for Mg^{2+} was suspected [144]. In 2002, recessive loss of function mutations in TRPM6 encoding a member of the transient receptor potential (TRP) family of ion channels were discovered as the underlying genetic defect [145, 146]. To date, mutations in *TRPM6* have been identified in more than 50 families affected by HSH [145–149]. The mutational spectrum mainly comprises truncating mutations. In addition, a number of missense mutations have been described for which functional analyses also indicated a complete loss-of-function [145, 147, 149, 150].

TRPM6 is expressed along the intestine (duodenum, jejunum, ileum, colon) as well as in the DCT of the kidney (Fig. 37.5) [145].

In the intestine, intraluminal Mg^{2+} concentrations and rates of Mg^{2+} absorption show a curvilinear relationship presumably reflecting two transport processes working in-parallel: an active and saturable transcellular transport essential at low intraluminal Mg^{2+} concentrations and a passive paracellular Mg^{2+} absorption gaining importance at higher intraluminal Mg^{2+} concentrations [87]. The observation that in HSH patients the substitution of high oral doses of Mg^{2+} achieves at least subnormal serum Mg^{2+} levels supports the hypothesis of two independent intestinal transport systems for Mg^{2+}. By participating in the formation of apical magnesium-permeable ion channels, TRPM6 probably represents a molecular component of active transcellular Mg^{2+} transport. An increased intraluminal Mg^{2+} concentration (by increased oral intake) enables to compensate for the defect in active

transcellular transport by increasing absorption via the passive paracellular pathway (Fig. 37.1).

In the kidney, TRPM6 is expressed predominantly in the DCT arguing for an important role of renal Mg^{2+} wasting for the pathogenesis of HSH [151]. This is also supported by intravenous Mg^{2+} loading tests in HSH patients, which disclosed a considerable renal Mg^{2+} leak albeit still being hypomagnesemic [146].

Hypocalcemia in patients with HSH is resistant to treatment with Ca^{2+} or vitamin D. Relief of clinical symptoms, normocalcemia, and normalization of PTH levels are only achieved by administration of high doses of Mg^{2+} [152]. Oral magnesium supplementation is preferentially performed with organic magnesium compounds (i.e. Mg-citrate, -aspartate, or -gluconate), doses vary between 0.5 and 4 mmol/kg/day. Serum magnesium levels usually remain in the subnormal range despite adequate treatment, but usually enable an undisturbed physical and mental development. However, delayed diagnosis or noncompliance with treatment can be fatal or result in permanent neurological damage.

Hypomagnesemia, Refractory Seizures and Mental Retardation Type 2

Heterozygous de-novo mutations in the *ATP1A1* gene encoding the α1-subunit of Na^+K^+-ATPase have recently been described in three children with severe hypomagnesemia due to renal magnesium wasting [153]. The affected children presented in infancy with cerebral seizures that were refractory to antiepileptic medication and also did not respond to high dose magnesium supplementation. All three children developed a significant degree of mental retardation and global developmental delay. Serum magnesium concentrations remained low despite adequate oral supplementation.

The α1-subunit (ATP1A1) is one of four different α-subunits of Na^+K^+-ATPase in human, but it represents the exclusive α-subunit in kidney. Along the kidney tubule, the DCT represents the segment with the highest energy consumption and density of Na^+K^+-ATPase expression [154]. Here, basolaterally expressed Na^+K^+-ATPase generates favorable electrochemical gradients for transcellular salt and magnesium reabsorption (Fig. 37.5). The critical role of Na^+K^+-ATPase for magnesium reabsorption had previously been demonstrated by discovery of mutations in its γ-subunit (*FXYD2*) in patients with isolated dominant hypomagnesemia (see below). In the central nervous system, the α1-subunit is ubiquitiously expressed and thought to maintain neuronal housekeeping functions by generating the resting membrane potential and clearing extracellular K^+ during neuronal activity [155].

The ATP1A1 mutations discovered in hypomagnesemic children were shown to not only lead to a loss of ATPase function, but also to result in abnormal ion permeabilities and leak currents [153]. Therefore, the severe hypomagnesemia phenotype might not be the result of a simple ATP1A1 haploinsufficiency. Whereas a homozygous loss of ATP1A1 function is not compatible with life, heterozygous germline ATP1A1 mutations have also been described in patients with Charcot-Marie-Tooth disease type 2 and hereditary spastic paraplegia [156, 157]. Originally, somatic ATP1A1 mutations had been identified in patients with primary hyperaldosteronism due to aldosterone producing adenomas [158].

Isolated Dominant Hypomagnesemia

A first variant of isolated dominant hypomagnesemia **(IDH)** was described in 1999 in two related families by Meij et al. who discovered a mutation in the *FXYD2* gene encoding the γ-subunit of renal Na^+K^+-ATPase [159]. The γ-subunit of Na^+K^+-ATPase is a member of the FXYD family of small single transmembrane proteins that constitute regulatory, tissue-specific subunits of the Na^+K^+-ATPase. Along the kidney tubule, F*XYD2* is preferentially expressed in the DCT, where it is thought to increase the affinity of Na^+K^+-ATPase for ATP while decreasing its Na^+ affinity thereby providing a mechanism for balancing energy utilization and maintaining appropriate salt gradi-

ents [160, 161] The reported G41R mutation in the γ-subunit leads to retention of the γ-subunit within the cell.

Urinary Mg^{2+} wasting together with the expression pattern of the *FXYD2* gene point to a defect in transcellular Mg^{2+} reabsorption in the DCT in IDH patients. Affected children present with cerebral seizures and hypomagnesemia around 0.5 mmol/L. [162] Hypomagnesemia is due to renal losses while intestinal Mg^{2+} absorption is preserved or even stimulated [162]. Low Ca^{2+} excretion, hypokalemia and metabolic alkalosis reminiscent of Gitelman syndrome have also been reported in some families [163]. Selective magnesium supplementation partially corrects hypomagnesemia and normalizes serum potassium levels [163].

Hypomagnesemia, Episodic Ataxia/ Myokymia Syndrome

Another form of dominant hypomagnesemia was established by the identification of a heterozygous missense mutation in *KCNA1,* which encodes the voltage-gated potassium channel KCNA1 (Kv1.1) [164]. The clinical phenotype associated with the reported p.N255D mutation in Kv1.1 includes muscle cramps, tetany, tremor, and muscle weakness starting during infancy.

Originally, dominant *KCNA1* mutations had been identified in patients with episodic ataxia with myokymia (OMIM #160120), a neurologic disorder characterized by an intermittent appearance of incoordination and imbalance as well as myokymia, an involuntary, spontaneous, and localized trembling of muscles [165]. In addition to muscle cramps and tetany attributed to Mg^{2+} deficiency, these symptoms were also present in hypomagnesemic patients with the p.N255D mutant. Urine analyses in these patients revealed a renal Mg^{2+} leak without alterations in renal Ca^{2+} handling.

Co-expression studies of the mutant and wild-type Kv1.1 channel subunits indicate a dominant-negative effect of the mutant [166]. Kv1.1 is expressed at the apical membrane of the DCT. As Kit is co-localized there with TRPM6, Kv1.1 may allow for hyperpolarization of the apical membrane of DCT cells as a prerequisite for TRPM6-mediated Mg^{2+} entry (Fig. 37.4b), thereby linking Mg^{2+} reabsorption to K+ secretion in the DCT [164].

Isolated Recessive Hypomagnesemia

In the 1980s Geven et al. first reported a form of isolated hypomagnesemia in a consanguineous family indicating autosomal recessive inheritance [167]. Two affected sisters presented in infancy with generalized seizures. Unfortunately, a late diagnosis resulted in neurodevelopmental deficits in both girls. A thorough clinical and laboratory workup at 4 and 8 years of age, respectively, revealed serum Mg^{2+} levels around 0.5–0.6 mmol/L with no other associated serum electrolyte abnormality. Of note, renal Ca^{2+} excretion rates were in the normal range. A ^{28}Mg-retention test in one patient indicated a primary defect in renal Mg^{2+} conservation [167].

Groenestege et al. identified a homozygous missense mutation in the *EGF* gene leading to a nonconservative amino acid exchange in the encoded pro-EGF protein (pro-epidermal growth factor) in the two sisters [168]. In the kidney, co-expression with key proteins of transcellular Mg^{2+} reabsorption including TRPM6 in the DCT was demonstrated. Pro-EGF is a transmembrane protein that is inserted in both the luminal and basolateral membrane of polarized epithelia. After the soluble EGF peptide is cleaved, it binds to and activates specialized EGF receptors (EGFRs). In case of the DCT, these EGFRs are exclusively expressed at the basolateral membrane (Fig. 37.5). Their activation leads to increased trafficking of TRPM6 to the luminal membrane and increased Mg^{2+} reabsorption [169]. The mutation described in IRH (p.P1070L) disrupts the basolateral sorting motif in pro-EGF leading to a mistargeting of pro-EGF [168]. Therefore, the activation of basolateral EGFRs is compromised which ultimately causes impaired active transcellular Mg^{2+} reabsorption. Despite

acting in a paracrine fashion in the DCT, the authors speculate on a role of EGF as a first selectively acting magnesiotropic hormone [168].

Hypomagnesemia, Refractory Seizures, and Mental Retardation 1

Another form of hereditary Mg^{2+} wasting has been linked to mutations in *CNNM2* encoding the transmembrane protein CNNM2 or Cyclin M2 [170]. CNNM2 was identified by differential expression in murine DCT cells exposed to varying Mg^{2+} concentrations and by transcriptome studies in mice lacking claudin-16 [170, 171]. In addition, common variants in CNNM2 were found to be associated with serum Mg^{2+} levels in a genome-wide association study [172]. The precise physiological function of CNNM2 is still elusive. CNNM2 is ubiquitously expressed in mammalian tissues, most prominently in kidney, brain and lung [173, 174]. In the kidney, CNNM2 is expressed at the basolateral membrane of TAL and DCT. Whereas CNNM2 had initially been proposed as a Mg^{2+} transporter, more recent data point to a role in Mg^{2+}-sensing [171, 174].

CNNM2-associated disease shows a wide phenotypic as well as genetic spectrum. Most patients identified thus far carry heterozygous de novo mutations in *CNNM2*. These patients mainly present in infancy with generalized convulsions and display a mild to moderate degree of neurodevelopmental delay with a disturbed speech development and dysarthria as prominent features [175]. Cerebral seizures tend to subside during follow-up in the majority of patients. A considerable number of patients of both genders develops severe obesity as the most prominent extraneurological symptom [175]. Serum magnesium levels are typically in the range of 0.5–0.6 mmol/L and remain in the subnormal range upon oral magnesium supplementation.

A milder clinical phenotype without significant intellectual disability was originally described in members of two families with dominant inheritance [170]. By contrast, patients with bi-allelic *CNNM2* mutations exhibit profound hypomagnesemia and a severe neurological phenotype with refractory epilepsy, microcephaly, global developmental delay, and severe intellectual disability [176, 177]. Brain MR imaging in these patients demonstrate widened outer cerebrospinal liquor spaces indicative of cerebral atrophy as well as myelinization defects.

HNF1B Nephropathy

Hepatocyte nuclear factor 1β (HNF1B) is a transcription factor critical for the development of the kidney and the pancreas. *HNF1B* mutations are present in heterozygous state, either inherited or de novo, and comprise point mutations as well as whole-gene deletions [178]. *HNF1B* mutations were first implicated in a subtype of maturity-onset diabetes of the young (MODY5) [179]. Later, an association with anomalous kidney development was reported. The renal phenotype is highly variable comprising enlarged hyperechogenic kidneys, multicystic kidney disease, renal agenesis, renal hypoplasia, cystic dysplasia, as well as hyperuricemic nephropathy (see Chap. 8). Since neither a renal cystic phenotype nor diabetes are constant clinical findings, the neutral term HNF1B nephropathy has been introduced [180]. Interestingly, 25–50% of patients present with hypomagnesemia due to impaired renal Mg^{2+} conservation [181, 182]. As *HNF1B* regulates the expression of *FXYD2* (see above), defective basolateral Na^+K^+-ATPase function potentially explains renal Mg^{2+} wasting in patients with HNF1B mutations [182]. In agreement with this assumption, renal Mg^{2+} wasting in HNF1B nephropathy can be part of a Gitelman syndrome-like picture with hypokalemia, metabolic alkalosis and hypocalciuria, compatible with dysfunction of the DCT [182, 183].

The observed variable prevalence of hypomagnesemia in children with HNF1B nephropathy suggests that this phenotypic feature of HNF1B nephropathy may represent an age-dependent phenomenon and develop over time [184]. Indeed, a study from Poland reports an increasing fraction of hypomagnesemic HNF1B patients during follow-up [185].

Transient Neonatal Hyperphenylalaninemia

Renal Mg^{2+} wasting has been demonstrated in transient neonatal hyperphenylalaninemia due to recessive mutations in the *PCBD1* gene [186]. Affected patients developed hypomagnesemia and a MODY type diabetes in adulthood. Functional studies revealed that PCBD1 is an essential dimerization cofactor of HNF1B. Defective dimerization of PCBD1 with HNF1B abrogates the HNF1B-mediated stimulation of *FXYD2* promoter activity in the DCT [186].

Mitochondrial Hypomagnesemia

A mutation in the mitochondrial tRNA gene for Isoleucine, $tRNA^{Ile}$ or MTTI, has been discovered in a single large Caucasian kindred [187]. An extensive clinical evaluation of this family was prompted after the discovery of hypomagnesemia in the index patient. Pedigree analysis was compatible with mitochondrial inheritance as the phenotype was exclusively transmitted by affected females. The phenotype included hypomagnesemia, hypercholesterolemia, and hypertension. Of the adults on the maternal lineage, the majority of offspring exhibited at least one of the mentioned symptoms, approximately half of the individuals showed a combination of two or more symptoms, and around 1/6 had all three features [187]. Serum Mg^{2+} levels of family members on the maternal lineage greatly varied ranging from 0.3 to 1.0 mmol/L with approximately 50% of individuals being hypomagnesemic. Hypomagnesemic individuals showed higher fractional excretions (median around 7.5%) than their normomagnesemic relatives on the maternal lineage (median around 3%) clearly pointing to renal Mg^{2+} wasting as causative for hypomagnesemia. Interestingly, hypomagnesemia was accompanied by decreased urinary Ca^{2+} levels, a finding pointing to the DCT as the affected tubular segment. As ATP consumption along the tubule is highest in the DCT, energy metabolism of DCT cells may be impaired as a consequence of the mitochondrial defect which in turn could lead to disturbed transcellular Mg^{2+} reabsorption [187].

Acquired Hypomagnesemia

Cisplatin and Carboplatin

The cytostatic agent cisplatin and the newer antineoplastic drug, carboplatin, are widely used in various protocols for the therapy of solid tumors. Among different side effects, nephrotoxicity receives most attention as the major dose-limiting factor. Carboplatin has been reported to have less severe side effects than cisplatin [188–190].

Hypomagnesemia due to renal Mg^{2+} wasting is regularly observed in patients treated with cisplatin [189, 191]. The incidence of Mg^{2+} deficiency is greater than 30% and even increases to over 70% with extended cisplatin usage and greater cumulative doses. Notably, cisplatin-induced Mg^{2+} wasting is relatively selective [189]. Hypocalcemia and hypokalemia may be observed but only with prolonged and severe Mg^{2+} deficiency [192]. The influence of Mg^{2+} deficiency on PTH secretion and end-organ resistance is a possible explanation for enhanced urinary Ca^{2+} excretion and diminished mobilization resulting in low serum Ca^{2+} concentrations [193]. The effects on K^+ balance are more difficult to explain. The hypokalemia observed with Mg^{2+} deficiency is refractory to K^+ supplementation. The effects of cisplatin may persist for months or years, long after the inorganic platinum has disappeared from the renal tissue [194, 195].

In the rat model cisplatin treatment resulted in EGF and TRPM6 downregulation in the DCT [196]. Nephrotoxicity was effectively prevented by Mg^{2+} supplementation either during or even before cisplatin administration, demonstrating the close relationship between cisplatin-induced Mg^{2+} deficiency and nephrotoxicity [197].

Aminoglycosides

Aminoglycosides, such as gentamicin, induce renal impairment in up to 35% patients dependent on the dose and duration of administration. In addition, aminoglycosides cause hypermagnesiuria and hypomagnesemia [198]. As many as 25% of patients receiving gentamicin develop hypomagnesemia [198]. The hypermagnesiuric response occurs soon after the onset of therapy; it is dose-dependent and readily reversible upon withdrawal. As with adults, neonates also display an immediate increase of Ca^{2+} and Mg^{2+} excretion after gentamicin infusion [199, 200]. Mg^{2+} wasting is associated with hypercalciuria that may lead to diminished plasma Ca^{2+} concentrations. This would suggest that aminoglycosides affect renal Mg^{2+} and Ca^{2+} transport in the distal tubule where both are reabsorbed. The cellular mechanisms are not completely understood but hypermagnesiuria and hypercalciuria are observed in the absence of histopathological changes. Because gentamicin is a polyvalent cation it has been postulated that it may interfere with the function of the Ca^{2+}-sensing receptor (CaSR) [89, 201]. CaSR activation by polyvalent cations would inhibit passive absorption of Mg^{2+} and Ca^{2+} in the loop of Henle and active hormone-mediated transport in the DCT, leading to renal Mg^{2+} and Ca^{2+} wasting. The observation that gentamicin treatment results in an up-regulation of Ca^{2+} and Mg^{2+} transport proteins in the DCT, namely TRPV5, TRPM6 and calbindin-D28k, suggests that this adaptation represents an attempt to counter upstream losses, i.e. in the TAL [202]. This would be in accordance with the hypothesis that gentamicin affects Na^+ reabsorption in TAL leading to a reduced lumen-positive voltage and a subsequent reduction in Ca^{2+} and Mg^{2+} reabsorption.

Calcineurin Inhibitors

The calcineurin inhibitors cyclosporine and tacrolimus are widely prescribed as immunosuppressants to organ transplant recipients and in numerous immunologic disorders. Under this therapy, patients are at high risk of developing renal injury and hypertension. Tubular dysfunction with subsequent disturbance of mineral metabolism is another common side effect. Both drugs commonly lead to renal Mg^{2+} wasting and hypomagnesemia [203]. Unlike the other agents mentioned above, these drugs also cause modest hypercalcemia with hypercalciuria and hypokalemia [203]. The hypomagnesemic effect is probably attenuated by the fall in GFR and reduction in filtered Mg^{2+} but this defect appears to be specific for Mg^{2+}. Calcineurin inhibitor therapy is associated with an inappropriately high fractional excretion rate of Mg^{2+}, suggesting impaired passive reabsorption in the TAL or active Mg^{2+} transport in the DCT [204]. Cyclosporine reduces claudin-16 expression in the TAL [205]. Moreover, tacrolimus downregulates specific Ca^{2+} and Mg^{2+} transport proteins in the DCT. In an animal study, tacrolimus suppressed the expression of TRPV5, calbindin-D28k and TRPM6 [206]. In accordance with these observations, urinary EGF levels were found decreased in adult and pediatric hypomagnesemic renal allograft recipients treated with cyclosporin pointing to a defect of transcellular magnesium reabsorption in the DCT [207, 208].

EGF Receptor Antibodies

The EGF hormone axis has been implicated in renal Mg^{2+} handling by the identification of a homozygous mutation in the *EGF* gene in a family with isolated recessive hypomagnesemia (see below) [168]. The way for this discovery was paved by the observation that anticancer treatments with monoclonal antibodies against the EGF receptor (EGFR) resulted in renal Mg^{2+} wasting and hypomagnesemia [209]. Of note, patients treated with EGFR targeting antibodies (cetuximab, panitumumab) for colorectal cancer usually receive a combination therapy with platinum compounds potentially aggravating the effects on serum Mg^{2+} levels. A significant number of patients receiving such a chemotherapeutic regimen shows decreasing serum Mg^{2+} concentrations over time [209–211]. 24-h urine

collections as well as Mg^{2+} loading tests in single patients demonstrated defective renal Mg^{2+} conservation [209]. Together with the genetic findings in patients with isolated recessive hypomagnesemia due to a pro-EGF mutation, these observations imply a selective effect of EGF-receptor targeting on transcellular Mg^{2+} transport in the DCT. There, TRPM6 mediated Mg^{2+} uptake into DCT cells is stimulated by basolaterally secreted EGF via its receptor (EGFR) [168]. It is still controversial If the development of hypomagnesemia correlates with the efficacy of anti-EGF receptor treatment [212, 213].

Proton-Pump Inhibitors (PPIs)

Over the past two decades, PPIs for the reduction of gastric acidity have emerged to one of the most widely prescribed classes of drugs worldwide [214]. Symptomatic hypomagnesemia has been observed in a small but significant number of patients receiving PPIs [215]. A systematic review of the published cases showed severe hypomagnesemia (below 0.4 mmol/L) with concomitant hypocalcemia, a laboratory constellation reminiscent of Hypomagnesemia with Secondary Hypocalcemia (HSH) due to TRPM6 defects (see below) [214]. The initial report on hypomagnesemia following PPI treatment had already described suppressed PTH levels during episodes of severe hypomagnesemia as a probable cause of hypocalcemia [215]. Although a number of patients additionally receive diuretics, this finding does not explain the profound degree of Mg^{2+} deficiency observed in patients receiving PPIs.

Unfortunately, the molecular link between proton-pump inhibition and hypomagnesemia still remains unclear. Data regarding renal Mg^{2+} losses in hypomagnesemic patients receiving PPIs are inconclusive. Fractional Mg^{2+} excretion was reported to be low in face of profound hypomagnesemia, possibly pointing to an intact tubular Mg^{2+} reabsorption [215, 216]. However, as observed in HSH patients, a renal Mg^{2+} leak might only become apparent if serum Mg^{2+} levels reach a certain threshold. An alternative explanation could involve disturbed intestinal reabsorption of Mg^{2+}. Possible molecular mechanisms include an inhibition of TRPM6 leading to a combined intestinal and renal defect, but also a disturbance of ATPases or ATPase-subunits other than gastric H^+-K^+-ATPase involved in epithelial Mg^{2+} transport.

It is recommended to monitor serum Mg^{2+} levels patients receiving PPIs, particularly on those with concomitant cardiac disease at risk for arrhythmia.

Miscellaneous Agents

A number of antibiotics, tuberculostatics, and antiviral drugs may result in renal Mg^{2+} wasting [198]. The cellular basis and molecular mechanisms by which these agents lead to abnormal Mg^{2+} reabsorption are largely unknown. Many are associated with general cytotoxicity. Amphotericin B may lead to an acquired distal tubular acidosis which in turn reduces renal Mg^{2+} reabsorption. Pamidronate used in the treatment of acute symptomatic hypercalcemia of various origin has also been reported to cause transient hypomagnesemia. Again, the cellular mechanisms are difficult to predict since this drug is used in patients with hypercalcemia that may aggravate renal Mg^{2+} wasting [217].

Particular attention should be given to these medications in patients with pre-existing hypomagnesemia and especially hereditary disorders of magnesium metabolism.

Therapy of Hypomagnesemia

The substitution of Mg^{2+} in patients with hypomagnesemia is primarily aimed at the relief of clinical symptoms. Unfortunately, in patients with renal Mg^{2+} wasting, normal values for total serum Mg^{2+} are hardly achieved by oral substitution without considerable side effects, mainly resulting from the cathartic effects of Mg^{2+} salts.

The primary route of administration depends on the severity of the clinical findings. Acute intra-

venous infusion is usually reserved for patients with symptomatic hypomagnesemia, i.e. with cerebral convulsions or tetany [218]. Intravenous administration should be preferred to painful intramuscular injections, especially in children.

In neonates and children, the initial treatment usually consists of 25–50 mg Mg^{2+} sulphate (0.1–0.2 mmol Mg^{2+}) per kilogram body weight slowly given intravenously (over 20 min) (up to a maximum of 2 g Mg^{2+} sulphate, which is the adult dosage). This dose can be repeated every 6–8 h or can be followed by a continuous infusion of 100–200 mg Mg^{2+} sulphate (0.4–0.8 mmol Mg^{2+}) per kilogram body weight given over 24 h [178, 219].

In the presence of hypocalcemia, this regimen can be continued for 3–5 days. When Mg^{2+} is administered intravenously, Ca^{2+} gluconate (i.v.) should be available as an antidote. Control of blood pressure, heart rate, and respiration is important as well as a close monitoring of serum Mg^{2+} levels. Before administration, normal renal function has to be ascertained.

In asymptomatic hypomagnesemic or Mg^{2+}-deficient patients, oral replacement represents the preferred route of administration. Exact dosages required to correct Mg^{2+} deficiency are largely unknown. For the pediatric population, 10–20 mg Mg^{2+} (0.4–0.8 mmol) per kg body weight given three to four times a day have been recommended to correct hypomagnesemia [220]. Dosages for maintenance therapy (i.e. in hereditary disorders (see below)) vary between 10 and 100 mg Mg^{2+} (0.4–4 mmol) per kg per day.

Due to the laxative effect of oral magnesium and due to rapid renal excretion especially in case of high peak serum levels, the required daily amount should be given in two to four divided doses preferentially with meals. Solubility, intestinal absorption, and side effects greatly differ depending on the Mg^{2+} salt used for oral treatment. The bioavailability and pharmacokinetics of diverse Mg^{2+} salts have been reviewed [221]. Considering solubility, intestinal absorption and bioavailability, organic Mg^{2+} salts such as Mg^{2+} citrate or aspartate appear most suitable for oral replacement therapy. In addition, the laxative effect of these preparations seems to be less pronounced compared with inorganic Mg^{2+} salts. Moreover, slow-release formulations might be used if available. In our personal experience continuous administration of Mg^{2+}, for example dissolved in mineral water, has proven useful, as peak Mg^{2+} blood levels are avoided. When initiating therapy, dosages should be titrated based on blood levels and intestinal tolerance.

In addition to replacement therapy, the use of certain diuretics has been proposed for the reduction of renal Mg^{2+} excretion. The aldosterone antagonist spironolactone, as well as K^+ -sparing diuretics such as amiloride, exert Mg^{2+}-sparing effects [222, 223]. Studies in patients with hereditary Mg^{2+} wasting disorders showed beneficial effects of these diuretics on renal Mg^{2+} excretions, serum Mg^{2+} levels, and clinical manifestations [224, 225].

Disorders of Phosphorus Metabolism

38

Dieter Haffner and Siegfried Waldegger

Introduction

The underlying pathophysiological mechanisms of hypophosphatemic disorders have been unraveled during the last decade, although some puzzles remain to be solved. In 1937, Albright first reported on a patient with rickets and severe hypophosphatemia not responding to high doses of vitamin D. The term vitamin D resistant rickets was coined, and later the disease was named X-linked hypophosphatemic rickets respective X-linked hypophosphatemia (XLH) [1].

In recent years several underlying genes have been identified in distinct forms of hypophosphatemic rickets [2, 3]. Rickets is a disease of the growth plate and therefore only growing children are affected [4]. Whereas in the past rickets was thought to be a disease of calcium and vitamin D metabolism, there is growing evidence that rickets is due to insufficient availability of phosphate which is required for normal bone metabolism [5].

In principle, phosphate deficiency may result from inappropriate absorption in the gut or reabsorption in the kidney. The latter situation can be further divided between defects in the tubular reabsorption apparatus and abnormalities of circulating factors which regulate phosphate reabsorption [6]. The major breakthrough in our understanding of hypophosphatemic disorders was the discovery of fibroblast growth factor 23 (FGF23), a member of the FGF family, which mediates the combined renal tubular defects in phosphate reabsorption and altered vitamin D metabolism observed in patients with hypophosphatemic rickets [7].

Currently, specific disease-causing mutations in genes involved in the regulation of phosphate homeostasis can be identified in approx. 85% of familial or sporadic cases of hypophosphatemic rickets [8–11]. This chapter focuses on the etiology, pathogenesis, clinical presentation, differential diagnosis and treatment of hypophosphatemic disorders due to a reduction of renal tubular reabsorption.

Phosphate Homeostasis

Inorganic phosphate (Pi) is a key player in cellular metabolism and skeletal mineralization. It accounts for about 0.6 and 1% of body weight of a neonate and an adult, respectively. Approximately 85% of total body Pi content is

deposited as hydroxyl-apatite [$Ca_5(PO_4)_3OH$] in the skeleton and the teeth. About 14% distributes within the intracellular compartment. There, Pi participates in as diverse cellular processes as cell membrane function (phospholipids), energy metabolism (ATP), cell signaling (phosphorylation by kinases), and DNA- or RNA-biosynthesis (phosphorylated nucleotides). Only 1% of the total body Pi content is found as a soluble fraction in the extracellular compartment. There, Pi contributes to the acid-base buffering capacity of the plasma and even more important of the urine. Solely this tip of the iceberg is amenable to conventional laboratory investigations from blood and urine samples. Moreover, circulatory Pi is the central mediator between bone, the parathyroid glands, the gut and the kidneys, which are fine-tuned by numerous hormonal signals to keep the serum phosphate concentration within close limits.

In a steady state condition, as it is the case after completion of skeletal growth, the serum Pi concentration is determined by the balance between intestinal absorption of phosphate from the diet (16 mg/kg per day), bone-turnover of phosphate in the skeleton (3 mg/kg per day), and excretion of phosphate through the urine (16 mg/kg per day), (Fig. 38.1). In growing individuals, the balance of Pi must be positive to meet the needs of skeletal growth and consolidation. A typical Western diet commonly provides plenty of alimentary Pi, most of which provided by protein-rich foods like meat, milk and eggs. In contrast to plant-derived phosphate in the form of phytate (hexa-phospho-inosite), the animal derived phosphate is easily absorbed by the intestine, where roughly two thirds of the ingested phosphate are absorbed. Intestinal Pi absorption in growing infants is higher than in adults and can exceed 90% of dietary intake. Absorbed Pi first distributes in the extracellular compartment and then equilibrates with the bone and intracellular compartment. Within the kidney, Pi is freely filtered at the glomerular capillaries and is reabsorbed mainly along the proximal nephrons according to the actual requirements of the organism. The majority of the transepithelial Pi transport in the intestine

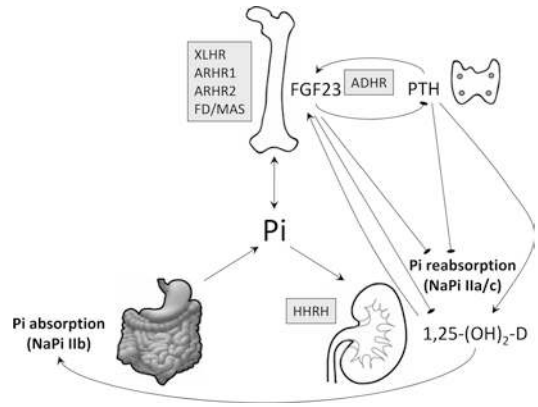

Fig. 38.1 Regulation of phosphate (P_i) homeostasis. FGF23 and PTH reduce renal tubular phosphate reabsorption via a decrease in apical expression of the sodium-phosphate cotransporters NaPi IIa and NaPi IIc. In contrast to FGF23, which inhibits 1,25-$(OH)_2$D synthesis, PTH stimulates 1,25-$(OH)_2$D production. 1,25-$(OH)_2$D increases intestinal absorption of dietary P_i via increased expression of NaPi IIb and activates FGF23 production. PTH and FGF23 affect each other's production through a negative feedback loop that is not yet fully elucidated. The mode of action of the therapeutic antibody burosumab is indicated. Note, burosumab is currently licensed for treatment of XLH and tumor induced osteomalacia (TIO), only. The sites of defect of the different genetic forms of hypophosphatemic disorders are given. *XLH* X-linked hypophosphatemia, *ARHR1/2* autosomal recessive hypophosphatemic rickets 1/2, *Raine S.* Raine syndrome, *FD/MAS* Fibrous dysplasia/McCune-Albright syndrome, *HHRH* hereditary hypophosphatemic rickets with hypercalciuria, *ADHR* X-linked dominant hypophosphatemic rickets. *FGF23 protein resistant to degradation

and the kidney is mediated by the type II family of sodium-coupled phosphate transporters, i.e. NaPi-IIa (NPT2a; *SLC34A1*), NaPi-IIb (NPT2b; *SLC34A2*), and NaPi-IIc (NPT2c; *SLC34A3*) [12]. NaPi-IIa is primarily localized at the brush border of proximal tubular epithelial cells and accounts for roughly 90% of renal phosphate reabsorption. Reabsorption of the remaining 10% is accomplished by NaPi-IIc exclusively expressed along proximal tubules of deep nephrons. Its critical contribution to Pi homeostasis is demonstrated by loss-of-function mutations, which leads to renal phosphate wasting resulting in the rare syndrome of hypophosphatemic rickets with hypercalcemia (HHRH) [13].

In contrast to NaPi-IIa and NaPi-IIc, NaPi-IIb shows a broader expression pattern including

pulmonary alveolar type II cells, where it participates in Pi uptake from the alveolar fluid for surfactant production. *SLC34A2* mutations cause pulmonary alveolar microlithiasis, a disease characterized by the deposition of calcium-phosphate crystals throughout the lungs [14]. In the intestine, NaPi-IIb is expressed in the brush border membrane of enterocytes and mediates absorption of ingested phosphate.

Regulators of Phosphate Homeostasis

The amount of intestinal phosphate absorption directly correlates with dietary supply. Only 30% of intestinal Pi absorption occurs in a regulated, 1,25-dihydroxyvitamin D [1,25-$(OH)_2$D] dependent manner. This poor regulation at the uptake level contrasts with the meticulous regulation of phosphate excretion within the kidney. Proximal tubular reabsorption of phosphate, mainly via regulation of expression of NaPi-IIa and NaPi-IIc within proximal tubular brush border membranes, thus plays a key role in maintaining serum phosphate homeostasis. The amount of renal phosphate reabsorption is tightly regulated primarily by dietary Pi intake, parathyroid hormone (PTH) and fibroblast growth factor 23 (FGF23). Other factors like insulin, human growth hormone, and possibly FGF7 also affect renal phosphate handling, but their actions are less well understood [15].

Dietary Pi intake directly affects the amount of renal phosphate reabsorption. An increase or decrease in dietary Pi induces an increase or decrease, respectively, in renal Pi excretion independent of vitamin D, PTH or FGF23. Part of this effect might be explained by a phosphate-responsive element in the promoter of the *SLC34A1* gene [16].

Parathyroid hormone is a major hormonal regulator of proximal tubular Pi reabsorption. PTH synthesis and secretion are up-regulated by low serum calcium and increased serum phosphate levels, and down-regulated by increased serum calcium and 1,25$(OH)_2$D levels. Its binding to proximal tubular PTH receptors results in an inhibition of NaPi-cotransport through mechanisms that involve rapid clearance of NaPi-IIa from the tubular epithelial brush border membrane [17]. On the other hand, PTH stimulates the synthesis of 1,25-$(OH)_2$D. The net effect of these actions is an increase of serum calcium levels and a decrease in serum phosphate levels.

Fibroblast Growth Factor 23 is a glycoprotein primarily synthesized in osteocytes and osteoblasts. FGF23 expression is induced by increased serum phosphate and 1,25$(OH)_2$D levels. In the presence of Klotho, a membrane bound protein with ß-glucuronidase activity, FGF23 binds with high affinity to the FGF receptor FGFR1 [15]. Klotho/FGFR1 mediated renal effects of FGF23 result in inhibition of proximal tubular Pi reabsorption and 1,25$(OH)_2$D synthesis. Its net effect thus is a reduction in serum phosphate and 1,25-$(OH)_2$D levels, which may result in hypocalcemia (Fig. 38.1).

Hypophosphatemic Disorders

Clinical, Biochemical, and Radiological Manifestations

Clinical Findings

The clinical and radiological features of the various types of hypophosphatemic rickets are similar, although not identical. In children, the primary clinical symptoms are rickets, skeletal pain and deformity, disproportionate short stature, and dental abscesses' (Figs. 38.2 and 38.3) [19]. In adults, osteomalacia, bone pain and stiffness, pseudofractures, enthesopathy and poor dental condition including periodontitis are typical findings. With medical therapy these abnormalities can be improved, but usually do not entirely resolve [18, 20]. Most children with hypophosphatemic rickets are identified in the first year of life if there is a known family history of the disorder. By 6 months of age, classic skeletal deformities may already appear including frontal bossing with flattening at the back of the head. In the absence of a family history, children often present at 2–3 years of age with delayed walking, muscle weakness, a waddling gait and

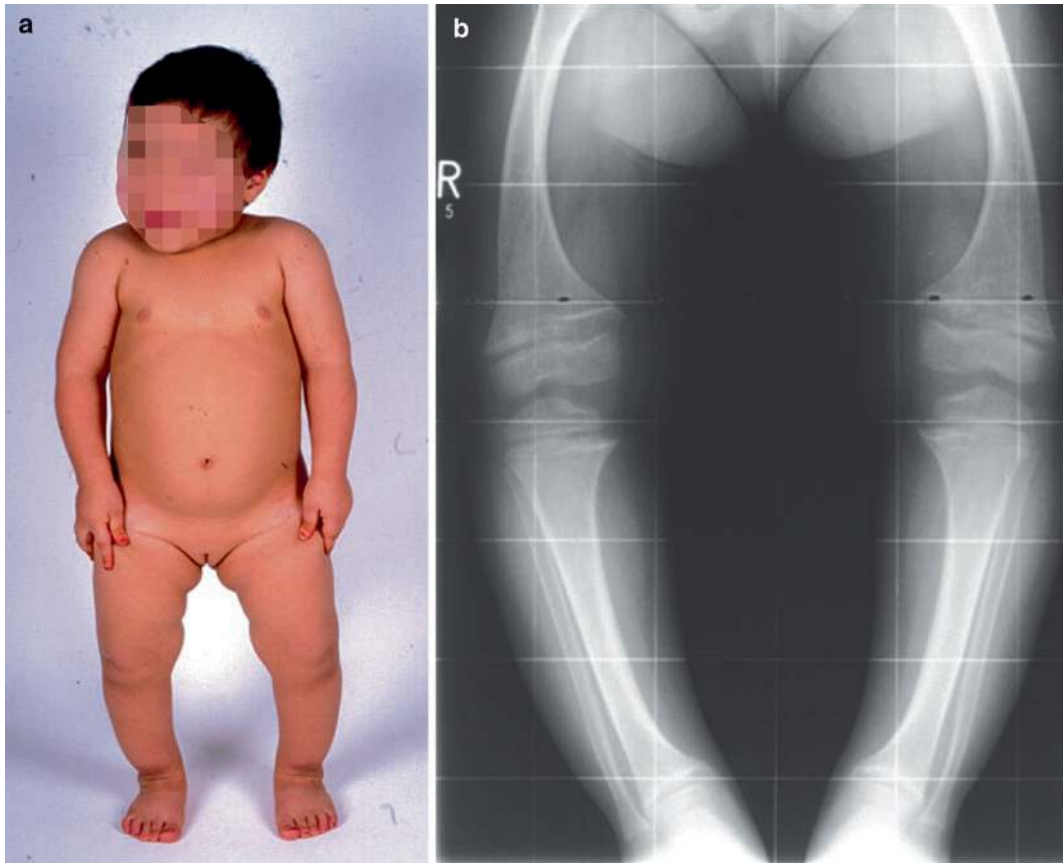

Fig. 38.2 Photograph (**a**) and radiograph of the lower extremities (**b**) of a 3-year-old girl with X-linked hypophosphatemia. The patient shows disproportionate stunting with bowed legs. The radiograph reveals severe leg bowing, partial fraying and irregularity of the distal femoral and proximal tibial growth plates

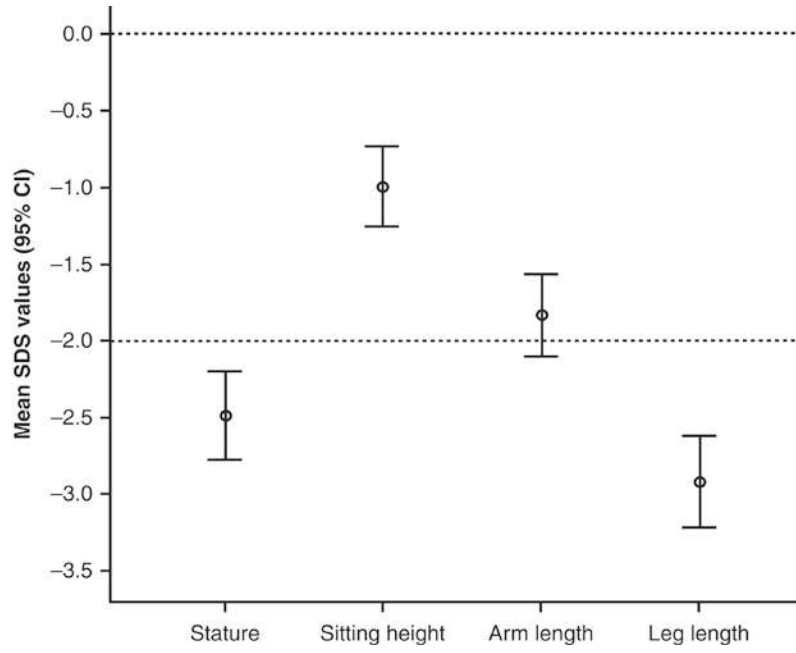

Fig. 38.3 Mean standard deviation scores (SDS) and 95% confidence intervals (CI) of stature, sitting height, and arm and leg length in 76 children with X-linked hypophosphatemia. Patients showed disproportionate stunting. Leg length was the most impaired and trunk length the most preserved linear body dimension (Used with permission of Nature/Springer from Zivicnjak et al. [18])

progressive lower extremity deformities (bow-legged). Leg growth is often more impaired than trunk growth resulting in disproportionate short stature [18]. Patients may present with abnormal skull shape, i.e. dolichocephaly, characterized by frontal bossing, parietal flattening and widened sutures due to premature cranial synostosis [21]. Common misdiagnoses are metaphyseal dysplasia and nutritional rickets. Long-term outcomes are substantially better when treatment is applied at an early age, i.e. in the first year of life [22–24]. In adults, the occurrence of pseudofractures of the long bones and enthesopathies may result in additional pain and substantially compromised quality of life [25].

Bone histology is influenced by the pathophysiology of the disease. In general, pure hypophosphatemia results in accumulation of unmineralized osteoid (Fig. 38.4), while the concomitant presence of hyperparathyroidism adds the component of enhanced bone resorption by osteoclasts [27]. However, establishing a diagnosis of phosphopenic osteomalacia requires histopathological proof that the abundant osteoid results from abnormal mineralization and not increased osteoid production. Thus, histopathological detection of an increase in the bone-forming cell surface by incompletely covered mineralized osteoid, an increase in osteoid volume and thickness and a decrease in the mineralization front (the percentage of osteoid-covered bone-forming surface undergoing calcification) or the mineral apposition rate is a prerequisite [27].

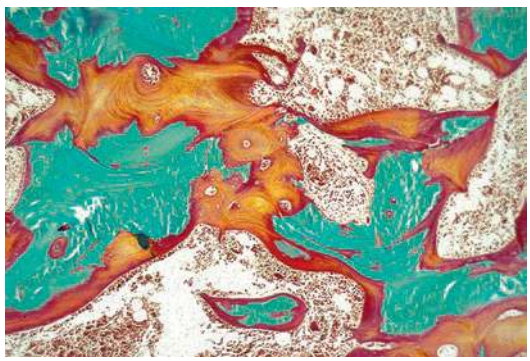

Fig. 38.4 Bone biopsy in a patient with X-linked hypophosphatemia showing abundance of unmineralized osteoid (orange), and decreased mineralization of trabecular and cortical bone (Used with permission of Nature/Springer from Schnabel and Haffner [26])

In addition to these skeletal defects, dental abnormalities contribute to considerable clinical morbidity. Tooth eruption may be delayed and teeth may exhibit inadequate dentine calcification [28–32]. As a result, the pulp chambers expand, and the overall barrier to external pathogens is compromised, thereby predisposing to dental abscesses. The prevalence of dental abscesses is about 25% in children and more than 85% in adults [33]. Individuals who present with one abscess usually develop multiple abscesses during follow-up, indicating that the development of one abscess predicts future abscesses. It is important to note that dental abscesses usually occur in the absence of caries. Finally, hypertension, left ventricular hypertrophy, nephrocalcinosis, and hearing loss have been identified in patients suffering from hypophosphatemic rickets, although it is not clear if these abnormalities are due to the disease itself or to the treatment [34–36].

Radiological Findings

The rachitic abnormalities in children with phosphopenic disease result in a variety of characteristic radiological findings in the skeleton. The growth plates of the long bones are cupped and show increased thickness and irregular, hazy appearance at the diaphyseal line (Fig. 38.2). The latter is due to an irregular invasion of recently calcified cartilage in bone tissue. These abnormalities preferentially occur at sites of rapid growth. Therefore, widening of the forearm at the wrist and thickening of the costochondral junctions frequently occur. For clinical confirmation, an x-ray of the knees and/or the wrist is usually sufficient to diagnose rickets [19]. In addition, other typical signs of rickets such as rachitic rosary and Harrison's groove may also develop.

Biochemical Findings

In general, the primary diagnosis of rickets is based on typical clinical and radiological findings (see above) in combination with an elevated serum alkaline phosphatase activity. Physicians often overlook the latter abnormality in children,

since normal levels in young children are high. On the other hand, in some affected patients, normal alkaline phosphatase activity might be observed. Moreover, in adults, the alkaline phosphatase levels are often inexplicably normal. For differential diagnosis of the various forms of rickets, additional biochemical parameters are needed. Phosphorus is the common denominator of all types of rickets [5, 6]. Therefore, the diagnostic approach focuses on the mechanisms leading to hypophosphatemia, i.e. (1) high PTH activity, (2) inadequate phosphate absorption from the gut, or (3) renal phosphate wasting. The latter may be due to either intrinsic tubular defects or high circulating FGF23 levels (Fig. 38.5) [5, 6, 19].

Renal phosphate loss can be evaluated through the tubular reabsorption of phosphate per glomerular filtration rate (TmP/GFR) as: $TmP/GFR = P_p - (U_p \times P_{cr}/U_{cr})$, where P_p, U_p, P_{cr} and U_{cr} refer to plasma and urine concentration of phosphate and creatinine, respectively. All values must be expressed in the same units, e.g. in milligrams per deciliter [37]. The normal range of TmP/GFR in infants and children (6 months – 6 years) ranges from 1.2 to 2.6 mmol/L and in adults from 0.6 to 1.7 mmol/L. An important pitfall to recognize is that in patients with insufficient intake or absorption of phosphate from the gut TmP/GFR might be falsely low when serum phosphate levels have not been restored to normal. This can usually be assumed in the presence of low urinary phosphate levels. In such cases, TmP/GFR should only be calculated after phosphate supplementation when serum and urine phosphate concentrations are raised.

Typically, in cases of hypophosphatemic rickets due to renal tubular abnormalities or elevated serum levels of FGF23, serum concentrations of calcium and PTH are normal before initiation of treatment. Circulating $1,25(OH)_2D$ levels are low or inappropriately normal in the setting of hypophosphatemia. Plasma FGF23 levels are usually elevated with the exception of HHRH patients. Measurement of serum $1,25(OH)_2D$ levels may be a useful tool for diagnosis in HHRH patients. In Table 38.1, the main biochemical features of the various forms of hypophosphatemic rickets due to perturbations in proximal tubule phosphate reabsorption compared to vitamin D defi-

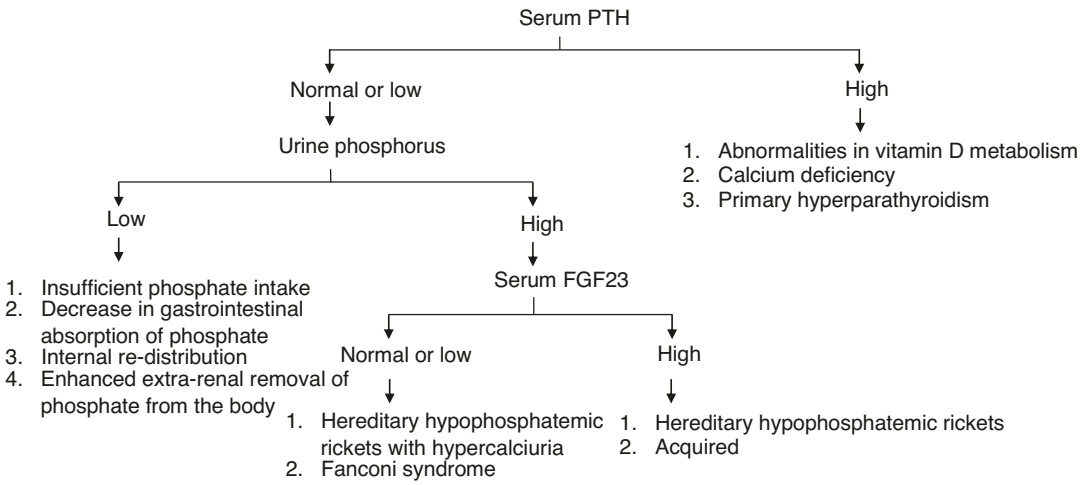

Fig. 38.5 Algorithm for the evaluation of the child with rickets presenting with hypophosphatemia. The differential diagnoses are based on the mechanisms leading to hypophosphatemia, namely high parathyroid hormone (PTH) activity, inadequate phosphate absorption from the gut, or renal phosphate wasting. The latter may be due to either primary tubular defects or high levels of circulating FGF23. Further details of individual entities can be found in Table 38.1; *FGF-23* fibroblast growth factor 23 (Used with permission of Nature/Springer from Haffner et al. [19])

[a] Cave: prevalence of vitamin D deficiency was reported to be up-to 50% in healthy children

[b] Normal after restoration of P, but falsely reduced before restoration

[c] PTH may be moderately elevated

[d] Decreased relative to the serum phosphate concentration

[e] Depending on the stage of chronic kidney disease

ciency rickets are summarized. Extended molecular genetic analysis may be required to establish diagnosis in unclear cases [38].

Hypophosphatemic Disorders with Increased FGF23 Activity

X-Linked Hypophosphatemia (*PHEX* Mutation)

X-linked hypophosphatemia (XLH) is the most frequent inherited phosphate wasting disorder, accounting for about 80% of familial cases with an incidence of 1:20,000 individuals. It typically presents within the first 2 years of life. Males usually show the full manifestation of the disease and females show a wide spectrum ranging from one identical to males to one with no clinical symptoms but only isolated hypophosphatemia. The characteristic laboratory results are hypophosphatemia, hyperphosphaturia, hyperphosphatasia and normocalcemia. Serum 25(OH)D and $1,25(OH)_2D$ levels are in the normal range [19]. However, the level of the latter appears to be decreased relative to the diminished serum phosphate concentrations. Elevated serum levels of FGF23 and mutations in the *PHEX* gene (phosphate regulating gene with homologies to endopeptidases on the X-chromosome) are found in most patients [11, 19, 39]. Of note, serum levels of phosphate, TmP/GFR and alkaline phosphatase activity might be in the normal range within the first 3 months of life in XLH patients. Therefore, in the case of a positive family history, affected patients should undergo mutation analysis of the *PHEX* gene in order to establish the diagnosis and treatment of XLH as early as possible [19]. More than 350 different PHEX mutations have been reported so far including nonsense, missense, frame shift, splice site, deletion and duplication mutations. Mutations were reported in all 22 *PHEX* exons without a hot spot and no genotype-phenotype correlations were found in children with XLH [8].

Although the genetic cause of XLH is well established, the exact pathogenic mechanisms of how mutations in the *PHEX* gene result in elevated plasma FGF23 levels remains to be elucidated. *PHEX* encodes for a membrane-bound endopeptidase and is primarily expressed in osteoblasts, osteocytes, odontoblasts, muscle, lung and ovary [40]. The finding that hypophosphatemia recurs in XLH patients undergoing kidney transplantation with prior parathyreoidectomy strongly suggested a circulating factor causing phosphate wasting in the kidney transplant [41]. Likewise, studies in *Hyp* mice, an orthologic animal model of XLH employing parabiosis and cross-transplantation of the kidneys between *Hyp* and normal mice, also showed recurrence of hypophosphatemia [42]. After it became clear that FGF23 is the cause of ADHR, FGF23 levels were measured in patients with XLH and *Hyp* mice. The majority of XLH patients as well as *Hyp* mice show elevated FGF23 levels [43, 44]. The normal FGF23 serum levels found in some XLH patients might still be viewed as inappropriately high in relation to the degree of hypophosphatemia. Administration of neutralizing antibodies to FGF23 corrects hypophosphatemia and decreases $1,25(OH)_2D$ levels in *Hyp* mice and patients with XLH and thus confirms the pathogenic role of FGF23 in XLH [45, 46]. Although PHEX is an enzyme, it is thought that *PHEX* affects the expression of FGF23 rather than its degradation [7, 47]. PHEX may regulate serum FGF23 indirectly via cleavage by proprotein convertases such as subtilisin/kexin-type 2 (PC2). In addition, *PHEX* malfunction results in increased skeletal synthesis of osteopontin and acid serine aspartate-rich-MEPE-associated protein (ASARM) peptide, both of which also contribute to impaired bone mineralization in XLH [7, 48]. Thus, XLH results from a complex osteoblast/odontoblast defect. Therefore, it remains to be seen whether therapeutic FGF23 blockade in patients with XLH (*vide infra*) will result in complete healing of bone and teeth abnormalities as well as prevention of rare complications like sensorineural hearing loss.

ADHR (*FGF23* Mutation)

Autosomal-dominant hypophosphatemic rickets (ADHR) is a rare disorder that was first described by Bianchine et al. in 1971 [49]. ADHR and XLH have marked clinical similarities but differ in their modes of inheritance. ADHR is due to activating mutations of the *FGF23* gene. The mutated

protein is resistant to cleavage by proteolytic activity, which in turn leads to elevated, circulating FGF23 level [50]. Elevated FGF23 levels result in phosphaturia, hypophosphatemia, and inappropriately low levels of $1,25(OH)_2D$. The penetrance of ADHR is incomplete, with a highly variable phenotype and, thus, variable symptomatology and biological findings. In contrast to XLH, patients suffering from ADHR may become symptomatic in adolescence or even during adulthood. During childhood, the clinical symptoms are similar to that observed in XLH, i.e. rickets with bone deformities, disproportionately short stature, and dental abnormalities (abscesses) [51]. If patients become symptomatic after puberty, complications due to osteomalacia, e.g. weakness, fatigue, bone pain and pseudofractures are the major symptoms. Adults present with symptoms similar to those with tumor induced osteomalacia (TIO), as discussed below. Interestingly, some children show improvement of phosphate wasting during puberty [52]. Studies in ADHR mice and humans suggest that iron status is an important regulator of FGF23 metabolic pathways [52–54]. Therefore, the onset of ADHR is the product of gene-environment interactions. Serum iron levels are negatively associated with FGF23 plasma level both in ADHR patients and in healthy subjects, indicating increased expression of FGF23 in the setting of a low iron status. A recent study in iron deficient adult ADHR patients demonstrated normalization of both serum FGF23 and phosphate levels by oral iron repletion [55]. Therefore, the standard approach to ADHR patients should also include the recognition and correction of iron deficiency.

ARHR (1, *DMP1* Mutation; 2, *ENPP1* Mutation)

The finding of hypophosphatemic rickets in consanguineous kindreds suggested an autosomal recessive form of hypophosphatemia (ARHR) [56]. Clinical symptoms are similar to those observed in XLH patients and affected individuals present with elevated FGF23 serum levels, renal phosphate wasting and inappropriately normal levels of $1,25(OH)_2D$. One characteristic radiological feature of this disorder is the relatively high bone density of the vertebral bodies. ARHR is either due to mutations in the *DMP1* gene encoding for dentin matrix acidic phosphoprotein 1 (ARHR1) or to mutations in the *ENPP1* gene encoding for ectonucleotide pyrophosphatase/phosphodiesterase 1 (ARHR2) [57–60].

DMP1 is a member of the short integrin-binding ligand interacting N-linked glycoprotein (SIBLING) family of skeletal matrix proteins and is highly expressed in mineralized tissues, e.g. in osteoblasts and osteocytes. It is an important regulator of the development of bone, cartilage, and teeth. How mutations in *DMP1* result in elevated FGF23 serum levels in ADHR1 patients is unclear.

Levi-Litan et al. identified an inactivating mutation in the *ENPP1* gene (later named ARHR2) that caused ARHR in a Bedouin family [60]. ENPP1 is a cell surface protein that catalyzes phosphoester cleavage of adenosine triphosphate, generating the mineralization inhibitor pyrophosphate. Mutations in *ENPP1* were initially reported in patients with infantile arterial calcifications [61] but clinical and biochemical manifestations can markedly differ even in patients presenting with the same biallelic *ENPP1* pathogenic variants and include enthesopathy and primary hyperparathyroidism [62]. It remains to be elucidated how inactivating *ENPP1* gene mutations result in increased FGF23 synthesis from bone.

Raine Syndrome Associated (*FAM20C* Mutation)

Raine syndrome is a rare skeletal disorder with highly variable clinical phenotype ranging from lethal to isolated teeth and/or bone phenotypes [63]. It is caused by biallelic mutations in the *FAM20C* gene coding for a protein kinase which phosphorylates FGF23 and thereby promotes FGF23 cleavage. Therefore, *FAM20C* mutations result in high serum FGF23 concentrations causing renal phosphate wasting with consecutive hypophosphatemic rickets [64, 65]. The majority of patients die in early life from respiratory failure [63].

Tumor-Induced Osteomalacia and Tumor-Induced Rickets (TIO)

Tumor-induced osteomalacia (TIO), also called tumor-induced rickets, is a rare disorder

characterized by hypophosphatemia, hyperphosphaturia, low $1,25(OH)_2D$ serum levels, and osteomalacia which develops in previously healthy individuals [66–68]. Therefore, in any patients presenting with hypophosphatemic rickets beyond the second year of life TIO should be excluded. Clinical symptoms are similar to that in XLHR or ADHR patients. TIO is caused by usually small, often difficult to locate, tumors. Most histologic diagnoses have been classified as phosphaturic mesenchymal tumors of the mixed connective tissue type. A characteristic histologic feature of these tumors is a background of spindle cells that tend to have low mitotic activity [66, 68]. Once the tumor is removed, the clinical symptoms quickly resolve, which has led to the notion that circulating factors produced by the tumor (phosphatonins) are causing renal phosphate loss in these patients. Later, TIO tumors were shown to contain high levels of FGF23 mRNA and protein, and TIO patients revealed elevated circulating FGF23 levels, which rapidly declined after removal of the tumor in parallel with resolution of clinical symptoms. The tumors are benign, but may recur. The paranasal sinuses, neck and mandible are common sites of these tumors. Newer imaging techniques such as nuclear magnetic resonance and positron emission tomography are helpful in establishing diagnosis of TIO. If tumor resection is not possible, treatment with the anti-FGF23 antibody Burosumab results in improvement of bone lesions [68].

Hypophosphatemic Rickets and Hyperparathyroidism

This is an extremely rare disorder caused by increased synthesis of α-Klotho. Patients reveal both hypophosphatemic rickets and hyperparathyroidism due to parathyroid hyperplasia. It is caused by *de novo* translocation resulting in elevated plasma α-Klotho levels [69]. Recently it was demonstrated that α-Klotho enhances FGF23-stimulated FGF receptor activation, and consequently inhibition of sodium phosphate transporter and hyperphosphaturia [70]. It is thought that the concomitant suppression of calcitriol production by α-Klotho/FGF23 action may cause increased production of FGF23 and PTH in these patients.

Fibrous Dysplasia (FD) and McCune-Albright Syndrome (MAS)

Fibrous dysplasia (FD) is characterized by fibrous skeletal lesions and localized mineralization defects. Patients may present with solitary or multiple bone lesions. When the skeletal findings occur in combination with abnormal skin pigmentation (e.g. café-au-lait spots), premature sexual development and/or thyrotoxicosis, the disease is called McCune-Albright syndrome (MAS) [71]. FD/MAS is a rare disorder due to post-zygotic gain-of-function mutations in the *GNAS1* gene, encoding for the α subunit of a stimulatory G protein [72]. G proteins function to couple specific receptors to intracellular signaling molecules. Phosphate wasting is due to increased secretion of FGF23 from bone lesions and the severity of hypophosphatemia correlates with the number of fibrous dysplasia lesions. However, how *GNAS1* mutations result in elevated FGF23 secretion is currently unknown.

Hypophosphatemic Disorders with Normal or Suppressed FGF23 Activity

HHRH (*SLC34A3* Mutation)

In 1985 Tieder et al. described an unusual case of hypophosphatemic rickets in a consanguineous Bedouin tribe [73]. In contrast to XLH, hypophosphatemia and phosphate wasting was associated with elevated $1,25(OH)_2D$ serum levels resulting in hypercalciuria and suppressed PTH plasma concentrations. The disorder was later shown to be caused by mutations in the *SLC34A3* gene encoding for the NaPi-IIc renal phosphate cotransporter in the proximal tubule, and many more patients were identified [74]. The reported mutations were all loss-of-function mutations and, most likely, reduced renal phosphate absorption through decreasing the apical membrane expression of NaPi-IIc or the uncoupling of sodium-phosphate co-transport in the proximal tubule [75]. Thus, in contrast to XLH and ADHR hypophosphatemia is not due to enhanced FGF23 serum levels in HHRH. The normal physiological reaction to hypophosphatemia resulting in increased serum elevated $1,25(OH)_2D$ levels results in increased

intestinal calcium absorption, hypercalciuria and suppression of PTH. Consequent to hypercalciuria, patients developed nephrocalcinosis and nephrolithiasis. Milder forms may be under-diagnosed and therefore careful evaluation of urinary calcium excretion before and during medical treatment is strongly recommended in all patients with hypophosphatemic rickets, especially in those without a proven underlying genetic cause [76].

Hypophosphatemia and Nephrocalcinosis (*SLC34A1* Mutation)

The *SLC34A1* gene is located on chromosome 5q34 and encodes for the NaPi-IIa renal phosphate cotransporter in the proximal tubule. *SLC34A1* mutations can lead to a wide range of clinical phenotypes including infantile hypercalcemia, kidney stones and rickets, all of which are accompanied by reduced serum phosphate levels [77, 78].

Nephrolithiasis and Osteoporosis Associated with Hypophosphatemia

Two different heterozygous mutations (A48P and V147M) in *NPT2a*, a gene encoding a sodium dependent phosphate transporter, have been reported in patients suffering from urolithiasis or osteoporosis and persistent hypophosphatemia due to decreased tubular phosphate reabsorption [79].

Fanconi Syndrome

Fanconi syndrome is characterized by generalized proximal tubular dysfunction with impaired ability to absorb water, phosphate, glucose, urate, amino acids and low molecular weight proteins. Other common features include increased excretion of sodium, potassium, calcium and bicarbonate. Clinical consequences result mainly from hypophosphatemia and metabolic acidosis, i.e. rickets and osteomalacia. The syndrome may be due to both genetic defects and acquired disorders (see Chap. 31).

Treatment of XLH

For more than four decades treatment of XLH patients was based on oral supplementation of inorganic phosphate salts and treatment with active vitamin D metabolites (calcitriol or alfacalcidol) [80]. Recently, a fully humanized anti-FGF23 antibody (burosumab) has become available for the treatment for XLH, which represents a major breakthrough and paradigm shift in the treatment of this disorder (Fig. 38.1). The advantages of burosumab over conventional treatment are (1) the removal of the burden to take medications several times a day as required with conventional treatment, which frequently leads to non-adherence particularly in adolescents and adults, (2) its greater efficacy in ameliorating rickets compared to conventional treatment, and (3) its excellent safety profile and removal of the typical side effects of conventional therapy such as diarrhea and nephrocalcinosis.

However, one has to keep in mind that the disease spectrum, and thus the medication requirement, is heterogeneous—some individuals are only minimally affected even without treatment [81]. Adults need less treatment than children or even no treatment depending on the clinical symptoms. Other forms of FGF23-dependent hypophosphatemic rickets like ADHR are usually treated with phosphate salts and active vitamin D, whereas FGF23-independent forms require disease specific therapeutic approaches *(vide infra)*.

The European Medicines Agency (EMA) and the U.S. Food and Drug Administration (FDA) approved burosumab to treat children ≥1 year and adults with XLH and TIO showing radiographic evidence of bone disease. If available, burosumab treatment should be considered in children with XLH ≥ 1 year and in adolescents with growing skeletons in the following situations: radiographic evidence of overt bone disease; disease that is refractory to conventional therapy; complications related to conventional therapy; or patient's inability to adhere to conventional therapy, presumed that adequate monitoring is feasible [19]. Evidence-based recommendations for the treatment of XLH were recently published and will be outlined below [19].

Phosphate Supplementation and Active Vitamin D Metabolites

Children in affected families should be screened for abnormal serum and urine phosphorus levels

and serum alkaline phosphatase activity within the first month of life and at 3 and 6 months, and if available should undergo *PHEX* gene mutation analysis [19]. In case of confirmed diagnosis, therapy with active vitamin D metabolites and phosphate should be started immediately. The required dosages differ largely depending on the severity of rickets (*vide infra*). In patients with negative family history for XLH, hypercalciuria should be excluded before initiation of calcitriol treatment. The latter would suggest the diagnosis of HHRH where calcitriol treatment is contraindicated.

Administration of phosphate increases the plasma phosphate concentration, which lowers the plasma ionized calcium concentration, and further reduces the plasma calcitriol concentration (by removing the hypophosphatemic stimulus of its synthesis). This causes secondary hyperparathyroidism [19, 82]. The latter can aggravate the bone disease and increase urinary phosphate excretion, thereby defeating the aim of phosphate therapy. Secondary hyperparathyroidism can be prevented by additional treatment with calcitriol. Calcitriol increases intestinal calcium absorption, and to a lesser degree phosphate, and consequently suppresses secondary hyperparathyroidism. In addition, it also directly suppresses PTH release.

The recommended starting dose of phosphate based on elemental phosphorus is 20–60 mg/kg/day (0.7–2.0 mmol/kg per day) in infants and preschool children, which should be adjusted according to the improvements of rickets, growth, alkaline phosphatase and parathyroid hormone levels [19]. Doses above 80 mg/kg per day should be avoided to prevent gastrointestinal discomfort and hyperparathyroidism. In infants diagnosed before they develop bone changes, the goal of the treatment is to prevent rickets. Important to note, serum phosphate levels increase rapidly after oral intake but return to baseline levels within 1.5 h. Therefore, phosphorus should be administered at least four times a day. Especially in infants and young children, a nighttime dose may be required to achieve satisfactory results. Liquid formulations may improve adherence and allow for more precise dosing in young children. Powders and crushed tablets may also be employed. Powders/tablets can be dissolved in water and the child may drink the solution at intervals during the day. It is important not to administer the phosphate preparation with dairy products, since their calcium content interferes with intestinal phosphate absorption. In general, phosphorus absorption is slower in capsule or tablet formulations than in liquid ones. Therefore, when possible, it is better to use the former. The recommended starting dose of calcitriol and alfacalcidiol is 20–30 ng/kg body weight and 30–50 ng/kg body weight daily respectively. Alternatively, treatment may be started empirically at 0.5 μg daily of calcitriol or 1 μg daily of alfacalcidiol in patients aged above 12 months and adjusted on the basis of clinical and biochemical response. In addition, supplementation with native vitamin D is recommended in case of vitamin D deficiency [19].

Monitoring and Dose Adjustments During Conventional Treatment

The primary goals of treatment are to correct or minimize rickets/osteomalacia, as assessed by clinical, biochemical and radiological findings. Serum alkaline phosphatase activity is a useful surrogate marker for bone healing. With adequate treatment, serum levels of alkaline phosphatase decrease, reaching normal or slightly elevated levels. A common misconception is that successful conventional treatment requires normalization of serum phosphate concentration, which is not a practical goal in these patients, since this could only be reached by excessive phosphate doses and paying the price of severe side effects like nephrocalcinosis and secondary hyperparathyroidism. Therefore, important measures of therapeutic efficacy include enhanced growth velocity, improvement in lower extremity bowing and associated abnormalities, and radiological evidence of epiphyseal healing.

Children should be seen every 2–4 months to monitor growth, serum concentrations of calcium, phosphate, alkaline phosphatase activity, creatinine, PTH and urinary calcium excretion. A random "spot" urine collection can be used to monitor urinary calcium excretion. The goal is to maintain a spot calcium/creatinine ratio < 0.3 mg/mg. Renal ultrasound should be performed at yearly intervals to detect nephrocalcinosis. The etiology of nephrocalcinosis, shown by kidney

biopsies to be composed of calcium phosphate precipitates, was thought to be due either to hypercalciuria, hyperphosphaturia, hyperoxaluria, hyperparathyroidism or any combination of these [19, 83–85]. However, the reported prevalence of nephrocalcinosis in XLH patients ranges between 17 and 80% and is clearly related to the dose of phosphate medication [18, 86, 87]. In addition, other soft-tissue calcifications, e.g. ocular, myocardial, and aortic valve calcifications, have been reported in XLH patients with persistent hyperparathyroidism and/or high dose treatment [34, 88]. Therefore, the calcitriol doses should be adjusted according to the serum levels of PTH and urinary calcium excretion. A high PTH level requires an increase in the calcitriol dose and/or a decrease of the phosphate dose.

The main side effect of an excessive dose of calcitriol is the development of hypercalciuria. In the presence of hypercalciuria the calcitriol dose should be reduced or thiazide diuretics added. The latter not only reduces urinary calcium excretion but also raises the TmP/GFR, most likely secondary to some degree of volume contraction.

Calcitriol and phosphate treatment increases FGF23 levels, thereby further stimulating urinary phosphate excretion [34]. Therefore, high dose treatment should not only be avoided to prevent hypercalciuria and nephrocalcinosis but also to prevent a vicious circle of therapy driven phosphate wasting. When secondary hyperparathyroidism cannot be adequately controlled by calcitriol treatment, i.e. persistent hypercalcemia and/or hypercalciuria, autonomous (tertiary) hyperparathyroidism can occur, necessitating surgical intervention.

It is often necessary to increase dosages of phosphate and calcitriol during the pubertal growth spurt as this may result in greater mineral demands and worsening of bowing defects so that a transient increase in dosage can be advantageous. Therapy with phosphate and calcitriol is maintained as long as the growth plates are open.

Burosumab

Efficacy and Safety

The efficacy and safety of burosumab has been investigated in three clinical trials in children with XLH [46, 89, 90]. In two open-label uncontrolled trials in a total of 65 children aged 1–12 years with severe XLH treated for 12–16 months, burosumab resulted in normalized TmP/GFR, near normal serum phosphate levels, increased $1,25(OH)_2$ vitamin D levels and significantly improved radiological rickets, bone pain and functional abilities [46, 91]. A head-on comparison between burosumab and conventional treatment was performed in an open-label phase 3 trial including 61 children aged 1–12 over 64 weeks [90]. After 40 weeks children treated with burosumab had significantly greater improvement in rickets severity scores than patients on conventional therapy (Fig. 38.6). Biochemical parameters such as serum alkaline phosphatase and serum phosphate levels were also rapidly normalized during burosumab treatment. Two-weekly dosing was superior to four-weekly dosing with respect to normalization of serum levels of phosphate and radiological improvement of rickets. The most common adverse reactions observed with burosumab were injection site reactions, headache and pain in the extremities.

Two open-label, uncontrolled trials and one randomized, double blind, placebo-controlled studies (including a total of 176 patients) have investigated burosumab in adult XLH patients, the majority of whom presented with skeletal pain associated with XLH and/or osteomalacia [91–95]. Four-weekly doses of burosumab given for 4–12 months yielded the following outcomes: significantly increased TmP/GFR and consequently raised serum levels of phosphate into the lower normal range and increased $1,25(OH)_2$ vitamin D levels; healed osteomalacia, and accelerated healing of active fractures and pseudofractures; and significantly reduced stiffness. It is important to note that conventional treatment with oral phosphate and active vitamin D metabolites should be stopped at least one week before the start of burosumab therapy for wash-out and to prove that fasting serum phosphate levels are below the normal reference for age.

Monitoring and Dose Adjustments During Burosumab Treatment

Burosumab should be started at a dose of 0.8 mg/kg body weight, given every 2 weeks subcutane-

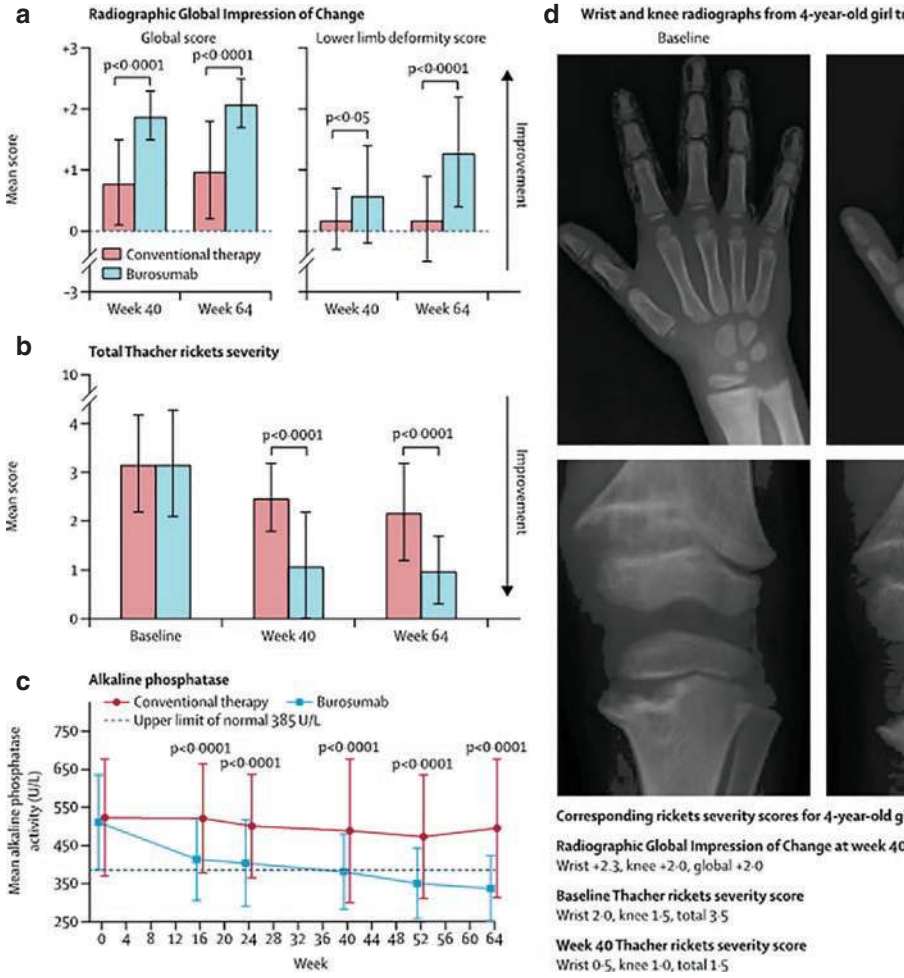

Fig. 38.6 Improvements in rickets severity in children on burosumab versus conventional therapy with phosphate and active vitamin D metabolites. Data in panels **a**, **b**, and **c** are reported as mean (SD). p values are based on the comparison between treatment groups in the least squares mean change from baseline, using the ANCOVA model for the week 40 Radiographic Global Impression of Change global score and week 40 Thacher rickets severity score assessments, and the generalized estimating equation model for alkaline phosphatase assessments, lower limb deformity assessments, and week 64 rickets assessments. The upper limit of normal for alkaline phosphatase varies by age and sex: girls aged 1–4 years 317 U/L, 4–7 years 297 U/L, 7–10 years 325 U/L, and 10–15 years 300 U/L; boys aged 1–4 years 383 U/L, 4–7 years 345 U/L, 7–10 years 309 U/L, and 10–15 years 385 U/L. These ranges were provided by Covance laboratories. Radiographs in panel **d** show improvement in rickets with burosumab in a 4-year-old girl who previously received conventional therapy for approximately 26 months (Used with permission of Elsevier from Imel et al. [90])

ously. Burosumab should be titrated in 0.4 mg/kg increments to raise fasting serum phosphate levels to the lower end of the normal reference range for age, to a maximum dosage of 2 mg/kg body weight (maximum dose 90 mg).

The half-life of burosumab is approximately 19 days and the peak serum concentration of burosumab occurs at 7–11 days after injection. Therefore, it is recommended to monitor fasting serum phosphate levels during the titration period

between injections, ideally 7–11 days after last injection in order to detect hyperphosphatemia. After achievement of a steady-state, which can be assumed after 3 months of a stable dosage, fasting serum phosphate levels should be assessed directly before injections in order to detect hypophosphatemia. In some patients burosumab might initially improve TmP/GFR while serum level of phosphate is still below the normal range owing to the high demand for phosphate of the bone. Therefore, TmP/GFR should be monitored together with fasting serum phosphate levels as a measure of drug efficacy. Serum levels of $1,25(OH)_2$ vitamin D might increase under burosumab therapy and should be monitored together with urinary calcium excretion.

Burosumab should be withdrawn if fasting serum phosphate level is above the upper range of normal. Burosumab can be restarted at approximately half of the previous dose when serum phosphate concentration is back within the normal range. Important to note, burosumab must not be given in conjunction with conventional treatment, when fasting phosphate levels are within the age-related normal range before initiation of treatment, or in the presence of severe renal impairment.

Adjunctive Therapies

Growth Hormone

Adult height is reduced in up to 60% of XLH patients and burosumab did not substantially improve longitudinal growth in pediatric XLH patients in clinical trials [19]. Although an impairment of the somatotropic hormone axis is not the primary cause of short stature in XLH patients, the physiological antiphosphaturic effect of growth hormone (GH) by stimulation of phosphate retention may be a useful adjunct to conventional treatment in improving growth in poorly growing XLH patients. Several mostly uncontrolled studies and a placebo-controlled randomized trial have documented sustained increases in age-standardized height during treatment periods of up to 3 years, and prepubertal patients responded better to GH than pubertal patients [96–102]. In a randomized trial on 3-year rhGH treatment in severely short prepubertal XLH patients, standardized height increased in the rhGH group by 1.1 SD scores with no change in body disproportion, whereas no significant change in standardized height was noted in controls [102]. In line with previous uncontrolled studies, a transient rise in TmP/GFR, and consequently of serum phosphate concentrations, was noted during the first 6 months of GH treatment but not in controls. Importantly, the degree of leg bowing tended to be higher in GH treated patients. Long-term follow-up of the same study failed to show significant benefits on the adult height, most likely due to the low number of patients followed up to adult height. In another study mean final height was significantly increased compared to non-randomized controls [97, 103]. Therefore, administration of rhGH should be considered in XLH patients with persistent short stature despite adequate metabolic control [19].

Calcimimetics

The calcimimetic compound cinacalcet reduces PTH levels in XLH patients, leading to increases in TmP/GFR and serum phosphate [104, 105]. The cinacalcet-induced decrease in serum PTH was accompanied by a slight decrease in serum-ionized calcium concentrations and was not associated with clinical symptoms. Similarly, Geller et al. proved the efficacy of cinacalcet in increasing serum phosphate levels in patients with TIO [106]. It has been suggested that long-term adjunctive treatment of XLH patients with cinacalcet may allow for lower doses of phosphate and calcitriol and thus may minimize the risk of secondary hyperparathyroidism, hypercalcemia, hypercalciuria and nephrocalcinosis caused by high-dose phosphate and calcitriol treatment [19]. However, randomized controlled trials on the long-term efficacy and safety of this drug in XLH patients are lacking.

Surgical Management

Many patients require surgical corrections of severe bowing, regardless of adequate medical treatment [19, 107]. In general, it is recommended that patients presenting with persisting

deformity despite optimized medical treatment and/or the presence of symptoms interfering with function should be considered for surgical treatment [19, 107–109]. The age of the child should be considered as an important factor in the decision-making process. Corrective osteotomies are not usually performed in children aged less than 6 years, as medical therapy often improves bone deformities in this age group. Newer, less-invasive approaches include epiphysiodesis, which induces differential corrective growth of the growth plate. Guided growth techniques depend on the remaining growth potential of the child and must therefore be carried out at least 2–3 years before skeletal maturity (age 14 in girls and age 16 in boys). By contrast, the complications associated with osteotomy reduce when the surgery is performed later in childhood or after skeletal maturity. Calcitriol medication should be adjusted during times of immobilization to avoid hypercalcemic episodes [19].

Dental Care

Children and adult patients with XLH might present with spontaneous endodontic infections on apparently intact teeth [19, 30]. Dental abscesses can develop on deciduous as well as on permanent teeth. The endodontic infection might be asymptomatic for months or years or it might evolve into dental abscesses, causing pain and swelling. Dental complications in patients with XLH are secondary to poorly mineralized dentin. On dental radiographs, the pulp chambers of deciduous or permanent teeth are larger than usual with long pulp horns extending to the dentino-enamel junction. In addition, the frequency and severity of periodontitis is increased in adult patients with XLH and can lead to tooth loss.

Conventional treatment improves dentin mineralization, reduces the number of dental abscesses, and decreases the frequency and severity of periodontitis [110, 111]. The effect of burosumab on dental health in XLH patients is currently unknown.

In children, in addition to standard preventative care, dental visits every 6 months are recommended and sealing of pits and fissures with flowable resin composite on both temporary and permanent teeth should be considered, as soon and as frequently as required. In adults, twice-yearly visits are recommended to perform conventional supportive periodontal therapy. Visits should include a thorough clinical investigation searching for pulp necrosis (color changes, fistula, swelling, abscess, cellulitis or pain), and performance of retrocoronal and/or periapical radiographs or orthopantomogram to search for enlarged pulp chambers and periapical bone loss depending on findings from a clinical examination. Finally, optimized conventional medical treatment of XLH is recommended before initiation of orthodontic treatment [19].

Expected Outcomes

Children with XLH have normal length at birth and show growth retardation, hypophosphatemia and rickets during the first year of life [112, 113]. With conventional treatment, growth and skeletal deformities generally improve. Height velocity commonly increases during the first year of treatment. Leg deformities may correct spontaneously obviating the need for surgery, although this is not always the case. Despite general growth improvement during treatment, correction is limited and adult height is often compromised. Median adult height in XLH patients on calcitriol and phosphate supplements (median age at start 2.3 years) published during the last two decades amounted to −2.3 SDS (range −2.7 to −1.2 SDS) [20, 22, 24, 103, 112–115]. However, growth outcome is significantly better if treatment is initiated early (<1 year). In three studies the mean standardized height after average treatment periods of 10 years was substantially higher in XLH patients with early compared to late treatment (−0.7 SDS versus −2.0 SDS, $p < 0.01$; −1.3 SDS versus −2.0 SDS, $p = 0.06$; Fig. 38.7; −0.7 SDS versus −2.0 SDS, $p < 0.01$) [22–24]. However, even early treatment does not completely normalize skeletal development, and the main effect of early treatment was the prevention of a severe height deficit during early childhood.

A recent North American cross-sectional study in 232 adult XLH patients treated with conventional therapy during childhood and adoles-

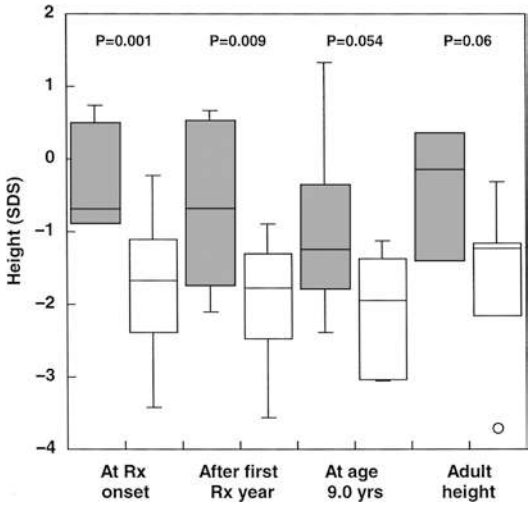

Fig. 38.7 Height z-scores in XLH patients started on calcitriol and phosphate treatment within the first 12 months of life 1 (■) and after the age of 12 months (□) at treatment onset, at the end of first treatment year, at age 9 years, and at final height (adult height or predicted adult height). The bottom of each box indicates the 25th, the cross line the 50th, and the top the 75th percentile; the bottom and top lines indicate the minimum and maximum values. P values refer to the difference between groups. *Rx* Treatment (Used with permission of Makitie et al. [23])

cence revealed a high prevalence of short stature (80%), bone or joint pain/stiffness (97%), and history of pseudofractures (44%) [116]. In addition, osteophytes, enthesopathy and spinal stenosis were reported in 46%, 27%, and 19% of patients, respectively. Similar results were reported in several European studies [25, 117, 118]. Reduced quality of life was shown in 84% of adult patients and associated with age and presence of structural lesions such as enthesopathy [25].

Zivicnjak et al reported on age-related stature and linear body dimensions in 76 children with XLH [18]. Despite calcitriol and phosphate treatment XLH patients showed progressive stunting and body disproportion during childhood, which was mainly due to diminished growth in the legs; growth of the trunk was less affected (Fig. 38.8). This resulted in an ever-increasing sitting height index (i.e. ratio between sitting height to stature).

Treatment with burosumab results in substantial improvement of ricketic bone lesions and degree of leg deformities but only minor changes in standardized height in children aged 1–12 years treated for up to 16 months. The observed limited growth improvement may be due to rather short observation periods and/or the primary osteoblast defect in XLH. Long-term outcome data on the impact of burosumab on linear growth and final height, dental health and rare complications such as hearing loss are urgently required, and multinational patient registries have been initiated to address this issue.

Treatment of Other Forms of Hypophosphatemic Rickets

Limited experience is available regarding the treatment of other forms of hypophosphatemic rickets. In general, hypophosphatemic conditions associated with elevated FGF23 and low/inappropriately low $1,25(OH)_2D$ levels, i.e. **ADHR and ARHR** are treated similarly as XLH. However, burosumab is currently not licensed for treatment of these FGF23 driven diseases.

In patients with **FD/MAS**, treatment with bisphosphonates results in decreased serum FGF23 levels and improves TmP/GFR [18, 119]. Treatment with bisphosphonates in combination with cabergoline, a synthetic ergot alkaloid which acts as a long-acting D2-selective dopamine agonist, successfully arrested both dysplastic bone growth and endocrine malfunction in a female patient with FD/MAS and severe facial involvement [119, 120]. This approach might be a suitable option in order to circumvent surgical interventions that might be of particular risk in patients suffering from polyostotic FD involving the skull base.

In patients with **TIO**, tumor removal usually results in a rapid clinical improvement but tumors might recur. Before surgery, patients are treated similarly to XLH patients. Cinacalcet was successfully used in TIO patients resulting in increased TmP/GFR and serum phosphate concentrations, thereby allowing the use of significantly lower doses of phosphate and calcitriol before surgery [106]. If available, patients may

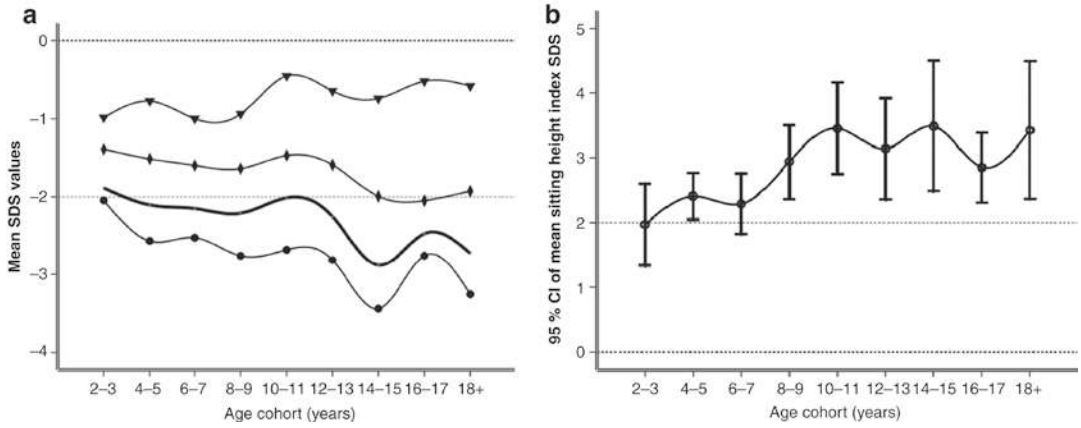

Fig. 38.8 Stature, sitting height, and arm and leg length (**a**) as well as the sitting height index (**b**) as a function of age in 76 children with XLH on conventional treatment. To assess age-related changes in body dimensions, all measurements were grouped according to age at the time of examination. Each age cohort comprised eight up to 26 children with 16 up to 38 measurements. A spline function was used to fit age-related changes. Unmarked solid line Stature, solid line with filled circles leg length, solid line with filled rhombuses arm length, solid line with filled inverted triangles sitting height. The 95% CI is indicated for sitting height index [18]

also be effectively treated by burosumab, which should be the preferred treatment option if tumor resection is not possible [68].

Treatment of **HHRH** usually requires the administration of phosphate salts alone. In fact, treatment with calcitriol may lead to nephrocalcinosis and chronic renal failure. The treatment goal is to provide sufficient phosphorus to improve mineralization of osteoid. In addition, oral phosphate supplementation is supposed to normalize decreased FGF23 levels and thereby suppress elevated circulating $1,25(OH)_2D$ level and consequently reduce intestinal calcium resorption and hypercalciuria [19, 121].

Renal Tubular Acidosis

39

R. Todd Alexander and Detlef Bockenhauer

Introduction

Plasma pH is maintained in a very tight range, from 7.35 to 7.45, via multiple regulatory mechanisms including buffering, altered respiration and ultimately fine regulation by the kidney. This tight control of plasma pH is essential for many physiological functions including but not limited to: proper folding and functioning of proteins, neural transmission and cardiac contractility. Typically, perturbations in plasma pH are caused by alterations in respiration or the presence of exogenous acids, which overwhelm the remarkable underlying capacity of the body to regulate plasma pH. However, less commonly, excess loss of bicarbonate from the gut or kidney, or the failure of the renal tubule to excrete acid is at fault. It is these less common causes of metabolic acidosis that are the subject of this chapter.

In order to understand the molecular pathogenesis of renal tubular acidosis, it is a prerequisite to know both the role of the kidney in the maintenance and regulation of plasma pH and its interrelation to other processes that participate in acid-base homeostasis. Proteins and phosphate mediate buffering in the cell. In the extracellular compartment bicarbonate is the predominant buffer preventing decreases in pH in response to an acid load. This is followed by an increase in respiratory rate and depth (respiratory compensation). Finally, the kidneys respond by increasing bicarbonate reabsorption, a process that leads to increased ammoniagenesis and ultimately facilitates increased acid secretion from the distal nephron. A detailed discussion of buffering and respiratory control of acid-base status is beyond the scope of this chapter. However, in order to inform the discussion of the pathophysiology of altered tubular handling of acid, we will begin by detailing the current understanding of how the kidney participates in acid-base homeostasis.

Physiology of Renal Acid-Base Handling

Bicarbonate Reabsorption

A significant amount of bicarbonate is filtered and consequently reabsorbed daily in order to preserve extracellular buffering capacity [1, 2]. Assuming a GFR of 120 mL/min in the average adult male and a plasma bicarbonate concentration of 24 mM, this amounts to approximately

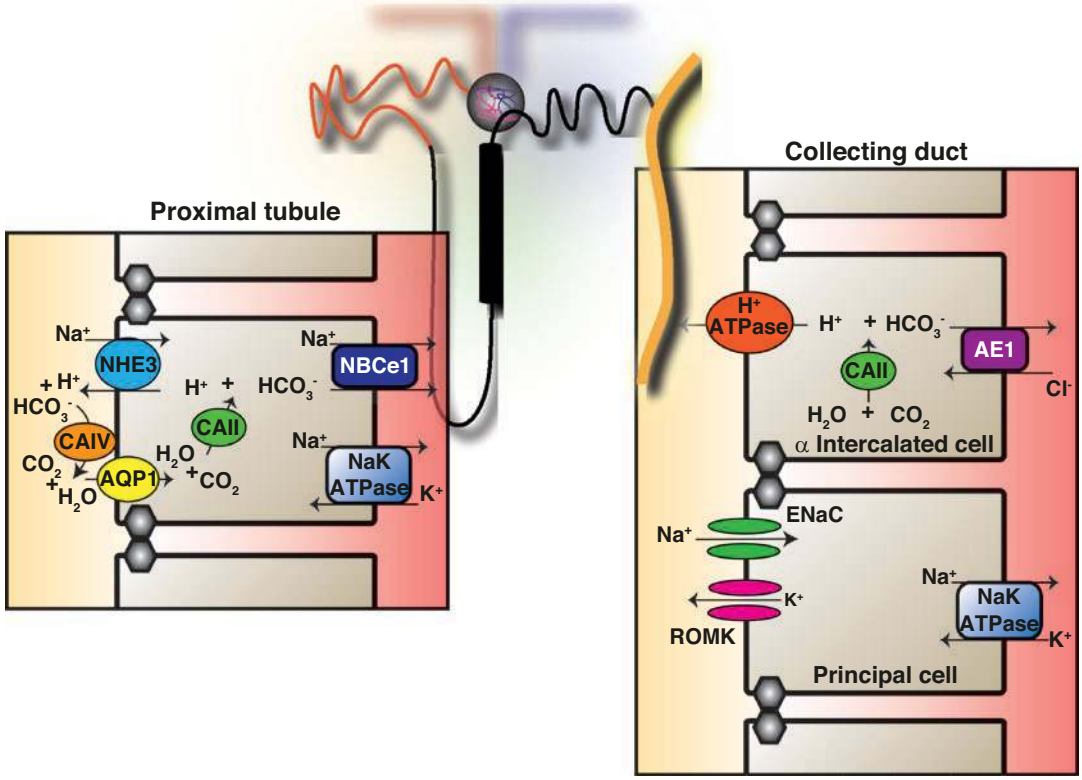

Fig. 39.1 Renal handling of bicarbonate and acid. The majority of filtered bicarbonate (HCO_3^-) is reabsorbed from the proximal tubule, after enzymatic (carbonic anhydrase IV, CAIV) conversion to water and carbon dioxide (CO_2). This is facilitated by proton excretion through the sodium proton exchanger isoform 3 (NHE3). In the cytosol carbonic anhydrase II (CAII), converts the water and CO_2 back into a proton, which is recycled through NHE3, and HCO_3^-, which is effluxed back into the blood through the sodium bicarbonate cotransporter NBCe1. In the collecting duct, H^+ is secreted from the α-intercalated cell via the apically expressed H^+ATPase. The proton is generated via the catalysis, by CAII, of water and CO_2. This also generates HCO_3^-, which is exchanged for Cl^- by the basolateral anion exchanger (AE1). In principle, cell sodium is reabsorbed through the epithelial sodium channel (ENaC). As this is an electrogenic process, either potassium (K^+) excretion trough ROMK or proton secretion via the H^+ATPase is required to maintain a permissive potential difference across the luminal membrane

4150 mmoles of bicarbonate that is filtered daily. Under normal circumstances the urine is free of bicarbonate, which means that all filtered bicarbonate is reabsorbed by the nephron [3] (Fig. 39.1). The vast majority is reabsorbed from the proximal tubule [4, 5]. Animal experiments provide evidence for bicarbonate reabsorption also in the thick ascending limb and the collecting duct, albeit to a much lesser degree [6–11]. The relative amount of bicarbonate absorbed from these sites varies depending on physiological status but in normal physiologic conditions is never more than a fraction of the proximal tubule's contribution to this process [3].

Proximal Tubule

There is no known bicarbonate transporter in the apical membrane of the proximal tubule. Consequently filtered bicarbonate is converted to water and carbon dioxide by a brush border membrane carbonic anhydrase [12]. Carbonic anhydrase IV and likely also the transmembrane isoform carbonic anhydrase XIV mediate this function [13–15]. The water channel, aquaporin-1, permits the rapid influx of water into the proximal tubular epithelial cell [16–19] and may also facilitate the permeation of carbon dioxide [20–22], in addition to diffusion across the membrane down its concentration gradient [23]. Cytoplasmic

carbonic anhydrase II, which interacts directly with aquaporin-1 enhancing water flux, then converts intracellular water and carbon dioxide back into bicarbonate and a proton (through the intermediate carbonic acid) [24–29]. The proton is exchanged for a sodium ion, predominantly by the apical sodium proton exchanger isoform 3 (NHE3) [30–33], while the bicarbonate is extruded back into the circulation across the basolateral membrane via the electrogenic sodium dependent bicarbonate transporter (NBCe1) [34, 35]. Yet, while mutations in *SLC4A4* (encoding NBCe1) are associated with a severe form of inherited pRTA, mutations in *SLC9A3* (encoding NHE3) cause congenital sodium diarrhea with only mild renal bicarbonate wasting [36–39]. This likely reflects redundancy provided by other NHE isoforms, such as NHE8 [40].

There is also a proton pump, H^+ ATPase which effluxes protons into the lumen of the proximal tubule [41, 42], although its contribution to proximal tubular bicarbonate reabsorption is minimal relative to that of NHE3 [32]. The majority of bicarbonate transport occurs in the first part of the proximal tubule [43]. This results in a slightly lumen negative transepithelial potential difference which is believed to be responsible for driving paracellular chloride reabsorption from the latter part of the proximal tubule [44, 45].

Thick Ascending Limb of Henle's Loop

NHE3, the epithelial sodium proton exchanger, is also expressed in the apical membrane of the thick ascending limb of Henle's loop (TAL) [46]. Consequently, bicarbonate reabsorption from this segment is felt to occur via a similar process as in the proximal tubule [47, 48]. The absence of aquaporin-1 from this segment may explain the decreased efficiency of bicarbonate reabsorption from the thick ascending limb relative to the proximal tubule [16]. Efflux across the basolateral membrane is mediated by the anion exchanger isoform 2 [49–51].

Collecting Duct

Any remaining bicarbonate reaching the collecting duct is reabsorbed by an analogous process [7, 8]. Efflux of a proton into the lumen permits the titration of bicarbonate back into carbonic acid and then carbon dioxide and water. Proton efflux is achieved via a luminally situated V-type H^+ ATPase, also called a proton pump [52]. Apically expressed proton pumps are only found in α-intercalated cells [41, 53, 54], whose apical membranes are largely impermeable to water, although carbon dioxide could diffuse into the epithelial cells of the collecting duct including α-intercalated cells. Intracellular carbon dioxide is hydrated, generating a proton and bicarbonate. This is achieved by cytosolic carbonic anhydrase II [54, 55]. The *de novo* generated bicarbonate is then extruded into the circulation via the basolateral anion-exchanger (AE1) [56]. This is the same mechanism permitting the trapping of ammonium in the distal nephron described below.

Acid Secretion

Acid secretion is achieved in the collecting duct via the mechanism described above for the titration of bicarbonate. The luminal H^+ ATPase in α-intercalated cells secretes a proton that is trapped by converting ammonia into ammonium, or by titrating another acid [57, 58]. These so-called titratable acids include: bicarbonate, phosphate and sulphate. The proton is generated from cytosolic carbon dioxide and water via the action of carbonic anhydrase II [24, 55]. The bicarbonate generated by this process is extruded back into the circulation in exchange for a chloride via AE1 [59, 60]. Moreover, there is a potassium-proton pump in the apical membrane of collecting duct α-intercalated cells, which also participates in acid secretion, although to a lesser extent [61–63].

Beta-intercalated cells exhibit essentially reverse polarity to α-intercalated cells and thus have an opposite function, as they can generate and secrete bicarbonate into the urine and a proton back into the circulation [8, 41, 53]. They contain a chloride bicarbonate exchanger in their apical membrane, Pendrin, and a proton pump in the basolateral membrane [54, 64–66]. They also contain a cytosolic carbonic anhydrase, CAII [60, 64]. Importantly, recent evidence has implicated

this cell type in sodium and chloride reabsorption [67, 68]. ß-intercalated cells nearly completely lack the expression of the Na^+/K^+ ATPase, instead the basolateral H^+ ATPase appears to drive transport across this cell type [69]. This facilitative role of the H^+ ATPase may contribute to the polyuria and volume contraction often observed in patients with distal renal tubular acidosis due to mutations in this pump [70, 71].

Ammonia Genesis and Recycling

Ammonia (NH_3) is the major urinary buffer and consequently its protonation to ammonium (NH_4^+) is essential for the efficient urinary excretion of acid [57, 72].

Ammonia Genesis

Ammonium is produced in the proximal tubule from glutamine and then secreted into the lumen [73]. Free circulating glutamine in the plasma enters the proximal tubular epithelial cell across the basolateral membrane via the LAT2 amino acid transporter [74]. Glutamine in the cytosol then enters the mitochondria via an electroneutral uniporter [75] where it is first converted to glutamate by glutaminase, then to ammonium by a glutamate dehydrogenase [76]. These enzyme-catalyzed reactions produce bicarbonate, which is returned to the circulation via the sodium-dependent bicarbonate transporter NBCe1. Of note, hyperkalemia inhibits the generation of ammonia [77].

Ammonia Recycling

Ammonium has been thought to be secreted into the proximal tubule by substituting for sodium on the apical sodium proton exchanger NHE3 [78–81]. However, a study employing a proximal tubular *Nhe3* knockout mouse argues against this role for the exchanger [39]. Alternatively, another EIPA (Ethylisopropyl-amiloride) sensitive sodium proton exchanger that is expressed in the apical membrane of the proximal tubule such as NHE8 may play this role [32, 82, 83], or free ammonia may diffuse into the lumen where proton excretion may trap it by conversion to ammonium.

Luminal ammonium then travels down the thin descending limb. In TAL, a nephron segment largely impermeant to ammonia, luminal ammonium is absorbed into the tubular epithelial cell across the apical membrane via the sodium potassium chloride co-transporter NKCC2 [84]. Ammonium is approximately the size of potassium and consequently can substitute for it. Thus hyperkalemia can inhibit ammonium excretion, as increased luminal concentrations of potassium will compete with ammonium for the transport site on NKCC2, preventing its influx into the tubular epithelial cell [85, 86]. Once transported across the luminal membrane of TAL cells, it diffuses across the basolateral membrane into the interstitium in the form of ammonia. Accumulation in the interstitium occurs as the apical membrane is impermeable to ammonia, preventing a back leak of ammonia into the tubular lumen [87].

This medullary interstitial accumulation of ammonia is essential to the efficient excretion of acid as it provides a concentration difference, from interstitium to lumen of the collecting duct for ammonia diffusion into the lumen. Consequently, ammonia diffuses into the lumen of the collecting duct where it is trapped via the excretion of protons as ammonium [88, 89]. The collecting duct is relatively impermeable to ammonium [90]. There is evidence implicating RhCG, a rhesus glycoprotein homologue, in this process as it forms a pore in the apical and basolateral membranes of the collecting duct epithelial cells permitting the passage of ammonia, but not ammonium [91–94]. Proton excretion is achieved as described above via apically expressed ATPases, predominantly the V-type H^+ ATPase and to a lesser extent the H^+K^+-ATPase. Ultimately, ammonium generation in the proximal tubule, recycling in the loop of Henle and finally trapping in the collecting duct permit significant and efficient proton excretion in the urine (Fig. 39.2).

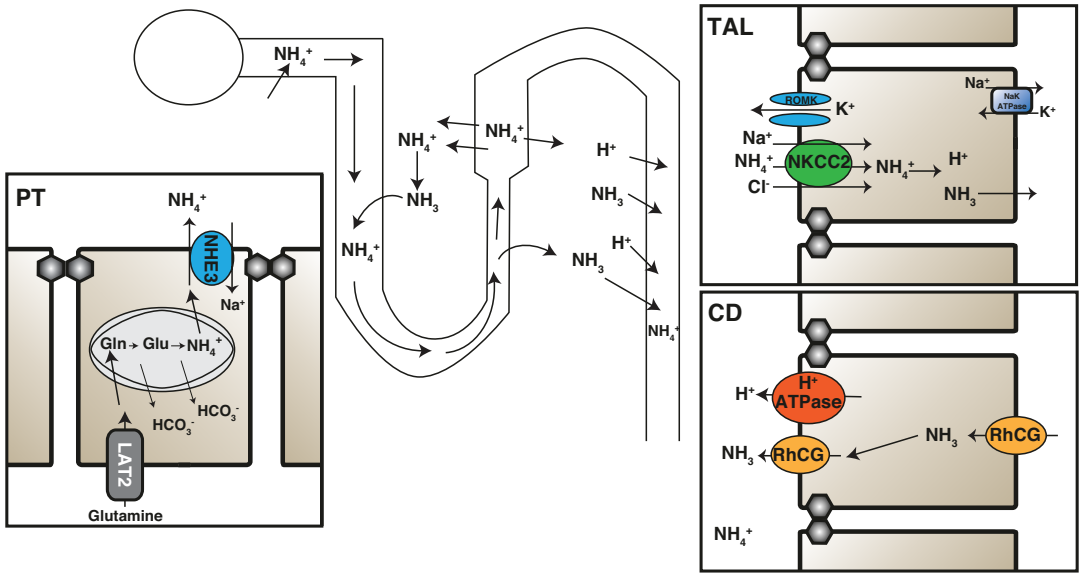

Fig. 39.2 Ammonia generation and recycling. Ammonium is generated in the proximal tubule (PT) and secreted into the lumen in exchange for sodium (Na^+) by the sodium proton exchanger isoform 3 (NHE3). It then travels down the nephron to the thick ascending limb (TAL) where it is reabsorbed by the sodium potassium chloride cotransporter, (NKCC2). Ammonia then diffuses into the interstitium where it either undergoes recycling in the loop or permeates the collecting duct through RhCG and is trapped by a proton secreted through the H^+-ATPase

Pathophysiology of Renal-Acid Base Handling

Definitions

The principles of renal tubular acid-base handling discussed above provide the foundation of the classification of renal tubular acidosis. Defects in bicarbonate reabsorption, which occurs predominantly in the proximal nephron, are referred to as proximal renal tubular acidosis, or pRTA [95]. Historically, pRTA has also been classified as type II RTA. Defects in distal tubular proton secretion are referred to as distal renal tubular acidosis, dRTA [95]. This type of RTA has also been referred to as Type I. Clinical syndromes with features of both proximal and distal renal tubular acidosis, *i.e.* a failure to reclaim both filtered bicarbonate and excrete acid in the urine, are known as mixed renal tubular acidosis or type III RTA. All these types of RTA are typically accompanied by normal or low plasma potassium levels, and are distinguished by the presence of bicarbonaturia and/or the failure to acidify the urine in the presence of an acid load. Due to the molecular link between sodium and acid-base homeostasis, RTA can also occur as a secondary consequence of impaired sodium reabsorption in the collecting duct, as sodium uptake by ENaC provides a favorable electrical gradient for proton secretion. The salt-wasting tubulopathy related to impaired ENaC activity is also referred to as aldosterone insufficient or resistant RTA, or type IV RTA. Since ENaC activity also facilitates potassium secretion, this type of RTA is distinguished from the other types by being associated with hyperkalemia. All forms of RTA are associated with a non-anion gap acidosis, consistent with loss of bicarbonate. For pRTA, this is obvious, as bicarbonate reabsorption is impaired. In dRTA the mechanism is indirect: bicarbonate is consumed for buffering the protons the distal tubule fails to excrete.

Proximal Renal Tubular Acidosis (Type II RTA)

Clinical Presentations

Isolated proximal renal tubular acidosis is a rare condition, which is almost exclusively due to a single gene defect in the sodium dependent bicarbonate transporter, NBCe1 (*SLC4A4*) [96–98]. This genetic form of pRTA is inherited in an autosomal recessive pattern [99]. Given that the renal isoform of NBCe1 is also expressed in the eye it is not surprising that affected individuals commonly display eye abnormalities, such as band cataracts, glaucoma or band keratopathy [99–101]. As with all untreated renal tubular acidosis, failure to thrive and hypomineralized bones are common at presentation [99]. There are also pancreatic and brain isoforms of NBCe1 and consequently, some patients with mutations affecting these isoforms also have increased circulating amylase levels (without evidence of pancreatitis) and there are reports of associated intellectual impairment [99].

Autosomal dominant pRTA has been described in two separate families. The responsible gene accounting for this syndrome has yet to be determined. The first family identified is Costa Rican. One affected brother presented with short stature, bilateral coloboma and subaortic stenosis, while another brother showed limited clinical symptoms, except metabolic acidosis with a urinary pH < 5.0 as did the affected sibling [102]. They both had evidence of hypomineralized bones. The other family described includes a father and all 4 of his children who have metabolic acidosis with increased bicarbonate excretion following bicarbonate loading. Despite sequencing a number of candidate genes the cause of their disease is yet to be defined [97]. As detailed above, mutations in NHE3 have not been reported to cause pRTA, but instead congenital sodium diarrhea [38]. Interestingly, affected patients have either absent or only mild acidosis. Similarly, mice with proximal tubule-specific knock out of Nhe3, also only have marginally lower serum bicarbonate levels compared to wild type [39]. There are some data suggesting compensatory upregulation of Nhe8 [103].

Other genetic and acquired forms of pRTA usually occur as part of the renal Fanconi syndrome [104], which is characterized by complex proximal tubular dysfunction due to genetic defects or proximal tubular toxicity from a drug, toxin or metabolite. Renal Fanconi syndrome causes are listed and described in Chap. 31.

Diagnosis

Patients with pRTA typically demonstrate a hyperchloremic non-anion gap metabolic acidosis, accompanied by hypokalemia. However, since the ability to acidify urine is preserved, patients with pRTA can lower their urine pH to less than 5.5 when plasma bicarbonate levels are lower than their renal threshold for tubular bicarbonate absorption. This distinguishes pRTA from dRTA. A definitive means of diagnosing pRTA is by assessing renal tubular bicarbonate absorption (or the fractional excretion of bicarbonate) across a range of plasma bicarbonate levels. A fractional excretion of bicarbonate greater than 15% in the context of a metabolic acidosis definitively diagnoses pRTA [104, 105]. Some authors have suggested an even lower cut off level, i.e. 5% [41]. In case of doubt, the diagnosis can be ascertained by assessing tubular bicarbonate handling as an alkali is given to the patient, resulting in a gradual increase in plasma pH [106]. Practically this can be done by measuring the fractional excretion of bicarbonate repeatedly while normalizing plasma bicarbonate levels with increasing doses of alkali (e.g., administration of intravenous bicarbonate at a rate predicted to increase blood bicarbonate by 2 mmol/L/h, until urine pH is >6.8 [103]). A marked increase in urinary bicarbonate excretion normally occurs at a specific serum bicarbonate level. This is called the bicarbonate threshold. A normal bicarbonate threshold is around 22 mmol/L in infants and 25 mmol/L in older children/adults [107]. A bicarbonate threshold less than 20 indicates pRTA. In practical terms, a pRTA patient with a bicarbonate threshold of 16 will stop wasting bicarbonate and be able to acidify the urine to <5.5 at a plasma bicarbonate at or below 16 [108].

In clinical practice, the fractional excretion of bicarbonate is rarely performed, due to technical

considerations especially relevant in children: when urine is exposed to air, CO_2 diffuses out, lowering urinary bicarbonate concentration, while at the same time increasing the pH ($CO_2 + H_2O$ <<<=> $H^+ + HCO_3^-$). Thus, fresh urine should be obtained and ideally under oil to minimize CO_2 loss. This is obviously challenging in non-toilet trained children, unless a catheter is inserted. Similarly, the lab should be alerted to handle these samples urgently and not every biochemical lab will measure urinary bicarbonate. From a practical point of view: isolated pRTA is exceedingly rare and virtually always associated with eye abnormalities. Otherwise, pRTA occurs in the context of a more generalized proximal tubulopathy. Thus, if pRTA is suspected, an eye examination and a screen for renal Fanconi syndrome (glycosuria, phosphaturia, low molecular weight proteinuria, amino- and organic aciduria, see Chap. 31) should be performed and is usually sufficient to establish a diagnosis. If typical abnormalities are present, a genetic diagnosis can be established by sequencing *SLC4A4* [96]. An algorithm for the diagnosis of RTA is presented in Fig. 39.3.

Treatment

For treatment of renal Fanconi syndrome, please see Chap. 31. For isolated pRTA, alkali replacement is the main line of therapy [109, 110]. This is especially important in prepubertal children as persistent metabolic acidosis will impair growth [109]. Given the pathophysiology, with bicarbonate wasting when plasma bicarbonate levels are above the threshold, it is not surprising that even with prodigious quantities (5–15 mEq/kg/day) of bicarbonate supplementation, plasma levels may remain low [104]. This is another distinguishing factor from dRTA, where normal plasma bicarbonate levels can be achieved with doses of usually 2–5 mEq/kg/day [111]. It is recommended to administer smaller doses of alkali replacement frequently, as the larger the dose, the higher the peak in subsequent plasma bicarbonate concentration which, in turn, will increase urinary bicarbonate losses [112]. The use of long-acting alkali replacement formulations has not been reported in pRTA, but should help to maintain more consistent plasma bicarbonate levels, while minimizing the frequency of daily doses.

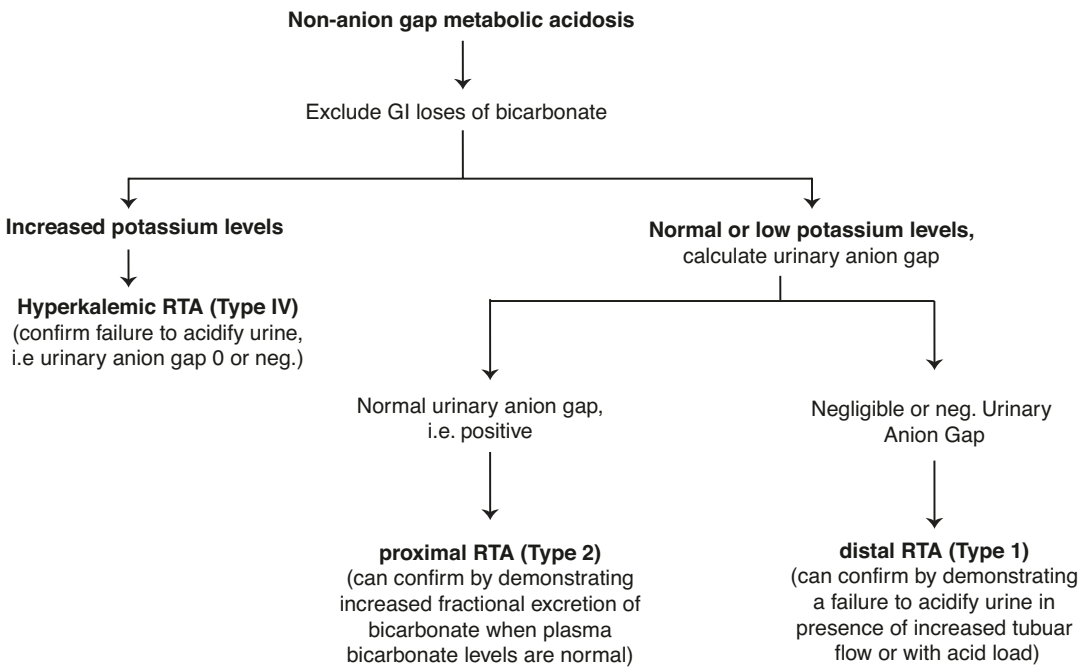

Fig. 39.3 Algorithm for diagnosis of RTA

Prognosis

Due to the extreme rarity of the disease, little information on the long-term outcomes of children with isolated pRTA is available. So far, renal failure has not been reported in contrast to dRTA, and growth can be improved with alkali supplementation [109, 113].

Distal Renal Tubular Acidosis (Type I RTA)

Clinical Presentation

Distal renal tubular acidosis is more common than the proximal form. Biochemically, it also presents as a hyperchloremic non-anion-gap metabolic acidosis, typically in association with hypokalemia, hypercalciuria and nephrocalcinois, although these features are not always present [114]. Some patients will also display renal cysts, although these typically develop later [115].

Mutations in at least 5 different genes have been identified and found to cause dRTA [116]. Moreover, a number of conditions, drugs and toxins can cause dRTA (see Table 39.1), yet this is more commonly seen in adults. In particular drugs targeting the distal nephron, autoimmune diseases and conditions characterized by hypercalciuria can be associated with dRTA [117].

Ehlers-Danlos syndrome
Carnitine palmitoyltransferase deficiency

[a]CAII deficiency causes a combined pRTA and dRTA i.e. type III RTA

Distal RTA with Mutations in AE1 (SLC4A1)

Mutations in the anion exchanger isoform 1, AE1, have been found to cause dRTA [118–120]. The encoding gene, *SLC4A1*, is expressed in both red blood cells as well as in α-intercalated cells of the collecting duct [121]. Some mutations in AE1 cause congenital forms of anemia including hereditary spherocytosis and ovalocytosis [122–126]. These mutations are predominantly found in regions of Southeast Asia with a historically high incidence of *plasmodium falciparum* infections, against which ovalocytosis provides protection [127]. Interestingly, mutations in AE1 that cause blood dyscrasias generally do not result in dRTA and conversely, mutations causing dRTA often do not cause anemia. Most mutations associated with dRTA are missense variants leading to aberrant trafficking (e.g. to the apical membrane) or ER retention. AE1 functions as a dimer, so that these mutations can have a dominant negative effect [127–129]. Since red cells are not polarized, aberrant trafficking is less of a problem. Moreover, red cells express glycophorin and other chaperones responsible for trafficking AE1 to the plasma membrane that are absent in renal epithelial cells. This explains how some mutations cause dRTA and not anemia [130]. In contrast, mutations causing isolated red cell dis-

orders typically affect transport function, suggesting a susceptibility of red cells to AE1 haploinsufficiency [128]. In addition, the isoforms of AE1 expressed in red cells and kidney are different; the latter lacks the first 65 amino acids, so that mutations in this region are not expected to cause kidney disease [131]. In a minority of patients both dRTA and anemia are present [132–136].

Mutations in AE1 were originally reported to only be transmitted in an autosomal dominant fashion [118]. Such families have been reported globally [118–120, 133, 137, 138]. Autosomal dominant mutations can cause complete or incomplete dRTA (note incomplete dRTA is evidence of a failure to acidify urine when challenged with an acid load in an individual *without* metabolic acidosis at baseline) [139]. Typically, patients with autosomal dominant dRTA present in adolescence or even at adult age. In general, biochemical abnormalities are less severe than in patients with recessive disease due to mutations in subunits of the H^+-ATPase, potentially explaining the later presentation [115]. Hypercalciuria, nephrocalcinosis and nephrolithiasis have been associated with this disease [120, 130, 138]. The frequency of these associations appears to increase with patient age.

Later, patients with mutations in AE1 inherited in an autosomal recessive fashion were reported [125, 130, 140–144]. Such recessive mutations typically cause a milder trafficking defect, so that both alleles need to be mutated to cause a clinically relevant problem. Patients who are compound heterozygous for one mutation causing ovalocytosis and one causing dRTA can have both disorders [128].

Distal RTA with Mutations in Proton Pump Subunits a4 (ATP6V0A4) and B1 (ATP6V1B1)

Mutations in at least two of the subunits of the vacuolar H^+-ATPase also cause dRTA [70, 145–149]. This 14-subunit proton pump is expressed in the luminal membrane of the α-intercalated cell and is responsible for the secretion of protons into the collecting duct. Mutations in the a4 (*ATP6V0A4*) and B1 (*ATP6V1B1*) subunit have been reported to cause complete dRTA [149]. These mutations are inherited in an autosomal recessive pattern, although a specific mutation in the B1 subunit (p. Arg394Gln) has been reported recurrently in heterozygous form without an identified mutation on the other allele [111, 150]. Both the a4 and B1 subunits are also expressed in the inner ear, so it is not surprising that they are also associated with sensorineural hearing loss [149]. Nevertheless, some genotype-phenotype correlations exist: mutations in *ATP6V0A4* are associated with more severe dRTA, as assessed by a trend to earlier presentation, increased frequency of nephrocalcinosis and higher prescribed daily alkali dose [111, 115]. Yet, only about a third of patients with mutations in the a4 subunit have documented sensorineural hearing loss, compared to almost 90% in patients with B1 mutations [111]. Moreover, age at diagnosis of hearing loss and prescription of hearing aids or cochlear implants is significantly younger in patients with *ATP6V1B1* mutations compared to *ATP6V0A4*. [146, 149, 151]. The vast majority of patients with mutations in the a4 and B1 subunits have nephrocalcinosis (98% with *ATP6V1B1* and 90% with *ATP6V0A4*), which is typically present already at diagnosis [116].

Distal RTA with Mutations in FOXI1

FOXI1 is a transcription factor expressed in acid secreting epithelia important for the regulation of several genes involved in acid secretion, including *SLC4A1*, *ATP6V1B1* and *ATP6V0A4* [152]. Foxi1 knock out mice had already been reported in 2004 to have dRTA with sensorineural deafness [153]. It took another 14 years until two families with recessive mutations in FOXI1 were identified, suggesting that this is a very rare cause of dRTA [154]. Reported patients also have sensorineural deafness with massive enlargement of the endolymphatic sac [154]. Of note, male Foxi1 knock out mice are infertile, due to insufficient acidification of the luminal fluid in the epididymis with consequent pathologic post-testicular

sperm maturation [153]. Whether male infertility is also a clinical problem in human FOXI1-related dRTA remains to be seen.

Distal RTA with Mutations in WDR72

WDR72 (tryptophan-aspartate repeat domain 72) is a protein presumed to be involved in intracellular vesicle transport that was initially identified as a cause of autosomal recessive amelogenesis imperfecta [155]. In 2018, two families with dRTA were reported with recessive mutations in WDR72 [156]. Subsequently, more families have been reported [157, 158]. Whether some families only exhibit dRTA, others only amelogenesis imperfecta and others both features is not clear. Potentially, the report of only one manifestation may betray the focus of the reporting specialist (dentist versus nephrologist). Interestingly, in one report, reverse phenotyping of patients with WDR72 mutations and a clinical diagnosis of dRTA revealed that all patients also had findings of amelogenesis imperfecta [158]. Interestingly, not all family members with *WDR72*-associated amelogenesis imperfecta have clear evidence of dRTA [157]. This suggests that *WDR72*-associated dRTA is typically milder than the forms associated with the other recessive disease genes.

Candidate Genes

Currently, about 60–80% of families with a clinical diagnosis of inherited dRTA have identifiable pathogenic variants in the known disease-causing genes described above, suggesting that there are more yet unidentified dRTA disease genes [115, 150, 158]. Further, subunits of the vacuolar H^+-ATPase expressed in the kidney, such as C2, G3 and d3 have been suggested as candidates, but thus far, evidence definitively linking them to dRTA is limited [158–160].

Diagnosis

The presence of a hypokalemic, hyperchloremic, non-anion gap metabolic acidosis in the absence of intestinal losses and in the presence of a normal GFR should make one suspect RTA [161, 162]. Notably, substantially reduced GFR (CKD stage >3) can cause a normal anion gap metabolic acidosis due to insufficient nephron mass to excrete sufficient protons to maintain normal plasma pH. This cause of metabolic acidosis due to renal insufficiency is not traditionally labeled as dRTA, and can be easily distinguished by assessment of global renal function and the presence of the other clinical consequences of kidney disease.

Urinary pH will be inappropriately elevated with dRTA. Unfortunately, this finding can also be observed with pRTA when plasma pH is above the bicarbonate threshold. Definitive diagnosis of dRTA is made by demonstrating an inability to acidify the urine. Since ammonium is the major component of acid secretion it should be measured, ideally directly. However, most clinical laboratories do not offer urinary ammonium determination, but excretion can be estimated indirectly, using the **urine anion gap** [163]. This is in analogy to the plasma anion gap, although it would better be termed "cation gap", as it serves to estimate the unmeasured cation ammonium [164]. It is calculated using the formula: $U_{AG} = [Na^+]_U + [K^+]_U - [Cl^-]_U$.

The unmeasured urinary anions sulphate and phosphate are generally constant and at low levels. Moreover bicarbonate is not typically present in urine. Similarly, the urinary excretion of calcium and magnesium is relatively low and constant relative to sodium and potassium. Consequently, the urinary excretion of ammonium (NH_4^+) represents the greatest unmeasured urinary cation, making this equation a useful estimate of ammonium excretion. In the presence of metabolic acidosis there should be significant urinary ammonium excretion and consequently a negative anion gap. An alkaline urine pH in the presence of a negative urinary anion gap is consistent with the diagnosis of pRTA. An anion gap >10 mmol/L reflects the inappropriate absence of ammonium excretion and supports a diagnosis of dRTA [165]. Alternatively (or additionally), the urinary osmolality gap can be used [166].

In clinical practice, in the absence of intestinal losses of bicarbonate, hypokalaemic hyperchloremic metabolic acidosis with elevated urine pH is most likely caused by dRTA. In contrast, generalized proximal tubular dysfunction is consistent with pRTA. It is important to remember though, that approximately a third of patients with dRTA have evidence of proximal tubular dysfunction at presentation, confounding an accurate diagnosis [115]. This is likely related to the acidosis, as proximal dysfunction resolves with resolution of the acidosis. The complete **normalization of plasma bicarbonate levels with alkali supplementation** suggests a diagnosis of dRTA. In contrast, the ongoing bicarbonate wasting present in pRTA usually **precludes complete normalization of plasma bicarbonate levels. Further, a diagnosis of dRTA is confirmed by the later resolution of proximal dysfunction with adequate alkali treatment. The diagnosis can be secured by genetic testing in the vast majority of cases.**

The diagnosis can be challenging in milder (incomplete) forms, as these patients typically have normal plasma biochemistries at baseline. Further **diagnostic procedures to assess distal acidification** can help. Two such procedures are commonly employed to this end. The first is the administration of an acid load typically as ammonium [167]. This is to induce an actual metabolic acidosis, so that appropriate urinary acidification can be assessed. Unfortunately, ammonium has a foul taste and may not be tolerated by patients. Alternatively, distal acidification can be stimulated by co-administration of a loop diuretic and mineralocorticoid, such as furosemide and fludrocortisone [168, 169]. Sodium reabsorption via the epithelial sodium channel ENaC (see Fig. 39.1) provides a favorable electrical gradient for acid secretion in the collecting duct. In patients with normal distal tubular function this results in an acidification of the urine (as sodium absorption stimulates the secretion of a counter ion, *i.e.* H^+ and K^+). Patients with dRTA will not acidify their urine under these conditions either. The tests are described in Fig. 39.4.

Once a diagnosis of dRTA has been made, identification of clinical conditions and/or toxins causing dRTA is important and their treatment or removal often effective therapy. In pediatric prac-

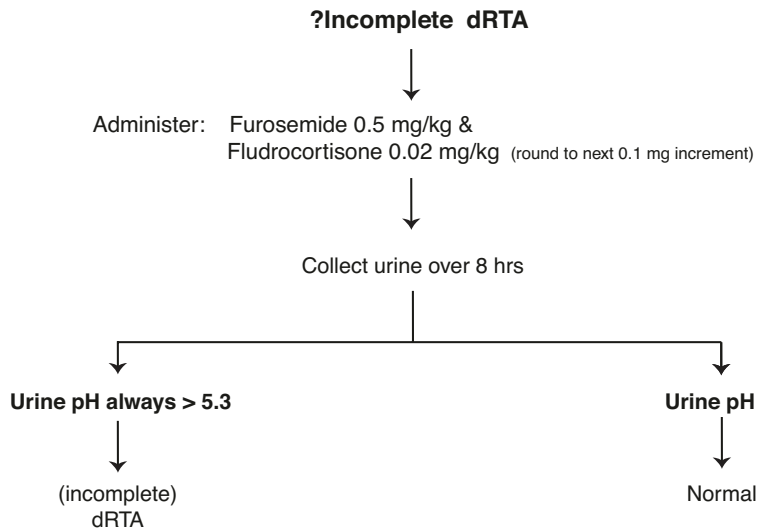

Fig. 39.4 Approach to diagnosis of incomplete dRTA. Note that one can substitute 100 mg/kg NH_4Cl for furosemide and fludrocortisone, however the described test is better tolerated and consequently preferable. Urine pH will be increased by sample exposure to air, due to diffusion of CO_2 and NH_3 from the sample. Thus, the test is difficult to do in non-toilet trained children, unless catheterised. Samples are ideally collected under oil and need to be analyzed straight away

tice, the etiology is almost always primary dRTA. A formal **hearing examination** is recommended. Patients with mutations in AE1 typically have normal hearing, patients with mutations in carbonic anhydrase II may have conductive hearing loss while patients with mutations in the H^+ ATPase often have sensorineural hearing loss, especially those with mutations in the B1 subunit [70, 111, 170].

Treatment

The goal of therapy is to ensure adequate growth, heal or prevent bony abnormalities and normalization of urinary calcium excretion to prevent worsening of nephrocalcinosis and the (re) occurrence of nephrolithiasis [161]. Treatment is simple in principle: provision of sufficient doses of alkali supplementation. Yet, in a large international study of 340 patients with primary dRTA, more than half had inadequate metabolic control, as judged by plasma bicarbonate and urinary calcium at last follow-up [111]. Importantly, inadequate metabolic control was associated with lower final height and lower eGFR at last follow-up, highlighting the importance of good treatment. Impediments to proper treatment likely include the need for frequent dosing, lack of approved alkali supplementation and poor taste of available preparations. Of note, more than 30 different preparations were prescribed and there was no apparent difference in outcome whether bicarbonate or citrate preparations were employed [165].

The key to optimal therapy is to provide a sufficient quantity of alkali frequently enough to maintain sustained control of the acidosis. The dose of alkali equivalents to compensate alkalosis decreases with age and is typically 3–6 mEq/kg/day below the age of 6 years (but up to 10 mEq/kg/day in infancy) and declines to 1–2 mEq/kg/day in adulthood [103, 115, 161]. Alkali supplementation reflects the renal acid load, which is derived primarily from dietary protein, specifically from sulfur-containing amino-acids which are metabolized to sulfuric acid [171]. Animal proteins have a higher content of sulfuric amino acids than plant proteins and consequently, a reduction in animal protein intake reduces the dose of alkali supplementation required for buffering. Nevertheless, sufficient protein intake (the recommended daily intake) is needed for normal growth and development in children.

In pRTA, because of the ongoing bicarbonate wasting, sustained normal plasma bicarbonate levels may not be achievable, despite often enormous prescribed doses. As detailed above, more frequent provision of smaller doses will provide more stable plasma levels and less wastage. However, this may be difficult for some patients and there families. Finally, the management of kidney stones, coexisting hearing loss or anemia may require other subspecialty support.

Prognosis

In dRTA, if the diagnosis is made early and alkali therapy provided consistently the prognosis is good, with final height in the normal range, albeit slightly below average [111]. While mild CKD is common, ESKD is exceedingly rare and was not observed in the cohort of 340 dRTA patients, which included 83 adults up to the age of 70 years [163]. Unfortunately, due to the non-specific nature of presenting symptoms, diagnosis is often delayed [151] and in these or non-compliant patients progression to renal failure and or significant growth impairment can occur [172, 173]. Importantly, alkali therapy does not prevent hearing loss [174].

When pRTA occurs in association with renal Fanconi syndrome, the prognosis depends primarily on the underlying condition. For isolated pRTA with eye findings, not enough patients have been reported to make meaningful statements on prognosis.

Mixed Proximal and Distal Renal Tubular Acidosis (Type III RTA)

Carbonic anhydrase II (CAII) is a metalloenzyme that catalyzes the reversible hydration of carbon dioxide into a proton and bicarbonate. This cytosolic enzyme is expressed in renal tubular epithelial cells along the nephron. The highest level of expression is in the intercalated cells with reduced

levels of expression in the proximal tubule and thick ascending limb. In both the proximal tubule and the α-intercalated cells it provides protons for secretion into the lumen (via NHE3 and the H^+-ATPase respectively). Its other product bicarbonate is effluxed into the peritubular interstitium via NBCe1 and AE1 respectively. Mutations in CAII lead to mixed proximal and distal RTA, or Type III RTA, which can be variable in severity and is often associated with nephrocalcinosis and nephrolithiasis [37, 175]. Carbonic anhydrase II is also essential for osteoclast function, and loss-of-function is therefore associated with excessive mineralization (osteopetrosis) accompanied by cerebral calcification, developmental delay, facial dysmorphism (low set ears, hypertelorism and a depressed nasal bridge), conductive hearing loss and cognitive impairment [145, 176–178]. This rare condition is inherited in an autosomal recessive fashion [179]. Bone marrow or stem cell transplantation has been used to prevent the progression of osteopetrosis although it may not be completely curative [180]. Alkali supplementation remains the mainstay of treatment for metabolic acidosis.

Hyperkalemic Renal Tubular Acidosis (Type IV RTA)

Clinical Presentation

Hyperkalemic renal tubular acidosis is typically the result of actual or functional (pseudo-)hypoaldosteronism [181]. This condition is primarily a salt-wasting tubulopathy of the collecting duct. Since sodium reabsorption and potassium and proton secretion are coupled in this nephron segment, hyperkalemic acidosis occurs as a secondary consequence. Aldosterone is required for sodium reabsorption through the epithelial sodium channel, ENaC, which generates the negative transmembrane potential required to drive both potassium and proton secretion across this nephron segment. While several rare genetic disorders are associated with hyperkalemic RTA, this type of RTA more commonly results from acquired causes such as renal damage from obstructive uropathy, due to an autoimmune disorder, drug therapy or interstitial renal disease (Table 39.2). Drugs such as amiloride, triamterene and spironolactone either directly or indirectly inhibit sodium absorption from the collecting duct through ENaC. Due to the coupling of sodium absorption to either potassium or proton excretion in this segment, these drugs also cause hyperkalemic metabolic acidosis. Ascending infections and urinary obstruction disproportionately affect collecting duct function resulting in Type 4 RTA, while autoimmune diseases can produce autoantibodies targeting col-

[a] Note KCNJ1/ROMK mutations can cause type IV RTA in infancy that evolves into a hypokalemic metabolic alkalosis as a young child

lecting duct epithelial cells thereby causing the disease.

Notably, hyperkalemia in type IV RTA is not only a consequence of impaired distal sodium reabsorption, due to aldosterone insufficiency or resistance. Hyperkalemia also appears to inhibit ammonia production in the proximal tubule, thereby reducing ammonium excretion and exacerbating the renal tubular acidosis [182, 183].

An important cause of hyperkalemic RTA is **pseudohypoaldosteronism (PHA**), both type 1 and type 2 [184]. **Type 1** is associated with lower blood pressure, hyponatremia and renal salt wasting, despite elevated circulating levels of aldosterone and renin. The condition results from mineralocorticoid resistance. Patients typically present as infants with dehydration, hypotension, weight loss and vomiting. There are two clinically and genetically distinct subtypes of this disorder. A milder renal-limited form, which is inherited in an autosomal dominant fashion, is due to loss-of-function mutations in the mineralocorticoid receptor [185, 186]. These patients typically present in the first few months of life with growth failure and subsequent work-up reveals the hyperkalaemic acidosis. Interestingly, plasma electrolytes spontaneously normalize with age, although renin and aldosterone levels usually remain elevated life-long [184, 187]. Genetic analysis of parents in the absence of a family history suggests that some cases may go undetected [150].

The more severe form of PHA type 1 is inherited in an autosomal recessive fashion and often displays evidence of multiple organ dysfunction, including increased sodium concentration in sweat, saliva and airway liquid with consequent pulmonary manifestations that can mimic cystic fibrosis [188]. This form of pseudohypoaldosteronism type 1 is caused by mutations in one of the three epithelial sodium channel subunits, α, ß or γ [189–192]. Affected patients typically present in the first days of life with failure to gain weight. Electrolyte abnormalities can be severe, with plasma potassium levels around 10 mmol/L or higher at presentation [193].

Pseudohypoaldosteronism type II, also known as hyperkalemic hypertension or Gordon's syndrome, describes a disorder characterized by hyperkalemic renal tubular acidosis and hypertension with variable aldosterone and low renin levels. In contrast to the salt-wasting hypovolemic disorder PHA type 1, type 2 is characterized by hypervolemia due to salt-retention in the distal convoluted tubule [194]. The consequent lack of delivery of sodium to the collecting duct causes the hyperkalemic acidosis. Consequently, PHA type 2 is highly sensitive to therapy with thiazide diuretics, whose target is the apically expressed sodium chloride co-transporter, NCC, which is expressed in the apical membrane of the distal convoluted tubule. Mutations in several genes have been identified to cause this disorder, including *WNK1*, *WNK4*, *CUL3* and *KLHL3* [195–197], (Table 39.3). Most patients with inherited PHA type 2 present during adolescence or even adulthood and especially hypertension may not be present until adulthood [194]. However, mutations in KLHL3 can be dominantly or recessively inherited and the latter ones can present already in infancy. Moreover, mutations in CUL3 appear to be associated with a more severe course with earlier presentation, early hypertension and failure-to-thrive [196].

Investigations into PHA have provided fascinating insights into the so-called "aldosterone paradox", i.e. the fact that the two key functions of aldosterone, regulation of volume and of potassium, can sometimes be competing. For instance, in a fasting state, the body may need to conserve volume (sodium) without sacrificing potassium. Conversely, in the presence of a high serum potassium, aldosterone is released to enhance potassium excretion, but without necessarily changing salt reabsorption [198]. The answer to this conundrum was provided by the identification of the WNK kinases and their associated regulatory proteins. If volume needs to be preserved without affecting potassium secretion, salt reabsorption is shifted to the distal convoluted tubule, so less sodium is delivered to the collecting duct where it could be exchanged for potassium. If potassium needs to be excreted without affecting sodium reabsorption, the process is shifted to the collecting duct, such that less sodium is reabsorbed in the distal convoluted

Table 39.3 Genetic causes of RTA

Gene name	Protein name	MIM #	Inheritance	Typical clinical features	Type of RTA
SLC4A4	NBCe1	603345, 604278	AR	Glaucoma, cataracts, band keratopathy	pRTA, Type II

WNK1	WNK1	6052323, 614492	AD	Pseudo-hypoaldosterism Type 2, Hypertension	Hyperkalemic RTA, Type IV
WNK4	WNK4	145260	AD	Pseudo-hypoaldosterism Type 2, Hypertension	Hyperkalemic RTA, Type IV
CUL3	Cullin 3	603136, 614496	AD	Pseudo-hypoaldosterism Type 2, Hypertension	Hyperkalemic RTA, Type IV
KLHL3	Kelch-Like 3	614495	AD or AR	Pseudo-hypoaldosterism Type 2, Hypertension	Hyperkalemic RTA, Type IV

[a] Mutations of the genes in grey are primarily disorders of renal sodium handling and may not always cause RTA

tubule and therefore available for exchange with potassium. Mutations causing PHA type 2 shift this regulatory response towards salt reabsorption in the distal convoluted tubule, leading to hypervolameia and hyperkalaemic acidosis. The actual regulation is quite complicated, involving further kinases, such as SPAK and OSR1 [199, 200]. The final consequence of the mutations identified in affected individuals is increased phosphorylation and cell surface expression of NCC with increased sodium reabsorption. The volume expansion caused by increased NCC activity suppresses renin and the reduced delivery of sodium to the collecting duct impairs the distal secretion of potassium and protons leading to a hyperkalemic metabolic acidosis. Aldosterone levels can be variable, as aldosterone is also stimulated by hyperkalaemia. While inherited PHA type 2 is rare, a much more common acquired form, associated with calcineurin inhibitor treatment, has been described [201]. Typically, this complication occurs with large doses of tacrolimus, as commonly prescribed for instance in heart transplants. The exact mechanism is unclear, but in the mouse model, tacrolimus exposure leads to increased abundance of SPAK and WNK4 kinases and consequent increased phosphorylation and surface expression of NCC, analogous to inherited PHA type 2 [201]. Most imnportantly, this acquired form of PHA type 2 responds just as well to thiazides as the inherited form (see "treatment" below), providing an elegant and simple treatment, if reduction of tacrolimus is deemed clinically unacceptable.

Diagnosis

The initial diagnosis of type IV RTA is rather straightforward. The combination of hyperchloremic normal anion gap metabolic acidosis with hyperkalemia is pathognomonic for the diagnosis. In the context of clinical hypovolemia and elevated aldosterone levels, this is PHA type 1, whereas normal or elevated blood pressure is consistent with type 2. The diagnosis of type 2 PHA can be further confirmed by the excellent response to thiazide diuretics.

Investigations to determine the underlying cause are guided by patient history and physical examination and may include serum and urinary biochemistry to screen for nephritis, as well as renal ultrasound to assess urinary tract obstruction. Potential inciting drugs should be identified. Ambiguous genitalia point to congenital adrenal hyperplasia. Genetic testing should be sought whenever available to confirm hereditary disorders. As most mutations causing PHA are inherited in a dominant fashion, a careful family history should be obtained and frequently, further family members are identified, who have often been given a diagnosis of treatment-resistant hypertension or may even have suffered complications, such as stroke or myocardial infarction.

Treatment

The treatment of type IV RTA is largely etiology dependent. Offending drugs should be discontinued and any underlying renal disease treated. This often leads to complete resolution of the hyperkalemic metabolic acidosis. In the case of obstructive uropathy adequate urinary flow should be achieved by catheterization or an appropriate urologic procedure. Unfortunately, the metabolic acidosis associated with some cases of congenital obstruction may be irreversible, especially if associated with marked GFR impairment, and continued alkali supplementation is required.

In PHA type 1, especially the recessive form, immediate supplementation with sodium chloride, such as infusion of 0.9% saline will help stabilize intravascular volume. Correction of the acidosis with sodium bicarbonate will also lower plasma potassium levels. For longer term control, oral supplementation with sodium chloride and bicarbonate is often needed in doses >10 mmol/kg/day. Sodium resonium is helpful to eliminate potassium and provide sodium supplementation [193]. In the dominant form, oral supplementation with sodium chloride and/or bicarbonate is typically needed only in the first year of life or so.

In the case of pseudohyperaldosteronism type 2, thiazide diuretics are very effective and resolve the biochemical abnormalities, as well as the hypertension [202–204].
