Diabetes Insipidus

40

Detlef Bockenhauer and Daniel G. Bichet

History

Diabetes insipidus derives from the Greek word *diabinein* for "flow-through" and the Latin word *insapere* for "non-sweet tasting", separating it from another polyuric disorder, diabetes mellitus ("like honey"). A familial form affecting "chiefly males on the female side of the house" was first described by McIlraith in 1892 [1]. De Lange in 1935 reported a family with diabetes insipidus and no male-to-male transmission unresponsive to injections of posterior lobe extracts [2]. Forssman [3] and Waring [4] in 1945 recognized the disorder in these families as a renal problem. In 1947 Williams and Henry established the unresponsiveness to arginine-vasopressin (AVP) in these patients and coined the term nephrogenic diabetes insipidus (NDI) [5]. In 1969 the "Hopewell Hypothesis" was proposed by Bode and Crawford, proposing that most cases of NDI in the USA and Canada could be traced to descendants of Ulster Scots, who arrived on the ship Hopewell in Novia Scotia in 1761 [6]. Bichet later refuted this by molecular analysis [7]. In 1992 the *AVPR2* gene encoding the AVP2 receptor was cloned and mutations identified in patients with X-linked NDI [8–11]. Shortly after, the *AQP2* gene encoding the vasopressin-regulated water channel aquaporin-2 (*AQP2*) was cloned [12, 13] and in 1994 mutations in *AQP2* were found to underlie autosomal recessive DI [14].

Clinic

Presentation in Infancy

Patients with congenital NDI typically present in the first weeks to months of life with dehydration [15]. Sometimes, patients receive repeated investigations for sepsis, as the dehydration can be associated with low-grade temperatures, until a set of serum electrolytes is obtained, revealing hypernatraemia. Failure-to-thrive with irritability are further symptoms. Often, patients suck vigorously, but develop vomiting shortly after starting to feed. Vomiting may be due to reflux exacerbated by the large volumes of fluid necessary to compensate for the renal losses. Interestingly, breast-fed infants with NDI typically thrive better

than formula-fed ones, as breast milk presents a lower osmolar load than most standard formulas (see below). Of note, pregnancies with babies afflicted with NDI are not complicated by polyhydramnios, since the AVP-dependent mechanisms for urinary concentration are not fully developed until after birth and the osmolar load is cleared by the placenta [16].

Clinical Features and Long-Term Prognosis

Symptoms typically improve with advancing age, especially once food intake has changed to mainly solids, so that caloric and fluid intake are separated. Free access to water allows for self-regulation of serum osmolality. Patients remain polyuric, however and the frequency of voiding and drinking, especially during the night is useful information to assess the severity of the problem. Constipation is a common complication, presumably due to maximal extraction of water from the gut and should be discussed with the families and treated appropriately. Nocturnal enuresis is a frequent concern in childhood, obviously aggravated by the large urine volumes (parents often refer to it as "bed flooding" rather than bed wetting) and the average age at which patients achieve nocturnal continence is between 10 and 12 years [17, 18]. Parents also often report problems with concentration and attention span in their children and in one study almost half the patients were diagnosed with attention deficit hyperactivity disorder [19]. The reason for this is unclear, but maybe partly due to the constant need to drink and void. In an international multi-centre study of 315 patients with primary NDI, 16% were reported to have ADHD and an additional 20% to have other mental health problems [17]. Nevertheless, with treatment, patients with NDI can function well and while the proportion of adults with a university degree (27%) was lower than in the overall population, the rate of full-time employment and independent living in adulthood was similar [17, 19]. Impaired mental development with intracranial calcifications used to be a common feature in NDI [20–22]. This likely reflected repeated episodes of severe hypernatraemic dehydration and with appropriate treatment of NDI this devastating complication is essentially no longer seen. And while failure to thrive is a common problem in infancy, final height is typically in the normal range [17]. Indeed, a surprising finding from the international cohort study was the increased incidence of obesity in adult NDI patients (41%), which may be an unintended consequence of the intense efforts in childhood to maximise caloric intake [17].

Some patients develop dilatation of the urinary tract from the high urinary flow, especially if they have poor voiding habits [20, 23, 24]. However, in those with hydronephrosis, anatomic causes of obstruction need also be considered, as these are potentially remediable and even minor impediments to flow can cause severe dilatation in this polyuric disorder [25]. In the international cohort study, 38% of patients had evidence of flow uropathy which may contribute to the increased prevalence of CKD Stage ≥2 in children (32%) and adults (48%) [17].

Physiologic Principles

Tubular Concentration/Dilution Mechanism (Countercurrent Mechanism with Figure)

The kidney creates a concentration gradient via a so-called countercurrent multiplication system [26, 27]. The tonicity (osmolality) of urine as it proceeds along the nephron is depicted in Fig. 40.1. In the proximal tubule the urine remains isotonic to plasma because of the high water permeability of this segment, mediated by aquaporin 1 (AQP1) [28–30]. Urine then enters the tubular segment most important for countercurrent multiplication: the loop of Henle. First, urine is concentrated as it descends the thin descending limb (TDL). The precise mechanism of concentration are still debated: initially, it was thought that the TDL also expresses AQP1, allowing water exit into the medullary interstitium [31]. More recent data, however, show that only about 10–15% of TDL (the "long-looped" nephrons) express AQP1, whereas the other ones do not [32].

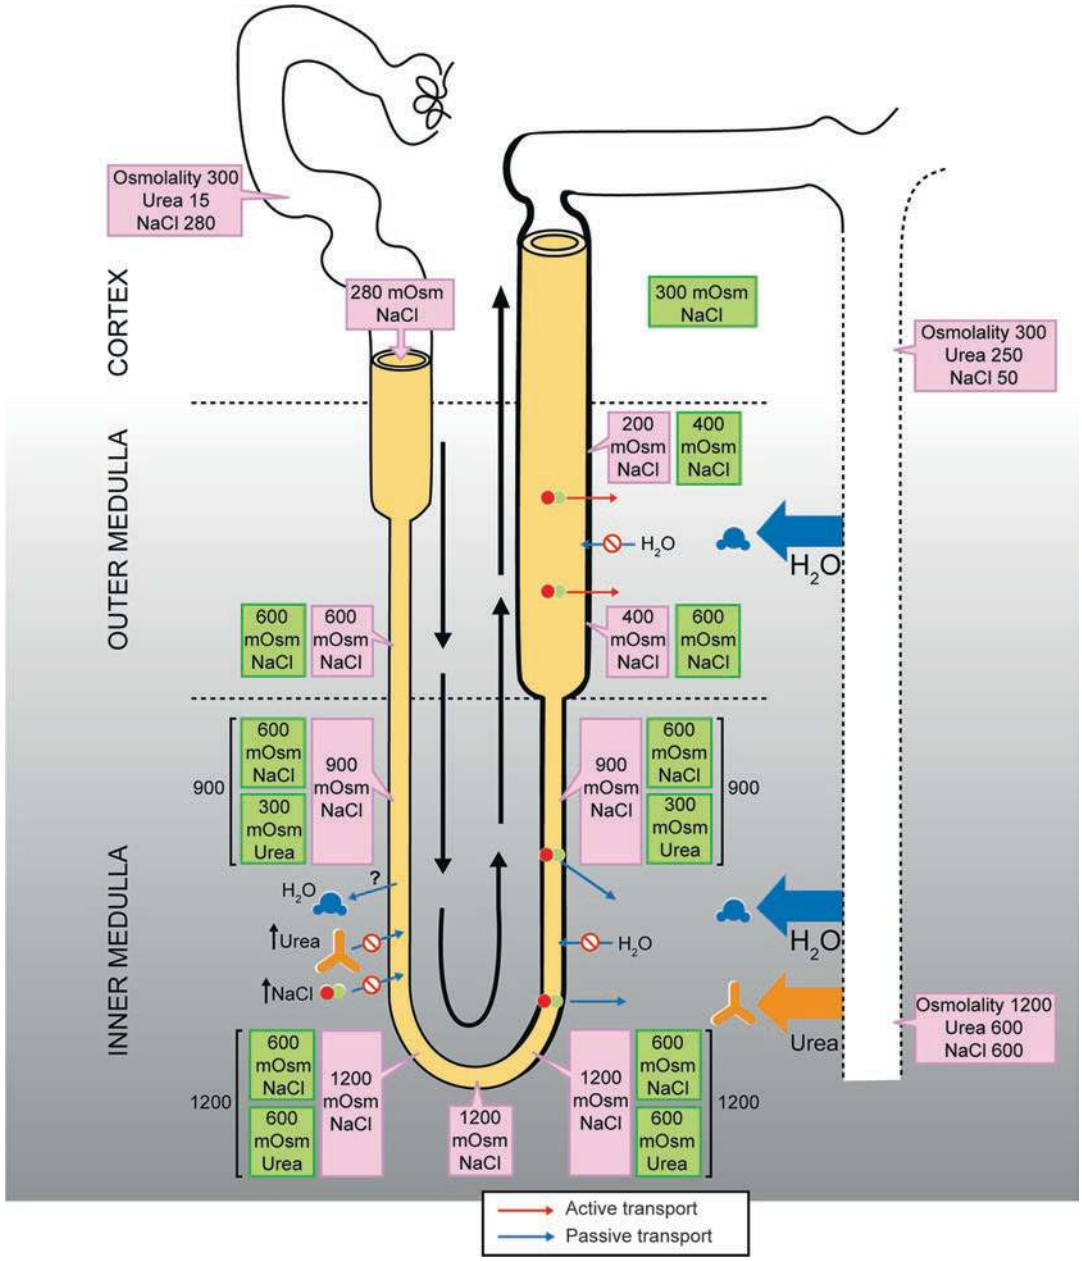

Fig. 40.1 Diagram of the renal concentration and dilution mechanism. The numbers indicate approximate osmolalities of the tubular and interstitial fluids. The names of the relevant transport proteins are indicated. The concentration gradient is mainly generated by the active reabsorption of solutes in the thick ascending limb by the transporter NKCC2. Note that urine exiting the loop of Henle is hypotonic. Final urine concentration is then dependent on the availability of AQP2 water channels in the collecting duct. For further details, see text

Consequently, concentration of the tubular fluid in TDL of these nephrons is assumed to occur via passive sodium influx [33]. Urine subsequently enters the thick ascending limb (TAL), which is impermeable for water, but actively removes sodium chloride, via the co-transporter NKCC2 [34]. Therefore, urine is diluted on its way up the TAL by active removal of solutes. The

accumulation of solutes in the interstitium in turn generates the driving force for the removal of water from the thin descending limb (in the long-looped nephrons) and the entry of sodium chloride (into the short-looped majority of nephrons), completing the countercurrent multiplier.

There is further removal of sodium chloride in the distal convoluted tubule via the thiazide-sensitive co-transporter NCC and at entry in the collecting duct, urinary osmolality is typically around 50–100 mOsm/kg. The final osmolality of the urine is now solely dependent on the water permeability of the collecting duct and thus the availability of water channels. If water channels are present, water will exit the tubule following the interstitial concentration gradient and the urine is concentrated. If no water channels are present, dilute urine will be excreted.

AVP Effects in the Kidney

The availability of water channels in the collecting duct is under the control of AVP. The final regulated step is the insertion of AQP2 into the apical (urine-facing) side of the membrane of principal cells in the collecting duct [35]. Figure 40.2 shows a model of a principal cell. AVP binds to the vasopressin receptor (AVPR2) on the basolateral (blood-facing) side. AVPR2 is a G-protein coupled receptor that upon activation stimulates adenylate cyclase, thus raising cAMP production [36–39]. Protein kinase A (PKA) is stimulated by cAMP and phosphorylates AQP2 at a consensus site in the cytoplasmic carboxy-terminal tail of the protein, serine 256 (S256) [12, 40, 41]. Unphosphorylated AQP2 is present in intracellular vesicles, which upon phosphorylation at S256 are fused in the apical membrane [42]. Of note, AQP2 water channels are homotetramers, i.e. consisting of four subunits. In vitro evidence suggests that minimally three subunits need to be phosphorylated for the channel to be fused in the plasma membrane [43].

After insertion of AQP2 in the apical membrane water can enter from the tubular lumen into the cell and exit via the basolateral water channels AQP3 and AQP4. While AQP4 appears to be constitutively expressed in collecting duct, there is some evidence that AVP may also regulate the expression of AQP3 [44–46].

Extrarenal Effects of AVP

The vasopressive and glycogenolytic effects of AVP are mediated through AVP1 receptors expressed in vasculature and liver [47], while the renal effects, especially the increase in water permeability of the CD are mediated by AVPR2 [48]. Interestingly, administration of the AVPR2-specific agonist 1-Desamino-8-D-Arginine Vasopressin (DDAVP) results not only in an increase in urine osmolality, but also has extrarenal effects, including:

1. A small depression of blood pressure with a concomitant increase in heart rate and increase in plasma renin activity [49, 50].
2. An increase in factor VIIIc and von Willebrand factor with a decrease in bleeding time [49, 51, 52].

These extrarenal effects are abolished in patients with X-linked NDI, suggesting that AVPR2 is expressed beyond the kidney. Clinically, this can be used to differentiate between X-linked and autosomal recessive NDI (see below).

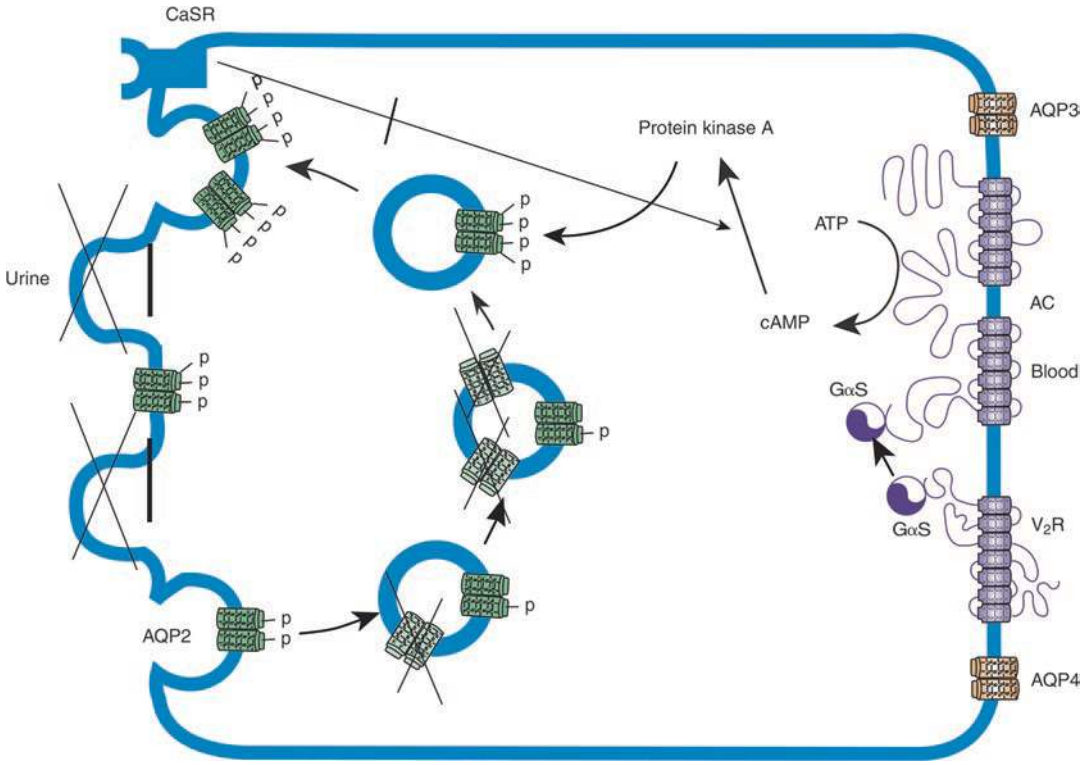

Fig. 40.2 Diagram of a principal cell. Depicted is a schematic of a principal cell with relevant proteins for water transport. AVP binds to the AVR2 receptor (depicted in green), expressed on the basolateral side of the cell. AVPR2 is a G-protein-coupled receptor and AVP binding releases the stimulatory G-protein GαS, which, in turn, stimulates adenylcylase. The increased production of cycline adenosine monophosphate (cAMP) stimulates protein kinase A (PKA), which phosphorylates the water channel AQP2, leading to insertion of these channels into the apical membrane. Water can then enter the cell from the tubular lumen and exit into the interstitium via the constitutively expressed water channels AQP3 and AQP4

Diagnosis

The presence of inappropriately dilute urine in the face of an elevated serum osmolality defines DI. Dehydration in a child with good urine output should always prompt consideration of a urinary concentrating defect. The diagnosis is easily made by obtaining serum and urine biochemistries. Maximal urinary concentrating ability increases with age, but a urine osmolality below plasma osmolality in a dehydrated child establishes a diagnosis of DI [53]. In classic NDI the urine osmolality is always below 200 mOsm/kg.

Diagnostic Procedures

Water Deprivation Test

The aim of the water-deprivation test is to induce mild dehydration and thus challenge the kidney to preserve water. Water is withheld until serum osmolality is just above the upper limit of normal (>295 mOsm/kg). Obviously, no child presenting with hypernatraemia and inappropriately dilute urine needs to undergo this test, as the challenge had already presented naturally. A water deprivation test carries the risk of severe hypernatraemic dehydration, especially in infants, as

there may be delays in obtaining and reacting to laboratory results. It is useful to distinguish habitual polydipsia from central DI in patients with a good response to DDAVP, and is usually reserved for those particular patients: those with habitual polydipsia will be able to increase urine osmolality with water deprivation, whilst those with central DI will not. For a first assessment, a simple and informal water deprivation test is to ask the parents to obtain the first morning urine on their child and note the last time the child has drunk (water should not be withheld from the child). This can be used as an initial screening test in polyuric patients, as a concentrated urine excludes a diagnosis of DI.

DDAVP Test

The kidney concentrates the urine in response to the pituitary hormone AVP. Failure to concentrate can therefore be due to a deficiency in AVP (central DI or CDI) or an inability of the kidney to respond to it (NDI). AVP effects are mediated via two different receptors: the vasoconstriction ("vasopressin") is mediated by AVP receptor 1 (AVPR1), while the antidiuretic response is mediated by receptor type 2 (AVPR2). DDAVP has a high specificity for AVPR2 and can therefore be used to assess the renal response while avoiding the systemic effects mediated by AVPR1. Different protocols exist in the literature with respect to dosage and route of administration of DDAVP. Some authors use intranasal DDAVP, others oral, subcutaneous (sc), intramuscular (im) or intravenous (iv) administration [49, 54, 55]. While oral or intranasal DDAVP is less invasive, absorption is less reliable. Thus, if the result of the test is inconclusive, it may need to be repeated using injected DDAVP. DDAVP given iv requires a shorter observation period (2 h) than other modes of administration (4–6 h), where absorption is more protracted. Moreover, DDAVP at the dose commonly used in von Willebrand disease (0.3 μg/kg iv) induces some systemic side effects in the form of a mild decrease in blood pressure and concomitant increase in heart rate via AVPR2 (see above). Consequently, patients with mutated AVPR2 (X-linked NDI) do not experience these haemodynamic changes, while patients with intact AVPR2, but mutated AQP2 (autosomal DI) do. The DDAVP test can therefore help differentiate between these two forms. A typical protocol, modified from [49] is given in Table 40.1. A commonly feared, but actually rare complication of

Patients should be observed for a minimum of 2 h (iv) to 6 h (oral and nasal) after DDAVP administration. Volume of fluid intake during the test must be limited to the volume of urine produced in order to avoid hyponatremia
See text for more information and interpretation of results

the DDAVP test is hyponatraemia. Patients with intact thirst mechanism who respond to DDAVP will stop drinking water, due to their stable serum osmolality. Yet patients with habitual polydipsia, who will keep on drinking despite lowered serum osmolality, and infants, who continue to be fed by their caregivers throughout the test are at risk for hyponatraemia. Thus, close observation and strict limitation of fluid intake to a volume equal to urine output during the test period is critical to prevent this complication.

A urine osmolality after DDAVP below 200 mOsm/kg is consistent with a diagnosis of NDI, while patients with intact urinary concentrating ability typically achieve urine osmolalities greater than 800 mOsm/kg (>300 in infants) [53]. Patients with intermediate values should be assessed for inaccurate test results (especially when DDAVP was administered intranasally) or intrinsic renal disease limiting the urinary concentrating capacity (including chronic renal failure and obstructive uropathy, see below).

Differential Diagnosis

Central DI

A urinary concentrating defect can be due to a lack of AVP (central DI) or the inability of the kidney to respond to it (NDI). A DDAVP test helps to differentiate between the two (see above). Central DI is most commonly the consequence of head trauma, or other diseases affecting the hypothalamus or pituitary, but there are some rare cases of hereditary DI due to mutations in the gene encoding *AVP* [56–58]. In addition, loss-of-function variants in the *PCSK1* gene, encoding Proprotein Convertase 1, an endopeptidase involved in cleaving of precursor proteins into active peptide hormones have a complex endocrine phenotype that can include polyuria-polydipsia [59].

X-Linked and Autosomal NDI

A careful family history and assessment of systemic effects in the DDAVP test can discriminate the more common X-linked (90% of patients with identified mutations) from the rare autosomal NDI (10%). In approximately 10% of patients with presumed primary NDI, no mutation in either AVPR2 or AQP2 is identified [60]. Thus, these patients either have mutations in genes not yet identified to cause primary NDI, or in regions of the two known genes not assayed (e.g. introns or promoter), or have been misdiagnosed and actually have a secondary form of NDI (see below).

Partial NDI

An intermediate urine osmolality, that is between 200 and 800 mOsm/kg after administration of DDAVP is referred to as partial NDI. As discussed above, children less than 3 years of age, and especially in the first months of life, may not be able to maximally concentrate their urine yet and a value below 800 can be physiologic [53]. Further, technical problems with the DDAVP test should be excluded, especially if administration was intranasally, before a diagnosis of partial NDI is considered.

Inherited forms of partial DI are typically due to mutations in the *AVPR2* gene, that allow proper expression of the receptor at the cell membrane, but decrease the affinity to AVP, thus shifting the dose-response curve and requiring higher amounts of AVP to increase urinary concentration [61, 62]. However, mutations in *AQP2* with some retained urinary concentrating ability have also been identified [63]. Obviously, since these patients have a partially retained ability to concentrate their urine, their clinical symptoms are milder.

Secondary NDI

The defining feature of NDI is a pathologic deficiency of AQP2 in the apical membrane of the collecting duct. This can be primary inherited, i.e. due to mutations in either *AQP2* itself or in *AVPR2*, or occur as a secondary phenomenon: as a side effect of medications, anatomical problems or in the context of other tubulopathies [64]. The distinction is important, as misclassification as

primary NDI may miss the opportunity to identify a remediable cause, such as urinary obstruction, or to make the correct diagnosis, which may result in potentially harmful treatment. Thus, in any patient with clinical NDI who displays unusual features, such as a history of polyhydramnios or hypercalciuria/nephrocalcinosis or hypokalaemia (before thiazide treatment), a secondary form of NDI should be considered and consequently a primary diagnosis sought.

Secondary Inherited NDI

A secondary form of NDI has been observed in other inherited tubulopathies, which can lead to misdiagnosis [65]. This seems to occur most commonly in Bartter syndrome types 1 and 2 [66–68]. Whilst isosthenuria (i.e. an impaired ability to either concentrate or dilute the urine with a urine osmolality similar to that of plasma) is an expected feature of Bartter syndrome (see section "Disorders Impairing the Generation of a Medullary Concentration Gradient" below), some of the affected patients clearly have hyposthenuria (i.e. a urine osmolality persistently below that of plasma). Indeed, in the laboratory in Montreal, the genes underlying type 1 and type 2 Bartter syndrome, *NKCC2* and *KCNJ1*, are tested next if no mutations were identified in *AVPR2* or *AQP2* in the DNA of patients referred with a clinical diagnosis of NDI [64].

Secondary NDI has also been described in many other inherited diseases affecting the kidney, including renal Fanconi syndromes, especially cystinosis, distal renal tubular acidosis (dRTA), apparent mineralocorticoid excess (AME) and ciliopathies [64, 65].

The precise etiology of this secondary NDI is unclear, but may be related to the electrolyte abnormalities inherent in these disorders, especially hypercalciuria and hypokalaemia (see below). Regardless of the etiology, establishing the correct diagnosis is obviously important: some of the primary disorders can be treated specifically (e.g. cystinosis, dRTA or AME). Moreover, the thiazide treatment commonly used in NDI could compound the defect in tubular salt reabsorption inherent to some of these disorders (e.g. renal Fanconi syndromes, Bartter syndrome) resulting potentially in serious hypovolaemia.

Obstructive Uropathy

Polyuria after release of urinary tract obstruction is a well-recognized phenomenon (post-obstructive diuresis). However, if obstruction is incomplete, it is often associated with polyuria, as well. Animal studies show a decreased level of AQP2 expression with bilateral ureteric obstruction [69]. Experiments with unilateral obstruction show a marked decrease in AQP2 in the obstructed kidney, consistent with the view that local factors, such as increased pressure, affect AQP2 expression [70]. Supporting this view is also the fact that other signs of distal tubular dysfunction are usually present in obstructive uropathies, like hyperkalaemia and acidosis. The downregulation of AQP2 persists up to 30 days after release of obstruction, explaining the post-obstructive diuresis [35].

Interstitial Renal Disease

Polyuria is frequently seen in renal failure, especially if the underlying aetiology primarily affects the interstitium, such as in renal dysplasia (see Chap. 9), nephronophthisis (see Chap. 12) or tubulointerstitial nephritis (see Chap. 37). It is also commonly seen after ischemic renal failure [71, 72]. However, these patients will typically have isosthenuria. This is in contrast to the hyposthenuria, i.e. a urine osmolality persistently below that of plasma that characterizes NDI.

Lithium

While rarely used in children, lithium therapy is a common treatment for manic-depressive disease in adults and roughly a fifth of patients develop polyuria [73]. Animal studies have shown decreased expression of AQP2 in principal cells, probably due to inhibition of cAMP formation in the collecting duct [38, 74–76].

Hypercalcaemia and Hypercalciuria

Hypercalcaemia can be associated with polyuria and two mechanisms have been proposed to explain the AVP-resistant concentrating defect; both likely involving the calcium-sensing receptor (CaSR). This receptor is expressed on the basolateral (blood) side of thick ascending limb cells and indirectly inhibits the NKCC2 co-transporter, thus impairing the generation of a

medullary concentration gradient [77–79]. Second, this receptor is also expressed on the luminal (urine) side of collecting duct cells and thought to affect AQP2 trafficking [80, 81]. The latter mechanism would thus be mediated by hypercalciuria and has been proposed to constitute a protective measure against the formation of calcium-containing stones [82]. It would also provide an explanation for the hypercalciuric forms of secondary NDI, such as in Bartter syndrome (see above). However, doubts have been raised about the clinical relevance of this mechanism, as the protection against stones would come at the risk of dehydration. Indeed, in healthy control subjects the highest urine calcium concentrations were found in the most concentrated urine samples, arguing against a clinically relevant effect of urine calcium on urine concentration [83].

Hypokalaemia

Hypokalaemia causes an AVP-resistant concentration defect. As in the other forms of acquired NDI, reduced expression of AQP2 has been demonstrated [84]. Thus, downregulation of AQP2 seems to be a common feature in acquired NDI [35]. However, the mechanism by which hypokalaemia affects this remains to be elucidated.

Disorders Impairing the Generation of a Medullary Concentration Gradient

Bartter Syndrome

As discussed above, the loop of Henle and active salt reabsorption in thick ascending limb are necessary for the generation of a medullary concentration gradient. Therefore, factors impairing salt reabsorption in the thick ascending limb will lead to a urinary concentration defect (hypo- or isosthenuria). Patients with Bartter syndrome have inherited defects in thick ascending limb salt transport and symptoms include polyuria and episodes of hypernatraemic dehydration (see Chap. 29), similar to patients with NDI. However, the presence of a hypokalaemic alkalosis and elevated urinary electrolytes, particularly chloride, help differentiate it from NDI, although the former may be absent in young infants [67]. A history of polyhydramnios further helps to exclude a diagnosis of NDI.

Urea Transporter

Urea is an important constituent of the medullary interstitial concentration gradient. Urea is a bipolar molecule and thus can only diffuse slowly through membranes [85]. Diffusion is facilitated by urea transporters and two genes encoding these transporters have been identified in humans [86]. A mild urinary concentrating defect has been described in patients not expressing the minor blood group antigen Kidd (Jk) [87]. Later, this antigen was identified to be identical with the urea transporter UT-1, encoded by *SLC14A1* and several mutations in this gene have been identified in Kidd-negative individuals [88–90]. Recent evidence suggests that UT-1 is also expressed in the endothelium of the vasa recta and that the combined defect in red cell and vascular urea diffusion impairs countercurrent concentration [91, 92]. Interestingly, no mutations have been found so far in the gene encoding the urea transporter expressed in renal tubule UT-2 (*SLC14A2*).

Genetics

AVPR2

The majority of cases of NDI (90%) are due to mutations in the *AVPR2* gene [93, 94]. The gene is located on chromosome region Xq28 and the mode of inheritance is X-linked recessive. Therefore, the majority of patients with NDI are male, but due to skewed X-inactivation (lionization), females can be affected with variable degrees of polyuria and polydipsia [20, 95–97]. Indeed, in some families, X-inactivation is strongly biased leading to a pseudo-dominant inheritance pattern [98]. X-inactivation may be strongly biased because of (a) chance, (b) a co-existent mutation on the affected X-chromosome affecting cell survival or (c) a co-existing mutation in a gene regulating X-inactivation [99].

So far, more than 211 distinct putative disease-causing mutations have been described in more than 326 families [93, 100]. When investigated in vitro, these mutations can be classified according to their effect [101–118]:

Class 1 mutations result in frame-shifts, premature stop-codons and aberrant splicing and prevent translation of the receptor protein.

Class 2 mutations are missense mutations that allow for translation of the protein, but lead to aberrant trafficking. Typically, these mutations induce improper folding with subsequent trapping in the endoplasmic reticulum (ER).

Class 3 mutations allow the mutated protein to reach the cell-surface, but impair the receptor's signaling, typically by affecting binding of AVP.

The majority of mutations identified in X-linked NDI belong to class 2 [119]. Conversely, mutations identified in inherited partial NDI fall into class 3: these mutated receptors reach the cell membrane, but have a decreased affinity for AVP [54, 61].

Interestingly, three distinct class 3 mutation have been identified in the *AVPR2* gene, leading to gain-of-function with constitutive activation of the receptor and thus to a "nephrogenic syndrome of inappropriate antidiuresis" [120, 121].

AQP2

The analysis of a pedigree with affected females and the presence of intact extrarenal responses to DDAVP in some patients with NDI lead to the postulation of an autosomal inherited "post-receptor" defect in these individuals [122–124]. The molecular basis for this distinct form of NDI was identified in 1994 to be the water channel aquaporin-2, which is expressed in collecting duct [14]. Approximately 10% of all patients with NDI carry mutations in the *AQP2*. As expected for a loss-of-function defect, inheritance is usually recessive and—similar to AVPR2—the majority of mutations fall into class 2 with retention in the endoplasmic reticulum [119, 125]. Interestingly, there are some families with autosomal dominant inheritance of NDI. Molecular analysis has shown that affected members carry mutations in the c-terminus of AQP2 [43, 126–128]. So why does this lead to a dominant inheritance? The final waterchannel is a homotetramer, meaning it consists of four AQP2 subunits (see Fig. 40.2). Dominant mutations in the C-terminus lead to aberrant trafficking (class 2), but are able to oligomerize with wild-type protein to form the tetramer. As tetramerization takes place before export to the plasma membrane, these mutations exert a dominant-negative effect on AQP2 function, by misguiding trafficking of the assembled tetramer. Interestingly, specific mutations direct AQP2 trafficking to distinct cellular compartments, such as the Golgi complex [43], late endosomes/lysosomes [126] or the basolateral membrane [128, 129].

Treatment

General Aspects of Treatment

The importance of prompt treatment of NDI is highlighted by the fact that mental retardation used to be an invariable feature, but can be completely prevented by proper treatment. Caring for a patient with NDI is most difficult during infancy, when the babies are dependent on their caregivers for access to fluids. Therefore fluids should be offered in 2-h intervals, placing a considerable burden on the caregivers, particularly at night. Feeding per nasogastric tube is often helpful in this period. A continuous overnight feed delivered by a pump will provide fluid and calories to the baby and much needed rest to the parents. Families also need to be instructed to bring the child to immediate medical attention, when there are increased extra-renal fluid losses, such as when diarrhoea, vomiting or fever are present. It is often helpful for the parents to have a letter detailing the condition of their child and the need for prompt physical and biochemical assessment, that they can present in these instances in order to avoid being sent home by medical personnel with no experience in this condition. There should be

a low threshold for admission and intravenous hydration in these instances to prevent dehydration. When in hospital, hypotonic fluids, such as 5% Dextrose or 0.22% saline are usually appropriate for intravenous hydration, because of the obligate water losses in the urine. Replacement fluids with a higher osmolality than urine osmolality will exacerbate hypernatraemia. For instance, 0.45% saline results in an osmotic load of 154 mOsm/L (77 mOsm Na and 77 mOsm Cl). A patient with a maximal urine osmolality of 100 mOsm/kg will need to excrete 1.54 L of urine for each litre of 0.45% saline received in order to excrete the osmotic load presented by the replacement fluid (see below). Thus, in patients with NDI, the administration of fluids that are hypertonic compared to urine can lead to hypernatraemic dehydration, even though the fluid may be hypotonic to plasma. However, if there are increased salt losses, as can occur with diarrhea, or if hypotonic fluids are administered at a rate higher than the urine losses, hyponatraemia could ensue. Close monitoring of the patient with respect to weight, fluid balance, clinical symptoms and biochemistries is therefore imperative to prevent complications.

Osmotic Load Reduction

The most important part in the treatment of patients with NDI is a reduction in their osmotic load, also called renal solute load, which determines urine volume. Therefore close involvement of a dietician with experience in the management of children with kidney problems is necessary. The osmotic load consists of osmotically active substances that need to be excreted in the urine, i.e. proteins, as they are metabolized to urea, and salts. A typical western diet contains about 800 mOsm per day. Thus, an individual with a urine osmolality of 800 mOsm/kg only needs 1 L of water to excrete that load. Yet a patient with NDI and a maximal urine osmolality of 100 mOsm/kg needs at least 8 L of water for excretion and if the urine osmolality is 50 mOsm/kg then 16 L of water are required. One gram of table salt is equivalent to about 18 mmol NaCl, providing an osmolar load of 36 mOsm (18 mOsm Na and 18 mOsm Cl). Consequently, for a patient with a urine osmolality of 100 mOsm/kg, each gram of salt ingested increases obligatory urine output by 360 mL. The osmolar load of a diet can be roughly estimated by the following formula: twice the millimolar amount of sodium and potassium (to account for the accompanying anions) plus protein [g] times 4 (as metabolisation of each g of protein yields approximately 4 mmol of urea) [130]. Since lipids and sugars are metabolized without byproducts requiring renal excretion, only protein intake needs to be limited, but should still meet the recommended daily allowance to enable normal growth and development. A reasonable goal is a diet containing about 15 mOsm/kg/day. A child with a urine osmolality of 100 mOsm will need a fluid intake of 150 mL/kg/day to be able to excrete that load, which is achievable. Enriching the fluid intake with carbohydrates will provide additional calories without increasing the osmolar load.

Diuretics

The use of a diuretic in a polyuric disorder appears at first glance counterintuitive, but does make physiologic sense. The successful use of thiazides in NDI with a subsequent increase in urine osmolality and concomitant decrease in urine output was first reported in 1959 [131, 132]. Thiazides inhibit reabsorption of sodium and chloride in the distal convoluted tubule (part of the section "Tubular Concentration/Dilution Mechanism (Countercurrent Mechanism with Figure)"—see above) and thus increase the salt concentration and osmolality of the urine. The increased salt losses decrease intravascular volume with a subsequent up-regulation of proximal tubular reabsorption of salt and water. Consequently, less volume is delivered to the collecting duct and lost in the urine. Typically used is hydrochlorothiazide at 2 mg/kg/day in two divided doses. The more long-acting Bendroflumethiazide (50–100 μg/kg/day) can be given as a single daily dose. Hypokalaemia is a common complication of thiazide administration, but supplemen-

tation with potassium salts increases the osmolar load. Therefore, combination of the thiazide with a potassium-sparing diuretic, such as amiloride (0.1–0.3 mg/kg/day) is advantageous, but the latter can cause gastrointestinal side effects, especially nausea.

Non-steroidal Anti-inflammatory Drugs (NSAID)

Like in many other tubular disorders NSAID (prostaglandin synthesis inhibitors) are used in NDI. Initially, it was thought that these worked by reducing GFR and thus a "partial chemical nephrectomy" to minimize losses. However, observations in animals and humans suggest that NSAID can increase urine osmolality without decreasing GFR. In fact, an improvement in GFR can be observed, presumably reflecting improved volume status [66]. The exact mechanism remains to be elucidated, but appears to be ADH-independent [133–135]. Some evidence suggests that activation of basolateral prostaglandin receptors by prostaglandin E2 inhibits Adenylcyclase and/or the shuttling of AQP2 to the apical membrane [136–138].

Typically used is Indomethacin (1–3 mg/kg/day in three to four divided doses). The long-term use of this drug is associated with deterioration of renal function and haematological, as well as gastro-intestinal side effects including life-threatening haemorrhage [139, 140]. The latter may be avoided by using a selective COX-2 inhibitor and the successful use of these in NDI has been reported [141, 142]. However, there are concerns about cardiotoxic side effects of these drugs, as evident by the removal of Rofecoxib from the marketplace [143]. In our experience, the combination of Hydrochlorothiazide with an NSAID is useful during the first years of life, with a subsequent switch to Bendroflumethiazide with or without Amiloride. Key is the close observation of the individual patient for side effects and for changes in urine output or growth percentiles.

The concurrent use of antacids can help with the vomiting often seen in infants with NDI and help prevent gastro-intestinal side effects of NSAID.

Future Perspectives

An increasing understanding of the molecular mechanisms of the (patho)physiology of urinary concentration opens up perspectives for novel treatments [144].

Molecular Chaperones

The vast majority of mutations identified in the *AVPR2* gene lead to improper folding of the resultant protein with entrapment in the endoplasmic reticulum (see section "AVPR2"). Retention is dependent on specialized endoplasmic reticulum proteins, many of which require calcium for optimal function. Therefore, depletion of endoplasmic reticulum calcium stores by inhibiting the sarcoplasmatic calcium pump may be useful to overcome entrapment [145]. Indeed, this approach has been successfully used in vitro to induce surface expression of an AVPR2 mutant [146]. More specific, is the idea to use small pharmacological chaperones that can enter the cell, bind to the mutant receptor and thus induce proper folding with subsequent release from the endoplasmic reticulum [147, 148]. With the development of small membrane-permeable AVPR2-receptor antagonists, designed to fit neatly into the binding fold of the receptor, this approach has become feasible and indeed successful in vitro [149–151]. More importantly, a recent trial of a AVP antagonist in five patients with NDI, bearing either the mutation del62-64, R137H or W164S (all of which lead to ER retention), has shown a significant decrease in urine output with a concomitant increase in urine osmolality [152]. Total 24-h urine volume decreased from a mean of 11.9–8.2 L and mean urine osmolality rose from 98 to 170 mOsm/kg and thus the observed effect was modest. Nevertheless, these results hold the promise of a targeted, mutation-specific therapy in patients with NDI. Increasingly, gene therapy is becoming a reality, either by provision of the wild-type gene or by correcting the specific genetic mutation through gene editing [153]. Once safe and efficacious methods to deliver such treatments to the kidney have been developed, these obviously would provide specific treatments for inherited NDI.

Prostaglandin Receptor Agonists

The identification of cAMP as a key messenger in urinary concentration has led to the search for compounds that could increase cAMP in the principal cell independent of AVPR2. Recently, it was shown that agonists for the prostaglandin receptor EP2 and EP4, such as prostaglandin E2 could provide such an alternative pathway [154]. Indeed, in a rat model of NDI these compounds were able to reduce urine output significantly. Yet, giving prostaglandins to treat NDI is in apparent contradiction to the clinically proven efficacy of prostaglandin synthesis inhibition (see above) and more data are needed to resolve this conundrum.

Part VIII

Renal Neoplasia and Tubulointerstitial Disease

Pediatric Renal Tumors

41

Kathryn S. Sutton and Andrew L. Hong

Introduction

Pediatric renal tumors include a heterogeneous group of diagnoses that vary greatly in both required treatment and long-term outcome. This chapter will review both benign and malignant renal masses, with a particular emphasis on pediatric kidney cancers given their impact on morbidity and mortality. Approximately 600 children are diagnosed with renal cancer each year in the United States, accounting for 7% of all pediatric malignancies. The predominant renal tumor pathology in young children is Wilms tumor, although renal cell carcinoma overtakes Wilms tumor in older adolescents [1, 2]. Additional tumor types of varying malignant potential arising in the kidney include renal medullary carcinoma, malignant rhabdoid tumor, clear cell sarcoma of the kidney, and congenital mesoblastic nephroma (Table 41.1) [3]. Pediatric leukemia and lymphoma can also present as a renal mass, although often there are additional sites of disease [4–6]. Benign kidney masses include metanephric neoplasms and cystic nephroma [3]. Rounding out the differential diagnosis of a pediatric renal mass are tumors that are adjacent to, but not arising from the kidney, most commonly adrenal tumors such as neuroblastoma and adrenal cortical carcinoma, or kidney malformations such as multicystic dysplastic kidneys.

Typical presentations of each diagnosis will be discussed in detail below; however, in general presenting symptoms of pediatric renal tumors may include painless abdominal masses or swelling, abdominal pain, hypertension, and hematuria. The initial workup for pediatric abdominal masses includes ultrasonography and laboratory evaluation, with further imaging recommended based on preliminary findings. Laboratory testing can both help to rule in and classify a renal tumor and to rule out other common pediatric abdominal cancers (Table 41.2).

Table 41.1 Pediatric renal tumors

Malignant	Wilms tumor (nephroblastoma) Nephroblastomatosis (pre-malignant)
	Clear cell sarcoma of the kidney
	Renal cell carcinoma
	Renal medullary carcinoma
	Malignant rhabdoid tumor
	Ewing sarcoma of the kidney
Low malignant potential	Angiomyolipoma/malignant epithelial angiomyolipoma
	Congenital mesoblastic nephroma
Benign	Cystic nephroma
	Ossifying renal tumor of infancy
	Metanephric adenoma/metanephric stromal tumor/metanephric adenofibroma
Secondary tumors	Leukemia/Lymphoma
	Neuroblastoma (suprarenal)

Table 41.2 Initial laboratory evaluation for pediatric renal masses

Lab	Possible findings/interpretation
Complete Blood Count with differential	Anemia due subcapsular hemorrhage Pancytopenia or blast cells due to leukemia/lymphoma Polycythemia in metanephric adenoma/adenofibroma or renal cell carcinoma
Complete Metabolic Panel	Renal dysfunction Hypercalcemia in congenital mesoblastic nephroma Liver dysfunction in the setting of metastatic disease
Urinalysis	Hematuria
Coagulation studies (PT/PTT)	Acquired Von Willebrand's Disease in Wilms tumor
Urine catecholamines	Elevated in neuroblastoma (arises in suprarenal region)
LDH/Uric acid	Elevated in tumor lysis syndrome, especially in leukemia/lymphoma

Wilms Tumor

Epidemiology

Wilms tumor (WT), also known as nephroblastoma, is named for Max Wilms, a German pathologist and surgeon, who described the tumor in 1899 [7]. Wilms tumor represents the vast majority of pediatric renal tumors, accounting for 85–90% of kidney tumors diagnosed in children younger than age 14 [1]. There are approximately 600 new cases of WT in the United States annually, and worldwide the incidence approaches 1:10,000 children. There is a very slight female predominance, and WT is more common in Blacks and Whites than Asians [8].

Wilms tumor presents most commonly in preschool aged children, with the majority of cases diagnosed before the age of 5 years and nearly all before 10 years. Boys tend to present at a younger age than girls. Approximately 5–10% of WTs are bilateral at diagnosis, and these patients present earlier, with a median age at diagnosis of 31 months as compared to 44 months for patients with unilateral tumors [8]. Ten to 15% of WT are associated with an underlying predisposition syndrome (Table 41.3) [9, 10].

Predisposition Syndromes

The majority of Wilms tumor predisposition syndromes are associated with two genes, *WT1* and *WT2*, both located on chromosome 11 [9]. Patients with predisposition syndromes are more likely to present at a younger age and with bilateral disease [8]. The treatment approach to WT arising in patients with underlying predisposition syndromes requires modification to preserve

Table 41.3 Wilms tumor predisposition syndromes [9–11, 20, 22, 23]

Syndrome	Gene (locus)	Wilms tumor risk
WAGR	*WT1* (11p13)	50%
Denys-Drash	*WT1* (11p13)	>90%
Frasier	*WT1* (11p13)	8%
Beckwith-Weidemann	WT2 locus: *CDKN1C*, *H19*, *LIT1*, *IGF2* (11p15.5)	5% (Can be higher depending on specific genetic finding)
Simpson-Golabi-Behmel	*GPC3* (Xq26), *GPC4* (Xq26), *OFD1* (Xp22)	8%
Sotos	*NSD1* (5q35.3)	<5%
Perlman	*DIS3L2* (2q37.1)	50–75%
Trisomy 13	Chromosome 13	Rare
Trisomy 18	Chromosome 18	>1%
Mulibrey nanism	*TRIM37* (17q22)	7%
Bohring-Optiz	*ASXL1* (20q11.21)	7%
Isolated hemihypertrophy	WT2 locus (11p15.5), among others	5%
Familial Wilms	*FWT1* (17q12-21), *FWT2* (19q13)	Variable, approximately 15–30%
Gorlin (9q22.3 Microdeletion)	*PTCH1* (9q22.3)	<5%
Mosaic Variegated Aneuploidy/ Premature Chromatid Separation	*BUB1* (2q13), *TRIP13* (5p15.33)	>20%
Bloom	*RECQL3* (15q26.1)	<5%
Fanconi Anemia with Bialleic BRCA2/PALB2 mutations	*BRCA2* (13q13.1), *PALB2* (16p12.2)	>20%
DICER1	*DICER1* (14q32.13)	<5%
Li Fraumeni	*TP53* (17p13.1)	<5%
Hyperparathyroidism-Jaw Tumor	*HPRT2* (1q31.2)	<5%
PIK3CA-related Segmental Overgrowth (CLOVE)	*PI3KCA* (3q26.32)	<5%
2q37 microdeletion	2q37.1	3%

normal kidney tissue and function and will be discussed later.

WT1, found at chromosome 11p13, encodes for a transcription factor associated with kidney and gonadal development [9]. Mutations of *WT1* are typically autosomal dominant and the majority arise *de novo* [11]. Deletion of *WT1* results in Wilms tumor-Aniridia-Genitourinary anomalies- Intellectual disability (formerly mental Retardation) (WAGR) Syndrome first described in 1964 [12]. Patients with WAGR Syndrome have an approximately 50% lifetime incidence of Wilms tumor [13]. Aniridia is nearly universal and is due to deletion of the neighboring *PAX6* gene, and developmental delay is present in the majority of patients. Renal failure can occur secondary to nephropathy and glomerulonephritis and occurs in 20–40% of patients [14, 15]. Variable screening recommendations for WT in patients with WAGR Syndrome have been proposed. All groups recommend renal ultrasounds every 3–4 months beginning at the time of diagnosis of the underlying syndrome; however, recommended duration varies from through age 5 to through age 8 years [11, 14, 16, 17]. Point mutations of *WT1* result in multiple syndromes, including Denys-Drash and Frasier Syndromes [10, 18, 19]. Denys-Drash Syndrome portends a greater than 90% incidence of WT [10]. On the contrary, patients with Frasier Syndrome have only an 8% likelihood of developing WT [20]. Both may present with nephropathy and genitourinary abnormalities. Males with Denys-Drash Syndrome may present with hypospadias, ambiguous genitalia, or streak gonads. The associated nephropathy (mesangial sclerosis) commonly progresses to end stage kidney disease (ESKD) by the second decade of life. Frasier Syndrome is associated with focal segmental glomerulosclerosis with later onset of renal failure. Patients with Frasier Syndrome have gonadal dysgenesis and a propensity for development of gonadoblastoma in addition to WT [20].

Syndromes associated with the *WT2* gene found at chromosome 11p15 are associated with imprinting or hypermethylation of *WT2* as well as neighboring genes, including *IGF2* and *CDKN1C*. Due to effects on *IGF2*, these syndromes are frequently associated with body and visceral overgrowth [11, 21]. Beckwith-Weidemann Syndrome (BWS) may present with hemihypertrophy, omphalocele or abdominal hernia, macroglossia, ear creases or pits, and neonatal hypoglycemia [20]. Patients with BWS are at increased risk of multiple embryonal tumors, including Wilms tumor, neuroblastoma, hepatoblastoma, and embryonal rhabdomyosarcoma, as well as adrenal cortical carcinoma. The overall malignancy rate approaches 10%, with WT making up approximately 50% of those cancers. Cancer screening recommendations in BWS may be further tailored depending on the specific genes affected; however, general recommendations include ultrasound every 3 months through age 7: abdominal ultrasound until the fourth birthday to also screen for hepatoblastoma followed by renal ultrasounds until the seventh birthday. In addition, alpha fetoprotein (AFP) and urine catecholamines are employed to screen for hepatoblastoma and neuroblastoma, respectively [11, 21]. Table 41.3 provides a complete list of syndromes predisposing to WT.

Pathology

Wilms tumor is an embryonal tumor, arising from pluripotent fetal metanephric tissue. WTs display triphasic histology, including epithelial, stromal, and blastemal components, though monophasic and biphasic tumors can occur (Fig. 41.1). The epithelial component often resembles rudimentary renal tubules; whereas, the blastemal component consists of undifferentiated small blue cells favoring embryonic renal mesenchyme [24]. The compilation of histologic subtypes is a key feature in defining prognosis and occurs along a continuum with epithelial-predominant tumors behaving less aggressively and blastemal-predominant portending increased risk [25–28].

Wilms tumor histology is further classified as favorable histology Wilms tumor (FHWT) versus anaplastic Wilms tumor (AWT) by the presence or absence of anaplasia, described as large, pleomorphic, hyperchromatic tumor cell nuclei with abnormal multipolar mitotic figures (Fig. 41.1) [25]. Anaplasia may be focal or diffuse, and is present in the tumors of 6–8% of patients. Anaplastic Wilms tumor is more common in older patients and in patients of African descent. Anaplasia, especially when diffuse, is associated with chemotherapy resistance and overall poor prognosis [25, 28–30]. Anaplastic Wilms tumors frequently express aberrant *TP53*, a prominent

(Courtesy of Hong Yin, MD; Children's Healthcare of Atlanta)

tumor suppressor gene known to be somatically mutated in many aggressive cancers and associated with the cancer predisposition syndrome, Li Fraumeni Syndrome, when mutated in the germline [31].

Further pathologic characteristics critical for appropriate staging and, therefore, treatment of WT include tumor size and weight; the extent of tumor including involvement of the renal sinus, renal vein, or extension through the renal capsule; margin status following resection; pathologic status of resected peri-renal lymph nodes; and evaluation of additional somatic mutations.

In addition to germline syndromes, somatic mutations commonly found in WTs have both prognostic and therapeutic implications. The most commonly mutated genes in WT include *WT1*, Wnt-signaling pathway genes such as *CTNNB1*, and the oncogene *MYCN*. Therapies targeting several of these frequent mutations are in development [9]. In addition, specific genomic findings, including copy number variations and loss of heterozygosity (LOH), are prognostic in WT, allowing for therapeutic risk-stratification in clinical trials. Adverse biologic markers include LOH of chromosome 1p and 16q, LOH or loss of imprinting at 11p15, gain of 1q, and loss of 17p [9, 31–42].

Nephrogenic Rests and Nephroblastomatosis

Nephrogenic rests and nephroblastomatosis are pre-malignant lesions associated with Wilms tumor. Fetal metanephric cells typically disappear by 36 weeks gestation. Nephrogenic rests are clusters of pluripotent embryonal cells persisting past that developmental time point and into post-natal life [43]. They are common, being incidentally found in 1% of unselected pediatric kidneys at autopsy, 35–40% of kidneys with unilateral WT, and nearly 100% of kidneys with bilateral WTs. Nephroblastomatosis is the presence of multiple or diffuse nephrogenic rests and can be perilobar or intralobar. Nephrogenic rests and nephroblastomatosis may self-resolve, persist, or undergo malignant transformation into WT [44]. Diffuse hyperplastic perilobar nephroblastomatosis (DHPLN) is a specific form of nephroblastomatosis, strictly defined as "massive enlargement of the kidney with a rind-like expansion of the renal cortex of homogeneous signal intensity, and preservation of the renal shape." DHPLN carries an incredibly high likelihood of malignant transformation and treatment with chemotherapy should be strongly considered even before the development of frank WT [43].

Presentation

Wilms tumor most commonly presents as a painless abdominal mass in a young child, although a minority of patients may present with abdominal pain, gross hematuria, fever, or constipation. Rarely, patients will report anorexia or weight loss. Approximately 25–67% of patients are hypertensive at presentation, predominantly secondary to renin-angiotensin system activation in the setting of renal ischemia. These patients frequently require anti-hypertensive medications prior to nephrectomy which can often be weaned in the weeks following tumor removal [45–48]. Quite rarely, male patients with left-sided renal tumors can present with a left-sided varicocele secondary to compression of the left renal and testicular veins. (The right testicular vein does not arise from the right renal vein, so right-sided varicoceles do not occur) [49]. Although not common, patients can present acutely following subcapsular hemorrhage of their tumor. This can lead to rapid abdominal enlargement, acute anemia, blood pressure abnormalities (hyper- or hypotension), and fever and often requires urgent surgical intervention [50–52]. Patients with WT should be assessed for findings of an associated predisposition syndrome as described previously, including hemihypertrophy, macroglossia, aniridia, genitourinary anomalies, and developmental delay.

Metastatic disease is present in approximately 12% of patients at the time of diagnosis. The lungs are by far the most common site of spread (80%), followed by lymph nodes (15–20%) and the liver (15%), with other sites being extremely

rare at the time of presentation. The likelihood of metastatic disease increases with increasing age at diagnosis and with signs of aggressiveness at the primary tumor site [53]. It is rare for a child to present with symptoms related to metastases, which are often only discovered during a thorough staging evaluation.

Evaluation and Staging

Following initial history and physical, pediatric abdominal masses are typically evaluated via ultrasonography. On ultrasound, Wilms tumor can frequently be identified as a well-circumscribed mass of varying echogenicity arising from the kidney. The classic finding is a "claw sign" where the renal parenchyma is seen wrapping around the mass like an open hand or claw [54]. Recommended initial laboratory evaluation includes a complete blood count with differential, complete metabolic panel, urinalysis, coagulation studies, and tumor markers to rule out other common pediatric abdominal tumors (Table 41.2). The complete blood count is important for the evaluation of intra-tumoral hemorrhage, the urinalysis for the evaluation of hematuria, and coagulation studies to evaluate for paraneoplastic acquired Von Willebrand Disease which can accompany WT [55].

Once a renal tumor is suspected on ultrasound, further anatomic imaging of the chest, abdomen, and pelvis should be completed along with consultation of a pediatric oncologist. Abdominopelvic computed tomography (CT) and magnetic resonance imaging (MRI) are both appropriate for further evaluation of renal tumors, although CT is often more facile to obtain at the time of diagnosis (Fig. 41.2). MRI is preferred in cases of suspected bilateral Wilms tumor and in patients with known predisposition syndromes due to improved ability to detect small tumors and nephrogenic rests [54]. In comparison to neuroblastoma, the other most common pediatric abdominal tumor, WTs lack calcifications and push away rather than encase surrounding structures [56]. In addition to further description of the renal mass, including measurement of volume and extent of disease, CT/MRI serve to evaluate for tumor thrombus in the renal vein and inferior vena cava (IVC), assess for pathologic adenopathy, and screen the contralateral kidney and liver for additional sites of disease. Finally, a CT of the chest should be obtained to assess for pulmonary metastases [54].

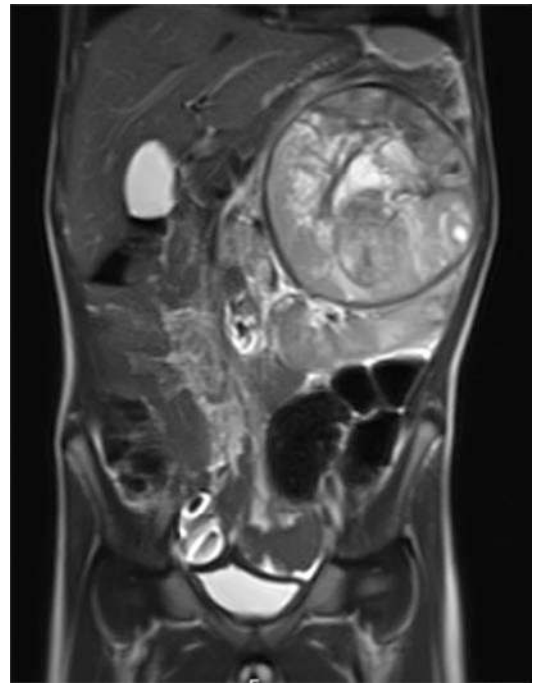

Fig. 41.2 Abdominopelvic T2 sequence magnetic resonance image displaying a left-sided Wilms tumor with left kidney displaced inferiorly and displaying a characteristic "claw sign"

Two different staging systems are employed for Wilms tumor. The varied approaches correspond with the opposing schools of thought regarding treatment approach between the North American and European pediatric oncology cooperative groups. While these differences will be discussed in more detail in the subsequent section "Treatment", it is imperative to understand that the North American (Children's Oncology Group [COG], formerly National Wilms Tumor Study Group [NWTS]) approach to WT includes up front nephrectomy when feasible. This lends itself to a pre-chemotherapy staging system based on extent of local and distant disease, as well as operative findings, including margin

Table 41.4 Renal tumors staging (Children's Oncology Group), applicable to Wilms tumor, clear cell sarcoma of the kidney, malignant rhabdoid tumor, and congenital mesoblastic nephroma; renal cell carcinoma staging discussed separately

Stage	Description
I	Completely resected primary tumor with negative margins Tumor limited to the kidney with renal capsule intact
II	Completely resected primary tumor with negative margins, but with extension outside of the kidney via penetration of the capsule, invasion of soft tissue or renal sinus, involvement of extra-renal blood vessels
III	Residual tumor confined to the abdomen • Incomplete resection/positive margins • Penetration through the peritoneal surface or peritoneal implants • Tumor rupture/spillage • Pre-operative chemotherapy • Pre-operative biopsy • Tumor removed in multiple pieces • Positive lymph nodes in the abdomen/pelvis Tumor excised from the thoracic vena cava or heart
IV	Distant metastases (lung, liver, bone, brain, other) Positive lymph nodes beyond the abdomen/pelvis
V	Bilateral renal tumors

status after nephrectomy and the presence of tumor spill into the peritoneal cavity. In addition, patients are up-staged in this system if pre-nephrectomy biopsy or neoadjuvant chemotherapy are undertaken (Table 41.4). On the contrary, the European equivalent to COG, the International Society for Pediatric Oncology (SIOP), uniformly recommends neoadjuvant chemotherapy and utilizes a staging system incorporating post-chemotherapy response. Additionally, pre-operative biopsy does not necessarily require up-staging of the patient in the SIOP system [57].

Treatment

The treatment of Wilms tumor has evolved over the past half century through the efforts of large collaborative groups. In North America this effort was undertaken initially by the NWTS, which has now become COG, while the European approach was developed by SIOP. The treatment paradigms now practiced by both groups espouse multimodal therapy (surgery, chemotherapy, and radiation) tailored by tumor risk classification. SIOP risk assignment is based upon stage, patient age, and post-chemotherapy histology, including extent of tumor necrosis, degree of blastemal tissue, and the presence of focal or diffuse anaplasia. In comparison, COG risk definitions include additional prognostic factors such as tumor weight and adverse biomarkers such as LOH of 1p and 16q, in addition to stage and histology (favorable vs. anaplastic) [57–59].

In general, the surgical approach for Wilms tumor is radical nephrectomy with sampling of the most proximal draining retroperitoneal lymph nodes. Ideally, the tumor is removed via a trans-abdominal incision with the capsule intact and tumor thrombus removed *en bloc* [58]. COG advocates for nephrectomy at the time of diagnosis whenever feasible. Reasons to delay nephrectomy in the setting of unilateral disease may include tumor thrombus extending above the hepatic veins, tumor invading contiguous organs, high risk of tumor spill or gross residual disease, or pulmonary compromise at the time of diagnosis. In such cases, biopsy is acceptable, although this does up-stage the patient. Nephrectomy should then be performed by weeks 6–12 of therapy. As discussed previously, the European standard is delayed nephrectomy regardless of initial tumor characteristics. This method allows for the incorporation of histologic chemotherapy response into further treatment decisions [57]. Despite their differences, both groups have achieved overall excellent response rates (see section "Prognosis and Outcomes" below).

In the setting of bilateral disease or a known Wilms tumor predisposition syndrome, focus

changes to preservation of normal renal parenchyma. This nephron-sparing approach includes neoadjuvant chemotherapy, which may proceed with or without upfront biopsy, followed by partial nephrectomy(ies) with a surgeon with such expertise depending upon tumor response [58, 60, 61].

A small subset of very low-risk patients may be cured by surgery alone, including patients younger than 2 years of age with small stage I tumors. This approach was initially established in the early NWTS trials and confirmed through a later COG trial for low-risk FHWT [40].

The vast majority of patients require chemotherapy in addition to surgery for cure of Wilms tumor. The goal of chemotherapy is to shrink known tumors and prevent the development of distant metastatic disease. Chemotherapy for FHWT builds upon a backbone of two drugs, vincristine and dactinomycin initially established in the first NWTS trial completed in 1975 [62]. Patients with low-stage disease have excellent cure rates with these two drugs alone [42]. Treatment for stage III–IV tumors or tumors with adverse prognostics markers such as combined LOH at 1p and 16q, includes at minimum the addition of the anthracycline doxorubicin and treatment for longer duration [39]. Additional agents such as cyclophosphamide and etoposide may be required for stage IV patients based on response of pulmonary metastatic disease and the presence of extra-pulmonary metastases [63]. Anaplastic Wilms tumor routinely requires aggressive chemotherapy, especially in the setting of diffuse anaplasia [30].

In patients with FHWT, radiation is reserved for patients with stage III–IV disease. Radiation to the primary renal tumor site is confined to the flank unless there is concern for gross tumor spill or peritoneal spread and is given at modest doses of 10.5–10.8 Gy. Radiation is also indicated for local control of extra-abdominal sites of metastatic disease, except that pulmonary radiation may be avoided in patients with a complete response of pulmonary disease to chemotherapy by week 6 [63]. Patients with stage II–IV AWT also require radiotherapy, while results from both COG and SIOP suggest omission of radiation for patients with stage I disease is possible in the setting of three-drug chemotherapy including doxorubicin [64, 65].

Prognosis and Outcomes

The overall prognosis for Wilms tumor has improved significantly since the adoption of multimodal therapy from 0% overall survival in the early twentieth century to 90% today; however, there remain a significant number of patients with more guarded outcomes [2, 58, 62, 66, 67]. In addition, the excellent outcomes for patients with low-risk disease require evaluation of when and where therapy can be further de-escalated.

Prognosis depends mostly upon stage and histology. Patients with low stage and favorable histology with epithelial predominance fare best even with limited therapy, while patients with higher stage and blastemal predominance or anaplasia fare the worst [26, 27, 30, 40, 63, 68]. Additional indicators of poor prognosis include older age at diagnosis, larger tumor size, and adverse chromosomal abnormalities including LOH at 1p and 16q, gain of 1q, loss of 11p15 (specific to very low-risk WT), and loss of 17p [9, 31–41, 57, 69–73]. Outcomes based on the most recently completed series of COG clinical trials are reviewed in Table 41.5. SIOP results have been similar. Salvage after relapse is possible, with a 5-year overall survival of 50%. Outcomes following relapse depend upon initial stage and treatment with patients initially receiving fewer chemotherapy agents faring better than those who required more aggressive treatment up front [74–76].

Late Effects

The multimodal therapy required to produce such excellent cure rates for Wilms tumor leads to significant late effects, with approximately 20% of long-term survivors reporting severe (grade 3–5) late effects at 20 years after diagnosis [78, 79]. In general, the adverse effects expected vary significantly based upon the presence of bilateral renal

Table 41.5 Results of COG renal tumors studies

Study	Stage/histology	Subgroup	Chemotherapy	Outcomes	Reference
AREN0532	Stage I FHWT	Very low-risk (age < 2 years, tumor < 550 g)	None	4-year EFS: 89.7% 4-year OS: 100%	[40]

tumors, chemotherapy regimen, and use of radiation.

The cumulative incidence of ESKD in patients with unilateral WT at 20 years after diagnosis is less than 1%; whereas, the incidence increases to 12% in patients with bilateral WT [80]. The rate is increased in patients with metachronous presentation of bilateral disease and is as high as 19.3% [81]. The risk of renal disease is also impacted by underlying predisposition syndromes associated with nephropathy such as WAGR, Denys-Drash, and Frasier Syndromes, as well as the presence of intralobar nephrogenic rests [13, 80, 81]. Lower-stage chronic kidney disease occurs, however, in 23–55% of patients, and a significant proportion of patients have chronic hypertension by their mid-20s [82–84]. Patients requiring only unilateral nephrectomy without nephrotoxic chemotherapy or radiation have a much lower risk of chronic kidney disease and hypertension [85].

Renal toxicity can occur due to nephron loss during surgical resection and secondary to chemotherapy and ionizing radiation. The etiology of renal failure is more commonly surgical for patients with bilateral disease who require either bilateral nephrectomies or partial nephrectomies resulting in less than 25% residual renal parenchyma [80]. Patients requiring only unilateral nephrectomy are typically able to maintain renal function through compensatory hypertrophy of the remaining kidney [86]. The frequency of nephron-sparing surgery in patients with bilateral disease and those with WT arising in a solitary kidney is an on-going focus of research. On the COG study AREN0534, 39% of patients with bilateral WT retained parts of both kidneys and only 2.5% required bilateral nephrectomies following neoadjuvant chemotherapy [61].

The chemotherapy agents required for the majority of Wilms tumor patients (vincristine, dactinomycin, and doxorubicin) are rarely implicated in long-term renal toxicity; however, the alkylating agent ifosfamide and platinum agent carboplatin utilized for augmentation of therapy in more aggressive disease or in the setting of relapse may adversely affect renal function [87]. This risk is higher in younger patients and when combined with other nephrotoxic exposures, including additional nephrotoxic medications, renal radiation, and nephrectomy [88]. Radiation nephritis is the cause of renal failure in a minority of patients and is rare at the typical radiation doses used in the treatment of WT [88, 89]. Recommendations for screening for renal late effects is variable based on treatment received. Most patients treated for WT will require annual blood pressure monitoring, creatinine assessment, and urinalysis, with electrolyte monitoring recommended at the time of entry into long-term follow-up and then as needed. Counseling is required regarding risk of renal injury in the setting of a single kidney and use of nephrotoxic medication should be limited [90].

The most notable non-renal late effects for these patients include cardiac toxicity in the setting of doxorubicin exposure, secondary malignancies and poor growth due to both chemotherapy and radiation exposure, and infertility for patients requiring alkylating agents or carboplatin [91].

Clear Cell Sarcoma of the Kidney

Epidemiology

Clear cell sarcoma of the kidney (CCSK) is the second most common renal neoplasm in young children, accounting for 2–5% of primary kidney cancers in this demographic [92, 93]. It was first described by Kidd in 1970 and subsequently noted to be distinct from Wilms tumor due to its propensity to metastasize to bone [25, 92–95]. It presents more commonly in males than females at a 2:1 ratio. Clear cell sarcoma of the kidney is seen most commonly in toddlers with a median age at diagnosis of 36 months, and 50% arising in 2–3 year olds in the NTWS trials. It is incredibly rare in infants less than 6 months [92, 93, 96]. There are no known predisposition syndromes, although there is at least one case reported in a patient with Fanconi anemia [97].

Pathology

Clear cell sarcoma of the kidney typically presents as a large, unilateral, well-circumscribed mass. CCSK displays heterogeneous histology, with upwards of nine different histologic types described. Most tumors include the classic variant described as nests and cords of round or oval cells separated by fibrovascular septae. The clear cell appearance arises from extracellular mucopolysaccharide matrix located between the cord cells. Additional variants include: myxoid, sclerosing, cellular, epithelioid, palisading, spindle cell, storiform, and anaplastic patterns [92, 93, 98]. Most tumors contain a mixture of subtypes and, unlike WT, histologic subtypes are not used for risk stratification. There are two predominant known somatic genetic findings in CCSK which are mutually exclusive: a translocation involving *YWHAE* and *NUTM2B/E* (previously *FAM22*), t(10;17)(q22;p13), and internal tandem duplications of the BCL-6 co-receptor, *BCOR*. A third subset of patients displays neither event [92, 99, 100]. *TP53* is located at 17p13 and is overexpressed in the small subset of anaplastic CCSK, but does not seem to be a predominant driver in CCSK. A BCOR fusion has also been identified in a small case series of CCSK [99, 101]. Like histology, to date specific genetic findings have not been utilized for risk classification.

Presentation and Evaluation

Similar to WT, CCSK presents in young children as a painless abdominal mass or distension, although abdominal pain, hematuria, vomiting, anorexia, fever, constipation, and hypertension have all been reported. In addition, patients with metastatic disease may present with symptoms of bone pain or mass [92, 100, 102]. The initial workup mimics that of WT, including ultrasound followed by cross sectional imaging with CT or MRI. There are no defining imaging characteristics to differentiate CCSK from the much more common WT, and the diagnosis is often not made until postoperative pathologic review of the nephrectomy specimen.

The staging of CCSK is similar to that for WT. A minority (4–7%) of cases of CCSK are metastatic at diagnosis. The pattern of metastatic spread differs from WT, with CCSK having a strong propensity for bone and brain, although like WT can also affect regional lymph nodes and liver. Bilateral tumors are exceedingly rare [92, 93, 96]. As a result, in addition to a chest CT, the metastatic workup includes a brain MRI and systemic imaging for bony disease such as nuclear medicine bone scan or positron emission tomography scan.

Treatment

The treatment of CCSK is multimodal and includes surgery, chemotherapy, and radiation. The chemotherapy and radiation is more aggressive than that required for many patients with WT.

The surgical approach mimics that for WT, with COG advocating for upfront nephrectomy when feasible while SIOP recommends delayed nephrectomy following neoadjuvant chemotherapy [100, 103]. As in WT, sampling of lymph nodes is important for accurate staging [96, 104]. Given the rarity of bilateral disease, the focus on nephron-sparing surgery is less consequential in CCSK. Surgical metastasectomy is considered for feasible sites and level of disease burden.

Chemotherapy recommendations for CCSK are similar to those for high-risk WT. In the SIOP approach, patients with localized disease are treated initially with vincristine and dactinomycin, with doxorubicin added for patients with distant metastatic disease at diagnosis [103]. Both SIOP and NWTS/COG have demonstrated improved survival when doxorubicin is included in the treatment of CCSK, so the anthracycline is started or continued after nephrectomy once the diagnosis of CCSK is confirmed [93, 103]. In addition, the alkylating agents ifosfamide and cyclophosphamide along with etoposide are added for all stages [103]. In North America, patients with CCSK have been treated with a regimen of cyclophosphamide and etoposide alternating with vincristine, doxorubicin, and

cyclophosphamide since the study NWTS-5 in the mid-1990s [92, 104].

Most patients with CCSK require additional local control with radiation. In Europe, stage I CCSK patients have been spared radiation. A study in the United Kingdom omitted radiation for stage II patients, but revealed a high rate of local treatment failures, emphasizing the importance of radiotherapy in this group [92, 96]. Both collaborative groups recommend radiation for local control of metastatic disease [103, 104].

Prognosis and Outcomes

Outcomes for patients with CCSK are more guarded, leading to its label as a high-risk renal tumor. Prognosis depends most notably upon stage, with 5-year event-free survival (EFS) of 91% and overall survival (OS) of 98% for patients with stage I/II disease on the COG trial NWTS-5, compared with 79% and 90% for stage III/IV patients. The relatively poor prognosis is most pronounced in the metastatic patients, who when evaluated individually had a 5-year EFS of only 29% and OS of 36% [104]. Results by stage follow a similar trend in SIOP trials, with the 5-year EFS and OS for stage I patients reported as 79% and 87%, respectively, and that for stage IV being 59% and 73%, respectively [96]. Patients who fall outside of the typical age-range of 2–3 years at diagnosis also seem to fare more poorly [93, 96]. Clear cell sarcoma of the kidney differs from other pediatric renal tumors concerning the timing of relapse. Although most relapses occur by 3 years, a small subset of patients present with recurrent tumor 5–10 years after initial presentation, necessitating prolonged surveillance. The frequency of late relapses does, however, appear to be decreasing in the era of modern chemotherapy regimens [92, 100, 103, 104]. Most relapses are to metastatic sites, including brain, lung, and bone. Patients with relapsed disease are potentially salvageable with aggressive multimodal therapy; therefore, long-term follow-up to detect potentially treatable relapses is critical [105].

Late Effects

The late effects following treatment for CCSK are less well studied than that of WT due to the significantly smaller patient population. In general, the renal long-term complications of unilateral nephrectomy are the same as for WT, and the need for bilateral renal surgeries is essentially non-existent. However, the chemotherapy used up front, most notably ifosfamide and carboplatin, is more nephrotoxic than the therapy required for the majority of WT patients, and most patients require radiation. Nearly all patients will require routine monitoring of renal function and blood pressure. The risk for non-renal late effects is higher secondary to the augmented therapy required for all patients with CCSK and includes cardiac toxicity, secondary malignancies, poor growth, and fertility concerns.

Malignant Rhabdoid Tumor

Malignant rhabdoid tumor (MRT) of the kidney was identified in the late 1970s and early 1980s as part of the NWTS [106]. This tumor is an aggressive cancer with poor prognosis despite intensive chemotherapy, radiation therapy, and surgical management. These cancers share biology with renal medullary carcinomas (below), atypical teratoid rhabdoid tumors, and epithelioid sarcomas through the loss of *SMARCB1* and less commonly *SMARCA4*, both members of the SWI/SNF chromatin-remodeling complex. Rhabdoid tumor only causes 3% of pediatric renal tumors [107]. Studies have shown that children with rhabdoid tumors were demographically similar to case controls [108] and usually presented in the first year of life [109–111].

There are two known predisposition syndromes associated with MRT: rhabdoid tumor predisposition syndromes 1 and 2 (RTPS1/2). Patients have germline pathogenic variants in *SMARCB1* and *SMARCA4* [112]. These patients usually develop cancer at a median age of 4–7 months; whereas, those with sporadic MRT have a median age of presentation of 18 months. There are other germline variants of *SMARCB1*

and *SMARCA4* that lead to Coffin-Siris Syndrome, but these mutations are not known to lead to cancer. Recently, SIOP has put forth a set of recommendations for patients/probands with RTPS [112].

SMARCB1 is part of the SWI/SNF complex and serves as a tumor suppressor. This complex is preserved across species and affects many cancer related pathways such as the Hedgehog-Gli, Wnt/b-catenin, and retinoblastoma pathways along with pathways involving cell motility and differentiation [113–115].

Patients present similarly to others with abdominal masses, but in some cases disease progression is swift, prompting emergent chemotherapy. Staging of MRT is the same as for WT and CCSK. Currently, therapy is a combination of chemotherapy, surgery, and radiation therapy (depending on the age of the patient). There is suggestion that lower-stage MRTs are able to achieve cure with a 4-year overall survival in the 40% range. Yet, many patients have higher-stage disease, with 4-year overall survival <20% [109–111, 116, 117].

Pediatric Renal Cell Carcinoma

Renal cell carcinomas (RCC) are a group of heterogenous kidney tumors predominantly seen in adults. However, RCCs occur in children and young adults as well [118].

Pediatric and adolescent/young adult (AYA) renal cell carcinomas (pRCCs) account for 2–4% of childhood kidney cancers [119]. When further subtyped, MiT-RCC (or translocation RCC) are the most common RCC in childhood, causing 42% of RCCs. Other RCCs include papillary, chromophobe, clear-cell (the most common kidney cancer in adults), renal medullary carcinomas (RMC; further discussed below), fumarate hydratase-deficient, succinate dehydrogenase-deficient, TSC-associated (further discussed below), ALK-rearranged, thyroid-like, and myoepithelial carcinomas (see Fig. 41.3) [118]. Another 7–8% of RCCs are unclassified.

A number of predisposition genes have been implicated in this group of heterogenous cancers [120]. These include *VHL* (Von Hippel-Lindau disease and clear cell RCCs), *MET* (hereditary

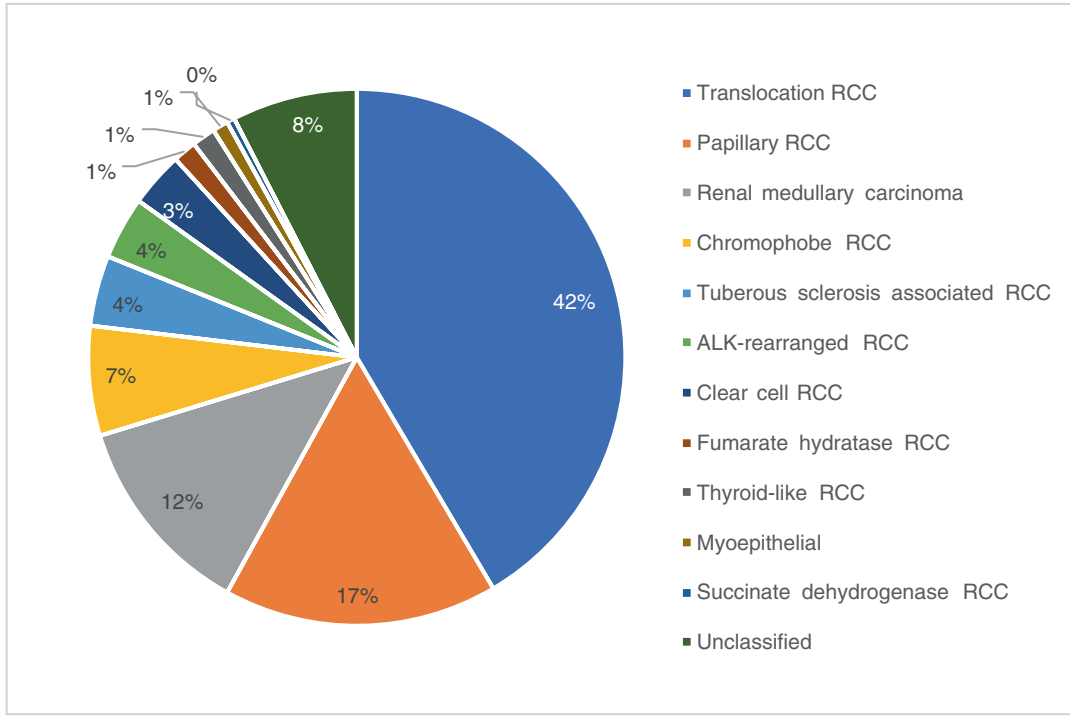

Fig. 41.3 Distribution of 212 pediatric and young adult RCCs from Cajaiba et al. [118]

papillary renal carcinoma; HPRC), *FLCN* (Birt-Hogg-Dube syndrome and various RCCs), *FH* (hereditary leiomyomatosis and renal cell carcinoma; HLRCC), *SDHB/C/D* (Succinate dehydrogenase-deficient renal cell carcinoma), *TSC1/2* (tuberous sclerosis complex; TSC), and mutations in *BAP1* and *MiTF*. Presentations of such tumors can occur in the second decade, but some are not seen until the sixth or seventh decade (e.g., HPRC). While the pathogenesis of cancer predisposition syndromes such as VHL have been well characterized [121], other genes of importance remain an area of study.

The clinical presentation of most pRCCs is similar to that of a child or young adult with any new renal tumor. Usually, the patient will have a painless but enlarging abdominal mass. Occasionally, there will be microscopic or gross hematuria depending on the location of the tumor, unexplained hypertension, or polycythemia. As described for WT, workup usually proceeds with imaging of the abdomen via ultrasound followed by a CT of the chest and CT or MRI of the abdomen and pelvis. Outside of a classical "claw sign," which usually is suggestive of a WT, the COG approach is to either request a pediatric surgical consultation to determine the feasibility of a nephrectomy or biopsy. In cases with bilateral tumors and depending on the patient's age, further discussions are needed to determine if upfront chemotherapy is preferred over biopsy.

Staging of pRCCs is based on the adult RCC staging system, the American Joint Committee on Cancer (AJCC)—TNM Staging System for Kidney Cancer [122]. The primary tumor is assessed by size in greatest dimension (T1 is 7.0 cm or less while T2 is greater than 7.0 cm) and whether the tumor has invaded or extended into the renal veins or above the diaphragm (T3a–c) or beyond Gerota's fascia (T4). Regional lymph nodes are then assessed as the lack of lymph node involvement (N0); involvement of a single lymph node (N1); or of more than one (N2). Metastasis is a binary categorization (M0 for no distant metastasis and M1 for distant metastasis). Based on the TNM status, stage grouping is assigned. Primary tumors at or less than 7.0 cm in dimension are classified as stage I, while stage II is larger than 7.0 cm in dimension. Single regional lymph node involvement (N1) or invasion of the renal veins (T3a–c) is considered stage III. Stage IV disease includes any T1–3 which has multiple regional lymph node involvement (N2) or distant metastasis (M1) and includes tumors that invade Gerota's fascia (T4).

While it is unclear whether the biology of pRCCs is similar to adult RCCs, there is evidence that outcomes are different. COG AREN0321, a phase II study, prospectively assessed outcomes in children and young adults with pRCCs. If complete resection was done, there was no further therapy. For those who had incomplete resections, given the generally poor outcomes and lack of definitive therapies, institutional preference dictated treatment options (e.g. immunotherapy or tyrosine kinase inhibitors). Those with stage I, II, and III disease had 96%, 100% and 88% 4-year overall survival, respectively [123]. However, those with stage IV disease had poor outcomes, with a 29% 4-year overall survival. Primary deaths occurred in patients with either translocation RCC or renal medullary carcinoma.

In summary, pRCCs are a heterogeneous group of kidney cancers for which some have an underlying cancer predisposition syndrome. This group of cancers make up the second most common kidney cancers in children, with the majority occurring in adolescent patients. Short-term outcomes for stage I–III pRCCs remain good with a 4-year overall survival in the 88–100% range. However, stage IV pRCCs (primarily translocation RCCs and renal medullary carcinomas) have poor outcomes.

Renal Medullary Carcinoma

Renal medullary carcinoma (RMC) is a subtype of renal cell carcinoma driven by loss of *SMARCB1*. Unlike malignant rhabdoid tumor, RMC occurs primarily in adolescents and young adults of African descent with sickle cell trait [124–128]. Estimated prevalence based on United States data is 5 in 100,000 patients with sickle cell trait [126, 129]. Although sickle cell trait is the primary hemoglobinopathy associated

with this cancer, there are case reports of other hemoglobinopathies such as sickle cell disease (HbSC and HbSS). There is no known predisposition syndrome other than the association with sickle cell trait. The gene implicated in RMC is *SMARCB1,* which has been discussed in reference to MRT above. Here, the primary mode of disruption is through a translocation event.

Currently, there is no standard of care treatment for RMC given the rarity of this disease and age of presentation (around 10–40 years). However, general consensus among physicians involved in the care of patients with RMC has been to treat with a platinum agent along with other chemotherapy, nephrectomy, and radiation therapy [130, 131]. Despite this aggressive approach, outcomes for RMC remain very poor as overall survival ranges from 4–5 months to 17–18 months for those with or without metastatic disease, respectively [129, 132].

Renal Angiomyolipoma and Epithelioid Angiomyolipoma

Renal angiomyolipomas (AML) are another rare kidney tumor which are considered benign tumors, but may lead to complications given the location [133]. First identified in 1900, AML describes the histopathological features of abnormal blood vessels with components of smooth muscle and adipose tissue [134]. Even more rare is epithelioid angiomyolipoma (EAML), a subtype of angiomyolipoma which is defined by having >10% epithelioid cells by histopathology. Renal AML, depending on the populations studied, affects women more than men [134, 135]. There is a bimodal distribution for the time of presentation. For those with an underlying genetic predisposition, they usually present during the first several decades, while sporadic renal AMLs tend to occur in the fourth or fifth decade [134–136].

Predisposition for renal AML has been associated with tuberous sclerosis complex (TSC) or lymphangioleiomyomatosis (LAM). Genes involved in TSC or LAM include *TSC1* and *TSC2*. TSC1 and TSC2 form a complex which inhibits downstream targets of mechanistic target of rapamycin (mTOR) [137]. For patients with TSC diagnosed in childhood, renal AML occur in over 50% of patients, typically arising in adolescents/young adults [138].

The clinical presentation for renal AMLs differs slightly from other renal tumors as hemorrhage is more commonly seen as compared to microscopic or gross hematuria [134]. Patients also present with abdominal pain or flank pain. AML is likely in a child with TSC presenting with a new renal mass.

Prior management was a complete or partial nephrectomy, but as the natural history of this tumor has been studied for the past century, more conservative approaches are being taken [139]. These lesions grow slowly so surveillance may be used as an initial approach in many patients. Medical therapy with an mTOR inhibitor, everolimus, is an option in select patients (sirolimus is also effective). Outstanding questions remain regarding the duration of therapy as lesions may regrow after a year of treatment. Recent studies have looked at extending therapy to 2 years with minimal regrowth during the second year of therapy. Overall response rate was 44% in patients with TSC or LAM [140]. These findings were further validated in the phase III EXIST-2 trial and the follow-up extension phase where patients received treatment for up to 4 years [141, 142]. Currently, surgery is not recommended, particularly for those with TSC given the potential growth of new renal AMLs in the remaining tissue, thereby compromising renal function further. Another approach is embolization of the vascular supply for the renal AMLs, but this is considered second-line therapy. For EAMLs, little is available to suggest a standard of care. Furthermore, for patients with a known history of TSC, abdominal imaging (ideally MRI) is recommended every 1–3 years throughout the patient's lifetime.

Ewing Sarcoma of the kidney

Ewing sarcoma of the kidney is a rare renal tumor with few cases in the literature. As the name implies, this renal tumor has a fusion oncoprotein between *EWS* and members of the

ETS family such as *FLI1* or *ERG*. Furthermore, these tumors express CD99, which can be detected by immunohistochemistry. The epidemiology of this cancer is not well described given the rarity and is limited to single institution experiences. Furthermore, there is no known predisposition syndrome related to this particular renal tumor.

Here, we will describe the M.D. Anderson experience as it is the most comprehensive institutional review to date of patients presenting with this renal tumor over 23 years [143]. Patients with Ewing sarcoma of the kidney presented with new flank or abdominal pain and/or hematuria. Age of presentation ranged from 8 to 69 years, with a median age at diagnosis of 30.5 years.

Staging was as follows: Group I had tumor confined to the kidney, Group II had local extension, and Group III had metastatic disease. Therapy included nephrectomy (Groups I and II primarily had upfront surgery, whereas Group III patients had biopsy initially and then subsequent nephrectomy with or without neoadjuvant chemotherapy), chemotherapy, and in some cases radiation therapy. Chemotherapy regimens included those utilized to treat extra-renal Ewing sarcomas, but a limitation noted by the authors was that this was inconsistent over the 23-year experience.

Overall, outcomes were poor. Four-year event free survival was 43% and overall survival was 63%. Those with metastatic disease had poorer outcomes. For those with Group I disease, nephrectomy followed by chemotherapy had a more favorable outcome, suggestive of potential for cure.

Congenital Mesoblastic Nephroma

Congenital mesoblastic nephroma (CMN) is a renal tumor that occurs in infancy. It has a low malignant potential and accounts for 2–3% of all pediatric renal tumors [144–146]. With respect to predisposition syndromes, there has been a rare association of Beckwith-Wiedemann syndrome in several case reports. Otherwise, congenital anomalies have been identified in several patients, but there have been no other constitutional syndromes identified. There are three subtypes of CMNs: classic, cellular and mixed (both classic and cellular) type. The genomics of the classic and mixed type of CMNs have not been well characterized. However in cellular, the most common genetic aberration is a translocation of t(12;15)(p13;q25) leading to a fusion of *ETV6* and *NTRK3* [147, 148]. Furthermore, trisomy 11 has been identified in this group.

CMN may present as either a mass detected during a prenatal ultrasound or in an infant found to have a new abdominal mass, hypertension, or hematuria. There may also be polyhydramnios, hypercalcemia, and hyperreninemia, with the latter two resolving following resection of the tumor [146]. Staging for CMNs follows that of WT, MRT, and CCSK. Please refer to staging in those sections. Treatment for these patients has primarily been surgical, with less consensus on postoperative therapies such as chemotherapy and radiation therapy.

The SIOP/German Society of Oncology and Hematology (GPOH) experience with CMNs showed that 5-year relapse free survival and overall survival were 93.8% and 96.1%, respectively [144]. Those with cellular or mixed MN had inferior relapse free survival as compared to classic MN, but overall survival was similar across these subtypes. This experience was similar to that of the United Kingdom Children's Cancer and Leukaemia Group [149]. Similar to that of other renal tumors, long-term issues relate to caring for a patient with a solitary kidney.

Cystic Tumors

Cystic tumors are rare and usually benign renal tumors which account for <1% of pediatric renal tumors [150]. These are further sub-categorized into cystic nephromas (CN) or cystic partially differentiated nephroblastoma (CPDN). In the case of CNs, there is an association with *DICER1* [151] and *DICER1* syndromes which may lead to tumors in the lungs, ovaries, thyroid and kidneys. Patients usually present with CNs in the first few years of life or during the AYA period. There is a

skew toward females being affected. For CPDN, there is no known genetic predisposition.

Children present with a new abdominal mass (may be an incidental finding unless there is a known personal or family history for *DICER1)*. Bosniak imaging scores (based on classifying adult renal cysts from a benign simple cyst to a malignant cystic mass) allows one to assess concerns for malignancy based on imaging [152]. Staging in CNs or CPDNs requires chest to pelvis imaging given risks of identifying an underlying *DICER1* syndrome. Pathology and treatment is primarily surgical in nature and, given the rarity, it is unclear if chemotherapy plays a role in these relatively benign tumors [150]. However, there is an association with *DICER1*-renal sarcomas in CNs suggestive that similar to pleuropulmonary blastoma in the lungs, there is a range of potential tumors that can develop in the kidney for those with *DICER1* syndrome [153].

Overall outcomes from small patient cohorts in national or international trials suggests that CNs or CPDNs are benign in nature. Given the potential risk of additional malignancies in patients with CNs in particular, referral to a cancer predisposition clinic is warranted.

Ossifying Renal Tumor of Infancy

Ossifying renal tumor of infancy (ORTI) was first described in 1980 [154]. It is extremely rare, with well under 50 cases reported in the literature [155]. Approximately 90% present in the first year of life and the oldest reported patient presented at 30 months. There is a strong male predominance [156, 157]. It most commonly presents with gross hematuria, although rarely a palpable abdominal mass is appreciated [156, 158]. Reported cases have been exclusively unilateral, and ORTI carries no known risk of metastasis [155, 156]. Imaging reveals an intact renal outline with a calcified intrapelvic mass which is hypointense on T2-weighted MRI [159]. Upon resection, ORTI is typically attached to a papilla within the calyceal lumen. On histopathologic examination, ORTI are composed of osteoid, osteoblastic cells, and spindle cells. The degree of ossification increases with older age at presentation. Interestingly, the spindle cell component may represent hyperplastic intralobar nephrogenic rests (see section "Nephrogenic Rests and Nephroblastomatosis" under Wilms Tumor) while the osseous component may be urothelial in origin [157]. No predisposition syndromes are known to be associated with ORTI. Clonal trisomy 4 has been detected in multiple tumor specimens [156, 160].

Although quite rare, knowledge of ORTI, including the typical presentation and imaging appearance, is important. Treatment for ORTI is surgical and may be via complete or partial nephrectomy as dictated by size and location within the kidney. There is no requirement for systemic therapy and to date no recurrences have been reported [155, 156]. The late effects of treatment are limited to the risk of nephron loss due to nephrectomy.

Metanephric Tumors

Metanephric adenoma (MA), metanephric adenofibroma (MAF), and metanephric stromal tumor (MST) are described together as metanephric tumors in the 2016 World Health Organization Classification of tumors of the kidney [161]. These three neoplasms share morphologic features with WT and are considered by some authors to represent differentiated tumors along the same spectrum [162]. Metanephric adenoma is purely epithelial and can closely resemble epithelial-predominant WT, MST is purely stromal, and MAF is biphasic, containing both epithelial and stromal elements. There are no reliable distinguishing imaging features allowing separation of these mostly benign tumors from WT, and as such, they may inadvertently be treated with neoadjuvant chemotherapy.

Metanephric adenoma was first described in detail in 1995. It can occur across the age spectrum, and when compared with MST and MAF, is the most common of the three in adult patients. There is a female predominance. In nearly 50% of cases, it is identified incidentally; however, it can present with polycythemia,

hypertension, hematuria, abdominal pain, or a palpable abdominal mass. It is routinely unilateral. Histologically, MA is described as small acinar cells within an acellular stroma, and the majority of cases express BRAF V600E mutations [163–165]. It is considered a benign lesion, although several reports of metastatic disease do exist [166]. In addition, there are overlap lesions between MA and epithelial WT [167]. Treatment is nephrectomy or partial nephrectomy followed by observation excepting in cases overlapping with WT or with metastases, and outcomes are typically excellent.

A purely stromal metanephric neoplasm coined metanephric stromal tumor was first noted by Beckwith in 1998 and further described in a review of 31 cases by Argani and Beckwith in 2000. In this initial review, the median age at diagnosis was 13 months, ranging from newborns to 11 years [168]. A more recent review reported a median age of 2 years and included three adult patients. There does not appear to be a strong gender predilection. Most patients present with an asymptomatic abdominal mass, although hematuria, hypertension, and abdominal pain have been reported. All cases are unilateral, although multifocal disease does occur [169]. Under the microscope these tumors develop a characteristic "onion skin" pattern of rings of cells surrounding renal tubules or blood vessels [168, 169]. A majority of MST have BRAF V600E mutations which can serve to differentiate them from other renal stromal tumors and provides further link to MA [170]. Despite one report of metastatic disease, most MST are cured with nephrectomy alone. As such, care must be taken to distinguish these tumors from more aggressive stromal renal tumors such as CCSK, which require much more aggressive intervention [168, 169].

The mixed lesion, metanephric adenofibroma, was originally reported in 1992 [171]. The stromal component of these tumors resembles, although is distinct from, mesoblastic nephroma, and is identical to MST, while the epithelial component favors nephroblastomatosis and epithelial WT and is identical to MA. Additionally, some tumors are described as MAF transitioning to epithelial-predominant WT. Finally, there may also be a component of low-grade papillary carcinoma or adenosarcoma present. Similar to MA and MST, patients presented with polycythemia, hypertension, or hematuria which resolved following nephrectomy [171, 172]. The median age at diagnosis in a series of 25 patients from the NWTS studies was 30 months, although MAF can present in adolescents and young adults [173]. This tumor is more common in males at a ratio of 2:1 [172]. Historically, all patients were treated similar to WT, with nephrectomy and adjuvant chemotherapy. More recently, patients with MAF without evidence of a malignant component are typically observed after nephrectomy with good outcomes [172].

Summary

Although overall uncommon, within the context of pediatric extra-cranial solid tumors pediatric renal tumors make up a large proportion of diagnoses. Accurate diagnosis is critical as the necessary treatment and prognosis varies greatly. Pediatric nephrologists may be involved at many points during the care of these patients, including initial diagnosis in a patient who presents with hematuria, early management in a patient with hypertension, and long-term in patients with significant nephron-loss or treatment-induced nephropathy.

Tubulointerstitial Nephritis in Children

42

Priya S. Verghese, Kera E. Luckritz, and Allison A. Eddy

Introduction and Historical Perspective

An estimated 85% of the kidney consists of tubules and their surrounding interstitial space. Given their preeminence, it is crucial to understand the contribution of the tubulointerstitium in all renal disease processes. Despite its anatomical dominance, current understanding of the role of the interstitium in both primary and secondary disease processes remains incomplete.

The term acute interstitial nephritis (AIN) was coined by Councilman in 1898 when he provided the first and now classic description of the histopathologic changes following an investigation of autopsy specimens from patients with diphtheria, scarlet fever and other infectious diseases [1, 2]. Primary AIN is typically an immunologically-mediated disease characterized by tubular injury and interstitial inflammation, with relative sparing of the glomeruli and vessels, initiated by drugs, infections or other causes mentioned in detail in section "Etiology" [3]. Councilman's early description still has merit, though it may be more accurate to categorize the disease process as acute tubulointerstitial nephritis (TIN) since the renal tubules are also involved in all cases, both clinically and histopathologically.

In the pre-antibiotic era, systemic infections were the most common cause of tubulointerstitial disease. Today, a drug hypersensitivity reaction is a more common inciting event. Ironically many of these drugs were developed to treat the infectious disorders that had often been implicated as causes of AIN. In kidney transplant allografts, TIN can occur due to drugs, but also due to infections such as BK polyomavirus and adenovirus [4, 5] that often necessitate drastic reduction in immunosuppression to enable viral clearance.

Progressive chronic kidney disease (CKD), irrespective of the primary disease process, is characterized by significant chronic TIN indicating that TIN is a spectrum of pathologies, ranging from acute and reversible nephritis to chronic and

irreversible disease with fibrosis. For each individual patient, it is critical to try to identify and discontinue the offending toxin or agent before acute injury progresses to the chronic stage.

Epidemiology

Acute injury to the interstitium and the surrounding tubules is an important cause of renal dysfunction, currently accounting for 5–27% of kidney biopsies performed for acute kidney injury [6–9]. Reliable data on the incidence and prevalence of TIN are lacking, especially in the pediatric population. Within available biopsy registries, TIN represents approximately 1–3% of all biopsy diagnoses [7, 10]. Often the diagnosis is made clinically without performing a renal biopsy to confirm the diagnosis. Furthermore, it is likely that many cases are self-limited and remain clinically silent. Thus, the estimated numbers are likely conservative and lower than the true incidence. The incidence of TIN in kidney transplant allografts is also unknown [4, 5].

Histology and Pathogenesis

By definition, TIN is characterized by interstitial cellular infiltrates, usually sparing the vessels and glomeruli (Fig. 42.1a), although it is noted that severe primary glomerular injury rarely occurs without concurrent tubulointerstitial injury. Tubular cell damage may be manifest as epithelial proliferation and/or tubular dilatation. Intratubular cast deposition is often present as well [11]. Interstitial fibrosis and tubular atrophy, often accompanied by the persistent mononuclear cell infiltrate [11], can be representative of chronic TIN. The infiltrate is composed predominantly of T cells with some macrophages and plasma cells [6, 11, 12]. An impressive number of eosinophils may be present and suggests a drug-induced etiology (Fig. 42.1d). These lymphohematopoietic cells are a rich source of cytokines that contribute to kidney injury. Granuloma formation is a feature of biopsies in 6% of the patients and can occur in any form of AIN; granulomas are considered common in drug-induced TIN, infection-associated TIN and renal vasculitis

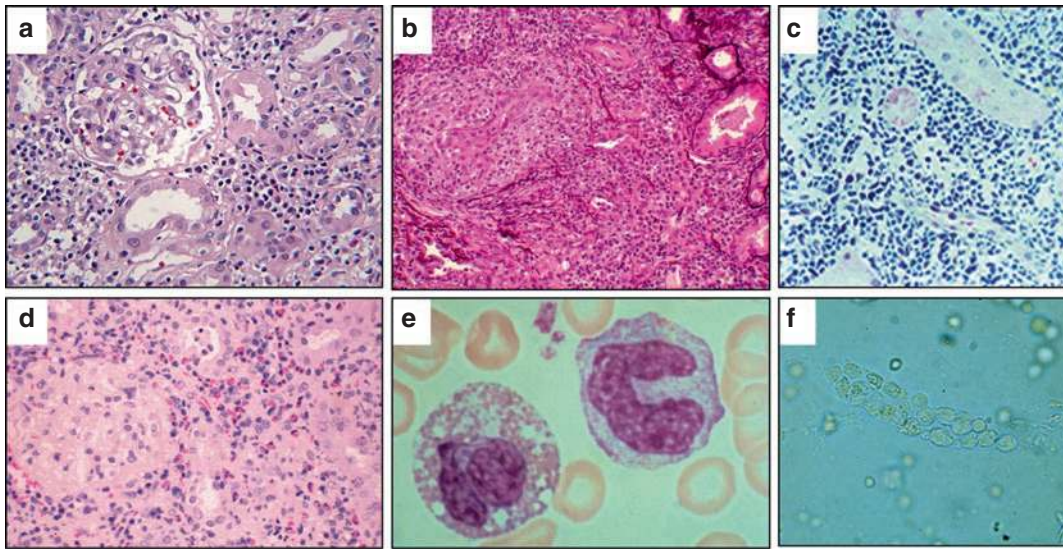

Fig. 42.1 Histological and urinary sediment features of acute tubulointerstitial nephritis (TIN). Histological photomicrographs illustrate an interstitial infiltrate of mononuclear cells, interstitial edema and tubular dilatation in acute TIN (**a**); acute TIN with granuloma formation (**b**); TIN characterized by an infiltrate of monomorphic interstitial mononuclear cell due to lymphoma (**c**); acute drug-induced TIN with numerous polymorphonuclear eosinophils (**d**). Examination of the urinary sediment may show eosinophils in drug-induced TIN (**e**), white blood cells and while blood cell casts (**f**)

[13] (Fig. 42.1b). Some studies have suggested that the degree of tubulointerstitial inflammation may be predictive of renal functional outcome, even in primary glomerular diseases [3, 8, 14, 15]. However, other studies have suggested the extent of chronic changes such as tubular atrophy on the initial biopsy are more predictive of long-term outcomes [8, 16]. Interestingly, in kidney transplant allografts, inflammation in areas of interstitial fibrosis is associated with decreased graft survival with or without concurrent evidence of rejection [17], once again supporting the prior theory that the degree of inflammation is more predictive of long-term outcomes.

In primary TIN, immunofluorescence staining for antibodies and complement proteins are typically negative. Occasionally, linear or granular deposits of IgG or IgM may be present along the tubular basement membranes [3]. Electron microscopy may reveal loss of continuity of basement membranes as well as thickened and multilaminated areas indicative of chronic damage [3].

These histopathologic findings, together with the apparent clinical response to corticosteroid therapy, supports a role for immune-mediated pathogenic mechanisms. Though the specific mechanisms remain unclear, an important role of chemokines and other inflammatory mediators is presumed [18]. A reliable animal model that faithfully mimics human acute drug or infection associated TIN is not available to elucidate specific pathways. Animal studies have shown that three endogenous kidney antigens (uromodulin, megalin, and a tubular basement membrane glycoprotein named TIN antigen) can elicit TIN, but the relevance of these findings to human acute TIN is unknown [9]. Isolated case reports describe autoantibodies to aquaporin 2 and HOXB7 [19], mitochondrial M2 protein [20] and two unidentified brush border antigens [21]. Current concepts suggest that an antigen, be it a hapten derived from a drug or microbe, can mimic a yet-to-be identified antigen normally present in renal tubules. When this antigen is presented to T-helper cells, an immune response is triggered. Macrophage and natural killer cell recruitment and activation follows. Evidence of a primary pathogenic role of T cells is supported by a study that demonstrated the presence of drug-specific sensitized T cells in the peripheral blood of patients with acute drug-induced TIN [22]. Four non-mutually exclusive theories of immune pathogenesis have been proposed [23]. (1) A component of the drug may be trapped along the tubular basement membrane (TBM) where it acts as a hapten, becoming the target of immune attack by sensitized T-cells, or less commonly, antibody producing B-cells. (2) A component of the circulating drug may be recognized as a foreign antigen that triggers an immune response. The antigen may be structurally similar (molecular "mimic") to a normal component of the tubulointerstitium (endogenous antigen) that becomes a target of the immune attack. (3) A drug-derived antigen may first be trapped "in situ" in the tubulointerstitium where immunologically reactive cells and/or antibodies are recruited. (4) Circulating antibodies generated against a drug-derived antigen may form immune complexes within the circulation that are subsequently trapped within the tubulointerstitium and initiate inflammation. Similar theories of pathogenesis have been proposed for "reactive" acute TIN triggered by an infectious agent.

A related drug-induced hypersensitivity syndrome is DRESS (drug reaction with eosinophilia and systemic symptoms), which is more common in adults than children. DRESS is characterized by a severe rash and visceral involvement that includes TIN in 10–30% of cases [24].

There is an animal model of anti-tubular basement membrane disease that has been well-characterized and thought to be mediated by an immune response to an endogenous TBM antigen [25]. However, human anti-TBM nephritis is distinctly rare; it is most commonly encountered in association with anti-GBM disease. Of interest, a patient harboring a deletion in the gene that encodes the human TIN antigen has been reported with CKD [26]. Three patients with autoimmune polyendocrine syndrome type 1 developed end-stage kidney disease (ESKD) due to TIN associated with autoantibodies to aquaporin 2 and HOXB7 [19]. Despite several studies, it is not clear that specific phenotyping studies of the infiltrating interstitial cells can differentiate the

antigenic trigger. The one exception is TIN due to lymphoma/lymphoproliferative disease where a single monomorphic cellular population invades the interstitium (Fig. 42.1c). The kidney is the most common solid organ to be infiltrated (60–90%) in patients with hematological malignancies [27].

Overlooked for many years, it is increasingly appreciated that many drug-induced nephrotoxic reactions triggered by tubular epithelial cell damage are associated with significant interstitial inflammation that also contributes to renal functional impairment. Recent studies have elucidated mechanisms that define "necroinflammation", which is distinct from the hypersensitivity-type responses that cause acute TIN (Fig. 42.2). Necroinflammation is defined pathologically as a pattern of injury associated with an auto-amplification loop that is triggered by a specific form of cell death called necroptosis—characterized by the release of intracellular debris into the interstitial space. This "debris" includes "danger-associated molecular patterns" or DAMPS that bind to unique pattern recognition receptors; an interstitial inflammatory response ensues. It is curious that a few drugs such as vancomycin [29], ciprofloxacin [30] and non-steroidal anti-inflammatory drugs are able to initiate either response. The nephrotoxic effects of some drugs are linked with intratubular crystal or cast formation that trigger necroinflammation (Fig. 42.2).

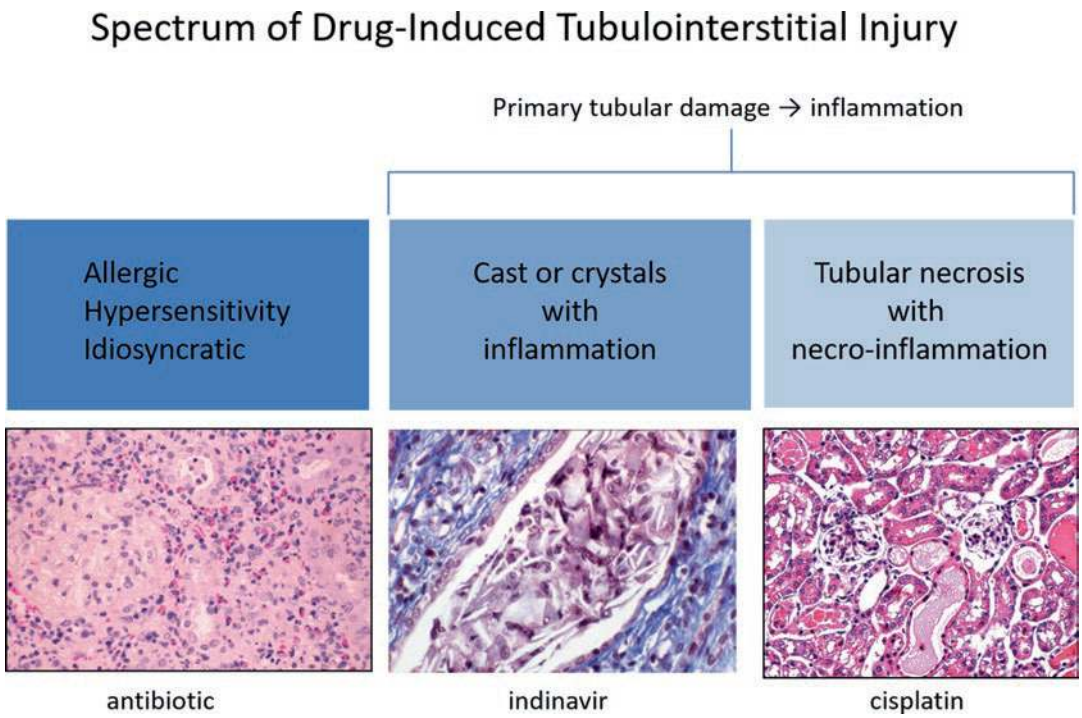

Fig. 42.2 Mechanisms of drug-induced TIN. Classical acute TIN results from an idiosyncratic allergic reaction with a primary interstitial inflammatory response (left). The nephrotoxic effects of some drugs such as indinavir are linked with intratubular crystal or cast formation, which causes tubular injury followed by interstitial inflammation (middle). Necroinflammation is a more recently recognized mechanism of tubular injury that can be initiated by drugs and is characterized by an auto-amplification loop of interstitial inflammation (right). Tubular death is caused by a specific mechanism called necroptosis, characterized by the release of intracellular debris into the interstitial space that activates unique pro-inflammatory signaling pathways. (The indinavir photomicrograph was reproduced from Fogo et al. [28] with copyright permission. The cisplatin photomicrograph was provided by Dr. Prasad Devarajan, University of Cincinnati College of Medicine)

In kidney transplant allografts, viral TIN secondary to BK polyomavirus or adenovirus is likely secondary to viral transmission via the donor organ [31].

Clinical Findings

When TIN was originally described, it was typically associated with systemic signs of inflammation. A "classic" triad of fever, eosinophilia and rash was observed in a third of the patients with methicillin-induced TIN. Recently, based on European studies of children with severe biopsy-confirmed TIN, clinical manifestations are frequently encountered but heterogenous and often non-specific [6, 8, 32–34]. When TIN occurs as a manifestation of a multi-system disease process, associated systemic symptoms may be present.

The classical clinical presentation of drug-induced TIN is acute kidney injury that begins after exposure to the offending drug. The kinetics of the onset of TIN varies depending upon the exposure history. Symptoms typically begin 3–5 days after re-exposure to the inciting drug, with a mean of 10 days until diagnosis, while it may take several weeks for the symptoms to develop with first-time drug exposure. The TIN risk is not dose-dependent, an observation that supports the theory that the pathogenesis of this disease is a 'hypersensitivity-type' immunological reaction. TIN recurrence following drug re-challenge also supports this hypothesis. Extra-renal symptoms and signs of hypersensitivity, including low-grade fever, a maculopapular rash and mild arthralgias, are more common in TIN associated with infectious and autoimmune diseases. Today, hypersensitivity symptoms are rare in drug-induced TIN and their presence does not exclude the possibility of drug-induced nephrotoxicity and/or acute tubular necrosis (ATN) rather than TIN as the primary kidney lesion. Nonspecific symptoms due to acute kidney injury including anorexia, nausea, vomiting and malaise were frequently reported in a significant number of the 106 children with a biopsy confirmed diagnoses of TIN [mean/median age ranged from 11.6–14 years; 22% males] published in five separate European studies (Table 42.1) [6, 8, 32–34]. Unlike limited studies in North America, however, a significant number of these children had tubulointerstitial nephritis and uveitis (TINU) syndrome. Kidney interstitial edema may cause renal enlargement and capsular swelling, thought to be the cause of flank pain that is present in some patients with AIN (33–79% of children as reported in the European studies) [6, 8, 32–34]. Adults (121 cases with 91% drug-induced TIN) [9, 35, 36] had similar clinical features as pediatric TIN patients, but with an increased reporting of skin rash and arthralgia.

Antimicrobials and non-steroidal anti-inflammatory drugs (NSAIDS) are most frequently suspected as the cause of drug-induced TIN, but the list of potential offending pharmacological agents is endless (Table 42.2). The risk of acute TIN is very low for an individual drug, despite a long list of single published case reports. The hallmark of TIN is an acute decline in renal function as evidenced by the rise in serum creatinine. This may be the only laboratory abnormality [3]. Acute TIN may also present as one of several more complex clinical scenarios:

1. Acute kidney injury. The absence of hypertension, significant albuminuria and red blood cell casts are clues to a diagnosis of TIN rather than glomerular or vascular disease, though in a given patient clinical manifestations may overlap considerably. Recent exposure to a potentially offending agent, significant pyuria in the absence of bacteriuria, a good urine output and evidence of tubular dysfunction suggest a diagnosis of TIN. Distinguishing between acute TIN and ATN may be challenging, although the presence of many renal tubular cells and muddy brown casts in the urine sediment is more suggestive of a diagnosis of ATN.
2. Chronic renal failure. When evaluating a new patient, the diagnostic challenge may be differentiating acute from chronic TIN. Small kidneys with increased echogenicity and anemia suggest a long-standing process. Many of the causes of chronic TIN in the pediatric population are associated with extra-renal

manifestations such as cystinosis, certain inborn errors of metabolism, and inflammatory bowel disease (IBD). More recently, chronic TIN has become a major cause of CKD in agricultural communities and is thought to be associated with heavy metal and/or pesticide exposure.

3. Tubulopathy. Patients may come to medical attention due to signs and symptoms of tubular dysfunction. The specific manifestations of tubular cell injury/dysfunction vary depending on the primary site of injury. Proximal tubular injury may cause Fanconi's syndrome with glucosuria, proteinuria, and phosphaturia, or it may present as a proximal renal tubular acidosis (RTA). Distal tubular cell injury may manifest as acidosis and hyperkalemia (type 4 RTA) while collecting duct damage typically results in a urinary concentrating defect (nephrogenic diabetes insipidus) (Fig. 42.3). Tubular cell injury may also manifest as potassium wasting. The pediatric case series by Howell et al. reported 7/10 with potassium wasting, 8/13 with reduced phosphate reabsorption and 7/16 with metabolic acidosis [32].

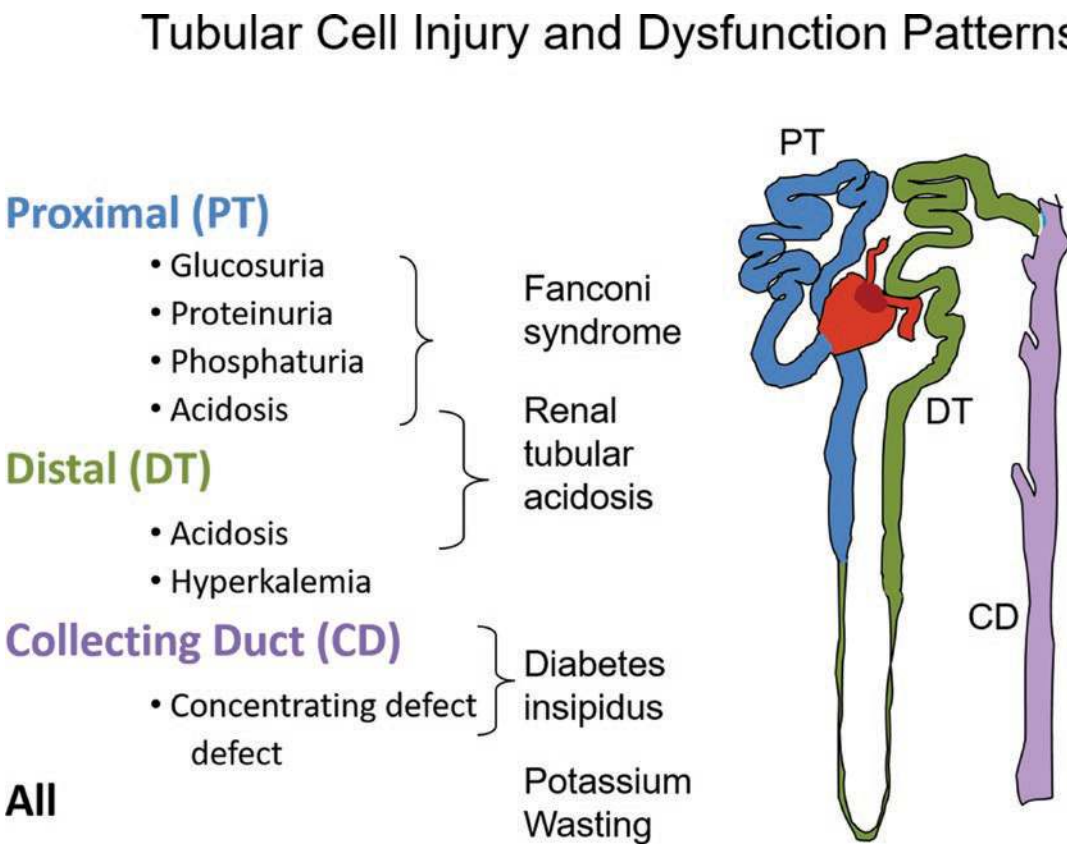

Fig. 42.3 Variable patterns of renal tubular functional defects present in patients with TIN, depending on which nephron segments (proximal, distal or collecting ducts) are injured because of the primary disease process and/or the associated interstitial inflammation

Diagnosis

Often diagnosed clinically, the sensitivity and specificity of the non-invasive diagnostic studies that are performed to diagnose TIN are poor.

Urinary Sediment

The urinary sediment often shows red cells, white cells and white cell casts (Fig. 42.1f) [3]. Sterile pyuria may or may not be associated with eosinophiluria. Urinary eosinophils (Fig. 42.1e) were once considered helpful, but more recent studies and a review of published data by Lusica et al. [67] conclude that urinary eosinophil counts lack adequate sensitivity or specificity. It is also important to remember that a bland urinary sediment does not exclude the diagnosis of acute TIN [15]. Proteinuria may be present, but is typically less than 1 g/24 h. Nephrotic range proteinuria is rare except in NSAID-induced TIN, where it is thought to be mediated by cytokine-induced glomerular injury.

Low Molecular Weight Proteinuria

Beta 2-microglobulin is a low molecular weight (~12 kDa) protein used in the evaluation of the

re-absorptive capacity of the proximal kidney tubule. Its daily production is constant and its clearance is almost exclusively by glomerular filtration followed by 99.9% reabsorption by the proximal tubule. Therefore, urinary beta 2-microglobulin levels are often elevated in patients with proximal tubular dysfunction, as frequently observed in TIN; an elevated urinary beta 2-microglobulin/creatinine ratio can help support a diagnosis of TIN [8]. Recent studies suggest that quantitative assessment of other low molecular weight urinary proteins such as α1 microglobulin, retinol binding globulin and vitamin D binding protein may also be informative [68, 69].

Blood Work

In the five most recent pediatric retrospective case series of biopsy-confirmed acute kidney injury due to TIN, the initial serum creatine (median in 4 series, mean in 1 series) ranged from 183 to 303 μmol/L (2.1–3.4 mg/dL). Anemia and elevated serum inflammatory markers (C-reactive protein and erythrocyte sedimentation rate) are common in patients with severe disease [6, 8, 32–34] (Table 42.1). Peripheral eosinophilia may be present in patients with TIN; and was described frequently in the era of methicillin-induced TIN.

Urinary TIN Biomarkers

There is considerable interest in the use of biomarkers to both differentiate causes of kidney disease non-invasively and to follow the disease course. A recent study of adult patients undergoing a kidney biopsy reported that patients with AIN have significantly higher urinary TNF-alpha and IL-9 levels than those with other causes of acute kidney injury [70]. Other promising urinary biomarkers include kidney injury molecule-1 (KIM-1) [71], N-acetyl-beta-D-glucosaminidase (NAG), complement C5b-9 [72] and increased urinary magnesium excretion [73].

Radiology

The renal ultrasound usually demonstrates increased echogenicity, often associated with an increased renal bipolar length, but these findings are non-specific [2, 3]. Gallium scanning has been proposed to differentiate between acute TIN and ATN, but the findings are often non-conclusive and the study is rarely performed now [2].

Biopsy

Since none of the non-invasive studies are both specific and sensitive for TIN, kidney biopsy remains the only definitive diagnostic study. For details on biopsy findings, see the section "Histology".

Causes, Treatment and Outcomes

The causes of TIN are numerous, but can be broadly divided into acute and chronic disorders, though there may be considerable overlap for any single etiology. Most of the larger case series have been conducted in adults and conclude that the majority (approximately 70%) are drug-related, followed by infections (16%) [12, 74]. In the five pediatric case series published since 2010 ($n = 106$ cases), 39% were due to drugs, followed by 36% due to TINU (5% in the adult series) and 17% associated with infections [6, 8, 32–34]. In a systematic review of 592 published TINU cases, it was reported that the median age was 17 years (interquartile range 13–46); 51% were under the age of 18 years [75]. The most common causes of acute TIN in pediatric patients are summarized in Fig. 42.4 and discussed in more detail in the following sections and Tables 42.2, 42.3 and 42.4.

Drugs

In the current era, drugs clearly surpass infections as the most commonly implicated cause of

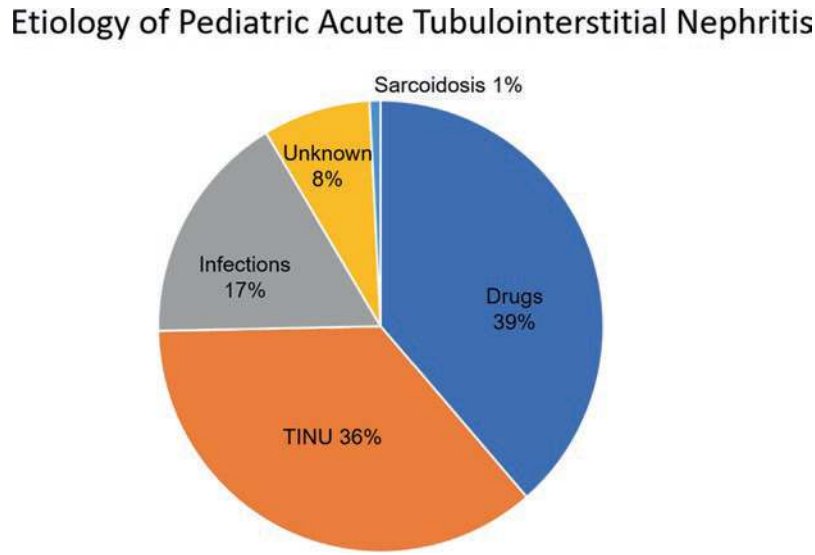

Fig. 42.4 Causes of pediatric acute TIN. Data are based on five European pediatric case series published since 2010, that also from the basis for Table 42.1. (n = 106 individual patients; etiology counted twice for 8 patients in the series by Howell et al. who had TINU plus a secondary etiology identified) [6, 8, 32–34]

acute TIN. In the adult literature, where there are more data, 35% are caused by PPIs, 35% by antibiotics and 20% by NSAIDS [78]. However, the list of potentially causative agents is extensive, expanding, and variable over time as drug prescribing practices change (Table 42.2).

Methicillin was long considered the prototypical cause of drug-induced TIN, as first reported in 1968 [79]. In fact, due to its infamy, its use has declined worldwide and it is no longer available in most countries. Methicillin and other beta-lactam antibiotics (penicillins and cephalosporins) are still more commonly associated with systemic signs of hypersensitivity, including the classic triad of rash, fever, and eosinophilia than any other group of drugs.

Rifampin has frequently been implicated as a cause of acute TIN. Affected patients fall into two groups: (1) Patients who receive short duration therapy with rifampin and (2) patients who have had prior or intermittent exposure to the drug. The first group typically lacks anti-rifampin antibodies and the onset of clinical symptoms is insidious. The second group may develop antibodies and clinical symptoms often begin abruptly [23]. Associated with certain agents such as rifampin and allopurinol, hemolysis or hepatitis may also be present [23].

NSAID-induced TIN may be associated with nephrotic syndrome in as many as 70% of the cases [23]. It is reported to occur more frequently in older patients, but it is unclear whether this is due to under-reporting in pediatrics, lower exposure rates or other factors. In NSAID-induced TIN, hematuria is almost always microscopic and extra-renal symptoms such as fever and rash occur in less than 10% of the patients [23]. The degree of interstitial inflammation is often less with NSAID-induced TIN. In addition to the classic TIN accompanied by "minimal change" glomerular disease, NSAIDs can also cause membranous nephropathy. Therefore, all patients with nephrotic syndrome associated with NSAID use should undergo a diagnostic renal biopsy [80].

The epidemiology of drug-induced TIN has changed significantly in the past two decades, especially following the first published report of PPI-induced TIN in 1992 [81]. In adults taking PPIs, a three times increased risk of developing TIN [82], a four times increased risk of acute kidney injury and a 20% increased risk for CKD [83] were reported. A meta-analysis also identified a 1.2 increased risk of CKD among PPI users, but no increased risk among H2 receptor antagonists [84]. Additionally, there is evidence that the duration of exposure to PPI is associated with increased risk and progression of CKD [85]. As newer therapies and drugs are introduced, one must maintain a high index of suspicion for drugs

as a cause of acute renal dysfunction without relying on the presence of the historically "classical" clinical features [86]. Future pharmacogenomic studies may identify patients at higher risk of TIN in association with the use of specific medications. One study failed to show that individuals with the CYP2C19 slower metabolizer genotype were at increased risk of omeprazole-induced AIN [87].

The primary treatment of drug-induced TIN is to identify and stop the offending agent. The immunologic trigger must be removed, particularly since persistent tubulointerstitial injury can progress to chronic irreversible damage. Early removal of the offending agent alone frequently leads to complete reversal of renal injury. Kidney biopsies are not performed and additional therapy is not required, if the drug exposure time was short and renal function improves quickly. After drug-induced acute TIN, the mean recovery time to the nadir creatinine is 1.5 months [23]. There are an increasing number of long-term follow-up studies in adults reporting an increased risk of CKD after PPI-induced TIN [85, 88].

Therapy with corticosteroids has been used for several decades to treat severe acute drug-induced TIN, but indications for treatment and evidence of efficacy are problematic due to the lack of prospective randomized controlled clinical trials. Earlier case series have suggested faster

rates of renal recovery with steroids, but their benefit to long-term kidney function is still debated. A systematic review of all studies published between 1975 and 2016 concluded: (1) Findings suggest that the evidence for the use of corticosteroids in the treatment of drug-induced AIN remains uncertain, (2) Given the shortage of proven treatments for drug-induced AIN to ameliorate the burden and consequences of acute kidney injury, suitably designed studies should be prioritized [89]. In the interim, there is a growing consensus of expert opinions that a course of corticosteroids is reasonable to treat acute kidney injury secondary to biopsy-proven acute TIN (in the absence of significant tubular atrophy and interstitial fibrosis) when kidney function does not improve within 3–6 days after the offending drug is withdrawn [90]. Studies by Gonzales et al. [36] and Fernandez-Juarez et al. [91] report worse renal functional outcome if treatment is delayed for more than a few weeks after the diagnosis is made (Fig. 42.5).

While older studies may have argued against the use of routine corticosteroids for severe drug-induced TIN, there are several possible explanations for a lack of glucocorticoid efficacy in

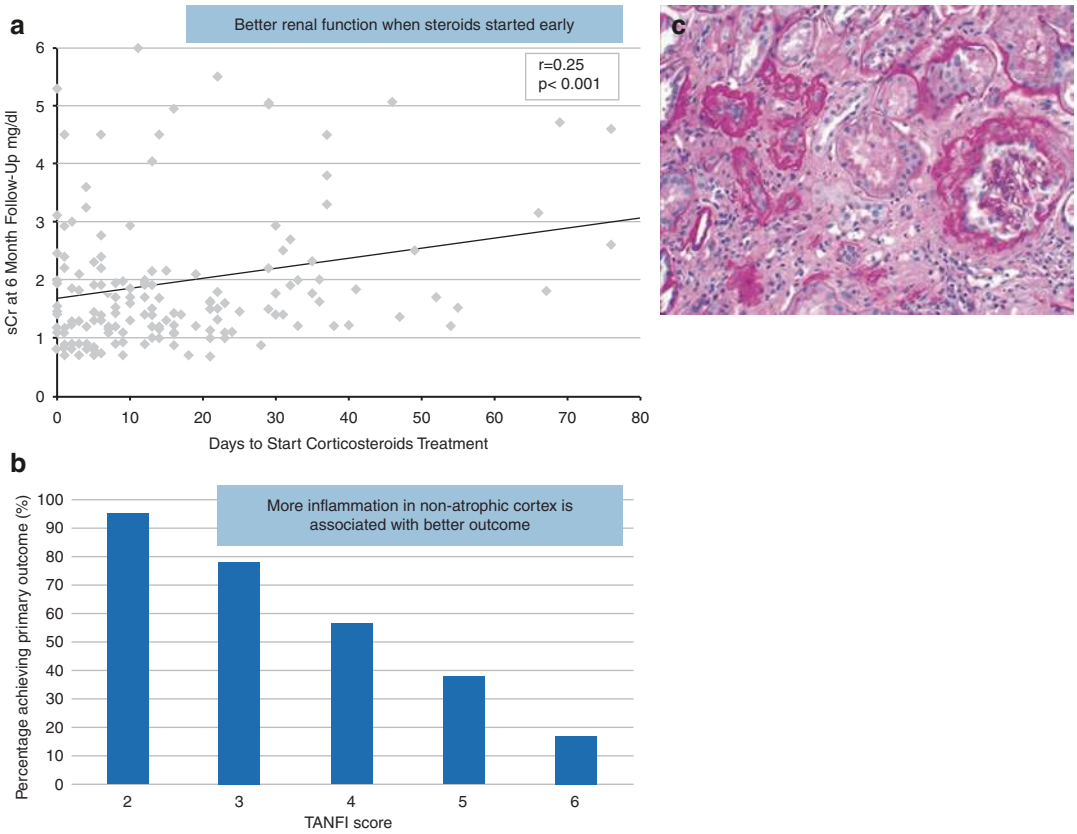

Fig. 42.5 Prognostic impact of early steroid initiation, and degree of tubulointerstitial inflammation and fibrosis/tubular atrophy on TIN outcomes. In a study of 182 adults with severe drug-induced TIN treated in Spain (mean peak creatinine 504 ± 309 μmol/L), the serum creatinine level 6 months after diagnosis was better when corticosteroid treatment was started early [91] (**a**). A kidney injury chronicity score applied to 120 adult kidney biopsies with primary acute TIN reported better clinical outcomes (50% reduction in serum creatinine or eGFR greater than 60 mL/min/1.73 m^2 at 1 year) in patients with low cortical tubular atrophy and with higher interstitial inflammation in non-fibrotic cortex scores. These data were combined into a single score called TANFI, calculated as the tubular atrophy score pulse the inverse of the non-fibrotic cortex with inflammation [92] (**b**). Representative photomicrograph of renal biopsy illustrating the features of chronic TIN—tubular atrophy, thickened tubular basement membranes and an expanded interstitial space occupied by scar tissue (**c**). (**a**, **b** were originally published in *Histopathology* and *CJASN*, respectively, and are reproduced with copyright permission)

earlier studies, including a bias towards treating the patients with worse disease, the possibility that a significant proportion of the patients had NSAID-associated TIN, which appears to be less likely to respond to glucocorticoid therapy, and the negative impact of delayed therapy onset [9, 23, 35]. Future studies will also need to control for the degree of chronic damage as quantified on the kidney biopsy (tubular atrophy and interstitial fibrosis), which negatively impacts reversibility and long-term prognosis [92]. When indicated, the leading experts recommend treating acute drug-induced TIN with prednisone 1 mg/kg/day for 2–4 weeks, followed by tapering to discontinuation over 3–4 weeks. The retrospective study by Fernandez-Juraz et al. with 182 adults from 13 centers in Spain reported that using high dose corticosteroids for longer than 3 weeks and total therapy duration longer than 8 weeks has a non-significant effect on renal recovery and may increase the risk for adverse steroid therapy effects [91]. Data on the use of immunosuppressive agents such as mycophenolate mofetil are too sparse to draw any conclusions.

While the serum creatinine at the time of biopsy is a poor prognostic indicator [36], evidence is emerging to suggest that patients with acute systemic inflammation (elevated ESR and CRP) [93] and low chronicity scores on biopsy [92] have better renal function outcome (Fig. 42.5).

Drugs have also been implicated in unusual cases of TIN. For example, anti-carbonic anhydrase II antibodies were detected in a patient with TIN associated with the use of famotidine [94].

Tubulointerstitial Nephritis with Uveitis

An association between TIN and anterior uveitis, occasionally associated with bone marrow granulomas, was first reported in 1975 and called TINU [95]. While anterior uveitis is more common, posterior uveitis can also occur. When first described, there was a female predominance; recent studies also indicate that 65% are female. The median age of onset is 17 years (55% are under 18 years of age) [75]. TINU is a syndrome of multiple etiologies. Though often idiopathic and presumed to be autoimmune in pathogenesis, it is important to search for evidence of the known causes of TIN with uveitis that are summarized in Fig. 42.6. It is speculated that disease pathogenesis involves an immunological response triggered by a recent drug exposure (often an

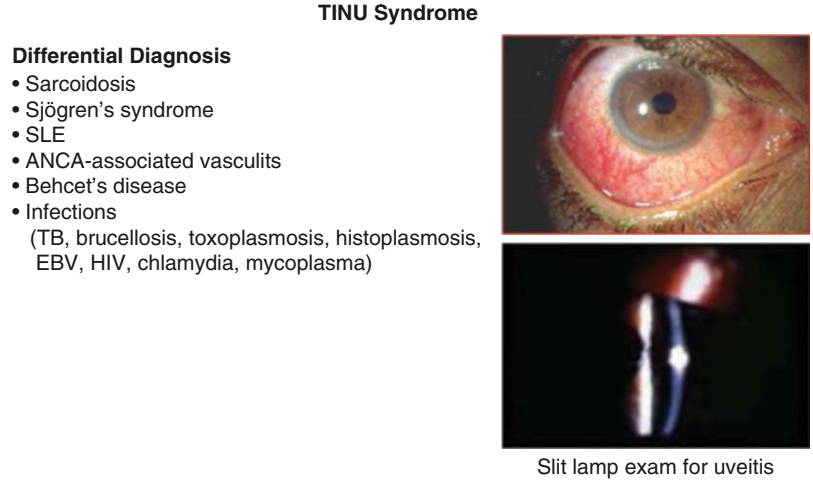

Fig. 42.6 Tubulointerstitial nephritis with uveitis syndrome (TINU). While often idiopathic, the known secondary causes of TINU listed in this figure should be considered in the differential diagnosis as specific therapy is available for many of them. The ocular photomicrographs, taken from patients with acute uveitis, serve as a reminder of the importance of performing a slit lamp examination as part of the evaluation of a patient with suspected acute TIN of unknown etiology

antimicrobial agent), an infection or an unknown agent. The systematic review of 592 cases, reported an association with drugs in 21%, infections in 6% and no identified trigger in 63% [75]. Some patients have serum auto-antibodies such as antinuclear antibodies, rheumatoid factor, antineutrophil cytoplasmic antibodies and/or anticardiolipin antibodies. One study posits that modified C-reactive protein might be a target antigen [96]. Some patients have associated autoimmune diseases such as hyperthyroidism [97], hyperparathyroidism, or rheumatoid arthritis. Patients may also have a history of recent insect bites [98].

The report of TINU in monozygotic male twins separated in onset by 2 years suggests the possibility of a genetic predisposition to the syndrome [99], as does a report in 1994 of identical female twins with the onset of TINU syndrome 1 year apart [100]. However, the lack of reports of multiple affected family members and the lack of geographic clustering questions the influence of environment and genetic factors. Reviewed by Cline and Vanguri [101], several small studies (2–20 patients from several countries), have suggested different HLA associations (especially some DRB1* alleles), but ethnic diversity among the cohorts prevents broader extrapolation of the findings.

Several of the non-specific symptoms associated with TIN may be present in patients with TINU syndrome. These include fever, weight loss, fatigue, malaise, loss of appetite, weakness, asthenia, abdominal or flank pain, arthralgias and myalgias. Less commonly, headache, polyuria, lymphadenopathy, edema, pharyngitis or rash may occur. The ocular manifestations commonly include eye pain and redness (77%), decreased visual acuity (20%) and photophobia (14%) [98], but recent studies have suggested that up to 58% of patients with TINU have reported no ocular symptoms despite slit-lamp confirmation of uveitis, making it critical that patients with acute TIN undergo regular eye examinations [8]. Onset of uveitis varies from several weeks before the onset of renal involvement, concurrent with the TIN, or up to 15 months after the onset of TIN. The systematic review by Regusci et al. reported the onset of uveitis after renal involvement in 52% of the patients [75]. Both recurrent acute and chronic uveitis are commonly described. The timing of uveitis recurrence has varied from 3 months after steroid tapering to 2 years after the first episode. The renal and ocular manifestations of TINU have also been reported to recur years after initial presentation, even after transplantation, further supporting a role for systemic immunological factors in the disease pathogenesis [102].

Laboratory findings may include elevated serum creatinine, evidence of tubular dysfunction, anemia, slightly abnormal liver function tests, eosinophilia, hypergammaglobulinemia and elevated erythrocyte sedimentation rate. A variety of serological markers have been reported without evidence of the associated diseases in 15% of patients (such as SLE, ANCA-associated vasculitis, anti-phospholipid syndrome, rheumatoid arthritis). However, definitive diagnosis requires a renal biopsy and a formal ophthalmologic slit-lamp examination to diagnose uveitis. Bone marrow and lymph node granulomas have been reported, but these studies are rarely performed now that TINU syndrome has become recognized as a distinct clinical entity.

The tubulointerstitial disease is self-limited in most patients, but there are reports of individuals progressing to ESKD [8, 102]. In the 2021 systematic review, 11% of the patients under 18 years had CKD at a median follow-up of 18 months [75]. The ocular disease usually requires treatment, with both topical and systemic steroids. There are anecdotal reports of utilizing other immunomodulatory therapies in the treatment of recalcitrant eye disease. While the acute eye disease usually improves, recurrences, complications, and chronic ocular disease are not uncommon. Most of the long-term complications of TINU have been ocular, estimated to occur in 20% of patients. These include posterior synechiae, optic disc swelling, cystoid macular edema, chorio-retinal scar formation, cataracts and glaucoma [95, 98]. Fortunately, the risk of visual loss appears low. Due to the morbidity associated with the ocular manifestations, early detection by slit lamp examination is essential.

Infections

Numerous infectious agents have been implicated in the pathogenesis of TIN, both acute and chronic. TIN was first recognized as a unique clinical entity in 1860 in a patient with scarlet fever. However, it was several decades later before Councilman introduced the term "interstitial nephritis" and described the histologic lesions. To quote his landmark paper "Acute interstitial lesions of the kidneys have been considered as common in scarlet fever, and are regarded by some authors as constituting the most frequent pathological alteration of the kidney in this disease. This has also been described in diphtheria and in other infectious diseases" [1]. The 1939–1945 era saw the eradication of serious and fatal streptococcal infections due to the introduction of antibiotics. In the current era, the infections implicated as causes of TIN vary from Councilman's time due to childhood immunizations and the use of effective antibiotics. In fact, since 1960 antibiotics rather than infections are a more common cause of acute TIN (Table 42.3, Fig. 42.4).

The infectious microorganisms may directly invade the renal parenchyma to cause a specific form of TIN (pyelonephritis). TIN is the most frequent renal biopsy finding in patients with renal tuberculosis [103]. Rare infectious processes may induce emphysematous or necrotizing interstitial parenchymal lesions [104, 105]. However, the traditional form of acute TIN is associated with infection at an extrarenal site and the tubulointerstitial inflammation is thought to represent a secondary or "reactive" immunological response to the infection. In the latter, the infectious agent is not cultured from the kidney or urine and cytokines derived from inflammatory cells are key kidney disease mediators.

When a renal biopsy is performed in a patient with pyelonephritis (not typically required or recommended), the interstitial lesion is often localized to a single pyramid and characterized by neutrophil predominance. In contrast, "reactive" TIN associated with a systemic infection is characterized histologically as either patchy or diffuse lesions that are associated with interstitial edema and a predominance of mononuclear cells. The pathogenic microbial antigens that initiate the immune response to cause TIN are largely unknown. One exception is leptospirosis, where an isolated outer membrane protein has been shown to interact in vitro with Toll-like receptor 2 to stimulate synthesis of inflammatory cytokines, chemokines and collagen by renal tubules [106]. The primary therapeutic measure is to treat the infection, preferably with non-nephrotoxic antimicrobials.

Viral infections are an important cause of TIN. Epstein-Barr virus (EBV) may have a pathogenetic role in certain forms of "idiopathic" TIN based on the detection of EBV genome in the proximal tubules in one case series [107]. HIV-1-assocated nephropathy is typically characterized by significant glomerular pathology, but coexistent TIN is common and more severe than observed in other primary glomerular disorders. This is likely related to the ability of HIV-1 to infect and damage tubular cells [108]. In a kidney biopsy series of 222 HIV-infected patients, 27% had TIN as the predominant lesion [77]. However, in at least half of the latter patient group, the concurrent use of nephrotoxic agents such as antiretroviral drugs may have contributed to the TIN. TIN has also been reported as a feature of the immune reconstitution syndrome in the HIV-infected population [109].

BK polyomavirus is an important cause of TIN in immunocompromised patients, especially following kidney transplantation, though it has been reported in other transplants recipients as well and rarely in children with a lymphoid malignancy [4, 110–112]. Adenovirus DNA has also been identified in a few kidney allografts with granulomatous TIN [5, 76]. Many other viruses listed in Table 42.3 have been associated with reported cases of TIN.

Granulomatous Interstitial Nephritis

TIN may be associated with the presence of granulomas on renal biopsy (Fig. 42.1b). Granulomatous TIN is found in approximately 6% of renal biopsies with TIN [13]. The differential

diagnosis of this histologically distinct variant includes drug-induced TIN (~25% of cases), infectious causes (tuberculosis, brucellosis, histoplasmosis, adenovirus, fungal), ANCA-associated vasculitis, sarcoidosis, TINU syndrome, multiple myeloma, IBD [113] and other dysproteinemias; it may be idiopathic in as many as 50% of the patients [114]. While TIN has been reported in up to 20% of renal biopsies performed in patients with IBD [41], granulomatous TIN is exceptionally rare and limited to a few IBD case reports [115].

Additionally, there is the frequent challenge of distinguishing between drug-induced AIN associated with IBD treatment and extra-intestinal manifestations of IBD primary disease. There are reports of biopsy proven AIN in IBD patients before they have started IBD treatment, suggesting a pathogenesis distinct from drug-induced AIN [116].

There are several systemic diseases that may cause acute TIN even in the pediatric age group (Table 42.4). A few of the more common examples are discussed briefly in the next sections.

Sarcoidosis

Sarcoidosis is a multisystem disease characterized by non-caseating granuloma formation in various organs, including the kidney. While the exact incidence of granulomatous TIN among patients with sarcoidosis is unknown, studies have cited an incidence up to 30% [114]. Although histologic evidence of renal involvement is said to be common in sarcoidosis, isolated renal sarcoidosis is rare [117, 118].

Patients with sarcoidosis tend to avidly absorb dietary calcium, leading to hypercalciuria and, less commonly, hypercalcemia. The clinical manifestations of calcium hyperabsorption may be silent or may cause nephrolithiasis, nephrocalcinosis, renal insufficiency or polyuria. Nephrocalcinosis is the most common cause of chronic renal failure in sarcoidosis [119]. Polyuria may be the result of hypercalcemia and hypercalciuria that decreases tubular responsiveness to antidiuretic hormone, or it may be a manifestation of diabetes insipidus or primary polydipsia as a consequence of granulomatous infiltration of the hypothalamus. It is important to recognize that the abnormalities in calcium metabolism can occur in other chronic granulomatous diseases due to increased calcitriol produced by activated mononuclear cells [120].

The urinary manifestations of sarcoid granulomatous TIN are similar to other forms of chronic TIN, often associated with a bland urine sediment, sterile pyuria and/or mild proteinuria. The serum creatinine is usually normal and CKD is rare. The renal biopsy findings may include TIN with mononuclear cell infiltration and non-caseating granulomas in the interstitium [121]. When glomerular disease is present, it is most frequently membranous nephropathy; however, granulomatous TIN is present in 2/3 of the cases with glomerular disease [122]. Chronic injury, manifest as interstitial fibrosis and tubular damage, is common in the primary sarcoidosis-associated glomerulopathies.

Corticosteroids remain the treatment of choice, with slowly tapered protocols to prevent disease recurrence [122–125]. While there are currently no large trials of therapeutic protocols for renal sarcoidosis, there are reports of tumor necrosis factor-α blocking agents improving renal function, supporting the theory that TNF-α may play a pathogenetic role [119, 126]. In the rare patient who develops ESKD, it is usually due to hypercalcemia and hypercalciuria rather than TIN [119]. Renal sarcoidosis has been reported to recur in approximately 15% of renal allografts [127, 128].

Sjögren's Syndrome

Sjögren's syndrome is classically described as a sicca syndrome that occurs as a consequence of lymphocytic (mainly activated CD4+ cells and B cells) and plasmacytic infiltrates in the exocrine glands, especially the salivary, parotid and lacrimal glands. This causes dry mouth and dry eyes. These sicca symptoms are less common in children; recurrent parotitis is a common presenting symptom [129]. The pathogenic immune process may also affect non-exocrine organs, including the skin, lung, gastrointestinal tract, central and peripheral nervous systems, musculoskeletal sys-

tem and the kidney. The most common renal manifestation is TIN with associated tubular dysfunction (Fanconi syndrome); glomerular disease has also been reported [130–132]. Though the presence of renal disease in patients with Sjögren's syndrome was first reported in the 1960s, its prevalence and primary pathogenesis remain ill-defined. In the literature, the frequency of renal abnormalities varies widely from 16% to 67% [130, 133]. The diagnosis of idiopathic Sjögren's syndrome is based on clinical and/or histopathological evidence of ocular, oral or salivary involvement and the presence of anti-Ro/SSA and/or anti-La/SSB auto-antibodies. Symptoms due to renal disease, such as polyuria and renal tubular acidosis, may precede sicca syndrome-related symptoms [133]. TIN is the most common renal finding in Sjögren's syndrome and carries the best prognosis [134], although one case series reported four patients with isolated TIN and primary Sjogren's disease that progressed to ESKD [131]. While steroids remain the mainstay of therapy for the renal manifestations, other medications such as rituximab have shown improvement in the extrarenal manifestations [131, 132, 135, 136].

Other Systemic Autoimmune Diseases

Renal involvement is common when systemic lupus erythematosus begins in the pediatric age group: 20–80% within a year of diagnosis and 48–100% at some point during the course of the disease [137]. Isolated TIN associated with tubular basement membrane (TBM) immune deposits can occur, but is extremely rare. Conversely, focal or diffuse interstitial inflammation in association with glomerular disease is relatively common and does not typically show a clear association with TBM immune deposits and the presence of TIN is not considered in the primary classification of lupus nephritis (Classes 1–VI) [138]. The severity of interstitial inflammation and, in particular, its association with tubular atrophy and interstitial fibrosis, are strong predictors of renal outcome [139].

The majority of pediatric patients with ANCA-associated systemic vasculitis have renal involvement (75–88%) [140]. TIN is typically present in association with focal necrotizing glomerulonephritis, though isolated cases of TIN have been reported [141]. The "signature" interstitial granuloma is only present in 6–12% of renal biopsies performed in patients with granulomatosis with polyangiitis [142].

Over the past decade, an increasing number of adults have been diagnosed with TIN due to an autoimmune multisystem disease referred to as IgG4-related disease [143], but there are very few published pediatric cases [144]. It is noted that IgG4+ cells can be detected in other forms of TIN [145]. Other causes of primary TIN include IBD [115, 116] and ankylosing spondylitis [113, 146]. In a study of native kidney biopsies performed in Finland, 13.3% of the patients with TIN had IBD [147]. Both IBD and some of the drug treatments (5-aminosalicylic acid, infliximab, vedolizumab) have been implicated as TIN triggers. Since many patients with systemic autoimmune disorders have complicated medical courses, it is always important to consider alternative causes for their TIN such as drugs and infection.

TIN has been reported in young boys with immunodysregulation, polyendocrinopathy. Enteropathy X-linked (IPEX), a rare genetic disease caused by an inherited mutation in the gene encoding forkhead box P3 (FOXP3) [148].

Xanthogranulomatous TIN

Xanthogranulomatous pyelonephritis (XGP) is a rare entity usually occurring in the fifth or sixth decade of life, though neonatal and childhood cases have been reported [149–151]. In a review of 66 children who underwent nephrectomy in Ireland between 1963 and 2016 for XPN, the median age was 4.84 years (range 1.1–14.8 years) [151]. It is a chronic destructive granulomatous inflammation of the renal parenchyma first described in 1916 by Schlagenhaufer in association with *Escherichia coli* and *Proteus mirabilis* urinary tract infections [152]. The exact etiology

remains unknown, but it is thought to be a result of chronic obstruction with persistent urinary infection [150, 153]. The disease may be mistaken for malignancy, with the consequence that diagnosis is often made on histology after nephrectomy. Medical management of the suppurative infection is possible when an early diagnosis is made, but this is unusual. Nephrectomy is not uncommon due to irreversible parenchymal destruction [154, 155].

Idiopathic TIN

Approximately 8–10% of cases of acute TIN remain idiopathic [6–8, 12, 32–34]. This diagnosis can only be made after all other possible causes have been eliminated by a thorough history, clinical examination, and relevant laboratory investigations.

Chronic Interstitial Nephritis

Epidemiology

The exact incidence and prevalence of primary chronic TIN is poorly documented. This topic is complicated by the fact that chronic interstitial changes typify virtually all chronic renal disorders that eventually progress to CKD stage 5.

Pathology

The early phase of chronic TIN shares histopathologic features with acute TIN, including interstitial inflammation and tubular cell activation. However, as the disease progresses, interstitial fibrosis and chronic tubular injury (dilated tubules with/without cast formation, atrophied tubules and thickened tubular basement membrane) appear (Fig. 42.5) [156, 157]. In the advanced stages, glomerulosclerosis may occur as a secondary consequence of the tubular damage or periglomerular interstitial fibrosis. For all chronic kidneys diseases, whether initially a glomerular or tubulointerstitial disorder, interstitial fibrosis severity is a strong predictor of renal functional loss and risk of progressive renal disease, as illustrated by a recent study of 1022 patients with IgA nephropathy [158].

Clinical Findings

The clinical findings in chronic TIN are similar to those in acute TIN, but tend to be more subtle and often go undetected until the patient develops signs and symptoms due to chronic renal insufficiency. Compared to chronic glomerular disease, in patients with chronic TIN hypertension is less common, daily protein excretion rates rarely exceeds 1.5 g/day and anemia may be disproportionately worse than the degree of renal functional impairment due to the loss of erythropoietin-producing cells in the peritubular interstitium. Bone disease may also be more prominent as a result of chronic phosphate wasting due to proximal tubular dysfunction.

Etiology

As in acute TIN, there are numerous causes of chronic TIN. In addition to diseases that may progress from acute TIN to chronic TIN, several diseases more typically present as chronic TIN. In the pediatric population, the causes of chronic TIN that are not sequelae of acute TIN can be broadly grouped into the following categories that are also summarized in Table 42.5; many are reviewed in greater detail in other chapters.

Genetic Kidney Diseases, especially the ciliopathies (nephronophthisis) and polycystic kidney disease, are associated with significant tubular damage and interstitial inflammation and fibrosis. Another group of inherited diseases that are increasingly recognized since first reported in 2002 are now classified as autosomal dominant tubulointerstitial kidney disease (ADTKD) [159]. They are rare diseases that are largely undetected in childhood, as the kidney disease is typically silent until clinical manifestations of chronic renal failure develop. Some patients provide a history of polyuria and/or enuresis due to a uri-

Table 42.5 Common causes of chronic TIN in childhood and adolescence

Category	Specific entity
Persistent TIN	All categories (late diagnosis)
Inherited kidney disease	Autosomal Dominant Tubulointerstitial Kidney Diseases (ADTKD) (*UMOD*, *MUC1*, *REN* and other less common gene mutations)
	Karyomegalic TIN (*FAN1* mutation)
	Nephronophthisis (ciliopathies)
	Polycystic kidney diseases
Inherited metabolic disease	Cystinosis
	Oxalosis
	Methylmalonic acidemia
	Mitochondrial cytopathies
	Adenine phosphoribosyltransferase (APRT) deficiency
Acquired metabolic disease	Nephrocalcinosis
	Uric acid-induced injury
	Potassium deficiency (anorexia nervosa)
Chronic nephrotoxicity	Chronic interstitial nephritis in agricultural communities (CINAC)
	Heavy metals (lead, cadmium)
	Calcineurin inhibitors
	Analgesic nephropathy
	Chinese herbs (Aristolochia fangchi)
	Chemotherapy (cisplatinum, isophosphamide)
Structural renal disease	Dysplasia
	Obstruction
	Reflux

nary concentrating defect. The first cases reported were caused by autosomal dominant mutations in *UMOD*, the gene that encodes the kidney-specific protein uromodulin (also known as Tamm-Horsfall protein). Patients often present with symptoms of gout between 15 and 40 years of age due to hyperuricemia (present in ~70% of affected patients) [160]. Stage 5 CKD due to chronic TIN develops between ages 30–60 years; the rate of progression may be decreased in the hyperuricemic patients with the use of allopurinol. Mutations in the *MUC1* gene, which encodes the glycoprotein mucin-1, were first reported in 2013. Mutations in *UMOD* and *MUCI* are the most prevalent etiologies of ADTKD [161]. It is estimated that ~50% of the ADTKD patients currently lack a genetic diagnosis [160]. Eight mutations have been reported in the *REN* gene that encodes prorenin [162, 163]. These patients may develop transient childhood anemia, have a tendency for hyperkalemia, defective urinary concentration and gout. Additional diseases have been classified as ADTKD, although the kidney phenotype may include features in addition to chronic TIN. These include patients with mutations in the genes *HNF1B* encoding hepatocyte nuclear factor 1 beta, and *SEC61A1* that encodes the alpha 1 subunit of SEC61 [161].

There is another rare genetic disease that resembles nephronophthisis histologically except for the presence of hyperchromatic and abnormally enlarged tubular epithelial cell nuclei that causes ESKD in the third or fourth decade of life. It was first recognized as a distinct entity and named karyomegalic interstitial nephritis (KIN) in 1979 [164]. In 2012 Zhou et al. [165] identified an autosomal recessive mutation in *FAN1* as a cause of TIN.

Other causes of chronic TIN include:

1. ***Congenital anomalies of the kidney and urinary tract.***
2. ***Inborn error of metabolism***, including cystinosis, oxalosis, methylmalonic acidemia, the mitochondrial cytopathies, adenine phosphoribosyltransferase (APRT) deficiency.
3. ***Chronic nephrotoxin exposure***, especially the calcineurin inhibitors, lithium, heavy met-

als (cadmium, mercury, and lead), chemotherapeutic agents (cisplatinum, ifosfamide), antimicrobials (amphotericin B, antiretroviral drugs), NSAIDs and certain Chinese herbs.

4. ***Chronic interstitial nephritis in agricultural communities (CINAC)***. This disease entity is increasing in endemic areas of the world, characterized as agricultural communities in hot tropical communities (patients in Sri Lanka and Central America are best studied) [166]. While male agricultural workers in the 20s to 40s age group are most frequently reported, it has also been reported in women, and markers of kidney damage can be found in children [167]. Histopathologically CINAC is a chronic TIN. The etiology is unclear and likely multifactorial. A recent kidney biopsy study by Vervaet et al. [168] reported abnormal proximal tubular lysosomes; by electron microscopy they contained electron-dense aggregates suggestive of a toxin-associate proximal tubulopathy. Several toxic agrochemicals and pesticides have been identified as candidates, but definitive proof of their role is still lacking. Exposure might be direct or may occur from contaminated water consumption or by inhalation. Heat stress and recurrent dehydration may be a contributing factor.
5. *Chronic allograft nephropathy.*

Treatment and Prognosis

Treatment of chronic TIN is based on the treatment of the primary disease process. In addition, there is increasing evidence that correction of anemia, reduction of proteinuria and suppression of inflammation may also slow the rate of the kidney disease progression [156]. Angiotensin converting-enzyme inhibitors and angiotensin receptor type 1 blockers are being used with increasing frequency for a variety of chronic renal diseases, especially when associated with hypertension and/or proteinuria. It is believed that in addition to decreasing intraglomerular pressure, these drugs reduce proteinuria and may also have an anti-fibrotic role related to angiotensin II blockade [169].

Outcomes

Patients with chronic TIN and CKD stage III (GFR 30–59 mL/min/1.73 m^2) or stage IV (GFR between 15 and 29 mL/min/1.73 m^2) are destined to progress to ESKD (GFR < 15 mL/min/1.73 m^2). Numerous comorbid factors correlate with a faster rate of renal functional decline, including hypertension, high-grade proteinuria, diabetes, smoking, obesity, dyslipidemia and anemia [12, 96].

While definitive therapy may not be available for the primary disease process that is responsible for chronic TIN, many of these comorbidities can be addressed therapeutically to preserve residual nephrons and slow the rate of CKD progression. Landmark studies by Risdon and Shainuck, more than half a century ago, highlighted the central importance of chronic TIN, assessed as the degree of tubular atrophy and interstitial fibrosis, to renal functional outcomes irrespective of the primary etiology of the CKD. Since then, advances in the field of cellular and molecular biology and genome sciences have utilized animal models and human kidney tissue biorepositories to decipher fundamental mechanisms that cause the chronic TIN component in human CKD. A major priority for ongoing and future studies is the identification of new therapeutic targets, development of safe therapeutic agents based on these "candidate" targets and subsequent randomized prospective clinical trials to establish their efficacy in patients with CKD. Analogous to current cancer treatment protocols, a multi-agent approach will almost certainly be necessary, taking into consideration specific genetic and molecular disease markers that get us closer to personalized medicine. Based on the current state of knowledge, several interrelated pathogenic pathways are potentially amenable to drug therapies [157]:

1. Preserving tubular epithelial cell integrity (and thus intact nephrons) by minimizing tubular injury/death/senescence and enhancing the repair of damaged tubules. Reactivating key kidney developmental pathways has been promising in experimental models. Permanent

tubular loss is a key predictor of irreversible CKD.
2. Blocking the numbers and/or function of a unique population of interstitial myofibroblasts that are the primary source of the scar-forming extracellular matrix proteins.
3. Regulating the interstitial cell inflammatory response that has multiple consequences—some harmful and others healing. The role of macrophages appears to be particularly important.
4. Disrupting the vicious circle of hypoxia and oxidant stress that develops at least in part because of the lack of preservation of a healthy interstitial capillary network vital for adequate kidney oxygenation.
5. Reducing the progressive accumulation of extracellular matrix proteins in the interstitium. Despite the identification of several matrix-degrading proteases in kidneys, there is still no convincing evidence that renal fibrosis can be reversed in humans. Effective therapies will need to target the extracellular matrix production pathways.

Further laboratory and clinical studies are needed to identify new evidence-based therapeutic options to improve long-term outcomes for patients with chronic TIN.

Part IX

Urinary Tract Disorders

43 Diagnosis and Management of Urinary Tract Infections

Ian K. Hewitt and Giovanni Montini

Introduction

Urinary tract infection (UTI) represents colonisation and invasion of the urinary tract by bacteria. The term cystitis is used when the organisms are confined to the bladder and urethra, and usually accompanied by localized symptoms such as dysuria, frequency, malodorous urine, day time and night time urinary incontinence. They occur most predominantly in girls older than 3 years of age and are easily treated. Acute pyelonephritis, considered by many to be the most common serious bacterial illness in childhood, is an infection that involves the renal parenchyma. Most affected children, particularly infants, present systemically unwell with symptoms including high fever, which may be the only indicative feature, lethargy, abdominal pain, nausea, vomiting and irritability. These infections have been considered of most concern for their potential to result in renal scarring, with the potential for long-term morbidity. Asymptomatic bacteriuria is a further type of urinary tract infection whereby a significant growth of organisms from the urine occurs in the absence of any illness or symptoms. It has been found in approximately 1% of school-aged girls on screening, and does not warrant treatment or investigation, as trials have demonstrated a good outcome, uninfluenced by any intervention.

Approximately 2% of boys and 7–8% of girls will experience a urinary tract infection in the first 8 years of life [1]. Febrile urinary tract infections suggestive of acute pyelonephritis are most common in the first year of life with a male predominance in the first 6 months, after which they are more often seen in girls (Fig. 43.1). Non-febrile UTI, typically cystitis, is seen more commonly in girls as they get older.

Background

In recent years there has been a re-evaluation of the potential for UTI to culminate in severe long term renal parenchymal damage. In the past children usually came to attention only after experiencing UTIs, and were investigated with invasive imaging modalities, such as intravenous pyelography and voiding cystourethrograms. Small hypodysplastic and scarred kidneys, often in association with vesicoureteral reflux (VUR), were occasionally found, and were thought to be the consequence of previous episodes of unrecognized pyelonephritis. This led to the concept of reflux nephropathy, linking VUR to ascending infection and pyelonephritis, with subsequent renal scarring [2]. Consequent upon this, children with reflux were often placed on long term antibiotic prophylaxis or underwent surgical correction (Fig. 43.2a). Already at this time, not all agreed with this view. A French paper demonstrated that 11 of 12 nephrectomies performed because of severe reflux nephropathy were congenital small kidneys, with the remaining kidney showing isolated and specific histologic signs of chronic pyelonephritis [3]. Two early studies randomized children with VUR detected following a UTI to either antibiotic prophylaxis with surgical correction alone or combined with adjuvant prophylaxis [4, 5]. In one study the rate of scarring was 38% at presentation, while subsequent rates of scarring were low (2% and 9%) and unrelated to the presence or absence of VUR or breakthrough infection [4]. These two studies already demonstrated the difference between congenital renal mal-development and acquired scarring as a consequence of pyelonephritis. The introduction of routine antenatal ultrasound from the mid1980s onward, led to the recognition that much of the significant renal damage, often familial and seen in association with high grade VUR was the consequence of congenital abnormalities of the kidney and urinary tract (CAKUT) (Fig. 43.2b) [6]. This has led to questioning the role of acquired renal damage as a consequence of pyelonephritis as the major contributor to chronic kidney damage.

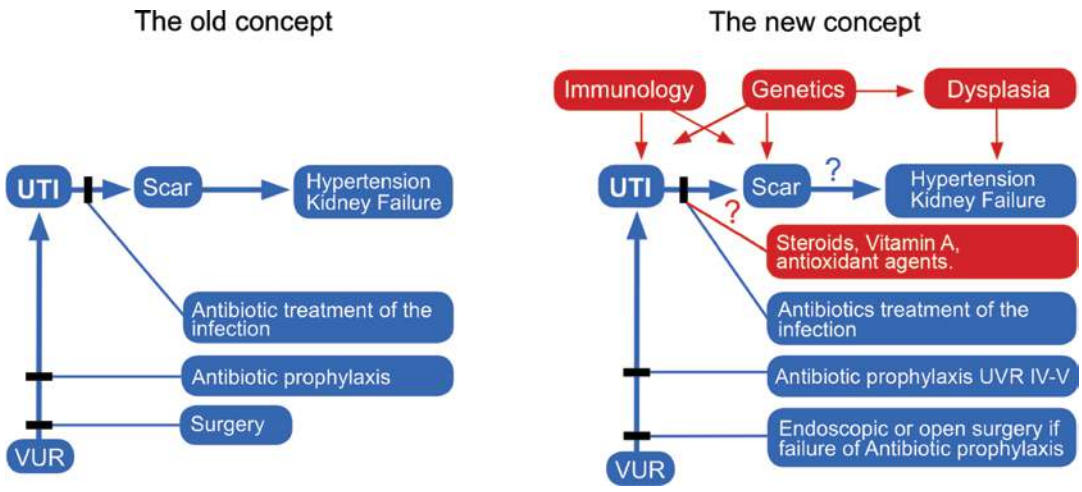

Fig. 43.2 The old concept (**a**). A casual relationship between febrile urinary tract infections and chronic renal failure was believed in the past to be the cause of major scarring. Vesicoureteric reflux was thought to be a major predisposing factor. Prompt antibiotic treatment of the acute infection was suggested to prevent renal scarring. Long term antibiotic prophylaxis and surgical correction of vesicoureteric reflux were employed to prevent recurrent urinary infections. The new concept (**b**). An enhanced understanding of genetic and immunologic mechanisms and prenatal ultrasound have revealed that major kidney damage appears to be congenital in origin. Trials have demonstrated surgery and antibiotic prophylaxis to be of limited if any benefit in preventing kidney damage. New treatments, such as the use of steroids and vitamin A, show promise in reducing the burden of post-infectious scarring

Clinical Presentation

Symptomatology of urinary tract infection varies considerably and is influenced by the child's age, level of infection, virulence of the organism and the inflammatory immune response. In newborns and infants, nonspecific symptoms such as prolonged neonatal jaundice, labile temperature, slow feeding and poor weight gain, irritability or listlessness with the infant unusually floppy are all hallmarks of infection. There is a propensity for infection in the very young to result in septicemia and sepsis, with possible adverse consequences such as seeding of infection at other sites, including meningitis.

Symptoms directly referable to the urinary tract such as frequency and pain on micturition are not usually recognised until around 2 years of age and beyond. Loin pain as a consequence of pyelonephritis, even if present, is not generally commented on by the child until 4–5 years of age. Cystitis can be associated with fever, however when this is 38.5 °C and above the likelihood of renal parenchymal infection is increased.

In older children, recurrent cystitis and, less frequently recurrent febrile UTIs, may be a feature of voiding disturbances, including hyperactivity and dysfunctional bladder emptying. Therefore, in these children, it is important to obtain a precise history of voiding patterns including incontinence, enuresis, frequency of micturition, urgency and bowel habits (see Chap. 47 for further discussion).

Diagnosis of Urinary Tract Infection

The diagnosis of urinary tract infection is contingent upon the culture of a single organism in significant numbers from an appropriately collected urine specimen. Laboratories use a standardized technique taking 0.001–0.002 mL (1–2 μL) of urine in a sterile loop, plating it out and on a culture medium and incubating in air at 35 °C with

the plates checked for the nature and number of colonies (Fig. 43.3). Dipslide cultures (Fig. 43.4) are an alternative to the loop technique, particularly when specimens are collected after hours, thus allowing earlier reporting of culture results. While urinalysis is a useful adjunct in the diagnosis, particularly as culture results may take 24–48 h, it can never be a substitute for urine culture. The cut-off level for significant growth of organisms was first set by Kass 60 years ago at $\geq 10^5$ organisms/mL studying pyelonephritis in pregnant women [7]. It was apparent to Kass at the time that such a cut-off would by necessity miss UTIs. This is no less so in the childhood population. A recent study of infants <1 year with a symptomatic UTI diagnosed by supra-pubic aspirate demonstrated 19% to have colony counts $<10^5$ of whom 87% had counts $<5 \times 10^4$ [8]. In an editorial comment on the paper it was noted that diagnosing a UTI on a strict cut-off level was inappropriate [9]. Most guidelines on investigation and management of UTI in children have avoided a detailed discussion of what constitutes an infection. Recently the Diagnosis of Urinary Tract infection in Young children (DUTY) study aimed at validating a clinical algorithm for the diagnosis of a UTI in children presenting with an acute illness to primary care. Collection was by pads in infants and clean-catch in older children. Agreement on UTI diagnosis was lower than expected between government and research laboratories and clean-catch encouraged as the preferred collection method [10]. A particular problem that creates difficulty with interpretation of urine cultures, resulting in false positive tests, is contamination during collection, which can be influenced by a number of factors. Contamination occurs when organisms from the genitalia, surrounding skin, urethra or periurethral area infect the specimen during collection. *Suprapubic aspiration* of urine and samples obtained by percutaneous nephrostomy are considered to be the "gold" standard for diagnosis of UTI, as they are the least likely to be contaminated, with the culture of any organism generally considered to be significant. Ideally suprapubic aspiration should be performed under ultrasound guidance, even then the invasive nature and lack of skill in the procedure often preclude its use. *Urethral catheterization* is the next most effective method of obtaining a reliable specimen for culture with a growth of 10^3–10^4 colonies per mL considered significant. Once again parents may consider this invasive and distressing for the child, with concerns that infection may be introduced by the procedure. A *voided clean catch midstream urine collection* has been long been considered the most practical method, particularly when children are toilet trained and can void on request. Colony counts of a single organism $\geq$50,000 colonies per mL accompanied by pyuria are considered diagnostically significant [11]. In our experience, mainly using midstream samples, we believe that both urinary leucocytes and a sig-

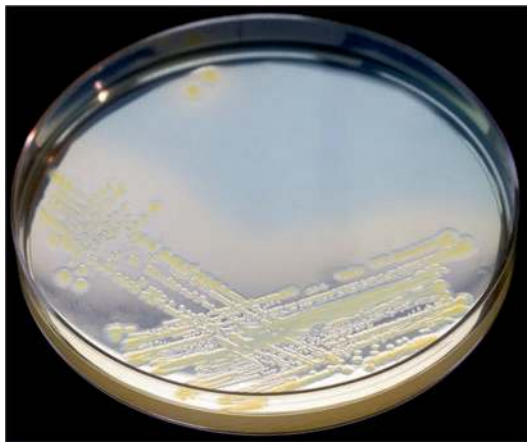

Fig. 43.3 This image shows bacterial colonies growing on an agar plate incubated at 35°C

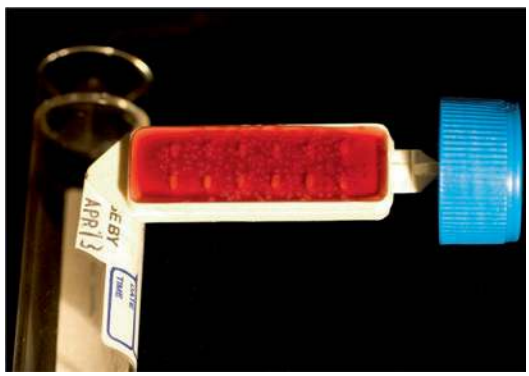

Fig. 43.4 Dipslide culture, which consists of a sterile culture medium on a plastic carrier that is dipped into the urine to be sampled and then incubated at 30°C for 48 h

nificant colony count are needed for the diagnosis of UTI [12]. The presence of pyuria is a useful means to assist in the differentiation between contamination, colonization and clinically significant infection. When sterile pyuria is detected with leukocyte counts >100 × 10^6/L, the urine should be tested for antibacterial activity, if negative, consideration should be given to the culture of fastidious organisms such as *Ureaplasma* and *Gardnerella* species that require specific growth media. When multiple organisms are cultured, there is an increased likelihood of contamination and the culture should be repeated.

Clean catch urine specimens can be obtained on occasion in infants and the very young, with the diaper removed and the parent waiting patiently for voiding to occur, however this is not always successful. One study described a success rate of 86.3% for obtaining a midstream urine specimen within 5 min in infants up to 30 days of age, using a bladder and lumbar stimulation technique [13]. *Bag collections* are practiced in a variety of settings and are of use as a screening procedure when the risk of infection is considered low or the child is afebrile. Controversy exists when bags are employed as the sole method of collection, with many claiming contamination rates are too high [14], such that a single positive specimen should be repeated, preferably with a catheter collection or supra-pubic aspirate. From a practical viewpoint, the use of bag collections is widespread, particularly in the primary care setting, where practitioners often do not have formal training in how to perform a suprapubic or catheter collection [15]. A bag specimen is particularly useful if negative for leukocytes on dipstick, in which case culture is unnecessary. If positive for leukocytes then a clean catch or catheter specimen for culture is appropriate. It has to be emphasized that if bag collection is the only method employed, strict protocols for the procedure are mandatory to reduce the contamination risk (how to wash the genitalia, how to apply the bag, the need to change the bag every 20–30 min). In our experience, when a count >10^5 of the same single organism in two consecutive carefully collected bag specimens is obtained, the likelihood of a genuine infection is extremely high.

Because of the delay in obtaining a urine culture result, the initial diagnosis and treatment is often guided by results of preliminary urinalysis and clinical symptoms. If a UTI is strongly suspected, particularly when accompanied by fever, antibiotic treatment should be initiated, based on the knowledge of local drug sensitivities, prior to availability of culture results. When urine microscopy is available this can be used to determine the number of white cells per mL in an un-spun urine specimen as well as document the presence of bacteria and non-glomerular hematuria that may occur with cystitis. Urine dipsticks provide a rapid, easy and cost-effective way of guiding initial management and treatment (Table 43.1). Leukocyte esterase activity in the urine is a sensitive indicator of pyuria while the nitrite test is based on the ability of most uropathogens to convert nitrite to nitrate. While a positive nitrite test is a good indicator of infection, it can be positive with asymptomatic bacteriuria and thus requires significant pyuria for confirmation [12], in addition, up to 4 h is required for the organisms to generate sufficient nitrite such that infants and those with urine frequency often have a false negative test. When more than one abnormality is found on urinalysis the likelihood of UTI is increased. Difficulties can arise with a single abnormality and subsequent borderline culture result, particularly when antibiotics have already been commenced.

Table 43.1 Interpretation and suggested practical approach following the result of nitrite and leukocyte esterase urine dipstick testing, performed immediately following collection (Adapted from Ammenti et al. [12] with permission)

Nitrite positive Leucocyte esterase positive	UTI very likely	Perform urine culture and start antibiotics empirically
Nitrite negative Leucocyte esterase positive	UTI likely	Perform urine culture and start antibiotics empirically
Nitrite negative Leucocyte esterase negative	UTI quite unlikely	Search for alternative diagnosis

Abbreviation: *UTI* urinary tract infection

There is a need for studies on appropriate urine sampling, interpretation of urine culture results (in particular the appropriate cut-offs for various methods of urine collection in children) and to determine if a negative urine leucocyte test can safely rule out a UTI or whether a culture is required.

Differentiating Upper from Lower Urinary Tract Infections

Differentiating between lower tract cystitis and upper tract pyelonephritis can be difficult in the acute setting. While fever and loin pain can result in a presumptive diagnosis of renal parenchymal infection it is not always the case. Currently there is no marker that can reliably predict the presence of acute pyelonephritis. While C-reactive protein and white cell count are often elevated they are insufficiently sensitive and specific for the diagnosis of renal parenchymal infection. Procalcitonin, a precursor of calcitonin, produced by the thyroid gland, and released in response to bacterial infections, appears to be the most robust blood test, but not a perfect predictor, of pyelonephritis and propensity for subsequent renal scarring [16]. Urinary markers that differ in pyelonephritis compared with cystitis include chemokine ligand CXCL1, CXCL9, CXCL12, INF gamma and IL15, however none has proved better than Procalcitonin [17]. Technetium-99m-labelled DimercaptoSuccinic Acid (DMSA) scans are considered the "gold standard" for confirmation of acute pyelonephritis (Fig. 43.5). DMSA scanning had been recommended as an initial investigation in the past, but did not receive wide uptake as it causes a significant radiation dose, needs to be performed within a week of the infection and is not available in many non-tertiary centers. Fever associated with the UTI has become indicative of likely pyelonephritis for clinical purposes [18, 19].

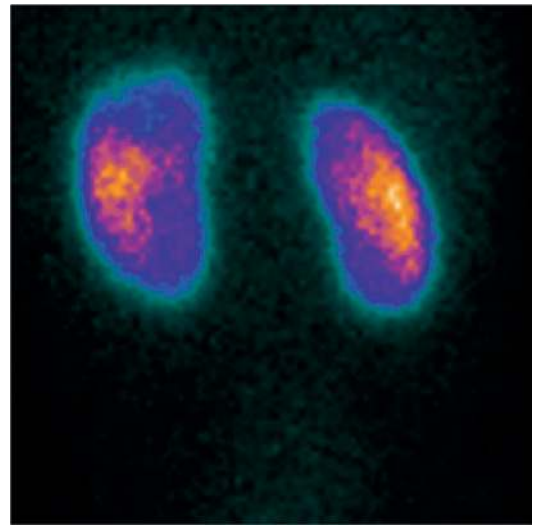

Fig. 43.5 Renal DMSA scintigraphy during the acute phase of a febrile urinary tract infection, showing acute pyelonephritis involving the left kidney

Pathogenesis

The kidneys and urinary tract are germ free environments under normal circumstances, while some infections may be blood born in origin, the majority are considered to be ascending in nature. When bacteria enter the bladder they are frequently washed out without causing infection [20]. Some develop asymptomatic bacteriuria while others develop cystitis with inflammation of the bladder mucosa. A few children will experience febrile UTIs with systemic activation of the immune inflammatory process.

A variety of host factors are thought to contribute to UTI in early childhood in the absence of significant renal tract anatomical abnormalities, these include dysfunctional bladder emptying prior to and after the development of urinary continence [21, 22], detrusor instability [23], constipation and fecal soiling prior to establishing bowel continence. Children with primary immunodeficiency do not appear particularly prone to

UTI, even those with frequent bacterial infections elsewhere, secondary to primary antibody deficiency states [24–26]. Information on UTIs in this group is scarce as the majority of infections are respiratory, gastrointestinal and skin. In the few instances where mention is made of UTIs in primary immunodeficiency diseases, associated renal tract abnormalities appear a feature. Similarly, with acquired immunodeficiency, such as organ transplantation, immunosuppression with steroids and chemotherapy, the issue of UTIs arises only in the context of catheterisation, instrumentation, stents involving the renal tract and not isolated immunosuppression per se. These observations support the contention that urine flow and integrity of the uroepithelium are the important factors in preventing infection. In addition, the intact uroepithelium appears to have an innate immune system with the intercalated cells secreting antimicrobial peptides that demonstrate potent bactericidal activity toward uropathogens [27]. Recent interest has focussed on uromodulin (UMOD), a glycoprotein secreted by the kidney into the urine. Eighty percent of humans have a UMOD promoter variant that results in a doubling of the urinary UMOD concentration, resulting in a reduced predisposition to UTIs [28, 29]. UMOD protein filaments aggregate around uropathogens causing bacterial clumping; it is likely that this inhibits adhesion, allowing clearance of the organisms by micturition [30].

Certain bacterial characteristics predispose to infection. In excess of 80% of infections are caused by *Escherichia coli*. These are the predominant bowel organisms found in close proximity to the urethral orifice. In addition, they have P fimbriae that enable uroepithelial adherence even in the presence of adequate urine flow. When children have neurogenic bladders or renal tract malformations that lead to urine stasis or residual urine after voiding, non-attaching bacteria may cause infection.

When uropathogens infect kidney parenchyma localized inflammation occurs, triggering the innate immune system through a variety of pathways. Recognition of bacteria initiates toll like receptor signalling that in turn causes an immune response involving nuclear factor κβ, cytokines and chemokines. Interleukin 8 (IL-8) is an important chemokine that activates neutrophils via receptors CXCR1 and CXCR2. Children with polymorphisms of IL-8, CXCR1 and CXCR2 have reduced trans-epithelial migration of neutrophils, defective clearance of bacteria and demonstrate a predisposition to recurrent pyelonephritis [31–33].

Full recovery can occur, however if the inflammation is prolonged, scarring can result, though the exact predisposing factors and mechanisms remain ill understood, a number of possible genetic determinants have been identified [34]. Interleukin 6 is one factor that plays a role in the immune response and has been shown to be a marker of children who develop later scarring [35]. Functional variants in genes that encode for vascular endothelial growth factor and transforming growth factor β1 and factors that regulate fibrosis in response to tissue inflammation have also been implicated in renal parenchymal scarring following pyelonephritis in children [36]. Ethnicity has been proposed as an additional risk factor: a meta-analysis demonstrated that post pyelonephritic scarring in children varied by region from 27% in Australia to 49% in Asia [37].

Several pharmacological approaches to limit renal scarring have been explored. Three randomized controlled trials (RCTs) on the use of **steroids** yielded conflicting results. One study of oral methylprednisolone compared with placebo in 84 children with a first episode of pyelonephritis on DMSA scan demonstrated a significant reduction in scarring at 6 months (33% vs. 60% $p < 0.05$) in those given steroid [38]. The second study comparing dexamethasone with placebo in 52 children with pyelonephritis showed no benefit in scarring [39]. The most recent double blind RCT evaluated the efficacy of an oral 3-day course of dexamethasone in reducing kidney scarring in children 2 months to 6 years of age [40]. Unfortunately, only 254 of the 546 children randomized had the primary outcome evaluated with a late DMSA scan. The absolute risk reduction was 5.9% (95% confidence interval: −2.2; 14.1), which did not reach statistical significance.

Vitamin A has been promoted as an agent that might alleviate scarring following acute pyelonephritis. It has also been demonstrated to impact urinary tract morphogenesis, with a deficiency or excess resulting in CAKUT [41]. A meta-analysis including 4 RCTs of 248 children concluded that Vitamin A may be of benefit, however the studies were of low methodologic quality [42]. A recent high-quality double-blind placebo RCT assigned 90 girls (mean age 5, range 2–12 years) with DMSA scan-confirmed acute PN to a 10-day course of oral vitamin A (1500 U/kg/day) or placebo. Symptoms were briefer in the treatment group. A late DMSA scan demonstrated worsening in 8 (21%) on vitamin A vs. 17 (48%) on placebo ($P = 0.003$), while 23 (64%) on vitamin A and 8 (21%) on placebo demonstrated improvement in photopenia ($P < 0.0001$) [43].

In experimental models a variety of agents including montelukast, a leukotriene CysLT1 receptor antagonist that reverses oxidative effects [44], COX-2 inhibitors [45], melatonin [46], an inhibitor of neutrophil infiltration, and losartan, that down regulates TGFβ production [47], have all shown potential as therapeutic agents, though all lack clinical corroboration. More needs to be understood regarding the renal parenchymal inflammatory response and mechanisms of scar formation if effective strategies are to be developed to prevent or reduce scarring.

Bacterial Virulence

Uropathogenic *Escherichia coli* (UPEC) are a subgroup of the *Escherichia coli* that form the normal bowel flora. They express a range of virulence mechanisms that make them well suited to invade the renal tract and kidneys, resist the innate immune responses and initiate a damaging inflammatory cascade. Specific adhesins that form part of fimbriae or pili on the external surface of the organism facilitate attachment to uroepithelial cells [48]. Type 1 pili found on virtually all UPEC predispose to bladder infection, while P pili are associated with acute pyelonephritis [49]. Once they invade the uroepithelial cells, additional virulence factors, termed autoinducers, can coordinate the formation of an intracellular biofilm like cluster of rapidly multiplying organisms, that are protected from the host immune system. The bacteria can go on to infect other cells or remain dormant for a period with the ability to cause recurrent infections [50]. Additional virulence factors transmitted by plasmids promote tolerance to antibiotics [51]. Understanding these host pathogen interactions is of increasing importance at a time where drug resistance is a serious issue. Strategies specifically targeting virulence factors are being investigated as an alternative to antibiotics [52–54] as is the colonization of at-risk patients with non-pathogenic *Escherichia coli* in the hope that they might keep uropathogenic organisms at bay [55].

Organisms Causing Infection

Escherichia coli is the causative organism in 80–90% of UTIs that occur in the outpatient setting [56, 57]. The remaining 10–20% of infections are caused by a variety of organisms including *Klebsiella, Enterococcus, Enterobacter, Proteus* and *Pseudomonas species.* Infection with atypical organisms such as *Pseudomonas* increase the risk that underlying renal pathology exists, such as a neurogenic bladder or significant anatomic abnormalities [58]. In the inpatient setting *E. coli* account for approximately 60% of infections with the higher incidence of atypical organisms a reflection of underlying pathology as well as urinary tract procedures undertaken in this context [59].

Candida UTIs are predominantly a concern for neonatal intensive care units. The infections are associated with prematurity, respiratory distress, congenital heart disease, major renal tract abnormalities and sepsis, while systemic corticosteroids use is a probable additional risk factor. Mortality has been reported as high as 30% and is more likely when systemic spread has occurred, with the co-morbid conditions also playing a role [60].

Granulomatous interstitial tuberculous nephritis is a recognised entity that can occur on rare occasions in children, almost always in devel-

oping countries, and often associated with co-morbid conditions such as human immunodeficiency virus (HIV) [61] or underlying renal disease that predisposes to the infection [62]. It should be considered when sterile pyuria occurs in association with tuberculosis elsewhere in the body [63]. *Schistosomiasis* is a common tropical blood fluke infection, particularly in sub-Saharan Africa. A fresh water snail is the intermediate host, with infection following exposure to the infected water; children have the highest burden of disease [64]. The organism enters through the skin and can infect the ureters and bladder causing hematuria. It is being seen with increasing frequency in high income countries with the arrival of travellers and refugees from endemic areas [65].

Treatment of the Acute Episode

With their advent, antibiotics have become the cornerstone of treatment for UTIs resulting in dramatically improved outcomes. In the early twentieth century infants and young children hospitalized with acute pyelonephritis frequently died as a consequence [66]. Despite the recognized effectiveness of antibiotics in treating UTIs and impeding their parenchymal localization, until the mid-1990s there was a lack of research regarding the appropriate agent, manner of administration and duration of treatment required. Uncomplicated afebrile UTIs were and remain for the most part treated with oral antibiotics that have a high renal excretion and a restricted spectrum of activity. A recent systematic review of antibiotic treatment for uncomplicated lower UTI in children concluded that short course oral therapy (3–7 days) was as effective as long course (7–10 days) treatment with single dose therapy not recommended until further studies are undertaken to determine its effectiveness [67]. In contrast, for febrile UTIs, particularly when occurring in infants and younger children, hospital admission and broad-spectrum intravenous antibiotics became the norm. Between 1995 and 2004 five trials demonstrated that short courses of intravenous antibiotics (up to 4 days) followed by oral therapy, were as effective as longer courses of intravenous treatment (7–14 days) [68–72]. Four studies involving a total of 1344 infants and children as young as 1 month of age with a first febrile UTI went further, demonstrating that oral antibiotics alone were as effective as intravenous antibiotics followed by oral antibiotics, the studies showed no difference in time to resolution of fever or subsequent renal damage [56, 57, 73, 74]. Current guidelines for treatment of a febrile UTI recommend oral antibiotic administration on an outpatient basis, with hospital admission and parenteral administration restricted to those children who appear to be severely ill, vomiting or where poor compliance is a risk (Table 43.2) [75, 76]. The choice of antibiotic should be guided by local resistance patterns and the lead organism, *E. coli*. Where good β lactam and cephalosporin sensitivity has been demonstrated, these are the preferred antibiotics. Of concern, there is an increased prevalence of *E. coli* producing extended spectrum beta-lactamase (ESBL) [77]. Commonly used antibiotics are listed in Table 43.3. Provided an organism is sensitive to the drug chosen, no antibiotic has been shown as superior to another. Hence, we encourage cephalosporins (cefixime or ceftibuten for the oral route and cefotaxime or ceftriaxone for iv administration) in children with severe infections. Cephalosporins are recognized to have a more rapid onset of action, making the possibility of resistance a less important issue. When a febrile infection occurs in children receiving antibiotic prophylaxis, a different antibiotic is required, because of an almost certain resistance to the prophylactic agent.

Table 43.2 Treatment of complicated and uncomplicated febrile urinary tract infections

Uncomplicated febrile UTI ↓ Oral antibiotic on an outpatient basis	Complicated febrile UTI ↓ Parenteral antibiotic—hospital admission
Good general condition	Septic child
Able to drink	Vomiting
Absent to mild dehydration	Moderate to severe dehydration
Good compliance	Possible poor compliance

Table 43.3 Antibiotics commonly used for the treatment of febrile urinary tract infections in children. (Adapted from Montini et al. [6] and Ammenti et al. [12]). Antibiotic choice should be based on local antimicrobial sensitivity patterns

Intravenous treatment	*Dose*	*Comments*
Penicillins		
Ampicillin-Sulbactam	100 mg/kg/day of ampicillin in 3–4 doses	
Amoxicillin-clavulanic acid	100 mg/kg/day of amoxicillin in 3–4 doses	
Cephalosporin		
Cefotaxime	20–40 mg/kg four times per day	Increasing resistance
Ceftazidime	30–50 mg/kg three times per day	Good coverage for Pseudomonas
Ceftriaxone	50 mg/kg once per day	Advantage of once daily dosing Contraindicated in neonates, especially prematures
Aminoglycoside		Useful if beta-lactam allergy. Nephrotoxic. Must monitor with serum levels and adjust dosage accordingly. A recent meta-analysis supports single daily dosage[a]
Gentamycin	6–7.5 mg/kg once per day or 2–2.5 mg/kg three times per day	
Amikacin	15 mg/kg once per day or 7.5 mg/kg twice per day	
Oral treatment	*Dose*	*Comments*
Trimethoprim-sulfamethoxazole	4 mg/kg twice per day (dose expressed as trimethoprim)	High resistance rates Risk of allergic reaction
Amoxicillin-clavulanic acid	25–50 mg/kg twice per day (dose expressed as amoxicillin)	Increasing resistance
Cephalosporin		Increasing resistance
Ceftibuten	9 mg/kg twice per day the first day, once daily thereafter	
Cefixime	8 mg/kg twice per day the first day, once daily thereafter	
Quinolone		Treatment of complicated UTIs as a second choice. Increasing resistance Increased risk of musculoskeletal adverse events
Ciprofloxacin	10–20 mg/kg twice per day (maximum 750 mg per dose)	

[a]Contopoulos-Ioannidis DG, Giotis ND, Baliatsa DV, Ioannidis JP. Extended interval aminoglycoside administration for children: a meta-analysis. Pediatrics 2004;114(1):e111–e118

Infants in the first month of life who present unwell with unstable temperature, lethargy, poor feeding or prolonged jaundice, and are thought to be septic, are a particular group that warrants intravenous antibiotics after appropriate cultures, including blood and urine, are taken. Sepsis in the first 72 h is most commonly group B streptococcus, although *E. coli* infections can occur in this period and become more common thereafter. There is a lack of controlled trials in this age group, as neonatal sepsis is recognized as a serious illness, particularly when it occurs in low birth weight preterm infants. Contributing factors to the potential severity of bacterial infection in infants include an immature immune system, and in the case of preterm infants, reduced placental transfer of protective maternal antibodies. Thus, intravenous penicillins combined with aminoglycosides are commonly used on an empiric basis. Care should be taken to monitor aminoglycoside levels because of their potential nephrotoxicity, particularly in infants with impaired renal function secondary to renal dysplasia.

Imaging After a Febrile Urinary Tract Infection

There is a lack of consensus as to the recommendations for imaging after a fUTI, although recent improved understanding of UTIs and their sequelae has resulted in a lessening of the nature and number of procedures indicated (Table 43.4). Published protocols give guidance on the investi-

Table 43.4 Imaging tests routinely recommended by the most recent published guidelines in children following a first febrile urinary tract infection

Guideline	Ultrasound	VCUG	DMSA	Prophylaxis
NICE (2007, updated 2017)	Atypical, <6/12 age	No unless <6 months of age with positive US or atypical UTI	Yes >6/12 post UTI	No
AAP (2011)	Yes	No unless abnormal US	No	No
ISPN (2020)	Yes	No unless abnormal US or bacteria other than UPEC	Consider if major abnormalities at US	Considered for VUR IV–V
CARI (2014)	Yes, if: no second or third trimester US, <3/12 age or atypical UTI	No unless abnormal US	No	No
Canadian (2014)	Yes	No unless abnormal US	No	No

gation of febrile UTIs in infants and younger children; however, there is little advice regarding afebrile UTIs or infections occurring in older children.

Ultrasonography

Ultrasonography is a non-invasive procedure that can detect a variety of anatomical abnormalities, but is dependent on the expertise of the radiologist. In recent years antenatal ultrasound has proved of value in detecting most of the significant CAKUT prior to birth, including renal hypodysplasia, pelviureteric junction obstruction, vesicoureteric obstruction often as a result of ureteroceles and posterior urethral valves [78]. In three prospective trials involving 864 children investigated after a first febrile UTI, ultrasonography did not reliably detect changes associated with reflux or predict subsequent scarring. Minor abnormalities were found in 12–14% of cases that had little influence on subsequent outcomes [79–81].

The American Academy of Pediatrics (AAP) recommends ultrasonography in all children under 2 years of age after an initial febrile UTI [11], as does the Italian Society of Pediatric Nephrology (ISPN) [75]. The recently published Italian guideline identifies specific ultrasound abnormalities which represent an indication to perform VCUG: mono- or bilateral renal hypoplasia, abnormal parenchymal echogenicity, ureteral dilatation, kidney pelvis epithelial thickening, pelvi-calyceal dilatation, and bladder abnormalities [12].

The National Institute for Health and Care Excellence (NICE) guidelines restrict ultrasonography further to those <6 months of age, unless the infection is atypical or additional risk factors are present [76]. The Australian guidelines even restrict ultrasound to <3 months of life or to children with an atypical UTI or absent antenatal ultrasound [82]. Given the low detection rate of clinically significant findings following an uncomplicated UTI in childhood, we enquire as to whether a reliable second or third trimester antenatal ultrasound is available to be reviewed and limit ultrasound to those where this is not the case (Fig. 43.6). If the infection appears atypical, there is evidence of renal function impairment, inadequate urine stream or repeated infection, we believe ultrasonography to be indicated [83, 84]. For older children ultrasonography is indicated for repeated febrile and nonfebrile UTIs after a precise history of voiding patterns has been taken, particularly in girls.

The ultrasound examination should assess bladder filling and emptying, post-micturition residual urine and bladder wall thickness when full and empty. Normal values are usually less than 3 mm when the bladder is full and less than 5 mm when empty. In case of significant abnormal findings on bladder ultrasound, urodynamic studies should be considered.

Voiding Cystourethrography

Voiding cystourethrography generally requires the bladder instillation of a radiopaque, radioactive or echogenic contrast medium via urethral

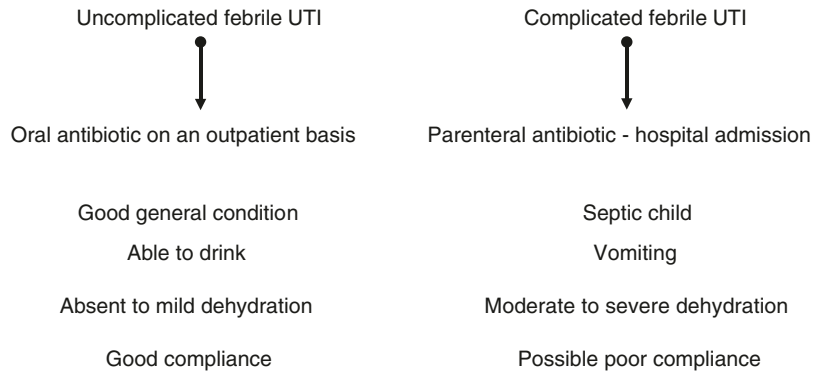

Fig. 43.6 Treatment of complicated and uncomplicated febrile urinary tract infections

catheterization, followed by serial imaging. It can demonstrate VUR during the filling and voiding phases, as well as demonstrate urethral obstruction due to posterior urethral valves in boys. Much controversy has centred on the need or otherwise for this study, given the distress this invasive procedure can cause children. Those advocating cystourethrography cite a strong association between the severity of reflux and presence of renal damage [83], which is being increasingly recognized as congenital rather than acquired in origin [85, 86]. As there is a lack of evidence that intervention is beneficial for all but those few children with high grade dilating reflux, in terms of medical or surgical procedures [87], published protocols support a selective approach to this investigation. In children following a febrile UTI in the first 2–3 years of life, they recommend this study if the ultrasound is positive or the UTI atypical (Table 43.4). We believe that this investigation is rarely indicated following a first febrile UTI and should be restricted to those few children with significant bladder abnormalities, ureteric dilatation on ultrasound or inadequate urine stream (Fig. 43.6). For older children with febrile UTIs and those with recurrent cystitis, we believe voiding cystourethrography is rarely indicated, as a precise history of voiding patterns and an ultrasound are usually sufficient to establish the diagnosis and treatment (see Chap. … for further discussion).

Renal Scintigraphy

Renal imaging with DMSA requires the intravenous administration of a radio-active isotope which localizes to the renal parenchyma, the procedure is highly sensitive, with decreased uptake that may represent inflammation as seen in acute pyelonephritis (Fig. 43.5) or may represent scarring (Fig. 43.8a). The main concern is the radiation dose of approximately 1 mSv. The procedure has been used to confirm pyelonephritis when performed in close proximity to a febrile UTI, or from 6 to12 months after to determine if scarring has resulted. The delay is important for the determination of scarring, as uptake defects can persist for some months following the acute infection, without necessarily indicating scarring. The technique may also detect congenital renal hypodysplasia (Fig. 43.8b), which can sometimes be difficult to differentiate from acquired scarring, however the former usually appears as a small kidney with uniform uptake of isotope while the latter is more likely to present as a loss of smooth contour with a focal uptake defect (Fig. 43.8a, b).

The AAP guidelines do not recommend an acute or late DMSA scan following a febrile UTI [11], while a late DMSA scan is recommended by NICE when the infection is atypical [76] and by the ISPN where ultrasound shows abnormalities or there is evidence of VUR [75]. In both cases the purpose is to detect any scarring. An

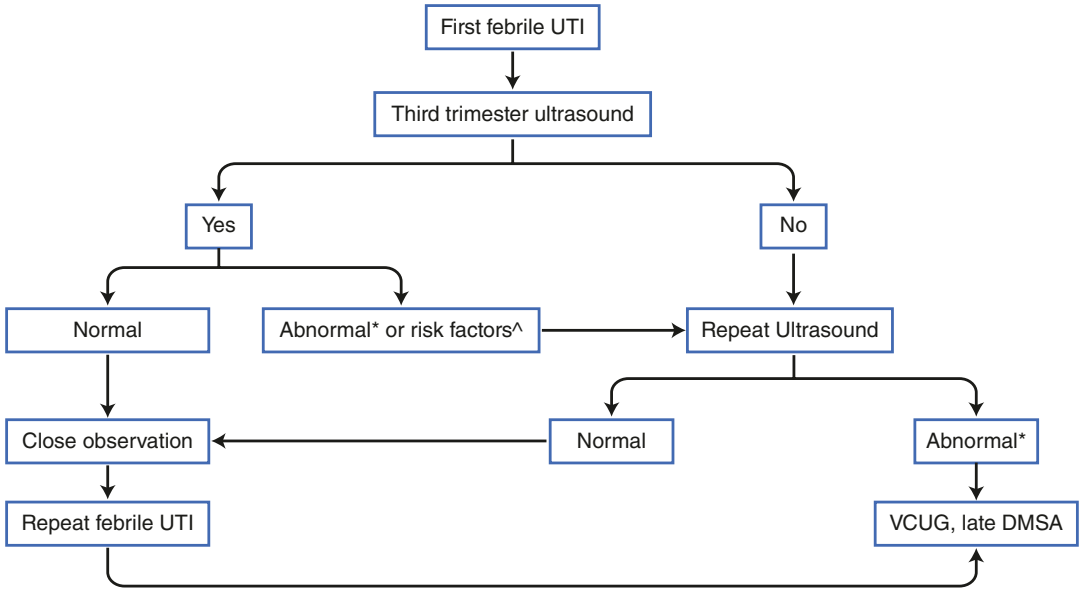

Fig. 43.7 Diagnostic flow chart of the suggested diagnostic protocol in a child 2 months to 3 years of age, following a first febrile urinary tract infection

alternative that was never widely accepted was the "top down" approach whereby a DMSA scan is performed in the acute phase of the illness, followed by cystourethrography if the scan is positive. Two studies claimed a strong correlation between high grade dilating VUR and abnormal scans. In contrast, a later study demonstrated 14/46 children with grade III–IV reflux to have a normal DMSA scan during the acute infection [88]. Some investigators have recommended a DMSA scan 6–12 months following an infection as the most appropriate investigation, as this would detect those children with permanent renal scarring that requires follow-up [81, 89]. When UTIs are afebrile, DMSA scans are not indicated.

Technetium-99m-labelled diethylenetriaminepentaacetic acid (DTPA) and technetium-99m-mercaptoacetyltriglycine (MAG 3) are radionuclides that as well as being taken up by the kidney have an early excretory phase. As such that they are useful for assessing the presence and severity of any obstruction, and are indicated when other imaging raises this possibility. They are not used primarily for the detection of pyelonephritis or scarring.

Other Imaging Modalities

Plain abdominal X-ray may detect radio-opaque renal calculi, however most calculi can now be detected on ultrasound**. Intravenous pyelography** has for the most part been superseded by ultrasound and radionuclide scintigraphy. **Magnetic resonance urography** is a newer modality that gives excellent anatomical detail as well functional imaging without an attendant radiation dose. It appears to have some ability to indirectly assess obstruction, by measuring cortical transit times, when used in conjunction with contrast material. While at the present time it cannot be recommended as a first line procedure, in future as the technology becomes more available and cost effective, it may supplant a range of current imaging procedures (Fig. 43.8) [90]. A major limitation in younger children is the need for sedation or general anesthesia.

Impact of Reduced Imaging

Some concern has been expressed that the trend toward reduced imaging may be accompanied by adverse risks, with voiding cystourethrography being the most contentious procedure. Several studies have addressed this issue.

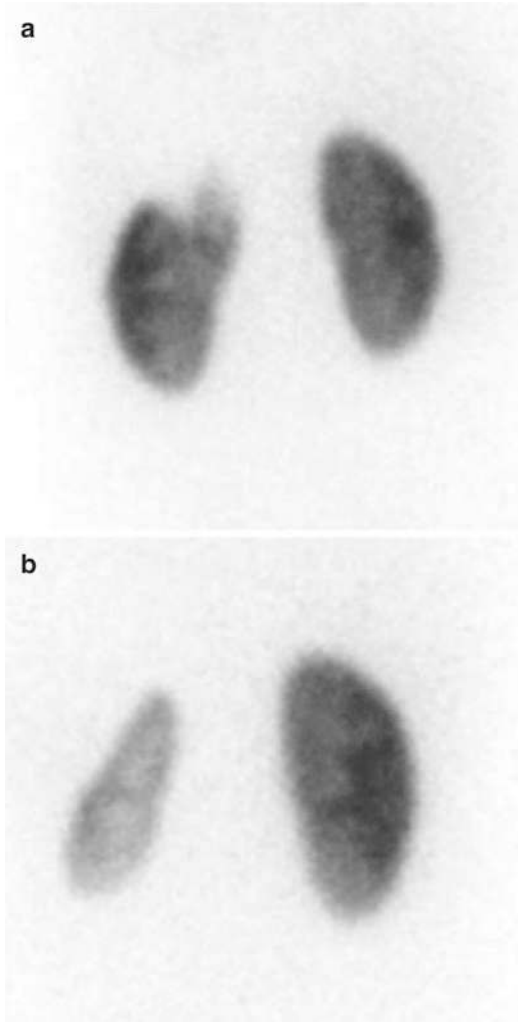

Fig. 43.8 Renal DMSA scintigraphy demonstrating a left upper pole scar (panel a) and a left hypodysplastic kidney (panel b)

Following publication of the NICE guidelines, two studies assessed their impact [91, 92]. Schroeder et al. compared the more selective imaging algorithm (NICE) with the formerly employed comprehensive algorithm (AAP 1999) [76, 91, 93]. The change led to a reduction in cystourethrograms performed following a febrile UTI from 99% to 13% and ultrasounds from 99% to 67%. The recurrence rate of UTI and detection rate of grade 4 and 5 VUR did not change, and the use of prophylactic antibiotics diminished. Deader et al. performed a retrospective analysis of 346 children who had an ultrasound performed at their institution following a UTI, to determine if significant renal pathology would have been overlooked had the procedure been restricted to those <6 months of age in accordance with NICE. Three scars confirmed on DMSA and one ureterocele would have been missed, such that the more restrictive guidelines regarding ultrasound appeared safe and provided significant cost savings [92]. Similarly, Jerardi et al. instituted a rapid uptake of the revised AAP guidelines [11] that significantly reduced the number of investigations performed, without any significant difference in the rate of abnormalities detected pre and post-intervention [94]. La Scola et al. evaluated the yield, cost and radiation dose of five different investigative guidelines if they had been applied to 304 children 2–36 months of age with a first febrile UTI that had been comprehensively evaluated in a RCT [95]. Scarring would have been detected by those that recommend a late DMSA scan in all cases [18], while guidelines that recommend a late DMSA in selected circumstances missed approximately half of the scars [75, 76] and all scars were missed in those guidelines that do not recommend a DMSA scan [11, 96]. Four of the five protocols failed to reliably detect high grade VUR, and proved even less effective when all grades of reflux were considered [11, 75, 76, 96]. Conversely the protocol that would detect all scarring had the highest cost and radiation burden [18], while the more selective protocols including the AAP guidelines, are the least costly with the lowest radiation dose.

Antibiotic Prophylaxis

Recent prospective studies have demonstrated antibiotic prophylaxis to be of little or no benefit in preventing recurrent infections, or reducing the risk of scarring in the majority of children following an uncomplicated first febrile UTI. Antibiotic prophylaxis has been widely recommended in the past following pyelonephritis, particularly where VUR was present, on the assumption that it would reduce the recurrence rate of infections and prevent renal scarring [93]. Eight randomised prospective studies involving 2390 children and

adolescents evaluating the effectiveness of prophylaxis have been published between 2006 and 2015 [97–104]. While a direct comparison between the studies is not possible, due to their disparate populations, duration of follow-up and investigations undertaken, it is reasonable to draw a number of conclusions. All studies had recurrent UTI as a primary end-point. Four studies in patients with absent or predominantly low grade reflux showed rates of recurrence to be similar in the prophylactic compared with no treatment groups [97–100], two of these studies demonstrating a trend toward increased infections in the children with grade III reflux who were not on prophylaxis [99, 100]. One smaller study demonstrated an increase in UTIs on prophylaxis compared with controls [104]. A further study, the Swedish Reflux Trial, restricted to 203 infants with higher grade (III–IV) dilating reflux, demonstrated a clinically significant reduction in febrile UTIs on prophylaxis compared with controls (19% vs. 57%, $p < 0.001$) over a 2 year period in girls, but not boys [102]. The two largest and only studies to be placebo controlled, the PRIVENT and RIVUR trials involving 1183 children showed prophylaxis to result in a statistically significant though clinically insignificant reduction in UTIs, with 14–16 patient years of prophylaxis needed to prevent one symptomatic infection and 22 patient years of treatment to prevent one febrile infection [101, 103]. In both studies the maximum benefit of prophylaxis occurred in the initial 6 months. A systematic review of antibiotic prophylaxis for prevention of recurrent UTI in children demonstrated a small benefit of low dose antibiotic prophylaxis in preventing recurrent UTI, at the expense of increasing bacterial resistance to the treatment drug with subsequent infections. The analysis did not address the severity of VUR as a risk factor neither did it evaluate scarring as an adverse outcome [105].

Seven studies looked at late renal scarring on DMSA scan as a secondary endpoint. Only one paper, restricted to infants with high grade reflux, demonstrated a benefit of prophylaxis in preventing scarring, once again only in girls [87]. This benefit was not confirmed in the larger RIVUR trial, comparing antibiotic prophylaxis to placebo, which recruited 607 children (92% female) following a UTI, 46% of whom had grade III–IV dilating reflux [103]. No study was sufficiently powered to detect a possible benefit of prophylaxis in prevention of renal scarring. To address this, a systematic review and meta-analysis of 1427 subjects from 7 RCTs was undertaken and demonstrated no prevention of renal scarring by antibiotic prophylaxis, as did a sub-analysis restricted to the 1004 subjects with VUR [106].

These findings suggest that antibiotic prophylaxis is of minimal if any benefit in infants and children with absent or grades I–III reflux with a low recurrence rate for infection [101]. In a single study prophylaxis appeared to be of benefit in reducing recurrent pyelonephritis and scarring in the female infants and young children with high grade (III–IV) dilating reflux [102], although the finding in relation to scarring was not confirmed in the RIVUR trial with larger numbers of randomised girls who had the same degree of reflux [103]. In the few children with recurrent febrile UTIs who might benefit from prophylaxis, there is no consensus at what age or for what duration it should be prescribed.

Based on current evidence, we believe that antibiotic prophylaxis should be prescribed for 2 years in young girls and for 1 year in young boys with high grade reflux. Nitrofurantoin appears the most effective agent; however, the side effect profile and risk of poor compliance appear to outweigh any benefit of the medication, such that cotrimoxazole, amoxiclavulanate and the cephalosporins are generally preferred.

Antibiotic Prophylaxis in Children with Major Urologic Malformation, Spina Bifida, Neurogenic Bladder and Intermittent Catheterisation

Urinary tract infections are common in children with major urologic malformations that pertain particularly to the bladder. Children with ongoing bladder dysfunction for a variety of reasons including surgical resolution of posterior urethral valves, those with neurogenic bladders as a consequence of spina bifida or spinal cord injury, and children with bladder exstrophy, many of whom have undergone multiple surgical procedures and

are on clean intermittent catheterisation, are at risk of long-term bladder colonisation and recurrent UTIs. The role of antibiotics and prophylaxis remains unclear in these patients. In the only RCT of antibiotic prophylaxis in children on clean intermittent catheterization, those that continued prophylaxis had a significantly higher incidence of UTIs when compared with those that ceased treatment [107]. Furthermore, a meta-analysis of adolescents and adults with spinal cord dysfunction did not support the use of prophylactic antibiotics [108]. Despite these findings, there is a lack of uniformity in management of children with neurogenic bladder dysfunction, with a remarkable variation in the prescription of prophylactic and therapeutic antibiotics in this population.

Given the difficulty of eradicating organisms from the bladder of patients on long-term intermittent catheterization, an alternative approach with some promise is to colonize the bladder with an avirulent strain of *E. coli* using infected catheters [55]. A further study of children with neurogenic bladder showed they most commonly carried avirulent commensal clones [109]. Uropathogenic clones, when present, were associated with prolonged carriage, however this was not associated with symptomatic disease or deterioration of the upper urinary tract. Thus, urine culture and antibiotic treatment of any infection detected in these children should on current evidence be restricted to those with definite symptoms.

Infants and young children with chronic kidney disease due to dysplasia are at particular risk of early deterioration to the point of requiring kidney replacement therapy, with some evidence that the rate of deterioration is accelerated in those with recurrent febrile UTIs [110]. A large multicentre RCT, the PREDICT trial, is currently underway evaluating the usefulness of antibiotic prophylaxis in this at risk population.

Surgical Correction of VUR

Surgical correction of VUR can be achieved by either re-implanting a tunnelled ureter through the bladder wall or endoscopic injection of a bulking agent adjacent to the vesicoureteral orifice. The reported success rate for re-implantation is 98% (95% CI 95–99) and 83% for a single attempt at endoscopic treatment, with uncertainty regarding the permanency of the endoscopic approach [111]. Surgical correction is no longer routinely recommended, but may be considered when breakthrough febrile UTIs occur on prophylaxis, particularly in association with high grade dilating reflux in females.

A recent study, the Swedish infant high-grade reflux trial, randomized 77 infants <8 months of age with VUR grade IV–V to antibiotic prophylaxis or endoscopic correction of VUR with prophylaxis until VUR resolution was confirmed. The study showed no benefit of surgical intervention over prophylaxis in the risk of UTI recurrence or renal function deterioration. The study did not include a no-treatment control group to assess whether the interventions were of benefit. Of interest, over the 1-year follow-up 21% of the infants on antibiotic prophylaxis had a reduction in VUR severity to grades 0–II [112].

Additional Therapies

Circumcision

There are no RCTs on routine neonatal circumcision for the prevention of UTIs in males [113]. Two systematic reviews including predominantly cohort studies, reached opposite conclusions. One review concluded that routine circumcision to prevent UTI was not indicated in normal boys with the number needed to treat to prevent one UTI calculated at 111, however it could be considered in those with recurrent UTIs or high grade reflux, where the benefits appear to outweigh risks of the procedure [114]. A second review concluded that circumcision was indicated in all boys, as it reduced the lifetime risk of UTI, with a little over four low risk operative procedures to prevent one infection [115].

Cranberry Juice

Some studies suggest that cranberry juice may be of benefit in reducing recurrent UTIs, presumably by inhibiting bacterial adhesion to uroepithelial cells. A Cochrane review of 24 randomized

controlled or quasi randomized controlled trials failed to demonstrate any significant benefit of cranberry juice, concentrate or capsules/tablets in the management of recurrent UTI in a variety of circumstances, including children and those with neuropathic bladder or spinal injury [116].

Probiotics

Studies have been undertaken to assess the possible benefit of probiotics in reducing or preventing recurrent UTIs. Most studies have been undertaken in women with variable results [117]. The studies are difficult to assess, as they use different strains of organisms, predominantly lactobacilli that have a variable effect on intestinal flora. One retrospective study demonstrated a possible benefit of probiotic prophylaxis similar to antibiotic prophylaxis in prevention of UTIs over a 6 month period, however the paper had significant methodologic shortcomings such that further studies are needed before any recommendations can be made on probiotic use [118]. Given the low quality of studies, a systematic review failed to show a role of probiotics in reducing recurrent UTIs, however a benefit cannot be ruled out prior to larger scale prospective RCTs [119].

The treatment of **constipation** and soiling in at risk children, as well as strategies to manage **dysfunctional voiding**, are considered by many to be worthwhile in the prevention of recurrent UTI. Unfortunately, there are no RCTs that assess the efficacy of any particular intervention.

Long-Term Clinical Consequences

Uncomplicated UTIs are common in children. When associated with fever there is an increased probability of renal parenchymal involvement, which can result in permanent renal scarring. In the absence of scarring there is no documentation of any adverse long-term outcomes. The frequency and severity of scarring as a consequence of acute pyelonephritis, the age at which it occurs and the long-term sequelae have been points of conjecture, as has the risk of consequent chronic kidney disease (CKD), hypertension and pre-eclampsia. The introduction of routine antenatal ultrasound over the past 20–30 years, has demonstrated that much of the renal parenchymal damage previously attributed to pyelonephritis, is the result of congenital mal-development of the kidneys, often associated with significant urinary tract abnormalities such as high grade VUR or obstruction (Fig. 43.2b).

This recognition has led to a critical re-evaluation of the potential for pyelonephritis to cause scarring and result in adverse outcomes. A systematic review of renal scarring reported a prevalence of 15% following a UTI [120]. The risk and severity of scarring as a consequence of a single episode of pyelonephritis appears unrelated to age, when infants and young children are compared with older children [121]. In a meta-analysis involving 1280 children and adolescents following a UTI from 9 studies, a scar developed in 191, those with an abnormal ultrasound, fever >39 °C or an organism other than *E. coli* were at higher risk of kidney damage [122]. A review looking at long term consequences of UTI in children noted that despite numerous publications there are no clear data as to the outcomes [123]. They noted that earlier publications, often retrospective and from selected populations, had a tendency to record frequent adverse outcomes. More recent studies, particularly those that are population based, and with the benefit of prenatal ultrasound to exclude congenital kidney disease, reported a much lower incidence of harmful sequelae. In regard to kidney function they reported that only 0.4% of the 1029 children in prospective studies with normal function at the outset reported a decrease on follow-up. Conversely, virtually all the children with decreased kidney function at the conclusion of studies had scarring or kidney dysplasia at the beginning. There was a low risk of hypertension. In five studies involving 713 children where blood pressure was measured at the beginning and completion of follow-up (which ranged from 5 to 20 years), the incidence of hypertension increased from 2.4% to 4.6% [124–128]. In the studies reporting a high incidence of hypertension, up to 35%, scarring and kidney damage was almost always present on enrolment. In contrast, one study that followed two groups of children after a first UTI for 16–26 years found no significant differences in ambulatory blood pres-

sure monitoring between the 53 individuals with scars when compared with 51 controls without scars [129]. A further paper addressing the obstetric outcome of 72 parous women followed from their first UTI in childhood to a median age of 41 years noted that pregnancy complications were few. Irrespective of the presence or absence of kidney damage, none were diagnosed with hypertension prior to their first pregnancy. Hypertension was diagnosed in 10 of 151 pregnancies, all in women with renal damage of whom 4 experienced preeclampsia [130]. A well conducted population based controlled study evaluated pregnancy-related complications in 260 women who experienced childhood UTIs compared to a control group of 500 mothers without a childhood UTI [131]. There was no difference in essential or gestational hypertension, pre-eclampsia or pyelonephritis during their first pregnancy between the UTI group (40%) and the controls (41%). Thus, the data appears to exclude a major influence of childhood UTIs on subsequent growth and pregnancy related complications.

Summary

Children with normal kidneys at birth and no obstruction to drainage would appear to be the ones at minimal risk of developing chronic kidney insufficiency or other adverse outcomes following an uncomplicated febrile UTI. The infection can be treated with oral antibiotics and the child monitored to ensure recurrent episodes do not occur. Children with significant congenital abnormalities of the kidneys and urinary tract, appear at risk of progressive kidney impairment. Whether dysplastic kidneys are more prone to severe damage as a consequence of pyelonephritis remains to be determined. Further research is underway that will clarify a number of unresolved issues: the need for antibiotic prophylaxis in children with high grade reflux with and without kidney hypodysplasia, the use of new biomarkers to diagnose UTI and to differentiate upper from lower tract infections, the optimal duration of antibiotic treatment during the acute phase, and the appropriate cut-offs for culture results in children. Long term follow-up of children who have been prospectively studied following a first febrile UTI with normal kidneys, as well as those with prenatally diagnosed hypodysplasia, will be important to determine the late risks such as hypertension, pre-eclampsia, and chronic kidney insufficiency.

Vesicoureteral Reflux

44

Ranjiv Mathews, Tiffany L. Damm, and Sverker Hansson

Introduction

Vesicoureteral reflux (VUR) is the retrograde flow of urine from the bladder to the kidneys. VUR may be classified as primary, which is a congenital defect in the vesicoureteral junction anatomy, or secondary, which is the result of persistent high intravesical pressures that overwhelm the vesicoureteral junction. VUR has been implicated in renal injury prior to birth as well as postnatal development of urinary tract infections (UTIs) and further renal damage. Primary VUR is most commonly identified in infants and children, and historically has been most prevalent in infants 0–24 months of age. Although much is known about the diagnosis, medical, and surgical management of VUR, many questions remain regarding the potential of VUR to cause infections and renal injury.

Embryology

Anatomic Factors

Ureteral development has been studied to understand the anatomic factors that may lead to primary VUR. The development of periureteral sheaths, intravesical ureteral muscles and trigonal muscles have been studied for potential contribution in VUR [1]. Based on observations in 11–27 week fetuses, it has been determined that the superficial trigone is derived from the intravesical ureteral muscles and the deep trigone is derived from the deep periureteral sheath of the ureter. Fixation of the ureters in the appropriate location is important for the development of a normal trigone and non-refluxing ureters. The intravesical submucosal length of the ureter and the oblique path of entry of the ureter into the bladder have been identified as critical factors in the prevention of VUR (Fig. 44.1).

Development of renal scarring in children appears to be independent of the presence or absence of VUR. Anatomic factors in the ureterovesical junction, however, may play a role in the degree of renal injury produced by VUR in that higher grade VUR that occurs with lower bladder pressure is associated with increased risk of nephropathy [2].

Other anatomic anomalies outside the ureterovesical junction anti-reflux mechanism, such as periureteral diverticula or duplications of the

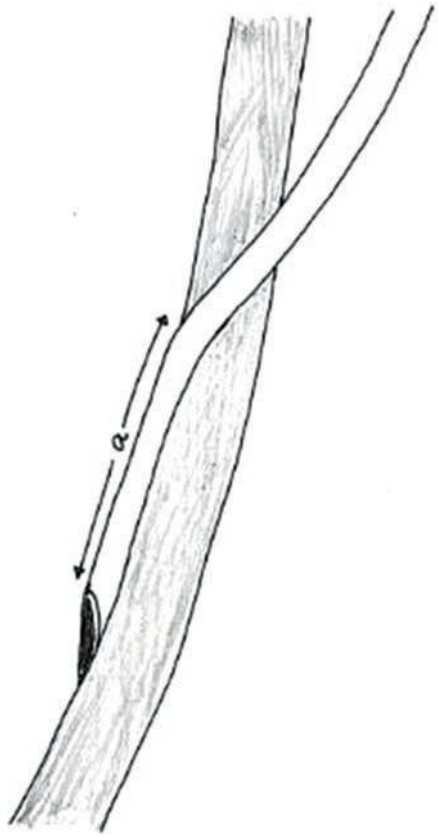

Fig. 44.1 Ureterovesical junction anatomy contributes to the anti-reflux mechanism of the compression valve, which includes the length of the tunneled ureter, angle of the ureteral insertion, and fixation of inlet and outlet points

collecting system, can contribute to persistence of VUR, increasing the risk of renal damage and the requirement for surgical correction.

Extra-anatomic Factors

Embryological development of the ureteral bud from the mesonephric duct is dependent on multiple factors. Signaling by glial cell line derived neurotrophic factor (GDNF)has been shown in the mouse model to induce the formation of ureteral buds [3]. Misexpression of GDNF has been shown to be associated with the development of multiple ureteral buds. Additionally, GDNF is focally expressed in the appropriate location of ureteral bud development. If GDNF is expressed in an ectopic location, the ureteral bud will develop in this ectopic location, leading to lateral or medial localization of the ureter in the bladder predisposing to VUR or obstruction. Additionally, trigonal development is dependent on apoptosis induced by a vitamin A signaling pathway [4]. Normal development of the trigone is also necessary to provide appropriate support to the distal ureter. Studies have shown that symmetric muscle contractions and unidirectional peristalsis also play a significant role in the competence of the ureterovesical junction [5].

Associated Conditions

Many anatomic and genetic conditions are associated with the presence of VUR in children. The most commonly noted anatomic conditions are multicystic dysplastic kidney (MCDK), renal agenesis and renal or ureteral ectopia and duplication. VUR is also a common occurrence with many syndromic conditions.

Multicystic Dysplastic Kidney (MCDK)

Contralateral VUR is the most common abnormality present in children with MCDK [6]. VUR has been noted in 12–28% of contralateral kidneys in children with MCDK [7]. The impact of this contralateral VUR continues to be debated. One study has indicated that contralateral renal growth is compromised in the presence of VUR [8]; however, other studies have revealed that VUR into the contralateral renal unit is usually low grade and does not lead to renal compromise [9]. Study of the natural history of VUR in the presence of MCDK indicates that in most boys and 40% of girls there will be eventual spontaneous resolution.

Renal Agenesis

As with MCDK, VUR is the most common abnormality noted in the contralateral kidney in children with unilateral renal agenesis.

Management of VUR in the context of a solitary kidney is not different from that in patients with two kidneys [10].

Ectopia and Duplication

Dilating VUR occurs in up to 26% of children with renal ectopia and hydronephrosis [11]. VUR is the most commonly associated anomaly noted in children with renal ectopia. The presence of renal ectopia does not seem to reduce the potential for VUR to resolve spontaneously [12].

Ureteral duplication is also associated with the presence of VUR, typically into the lower pole of the duplex system. The ureteral orifice is displaced proximally and laterally in children with duplex systems and plays a role in the development of VUR into the lower pole moiety. Following endoscopic management of ureteroceles associated with duplex systems, VUR into the lower poles unilaterally or bilaterally may be unmasked, and may even occur into the upper pole as an iatrogenic entity. Many patients with duplex systems will eventually require surgical management for their VUR [13]. Typically, surgery in these patients is indicated for the associated conditions that are present (i.e. ureteroceles, ectopic ureters, etc.).

Ureteral ectopia may also be noted into the bladder neck and urethra, leading to VUR during voiding. Bilateral or single system ureteral ectopia is associated with reduction in bladder growth and capacity and requires surgical management with ureteral reimplantation and possible later bladder neck reconstruction to provide continence [14]. Prognosis in this condition is based on development of adequate bladder capacity.

Syndromes

Syndromes that have been associated with the presence of VUR include the VATER-VACTERL syndrome, Townes-Brock syndrome (*SALLI* mutation), cat-eye Syndrome (tetrasomy, chromosome 22), Casamassima-Morton-Nance syndrome, renal coloboma syndrome (*PAX*2 mutation), branchio-oto-renal syndrome (*EYE1* mutation) and Frasier syndrome (*WT1* mutation).

Incidence

Although it is difficult to quantify a disease process that has the ability to be transient, several studies have sought to estimate the prevalence of VUR among children. In a meta-analysis, the incidence of VUR was classified based on initial presentation. The prevalence of VUR in children undergoing cystography for UTI was 30%, as compared to 17% in children who underwent radiographic imaging for other reasons such as hydronephrosis [15].

Guidelines from the American Academy of Pediatrics (AAP) and the National Institute for Health and Care Excellence (NICE) appear to have had an impact on the evaluation of children with UTI. A reduction in the utilization of voiding cystourethrogram (VCU) has led to decreases in the rates of VUR identified. This was reflected in a study that demonstrated a decline in the incidence of VUR in children 0–2 years of age from 38/100,000, to 25/100,000, following publication of the 2011 AAP guidelines. Additionally, reduction in the performance of VCUs was also noted in children 3–10 years of age [16], suggesting a reluctance to screen older children as well.

Age

VUR is more commonly identified in younger children. In a retrospective review of 15,504 children, the incidence of VUR was 35.3% in children less than 2 years of age, 22.7% in those 2–6 years of age, 15.3% in those 7–11 years of age, and 7.9% in those 12–21 years of age [17].

Gender and Race

There is a gender disparity between the patients diagnosed following identification of hydronephrosis on antenatal ultrasonography and those

diagnosed following initial UTI. The majority of infants with VUR following identification of antenatal hydronephrosis are male [18]. It has also been noted that the incidence of dysplasia is greater in male infants with VUR. Girls form a majority of patients presenting with VUR identified following UTIs, except for the first 6 months of life, when UTI is more common in boys [19].

African-American girls have a lower potential for development of VUR as compared to Caucasian girls. This difference in incidence was also noted in infants diagnosed with VUR following identification of antenatal hydronephrosis [20]. Additionally, few African American girls presenting with VUR following a UTI have high grade VUR [17]. The incidence of scarring, however, is higher in African-American girls than Caucasian girls, although progression of scarring is less in African American girls. Additionally, time to spontaneous resolution of VUR is shorter in African American girls [21]. The incidence of VUR in Hispanic girls is comparable to Caucasian girls [22].

Presentation

VUR is identified in four groups of children—those identified during evaluation of antenatally identified hydronephrosis, those with other congenital anomalies, those following a febrile or symptomatic UTI and those evaluated due to VUR in a child or parent.

Antenatal Diagnosis

The widespread utilization of antenatal ultrasonography has made early detection of hydronephrosis and subsequent diagnosis of VUR possible prior to the occurrence of UTIs. Fetal pelvic diameter of 7 mm during the third trimester or 10 mm at postnatal examination is considered an indication for further investigation, including possible evaluation for VUR. About 10% of such patients evaluated for hydronephrosis on antenatal ultrasonography are diagnosed with VUR [23]. Cohorts of infants with VUR diagnosed following antenatal identification of hydronephrosis have greater numbers of boys [24]. Additionally, compared to children with VUR following a UTI, there are more patients that have low grade VUR, with greater propensity for spontaneous resolution. Boys with even high grades of VUR (IV–V) have a 29–37% rate of spontaneous resolution in the first year of life [25]. This potential for VUR resolution is attributed to the resolution of a mixed pattern of voiding, with coordinated voiding interspersed with high pressure voiding due to increased sphincteric activity.

Urinary Tract Infections

Most children are diagnosed with VUR following an initial febrile UTI. Since UTIs are most prevalent during the first 2 years of life, the majority of VUR diagnosis is made in infants and young children. In a cohort of 1953 patients with UTI <2 years of age undergoing VCU, VUR was noted in 30% [26]. This incidence was similar to that noted by Hoberman et al. [27]. In more recent studies, the overall incidence of VUR has been 15–20% [28].

Siblings with VUR

There remains debate on the benefit of routine screening of siblings of index patients with VUR. In one study, 88% of siblings had VUR. However, index patients had high grade VUR, and siblings screened were less than 3 years old, and were generally symptomatic with UTI [29]. Therefore, restricting evaluation for VUR to siblings that present with an infection may have a better yield in identifying children with VUR that may benefit from intervention.

Genetics of Reflux

There is increasing evidence for a genetic basis for primary VUR. The reported incidence of VUR in siblings of an affected patient varies

from 27% to 45% [30]. A higher incidence of VUR has also been reported in children of parents with a history of VUR [31]. VUR is most certainly genetically heterogenous. Autosomal dominant inheritance with variable expression or multifactorial inheritance has been implicated for VUR and reflux nephropathy (RN). In a study of 88 families with at least one individual with primary VUR, the authors concluded that a single major locus was the most important causal factor [32]. Kaefer and colleagues found 100% concordance in monozygotic twins and 50% concordance among dizygotic twins [33]. One gene associated with apparent autosomal dominant VUR has been mapped to chromosome 1 [34], though two of the families studied showed negative linkage to this locus, further confirming the genetic heterogeneity of VUR.

Association of Urinary Tract Infections

VUR is believed to be the primary risk factor for pyelonephritis, although some studies dispute this association [35]. The International Reflux Study in Children (IRSC) reported recurrent UTI in 28% of children with medically managed severe VUR [36]. The risk of UTI recurrence is related to the degree of VUR: 6–8% for VUR grade I and II; 27% for grade III; and 43% for grade IV [37]. The usual organisms that cause UTI originate from fecal flora that colonize the perineum, and the organisms that cause recurrent UTI can be found on perineal cultures prior to the onset of UTI [38]. Escherichia coli (E. coli) is the most frequent organism, being responsible for approximately 80% of UTIs, the rest being due to Klebsiella, Enterobacter, Citrobacter, Proteus, Providencia, Morganella, Serratia and Salmonella species [39]. In prospective study of infants with a first UTI, the incidence of non-E. coli bacteria were associated with an increased VUR severity (12% with VUR I–II, 30% with VUR III–V) [28]. A variety of bacterial virulence factors increase the ability of E. coli to cause a UTI. The presence of P fimbriae allows E. coli to adhere to the epithelial cells of the urinary tract, while other virulence factors increase tissue damage and protect E. coli from serum bactericidal activity [35].

Diagnosis

There remains significant debate regarding which children should be evaluated for VUR, both those identified following antenatally identified hydronephrosis, and those that had a UTI. This is partially due to concerns about the efficacy of antibiotics in the prevention of UTI. Multiple radiographic modalities have been successfully utilized for the diagnosis of VUR.

Renal Bladder Ultrasound

The AAP guidelines recommend ultrasonography as the first imaging modality for evaluation of children ages 2–24 months presenting with UTI. Ultrasound is the initial modality for evaluation of *any* child that is being evaluated for possible VUR. This permits evaluation of the upper tracts to determine the presence of anomalies (e.g., duplication, hydronephrosis, MCDK, agenesis). Ultrasound should always include evaluation of the ureters and bladder before and after voiding to determine if there are lower tract changes that might suggest the possibility of VUR (i.e. diverticula, ureteral dilation) or other lower tract anomalies (ureteroceles, megaureter) that may predispose to UTI. Although the presence of abnormalities on ultrasound may increase the likelihood of VUR, there are no specific findings that have a definite correlation [40].

Voiding Cystourethrogram

The gold standard for the diagnosis of VUR is the radiographic voiding cystourethrogram (VCU). VCU requires urethral catheterization and fluoroscopy. This modality allows grading of VUR as standardized by the IRSC. The AAP and NICE UTI Guidelines have suggested limiting further evaluation of children presenting with a first UTI. This has led to a significant decrease in the

utilization of VCU since the publication of the guidelines. Although VCU is the best procedure for the identification of VUR, discrepancy can be noted in the grading of VUR even among experienced readers and when multiple filling cycles are utilized [41]. The timing for the performance of VCU has been debated. It was felt that early VCU may lead to increase in the diagnosis of VUR due to the "instability" of the VUR in the child with a recent UTI. Recent studies have demonstrated that performing the VCU within a week of presenting with a UTI leads to improved compliance with performing the study and does not change the potential for the identification of VUR [42].

The discomfort of catheterization is a contributor to the reluctance to perform VCUs. The use of sedation improves the tolerance for the procedure without changing the potential for the diagnosis of VUR [43]. Intermittent fluoroscopic evaluation reduces the exposure of radiation during the procedure, further improving the safety of the study [44]. The use of one or a few doses of antibiotics may help to prevent UTI due to catheterisation.

VCU is also used for the follow-up of VUR to determine its persistence or improvement. There is a trend to reduce the frequency of performance of VCU during follow-up of children with VUR. Additionally, VCU has been typically omitted following surgical correction of VUR, due to the high success rates achieved with most techniques.

In an effort to reduce the radiation associated with the use of standard (conventional) VCU, radionuclide cystogram (RNC) has been performed. This study uses technetium-99m (Tc-99m) sodium pertechnetate. It requires catheterization, but utilizes less radiation than a standard VCU. RNC has excellent correlation to conventional VCU [45]. The major limitation of this procedure is the inability to grade VUR as recommended by the IRSC. Using RNC, grading is limited to mild, moderate and severe. It is an excellent modality for the follow-up of VUR and for the determination of resolution of VUR. It is also used as the modality of choice for the identification of surgical success in the correction of VUR.

Dimercaptosuccinic Acid Scan

The major concern with the presence of VUR is the development of infections and subsequent renal scarring [46]. A nuclear scan with Tc-99m dimercaptosuccinic acid (DMSA) is the best modality for identifying renal scarring in the kidneys [47]. The difficulty is to determine if the scars that are identified are the result of prenatal hypodysplasia or secondary to recurrent UTI [48]. Some have suggested using a DMSA scan as the primary test for the evaluation of children presenting with UTI. The absence of renal involvement on DMSA scan performed during the acute phase of a febrile UTI makes higher grades of VUR unlikely [28].

Experimental Diagnosis Modalities

Voiding Ultrasonography

Another alternative to VCU is contrast-enhanced voiding urosonography with intravesical contrast, a method increasingly used in Europe. This method has the advantages of not using ionizing radiation and obtaining simultaneous images of the renal parenchyma. However, the use of this method for the evaluation of the male urethra is controversial [49, 50]. Urosonography has been recommended as a primary diagnostic modality for the diagnosis of VUR to reduce radiation exposure [51]. This modality is not widely available; the reduction in radiation exposure with current fluoroscopic techniques and the requirement for catheterization have limited its utilization.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) may be used in the diagnosis of renal scarring, and less frequently is used in the setting of voiding imaging. MR voiding cystography (MR VCU) has the benefits of not requiring catheterization, simultaneously imaging the upper tract, and no radiation exposure. However, in younger children sedation may be required. In a small study, MR VCU was

found to be 90% sensitive and 96% specific for detecting VUR [52]. When compared to the gold standard DMSA scan for detecting renal scars, magnetic resonance urography has a much higher interobserver agreement and may provide superior detection of renal scars due to its ability to differentiate swelling from renal scarring [53].

Grading of VUR

Grading of VUR was standardized in 1982 [54] using the radiographic VCU, by the International Reflux Study Committee (IRSC). This system of grading divides VUR into five grades (Fig. 44.2). Grading of VUR correlates with the degree of renal scarring as well as the potential for spontaneous resolution. Lower grades of VUR have greater potential for spontaneous resolution independent of the age at diagnosis [55]. In addition, the grade of VUR is a consideration in the appropriate choice of management (endoscopic vs. open surgical reconstruction) [56]. Unfortunately, there is significant interobserver variability when grading VUR by VCU. In an analysis comparing a local radiologist with the interpretations of two blinded reference radiologists, VUR grade was agreed upon unanimously in only 59% of ureters [57]. The ureter may also be dilated without renal calyx dilation, which could lead to inconsistent grading.

Bladder and Bowel Dysfunction

Bladder and bowel dysfunction (BBD) is the combination of lower urinary tract symptoms (urgency, frequency, hesitation, straining, and withholding maneuvers) with bowel symptoms such as painful defecation, encopresis and constipation [58]. At baseline this is a common disorder. In a prospective study of children diagnosed

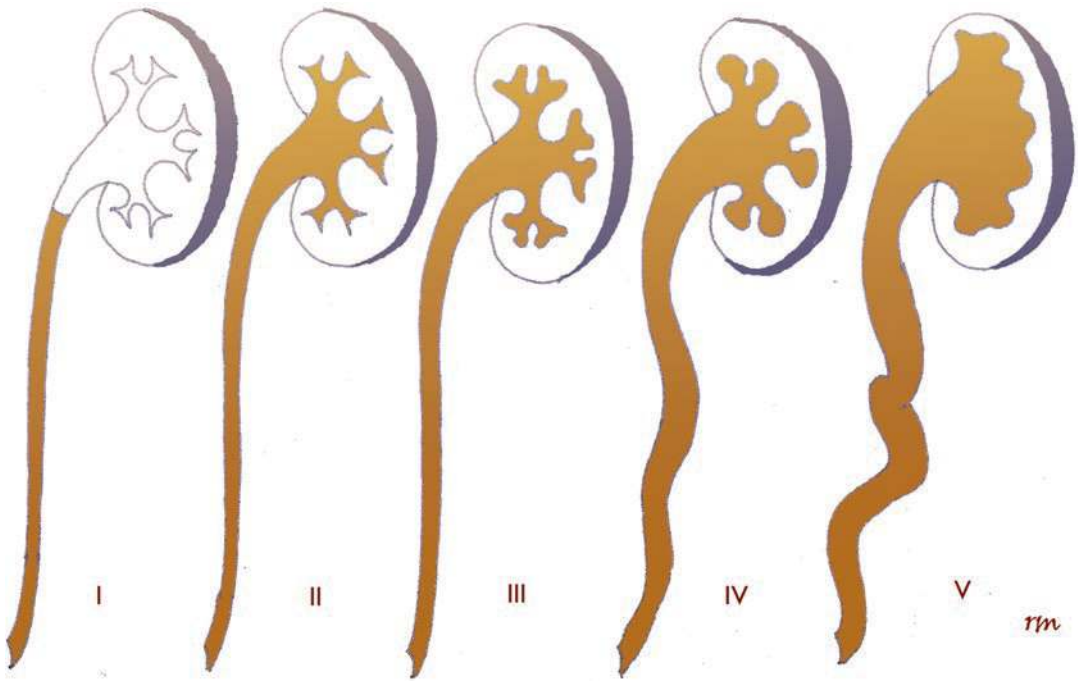

Fig. 44.2 International grading system for vesicoureteral reflux. Grade *I*—contrast in the non-dilated ureter; Grade *II*—contrast in the non-dilated ureter and renal pelvis; Grade *III*—mild dilation of the ureter and renal pelvis with minimal blunting; Grade *IV*—moderate tortuosity of the ureter and dilation of the renal pelvis and calyces; Grade *V*—gross dilation of the renal pelvis and calyces with significant ureteral tortuosity. (Grading based on International Reflux Study. *Pediatrics* 1981; 67:392–400; Figure copyrighted by Dr. Ranjiv Mathews)

with VUR, the presence of BBD significantly increased the rate of recurrent UTIs from 20% to 51% [59].

Potential for Reflux Resolution

The potential for spontaneous resolution of VUR is the basis for its conservative non-operative management. All grades of VUR have the potential for resolution, although the likelihood of resolution is based on the grade and presentation of VUR [60]. Overall 39% of refluxing ureters will have spontaneous resolution [61].

Multiple studies have evaluated the rate of resolution of the various grades of VUR. In one study, resolution of Grade I VUR was 82%, Grade II VUR was 80% and Grade III was 46% [62]. Similar rates of resolution have been noted in other studies evaluating the medical management of VUR [63]. Resolution rates over 5 years of Grade IV and V VUR were 30% and 11%, respectively [60]. In a study from Sweden, a negative correlation was found between bladder dysfunction and spontaneous improvement of VUR grades III and IV [64]. Boys are more likely than girls to have spontaneous resolution of high-grade VUR [61].

Potential for Renal Injury

A variety of factors influence the probability of scarring in children with VUR and UTI. The role of VUR, initially proven in piglets [65], has been shown in multiple clinical studies [66, 67]. Moreover, children with higher grades of VUR have an increased likelihood of developing renal scarring [68, 69]. Renal damage is more common in infants with UTI and VUR because of their unique kidney papillary morphology [70].

Factors affecting the probability of renal scarring in children with VUR and UTI include delay in the treatment of UTI, recurrent UTI and bacterial virulence [71]. Finally, there is evidence that genetic factors predispose patients with VUR to scarring as demonstrated by studies of angiotensin converting enzyme gene polymorphisms [72], and by studies of the IL-8 receptor CXCR1, which have identified a genetic innate immune deficiency with a strong link to acute pyelonephritis and renal scarring [73, 74].

Reflux Nephropathy

Several studies have shown that scarring develops at the same site as previous infection [75]. The pathogenesis of renal scarring following acute pyelonephritis is not well understood. The process is an inflammatory response, with chemotaxis and phagocytosis, release of lysosomal enzymes and superoxides, production of peroxide and hydroxyl radicals, tubular ischemia and reperfusion injury [76, 77].

Reflux nephropathy (RN) is the primary diagnosis in 5.2% of children undergoing renal transplantation according to a North American registry [78]. High grade VUR confers the greatest risk for kidney damage [79], and males with RN appear to have a poorer outcome than females [79, 80]. It is likely that the most severe renal damage associated with VUR is congenital hypoplasia/dysplasia and not postinfectious scarring. In a study from Sweden, boys were more inclined to have congenital lesions while girls were more likley to have acquired RN associated with prior infections [80]. While previous literature reported that younger children had the highest risk for new kidney scacrring, the Randomized Intervention for Vesicoureteral Reflux (RIVUR) trial and other studies reported that the risk for aquired scarring is higher in older children [79, 81, 82]. A lower threshold for identification of VUR in younger children may potentially have a protective role in preventing renal scarring. Despite succesful surgical management, patients with higher grades of VUR at diagnosis are more likely to progress to chronic kidney disease as compared to those with mild or moderate VUR, reflecting the possible role of prenatal dysplasia [83]. Long-term consequences from acquired renal damage, such as renal insufficency, hypertension and pregnancy complications, are considerably less than previously thought [84–86].

Management of VUR

A close relationship between pyelonephritis and VUR was demonstrated by Hodson and Edwards in 1960 [87]. VUR was believed to be detrimental to the kidneys and surgical procedures to correct VUR were developed during the 1960s [88]. However, the high rate of spontaneous resolution of VUR led to more limited surgical intervention [89]. Long-term antibiotic prophylaxis was implemented to protect children with VUR from renal damage induced by infection [90].

The potential for VUR to resolve spontaneously in many patients has changed the paradigm of management from one of immediate surgical correction to initial medical management with antibiotic prophylaxis [91]. Another alternative is watchful waiting. In current clinical practice, treatment decisions are made individually based on VUR grade, previous febrile UTIs, renal damage, bladder and bowel function, adherence to prophylaxis if given, and the parents' preferences. Surgical treatment is typically reserved for patients without spontaneous resolution and with recurrent infections.

Antibiotic Prophylaxis

The main objective of treatment in children with VUR is the prevention of recurrent UTI and renal parenchymal damage. Antibiotic prophylaxis was introduced in 1975 [91]. Controlled trials demonstrated the effectiveness of daily, low dose trimethoprim-sulfamethoxazole (TMP-SMZ) or nitrofurantoin in preventing UTIs [92]. Breakthrough infections are common in children with VUR, with rates ranging from 25% to 38% [93]. Side effects are not uncommon; these include gastrointestinal disturbances, skin rashes, hepatotoxicity and hematological complications [94].

There is no significant outcome difference between medical and surgical management in the incidence of renal scarring. The IRSC European cohort included 300 children with VUR randomly allocated to medical or surgical management. Follow-up with intravenous urography and DMSA scintigraphy over 5 years revealed no difference in the development of new renal scars or the progression of existing scars [95]. Similar results were reported by the Birmingham Study [96].

Recently, several randomized, controlled studies comparing antibiotic prophylaxis and no treatment were performed [97–101]. The results of these studies were summarized in a meta-analysis published in the latest AAP clinical practice guidelines [102]. These studies were unable to show a beneficial effect of antibiotic prophylaxis. However, most children in these studies had no VUR or low grades of VUR, underlining the fact that for most patients, prophylaxis is unnecessary. For children with higher grades of VUR, especially grades IV–V, there may be a benefit. The RIVUR trial, which randomized children with VUR to placebo or prophylaxis, demonstrated a 50% reduction in the risk of recurrent infections with the use of prophylaxis (TMP-SMZ). Additionally, the RIVUR trial showed that in children presenting with a second UTI, older children and those with grade IV VUR, there was greater potential for development of new renal scarring. Given these risk factors, it would suggest that there is a role for prevention of UTIs as a means to prevent new renal scarring [79]. A reanalysis of the RIVUR study divided patients into low risk and high-risk categories (high risk defined as grade IV VUR, female grade I–III, and uncircumcised males with grade I–III, with concurrent BBD) and showed that antibiotic prophylaxis significantly decreased UTI recurrence in the high risk patients. Thus, the treatment of high-risk patients confers greater benefit [103]. The necessity to analyze boys and girls separately was illustrated in the Swedish Reflux Trial, where a beneficial effect of prophylaxis was seen in girls with grades III–IV VUR, but not in boys [101].

Treatment of Bladder and Bowel Dysfunction

Since children with BBD have a higher risk of recurrent UTIs, it is imperative to treat BBD. Adequate hydration, timed voiding, pelvic

floor muscle awareness and a bowel regimen alleviate the urinary and bowel symptoms associated with BBD [58]. BBD increases the risk of UTI in VUR patients regardless of antimicrobial prophylaxis, decreases the likelihood of spontaneous VUR resolution, and may decrease the efficacy of surgical treatment of VUR [59, 64].

Surgical Management

The major indications for surgical intervention in children with VUR include recurrent UTI despite appropriate antibiotic prophylaxis, worsening of renal scarring during follow-up, and grade V VUR, which is unlikely to resolve spontaneously. Surgical correction of VUR may be more important in patients with a single renal system. Surgical management decisions, however, should be individualized based on potential risk to the renal units.

Minimally Invasive Treatment Options

Minimally invasive options for the treatment of VUR are endoscopic and laparoscopic techniques, with robotic techniques applied to improve the results with laparoscopy.

Endoscopic Treatment

Endoscopic techniques use bulking agents to increase resistance at the ureteral orifice to prevent VUR. Polytetrafluoroethylene (Polytef) has been used successfully for correction of VUR since the early 1980s [104]. Polytef had excellent surgical success that was maintained over time; however, the concern of particle migration prevented approval in the United States (US) and led to the gradual decline in use worldwide. Polydimethylsiloxane has been utilized in Canada and has been associated with no migration and high success rates [105], but this agent has also not been approved for use in the US. Bovine cross-linked collagen has been used in the US and, although initial results were acceptable, long-term recurrence of VUR was frequent due to absorption of collagen over time [106, 107]. Other agents that have been tried include expanded chondrocytes and placement of balloons; however, these techniques require multiple procedures [108, 109].

Dextranomer hyaluronidase (Dx/HA, Deflux™) has been utilized for bulking of the ureters for treatment of VUR (Fig. 44.3a, b). Initially reported by Stenberg and Lackgren in 1995 [110], worldwide experience has grown rapidly. The overall cure rates with Dx/HA are 94% for grade 1, 85% for grade II, 78% for grade

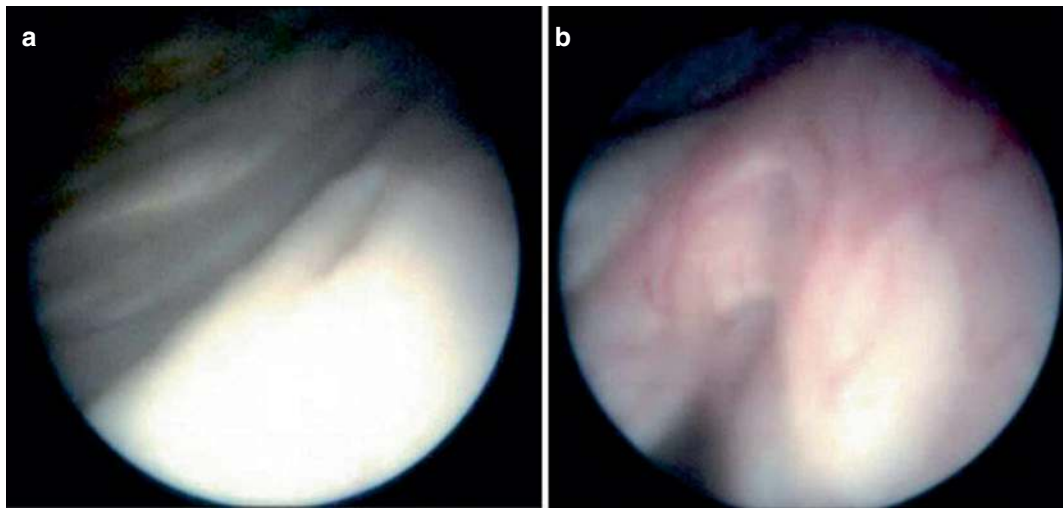

Fig. 44.3 (**a**, **b**) Injections are placed in one of several locations either within or near the ureter to increase coaptation of the ureterovesical junction. **a** depicts a ureteral orifice before injection, and **b** depicts after injection

III and 71% for grade IV VUR [111]. Dx/HA is effective in patients that fail prior treatment and in those that have associated urologic anomalies like ureteroceles and duplex systems. Patients that fail endoscopic management are still candidates for open surgical reconstruction. Late recurrence of VUR was noted in 20% of patients that had follow-up [112].

The efficacy and relative simplicity of the use of Dx/HA for the correction of VUR has led some to question the current paradigm of VUR management [113]. It has been suggested that Dx/HA should be used as a first line treatment for VUR. This procedure requires the use of general anesthesia, which is a significant consideration in infants.

Laparoscopic and Robotic Treatment

Laparoscopy has been successfully utilized for the surgical correction of VUR [114]. Laparoscopic techniques allow small incisions to be used and have the potential to reduce discomfort and length of hospital stays. The technique initially involved an extravesical approach for the correction of VUR [115]. Intravesical and transvesical techniques have since been reported [116]. The presumed benefit of reduction in hospital stay and smaller incisions have been eclipsed by the advent of improved endoscopic management with Dx/HA. The recent advent of the use of robotic techniques has shortened the length of the procedure and has made laparoscopic surgery for VUR more universally accepted. In a single surgeon direct comparison of open versus robotic approach to ureteral reimplant, surgical complications did not differ between the groups. There was a decrease in pain medication usage in the robotic group, albeit a 12% longer operative time in the robotic group [117]. However, in larger comparisons, there is more variation in reports of surgical complications in the robotic approach [118]. Wide variation in usage, success and complication rates of robotic surgery can be attributed to a learning curve and reported outcomes [119].

Open Surgical Techniques

Open surgery remains the gold standard for the surgical correction of VUR. The technique devised by Politano-Leadbetter combined an intra and extravesical technique and has been used widely with great success [87]. This technique, however, has been supplanted by the two techniques described below. In general, open surgical techniques are associated with 90–95% success rates and most can now be performed with a 1–3 day hospital stay. The success rates are so consistent across multiple studies that the use of routine post-procedure VCU has been abandoned. Despite high success rates for the correction of VUR, along with a decrease in the incidence of pyelonephritis [120], there has been no reduction in the incidence of renal scarring during follow-up.

Intravesical (Cohen) Cross-trigonal Reimplantation

Since the initial description of this technique, it has been rapidly adopted by most pediatric urologists due to the consistency of surgical outcomes and low rates of complications [121]. This technique involves the dissection of the ureters within the bladder and then the ureters are placed in submucosal tunnels created across the trigone of the bladder. Over time, significant improvement in pain management has permitted reduction in hospital stays, reduction in the need for stenting and suprapubic tube placement, and high patient satisfaction rates [121]. Because of the high rate of success, this technique is the most frequently performed and taught procedure for the correction of VUR. It is routinely used for the correction of bilateral VUR. It also allows for other bladder anomalies (e.g., ureteroceles, bladder diverticula) to be corrected concurrently. Potential complications associated with this technique are the development of contralateral VUR following correction of unilateral VUR, ureteral obstruction and residual VUR [122].

Extravesical (Lich-Gregoir) Reimplantation

This technique allows reimplantation without entry into the bladder. The ureters are dissected prior to the entry into the bladder and reimplantation is performed by placing the ureters into troughs created in the bladder wall [123]. It has been utilized most frequently for the

management of unilateral VUR as there is a concern that some patients that have had bilateral reimplantation using this technique have had secondary transient neuropathic bladder dysfunction requiring temporary intermittent catheterization [124]. This technique also has a high success rate for the correction of VUR. Many patients can be managed with a 24 h hospitalization as bladder spasms are less frequently noted.

Controversies and Conclusions

The routine use of antenatal ultrasound has increased identification of hydronephrosis. This has permitted early identification of high grade VUR, potentially permitting reduction in renal injury from postnatal infection. In children with VUR identified during the evaluation of antenatal hydronephrosis, there is a pattern of boys with dilating VUR and renal dysplasia and girls with mild VUR and normal renal units [125]. A similar pattern of renal injury has also been noted in a population-based cohort of children followed after a first episode of UTI [80]. However, it remains unclear if the renal damage identified is congenital or acquired. The ability to distinguish renal scarring from dysplasia on DMSA renal scan is at the center of this debate. Newer imaging modalities will potentially help to differentiate these two entities.

The AAP and NICE guidelines have recommended limiting evaluation for diagnosis of VUR to those children presenting with recurrent infections, or those with abnormalities identified on ultrasound. These recommendations have led to a significant reduction in the numbers of children being identified with VUR. Additionally, studies have demonstrated that these recommendations have led to some children with high grade VUR being missed [126]. The long-term impact of this remains a concern.

The role of antibiotic prophylaxis in the prevention of recurrent infections also remains debated. We would certainly recommend prophylactic regimens for those children in higher risk groups as identified by the RIVUR study and other studies.

Surgical management of VUR has been shown to have high success rates for the resolution of VUR, but patients with BBD may continue to develop lower tract infections despite abatement of VUR.

Obstructive Uropathies

45

Benedetta D. Chiodini, Khalid Ismaili,
David A. Diamond, and Michael P. Kurtz

Introduction

Obstructive uropathy is the partial or complete blockage to the flow of urine, which can occur as the consequence of an anomaly at any level of the urinary system: the ureteropelvic junction, distal ureter, ureterocele, urethra, or extrinsic compression by other structures (e.g., blood vessels, tumors).

As most of these conditions are congenital, they are currently routinely diagnosed on prenatal ultrasound (US) in developed countries. Early in fetal development, urinary tract obstruction starts a complex sequence of events affecting renal growth and development, and eventually leading to renal impairment. Congenital urinary tract obstruction is associated with a significant reduction in the number of nephrons and is the primary cause of end-stage renal disease (ESRD) in children [1, 2].

Detection of these conditions during pregnancy varies according to gestational timing at which screening is performed. Thanks to its safety, excellent anatomical resolution, wide accessibility and low-cost, US is the first examination to perform before and after birth [3].

From the beginning of the second trimester of gestation, the renal pelvis becomes detectable and appears as a sonolucent area in the middle of the kidney. Pyelectasis and hydronephrosis are the most common signs of obstruction detected on US. Other signs of obstructive uropathies are cysts, abnormal corticomedullary differentiation, increased echogenicity of the renal parenchyma, ureteral dilatation, pelvic or ureteral wall thickening, increased bladder size or wall thickness or presence of ureterocele [4–6].

Pyelectasis, defined as the dilation of the renal pelvis, and hydronephrosis, defined as the dilation of both the pelvis and calices, are evaluated in the sections of fetal abdominal transverse planes by measuring the anteroposterior diameter (APD) of the renal pelvis. APD may vary depending on the gestational week.

A third-trimester renal pelvis APD diameter of 7 mm is the most widely used criterion to select patients requiring postnatal investigation [4, 7]. Fetal distension of the urinary collecting system is often a dynamic and physiologic process which resolves spontaneously after birth [3, 8–10]. Among the prenatal mild pyelectasis cases, only a small proportion are associated with a serious problem in the postnatal period. However, in some cases pyelectasis can signal

the presence of severe urinary tract pathology [11], especially in patients with significant hydronephrosis [7]. Renal pathology is confirmed postnatally in 12–14% of mild, 45% of moderate and 90% of severe pyelectasis cases detected in the second and third trimesters of pregnancy [12].

After birth, a renal pelvis APD of 10 mm is the most commonly accepted upper limit threshold value of normal [5] while a renal pelvis APD >15 mm is often associated with significant uronephropathies [4, 6, 13]. Based on the American [4] and European recommendations [14] and on our experience [3, 6, 7], we have suggested an algorithm for a pragmatic postnatal imaging strategy [15] (Fig. 45.1).

Common Obstructive Uropathies

The presentation and management may be divided into upper and lower urinary tract obstruction. Upper urinary tract obstruction is often unilateral and therefore less critical for overall renal function. Lower urinary tract obstruction, especially of the bladder outlet, is usually associated with a more serious prognosis.

The most frequent congenital upper urinary tract conditions are ureteropelvic junction obstruction (UPJO), ureterovesical junction obstruction (also referred to as primary megaureter) and renal duplication anomalies. Posterior urethral valves (PUV) in boys are the most common cause of lower urinary tract obstruction.

The clinical management of these pathologies remains a challenge for nephrologists and urologists, due to the wide spectrum of severity and clinical progression and the difficulty in predicting long-term prognosis [1].

The different imaging and clinical features as well as current treatment options of the most common obstructive uropathies are reported below.

Ureteropelvic Junction Obstruction

UPJO is the most common cause of persistent prenatal hydronephrosis, occurring in 5–20% of children with antenatally diagnosed renal pelvis

dilation [3]. It is usually unilateral, more common on the left side and more often observed in males [16]. Bilateral UPJO has a higher risk of additional kidney anomalies and potential renal function impairment, and often has a poor prognosis when associated with oligohydramnios and hyperechoic renal parenchyma in utero. UPJO is primarily caused by an aperistaltic segment, or crossing vessels at the level of junction between the pelvis and the ureter [17]. Rarely, obstruction is caused by an epithelial polyp, a benign growth of urothelium blocking the lumen at, or distal to, the UPJ. UPJO is highly suspected when there is significant pyelectasis, often >15 mm, in the absence of any dilation of the ureter (Fig. 45.2), and once vesicoureteral reflux (VUR) has been excluded by voiding cystourethrography (VCUG). In severe obstruction, caliceal dilation, hyperechoic parenchyma and sometimes a perirenal urinoma may be seen. On US, perirenal urinoma appears as a perinephric pseudocyst confined to the Gerota's fascia [12, 18]. Although the development of a urinoma is rare, it is most common when there is an ipsilateral dysplastic kidney [12].

The postnatal management of children with antenatally detected UPJO remains controversial [19, 20]. The primary question is how to identify asymptomatic children with hydronephrosis at risk for loss of renal function if managed by observation alone. To date, there is no consensus about the criteria for surgery, even within the same center [21, 22].

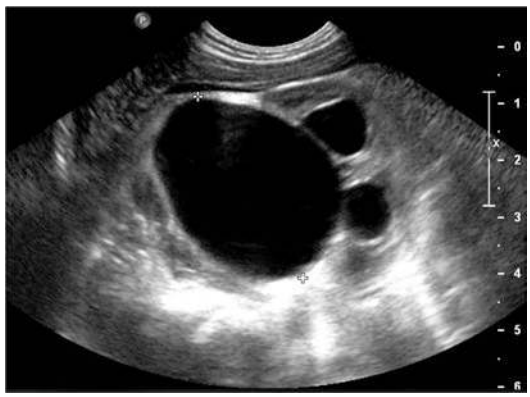

Fig. 45.2 Ultrasound of severe dilatation in a ureteropelvic junction obstruction

In 2016, the Cochrane review by Weitz et al. [23] focusing on unilateral UPJO evaluated the effects of surgical versus conservative management in newborns and children under 2 years of age. Unfortunately, the study was limited by the small sample size and short follow-up time and therefore was unable to clarify the optimal therapy for young children with unilateral UPJO. One year later, Weitz published a systematic review [21] on more than 1083 patients from 20 studies, with the aim of determining the effect of non-surgical management of unilateral UPJO. Although this review was also biased by the great heterogeneity of the included studies, it showed that more than 80% of the cases had improved drainage pattern over time, that about 20% of the patients were at risk for split renal function deterioration, and that nearly 30% underwent surgical intervention [21]. In order to definitively resolve the ongoing controversy and define the optimal management of unilateral UPJO, a randomized controlled trial with sufficient statistical power and adequate follow-up would be required.

A major challenge is that children with UPJO are often clinically asymptomatic and the criteria for surgery are primarily related to sonographic and isotopic parameters. In addition to the severity of the hydronephrosis on US, important predictors of the need for intervention are impaired differential renal function (DRF) and renal drainage on renogram [19, 21, 24]. MAG3 renogram is the gold standard for the evaluation of differential renal function and severity of obstruction. The Society of Fetal Urology and the Pediatric Nuclear Medicine Council of the Society of Nuclear Medicine have provided a consistent methodology for renography [25]. The Paediatric Committee of the European Association of Nuclear Medicine guidelines [26] has underlined the potential pitfalls in the acquisition, processing and interpretation of isotopic examinations.

Pediatric urologists decide on the need for pyeloplasty primarily based on poor drainage [25, 27–29] as indicated by delayed cortical transit time, which is the passage of the tracer from

the outer cortex to the collecting system [30]. The cortical transit is generally fast, and fairly homogeneous kidney filling can be observed in approximately 2 min. In cases of delayed cortical transit, the tracer is retained in the outer cortical rim and the remaining kidney remains hypoactive for several minutes. Severely delayed cortical transit is an important indication for surgery to avoid renal function deterioration [24, 31].

A sensible clinical approach can be summarized as follows:

- Absolute indications for surgical treatment include symptoms such as febrile urinary tract infections (UTIs), hematuria, and kidney stones. Surgery is also indicated in a solitary kidney with evidence of reduced overall renal function.
- For unilateral UPJO, observation with close monitoring is the prudent approach for the large majority of cases, even in those with severe hydronephrosis initially on US.
- A MAG3 renogram should be performed to exclude worsening drainage in the event of a significant increase of the pelvic diameter on US.
- Early surgical intervention is recommended in cases of severe hydronephrosis with impaired split renal function and/or delayed cortical transit.

Megaureter

Megaureter is a ureteral diameter greater than 8 mm [32] and represents nearly one fourth of all causes of urinary tract obstruction in children [32], with cases presenting initially on prenatal US. In utero, megaureter appears as a serpentine fluid-filled structure with or without dilatation of the renal pelvis and calices [6]. Primary megaureter (pMU) is a ureteral dilation caused by an obstruction at the junction between ureter and bladder. pMU can be caused by both an aperistaltic (adynamic) segment in the terminal ureter causing a functional obstruction or, less commonly, by anatomic causes such as congenital distal ureteral strictures or valves [32]. Secondary megaureter represents an obstructive process due to elevated intravesical pressure associated with an underlying bladder or bladder outlet condition. Common causes include high-grade VUR, neurogenic bladder and PUV. It is important to distinguish between primary and secondary megaureter, as in the latter treatment is directed at the underlying pathology and not at the ureter itself [32]. Differentiating primary and secondary megaureter relies on a VCUG.

With the exception of cases associated with the highest grades of hydroureteronephrosis, the prognosis of pMU is generally good and spontaneous resolution usually occurs within the first 3 years of life. The likelihood of requiring surgical correction increases with ureteral diameter exceeding 10 mm [33]. Regarding the management of pMU, two controversies remain. The first relates to the need for continuous antibacterial prophylaxis (CAP) to prevent UTIs while awaiting resolution. The second relates to indications for surgery.

Some authors recommend CAP in the first 6 months of life [34], although for others CAP is not considered mandatory, in the absence of recurrent UTIs and/or VUR [7]. Unfortunately, the risk of pyelonephritis in newborns with pMU is not clear [35]. A systematic review [36], including 16 studies and 749 patients, found a prevalence of UTIs in patients with pMU greater than 14% and a calculated number needed to treat for patients on CAP to prevent one UTI over the course of 1–2 years of 4.3. The authors recommended CAP in children with pMU selected for non-surgical management, at least in patients with poor emptying or greater ureteral dilatation, and for children in the first months of life [36].

When considering indications for surgery, Rubenwolf et al. reviewed a two-decade experience of pMU, and showed a constant decline of surgical interventions due to the favorable outcomes of conservative management in the majority of children [34]. However, in cases of severe hydronephrosis or a retrovesical ureteral diameter greater than 10 mm, resolution may take longer, and more commonly requires surgery [6]. The British Association of Pediatric Urologists (BAPU) recommends surgical intervention only

in case of recurrent febrile UTIs, impaired renal function associated with severe or progressive hydronephrosis, or a drop in differential function on serial renograms [37]. In these cases, the BAPU recommends megaureter repair in patients over 1 year of age even though the procedure may be challenging in small children [37].

A sensible clinical approach can be summarized as follow:

- For a patient with a megaureter, VCUG should be performed in order to differentiate between primary and secondary megaureter.
- In children with asymptomatic pMU, close surveillance is recommended.
- Continuous antibiotic prophylaxis can be recommended in newborns with the highest grades of hydronephrosis and children with a history of a febrile UTI.
- Surgical intervention is mainly required in case of recurrent febrile UTIs, impaired renal function associated with progressive hydronephrosis and/or deteriorating split renal function on serial renograms.

Duplex Kidney

Duplication of the renal collecting system is a congenital defect that involves a kidney drained by two ureters that may be completely or partially separated [38]. Most patients with duplex kidneys have no significant clinical symptoms. When there is no hydronephrosis or renal impairment, a duplex kidney should be considered a normal variant [39]. However, it can also be pathological, associated with the presence of VUR and/or obstruction. Fetal urinary tract dilatation is associated with renal duplication anomalies in under 5% of cases [39]. In those, VUR classically involves the lower pole ureter and tends to be of higher grade as compared to single system reflux [38, 40]. Obstruction of the upper pole may also present secondary to an ectopic insertion, or more often due to a ureterocele, which on US appears as a thin-walled anechoic cystic dilation of the intravesical submucosal ureter (Fig. 45.3). However, ureteroceles can sometimes escape

Fig. 45.3 Ultrasound of a ureterocele appearing as a thin-walled anechoic cystic dilation of the intravesical submucosal ureter

sonographic detection, as an overdistended bladder can compress the ureterocele or occasionally the ureterocele itself may be mistaken for the bladder.

In utero, duplex kidneys may be seen as two noncommunicating renal pelves, dilated structures within one pole, and a cystic dilation in the bladder, representing a ureterocele [41].

Postnatal investigations are US and VCUG [42]. Most authors agree that the surgical approach to pathological duplex systems is largely dictated by the anatomic etiology, clinical evolution, and the degree of function in the affected renal moiety [39, 42]. Children with a pathological duplex collecting system and/or ureterocele are also at higher risk of UTIs despite the use of prophylactic antibiotics [43].

A practical clinical approach can be summarized as follows:

- In children with dilated duplex system, US and VCUG are recommended after birth in order to diagnose VUR, assess renal parenchymal anatomy, and detect the presence of a ureterocele.
- In complex cases, prophylactic antibiotics should be started. Isotopic studies are recommended in order to evaluate renal function in the affected renal moiety.
- Decompressive surgery should be planned in cases of an obstructive ureterocele associated with good function, albeit depending on the clinical circumstance. Surgical options include

ureterocele puncture, ureteral reimplantation, and connecting an obstructed ureter to a non-obstructed, non-refluxing ureter. Poor renal function associated with a ureterocele may be an indication for removal of the affected moiety in cases with recurrent UTIs or lower urinary tract obstruction.

Posterior Urethral Valves

PUV are membranous folds fanning distally from the prostatic urethra to the external urinary sphincter and represent the most common cause of lower urinary tract obstruction in boys, affecting 1 in 4000–8000 infants [44]. This congenital malformation, depending on the severity of obstruction and the time of diagnosis, causes a wide spectrum of clinical manifestations. When suspected very early in pregnancy, as in the first or early second trimester, PUV carry a very poor prognosis [45] and are associated with high fetal and neonatal mortality. Impaired urine output leads to oligohydramnios and, ultimately, pulmonary hypoplasia and renal failure [46, 47]. With milder obstruction, the outcome is less predictable. In general, the obstruction leads to hypertrophy of the detrusor muscle, which often affects compliance and raises intravesical pressure. This elevated bladder pressure may be transmitted to the ureters, with or without VUR. This predisposes patients to an increased risk of UTIs, incontinence, and progressive renal impairment [44].

In utero, PUV should be suspected with the following findings: bilateral hydroureteronephrosis, abnormal renal cortex, failure of the bladder to empty, oligohydramnios, and an enlarged, thick-walled bladder with a dilated posterior urethra producing a keyhole configuration (Fig. 45.4). In rare cases, extravasation of urine can be recognized as a urinoma or urinary ascites due to bladder rupture [48] (Fig. 45.5).

Fetal urinary electrolytes and β-2 microglobulin are the most used biological markers to predict postnatal renal function. Fetal urine should be hypotonic, with osmolality less than 210 mEq/L. The combination of raised osmolality and a β-2 microglobulin greater than 4 mg/L suggests irreversible renal dysfunction, and is a contraindication of shunt placement to restore amniotic volume [49].

Fig. 45.4 Ultrasound of posterior urethral valves in a 32 weeks gestation fetus. It shows an enlarged thick-walled bladder with a dilated posterior urethra producing a keyhole configuration

Fig. 45.5 Ultrasound of a perinephric urinoma in the context of severe posterior urethral valves

Once PUV are suspected prenatally, management warrants the prompt involvement of a multidisciplinary team in a fetal and pediatric urology referral center. Various options can be discussed according to the severity of presentation, including termination of pregnancy, in utero therapy or follow-up with planned (active or palliative) postnatal management.

For decades, a variety of in utero approaches to therapeutically relieve obstructing posterior urethral valves have been utilized: open surgical technique of fetal vesicostomy [50], direct fetoscopic valve resection [51, 52], and vesicoamniotic shunting [53].

Vesicoamniotic shunting is the method most commonly used for bladder drainage. It involves the placement of a double pig-tailed catheter under US guidance with the distal end in the fetal bladder and the proximal end in the amniotic cavity to allow drainage of fetal urine [54, 55]. Its principal benefit is prevention of early neonatal pulmonary insufficiency and death. However, the risks of premature labor, perforation of fetal bowel or bladder, and fetal or maternal hemorrhage or infection are significant [56]. In 2013, the PLUTO (Percutaneous vesicoamniotic shunting in Lower Urinary Tract Obstruction) study was completed [57]. In this trial, fetuses diagnosed with lower urinary tract obstruction were randomly assigned to either vesicoamniotic shunting or conservative management. Despite its small sample size, PLUTO's results suggest that survival in the neonatal period was higher with vesicoamniotic shunting than with conservative management. However, there was substantial morbidity in both groups, with only two out of seven shunted survivors having normal renal function at 1 year of age. These results indicate a low likelihood of patients with severe PUV surviving with normal renal function, irrespective of management [58].

In summary, the experience with the intrauterine shunting technique as currently practiced suggests that postnatal survival may be increased, but that a significant improvement of postnatal renal function cannot be expected. Hence, the goals of care in patients with PUV are prompt urological care following a full gestation delivery with the aim of maximizing bladder and renal function.

The long-term outcome of PUV is far from satisfactory, with 15–30% of patients reaching ESRD during childhood [59, 60]. Indeed, PUV are the most frequent cause of chronic renal disease in boys and account for about 17% of children with ESRD [61]. In a retrospective study of more than 100 patients with PUV, the factors associated with a higher risk of CKD and ESRD were antenatal diagnosis, prematurity, abnormal renal cortex with loss of corticomedullary differentiation on initial US and elevated plasma creatinine at 1 year of age [62]. The decreased number of total nephrons present at birth leads to hyperfiltration injury, exacerbation of the underlying inflammatory process, renal fibrosis and, ultimately, renal failure.

In addition to renal impairment, the severity of bladder dysfunction in PUV patients varies widely, as the clinical spectrum ranges from severely pathological, high pressure bladders to late presentation with mild lower urinary tract symptoms, incontinence and recurrent UTIs. Indeed, children not diagnosed prenatally may present in infancy with urosepsis, poor urinary stream and/or failure to thrive. Older children may also present with urinary symptoms of incontinence, poor flow or retention. In a systematic review [63] of the outcomes of PUV in nearly 1500 patients, urodynamic bladder dysfunction was seen in more than half of the patients after endoscopic treatment of PUV, and nearly one in five cases had urinary incontinence.

A reasonable clinical approach can be summarized as follows:

- All cases antenatally suspected with PUV should be discussed by a multidisciplinary team, including obstetrician or maternal fetal medicine specialist, radiologist, pediatric nephrologist and urologist. All cases should then be referred to a pediatric center with a neonatal intensive care unit with nephro-urological expertise.
- Once the risks and benefits have been assessed, if an antenatal therapeutic intervention is proposed, the procedure should be performed selectively in qualified centers.
- In all children suspected of PUV, catheter drainage of the bladder should be performed at birth. Fluid status, serum electrolytes, and renal function should be monitored closely. Prophylactic antibiotics should be started.
- VCUG should be performed as soon as possible after birth. A voiding view of the urethra with the catheter removed is crucial for definitive evaluation of the urethra. Antibiotics should be administered 1 day prior and 1 day after the VCUG to prevent UTIs.
- The standard of care for PUV is endoscopic valve ablation when the child is medically

stable. Circumcision is also recommended to reduce the risk of infection.

- If catheter drainage improves hydronephrosis and plasma creatinine, then valve ablation is all that is necessary.
- If catheter drainage improves hydronephrosis, but renal function does not improve, this suggests renal dysplasia.
- If with catheter drainage the hydronephrosis and renal function do not improve, an upper tract diversion should be considered.
- If the newborn is too small (under 2 kg), the urethra might not safely allow standard resectoscope introduction. In these cases, alternative techniques such as vesicostomy, Fogarty balloon-based intervention, or laser ablation can be performed in order to alleviate or bypass the obstruction until the child is large enough for definitive treatment.
- Due to the high risk of chronic kidney disease in this patient population, patients should have close, long-term follow-up of renal function.
- Urodynamic studies are particularly valuable in order to evaluate bladder storage, pressure, compliance, emptying, and post-void residual volume, and help guide medical and surgical management.
- In children with ESRD, full assessment of the bladder is crucial before transplantation in order to prevent a hostile bladder from damaging the renal allograft. Moreover, with immunosuppression, the risks of transplant pyelonephritis and subsequent renal allograft damage need to be considered. If urological intervention is required, then reconstruction, such as bladder augmentation, should be performed pretransplant.

Renal Calculi

46

Larisa Kovacevic and Paul Goodyer

Introduction

Pediatric nephrolithiasis has shown a dramatic increase in incidence [1], hospitalization and complication rates over the past two decades [2], and is no longer considered a rare or benign disease. Shifts in epidemiology, etiology, and stone composition have been noted and are related, at least in part, to the modern life-style [3, 4]. New trends include: an increasing annual incidence among two specific age groups (young and adolescent children), and among girls and African-Americans [5]; a change in the etiology from infectious to metabolic [6], and in the main metabolic focus from hypercalciuria to hypocitraturia [7], along with alterations in stone composition (ammonium and urate to calcium) [8]. Additionally, there is an increasing body of evidence supporting the association of nephrolithiasis with other conditions such as hypertension, coronary heart disease, atherosclerosis, diabetes and low bone mineral density, supporting the hypothesis that nephrolithiasis has a multisystemic involvement rather than being a single disease [9–11]. Moreover, the serious consequences of kidney stones are increasingly recognized based on new data on its association with chronic kidney disease (CKD) [12, 13]. Altogether, this emphasizes the need for comprehensive re-evaluation of pediatric stone management, which will help identify the modifiable risk factors at an early stage, guide treatment, and allow better prevention strategy.

There are several unique characteristic features of pediatric stone disease compared to adult stone formers: heterogeneous clinical presentation, high frequency of an underlying etiology (anatomic and genetic in infants and younger children, metabolic in older children), great variability of risk factors in relation to age, gender and race, and high rate of recurrence.

In this chapter, we will address the differences between children and adults and recently observed trends in pediatric nephrolithiasis, as well as advances in pathophysiology and treatment strategies, and future directions.

Epidemiology

The true incidence of pediatric nephrolithiasis is not known because many cases are either misinterpreted or undiagnosed due to the lack of symptoms. The estimates obtained from population-based observational studies indicate a range from 36 to 57 stone cases per 100,000 children

[14, 15]. Overall, the incidence of pediatric nephrolithiasis is lower than in adults, and this may be due to higher concentration of urinary inhibitors of stone formation such as citrate and magnesium [16]. The presence of certain urinary macromolecules (UMM) in children, containing higher proportions of fibronectin and glycosaminoglycans, also exhibit crystal-cell adhesion inhibitory activity compared with adult UMMs [17].

A change in epidemiology and a 4–16% annual increase in incidence of pediatric nephrolithiasis were noted over the past two decades, with the greatest increased rates among children between 12 and 17 years old, females, and African-Americans. Although the cause of the increasing incidence of pediatric nephrolithiasis is not entirely clear, potential explanations focus on changes in dietary habits (increased intake of sodium and decreased water intake), an increase in antibiotic usage and other lithogenic drugs, and the increased use and sensitivity of imaging.

The prevalence, incidence and risk of nephrolithiasis varies with gender, race, climate/geographic location, dietary habits and socioeconomic factors.

Gender

The strong male gender predominance found in adults with nephrolithiasis is not seen in children [18]. An age-dependent gender distribution was reported in the United States, with boys being more affected in the first decade of life and girls in the second decade [19]. This could be due to the main risk factor of stones identified in these groups, namely obstructive urinary malformations in boys and urinary tract infections in post-pubertal, sexually active girls. Recent data show a higher prevalence in girls compared with boys (52% versus 48%) [20], and a male-to-female ratio of 1:1.4, a difference that becomes more pronounced in adolescence [2, 20]. Additionally, female gender imposes a relative risk (RR) of 1.5 for hospitalization for nephrolithiasis [21, 22]. This marked increase seen in females has special significance due to the association of nephrolithiasis with cardiovascular disease and fractures. The incidence of stone disease shifts towards a male predominance around 26 years of age, which continues throughout adulthood.

Age

During a 12-year period, one study reported the lowest incidence in children aged 0–3 years (0.6 per 100,000) and the highest in children aged 14–18 years (34.9 per 100,000) [6]. The same study showed that children aged 14–18 years had a 10.2-fold greater risk for nephrolithiasis and hospitalization compared to children 0–13 years of age [7]. Ureteral stones are more common in older children, whereas younger children are more likely to develop renal stones [19, 20]. Moreover, it seems that age is not predictive of spontaneous passage of stones, but stones less than 5 mm in size are more likely to pass compared to stones more than 5 mm [23, 24].

Race/Ethnicity

Nephrolithiasis is more common in non-Hispanic white children [5, 15, 17], followed by Hispanic and African American children [5, 7, 8, 14, 15]. However, it is unclear whether these differences are due to genetic differences or dietary habits.

Regional Differences

The incidence of pediatric nephrolithiasis varies by geographic area (rural vs. urban), and among countries, and is due to differences in climate, diet, socio-economic factors, and genetics. A higher incidence of kidney stones was found in children living in western countries (5–10% of that in adults) and in rural communities. In developed countries, stones are found mainly in the kidney and ureter, and are predominantly calcium-oxalate or calcium phosphate. In underdeveloped and developing countries, bladder stones are commonly seen, and usually consist of uric acid or ammonium [25].

Turkey and Thailand are endemic areas with the highest incidence of renal stones. "Stone belts" have been described in different parts of the world, and include Southeast US (Virginia, North Carolina, Georgia, Tennessee, and Kentucky), Sudan, Egypt, Saudi Arabia, the United Arab Emirates, Iran, Pakistan, India, Turkey, Myanmar, Thailand, Indonesia and Philippines. This is probably due to the hot, dry climate causing dehydration, and high rates of consanguinity.

Pathogenesis

The initiation and growth of calculi requires high urinary solute concentration (supersaturation) and low urinary volume. Supersaturation represents the ratio of a salt's concentration in urine to its solubility; a ratio of more than 1 favors crystal formation, while a ratio less than 1 allows the crystals to dissolve. Further growth and aggregation is favored by ionic strength, urinary pH, and the concentration of promoters and inhibitors of crystallization (Table 46.1). These aggregates may occlude the tubular lumen and serve as an initial nidus (the free particle theory) [26]. This mechanism is particularly important for stone formation in cystinuria, where high urinary levels of cystine initiate intratubular nucleation. Adherence to the epithelial renal tubule cells of the urinary tract is required to allow for crystal growth (the fixed particle theory) [27], a process especially important in patients with brushite and apatite stones. Injured renal tubular cells by either toxins, infection or medication (e.g., calcineurin inhibitors and gentamycin) favor crystal attachment. The expected urine washout of crystal aggregates is impaired by stasis caused by congenital anomalies of the urinary tract.

Table 46.1 Promoters and inhibitors of stone formation

Promoting factors	Inhibiting factors
Calcium	Citrate
Oxalate	Magnesium
Sodium	Pyrophosphate
Urate	Tamm-Horsfall protein
Cystine	Osteopontin
	Prothrombin fragment-1
	Bikunin
	Inter-alpha-inhibitor
	Alpha-1-microglobulin
	Calgranulin
	Fibronectin
	Matrix Gla protein
	Renal lithostathine
	Glycosaminoglycans (i.e. heparan sulfate)

In the Randall's hypothesis, apatite plaques or other sources of uroepithelial damage (infection, foreign body) represent the nidus for calcium oxalate stone formation [28]. Randall's plaque originates from the basal membrane of the thin loops of Henle, expands through the interstitium and protrudes into the papillary vasculature causing injury and repair in an atherosclerotic like fashion (vascular theory of Randall's plaque formation) [29]. This theory accounts for stones which appear to be embedded in the papillary wall and is supported by the physiology of renal papilla: turbulent flow, high osmolality and hypoxia [30, 31]. The reported association between vascular disease (hypertension, atherosclerosis, myocardial infarction) and nephrolithiasis [32] and the tendency of unilateral stones to develop on the sleeping side due to increased renal flow [33] are additional evidence supportive of the vascular theory.

Initial Presentation, Evaluation and Management

The presenting symptoms of nephrolithiasis in children differs from that in adults and depends on the child's age. Typical renal colic and gross hematuria are more often seen in older children and adolescents, who have higher rates of ureteral stones and spontaneous passage [6]. Flank pain may identify the position of stones: trapped at ureteropelvic junction (costovertebral angle tenderness), passing down the ureter (lateral flank tenderness) or trapped at the ureterovesical junction (lower abdomen or groin pain). In contrast, younger children may present with irritability, vomiting, failure to thrive, nonspecific

Table 46.2 Initial evaluation of a child with nephrolithiasis

Medical history
Diuretic use in premature newborns, urinary tract abnormalities, urinary tract infections, intestinal malabsorption (Crohn's disease, bowel resection, cystic fibrosis), immobilization, diabetes mellitus, hypertension
Medications (antibiotics, anticonvulsants, diuretics, corticosteroids, chemotherapy, antacids, protease inhibitors)
Dietary history
Daily intake of fluid, sodium, potassium, calcium, oxalate and protein; special diets (vegetarian, meat). Use of vitamins C or D, herbal products, special therapeutic diets (e.g. ketogenic diet)
Family history of stone, hematuria, or renal failure (pedigree to establish mode of genetic transmission)
Physical examination: obesity, growth failure (distal renal tubular acidosis), dysmorphic features (William's syndrome), rickets (Dent disease), lower urinary tract stasis (spina bifida)
Urine
Urinalysis (pH[a], specific gravity or osmolality, glucose[b], protein[c]) and culture
Urine solute to creatinine ratios in random urine: spot urine
Qualitative cystine screening
Urine solute concentrations and excretion rates in timed 24-h urine collection (volume, calcium, phosphorus, oxalate, citrate, uric acid, sodium, potassium)
Serum chemistry: calcium, phosphorus, magnesium, alkaline phosphatase, sodium, potassium, chloride, bicarbonate, uric acid, creatinine, urea nitrogen

[a] Urine pH higher than 6 favors calcium phosphate precipitation; higher than 7 suggests urease producing organisms and struvite stones; lower than 6 favors cystine or uric acid stones
[b] Glycosuria and proteinuria indicates tubular dysfunction
[c] Low-molecular weight proteinuria is consistent with Dent disease

abdominal pain, microscopic hematuria and urinary tract infection [34].

Some form of hematuria is present in about half of children with stones [35]. Dysuria or frequency is seen in about 10%, while urinary retention/bladder pain may be seen in others. Other features include failure to thrive, hypertension and kidney failure; stones are occasionally reported in association with enuresis, penile edema, and anorexia. Rarely, children present with acute anuria caused by bilateral obstructive stones.

The initial assessment of children with nephrolithiasis is presented in Table 46.2; a proposed algorithm for the initial management of suspected nephrolithiasis is shown in Fig. 46.1. At presentation in the emergency room or during primary outpatient consultation, patients should have a careful medical history, family history and physical examination as outlined in Table 46.2. Blood should be drawn for measurement of serum creatinine, urea nitrogen, electrolytes, uric acid, calcium, alkaline phosphatase, parathyroid hormone and 1,25-dihydroxy vitamin D. Urine should be obtained for standard urinalysis and microscopy to screen for specific crystals in the urinary sediment (Table 46.3). Urine should also be screened for the ratio of calcium, oxalate, uric acid and cystine to creatinine (measures of excess excretion of these solutes) and for the ratio of citrate and magnesium to creatinine (measures of suboptimal levels of these stone inhibitors) (Table 46.4). Fractional excretion of sodium can be calculated to identify renal salt-losing states.

Diagnostic Imaging

The goals of initial imaging are to confirm the presence of a stone, detect whether it is obstructing urinary flow, estimate stone size (and likelihood of passing), ascertain whether the stone contains calcium and identify any anatomic abnormality (congenital or acquired) which might cause local urinary stasis. Ultrasonography and a plain abdominal radiograph showing kidney/ureter/bladder (KUB) are the mainstay of radiological imaging in children (Table 46.5) [36, 37]. Color Doppler ultrasonography provides information about the "twinkling effect" that is characteristic of small stones and should be used in patients who show no stones by B mode ultrasonography. A simultaneous KUB should be performed to identify ureteral stones and assess the calcium content of the stone.

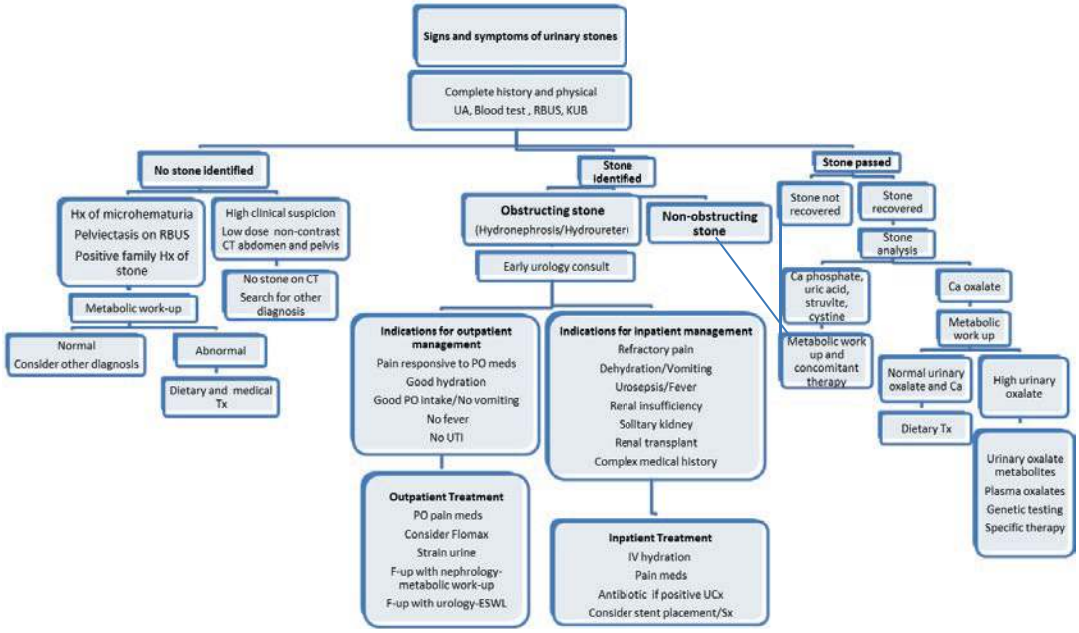

Fig. 46.1 Algorithm for the initial management of suspected nephrolithiasis

Table 46.3 Stone composition in children

Crystal type (stone incidence)	Possible causes	Appearance	Urine pH	Appearance
Calcium oxalate Monohydrate (Whewellite-80%)	Primary hyperoxaluria	Dumbbell or oval	Acidic	
Calcium oxalate dehydrate (Whedellite-20%)	Hypercalciuria Hyperoxaluria Hypocitraturia	Envelope	Acidic	
Uric acid (0.5–1%)	Hyperuricosuria (primary or secondary)	Varying sizes and shapes—rhomboids, parallelograms and rosettes	Acidic	
Struvite (triple phosphate) (Struvite 5–7%, Calcium phosphate 0.5–6%)	Infection	"Coffin lid"	Alkaline	Cystine (1–5%)	Cystinuria	Hexagonal	Acidic	2,8 dihydroxyadenine	Adenine phosphoribosyltransferase deficiency	Round, reddish brown with dark outlines and central spicules	Acidic	Drug related -sulfa -acyclovir		Needle like crystals		
Table 46.4 Normal value for urinary excretion of metabolites

	Age	Random (mg/mg)	Random (mmol/mmol)	Timed (all ages)
Calcium	0–6 months	<0.8	<0.8	<4 mg/kg per 24 h (<0.1 mmol/kg per 24 h)
	7–12 months	<0.6	<0.6	
	>2 years	<0.2	<0.2	
Oxalate	0–6 months	<0.26	<0.26	<40 mg/1.73 m^2 per 24 h (<0.5 mmol/1.73 m^2 per 24 h)
	7–24 months	<0.11	<0.11	
	2–5 years	<0.08	<0.08	
	5–14 years	<0.06	<0.06	
	>16 years	<0.32	<0.32	
Cystine	>6 months	<0.075	<0.075	<60 mg/1.73 m^2 per 24 h (<250 μmol/1.73 m^2 per 24 h)
Uric acid	<1 year	<2.2	<1.5	<815 mg/1.73 m^2 per 24 h (<486 mmol/1.73 m^2 per 24 h)
	1–3 years	<1.9	<1.3	
	3–5 years	<1.5	<1.0	
	5–10 years	<0.9	<0.6	
	>10 years	<0.6	<0.4	
Citrate[a]	0–5 years	>0.2–0.42	>0.12–0.25	>310 mg/1.73 m^2 per 24 h (>1.6 mmol/1.73 m^2 per 24 h) in girls and
	>5 years	>0.14–0.25	>0.08–0.15	>365 mg/1.73 m^2 per 24 h (>1.9 mmol/1.73 m^2 per 24 h) in boys
Magnesium	>2 years	>0.13	>0.13	>0.8 mg/kg (>0.04 mmol/kg)

[a] A range for normal random citrate values is presented in the table to account for regional variations

Table 46.5 Radiologic imaging of the urinary tract

Radiologic imaging	Advantages	Disadvantages
Ultrasonography[a] (Sensitivity 77–90% Specificity 88–94%)	Wide availability, easy to perform, no pain, no radiation, no anesthesia, can be repeated, low cost Shows stones of all compositions Shows the anatomy of the kidney and bladder Identifies associated hydronephrosis	Operator dependent Body habitus and bowel gas may affect stone visualization Can miss ureteral calculi Can miss papillary or calyceal stones, and small calculi (<5 mm) Overestimates stone size
Plain abdominal radiography (Sensitivity 45–58%)	Detects large ureteral stones not seen on ultrasonography: Detects calcium (radiodense), struvite and cystine stones (intermediate radiodensity)	Misses radiolucent stones: uric acid, xanthine and indinavir Risk of malignancy with radiation
Noncontrast computed tomography[b,c] (Sensitivity and specificity 90–100%)	Detects radiolucent and small stones Provides anatomic details	Can miss indinavir and small distal stones Risk of malignancy with radiation Potential need for sedation
Intravenous pyelogram	Indicated in medullary sponge kidney	

[a] First choice in the initial assessment
[b] Gold standard
[c] New pediatric protocols have decreased the radiation exposure by 60–90%

Although computed tomography (CT) scan without contrast is the gold standard for assessing nephrolithiasis in adults, it is used sparingly during the initial evaluation in children to minimize radiation and to avoid the need for sedation. However, low radiation dose, non-contrast CT scan protocols have been developed for pediatrics and are mainly indicated when the patient is symptomatic and stones are suspected but not seen by ultrasound. A single center study found

that a history of previous stones, vomiting, and the presence of blood on urinalysis were the strongest predictors for finding kidney stones on unenhanced CT scans [38]. Contrast agents can mask the presence of a stone and should be avoided on the initial CT scan; however, contrast may be useful in defining additional anatomical abnormalities.

Stone Analysis

If acute nephrolithiasis is suspected, patients should be asked to pass urine through a sieve to capture stones for analysis. This should continue until acute symptoms have resolved and/or passage of the stones are confirmed by repeat imaging. The composition of all recovered stone fragments should be analyzed by either infrared spectroscopy or X-ray diffraction, and components exceeding 5% should be reported. This should be done with each passage of stone since the composition may differ from the initial presentation. About two thirds of stones are composed of more than one substance. The composition of stones varies in children, although calcium oxalate is the most common [39, 40] (Table 46.3).

Differential Diagnosis

Abdominal or flank pain may be found in children with infections, such as gastroenteritis, urinary tract infections (UTI), appendicitis, ovarian torsion, intussusception, constipation, and pneumonia. UTI can concomitantly exist with nephrolithiasis. Worsening UTI or failure to improve within 24–48 h following antibiotic therapy may indicate the presence of renal stone, renal abscess, or underlying anatomic abnormalities/obstruction, and requires imaging of the urinary tract.

Gross hematuria may be caused by UTI, irritation of the meatus or perineum, trauma, and glomerular disease. Cola-colored urine, urinary sediment, and the possible presence of hypertension and/or edema indicate glomerulonephritis.

Acute Management

When a child presents with an acute stone episode, the immediate treatment goals are pain relief, nausea/vomiting control, rehydration, and treatment of associated infection if present. Nonsteroidal anti-inflammatory medications may be used with caution, provided renal function and hydration are adequate. If this is insufficient, oral or intravenous narcotics (e.g. morphine 0.3 mg/kg oral q3–4 h or 0.05 mg/kg intravenous q2–4 h) can be used for pain control, depending on oral tolerance. The preferred antiemetic agent is ondansetron due to its minimal side effects; metoclopramide hydrochloride or prochlorperazine are acceptable alternatives.

Once the diagnosis of nephrolithiasis is established, it must be determined if the patient can pass the stone spontaneously or whether surgical intervention is required. The size of the stone and its orientation are the critical determinants, with stones up to 5 mm having a high likelihood of spontaneous passage in children of all ages. With adequate pain control, uncomplicated unilateral stones causing only minimal or partial obstruction can be managed conservatively for several weeks before surgical intervention is considered. During this period, medical expulsive therapy (MET) for smaller ureteral stones has been used, especially in older children, with some success. However, the evidence to support this form of therapy in children is conflicting. There are a few randomized trials showing no efficacy in children [41] or adults [42]. In contrast, others concluded that MET is effective in pediatric patients [8, 43]. The most commonly used agent is tamsulosin, which causes relaxation of ureteral smooth muscle with inhibition of ureteral spasm and dilatation of the ureter. A prospective cohort study by Mokhless et al. demonstrated that ibuprofen and tamsulosin administered at bedtime (0.2 mg for children <4 years of age, and 0.4 mg for children >4 years of age) to children with distal ureteral stones led to significantly increased percentage of stone passage (88% vs. 64%), shorter passage time (8 vs. 14 days), and less need for analgesia (0.7 vs. 1.4 days) [44]. Tamsulosin is safe and has been approved by the US Food and Drug

Administration in pediatric patients. Alternatively, alpha blockers or calcium channel blockers can be used to facilitate the passage of ureteral stones under 10 mm in size [45]. Calcium channel blockers act by decreasing the intracellular calcium concentration, which induces relaxation of the ureteral smooth muscle. Alpha adrenergic receptors are abundant in the smooth muscle of the distal third of the ureter and ureterovesical junction and their blockage promotes relaxation of the ureteral wall.

In most cases, passage of the stone takes days or weeks and is usually managed as an outpatient, with careful medical oversight of pain control, expulsive therapy when stones are in the ureter and treatment of UTI if indicated. However, some children may need hospitalization. In general, this is restricted to those with an urgent need for upper tract decompression (nephrostomy tube or a lower tract stent), severe pain requiring intravenous analgesia, or need for intravenous antibiotic therapy for a UTI, as in urosepsis.

Evaluation for Risk of Recurrent Nephrolithiasis

Following the initial presentation and management, children with suspected or proven stones should be referred for evaluation of primary factors that might predispose to recurrence of nephrolithiasis, and provided with appropriate preventative measures. Ideally, this involves a clinic setting that can provide access to urologic expertise, genetic testing, nutritionist support and appropriate metabolic laboratory investigation. The risk of recurrent renal stones in children is high, with approximately 50% presenting with recurrent symptomatic stone within 3 years from the first episode of nephrolithiasis [46]. Those who have an identifiable metabolic abnormality are at fivefold higher risk compared to those without [23]. The rate of recurrence is also higher in those with a positive family history of stones in first-degree relatives.

Compared to adults, a predisposing cause for stone formation is found in about 2/3 of children and includes metabolic (33–95%), anatomic (8–32%) and infectious factors (2–24%), alone or in combination [47–49]. About 50% of children under 10 years of age with stone disease have an underlying metabolic condition [23] caused by a renal, enteric or endocrinologic abnormality. The chance of finding a metabolic risk factor is higher in infants, patients with a positive family history or consanguinity, and those with recurrent kidney stones [25]. The risk of CKD and end-stage kidney disease (ESKD) is doubled in recurrent stone-formers compared to non-stone formers [8].

Thus, the primary goal of the "stone work-up" in children is to identify hyperexcretion of specific solutes that are likely to drive stone formation and to characterize the urinary content of inhibitors that normally protect against precipitation of lithogenic salts. When possible, a timed 24-h urine collection should be obtained to confirm the results of initial screening with spot urine samples.

Due to day-to-day variation in diet and fluid intake, at least two initial 24-h urine collections should be done. Urine creatinine should be checked for the completeness of urine collection (>15 mg/kg/day). The timed collection should be performed without altering the child's usual fluid intake, diet or activity, in the absence of a urinary tract infection, and at least a month after the spontaneous passage of stone or surgical intervention. Results can be interpreted with respect to weight, body surface area and urine creatinine (Table 46.4). When 24-h timed urine collections are not possible, shorter collection periods or repeat spot urine specimens measuring solute to creatinine ratios are acceptable. Normal values vary by age and prandial state (Table 46.4).

Blood analyses for calcium, uric acid, parathyroid hormone (PTH) and for assessment of renal tubular function (Table 46.2) should be performed at the time of the urine evaluation. Calcium homeostasis should be assessed in detail among children with hypercalcemia or hypercalciuria. Primary hyperparathyroidism is rare in children, but suppression of PTH offers a clue to states of vitamin D excess.

A fundamental assumption underlying the management of recurrent nephrolithiasis is that

stones form when the urine is supersaturated with certain lithogenic salts (e.g. calcium oxalate, calcium phosphate). A 24-h urine identifies conditions that cause the urine to be supersaturated: (a) excessive excretion of calcium, oxalate, uric acid and cystine; (b) suboptimal excretion of citrate and magnesium; (c) unfavorable urinary factors such as pH, electrolyte concentrations. Supersaturation for calcium oxalate, calcium phosphate and uric acid are predicted by the well-established Equil2 program. Cystine saturation of the urine is established empirically by measuring the capacity of the urine to dissolve cystine crystals after 48 h. Serial determinations of supersaturation might be predictive of recurrence risk and, therefore, useful in monitoring successful interventions. Reduction of initial calcium oxalate supersaturation by 50% in stone-formers is a reasonable target. There are several publications supporting the utility of this approach in adults [50], but clinical trials in children are lacking, with the exception of cystinuria [51].

Other programs for calculating supersaturation of urine have been developed and adapted for use on personal computer platforms and smartphones [52]. A new web-based platform offers (for a fee) individual access to software that estimates supersaturation for calcium oxalate, struvite (NH_4MgPO_4-$6H_2O$), brushite ($CaHPO_4$-$2H_2O$), uric acid and cystine, using urinary parameters widely available in clinical labs.

Surveillance

Repeat renal ultrasound is needed to diagnose stone recurrence or increasing size of previous stones. The frequency of these tests depends on the presence and severity of the metabolic abnormality, the number of stones and recurrence rate. A child with a single stone and no evidence of an underlying metabolic abnormality will require less frequent monitoring than a child with multiple stones and a significant metabolic problem known to be at greater risk for recurrent nephrolithiasis (primary hyperoxaluria or cystinuria). Compliance with high fluid intake should be monitored by measuring the urine specific gravity.

In an asymptomatic child, a repeat kidney ultrasound is usually done 6 months after the initial episode. If the ultrasound shows no stone recurrence or change in residual stone size, the study can be performed yearly. Metabolic work-up is repeated 4–6 weeks after therapy has been initiated. If the metabolic abnormality was corrected, repeat studies should be done at 6 months, and then yearly. Re-evaluation is needed if metabolic abnormalities persist. A multidisciplinary approach through a combined "Stone Clinic" including nephrology, urology, and dietary services serves these children well for long-term management.

Types of Kidney Stones

Calcium-Based Stones

Isolated hypercalciuria (excretion of >4 mg calcium/kg/day) is the most common cause of stones in children (Table 46.4). Early work in adults by Coe and Pak led to the suggestion that patients with calcium nephrolithiasis could be subdivided into those with "renal hypercalciuria" (decreased calcium reabsorption in the renal tubules), those with "absorptive hypercalciuria" (excessive vitamin D-dependent hyperabsorption), and those with "resorptive hypercalciuria" (parathyroid hormone-driven resorption of calcium from bone). While these classifications refer to important mechanisms in calcium homeostasis, it has become increasingly clear that the majority of patients don't fit easily into one category, and the stone work-up has shifted to other approaches.

Urinary stones develop about three times more often in adults with a family history of nephrolithiasis [53]. Twin studies indicate that the heritability of stone disease ranges from 46% to 63% [53, 54]. In a family study of children with hypercalciuria, Goldfarb et al. noted evidence of heritability in more than 50% [13]. However, it has been difficult to identify a primary genetic cause in most patients with calcium stones. Large genome-wide association studies in adults

suggest that the heritable calcium stone trait is complex, influenced by multiple common variants of genes implicated in rare monogenic forms of nephrolithiasis. Among 3773 adult calcium stone-formers from Denmark and Iceland, homozygosity for a single nucleotide polymorphism (SNP) close to the claudin-14 gene conferred a 1.64 RR of developing stones among Icelanders [55], but could not be confirmed in the Danish group [56]. In large Japanese [57], Chinese [58] and British/Japanese cohorts, multiple SNPs were identified that conferred modest increased risk of nephrolithiasis (RR usually about 1.2), but there was little overlap between studies. Thus, the genetic factors predisposing to calcium nephrolithiasis in humans appear to be complex and remain elusive.

Increasingly, there is a focus on urinary factors that influence the saturation of lithogenic calcium salts. One major risk factor is urinary citrate excretion [7]. Hypocitraturia is defined in children as a urinary citrate excretion rate <310 mg/1.73 m^2/day in girls and 365 mg/1.73 m^2/day in boys, or less than 400 mg/g of creatinine in a 24-h urine collection (Table 46.4). Others have suggested even lower limit values (250 mg/1.73 m^2/day in girls and 180 mg/1.73 m^2/day in boys) due to decreased urinary citrate excretion per kg body weight with increasing age. Citrate is best interpreted in a 24-h urine collection because urinary citrate excretion appears to be influenced by diet and prandial state. It should not be measured during an active UTI because it may be artifactually low. Children have more citrate excretion than adults. Citrate combines with calcium in the tubular lumen to form a soluble complex resulting in less free calcium available to combine with oxalate. Moreover, citrate exerts a direct or indirect inhibitory effect on crystal aggregation, growth, and adherence to renal tubular cells. The indirect effect is due to enhancement of the inhibitory effect of Tamm-Horsfall protein on stone formation. Hypocitraturia is seen in patients with metabolic acidosis and hypokalemia, as well as in those with complete form of distal renal tubular acidosis (RTA).

Oral citrate supplementation is an effective strategy for treating adults with calcium-based kidney stones [59]. Two prospective studies in children showed that oral potassium citrate reduces the risk of stone recurrence by about 50% [60, 61]. Doses typically range from 0.5 to 1.0 mEq/kg/day in hypercalciuric patients; doses up to 2–3 mEq/kg/day may be required in children with dRTA. It is available in tablet and oral solution; a palatable, flavored form is commercially available.

The rationale for this approach is based on the well-established affinity of calcium for citrate (vs. oxalate or phosphate) and the relative solubility of calcium citrate. Individuals excreting suboptimal urinary citrate have increased risk of nephrolithiasis [62]. Srivastava et al. showed that hypercalciuric children with stones have higher calcium/citrate ratios (0.65 mg/mg) in urine than hypercalciuric non-stone formers (0.23 mg/mg) or controls (0.17 mg/mg) [63]. The authors suggested that calcium/citrate ratios of <0.33 mg/mg might decrease stone risk.

However, the decision to introduce citrate therapy for hypercalciuric children is sometimes complicated. There is theoretic concern about the potentially deleterious effect of citrate in raising urinary pH. Shen et al. found that oral supplements with potassium citrate (2 mEq/kg/day) for 5 days had marginal effect on urinary citrate levels, but did increase urinary pH [64]. An interesting resolution to this conundrum was proposed by Rodgers et al. who reported that the therapeutic effect of oral citrate may be due to formation of a pH-dependent soluble calcium/citrate/phosphate complex, and that clinical benefit is derived from the increase in urine pH, rather than from a change in citrate concentration [65].

Another well-established treatment for calcium stones is the use of a thiazide diuretic, sometimes with a potassium-sparing diuretic. The rationale for this therapy is to generate a mild volume deficit, which stimulates paracellular calcium reabsorption in the thick ascending limb of the loop of Henle. A thiazide diuretic consistently reduces urine calcium level in children [61, 66–68]. The RR of recurrent stones (3.3), episodes of hematuria (2.5) and osteopenia (3.0) are increased in those with hypercalciuria [68]. Interestingly, thiazide diuretics reduce stone

recurrence even when the pre-treatment urinary calcium is within the normal range [67, 69]. However, while hydrochlorothiazide (0.5 mg/kg bid) reliably decreases urinary calcium, long-term adherence is reported in only one third of patients and hypercalciuria recurs in 44% [68]. Furthermore, a thiazide diuretic may induce hypokalemia, requiring oral potassium supplements or the addition of a potassium-sparing diuretic.

Uric Acid Stones

The oldest known urinary tract stone was a bladder stone found in a 7000 year-old mummy in upper Egypt; the stone had a mixed composition, including uric acid [70]. About 11.7% and 7% of stones in adult males and females, respectively contain uric acid and it may be the dominant component, but it is often mixed with calcium salts [71]. In middle eastern regions, uric acid accounts for up to one third of stones [72], but only 1% in India [73].

On a typical Western diet, humans excrete about 10 mg/kg/day of uric acid, 50% derived from turnover of nucleic acids and 50% from the diet [70]. However, the dietary component can be doubled on diets containing high amounts of meat, fish and certain vegetables (e.g. asparagus, mushrooms) [70]. Since the pKa of uric acid is about 5.3, it tends to precipitate in acidic urine to form identifiable geometric crystals (Table 46.3). However, uric acid crystals easily dissolve at the higher urine pHs during the normal "alkaline tide" each day. Thus, it has been proposed that uric stones may form in those with sustained acidic urine, perhaps among individuals with blunted renal ammoniagenesis.

In children, pure uric acid stones are rare, and are seen mostly in settings where there is overproduction of uric acid such as tumor lysis syndrome, lymphoproliferative and myeloproliferative disorders, and genetic disorders (Lesch-Nyhan syndrome and glycogen storage disorders). However, mixed composition stones containing some uric acid are seen in 2–8% of children with nephrolithiasis and hyperuricosuria (>815 mg/1.73 m^2/day) (Table 46.4). Uric acid excretion is highest in infancy; pinkish-brown uric acid crystals may precipitate in the diaper and are often mistaken for blood, but are not associated with stone formation.

Children with uric acid-containing stones can be managed with oral citrate (0.5–1.0 mEq/day in divided doses) to maintain urine pH above 6.5, while also offsetting lithogenic calcium salt supersaturation. Sometimes an extra evening dose is required to manage overnight aciduria. In children with malignancy, use of a xanthine oxidase inhibitor (e.g. allopurinol or febuxostat) and recombinant rasburicase are remarkably effective, and have largely eliminated elevated uric acid as a cause of complications in tumour lysis syndrome.

Monogenic Forms of Nephrolithiasis

In a study of children (age at first stone <18 years) consecutively referred to a kidney stone clinic, patients were screened for 30 genetic disorders predisposing to kidney stones. In 20.8% of these cases, a causative mutant gene was identified. Thus, the work-up of pediatric patients presenting with urinary tract stones should include a focused effort to diagnose monogenic forms of nephrolithiasis.

Primary hyperoxalurias (incidence 1:120,000) are recessive, hereditary errors of glyoxylate metabolism, leading to overproduction and excessive urinary excretion of oxalate [74]. Hyperoxaluria is defined as a urinary oxalate excretion rate that is greater than 40 mg/1.73 m^2 per 24 h (Table 46.4), and is found in about 10–20% of children. The oxalate to creatinine ratio on a spot urine sample can also be used, but the normal values are age- and assay-dependent. Primary hyperoxaluria, type 1 (PH1), caused by biallelic mutations of *AGXT*, is the most common (80%), and about one third of these are responsive to oral pyridoxine (5–10 mg/kg/day). Excess oxalate in urine drives calcium oxylate crystallization within tubules, while elevated plasma oxalate causes tissue deposition in many tissues, including the renal parenchyma (nephrocalcino-

sis), leading to progressive renal insufficiency [75]. About one quarter of PH1 patients develop ESKD by 20 years of age. Most develop kidney stones in early childhood, and sometimes present with failure to thrive and stones in the first year of life. Those with milder mutations may be relatively asymptomatic until middle age. PH1 stones have a pale, yellowish surface, unlike the darker surface of those with idiopathic calcium oxalate stones.

PH2 (biallelic mutations of *GHPRH*) constitutes about 10% of the primary hyperoxalurias and is milder than PH1. PH2 patients usually excrete excess oxalate and glycerate in the urine [76]. PH3 (about 12% of hyperoxalurias), due to biallelic mutations of *HOGA*1, results from mutations of a mitochondrial enzyme that normally generates glyoxylate from 4-hydroxy-2-oxoglutarate (HOG). Although the pathomechanism is not entirely understood, PH3 urine has excessive oxalate and HOG [77].

Screening for the hyperoxalurias should be performed in all children with early onset nephrolithiasis. Normal urine oxalate/creatinine ratio ranges are age dependent (Table 46.4). Genetic diagnosis of primary hyperoxalurias involves mutation screening for the panel of *AGXT*, *GRHPR* and *HOAG1*.

Cystinuria is caused by mutations of the recessively inherited *SLC3A1* or the incompletely dominant *SLC7A9*, found in about 5% of children with renal calculi. These genes encode the two protein partners of the luminal reabsorptive transport mechanism for cystine and the dibasic amino acids in the renal proximal convoluted tubule. Cystinuria genotype can often be inferred from the level of urinary cystine in parents of affected children, since *SLC3A1* is recessive (urine cystine is normal in the heterozygote), whereas loss of one *SLC7A9* allele partially compromises cystine reabsorption (heterozygotes have moderate cystinuria).

Children with biallelic mutations of *SLC3A1* or *SLC7A9* excrete cystine in the range of 3000–5000 μmol half-cystine/g creatinine vs. normal levels of <150 μmol/g creatinine. Over 24 h, normal cystine excretion is <60 mg half-cystine/1.73 m^2/day. Microscopic hexagonal cystine crystals are pathognomonic. Crystal volume is thought to correlate with stone risk and commonly give rise to asymptomatic bladder debris visible on ultrasound. In one cohort, 1.1% required dialysis at a mean age of 35 years and 15.6% had an estimated glomerular filtration rate (eGFR) <60 mL/min/1.73 m^2 [78].

During the first 1–2 years, children who have heterozygous mutations in *SLC7A9* excrete cystine in the homozygous range, but with tubular maturation and elongation over the first 2 years, it decreases to an intermediate level, varying between 300 and 1500 μmol half-cystine/g creatinine. Although their urine cystine levels are usually below the threshold of solubility, *SLC7A9* heterozygotes may occasionally form stones in childhood during periods of dehydration. Halbritter et al. found that *SLC7A9* heterozygotes were the most common cause of nephrolithiasis among 101 pediatric stone-formers recruited from a stone clinic [79]; adult heterozygotes may comprise nearly half of the cystinuria patients in a stone clinic.

Pre-symptomatic children who excrete cystine in the stone-forming range (>1200 μmol/L) should be monitored carefully by annual ultrasonography and serial urine cystine/L measurements [80], but interventions are usually restricted to increased fluid intake (2–2.5 L/m^2/day) and avoidance of excessive salt intake. Among stone formers, alkalinization of the urine is usually initiated (particularly overnight), and some clinicians recommend low salt intake and limited animal protein diet. With frequent or obstructive stones, tiopronin (10–15 mg/kg/day in divided doses), which reduces free cystine, should be introduced. Malieckal et al. have shown in adults that a dose of 1 g/day reduces excretion of free cystine and increases cystine capacity of urine from −39 to +130 mg cystine/L [81].

Distal RTA is caused by dysfunction of the transport mechanism in alpha-intercalated cells of the cortical collecting tubule that pumps hydrogen ions (H^+) into the lumen and normally allows excretion of the daily metabolic acid load (about 2 mEq/kg/day). In adults, dRTA is seen with various autoimmune diseases (e.g. Sjögren

syndrome and systemic lupus erythematosus) and acquired tubular injury from drugs (e.g. lithium). In children, however, dRTA is usually the result of mutations in genes encoding subunits of the "vacuolar type" ATPase (*ATP6V1B1*, *ATP6V0A4*, *ATP6V1C2*) that secretes H^+ out of the cell across the apical membrane, the basolateral anion exchanger (*SLC4A1*) that pumps bicarbonate across the basolateral cell surface or the transcription factors that regulate the process (*FOX1*, *WDR72*) [31]. Mutations of *ATP6V1B1* and *FOX1* are associated with early deafness, while *ATP6V0A4* mutations cause later onset deafness. Heterozygous mutations of the *ATP6V1B1* [82] and *ATP6V0A4* have been linked to "incomplete" (mild) dRTA and kidney stones in adults, but this has not been described in children with nephrolithiasis.

dRTA presents in infancy, with normal anion gap, hyperchloremic metabolic acidosis and failure to thrive. Urine pH is inappropriately high (6–8) and urinary anion gap is inappropriately positive in the setting of a metabolic acidosis (reflecting absence of urinary $NH4^+$). Sustained acidosis causes dissolution of bone mineral and hypercalciuria. The acidosis also causes consumption of citrate by the mitochondrial citric acid cycle, so that urinary citrate levels are low. Thus, as the tubular fluid is progressively concentrated in the collecting ducts, when pH is high and citrate levels are low, urine becomes supersaturated with lithogenic calcium salts, particularly calcium phosphate (brushite). Brushite crystals are unusually large and may completely obstruct individual renal papillae, accounting for the characteristic medullary nephrocalcinosis on ultrasound. Crystals arriving in the renal calyces may coalesce to produce stones.

Given the pathogenesis of calcium phosphate stones in dRTA, management involves correction of acidosis, hypokalemia and hypocitraturia with potassium citrate 1–2 mEq/kg/day in 3–4 divided doses. In early infancy, slightly higher doses (2–3 mEq/kg/day) may be needed. In children with mild dRTA and erythrocyte abnormalities caused by heterozygous mutations of *SLC4A1*, lower doses of potassium citrate (0.5–1.5 mEq/kg/day) are needed.

Dent Disease is an X-linked recessive form of nephrocalcinosis and nephrolithiasis caused by mutations of *CLCN5* (Dent1, about 60% of cases) or *OCRL* (Dent2, about 15–20% of cases), causing endolysosome dysfunction in the kidney [83, 84]. Progressive proximal tubule damage leads to a partial Fanconi syndrome, with low molecular weight proteinuria in affected males, with some developing rickets. Hypercalciuria and nephrocalcinosis are common (99%) in young males, but only about 25% develop stones (calcium oxalate and calcium phosphate) in childhood [85]. Urinary oxalate and citrate are usually within the normal range [85]. About half develop ESKD between the third and fifth decades of life. Females may be mildly affected, but kidney stone and progressive renal insufficiency are uncommon.

The optimal treatment of Dent disease is unclear but, since hypercalciuria, nephrocalcinosis and nephrolithiasis are prominent early features, Raja et al. tested a combination of chlorthalidone and amiloride to treat a cohort of Dent disease patients. They found that the diuretics reduced hypercalciuria and decreased calcium phosphate and calcium oxalate supersaturation by 35% and 25%, respectively [86]. However, it is unclear whether this strategy can slow the progressive loss of GFR [86].

Bartter Syndrome, a recessively inherited disorder, is caused by mutations in genes (*SLC12A1*, *KCNJ1*, *ROMK*, *CLCNKB*, *BSND*) that cause dysfunction of the apical transport mechanism for sodium, potassium and chloride in the thick ascending limb of the loop of Henle (TALH). Massive salt and water loss may cause polyhydramnios, hyponatremia and failure to thrive in infancy and hyperreninemic hypokalemic alkalosis due to compensatory mechanisms in the distal nephron. Since TALH dysfunction causes hypercalciuria by blocking paracellular reabsorption of calcium, Bartter syndrome patients may develop stones in childhood, but this is rare. Halbritter found no mutant Bartter genes in their screen of 106 serial children with nephrolithiasis recruited from specialized stone clinics [79]. However, nephrocalcinosis is common.

Adenine Phosphoribosyl Transferase Deficiency is due to biallelic mutations of *APRT*, which causes recurrent stones from high urinary levels of 2,8 dihydroxy adenine (DHA) and progressive renal insufficiency [87]. The stones are radiolucent and urinary crystals have a Maltese cross pattern [88]. Excessive DHA production is treated with xanthine oxidase inhibitors (allopurinol and febuxostat) and these therapies can reduce new stone formation [89]. Patients with mistargeting mutations are often responsive to pyridoxal phosphate (10 mg/kg/day).

Idiopathic Infantile Hypercalcemia is a syndrome of 1,25-dihydroxy vitamin D excess caused by biallelic mutations of *CYP24A1* (encoding a key enzyme of the renal vitamin D degradative pathway) or *SLC34A1* (encoding the sodium-phosphate co-transporter, NaPi2). Infants with *CYP24A1 mutations* present with hypercalcemia due to 1,25-dihydroxy vitamin D excess, failure to thrive, episodes of vomiting and dehydration and sterile pyuria. Initial treatment usually involves strategies to limit intestinal calcium absorption such as prednisone (0.5–2.0 mg/kg/day) to suppress vitamin D receptor expression in the small intestine, oral phosphate supplements (25–50 mg phosphate/kg/day) to bind dietary calcium. Oral supplements of vitamin D should be discontinued. As a longer-term strategy, bisphosphonates can be used to limit the flux of calcium from bone. Infants usually show marked clinical improvement and normal weight gain once serum calcium is normalized. Calcium stone formation presumably correlates with normalization of urinary calcium excretion, but this has not been formally studied. Interestingly, the need for medical therapy tends to diminish in the first years of life, although the mechanism is unknown.

Hereditary hypophosphatemic rickets with hypercalciuria (HHRH) is caused by biallelic mutations of *SLC34A3*, which encodes the sodium-phosphate co-transporter NPT2c in the renal proximal tubule. Infants present with metabolic bone disease resembling X-linked hypophosphatemic rickets (hypophosphatemia, bowing of legs) but with higher levels of 1,25-dihydroxy vitamin D. The latter drives hyperabsorption of dietary calcium, suppression of PTH and hypercalciuria. About one third of these patients develop calcium phosphate (brushite) stones [90]. Treatment usually consists of oral phosphate supplements to repair bone (without oral vitamin D as would be given in X-linked hypophosphatemic rickets) but the long-term effect on nephrolithiasis has not been studied.

Stones and Structural Abnormalities of the Urinary Tract

Conditions associated with urinary stasis cause crystal and stone formation, and include primary megaureter, polymegacalicosis, medullary sponge disease, autosomal dominant polycystic kidney disease, ureteropelvic junction obstruction, ureterocele, horseshoe kidney, bladder exstrophy, neuropathic bladder and surgically reconstructed or augmented bladders. Polymegacalicosis is a congenital abnormality with a higher number (more than 12) and larger in size calyces, and can be isolated or part of a syndrome.

Stones and Urinary Tract Infection

UTIs occur in about 1/4 of children with nephrolithiasis and may be either the cause or the effect of a kidney stone. The distinction between the two is important for further management, but can be difficult to distinguish, but the stone analysis may provide helpful clues. Usually, the stone associated with infection has a mixed composition, with the surface made of struvite and the core containing calcium-oxalate. In contrast, the stone induced by infection (so-called infectious or triple-phosphate stone) is entirely made of struvite (magnesium ammonium phosphate). The infectious stone is commonly seen in boys younger than 5 years of age with obstructive uropathy (e.g. ureteropelvic junction obstruction, urethral valves, primary megaureter). Urease

produced by bacteria such as Proteus, Klebsiella, Pseudomonas, and enterococci metabolizes urea into ammonium and bicarbonate. This creates a favorable milieu for struvite stones, which can further grow into the renal calyces, and produce "staghorn" calculi with high morbidity. It is important to note that patients with struvite stones and negative urine culture should be evaluated for Ureaplasma urealyticum infection. Other patients prone to struvite stones are those with a neurogenic bladder.

An important consideration in children with urinary tract stones and urinary tract infections is that organisms within the stone may produce a biofilm that excludes certain antibiotics. Therapeutic options include a protracted course of an antibiotic, an antibiotic with good biofilm penetration and aggressive efforts to remove the stone.

Drug-Induced Nephrolithiasis

Drug-induced nephrolithiasis is uncommon in children, and causes 1–2% of stones, but its recognition is important for optimal management. Besides the specific drug, other contributory risk factors include higher drug dose, prolonged duration of treatment, poor hydration, the urine pH (which will affect the drug solubility), and the age of the patient (younger patients are at higher risk).

The responsible drugs are classified based on the mechanism involved in stone formation. The first category involves poorly soluble drugs that directly or through their metabolites induce urine supersaturation and increase the risk of crystallization. More common examples are triamterene (used in the treatment of Liddle syndrome), indinavir (used in HIV treatment) and antibacterial drugs, including third-generation cephalosporins (such as ceftriaxone and cefotaxime), sulfa drugs, nitrofurantoin, broad-spectrum penicillins, and fluoroquinolones. Usually these stones are radiolucent and therefore cannot be seen on plain X-rays unless they also contain calcium. The second category are drugs that cause metabolic changes in the urine, such as furosemide, acetazolamide, topiramate, zonisamide and allopurinol. Furosemide causes inhibition of calcium reabsorption and hence hypercalciuria, while acetazolamide inhibits the proximal tubular reabsorption of bicarbonate leading to metabolic acidosis, alkaline urine and hypocitraturia. Anticonvulsants such as topiramate and zonisamide have carbonic anhydrase inhibitory activity causing acidosis that leads to bone resorption and hypercalciuria, as well as hypocitraturia. Allopurinol increases urinary excretion of xanthine, which has low urinary solubility (Fig. 46.2).

Intoxication with ethylene glycol following accidental or intentional ingestion of antifreeze leads to excessive production of oxalic acid causing calcium oxalate deposition in the kidneys and resulting in acute renal failure. Other substances reported to cause similar problems include xylitol (a constituent of parenteral nutrition), methoxyflurane (anesthetic agent), ascorbic acid, piridoxilate, and food high in oxalate (carambola or start fruit, sorrel and rhubarb).

Specific Pediatric Populations at Risk for Nephrolithiasis

Premature and low birth weight infants have an increased risk for nephrolithiasis and nephrocalcinosis for several reasons: metabolic disturbances related to parenteral nutrition (hypercalciuria and hyperoxaluria), use of loop diuretic (e.g. furosemide) and nephrotoxic drugs [25], and renal tubular immaturity causing changes in urine composition. About half of these patients show spontaneous resolution of nephrocalcinosis within several years, although a few patients may have persistent hypercalciuria.

Inflammatory bowel disease and other diseases of the gastrointestinal tract associated with malabsorption can cause metabolic disturbances leading to stone formation. These patients can develop hyperoxaluria (due to increased enteric

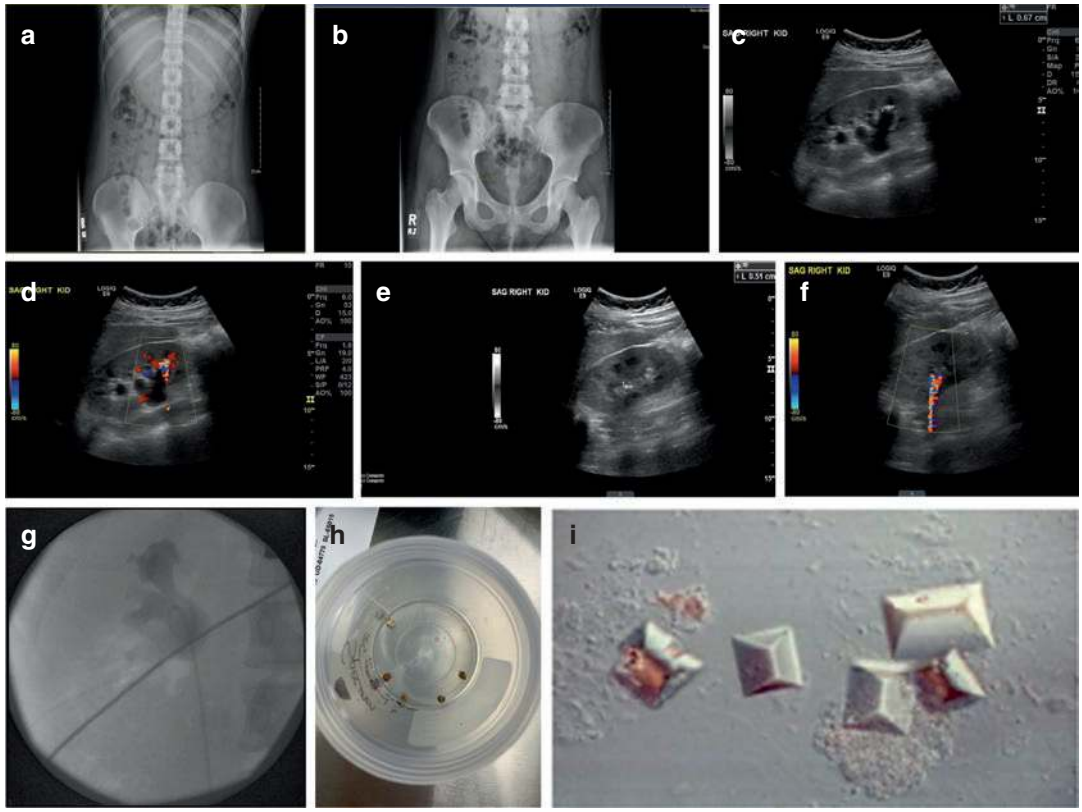

Fig. 46.2 Plain X-ray in an 18-year-old girl showing a 5 mm calcific density overlying the mid to lower pole of the right kidney consistent with calculus (**a**), and a 4 mm calcific density in the pelvis on the right side presumably in the distal ureter or bladder (**b**). Renal ultrasound showed moderate hydronephrosis of the right collecting system (**c**) and a 0.67 cm in the lower pole (**c**). Color ultrasound demonstrated acoustic shadowing behind the stone, creating the "twinkle artifact" (**d**). An additional stone was noted in the mid-polar region of the right kidney (**e**, **f**). Despite right hydronephrosis, no ureteral stones were detected by ultrasound. However, cystoscopy confirmed that there was a right obstructing ureterovesical junction stone and this required ureteral stent placement (**g**). Retrieved stones were composed of 80% calcium phosphate and 20% calcium oxalate (**h**). Urinalysis showed triple phosphate crystals (**i**). (**a**) A 5 mm calcific density overlying the mid to lower pole of the right kidney consistent with calculus (arrow). (**b**) A 4 mm calcific density in the pelvis on the right side presumably in the distal ureter or bladder (arrow). (**c**) Stone measuring 0.67 cm in the lower pole of the right kidney and right hydronephrosis. (**d**) Acoustic shadowing behind the stone creating the "twinkle artifact". (**e**) Stone measuring 0.51 cm in the midpole of the right kidney. (**f**) Acoustic shadowing behind the stone creating the "twinkle artifact." (**g**) Cystoscopy demonstrating placement of a right ureteral stent with its proximal pigtail in the region of the right renal pelvis, and the injection of contrast into a dilated right renal collecting system. (**h**) Macroscopic appearance of the surgically removed stones that showed mixed calcium phosphate and calcium oxalate composition. (**i**) Triple phosphate crystals on contrast microscopy (160× magnification)

absorption of oxalate), decreased urine citrate and hypomagnesuria (due to stool loses of bicarbonate and magnesium), hyperuricosuria (due to increased cell turnover), and low urinary volume induced by diarrhea. Patients with cystic fibrosis can develop calcium oxalate nephrolithiasis and nephrocalcinosis. Uric acid stones may also form due to acidic urine.

Patients with neurological disease represent another category at risk for renal stones. Risk factors in this population include reduced fluid intake, medications that predispose to stones (anticonvulsants), ketogenic diet used for the treatment of seizures, and decreased or absent ambulation.

Obesity has been associated with lower urine pH and volume, and increased urinary excretion

of uric acid, oxalate, sodium and phosphate, indicating that these children may be at higher risk for renal stones in general and uric acid stones in particular. Additionally, insulin resistance causes impaired renal ammonia production. While some studies found an association between body mass index and pediatric nephrolithiasis, others believe that additional lithogenic risk factors are necessary in order to develop a stone [5, 11, 91].

Management

Dietary Considerations

High intake of fluid, vegetables and fruit, and salt restriction should be recommended in all patients with nephrolithiasis regardless of cause [92]. Aggressive fluid intake at 1.5 times "maintenance" is aimed to prevent tubular precipitation of renal stone promoters. Targeted fluid goal can be calculated using either body surface area (minimum 2 L/m^2) or desired age-related daily urinary volume: infants ≥750 mL; children below 5 years of age ≥1000 mL; children 5–10 years of age ≥1500 mL; children >10 years of age ≥2000 mL. Water should be encouraged because other beverages may contribute to increased calorie intake, an undesired effect in overweight children. Additionally, the fructose found in sugary drinks could further enhance the stone risk by increasing urinary excretion of calcium and oxalate.

High intake of fruit and vegetables is desirable in all patients because they represent a good source of potassium (which facilitates urinary citrate excretion) and phytates (which increase calcium salt solubility). Sodium should be restricted to <3 mEq/kg/day. Patients should be advised to avoid adding salt or sodium-rich seasoning to food during preparation or consumption. Families should be educated to read food labels, and to choose food with low sodium High-salt foods such as processed and canned food, fast food, pickles and olives, salt crackers and pizza should be avoided.

Restriction of calcium and protein intake is not recommended in children because they are both needed for growth and bone health, and should be consumed at 100% of the daily allowance. Moreover, calcium binds to free oxalate in the digestive tract and prevents hyperoxaluria. If not consumed with meals, calcium supplements may increase the risk of calcium oxalate stones. Vitamin D should be monitored and supplemented if low.

Urinary alkalinization to achieve a pH >7.0 can be achieved with oral potassium citrate or high lemon extract intake ("Lemon Protocol") and is useful in patients with dRTA, hypercalciuria, hyperoxaluria, hyperuricosuria, hypocitraturia and cystinuria. This can be achieved with a diet rich in whole grains and with cranberry extract. However, high intake of lemon or cranberry may not be well tolerated by children leading to non-compliance.

The renal dietitian has a key role in identifying the nutritive risk factors for nephrolithiasis, which is important for both treatment and prevention of stone recurrence. Patients should be asked to complete a dietary diary at the same time as the 24-h urine collection. The diary should include the type and amount of each consumed food and drink. Disease-specific dietary considerations are addressed in Table 46.6.

Surgical Treatment

Surgical management is indicated for larger, obstructing and infected stones, and in those who develop sepsis, acute kidney injury and have pain refractory to analgesics. A retrospective pediatric study of 129 patients found it to be extremely rare for stones >5 mm to pass spontaneously [23]. Despite revolutionary advances in pediatric endourological techniques and the development of small endoscopic instruments such as Miniperc and Microperc, surgical management of stones continues to pose technical challenges and requires a skilled pediatric urologist. A shift in the surgical approach has been noted in recent years. While the majority of stones were treated by open surgery in the past, now this is mainly reserved for patients with

Table 46.6 Dietary and pharmacologic intervention in pediatric nephrolithiasis

Condition	Dietary	Pharmacologic
Hypercalciuria	• High fluid intake • Restricted sodium • High potassium diet • RDA for calcium intake • Moderate animal protein • High fiber and low in oxalate	• Hydrochlorothiazide (1–2 mg/kg per day, older children 25–100 mg/day)-may need potassium supplementation if hypokalemia occurs • Potassium citrate in dRTA (2–4 mEq/kg/day, older children 30–90 mEq/day)
Hypocitraturia	• High fluid intake • RDA for animal protein intake • High lemon intake • High in fruit and vegetables	• Potassium citrate (2–4 mEq/kg/day, older children 30–90 mEq/day)
Hyperoxaluria	• Very high fluid intake (>3 L/1.73/m^2/day) • Moderate oxalate restriction (avoid spinach, nuts) • High magnesium and potassium • Low-fat diet • Avoid excessive vitamin C • RDA for calcium intake	• Potassium citrate (2–4 mEq/kg/day, older children 30–90 mEq/day) • Pyridoxine (8–10 mg/kg per day) for primary hyperoxaluria • Neutral phosphate (25–30 mg/kg/day of elemental phosphate divided into 3–4 doses) • Magnesium
Hyperuricosuria	• High fluid intake • RDA for animal protein intake • Restricted sodium • Avoid red meats	• Potassium citrate (2–4 mEq/kg/day, older children 30–90 mEq/day) • Allopurinol (4–10 mg/kg/day, older children 300 mg per day)[a]
Cystinuria	• Very high fluid intake (day and night) • Low protein diet (avoid excessive consumption of eggs, fish, meat, cheese)	• Potassium citrate (2–4 mEq/kg/day, older children 30–90 mEq/day)[b] • Alpha-mercapto-propionyl-glycine (Thiola) (10–15 mg/kg/day) • D-Penicillamine (30 mg/kg/day divided in 4 doses) • Captopril (0.5–1.5 mg/kg/day divided in 4 doses)

Abbreviations: *RDA* recommended daily allowance, *dRTA* distal renal tubular acidosis
[a] Reserved for children with a known disorder of uric acid metabolism
[b] Dose targeted to achieve a urine pH equal to or above 7.0

associated congenital renal anomalies requiring anatomical repair combined with stone removal (such as ureteropelvic or ureterovesical junction obstruction), for infected and staghorn stones, and for patients with previous multiple abdominal surgeries (augmented bladder with large bladder calculus).

Various minimally invasive surgery (MIS) techniques have been developed and are increasingly being used. These include extracorporeal shock wave lithotripsy (ESWL), ureteroscopy (URS), percutaneous nephrolithotomy (PCNL), and laparoscopic and robotic surgery (pyelolithotomy and nephrolithotomy). Their specific indications, advantages and complications are presented in Table 46.7.

MIS allows faster recovery and less pain than open surgery, but has an increased risk for the need for repeated procedures.

The choice of surgical intervention depends on the child's age and body habitus, stone characteristics (composition, size, and location), number of calculi (single vs. multiple), presence of obstruction or infection, the anatomy of the urinary tract, associated conditions (bladder dysfunction), patient or family preference, and the surgeon's experience and skills. Careful patient selection for the best choice of MIS ensures a better outcome for stone treatment and renal preservation as well as increased safety. Complete stone clearance is crucial for the prevention of stone recurrence, known to be high in children [8, 93, 94]. The remaining stone fragments can facilitate bacteria growth and become a nidus for a new struvite stone. Each MIS technique can cause gross hematuria, UTI or urosepsis, renal subcapsular hematoma, renal parenchymal injuries and injury to surrounding structures.

Table 46.7 Surgical management of pediatric nephrolithiasis

Indications and advantages	Specific complications
Extracorporeal shock wave lithotripsy First line treatment of small renal and proximal ureteral stones<1.5 cm Non-invasive outpatient approach High safety, minimal morbidity Overall success range 81–96%	Ureteric obstruction with stone fragments causing pain Debate on the long-term effect on the kidney development
Ureteroscopy/retrograde intrarenal surgery Best choice for stones located in the lower pole calices (<1.5–2 cm) and for mid- or distal ureteral stones (<1 cm) Overall success rate 47–100% Good visualization due to their fiber optic and video systems Wide range in size scopes 4.5–12 Fr, allowing use in children of all ages and sizes The stone can be directly extracted (using basket or grasping forceps), or can be fragmented (by laser or electrohydraulic or ultrasonic probes)	Shorter operative time and in-hospital stay due to less invasive approach Ureteral injury, which may be prevented by a double stent placement for 2–3 weeks before the treatment to induce passive ureteral dilatation
Percutaneous nephrolithotomy Kidney stones >1.5 cm Staghorn stones Overall success range 67–100%	Longer operative time and in-hospital stay due to more invasive approach Hemorrhage (0.4–23.9% cases) (can be severe requiring blood transfusion) Can be difficult in patients with obesity, hemorrhagic diathesis and renal tumors Renal pelvis perforation
Laparoscopic and robotic surgery (pyelolithotomy and nephrolithotomy) Hard stones difficult to fragment (staghorn calculi, stone in calyceal diverticulum) When simultaneous reconstruction and repair is needed (concurrent ureteropelvic junction obstruction) Stones in ectopic kidney Failed previous endourological procedures; stones containing gas Excellent clearance rate up to 96% due to complete stone removal without fragmentation Reduced need for repeat procedures It can be done retroperitoneally Improving suturing and reconstruction	Shorter operative time and in-hospital stay due to less invasive approach Lower rate of bleeding and sepsis

Extracorporeal Shock Wave Lithotripsy

ESWL is usually successful in children and is becoming the first-line intervention in many centers. The likelihood of success depends on stone size (lower with larger stones), stone location (poorer with calyceal stones located in the lower pole compared to those located in the upper and mid-pole), stone composition (lower with struvite, cystine and calcium oxalate monohydrate), and the number of previous ESWL sessions. Struvite fragments in particular are friable facilitating stone fragment retention. Decreased urine output in CKD may also compromise the stone clearance. Success rates are lower in children with abnormal anatomy of the urinary tract or obesity.

During the procedure, it is important that the shock waves pass into the body and hit the stone with minimal loss of energy. New generation instruments that use a smaller focal area and provide less energy have been developed. The shock waves fragment the stones and the patient passes fragments spontaneously, although some need a stent placed at the time of ESWL. An ESWL method called ramping decreases the risk of complications. It starts with low energy shockwaves, followed by a stepwise increase in the power. This allows the surgeon to find the lowest energy level at which a stone starts to disintegrate, therefore avoiding overtreatment and decreasing the risk of tissue injury and bleeding. Repeated ESWL may be needed for stones >1.5 cm, and nomograms and scoring systems

for prediction of outcomes after ESWL have been developed [93, 95, 96]. Younger children require the insertion of a ureteral stent. One major concern with ESWL use is the potential for damaging the developing kidney. In a small study of 16 children, no significant changes in serum creatinine and kidney morphology were found on ultrasound imaging post ESWL. Subsequent studies showed no significant impairment in kidney growth, loss of kidney function or the development of parenchymal scarring or hypertension after ESWL/PCNL. However, transient enzymuria and elevated urinary β2-microglobulin indicating proximal renal tubular dysfunction can be found post ESWL, but resolves 14 days following the procedure [46] (Fig. 46.3).

Stones >1.5–2 cm are not usually amenable to ESWL, and will require other surgical techniques including PCNL, URS/retrograde intrarenal surgery (RIS) and robotic-assisted pyelolithotomy (RPL) [97]. Nephrectomy may be a consideration if renal function is markedly decreased, in association with a large stone burden and recurrent UTIs. Infected stones require careful antibiotic treatment because bacteria may be released during stone fragmentation following any surgical procedure. Bladder stones are managed endoscopically via the urethra (per-urethral cystolithotripsy), or via percutaneous cystolithotripsy. Open surgery may be needed in patients with reconstructed urinary bladders (Fig. 46.4).

Fig. 46.3 Real time gray scale ultrasound of the urinary bladder in a 20-year-old male with history of neurogenic bladder. Echogenic debris is noted within the bladder. A shadowing calculus that measures approximately 0.7 cm is noted within the dependent portion of the urinary bladder (arrow)

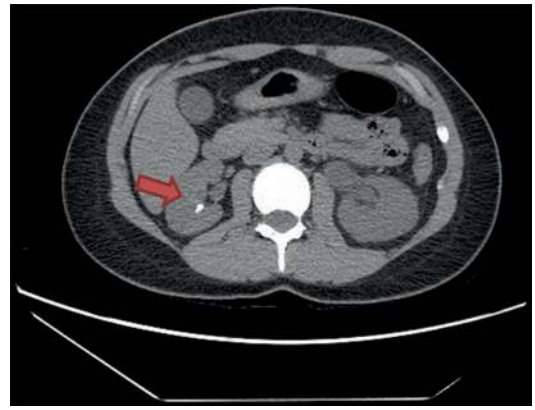

Fig. 46.4 CT imaging of stone: Non-obstructive 5 mm radiopaque calculus is demonstrated at the inferior polar region of the right kidney

Introduction

Wetting either the bed or pants is still one of the most feared events among children, especially when school age is reached, resulting in poor self-esteem and burden for child and parents [1–4]. It is one of the most common chronic disorders of childhood [5, 6]. Despite the high prevalence and negative psychological consequences, enuresis as a disease has not been of much interest to medical doctors, and there is little good clinical research, leading to a deficiency in medical training and absence of the subject in pediatric nephrology courses and handbooks [7–9]. Consequently, in most areas of the world the perception of pathophysiology and treatment are too simplified and guidelines insufficient, all resulting in a variety of non-evidence based approaches [10–16].

Voiding problems are often not benign, self-limiting conditions restricted to delayed acquirement of continence (daytime incontinence) and enuresis (bedwetting), but play a major role in many conditions in the interface between paediatric nephrology and urology. Voiding disorders include a complexity of conditions in children, caused by abnormalities in bladder function and diuresis. Bladder dysfunction is a well-known pathogenic or comorbid factor in urinary tract infections (UTIs) [17–19], in many congenital anomalies of the kidney and urinary tract (CAKUT) (uropathies) [20], constipation [21,

22] and neurogenic bladder [22–25]. The prevalence and importance of bladder dysfunction in children with chronic kidney disease (CKD) prior to and after transplantation is underestimated [26–28]. It is associated with hypertension, sleep disturbances, and cognitive dysfunction. Deficient concentrating capacity as well as circadian rhythm abnormalities of renal function, have been documented in patients with enuresis, but are also an essential characteristic of glomerular as well as tubular renal pathophysiology.

The International Children's Continence Society (ICCS) has standardized both the terminology and management of various aspects of incontinence in children, including enuresis, bladder overactivity, dysfunctional voiding, and psychological comorbidities. A number of guidelines have been published to aid those involved in the care of children with lower urinary tract (LUT) symptoms [8, 23, 29–35].

Nocturnal Enuresis

Definition and Epidemiology

Nocturnal enuresis (NE) is defined as intermittent incontinence that occurs exclusively during periods of sleep. Enuresis can be qualified as frequent (≥4 per week) or infrequent (<4 per week) [32, 36]. There is ample evidence that children with NE and concomitant symptoms of LUT dysfunction differ clinically and therapeutically from children without daytime symptoms [32, 34, 36, 37]. There is less evidence that the pathogenesis and genetic predisposition are different [38].

However, since enuresis is a common disorder and many patients can benefit from simple therapies (desmopressin, alarm and urotherapy), a strategy has been developed to identify patients who can be treated with a high success rate in primary care, thereby avoiding unnecessary exposure to secondary and tertiary care [2, 32, 36].

Enuresis without other LUT symptoms (nocturia excluded), and without bladder dysfunction, is defined as *monosymptomatic enuresis*. Children with enuresis and any LUT symptom have *non-monosymptomatic enuresis* (Fig. 47.1). Subtyping of NE in this manner is promoted in all guidelines, and helps direct the patient to the right therapy [33]. The rationale for this approach is the observation that non-monosymptomatic enuresis has a lower response rate to first line treatment with desmopressin, although the evidence is weak. Once daytime LUT symptoms have abated, the enuresis can be reclassified from the non-monosymptomatic to the monosymptomatic subgroup [33, 34] (Fig. 47.1). It is unclear if other LUTS symptoms beyond daytime incontinence have the same negative predictive value for therapy response.

In *primary* NE, the child has never been dry for a period longer than 6 months, whereas in *secondary* NE there has been such a period. Most

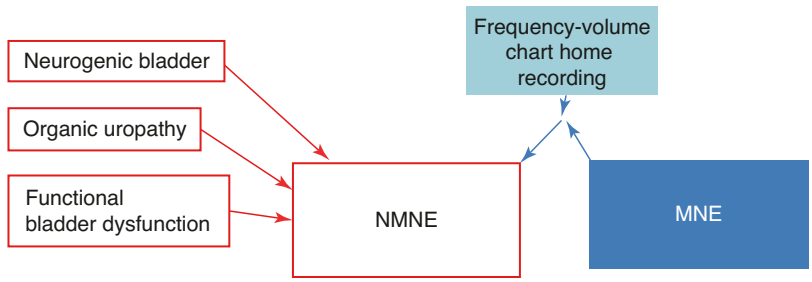

Fig. 47.1 Nocturnal enuresis can be subdivided into monosymptomatic enuresis (in absence of daytime symptoms) and non-monosymptomatic enuresis, when daytime symptoms (LUTS) are present. Children with daytime symptoms likely have underlying bladder dysfunction, and in the differential diagnosis, we should always exclude congenital uropathies and neurogenic bladder dysfunction, before considering it as functional bladder dysfunction

countries regard NE as pathological when it is present after the age of 5 years, but in practice it may be appropriate to delay treatment to 6–7 years of age. Although major importance was previously given to differences between primary and secondary enuresis, where secondary was more related to psychological problems [39, 40], there is an increase in the view that the diagnostic and treatment algorithm do not differ between the two subtypes.

NE is the most frequent disease in children after asthma, with a prevalence of 5–10% at the age of 7 years and of 0.5–1% during adulthood [5, 6, 9, 41–49]. More boys than girls have NE, although this difference tends to diminish after the age of 10 years. The spontaneous cure rate has been estimated to be approximately 15% annually between the age of 5 and 19 years, but is much lower in children with frequent bedwetting, making a 'wait and see' attitude unacceptable [5, 6].

Although only 15–30% of enuretic children were reported to experience daytime incontinence [8, 49] and were labelled non-monosymptomatic according to the old ICCS definition [50], a recent epidemiological, population-based study analyzed children aged 7.5 years and found that 15.5% wet the bed and 2.6% had a frequency of 2 or more wet episodes per week [51]. Of those children with 2 or more wet nights per week, 68.5% were classified as monosymptomatic and 31.5% as non-monosymptomatic. Other studies have estimated that more patients have subtle daytime symptoms of bladder dysfunction such as urgency or decreased or increased voiding frequency and thus qualify for the label non-monosymptomatic NE (NMNE) [34], leaving the subgroup of enuretic children who are truly monosymptomatic to less half of all bedwetting children [52–54]. The majority of guidelines and standardisation papers recommend to differentiate between MNE and NMNE, with the major aim to treat concurrent LUT symptoms before the enuresis. Thus, it has been documented that NMNE patients who have been resistant to desmopressin treatment become desmopressin responders after successful treatment of daytime LUT symptoms [52]. The prevalence of specific subtypes of NE is still unclear, since most of the available epidemiological studies either did not differentiate between MNE and NMNE, or used the previous pre-2006 ICCS definitions. After inclusion of all daytime LUT symptoms as qualifiers for NMNE, 30–50% of previously labeled MNE patients would be classified as NMNE [32, 55].

Pathophysiology

The pathophysiology of enuresis is complex, involving the central nervous system, circadian rhythm regulation (sleep, arousal, hormones), the kidney (diuresis, renal function), and bladder function disorders. It is widely accepted that the central nervous system, and especially dysregulation in control of biorhythms and bladder capacity, plays a major role. Several neurotransmitters and receptors may be involved. There is also a strong correlation with a variety of comorbidities, where it remains to be elucidated if there might be common pathways in pathogenesis and reciprocal effects (constipation, sleep, psychology, neurocognitive functions) [33].

NE in the majority of patients is caused by a mismatch between nocturnal diuresis and functional bladder capacity overnight in the presence of a deficient arousal mechanism [8, 56, 57]. Although some authors have proposed decreased arousability to be a primary mechanism in enuresis, direct evidence for this is rather week since only a minority of children (4.1%) acquire continence by waking them during the night [49]. Multiple mechanisms, discussed below, are involved in the pathogenesis.

Nocturnal Urine Production

In humans, a marked circadian rhythm of urine production is present from early childhood, with a pronounced nocturnal reduction in diuresis to approximately 50% of daytime levels [58–65]. This nyctohemeral rhythm of diuresis in children is controlled by increased nocturnal release of hormones that regulate free water excretion (arginine vasopressin, AVP) [58] as well as solute

excretion (renin, angiotensin II, aldosterone, and atrial natriuretic peptide). These mechanisms are associated with multiple other circadian rhythms: sleep, melatonin, and blood pressure. Circumstances such as light/dark, sleep/awake, activity/rest, body posture, fluid and food intake, and temperature as well as several drugs may interfere with the circadian rhythm of diuresis [66–70]. Interestingly, acute sleep deprivation results in elevated blood pressures and increased solute and water excretion overnight [71].

The initial description by Poulton in the 1950s that children with NE have significantly larger nocturnal urine productions than non-enuretic children [64] has been confirmed by multiple authors [58, 59, 65, 72–74]. Consensus has been obtained that the optimal method of measuring this variable is diaper weighing and measurement of morning voided volume [33]. Nocturnal diuresis has significant night-to-night variation, making nocturnal polyuria only present intermittently [75]. The demonstration that nocturnal urine volume is significantly larger on wet nights compared with dry nights has emphasized that nocturnal polyuria should only be evaluated during nights where enuresis is experienced [76]. Patients with nocturnal polyuria are likely to be desmopressin responders, in absence of associated bladder dysfunction [59, 77–79]. Nocturnal polyuria is defined as nocturnal diuresis >130% of expected bladder capacity for age ((expected bladder capacity = age + 1)*30 mL)

One NE archetype is the patient without an increase in plasma arginine vasopressin (AVP) level during the early night, correlating with the occurrence of increased nocturnal diuresis (nocturnal polyuria) with low urinary osmolality as well as a good response to the AVP analogue desmopressin. Whether this deficit in AVP is always the primary cause or if it is in some cases secondary remains to be elucidated.

There is, however, growing evidence from studies in children who are refractory to desmopressin that the pathogenesis of nocturnal polyuria might be much more complex. Increased solute and sodium excretion overnight has been documented, both in absolute values, as a loss of circadian rhythm in a subpopulation of children with nocturnal polyuria and is probably multifactorial [80–83]. High osmotic load, especially in the evening, is associated with high diuresis rate overnight, but whether dietary intervention would be beneficial in such patients remains to be elucidated [82, 83]. Indirect evidence may have been provided by reports of an association between enuresis and metabolic syndrome and obesity. The increased sodium and osmotic excretion overnight may be caused by increased osmotic load (due to increased caloric intake) as well as abnormal circadian rhythm of osmole excretion [84–86].

Vasoactive hormones also play a potential role in NE pathogenesis, but results have so far not been convincing except for prostaglandins (PGs). Kamperis et al. found an abnormal circadian rhythm of urine PGs. Intervention with a PG inhibitor was, however, not superior to placebo [65, 80, 87]. Increased sodium excretion overnight may be secondary to increased sodium retention during daytime [81], a mechanism described in adults with nocturia. There is certainly a continuum between the pathogenesis of enuresis in adolescence and nocturia in adulthood [88–90]. The role of hypercalciuria has been overestimated, and is secondary to nutritional intake and renal sodium handling [81, 91–93].

Many pharmacokinetic (PK) and pharmacodynamic (PD) studies with desmopressin demonstrate that only 75% of enuresis patients reach >850 mosmol/L on therapeutic desmopressin doses, which is clearly a lower percentage than in control studies. This does not indicate a renal diabetes insipidus diagnosis, but might reflect the lower end of the normal spectrum, where a 20% loss of maximal concentrating capacity results in a 20% higher diuresis rate (the difference between 300 and 360 mL, or possibly between a dry and wet night) [94–96]. Since none of the studied PK/PD enuresis populations received intravenous vasopressin to study their maximal concentrating capacity, the question remains open if a subpopulation of enuresis patients have suboptimal ability to maximally concentrate the urine.

Glomerular dysfunction and specifically an abnormal circadian rhythm of glomerular filtra-

tion rate (GFR) might also play a pathogenic role. In healthy children and young adolescents, GFR decreases overnight by approximately 25%, a phenomenon that is absent in a subgroup of refractory enuresis patients [97]. This observation is in line with the decreased nocturnal dipping of blood pressure in children with nocturnal polyuria. The relationship between hypertension and absent circadian rhythm of blood pressure and nocturnal polyuria is well-known in adults and renal transplant patients [28, 70].

Bladder Function

Bladder function comprises a storage phase and a micturition phase. Micturition in infants and young children, until the age of 2–4 years, is involuntary. The functional bladder volume increases with age, and reaches a maximum at teenage. This maturation requires intact pathways in the central, pontine, spinal, and peripheral nervous systems. The innervation of the bladder is complex, with an interplay between the voluntary motor system and the ortho- and parasympathetic nervous systems.

The pathogenic role of functional abnormalities of the bladder in the pathogenesis of daytime LUTS and NMNE is accepted, but remains unclear in children with MNE. Organic abnormalities and neurogenic bladder are rare in children presenting with MNE, but should always be considered in the presence of daytime symptoms, history of UTI or enuresis refractory to conventional therapy.

In MNE, most evidence points towards a deficient development of nocturnal bladder reservoir function, at least in a subgroup of patients. Nocturnal bladder capacity in normal children is significantly larger than daytime capacity, probably due to inhibitory effects of sleep on the micturition centers. Nocturnal bladder capacity is not easy to measure in enuretic patients, even with diaper weighing, as many enuresis episodes are incomplete voids associated with significant residual urine [98]. However, when estimated as maximal voided volume (MVV) during daytime and excluding the first morning void, daytime bladder capacity is also reduced in many enuretics, even in MNE patients. Clinically, an estimate of daytime bladder capacity is relatively easy to obtain and it has been shown to be of value when selecting a treatment modality in the individual patient. Thus, a MVV that is below 70% of the predicted MVV for age (age × 30 + 30 mL) has been shown to predict a poor response to desmopressin treatment [99–101]. This corroborates very closely the fact that alarm treatment, which that is highly effective in this patient subgroup, increases nocturnal bladder capacity, whereas nocturnal urine production does not change [101, 102].

Comorbidities

Voiding abnormalities are strongly associated with various comorbidities.

Constipation

The coexistence of LUT symptoms and functional constipation and/or faecal incontinence in children is not uncommon, and was previously identified as dysfunctional elimination syndrome (DES) [103–106] and more recently as ‘bladder and bowel dysfunction’ (BBD) [22]. Although the association with dysfunctional voiding, decreased voiding frequency and underactivity is obvious, there is also a clear comorbidity between bladder overactivity (urge), increased voiding frequency, bladder underactivity and constipation [21]. It is a well-established that treatment of defecation problems in children with BBD enhances successful management of LUT disturbances such as daytime urinary incontinence (DUI), enuresis, and UTIs [21, 22, 103]. Treatment of the bowel dysfunction ameliorates the voiding disorder and should be first-line treatment [21].

Psychological/Behavioural Problems: Attention Deficit, Neurocognitive Dysfunction

Psychological comorbidity among children with functional urinary incontinence is high: 20–30% of children with NE, 20–40% of children with DUI, and 30–50% of children with fecal incontinence (FI) [107–110]. Both internalizing and externalizing characteristics are represented [109, 111]. The best documented comorbidity conditions are attention deficit-hyperactivity disorder

(ADHD) and oppositional defiant disorder (ODD). Children with attention deficit disorders have a higher prevalence of enuresis (both MNE and NMNE), whereas the prevalence of ADHD in the enuresis population is up to four times higher than the background population. The association of abnormal prepulse inhibition (Startle reflex) in both ADHD and enuresis patients might suggest a common central nervous pathogenic pathway, but it is far from fully understood [109, 112–114].

Sleep

Regardless of the cause of the mismatch between nocturnal bladder capacity and nocturnal diuresis, enuresis only occurs when the child is unable to wake up; hence, lack of arousal is a prerequisite for NE. This has caused many to conclude that sleep disturbance *per se* is the major pathophysiological factor in enuresis and it is still a general belief in the general population that enuretic children are deep sleepers. However, this hypothesis has been questioned due to the inability to convincingly show abnormalities in sleep EEG patterns together with the observation that a considerable proportion of non-enuretic children also are unable to wake up when polyuria is induced overnight [11, 115–120].

It was documented that enuretic children did not exhibit deep sleep, but rather a disturbed sleep with increased periodic limb movements during sleep (PLMS), cortical arousals, and awakenings [66, 67, 121]. Polysomnography studies documented a significant difference in PLMS index, arousal index, and awakening index compared with healthy control subjects. The presence of sleep fragmentation does not exclude a high sleep pressure or high arousal threshold. The role of sleep fragmentation in children with NE was earlier emphasised using sleep actigraphy [122]. Obstructive sleep airway syndrome causes nocturnal polyuria in both children and adults, eventually resulting in enuresis [123–125]. The prevalence of this NE subtype in patients primarily consulting for NE is not known, but the anti-enuretic response to therapy to address obstructive sleep airway syndrome suggests that in refractory cases this might be considered [126–129].

In conclusion, albeit there is little doubt that sleep and/or arousal plays a role in the pathophysiology of NE, the clinical relevance and possible implications are still unclear and so far sleep investigation is not part of routine evaluation of enuretic children.

Hypertension

One of the first characteristics of arterial hypertension is the loss of nocturnal dipping and patients without nocturnal dipping have a poor cardiovascular prognosis. The association between hypertension and increased nocturnal diuresis is well-documented [28, 70].

Renal Diseases

Many renal diseases are associated with disrupted circadian rhythms of renal water and solute handling [60, 81, 83, 87, 97]. Thus, the kidney disease may have a role in causing the NE. However, such patients may have the same predisposition to NE as other children. Hence, they should have the same workup as any child with NE.

Drug Induced Changes in Circadian Rhythm

Many drugs result in disrupted circadian rhythms. The best known are the steroids, certainly when given twice a day or in high doses. Even a low dose at 08.00 h induces a shift in circadian rhythm, since the normal physiologic cortisol peak is 4 h earlier. Diuretics have of course a major effect on water and sodium excretion, especially long-acting thiazides, or loop-diuretics when they are given twice a day.

Genetics

NE has a strong hereditary component given that approximately 70% of NE patients have a positive family history and that monozygotic twin studies find concordance rates of 80%. Positive linkage was established between enuresis and several gene loci on different chromosomes (4p, 12q, 8q, 13q, and 22q). However, although several candidate genes have been proposed, no specific pathogenic variant has been identified. Moreover, it is unknown whether there is a

genotype-phenotype correlation to specific NE subtypes [38]. Interestingly, a recent genome wide association study in a large Danish population identified common genetic variants associated with NE. The study pinpointed potential NE risk genes, among which *PRDM13*, *SIM1*, and *EDNRB* might affect sleep, urine production, and bladder function, respectively. It also identified for the first time a significant genetic overlap between NE and ADHD [130].

Evaluation

In the child with *primary* NE, evaluation should not be initiated before 5 years of age. In contrast, children with *secondary* NE should be evaluated for an underlying etiology (e.g. diabetes mellitus, constipation, and UTI) when the wetting reappears. The initial approach to primary NE should avoid unnecessary investigations if there are no concerning symptoms (Fig. 47.1).

Evaluation should comprise a detailed history, with a focus on the duration and severity of the night wetting, but also inquire about LUT symptom such as daytime incontinence, increased or decreased daytime voiding frequency, urgency, voiding postponement, holding maneuvers, constant dribbling, and intermittent urinary stream. It is important to ask specific questions regarding LUT and bowel symptoms. A history of uropathy, UTI, and constipation suggests possible bladder dysfunction.

The physical examination should comprise the external genitalia (e.g. congenital anomalies, phimosis), the lumbar region (e.g. deformations, pigmentations, and hair growth), and neurological examination (e.g. ano-cutaneous and cremaster reflexes, lower extremity reflexes, muscle tone, and gait). Laboratory evaluation should include a urinalysis of a morning or spot urine sample, with examination for glucose, leukocytes, nitrite, and albumin. In the majority of children with NE, these investigations will be normal.

A cornerstone in the further evaluation of a child or adolescent with NE is an estimation of their bladder capacity and nocturnal urine production. For this purpose, a frequency-volume chart (registration of the time and volume of all micturitions and fluid intakes during daytime) during two weekends and a recording of nighttime urine production (weight of diaper in the morning (g) − weight of diaper before bedtime (g) = volume of morning micturition (mL)) during 1 week are very useful approaches for obtaining this information. Compliance is usually good when the purpose is explained to the parents. Measurement of MVV (excluding the first morning void) needs to be made over a minimum of 3–4 days for accuracy: weekends or school holidays are ideal, but have the disadvantage that lifestyle is significantly different and often less structured than on schooldays [33, 76].

Treatment

The simplified evaluation process enables the identification of two archetypes of NE that correlate with their pathophysiologic characteristics (Fig. 47.2). The first archetype is children with MNE and no apparent LUTS; the mismatch between nocturnal diuresis and functional bladder capacity is caused by nocturnal polyuria. The majority of these patients will have low urinary osmolality overnight due to low vasopressin levels [18, 19], and will be desmopressin responsive. The second archetype is the "small for age" bladder capacity. These patients will likely be desmopressin resistant, and are expected to have a good response to the enuresis alarm [33]. A combination of both types is not uncommon and such patients generally respond well to combined therapy with desmopressin and an alarm [33]. If patients do not respond to one of these treatments, a more complicated underlying mechanism might be present and referral to a tertiary multidisciplinary centre should be considered.

Thus, a simple "trial and error" treatment strategy for enuresis is no longer recommended as it may even have an adverse psychological effect on the child [2]. A rational therapeutic approach as outlined in the ICCS standardization document [31, 33] leads to higher success rates.

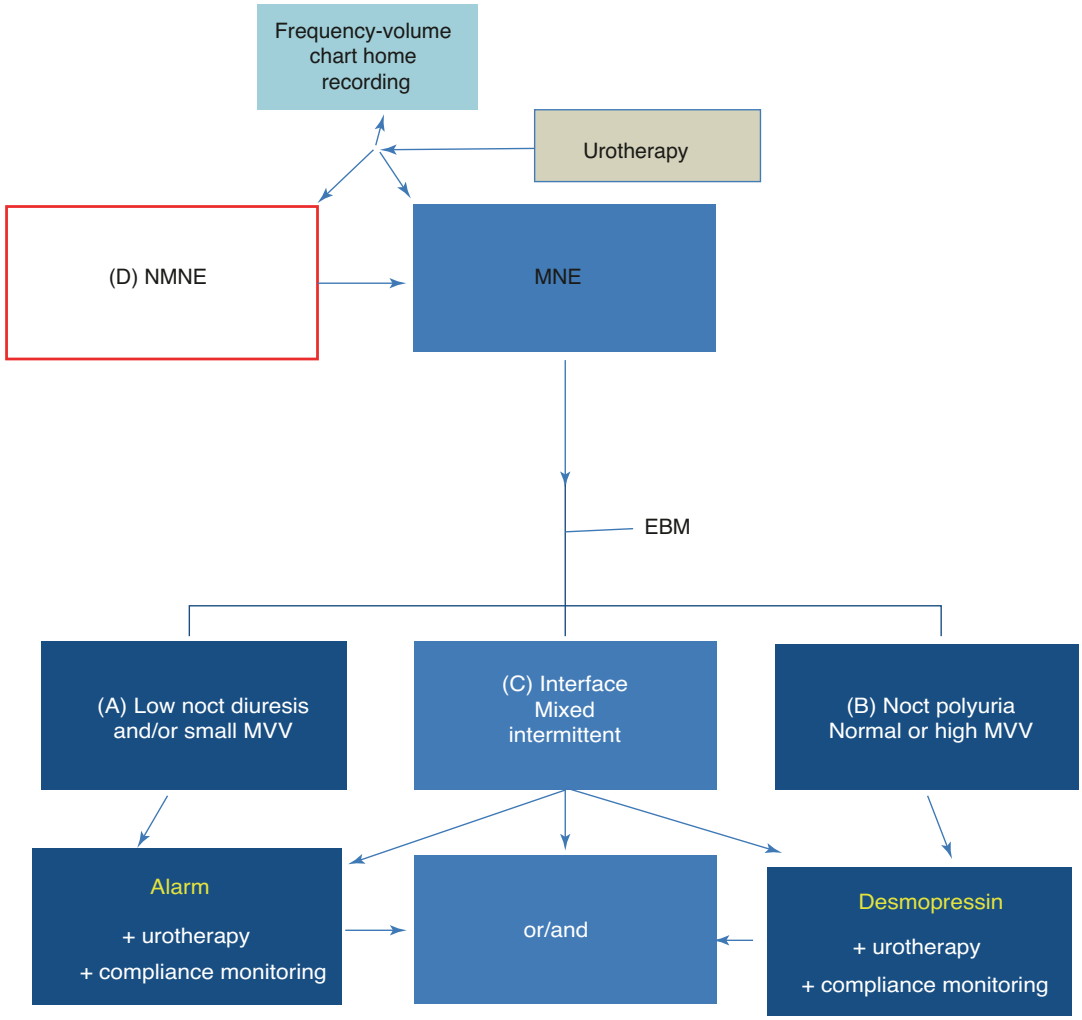

Fig. 47.2 A simple flow chart illustrating that noninvasive screening, identifying the subgroup of patients with monosymptomatic enuresis, may lead to a rationalized therapeutic approach in primary and secondary care avoiding unnecessary invasive investigations. All children should receive urotherapy according to the ICCS guidelines, including normalization of fluid- and nutritional intake, voiding pattern and sleep hygiene. If despite this urotherapy, enuresis persists, according to the ICCS standardization papers, children should only receive EBM therapies: the alarm and desmopressin. Although both therapies reach EBM IA levels, success rates vary between 30% and 60%, with high relapse rates. Targeting the underlying pathophysiological characteristics of the enuresis, and especially the mismatch between nocturnal diuresis volume and functional bladder capacity (MVV) overnight might lead to increased success rates. Patients can be subdivided into two archetypes, children with nocturnal polyuria (B) and children with overactive bladder (A). Children with low diuresis-rate overnight (and high osmolality) and/or small bladder capacity (MVV), are likely desmopressin resistant, and should receive the alarm as primary therapy. Children with nocturnal polyuria (+low osmolality) and normal bladder capacity (MVV) for age will likely benefit from antidiuretic therapy rather than from the alarm. Desmopressin should be first line therapy. For some there is a continuum between the two archetypes (C), where some children have only a mild, often intermittent mismatch, between diuresis and bladder, where each characteristic does not reach the level of abnormality as defined by the ICCS. In these children both therapy options are defendable. In cases, refractory to therapy or in the subgroup where we identify a combination of nocturnal polyuria and overactive bladder, combination therapy should be advocated. (D) NMNE-children with successful therapy of the LUTS symptoms can subsequently be treated as MNE patients

Therapy is often initiated at the age of 6–7 years, although enuresis is considered abnormal in children ≥5 years of age. Reasons for a proactive attitude towards treatment include the distress caused to child and family, difficulty with "sleeping over" on holiday or at friends' houses, social withdrawal, reduced self-esteem [2], disrupted sleep with possible secondary effects on cognitive function and health [119, 131–134], and the burden [3] and costs associated with frequent laundering of bedsheets and clothing [135, 136]. In addition, spontaneous resolution is low in children >5 years with frequent bedwetting; the negative impact on the child and family induces a risk for intolerance of some parents [137]. Whether early treatment reduces the prevalence in adulthood is unclear [5, 6, 88, 138–141].

Treatment [8–11]

Step 1: Demystification

Explanation of the pathophysiological mechanisms that are involved in enuresis is essential. Children and families should be convinced that bedwetting is a common problem, that they should not be embarrassed or feel guilt, and that it is definitely not a primary psychological problem. Patients should understand that the primary cause is a mismatch between nocturnal diuresis volume and the bladder capacity overnight.

Parents and children should be warned that success rates of monotherapy vary from 30% to 60%, leaving up to 1/3 with persistent symptoms after 1 year. This message is obligatory to prevent early frustration during therapy [8, 31, 33].

Step 2: Urotherapy [35, 142, 143] includes all nonspecific advice, including toilet habits, frequency, fluid intake, and nutrition advice. This is a well-accepted first line therapy in children with enuresis, especially in children with associated bladder dysfunction. Recently there is increasing evidence that urotherapy might not be effective at all in treatment of the enuresis component. Increased fluid intake might be beneficial in some patients, but might worsen enuresis in other patients. This data does not support starting with full spectrum urotherapy in all enuresis patients, but rather as an individualized modality in therapy refractory patients [144].

Advice on fluid and nutritional intake:

Many children have both their maximum fluid intake and main meal in the evening, and the high sodium and protein load may result in high osmotic excretion and polyuria overnight, as has been demonstrated in children with desmopressin refractory polyuria. Opinion leaders empirically advise that fluid and nutritional intake should be normalised, with fluid intake spread during the whole day, and avoiding caffeinated beverages and high fluid intake in the evening [8, 31, 33, 145]. This should be accompanied with healthy food intake in the evening, avoiding high protein and sodium load, to reduce osmotic diuresis [82, 83]. However, the evidence level for this strategy is weak.

Sleep advice is suggested due to the close interaction between sleep and several renal, hemodynamic, and endocrine circadian rhythms. Children should be encouraged to develop good sleep habits, including sufficient time for sleeping. Hyperstimulation of the brain (e.g. bright light exposure, computer games, television, music) should be avoided before sleeping, since it might have profound effects on the regulation of circadian rhythms, potentially affecting melatonin secretion and sleep patterns. Children should void immediately before going to bed, and lights should be turned off, once children are in bed. There is ample evidence that the overall sleep quality of children and teenagers is decreasing. There are also issues with timing and duration. The use of mobile devices once in bed is a big challenge, and should be discouraged. Children should not drink during the night [96, 146], and definitely not during therapy. However, the evidence supporting these interventions is weak.

Step 3: Non-medical behavioural management:

If urotherapy and lifestyle interventions are unsuccessful, more intensive treatment modalities are recommended. The alarm and desmo-

pressin are the only two evidence-based management level I, grade A recommended treatments. The choice between the two options should ideally be individualised based upon patient characteristics identified during the evaluation [33]. There is evidence that the response to these treatments is highly dependent on the underlying pathogenic mechanism: The alarm is the treatment of choice in the archetype patient with *small* bladder capacity (i.e. MVV) and *normal* nocturnal urine production on wet nights. Such patients are usually desmopressin resistance. In contrast, desmopressin is the treatment of choice in the patient with *large* nocturnal urine production on wet nights and *normal* bladder capacity. Such patients will likely not respond to the alarm, unless they are developing nocturia. In general, desmopressin and the alarm should not be regarded as competing modalities, but as complementary or even supplementary to each other and targeting different patient subtypes. If, however, initial evaluation of the underlying enuresis mechanism is not possible, or the clinical pattern is unclear, other factors such as family motivation and preferences, availability of close follow-up, cost, and frequency of enuretic episodes, should all be included in the decision process.

Enuresis alarms have a level 1, grade A International Consultation on Incontinence (ICI) recommendation [8, 31, 33, 147–149]. Different types of alarms exist, but the common feature is a sensor placed in the sheets or nightclothes that is triggered when it becomes wet, setting off an auditory or vibration signal and causing the child to awaken, cease voiding, and arise to finish the void at the toilet. Parents are advised to wake their child when the alarm is activated; otherwise, children are prone to ignore it or turn it off and go back to sleep. The first weeks are a burden for the child and parents, and thus appropriate education prior to initiation and close follow-up are essential. The alarm should be worn every night. Response is usually not immediate and treatment should be continued for 2–3 months or until the child is dry for 14 consecutive nights (whichever comes first). Often compared to Pavlov training mechanisms, the true mechanism remains poorly understood. However, successful alarm treatment has been associated with a significant increase in bladder capacity [101, 150], whereas nocturnal urine production and sleep is unchanged. There may be cultural differences in its acceptability, as it may be highly disruptive for the household. The family must be motivated and adhere to the regimen to be successful. Doctors should monitor the child's progress early to address any problems and facilitate adherence. The response rate is high in families who continue treatment for a sufficient period, with relatively low relapse rates, though the lasting cure rate is still <50% [147]. Poor compliance and early withdrawal from treatment are common [14, 151, 152], which may exacerbate parental intolerance. Identifying the motivated patient in the right family is essential, and in cases where the child or the family is reluctant to accept the alarm, desmopressin is the alternative [149]. Alarm therapy has high failure rates when the buzzer is activated more than once a night. The goal is to obtain continence without waking up, although up to 25% develop nocturia. Relapse rates vary from 30% to 60% [147].

Desmopressin (DDAVP) [78, 153–156]

Desmopressin also received a level 1, grade A recommendation from the ICI in 2009 [49]. Desmopressin is a synthetic analogue of arginine vasopressin, the naturally occurring antidiuretic hormone. One of its major actions via the renal V2 receptor is to reduce the volume of urine produced overnight to a normal amount. Since the demonstration of nocturnal polyuria in patients with MNE, and the lack of the normal rise in plasma AVP levels during night, the use of DDAVP became a logical choice [58, 59]. Beyond the major effect on free water reabsorption, DDAVP has been claimed to have additional effects in enuresis, including detrusor muscle activity, central control of micturition, tubular sodium handling [157], and sleep, or arousal

function, but the evidence in unselected enuretic populations is very low. The direct effect on sleep and arousal is controversial since it is unclear if DDAVP crosses the blood-brain barrier. Several formulations are available: rhinal nasal solution, nasal spray, oral tablet and oral lyophilisate (sublingual MELT formulation), all characterized by low bioavailability with large intra-individual variability (0.08–0.16% in adults), but only the oral tablet and lyophilisate formulations are labelled for treatment of NE in children. The low bioavailability is related to the peptide structure compromising oral and intestinal reabsorption. It is available for the treatment of enuresis as a tablet (dosage, 0.2–0.6 mg) or a fast-melting oral lyophilisate (MELT formulation, dosage, 120–360 μg). The latter is a recommended formulation for all children and is preferred for children under 12 years [94, 95, 158, 159]. Unlike other preparations, the MELT formulation is not affected by nasal congestion or gastrointestinal transit and does not require fluid intake. Since tablets usually require 1–200 mL of fluid intake, which is a significant percentage of a 7-year-old's bladder capacity and nocturnal diuresis, the MELT formulation seems more suited to the antidiuretic indication of desmopressin. Good pharmacodynamic data are available for the MELT formulation and its dosing in children with enuresis [94].

The efficacy of desmopressin in the treatment of NE is well documented. In a Cochrane analysis, 17 controlled trials all showed superiority of desmopressin compared to placebo regardless of the route of administration [153]. An estimated 70% of the NE population has full or partial response [95]; the response to desmopressin is highly dependent on factors such as nocturnal urine production and bladder capacity. The few studies that have tried to compare different doses of the drug reveal comparable efficacies [160–162]. Several key issues should be taken in consideration. First, 200–400 μg tablets are considered to be bioequivalent to 120–240 μg of the MELT formulation and represents the therapeutic range for children between 7 and 18 years with MNE. However, higher doses might be needed in larger children [159].

Desmopressin should be taken 1 h before the last void at bedtime to allow timely enhanced concentration of urine to occur. Fluid intake should be reduced from 1 h before desmopressin administration and for 8 subsequent hours to optimize concentrating capacity and treatment response, as well as to reduce the risk of hyponatremia due to water intoxication [94, 95]. Desmopressin is only effective on the day it is taken; full adherence is required to avoid wet nights [151, 152].There are different initial dosing regimens with comparable efficacy such as gradual dose escalation over a few weeks or starting with a high dose followed by gradual tapering to the lowest effective dose. If desmopressin is effective, then treatment can be continued for an additional 3 months; country-specific regulations regarding treatment breaks should be followed. If patients are dry on desmopressin treatment, breaks are recommended to ascertain whether the problem has resolved and therapy is no longer needed. If the child does not achieve complete dryness, or if wetting resumes once treatment is withdrawn, it should be continued or resumed, respectively. There is some evidence that structured withdrawal of medication may reduce relapse rates following its discontinuation [163, 164]. Desmopressin is well-tolerated, but clinicians should be aware that it is a potent antidiuretic and families must be educated regarding the rare possibility of developing hyponatremia due to water intoxication with symptoms including headache, nausea, and vomiting [155]. Self-titration of medication should be avoided.

Adherence to the management plan is crucial, especially for a drug whose action covers only the first night after intake. It is estimated that approximately 30% of non-responders are not taking medication correctly [151, 152]. Non-adherence to recommendations regarding timing of medication, voiding before bedtime, and limiting evening fluids can decrease treatment success [100]. Moreover, compliance is often overestimated by patients and caregivers; therefore, it should be documented in a diary. Regular contacts between caregiver and patient are necessary to maintain compliance. Patients who appear treatment-resistant should be advised of the

importance of full adherence and asked if they have had any difficulty complying with recommendations.

Desmopressin has higher success rates in children with large bladder capacity and nocturnal polyuria [100]. The response rates in the initial studies of >70% decreased to 20–30% in subsequent studies. This lower response rate is likely due to local referral patterns and the use of desmopressin among general practitioners and consequent selection of more challenging patients at tertiary referral centers, and higher incidence of patients with overactive bladder (OAB) since the prevalence of occult OAB patients with small bladder volume and low nocturnal diuresis volume was high in these populations [54].

There are several unanswered questions regarding desmopressin therapy. It is still unclear whether desmopressin treatment leads to better long-term outcome than the spontaneous cure rate. The long-term cure rate of 15–30% annually with desmopressin in unselected populations is higher than the spontaneous cure rate [79, 154, 165], but depends on the severity of the study population. Long-term follow-up showed persistent LUT symptoms in the patients with NMNE and not in the MNE patients [88]. The suggestion that tapering of the dose and the structured withdrawal program should be beneficial is still unproven [163, 164].

It is obvious that many renal patients (CKD, and tubulopathies) with NE have impaired response to desmopressin, and do not reach maximal concentrating capacity, but this does not exclude at least some antidiuretic effect overnight, not normalizing but at least optimizing antidiuresis [166].

Tricyclic antidepressants were among the first drugs widely used in NE [167–172].They act on adrenergic and serotonergic receptors in the central nervous system. Although the exact mechanism of action remains unclear, imipramine reduces both urinary sodium and the overall urinary osmolar excretion, decreasing the nocturnal urine output in children with nocturnal polyuria. Imipramine has potential to modulate sleep and increase arousability and it has a parasympatholytic effect on the detrusor and an alpha-mimetic activity on the sphincter. Side effects are the major drawback, ranging from postural hypotension, mouth dryness, and constipation to hepatotoxicity and cardiotoxicity in large doses [173]. Hence, imipramine is currently not recommended as a first line enuresis treatment but, has been suggested in treatment of refractory patients. Some recommend a pre-treatment ECG to exclude long QT-syndrome, but there is no evidence of benefit in children, and few MD's follow this strategy,

Anti-muscarinic Therapy

Anti-muscarinic therapy (e.g. oxybutynin, tolterodine, propiverine, solifenacin) has not been proven effective mono-therapy for patients with MNE, but may have a role in combination with first line modalities [174, 175]. These drugs are widely prescribed in children with NMNE for the daytime symptoms and are suggested to have beneficial effect on NE [175], but prospective there is no supportive evidence from randomized clinical trials. They might be indicated as add-on therapy in the subgroup of patients with MNE and small for age bladder capacity.

Cognitive Training and Psychotherapy

Cognitive training and psychotherapy was more widely used before desmopressin was available, and when physicians were less involved in treatment. Cognitive training and psychotherapy may still have value as an adjuvant to conventional therapy, although the evidence is weak. Most of studies were performed in patient groups defined by criteria from the Diagnostic and Statistical Manual of Mental Disorders, fourth edition, which does not differentiate between MNE and NMNE, and with a higher incidence of psychopathology [33].

Alternative Treatments

There are multiple alternative treatments for NE, but little or no evidence. There is no evidence supporting the efficacy of hypnosis [13, 176, 177], chiropractic [178–180], and reflexology. There is weak evidence demonstrating benefit from traditional acupuncture [181, 182]. There is insufficient evidence supporting acupuncture

variations such as manual acupuncture, acupressure, and electro- and laser-acupuncture [183]. Transcutaneous electrical nerve stimulation (TENS) may have benefit, but mainly in a NMNE population [184, 185].

Treatment Refractory MNE (Fig. 47.3)

The major reasons that patients with MNE are non or partial responders to first line treatment modalities are that (1) the initial evaluation was not sufficient and the patient was a NMNE patient, (2) non-adherence to the treatment prescribed (3) a complex phenotype with more than one underlying mechanism (e.g. both nocturnal polyuria and low bladder capacity) and (4) rare types of enuresis with underlying mechanisms not influenced by treatment (e.g. polyuria caused by large osmotic excretion) (Fig. 47.2).

In such patients, a repeat, extended evaluation should be performed, including detailed history of LUTS with particular emphasis on daytime OAB symptoms and constipation (classification of constipation according to the Rome IV criteria) [269]. The patient should keep a bladder diary with recordings of daytime intake and output and nighttime urine volume (diaper

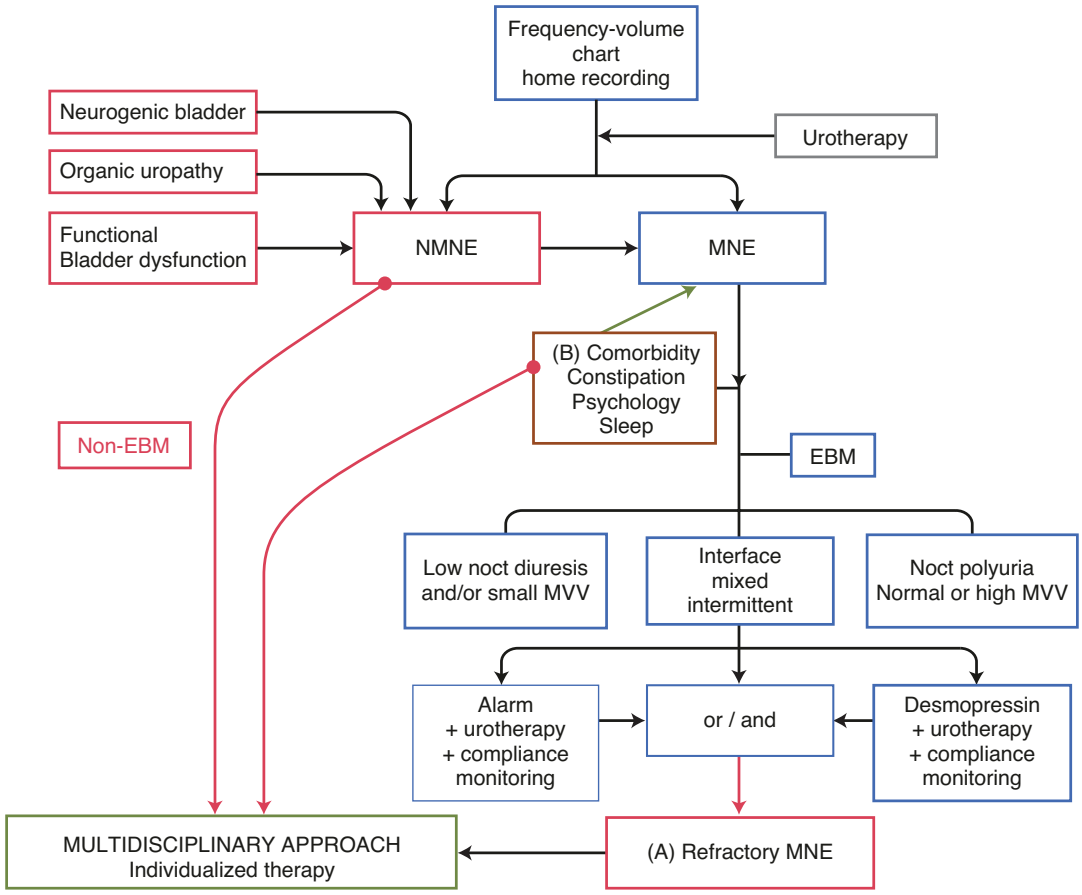

Fig. 47.3 Illustrates further the flow chart when children are refractory to initial therapy. (A) In these patients EBM therapy is insufficient and a multidisciplinary diagnostic and therapeutic approach should be offered, resulting in individualized therapy regimens. This multidisciplinary therapeutic approach should involve experts in pediatric nephrology and urology, as well as targeting psychological characteristics, compliance issues and comorbidities. Since the majority of comorbidities associated with therapy-resistance are easy to identify by simple questionnaires, we advocate not only to search for them in refractory cases, but also in the early stages of evaluation (B)

weighing). Advice the patient to keep the diary during a day with standardized fluid intake (1.5 L/1.73 m^2/day), since low fluid intake might mask frequency and daytime incontinence. The night-time recording can be repeated during 1 week of desmopressin treatment in order to verify whether the patient has the intended reduction in urine production. Spontaneous low fluid intake suggests a defence mechanism, and may mask OAB symptoms. These symptoms are often not mentioned by parents, and thus deserve repeated questioning or documentation in a bladder diary. Uroflowmetry, bladder ultrasonography and rectal diameter measurement can give additional information on the voiding pattern, bladder emptying, bladder wall thickness (OAB), and constipation.

In desmopressin refractory patients without bladder dysfunction, alternative explanations for the lack of efficacy may include (1) anti-enuretic effect = number of wet nights, (2) anti-diuretic effect (= nocturnal diuresis rate), and (3) concentrating capacity (= urinary osmolality). Partial response to desmopressin in MNE (anti-enuretic effect) is related to persistent nocturnal polyuria on wet nights [75] (Fig. 47.4).

Poor compliance should be excluded [152], including not taking the drug (record in drug-diary). Determine the number of filled prescriptions to monitor compliance. Other causes for suboptimal effect of desmopressin are:

1. The child forgets to void and empty the bladder before sleeping thereby increasing the risk of exceeding maximal bladder capacity during the night.
2. Fluid intake overnight or even the hour before desmopressin administration reduces both the maximum and duration of the anti-diuretic effect.
3. Intermittent polyuria might also be related to the PK/PD characteristics of desmopressin [94, 95, 159], but the phenomenon might be intermittent, varying from night to night. Factors which influence PK/PD include;
   (a) The recommended formulations (tablet, MELT formulation), but also the nasal spray, have poor bioavailability, ranging 0.2–2%, but with a large intra-individual variability. Only for the MELT formulation are dose-response and PK/PD data available in children. The MELT

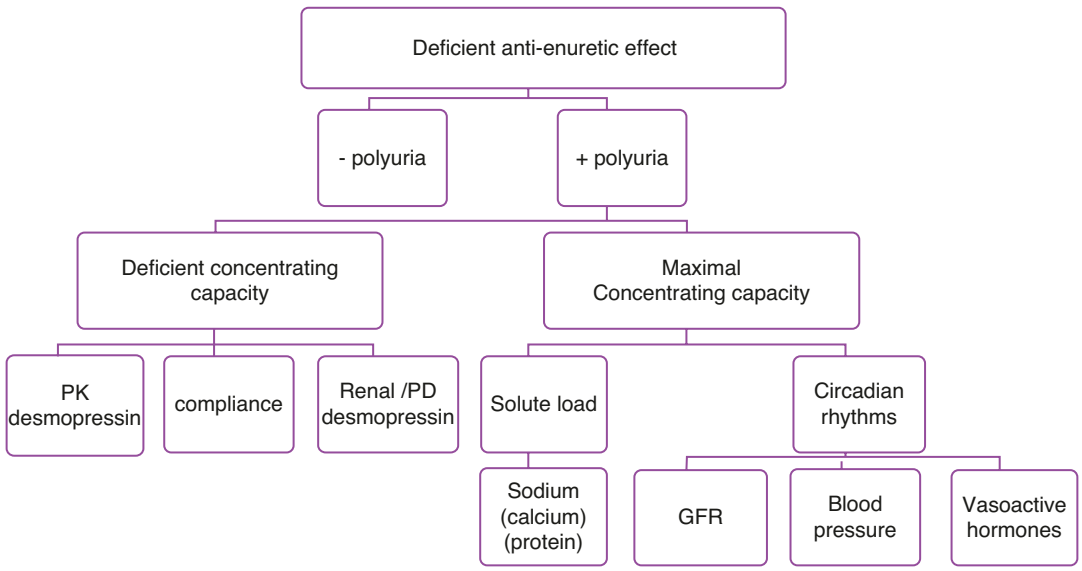

Fig. 47.4 Patients with desmopressin resistant monosymptomatic enuresis can be subtyped according to persistence or not of nocturnal polyuria and ability to reach maximal concentrating capacity. An individualized treatment choice is possible when by considering the different pathophysiologic mechanisms involved

formulation had superior PK and PD profile, better compliance, and some indices of higher response rates than the tablet, although there have been no randomized trials comparing the anti-enuretic effect of the two preparations. In treatment resistant patients on tablets, a switch to the MELT formulation should be considered.

(b) The child takes desmopressin just before sleeping time. Since the time to reach maximum concentrating capacity and anti-diuretic effect is 1–3 h, the drug should be taken at least 1 h before the last void at bedtime [94].

(c) Even in the therapeutic range of 120–240 μg, there are large standard deviations in maximal concentrating capacity and antidiuresis, as well as duration of action. Better understanding of this PK/PD, can lead to more personalized medicine, with individualized dose schemes. The PK/PD data demonstrate that at least 25% of patients might benefit from higher doses; these patients can be identified by a PD test in an ambulatory setting, especially the older patient (24 h concentration-profile). Increasing the dose should only be done following this test, typically done in expert centers, due to the risk of toxicity.

In desmopressin refractory nocturnal polyuria with low urinary osmolality, nephrogenic diabetes insipidus (NDI) should be excluded. The X-linked NDI in boys does not usually present as enuresis, but female carriers might have a more subtle phenotype with enuresis as the major symptom. Many renal diseases (CKD, tubulopathies, renal dysplasia, uropathy) may present with enuresis. Hypertension, especially nighttime hypertension, coincides with nocturnal polyuria, and should be considered in refractory patients.

Desmopressin resistant nocturnal polyuria might be associated with high urinary osmolality overnight. This can be caused by an increased solute load only in the evening or during all 24 h [82, 83]. Sodium is the major osmotic agent [80, 81, 83, 87, 186]. Although nutritional intake plays a major role, abnormalities of several circadian rhythms like prostaglandins [65, 80, 87], GFR [187], blood pressure [70] and sleep pattern [66, 67] may also have a significant impact. Extrapolation to primary care enuresis patients remains premature, but these findings suggest future treatment options. Some pilot studies had promising results such as sodium restricted diet, diuretics (furosemide [186]), nonsteroidal antiinflammatory drugs (NSAIDs), and melatonin [127, 188–190]. There was a focus on the role of calcium [91], and the efficacy of a calcium restricted diet [92]. However, hypercalciuria might be a secondary phenomenon, unrelated to diet.

Therapy resistance may be related to the *presence of comorbidities* [33], and addressing them, when possible, might increase the response rate. Constipation and FI should be treated before treating MNE, but are often underestimated and underreported. Psychological comorbidities, both internalizing as well as externalizing, are more frequent in NE patients. Attention deficit disorder and autism seem to have common central nervous pathways with enuresis. Renal dysfunction, hypertension, diabetes mellitus and sleep disturbances may worsen NE, and should be treated. NE may also be exacerbated by drug interfering with circadian rhythms, including diuretics, steroids, cyclosporine A, and neurotropic drugs.

In conclusion, children with MNE the two first-line treatment options are desmopressin and the enuresis alarm, as monotherapy or in combination. Outcomes are less favorable if therapy is not guided by patient characteristics, with initial success rates of monotherapy potentially below 30% and a relapse rate of up to 50%.

In summary, the optimal strategy is as follows:

1. The initial treatment choice should be guided by the family's level of motivation and their preference.
2. Based on the information from diaries, one can identify subtypes of MNE that should

allow further fine-tuning of treatment according to the child's characteristics and family motivation.

1. Children with a normal urine output during the night and normal bladder capacity can be given either the alarm or desmopressin.
2. Children with smaller than expected bladder capacity for age will likely be desmopressin-resistant and more responsive to the alarm.
3. Children with nocturnal polyuria and normal bladder capacity will be more sensitive to desmopressin.
4. Children with both nocturnal polyuria and reduced bladder capacity may have a successful outcome with the combination of alarm and desmopressin.

Other Forms of Urinary Incontinence (Fig. 47.5)

The classification of daytime LUT conditions is more complex than enuresis because of the heterogeneity of symptoms of LUT dysfunction and the considerable overlap between the conditions. Although there is a significant overlap with enuresis, not all LUT patients have enuresis, and not all enuresis patients have apparent LUT symptoms. Additionally, borderline cases are common and the rationale for grouping of symptom complexes into specific LUT dysfunction conditions is often not fully evidence-based. The ICCS has standardized the terminology and approach [31].

Epidemiology

Most children are toilet trained by 2 years of age, although there are important country and cultural differences. Early interventions might speed up toilet training, but have not been shown to decrease the prevalence of any LUTS at 5–7 years [191, 192]. Daytime symptoms from the LUT are very common in childhood, especially urgency and frequency (approximately 5–20% of 7-year olds), rapidly decreasing during the following years. As outlined above, the majority of these children have non monosymptomatic enuresis. Urinary incontinence is also relatively common, with a prevalence of approximately 3% of 7-year olds [49]. Voiding complaints, such as dysuria and interrupted stream, are far less frequent. Five years of age is the usual cutoff for reporting symptoms and LUT conditions. The prevalence of the various subtypes of LUTs, especially OAB, versus dysfunctional voiding is not known.

Definitions and Characteristics

Assessment

To classify daytime LUT dysfunction conditions, we recommend assessment and documentation be based on the following parameters:

1. Incontinence (presence or absence, and symptom frequency)
2. Voiding frequency
3. Urgency (presence or absence)
4. Voided volumes
5. Fluid intake

This is more important than subgrouping the children into the various recognized conditions listed below.

There are several archetypes, but with large overlap. Rather than forcing children into an archetype as was done historically (*non-neuropathic* bladder-sphincter dysfunction, *urge incontinence*, *dysfunctional voiding*, *lazy bladder syndrome, Hinman bladder) it is advised to start with a detailed clinical history and using a diary and uroflowmetry to describe the characteristics of the bladder during the filling phase (storage) and the emptying phase*. Urgency, holding manoeuvres and daytime incontinence are frequent with an overactive bladder, but infrequent in an underactive bladder.

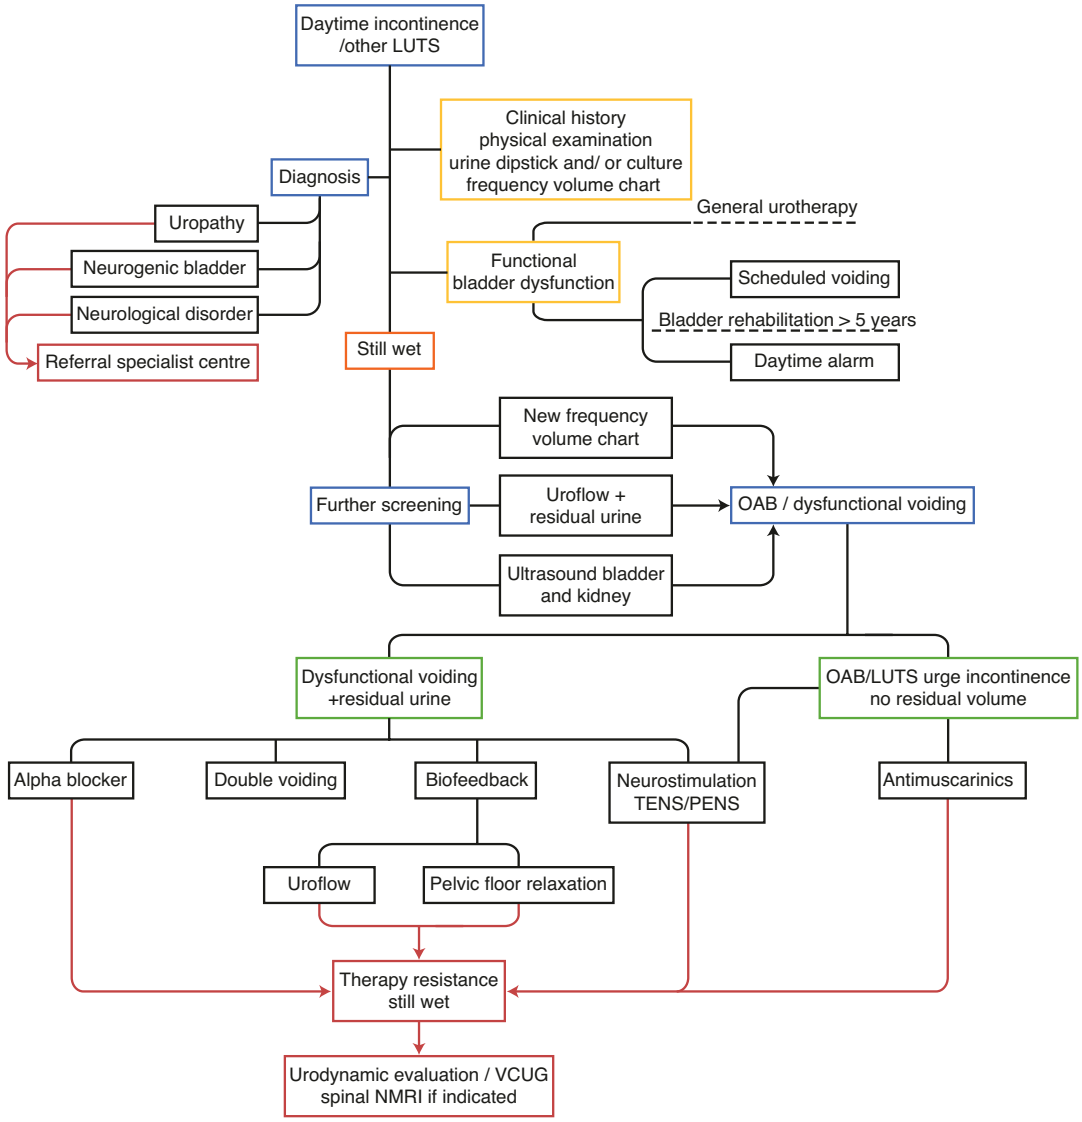

Fig. 47.5 Flow chart illustrating the evaluation and treatment of daytime incontinence/LUTS in children. The initial evaluation in children with LUTS starts at the age of 4–5 years. Clinical evaluation should focus not only on the bladder symptoms, but also on comorbidities such as constipation, neurologic disorders, neurologic bladder, and anatomical abnormalities uropathies. If these are excluded, we can conclude to a functional bladder dysfunction. Initial therapeutic approach, consists of treatment of constipation, and subsequent urotherapy. Bladder rehabilitation regimens and daytime alarm might be add on therapies. If this therapy fails, additional screening should be performed, including frequency-voiding chart during normalized fluid intake, uroflowmetry with US evaluation of residual volume, and ultrasound of kidney and the bladder. This non-invasive approach may lead to identification of the two archetypes, OAB and dysfunctional voiding, although there is a certain overlap between the two. In children with OAB, antimuscarinics are the treatment of choice, although neurostimulation offers an alternative treatment option. Patients with dysfunctional voiding benefit from a variety of urotherapy regimens, including pelvic floor relaxation- and uroflow biofeedback. In refractory cases, video-urodynamic investigation is mandatory. In cases where the videourodynamics give further indication for a neurologic disorder, spinal NMRI should be performed

Comorbidities: Dysfunctional voiding (previously called bladder-sphincter dysfunction), such as OAB with defence mechanisms, is associated with recurrent UTI, asymptomatic bacteriuria, vesicoureteral reflux and constipation and/or faecal incontinence (30–50% of children with urge incontinence). Furthermore, urinary incontinence is highly associated with increase in body mass index, constipation and/or faecal incontinence (10–15% of children with urge incontinence), neuropsychiatric conditions (e.g. ADHD, oppositional defiant disorder) and intellectual disabilities.

Urinary Incontinence Classification

Several structural congenital abnormalities (e.g. ectopic ureter, congenital urethral valve), and neurogenic bladder (e.g. spina bifida, sacral agenesia) often present with therapy refractory LUTS. Urinary incontinence can be divided into separate subtypes based upon the underlying mechanism [193]. The two subtypes that pose the greatest threat to the upper urinary tract and therefore should be identified and treated as early as possible are *neuropathic* bladder sphincter dysfunction and *structural* incontinence (organic). These two groups comprise only a few percent of incontinent children as most have no underlying neurological or anatomic cause. In *non-neuropathic* bladder-sphincter dysfunction, it is possible to further subtype the type of bladder dysfunction based upon clinical history, voiding pattern, uroflowmetry and residual urine. Continuous incontinence is often due to an organic disorder.

Bladder and bowel dysfunction (BBD): BBD is a condition of combined bladder and bowel disturbances that encompasses LUT and bowel function. *Severe BBD* is LUT and bowel dysfunction that is characteristic of the dysfunction seen in children with neurologic conditions, yet have no identifiable neurologic abnormality. This is almost synonymous with the historical term Hinman syndrome.

Overactive Bladder

OAB manifests as urinary urgency, usually accompanied by frequency and nocturia, with or without daytime incontinence, in the absence of UTI or other alternative etiology. Some patients may have minimal symptoms because they limit fluid intake during the day in an effort to decrease symptoms.

OAB is the most frequent cause of LUTS, with daytime incontinence, urgency, frequency, and small voided volumes as symptoms. Parents often notice efforts to prevent daytime enuresis, which they interpret as delaying micturition ("postponement"), but these children have high micturition frequency, in contrast with the typical postponers, who have low frequency of large voided volumes. Children with OAB usually have *detrusor overactivity*, but this should not be assumed without cystometric evaluation (see above). *Urgency incontinence* is involuntary loss of urine associated with urgency and is applicable to many children with OAB.

Voiding Postponement

Children who habitually postpone micturition using holding maneuvers have *voiding postponement*, which is diagnosed by clinical history. It is often associated with a low micturition frequency, and a feeling of urgency and possibly incontinence, due to a full bladder. Some children restrict fluid intake to reduce incontinence. The rationale for delineating this entity lies in the observation that these children often suffer from psychological comorbidity or behavioral disturbances such as oppositional defiant disorder (ODD).

Underactive Bladder

Children with underactive bladder need to strain with increased intra-abdominal pressure to void. The children may have low voiding frequency despite adequate hydration, but may also have frequency due to incomplete emptying with prompt refilling of the bladder. These children often produce an interrupted uroflow pattern, and have *detrusor underactivity* during invasive urodynamics. Flow patterns may also be plateau-shaped; pressure–flow studies will distinguish it from bladder outlet obstruction. The prevalence is higher in females and increases with age.

Dysfunctional Voiding

The child with *dysfunctional voiding* habitually contracts the urethral sphincter or pelvic floor during voiding and demonstrates a staccato pattern with or without an interrupted flow on repeated uroflowmetry when concomitantly recording electromyography (EMG) activity. There is a clear correlation with UTI and constipation, and in rare cases high intravesical pressure during voiding might lead to VUR and renal damage with or without UTI.

Bladder Outlet Obstruction

Bladder outlet obstruction has to some extent comparable symptoms as dysfunctional voiding, but it can only be diagnosed during urodynamic investigation.

Stress Incontinence

Stress incontinence is the involuntary leakage of small amounts of urine when intraabdominal pressure is increased. It is rare in children, in contrast to adult females, and can only be diagnosed during urodynamic investigation. This rare type of incontinence is occasionally seen in female elite athletes [194]. The underlying mechanisms are not fully understood, but may involve a hypermobile pelvic floor.

Vaginal Reflux

Vaginal reflux is frequent in young girls after they complete toilet training. They experience daytime incontinence in moderate amounts shortly after normal voiding and have no underlying mechanism other than obvious vaginal entrapment of urine. This is not associated with other LUT symptoms or enuresis. It is worsened by voiding with the legs closed, leading to urine entrapment inside the introitus. It may be seen in girls with labial adhesions and chronic, recurrent vaginitis.

Giggle Incontinence

Giggle incontinence is a rare condition in which complete voiding occurs specifically during or immediately after laughing in girls. Bladder function is normal when the child is not laughing. Giggle incontinence is not linked to any other disturbance of LUT function. It is often familial, and has a proven hereditary predisposition. It should be differentiated from giggling incontinence as a symptom, where the leakage is secondary to contraction of an overactive bladder, induced not exclusively by laughing but also by physical activity and coughing.

Extraordinary Daytime Urinary Frequency

Extraordinary daytime urinary frequency is seen in toilet-trained children who void very often and with very small volumes during the daytime only. The daytime voiding frequency is at least once per hour and average voided volumes are less than 50% of expected bladder capacity age for age (usually much smaller). Nocturia is absent, and it is not usually associated with incontinence.

Bladder Neck Dysfunction

Bladder neck dysfunction is impaired or delayed opening of the bladder neck, resulting in impaired flow despite an adequate or elevated detrusor contraction [195]. The prolonged opening time, which is the time between the start of a voiding detrusor contraction and the start of urine flow, can be seen on videourodynamics. Alternatively, bladder neck dysfunction can be diagnosed non-invasively with a uroflow/EMG when there is a prolonged EMG lag time, which is the time interval between the start of pelvic floor relaxation and the actual start of flow.

Evaluation

If a wetting child has daytime symptoms, initial evaluation should be started from the age of 4 to 5 years due to the importance of excluding neurological and structural causes. The history is very important, including the psychomotor development, the type of incontinence (e.g. constant dribbling indicating a structural cause), recurrent UTI, constipation, and FI. Information about the family situation, motivation and behavioral problems should be included in a structured history. The physical examination should focus on the

same areas as in a child with NE (above); urinalysis is also indicated. If the initial evaluation raises suspicion of an underlying disease, e.g. a neurological disorder or anatomical anomaly, the child should be referred to a secondary or tertiary referral center. The cornerstone in the initial evaluation of an incontinent child is a frequency-volume chart, as described for enuresis, with documentation of all incontinence episodes as well as the time and volume of all intake and voids during 2 days, typically during a weekend. This gives very valuable information about the severity of symptoms, drinking habits, voiding pattern and bladder capacity. Occasionally, just filling out a frequency-volume chart enables the parents to adjust an inappropriate voiding or drinking pattern, resulting in a continent child before the next clinic visit.

In a child with recurrent UTI, prophylactic antibiotics should be instituted and an ultrasound of the urinary tract obtained. If there is suspicion of constipation, and in all children with soiling or FI, this should be treated aggressively. If, however, no underlying disease is suspected, further evaluation is not necessary at this stage and treatment can be reduced to general advice about good voiding habits and awareness about signs of constipation and UTI. In the motivated child, bladder rehabilitation with scheduled voids can be commenced. If the incontinence symptoms persist after 5–6 years of age, the initial evaluation should be supplemented with an ultrasound examination of the urinary tract, uroflowmetry and measurement of postvoid residual urine by ultrasound. These investigations usually require referral to a specialist. These simple urodynamic evaluations characterize the voiding and bladder emptying and will enable differentiate between types of incontinence, e.g. urge syndrome and dysfunctional voiding, and may raise suspicion of a urinary tract obstruction. More invasive evaluations such as conventional transurethral cystometry, natural fill ambulatory continuous bladder pressure monitoring, and voiding cystourethrography are only indicated if there is suspicion of neuropathic or structural incontinence (abnormal uroflow, residual urine) or if the patient does not respond to the initial therapy.

Treatment

Overactive Bladder (Formerly Urge Incontinence)

1. Two to three percent of 7-year-olds have incontinence with concomitant signs of an overactive bladder, and up to one third of 7-year-olds have urgency with increased voiding frequency. This syndrome has undergone a conceptual change over the last decade. Previously, there was a clear-cut urodynamic definition of the "unstable" bladder, with bladder contractions during the filling phase of a cystometry; it has expanded to a diagnosis based on clinical history and diary.

   There is evidence that cystometry at screening adds no value to the initial therapeutic approach. Moreover, the majority of patients with OAB on cystometry had the typical clinical pattern of OAB (urgency, frequency, small voided volume). Hence, a clinical diagnosis and a cystometry diagnosis of OAB are viewed as equivalent on initial evaluation. OAB probably does not have a single pathogenic explanation. Rather, mechanisms include hypersensitivity of the bladder wall (efferent), low compliance of the bladder wall, and an imbalance between ortho and parasympathetic tone (documented in refractory patients by the therapeutic action of anticholinergics and beta-3-adrenoceptor mimetics).

   Because the clinical picture of this incontinence is so typical, the diagnosis can be made with confidence by a structured approach as described above and no further urodynamic testing is necessary unless the child fails to respond to initial therapy. The urodynamic definition, however, has been widened to include bladder and urethral dysfunction. Clinically, urge syndrome is characterized by frequent attacks of a need to void, countered by holding manoeuvres such as squatting, eventually resulting in usually small leaks of urine.
2. Treatment:
   (a) Urotherapy [143, 196]:
   Treatment of urge incontinence begins with elimination of concomitant

constipation and UTI followed by behavioural treatment (bladder rehabilitation).

- Standard urotherapy [143]
- Standard urotherapy (ICCS, ICI level 3C) will cure at least 50% of children and can be started by primary care physicians. The cornerstone of urotherapy is to establish the child's awareness about his/her particular voiding habits. Different specific strategies are utilized, but most include a normalisation of fluid intake and elimination of caffeine intake. The evidence is weak [145, 197]. Standard urotherapy also includes an initial increase in the number of voids, followed by a gradual decrease to normal frequency [35]. Based on a randomized study, it is helpful to use a programmable watch that gives a signal to the child when it is time to void. Inappropriate posture during voiding, if present, should be corrected. At referral centres, the clinical team should include a specialized team of doctors, specialist nurses (urotherapists), psychologists and eventually physiotherapists [198].
- Although the majority of urotherapy regimens concentrate mainly on the quality and quantity of fluid intake, elevated nutritional intake of sodium and protein will result in higher sodium and acid load in the urine [82, 83]. High urinary acidity and osmolality might trigger bladder overactivity [199, 200]. Furthermore, in patients with CKD, (who may have a deficit in concentrating capacity, a high osmotic load) will result in higher diuresis rate and therefore more OAB symptoms [201, 202].

(b) Anticholinergics/antimuscarinics

If urotherapy for a couple of months does not eliminate the symptoms, antimuscarinics should be initiated [203, 204].

There are only a few medications with substantiated effect in children, and some have significant side effects, especially in children with ADHD. More recently developed antimuscarinics seem to have less influence on cognitive function and are therefore better tolerated [205, 206]. Antimuscarinic therapy should not be instituted in a child with significant post-void residual urine and many centres monitor bladder emptying 4–5 weeks after initiation of treatment.

- Oxybutynin hydrochloride
  - Oxybutynin hydrochloride, a tertiary amine, is a moderately potent anticholinergic agent with strong musculotropic relaxant and local anaesthetic activity. In animal studies, it has weak anticholinergic activities, but strong spasmolytic effects [13, 207, 208]. It is worldwide the most prescribed drug for OAB.
  - The side effects are those of all antimuscarinic agents and include inhibition of salivary secretion (dry mouth), blockade of the ciliary muscle of the lens (disturbed accommodation, blurred vision), facial flushing during exercise, tachycardia, drowsiness and inhibition of gut motility, leading to constipation. Central nervous system side-effects, especially in children with ADHD, are quite important, including pronounced attention deficit and behavioural problems, and are related to ability of oxybutynin and its metabolites to pass the central blood barrier.
  - The half-life of the drug is low, necessitating at least three doses a day. One dose in the morning for daytime symptoms or one dose in the evening for OAB, is ineffective, based on this PK characteristics. Oxybutynin XL is absorbed in the large intestine, thereby bypassing the first pass liver metabolism

[209]. However, the tablets must be swallowed intact, and thus cannot be used in many young children. Transdermal administration has been proposed as an alternative, but data in children are absent [210]. Intravesical administration has been promoted, but is only feasible in neurogenic bladders with intermittent catheterisation [211–213].
  - Although widely prescribed, the therapeutic evidence in children as monotherapy is rather weak (Evidence 3C), certainly for the enuresis symptom, though it is mentioned in all guidelines [196, 214]. Many studies report the use of combination therapy (desmopressin, imipramine, urotherapy, neurostimulation) [175, 215–218].
- Tolterodine
  - Tolterodine is a selective antimuscarinic drug, which has a more pronounced antimuscarinic effect on the urinary bladder than on salivary gland, and there is less penetration through the blood-brain barrier, potentially decreasing side-effect [219]. This was supported by EEG measurements [203].
  - In adults, tolterodine effectively decreased the symptoms of detrusor overactivity and caused fewer side-effects than oxybutynin. Studies in neurogenic bladder were promising, but this was not confirmed in pediatric OAB studies. There were three explanations given for this failure: (a) the chosen primary endpoints in the study design, (b) pediatric OAB has never been proven to have the same pathophysiology as in adults, and (c) the large difference in metabolism of the drug, dependent of genetic differences in cytochrome P450 (CYP)-metabolism, resulting in underdosing in 1/3 of children. Therefore, the drug was never approved in children [220–222].
  - The extended-release form was developed for the adult indication, evaluated in two pediatric studies, but without clinically significant benefit [223, 224].
  - Although the evidence level 3C is in line with other available drugs, the large intra-individual PK variation related to the CYP-polymorphisms for metabolism of the drug suggests that it should not be first line therapy [220, 225, 226].
- Propiverine hydrochloride is an antimuscarinic drug with proven efficacy and better tolerability than oxybutynin in children with OAB. This was documented in a phase 3 trial. Both ICI and ICCS classifies this drug as evidence level 1 B/C, but there were never confirmatory data with propiverine as monotherapy [227–229].
- Solifenacin is a recently developed antimuscarinic with some interesting characteristics [206, 230–233]. Given once daily, it significantly decreased urgency episodes in a pooled analysis of four pivotal trials including more than 2800 adults. PK/PD data in adults demonstrated a long half-life, enabling once daily administration with a potential of increasing therapy compliance [234]. Additional studies showed promising results [205, 232]. The side effect profile, with a high affinity for the M3 muscarinic receptor, is more favourable than that of some nonspecific antimuscarinics. In children with neurogenic bladder and OAB, studies documented a good safety profile and a half-life almost comparable to adults [205, 235, 236].
- Preliminary PK data show that metabolism of the drug is even higher than expected from adult data. Recent PK/PD data in children with neurogenic bladder and OAB are in line with the

PK predicted data based on adult studies. The clinical effect seems to be better in neurogenic bladder than in OAB in the paediatric population, although the evidence is limited. The drug has a very acid taste, which makes crushing the pills to individualize the dose to the size of the child challenging. Moreover, the drug powder is very irritative, especially to the eye, if the pills are cut or crushed.

- Several drugs have been proposed off-label as alternatives to anticholinergics such as calcium channel blockers, NSAIDs, alpha-adrenergic blockers, and beta-3-adrenoceptor mimetics. However, none have enough evidence to recommend as first line OAB therapy in children.
- Calcium channel blockers and alpha-adrenergic blockers have common side effects, including hypotension, facial flushing, headache, dizziness, constipation, and nausea.
- Fesoterodine [237] has documented antimuscarinic PD-effect on OAB in adults, and comparable PK characteristics in children [238], but more side-effects than solifenacin, without improved efficacy [203, 225, 239–241]. Darifenacin is approved for adults, but without convincing data in children [203, 242].
- If one anticholinergic is not effective or has intolerable side effects, it is reasonable to switch to another given different PK and side effect profiles. However, combination therapy of two anti-muscarinics is not recommended since there are no clinical data regarding efficacy or side effects.

(c) Tricyclic antidepressants are useful agents for facilitating urine storage, by both decreasing detrusor contractility and increasing outlet resistance. They are no longer recommended as first line treatment for MNE. The mechanism of action NE remains unclear, but might involve anticholinergic effects on the bladder, effects on sleep patterns and reduced nocturnal polyuria (through reduced natriuresis) [169]. Many expert consensus papers consider imipramine as a third-line therapy for OAB after urotherapy and anticholinergics for LUTS. Imipramine has weak anticholinergic effects as well as adrenergic effects on bladder muscle. It may exert a local anaesthetic-like action on the bladder. Clinically, imipramine is effective by decreasing bladder contractility and increasing outlet resistance. Stimulation of the beta-receptor by peripheral blockade of noradrenaline reuptake could account for the decrease in bladder contractility, and stimulation of the alpha-receptors in the smooth muscle of the bladder base and proximal urethra increases bladder outlet resistance [203, 215, 243]. Some favour reboxetine because of efficacy and safety reasons, although convincing data are lacking [244, 245].

(d) The beta3-adrenoreceptor agonist mirabegron is the first of a new type of drugs targeting the orthosympathetic pathway [145, 246, 247]. In controlled randomised trials in adults mirabegron had a positive effect on OAB symptoms [145, 234]. A few limited studies have supported this effect in children [234, 248–251]. The tablets cannot be crushed or chewed because of major changes in bioavailability, and this limits their use in smaller children [231].

(e) Electro neuromodulation

Electro neuromodulation using cutaneous stimulation of either the sacral or peripheral nerves is a treatment modality in children, gaining interest over the last decade despite some controversy regarding efficacy. The devices and techniques are very heterogeneous, using skin surface or percutaneous electrodes (TENS or percutaneous electrical nerve stimulation), but also anal or intravesical

electrodes. The devices have varying frequencies, waveforms and intensities, but there is no evidence regarding the optimal choice for each subtype of patients. The major proposed indication is in OAB patients refractory to antimuscarinic drug therapy, either alone or in combination with the drug. If percutaneous needle sacral stimulation is beneficial, an implantable pacemaker is a possible option in very treatment-resistant patients.

(f) Botulinum toxin
There is increasing evidence to support the use of botulinum A-toxin in the detrusor for treatment-refractory OAB (EB 3C). It was approved by the Food and Drug Administration in 2021 for neurogenic bladder detrusor overactivity. The safety and efficacy is well-documented. Small, single center studies show promising results in children with OAB, but prospective controlled studies are ongoing.

Dysfunctional Voiding (Staccato Voiding)

Voiding dysfunction in children is rare. Approximately 1% of 7-year-olds will have a uroflowmetry clearly deviating from normal [55, 252]. The predominant pattern is that of staccato voiding, which consists of frequent interruptions of detrusor initiated voiding. Dysfunctional voiding has many names, including non-neuropathic bladder-sphincter dyscoordination and overactive urethra another, but ICCS recommends the term 'dysfunctional voiding' [36]. The symptoms are to some extent similar to those of the urge syndrome, although recurrent UTI, constipation and soiling are more prevalent in this patient group. It is generally agreed that diagnosis requires a consistent pattern of three consecutive characteristic uroflowmetry results. The aetiology of dysfunctional voiding is not fully elucidated. The simplest theory is that it can be a long-term effect caused by voiding pains following a UTI, where the child learns to protect the urethra from the full urine stream by contracting the sphincter and continues to do so after the urethral pain has disappeared. This may lead to overtraining of the pelvic floor and the urethral sphincter during holding. It is also hypothesized that it is a sign of a delayed maturation of the interaction between the detrusor and the pelvic floor or an increased nociceptive receptor response in the proximal part of urethra.

Besides elimination of UTI and constipation, initial treatment consists of bladder rehabilitation with timed voids and double voiding twice a day. If insufficient, uroflow-biofeedback training may provide additional pelvic floor relaxation [143]. A treatment trial with an alpha-adrenergic blocker can be considered in refractory cases, although the evidence is weak [252, 253]. This approach is based on the fact that the physiological internal sphincter is controlled by alpha-adrenergic receptors in the smooth musculature of the bladder neck and proximal urethra. Although the theoretical expected effect would be best in those patients with bladder neck obstruction, good results are described in patients with detrusor sphincter dyssynergia, suggesting that there may also be an effect on striated sphincter tone [254–257]. To date, alpha-adrenergic blockers have no approved indication in children. Terazosin, alfuzosin and other similar new alpha-adrenergic blockers are more selective for the urinary tract. The side effects are orthostatic hypotension, tachycardia and a possible first-dose phenomenon with faintness, dizziness, palpitations and syncope. Effectiveness can be monitored with a combination uroflowmetry and residual urine measurement. Special techniques have been used in therapy-resistant cases, like training in voiding schools, as well as intermittent catheterisation.

Underactive Bladder

This entity is characterized by few (≤3) daily voids with unusually large volumes, poor bladder emptying, and a very high prevalence of UTI, constipation, and vesicoureteral reflux; it is more frequent in girls [258, 259]. The child typically strains during micturition and leakage occurs secondary to overflow incontinence. The

aetiology is multifactorial but one hypothesis suggests that it is the result of sustained bladder-sphincter dyscoordination. In some children, the syndrome is associated with a prior history of previous infravesical obstruction. In order to establish the correct diagnosis, it is often necessary to perform a urodynamic examination to exclude an associated underlying neuropathy. The cystometry shows large bladder capacity, most often a weak detrusor, a negative bethanechol test and no signs of obstruction on the pressure-flow examination. The treatment is similar to that described for dysfunctional voiding except that a larger proportion of patients require a period of clean intermittent catheterisation [270]. Structured training programs offer a non-invasive alternative.

Neuropathic Incontinence

Although incontinence secondary to neuropathy is rare, it is associated with significant risks of serious long-term injury to the urinary tract as well as decreased renal function [260, 261]. This chapter will not provide details of the different types of incontinence due to neuropathic causes, but emphasize the importance of close and thorough long-term monitoring of bladder and renal function in such patients. The variability of urodynamic abnormalities and their ability to change over time in children with congenital neurological defects such as myelomeningocele illustrates the need for life-long specialist follow-up [9, 29]. Treatment of severe neuropathic incontinence usually requires a large interdisciplinary team, including pediatric nephrology, urology, neurology, neurosurgery, orthopedics, psychology, and physiotherapy. Furthermore, all incontinent children should be screened for neurological defects as outlined above. If a suspicion of neuropathy is raised, an MRI of the spinal canal should be performed together with urodynamic evaluation, cystourethrogram, and ultrasound of the urinary tract. Conservative treatment includes antimuscarinics, either peroral or intravesical, clean intermittent catheterization, laxatives, and prophylactic antibiotics. Surgical treatments include bladder augmentation, cutaneous vesicostomy, anti-reflux surgery, and continence preserving surgery. Intravesical injection of botulinum toxin represents a newer method of detrusor relaxant therapy.

Structural Incontinence

Anatomical abnormalities can also be associated with significant voiding symptoms and are potentially damaging forms of incontinence [262]. Although not all are visible by physical examination, it is mandatory to inspect the genital region of the incontinent child for a possible cause of the incontinence.

Sphincter by-pass: Dribbling incontinence should always raise suspicion of a structural defect in the urinary tract, such as an ectopic ureter, often arising from the upper segment of a duplex kidney. Other forms of structural incontinence with sphincter by-pass are the exstrophy complex and epispadia, where diagnosis is much less complicated than the subsequent complex treatment.

Urinary tract obstruction: Voiding dysfunction and incontinence resulting from congenital malformations that cause LUT obstruction is much more common in boys than girls. The classical example is a posterior urethral valve, which most often arises from the colliculus and forms a membrane that obstructs urinary flow. In the severe forms, the diagnosis may be detected by prenatal ultrasound showing a distended bladder, bilateral hydronephrosis, and hydroureter. In milder cases, the diagnosis is often obtained by urodynamic evaluation, either by reduced flow rate on a uroflowmetry or by detrusor hyperactivity during filling and high pressures during voiding on invasive urodynamic investigation in a boy with treatment resistant day-time incontinence. Valve patients have long-lasting bladder dysfunction that often requires treatment and should be followed to adulthood [7]. Another problem in these patients is polyuria caused by post-obstructive renal tubular damage. Especially

at night, this can result in bladder retention and a nocturnal catheter may be necessary. Other forms of LUT obstructions exist ranging from bladder neck obstruction, syringocele, meatal stenosis, and in rare cases a stenosis caused by phimosis.

Other Types of Incontinence

Giggle Incontinence

Giggle incontinence typically occurs during prepuberty and more commonly in girls [259, 263]. The aetiology is unknown [264]. Physical and urodynamic examination are most often normal. It has been postulated that the giggling, via central nervous system centres, triggers a reflex relaxation of the urethral sphincter, which starts a bladder contraction and micturition. The syndrome is often very disturbing for the affected child, and it is of little comfort to the child that the condition generally improves over time. Many different treatment modalities have been tried, but no controlled trials exist. No treatment is documented as effective, and most are ineffective. Sympathicomimetic agents, such as methylphenidate, and imipramine, together with biofeedback training for better pelvic floor control and for control of the sphincter are some of the treatment options. Others have tried anticholinergics. Only 50% of patients benefit from medication [263, 265–268].

Vaginal Voiding

In a substantial number of girls, the hymen is funnel-shaped or the labia are partly fused, and during voiding part of the stream will enter the vagina so that the urine will dribble after the patient has left the toilet. In addition, some girls, especially obese ones, tend to sit on the toilet with the thighs close together, which will obstruct normal urine flow and direct some urine into the vagina during micturition. Symptoms are diagnostic, with dribbling just after leaving the toilet and the treatment is simple in most cases: the child changes to a backward position on the toilet, with one leg on each side of the toilet so that she will be forced to spread her legs widely.

Summary

NE and voiding dysfunction are very common disorders of childhood and adolescence that despite their benign nature are often chronic and cause significant negative effects on the child's well-being. Furthermore, although the large majority of patients have a non-organic etiology, some have an underlying structural or neurogenic anomaly that causes not only resistance to standard therapy but also poses a threat to renal function. With a structured approach based mainly on a thorough history and physical examination and a frequency-volume chart, it is possible to identify subjects at risk for having underlying pathology and to obtain the correct diagnosis in the majority of cases. Only a minority of patients need invasive urodynamic investigation and imaging. In patients with NE, knowledge about functional bladder capacity and nocturnal urine volume facilitate the choice of treatment modality. The initial conservative treatment of daytime incontinence is based primarily upon bladder rehabilitation and only some patients need pharmacological treatment, biofeedback, or more aggressive treatment. Although there have been advances in our understanding of the mechanisms behind non-neuropathic bladder-sphincter dysfunction, there are still many unanswered questions and good evidence-based treatment modalities are still needed.

Introduction and Importance

Hypertension (HTN) remains an important but underappreciated medical condition in youth. In the short term, acute and chronic HTN rarely are associated with increased morbidity and mortality during childhood, though specific sub-populations of youth with secondary HTN (e.g., patients with kidney failure on dialysis) have an increased incidence of morbidity and mortality during childhood. Youth-onset HTN predicts persistent adult HTN and cardiovascular disease [1] and is associated with target organ damage both in childhood and adulthood [2]. While long-term outcome data remain limited [3], it is paramount that children

and adolescents continue to be appropriately screened for HTN and that patients with HTN are accurately diagnosed, evaluated, and treated by health care providers with sufficient expertise in pediatric HTN [4]. In this chapter, we will discuss blood pressure screening recommendations and high-risk populations, compare the different methods of blood pressure assessment, and review diagnosis and evaluation recommendations for children and adolescents with HTN.

Morbidity and Mortality During Childhood

Cardiac Complications

Subclinical cardiovascular disease is detectable in children and young adults with HTN. Left ventricular hypertrophy (LVH), defined by an elevated left ventricular mass index (LVMI) relative to body size, is detectable in approximately 40% of children and young adults with HTN [5–7]. Children with HTN had impaired ventricular relaxation and diastolic dysfunction compared to healthy peers with normal blood pressure [8]. Higher blood pressure was associated with fatty streaks and fibrous plaques in the coronary arteries and aorta of deceased children and young adults in the Bogalusa Heart Study [9]. Congestive heart failure may develop, presenting with peripheral or pulmonary edema, dyspnea, chest pain, or a gallop rhythm. Some or all of these symptoms can occur in up to 29% of patients with acute severe HTN [10]. Cardiomegaly may be detected on imaging, though chest radiographs have poor sensitivity and specificity and should not be used to screen for cardiomegaly in this setting [11]. LVH was found in 43% of pediatrics patients presenting with hypertensive emergency [12], suggesting a high prevalence of chronic HTN.

Neuropathy/Retinopathy

Neurologic manifestations are the most common symptoms and include headache and dizziness, with seizures occurring in up to 20% of patients [13]. Facial nerve palsy secondary to acute severe HTN is most commonly seen in children and can occur in 5% of cases [14]. Additional neurologic signs include vomiting, mental status changes and lethargy (i.e., encephalopathy), and visual disturbances including cortical blindness. The constellation of mental status changes, headache, visual disturbances, and seizures, coupled with radiographic findings, constitutes reversible posterior leukoencephalopathy syndrome. Increased blood pressure over time was strongly associated with development of reversible posterior leukoencephalopathy syndrome in children and adolescents at high risk [15]. Visual changes may be a sign of hypertensive retinopathy and can be due to ischemic neuropathy, retinal infarcts, optic disk edema, cortical blindness, or increased intracranial pressure. A careful physical exam can reveal papilledema or retinal hemorrhages, which indicate target organ damage in the eyes, and it is important to note that lack of visual changes does not exclude hypertensive retinopathy [16].

Cognitive Dysfunction

Increasing evidence suggests that HTN affects neurocognition during childhood and into adulthood. Multiple studies have shown that children with HTN perform worse in tests of neurocognitive function compared to normotensive controls, though of note these individuals still test in the normal range [17–19]. Recent evidence suggests that uric acid may play a role in HTN-associated neurocognitive changes [20]. Neurocognitive test results improve with successful HTN treatment [21, 22].

Kidney Disease

Kidney disease—both acute and chronic—remains one of the most common etiologies of acute severe HTN in children and adolescents [13]. Less robust evidence suggests that acute severe HTN may contribute to kidney dysfunction as well. In adults, hypertensive crisis has been associated with elevated levels of urine neutrophil gelatinase-associated lipocalin [23], an early urinary marker of acute kidney injury. The data in children are less clear, though hyponatremic hypertensive syndrome—severe HTN and natriuresis thought to be due to increased renin-angiotensin-aldosterone system activity—has been described in children with acute severe HTN [24, 25], particularly those with unilateral renal artery stenosis.

Risk Across Life Course

Numerous clinical and epidemiological studies with long-term follow up have consistently demonstrated that, across diverse populations, childhood blood pressure tracks with blood pressure throughout adulthood and that youth-onset HTN increases the risk of HTN, cardiovascular disease, and kidney disease, including associated mortality, in later adulthood [1, 26, 27]. Data from the Fels Longitudinal Study demonstrated that even a single childhood systolic blood pressure measurement that exceeded age- and sex-specific criteria (at approximately the 50th percentile) increased the odds of HTN and metabolic syndrome at ≥30 years of age [28]. This association increased exponentially with increasing numbers of blood pressure measurements [28, 29]. Individuals with higher blood pressure trajectories during childhood were more likely to have HTN as adults, a relationship that was more pronounced during adolescence in individuals who were Black and in females [30–32]. In the Childhood Determinants of Adult Health Study, children with high blood pressure had a 35% increased risk of having high blood pressure as adults compared to those with normal childhood blood pressure [27]. Higher blood pressure trajectories were also associated with the presence of more cardiovascular disease risk factors at age 38 years [32].

Pediatric blood pressure consistently has been shown to be associated with several intermediate markers of cardiovascular disease risk. Individuals with higher blood pressure during both childhood and adulthood had an increased risk of higher pulse wave velocity and higher carotid intima-media thickness (a marker of subclinical arteriosclerosis) as older adults [33–39]. Further, individuals who decreased their number of cardiovascular disease risk factors from childhood into adulthood, including resolution of prior pediatric high blood pressure, had a decreased risk of higher pulse wave velocity and higher carotid intima-media thickness compared to individuals whose risk factors did not improve into adulthood [40, 41]. Moreover, higher childhood blood pressure (12–18 years) and greater blood pressure trajectories in young adulthood (18–30 years) were associated with higher coronary artery calcification scores 25 years later [42, 43].

Higher blood pressure trajectories during childhood and adolescence were associated with greater left ventricular mass index and LVH in later adulthood [36, 44]. Cumulative exposure to higher blood pressure in childhood and young adulthood—defined by the total and incremental areas under the curve—were significantly associated with concentric LVH, eccentric LVH, and left ventricular systolic and diastolic dysfunction in later adulthood [45–47]. In the Bogalusa Heart Study, higher blood pressure beginning in childhood was associated with greater premature mortality due to coronary artery disease (mean age 45 years) [48]. In large population-based studies from Sweden, higher blood pressure in adolescents and young adults was associated with an increased risk of coronary heart disease, myocardial infarction, stroke, and death from cardiovascular causes [49, 50]. In the Harvard Alumni Health Study, high blood pressure at young adult age was associated with increased risk of death from coronary heart disease and cardiovascular disease in later adulthood (mean age 46 years) [51]. Compared to normal or elevated blood pressure, HTN in young adults was associated with shortened life expectancy of at least 2.2 years and accounted for 58.5% excess deaths from cardiovascular disease [52].

Blood pressure during childhood is also associated with the development of kidney disease later in life. In the Hanzhong Adolescent Hypertension Cohort, worse blood pressure trajectory starting in childhood (mean age 12 years) was associated with chronic kidney disease (CKD) in adults 30 years later, defined as either an estimated glomerular filtration rate 30–60 mL/min/1.73 m^2 or albuminuria [53]. In a study of over 2.6 million healthy adolescents in Israel (mean age 17 years), adolescents with HTN had double the risk of kidney failure and triple the risk of stroke mortality after a median of 20 years of follow up [54, 55].

As summarized by the 2020 U.S. Preventive Services Task Force, "there is adequate evidence about the longitudinal association between high blood pressure in children and adolescents and high blood pressure and other intermediate outcomes in adults" [3]. Despite this wealth of evi-

dence, long-term interventional trials are lacking due in large part to the difficulty to perform such studies. Hence, it remains unknown whether identifying or treating youth-onset HTN improves long-term outcomes.

Definition and Epidemiology

In adults, normative blood pressure thresholds and definitions for hypertensive disorders are based on robust outcomes data, including cardiovascular and all-cause mortality and morbidity [56]. However in children there is a lack of clinical outcome data, and pediatric blood pressure thresholds and definitions are instead based on epidemiological data from normative blood pressure distributions obtained from approximately 50,000 healthy children [57]. Normative distributions are based upon age, sex, and height, as these factors strongly influence blood pressure values.

In 2017, the American Academy of Pediatrics released a clinical practice guideline (CPG) for the diagnosis, evaluation, and treatment of high blood pressure in children and adolescents [4]. According to this guideline, normative blood pressure values should be based on age, sex, and height-based percentile distributions for children aged 1–13 years (tables can be found in [4]). These normative values are based on reference populations from which children with overweight or obesity were excluded since these individuals have higher blood pressure than their normal-weight peers [58–61]. Thresholds based on absolute blood pressure values were instituted for adolescents 13 years and older to integrate with the 2017 American College of Cardiology/American Heart Association (AHA) Guideline for the Prevention, Detection, Evaluation, and Management of High Blood Pressure in Adults [56].

Definition and Classification

Children and Adolescents Aged 1–17 Years of Age

The 2017 CPG instituted several changes in how it defined hypertensive disorders (Table 48.1). "Prehypertension" was replaced with "elevated blood pressure" to be consistent with adult guidelines and to emphasize the importance of lifestyle measures in preventing HTN development. Stage 2 HTN in children <13 years of age is defined as "≥95th percentile plus 12 mmHg". In adolescents 13 years of age and older, the definitions are now based only on absolute blood pressure values to be harmonious with the 2017 adult guidelines.

Table 48.1 Blood pressure classification by casual (office) measurement. Adapted from [4]

Classification	Age <13 Years[a]	Age ≥13 Years (mmHg)
Normal BP	<90th %ile or <120/80 mmHg	<120/80
High BP	≥90th %ile or ≥120/80 mmHg	≥120/80
Elevated BP	≥90th to <95th %ile or 120–129/<80 mmHg	120–129/<80
HTN	≥95th %ile or ≥130/80 mmHg	≥130/80
Stage 1 HTN	≥95th to <95th %ile + 12 mmHg or 130–139/80–89 mmHg	130–139/80–89
Stage 2 HTN	≥95th %ile + 12 mmHg or ≥140/90 mmHg	≥140/90

BP blood pressure

[a] Whichever is lower between the percentile-based or absolute blood pressure

Infants Under a Year of Age

The normative blood pressure tables in the 2017 CPG start at age 1 year [4]. For infants under a year of age, the definition of HTN is less clear due to a paucity of normative data and increased difficulty in obtaining accurate and consistent blood pressure measurements. The 2017 CPG recommended using data compiled in Dionne et al. 2012 to define high blood pressure values in neonates up to 44 weeks postmenstrual age [62] and the published blood pressure curves provided in the 1987 Second Task Force for infants aged 1–12 months of age [63]. However, important caveats remain and warrant further study, including validation in larger and more diverse populations and normative values for infants born preterm, small for gestational age, or who have additional early-life risk factors.

Hypertensive Emergency

Acute severe HTN—also termed hypertensive emergency, a type of hypertensive crisis—describes any episode of acute, symptomatic HTN with severely high blood pressure and is associated with acute target organ damage, including acute neurologic injury, acute kidney injury, and hypertensive cardiomyopathy/congestive heart failure [4]. There exist a wide variety of symptoms—and symptom severity—that may occur with acute severe HTN. There is no established, evidenced-based definition for what constitutes severely high blood pressure. According to the 2017 CPG, clinicians should be concerned when blood pressure is 30 mmHg or more above the 95th percentile for age, sex, and height [4]. Among pediatric patients presenting to the emergency department with hypertensive crisis, 98–100% had blood pressure at or above the stage 2 HTN threshold, and patients with hypertensive emergency had higher systolic and diastolic blood pressure ratios (blood pressure indexed to the stage 2 HTN threshold) compared to those with hypertensive urgency (i.e., severely high blood pressure without symptoms or evidence of target organ damage) [10, 64, 65]. Blood pressure equal to the stage 2 HTN threshold strongly predicted development of reversible posterior leukoencephalopathy syndrome in children and adolescents at high risk [15]. Future studies are warranted to better define acute severe HTN in children, including at which blood pressure thresholds predict organ or life-threatening injury, and to develop more specific criteria to define "symptomatic" HTN with adequate predictive capabilities.

Incidence and Prevalence

True HTN incidence in the general pediatric population has not been well described historically or after publication of the 2017 CPG. In the United States, a Houston, Texas school-based screening study estimated the yearly incidence of HTN in adolescents to be approximately 0.5% [66]. In that study, HTN incidence was significantly higher in at-risk groups, including 1.4% per year in adolescents who had a prior elevated blood pressure reading that normalized at follow up and 6.6% per year in adolescents with persistent elevated blood pressure [66]. Future investigation is needed to better define the true HTN incidence in the general pediatric population and select high-risk groups.

Prior to the 2017 CPG, multiple studies estimated youth-onset HTN prevalence to be 2–5% [67–69], while a recent meta-analysis reported the global prevalence to be 4% [70]. HTN is more common in certain pediatric populations: up to 50% of youth with CKD [71] and 24% of youth with obesity [72]. Several studies have assessed the change in prevalence of pediatric hypertensive disorders due to the 2017 CPG compared to the Fourth Report [59, 61, 73–76]. Due in part to the slightly lower threshold to define HTN in the 2017 CPG, high blood pressure prevalence increased in 6–17-year-olds in a large study in China compared to the Fourth Report [74]. A large, retrospective cohort study found prevalence of HTN to be 4.9% and of elevated blood pressure to be 4.3% [77]. Bell et al. found that high blood pressure prevalence (defined as elevated blood pressure plus HTN [78]) increased using the 2017 CPG criteria, while HTN prevalence decreased [59]. This was due, in part, to a large proportion of adolescent participants aged 13–14 years who were categorized using absolute thresholds rather than percentiles.

Screening Recommendations

There is a plethora of data demonstrating that youth-onset HTN increases the risk of morbidity and mortality in childhood (see section "Morbidity and Mortality During Childhood") and persists into adulthood and increases the future risk of cardiovascular disease, kidney disease, and related mortality across the life course (see section "Risk Across Life Course"). However, there remains insufficient evidence regarding which blood pressure thresholds predict future risk, the appropriate age to start blood pressure screening, or if screening is even efficacious [3]. Despite this, numerous organizations

have recommended routine HTN screening of asymptomatic children and adolescents [79–82].

The 2017 CPG was incorporated into the recommendations of the AHA, Hypertension Canada, and the American Academy of Family Physicians [83–85]. According to these guidelines, annual blood pressure measurements should start at age 3 years—ideally at annual health supervision visits. Children with known risk factors such as obesity, CKD, history of aortic arch obstruction or coarctation (regardless of repair status), diabetes mellitus, or who are taking medication known to increase blood pressure should have screening blood pressure measurement at every health care encounter [4]. The 2016 European Society of Hypertension guidelines for the management of high blood pressure in children and adolescents confirmed that routine blood pressure screening should start at age 3 years but clarified that, once normal blood pressure is established, further screening should occur every 2 years [86].

Children <3 years of age should continue to have screening blood pressure measurements at every health care encounter if they have certain high-risk conditions (Table 48.2) [4]. Unfortunately, several studies have shown that these children often are not screened appropriately [87]. It is important to note that for individuals who are otherwise healthy, a diagnosis of HTN should not be based on blood pressures measured during for acute illnesses or other complaints that could be associated with inaccurate blood pressure measurement. There remains no direct evidence that high blood pressure screening in children and adolescents aged 3–17 years improves health outcomes [3]. Thus, more evidence is needed to support routine blood pressure screening and to establish recommendations that are more specific.

Table 48.2 At-risk children in whom blood pressure screening should occur before 3 years of age. Adapted from [4]

Evidence of elevated intracranial pressure
Prematurity <32 weeks' completed gestation, small for gestational age, very low birth weight
Neonatal complications that required Neonatal Intensive Care Unit admission
Umbilical artery lines in the neonatal period
Congenital heart disease irrespective of repair status
Recurrent urinary tract infections
Hematuria or proteinuria
Known kidney disease, including congenital anomalies of the kidney and urinary tract
Family history of congenital kidney disease
Solid organ transplant or stem cell transplant recipient
History of malignancy, including active or in remission
Taking medications known to raise blood pressure
Systemic medical conditions associated with HTN: sickle cell disease, William syndrome, Marfan syndrome, neurofibromatosis, tuberous sclerosis complex, etc.

Emerging At-Risk Populations

Certain existing risk factors for HTN in youth such as antenatal and postnatal exposures require further investigation to clarify the precise nature of the risk conferred. Emerging evidence suggests novel risk factors may exist but that require further investigation.

Antenatal and early-life exposures are increasingly associated with higher blood pressure and risk of developing HTN during childhood and across the life course [88, 89]. Lower **birth weight** and greater relative weight gain in infancy have been associated with higher blood pressure trajectories during childhood [90]. Individuals born preterm with very low birth weight had higher blood pressure compared to term-born peers as adolescents (age 14–15 years) and young adults (age 18–23 years) [91, 92]. Young adults born extremely preterm with extremely low birth weight had higher ambulatory blood pressure at age 25 years and a greater trajectory of ambulatory blood pressure from 18 to 25 years compared to term-born peers [93]. Lower birth weight was associated with an increased risk of coronary artery disease in adulthood [94]. Individuals born preterm or small for gestational age demonstrated altered heart structure and function as young and middle-aged adults [95–97]. However, specific thresholds for prematurity and birth weight as well as the relative contributions of each exposure that confer risk for subsequent HTN, cardiovascular disease, and CKD remain unknown [89, 98]. It is unclear if being born prematurely

or small for gestational age per se are the relevant risk factors or if it is the antecedent maternal or fetal condition or exposures that led to premature birth and fetal size that actually confers the risk, such as maternal preeclampsia [99].

In addition, neonatal conditions such as **bronchopulmonary dysplasia** and postnatal exposures such as **acute kidney injury** during the neonatal period may increase the risk of HTN in the neonatal period and throughout childhood and adulthood, however these data remain limited and warrant further study [100–103]. The underlying mechanisms responsible for this increased risk of HTN remain incompletely defined but may include programming of key hormonal pathways such as the renin-angiotensin-aldosterone system, uric acid, klotho, and alterations to the structure and function of various tissues, including the kidneys, heart, vasculature, and brain [91, 92, 96, 104–109]. See Chap. 50 for a more detailed discussion of the mechanisms underlying development and etiology of youth-onset HTN.

There is increasing evidence that **unmet social needs**, health disparities, and adverse childhood experiences are associated with adverse health outcomes, including higher blood pressure, HTN, and cardiovascular disease [110–113]. Data from 7125 participants aged 8–17 years in the National Health and Nutrition Examination Survey revealed that household and child food insecurity were associated with high blood pressure [78]. The Georgia Stress and Heart study found that participants who experienced multiple childhood traumatic events had a greater blood pressure rise from childhood to after age 30 than those who did not [114]. Among participants in the Coronary Artery Risk Development in Young Adults study, low childhood socioeconomic status predicted increased blood pressure over a 10-year period directly and indirectly through childhood family environment, negative emotionality, and health behavior [115]. Thus, further investigation is needed to define these exposures and develop appropriate screening approaches and interventions to mitigate adverse health risks [116].

Blood Pressure Measurement

Normative blood pressure data in children are based on manual pressures taken in the upper portion of the right upper extremity in large cross-sectional studies [57]. For this reason, a definitive diagnosis of HTN continues to rely on manual blood pressures in the right upper extremity [4]. However, oscillometric blood pressure devices are commonly used in the clinical setting due to their ease of use and can be an appropriate screening approach, as long as any high blood pressure readings are confirmed with manual, auscultatory measurement [4]. Oscillometric devices provide some advantages compared to manual blood pressures. They require less training and are more user-friendly. The machines can be programmed to automatically take repeated measurements over time—useful in the inpatient setting—and they tend to provide consistent intra-individual results once the patient has acclimated to the cuff. Readings can be stored and retrieved from the device at a later time.

Despite these advantages, oscillometric devices have significant shortcomings. Importantly, they measure mean arterial pressure (MAP) rather than directly measuring systolic and diastolic blood pressures. The devices use proprietary algorithms to convert the MAP to systolic and diastolic blood pressure values that have not been independently evaluated or validated, leading to variability between brands and concerns about measurement bias in clinical research. Reputable resources to determine if a device has been properly validated are accessible on the internet and are summarized here [117, 118].

As a whole, oscillometric devices tend to overestimate systolic blood pressure when compared to auscultatory measurement, while diastolic measurement is often inconsistent and both over and underestimated [119, 120]. Generally, manual auscultated blood pressure more accurately predicts target organ damage in children [121]. Importantly, few oscillometric devices have been validated in children, and studies have found that certain devices differ in their accuracy between adults and children [122, 123]. U.S. Food

and Drug Administration device approval only indicates that the device is as good as previous devices already on the market, and less than 20% of all devices have undergone validation testing for accuracy.

For these reasons, oscillometric blood pressure readings obtained with devices—validated in children—are acceptable to use as a screening method but should not be used alone to diagnose hypertensive disorders in children [4]. High blood pressures obtained via the oscillometric method should be confirmed by auscultation [4, 124].

Technical Considerations

Appropriate measurement technique is critical for accurate blood pressure assessment and HTN diagnosis. Errors in technique are especially common in children and include incorrect positioning, improper cuff bladder size, inadequate equipment, or poor provider technique.

Best practice mandates that the patient should sit calmly in a quiet room for a minimum of 5 min prior to blood pressure measurement [4, 85]. The patient's back should be supported and their feet flat on the floor and uncrossed. Unless there is a contraindication, blood pressure should be measured in the upper portion of the right upper extremity. In addition to normative blood pressures being defined in the right upper extremity, this approach also avoids falsely normal blood pressures in the setting of coarctation of the aorta. Repeated blood pressure measurements should be taken in the same extremity at each visit.

Incorrect cuff size is a common source of error, especially in children; cuffs that are too small can provide a falsely high reading, while cuffs that are too large can provide a falsely low reading [125]. Health care providers must ensure that they have the full range of cuff sizes, including thigh cuffs. The provider should measure the mid-arm circumference, located at the midpoint between the acromion and the olecranon. The cuff's bladder length should cover 75–100% of the arm circumference, without overlapping itself, and the width should be 37–50% of the arm circumference. The cuff should be placed on bare skin—avoiding tightly rolled clothing proximally—and should fit snuggly but not too tightly approximately 2 cm above the antecubital fossa. The middle of the bladder cuff should be placed over the brachial artery proximal to the antecubital fossa; most cuffs have a line or marker to assist with lining the cuff up with the artery. The extremity should be supported at heart level (i.e., the midpoint of the sternum) by the provider or a table. The patient should remain calm and still during measurement, and both the provider and the patient should avoid talking.

For manual measurements, the provider should first palpate and locate the brachial artery, which is often just proximal and medial to the antecubital fossa. They should palpate the radial artery pulse as they inflate the cuff, up to 20–30 mmHg above the point at which the pulse is no longer palpable and avoiding over-inflation. Either the diaphragm or bell of the stethoscope should be placed over the brachial artery below the lower edge of the cuff, ensuring that the diaphragm or bell is not under the cuff itself. The provider should ensure a steady and appropriate rate of cuff deflation, typically 2–3 mmHg per second. The first audible sound (phase I Korotkoff) and last audible sound (phase V Korotkoff) should be noted as the systolic and diastolic blood pressures to the nearest even number (i.e., by 2 mmHg). If the Korotkoff sounds are heard at 0 mmHg, the point at which the sound is muffled (phase IV Korotkoff) should be taken as the diastolic blood pressure.

If the patient's initial blood pressure is high, it should be repeated at least two additional times separated by 1–2 min and the subsequent readings should be averaged. If the initial blood pressures were taken manually, this averaged value is used to classify the patient's blood pressure category. If measured via an oscillometric device, then two manual blood pressure measurements should be taken and averaged [4].

Lower Extremity Measurement

For blood pressure screening and HTN diagnosis, blood pressure measurement in the lower extremities should generally be avoided as blood pres-

sures measured in the lower extremities have been shown to correlate poorly and unreliably with blood pressures measured in the upper extremities and centrally [126–129]. However, there may be times that upper extremity blood pressures are medically contraindicated or four-extremity blood pressures are indicated (e.g., screening for coarctation of the aorta). For lower extremity measurements, the patient should be in the prone position and the appropriately sized cuff should be placed on the middle of the upper portion of the lower extremity. Cuff size recommendations are the same as for the upper extremity, and the stethoscope's diaphragm or bell is placed over the popliteal artery in the popliteal fossa [4].

Measurement in Infants

Infants provide a challenge to accurate and reliable blood pressures measurement [62]. Oscillometric readings are recommended, at least until the child's upper extremity is large enough to appropriately fit the smallest auscultatory cuff [4]. Ideally, the cuff should be left undisturbed for 15 min after placement and the measurement should not be taken within 90 min of a feed or medical intervention. Once the patient is in a relatively calm state, the blood pressure should be taken three times at 2-min intervals with the patient in the prone or supine position [62]. While these guidelines provide a standardized approach to measurement of infantile blood pressures, they are cumbersome and may be difficult to follow in practice, especially in an outpatient setting.

Importance of Repeated Measurements

As stated previously, high initial blood pressures need to be repeated at least two times at the same visit and the values averaged. Ample evidence has shown that misclassification of high blood pressure status occurs when based on only a single blood pressure reading [130, 131]. Studies in adult patients have consistently found a mean decrease in systolic blood pressure on repeat blood pressure measurements that can reclassify many patients to a lower blood pressure category [132–134]. In a cohort study of over 800,000 children in the United States, among children with an initially high blood pressure value 71% had normal blood pressure value when rechecked at the same visit; 51% had a mean blood pressure below the 95th percentile when the two blood pressure values were averaged [130].

Repeating blood pressure measurements at subsequent visits is also critical in order to appropriately classify children. Large, population-based studies have found that 63–66% of children with initial blood pressure measurements meeting criteria for HTN will have normal blood pressures when rechecked at subsequent visits [135, 136]. Unfortunately, many children do not have appropriate follow-up visits for repeat blood pressure checks within the recommended time period. A large, retrospective study found that among 6108 individuals that had initial blood pressure values at the HTN threshold by office measurement, only 45% had a repeat measurement obtained within 6 months of the original blood pressure measurement [135].

Blood Pressure Follow-Up and Diagnosis Protocol

No additional action needs to be taken if a patient's averaged manual blood pressure is normal (Fig. 48.1). The patient should continue to have their blood pressure measured at least yearly, depending on their specific factors. However, if a screening blood pressure value is high, specific follow-up recommendations to repeat and monitor blood pressure should be followed [4]. All patients with a confirmed high blood pressure measurement should undergo lifestyle counseling (see Chap. XX).

Elevated Blood Pressure

For patients whose initial blood pressure is in the 'elevated' category, blood pressure should be checked again in 6 months. If the blood pressure remains in the elevated category at the 6-month follow-up visit, a more thorough examination should be conducted, including blood pressure

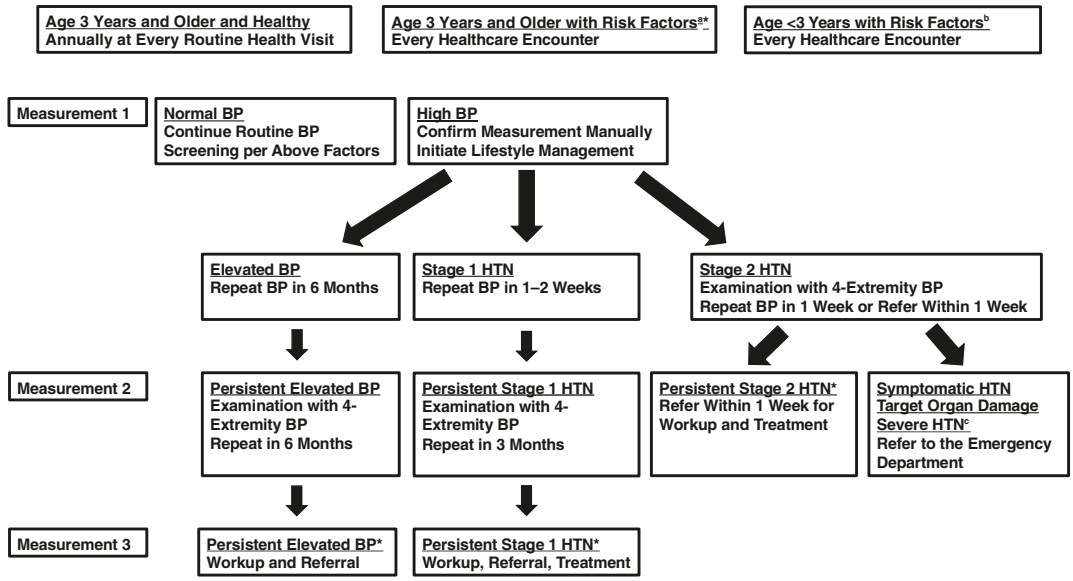

Fig. 48.1 Blood pressure screening and follow-up protocol. Recommendations based on the 2017 CPG [4]. Flow diagram based on classification of each BP measurement; a hypertension disorder diagnosis requires at least three BP measurements—obtained with appropriate methods—from different days. If BP changes classification on repeated measurement, follow flow diagram for most recent values. ABPM can be used to more accurately assess follow-up BP. [a]Obesity, chronic kidney disease, history of aortic arch obstruction or coarctation (regardless of repair status), diabetes mellitus, or taking medication known to increase BP; [b]see Table 48.2; [c]systolic or diastolic BP >30 mmHg above the 95th percentile for age, sex, and height if age <13 years or >180/120 mmHg if age ≥13 years; *indicates consideration for obtaining ABPM. ABPM, ambulatory blood pressure monitoring; *BP* blood pressure; *HTN* hypertension

measurements in both upper extremities and at least one lower extremity. The patient should be evaluated again in 6 months for another blood pressure assessment [4]. If at that point the blood pressure remains in the elevated blood pressure category—now persistent for at least 1 year—the patient should undergo ambulatory blood pressure monitoring (ABPM) under the direction of a qualified provider if available (see section "Ambulatory Blood Pressure Monitoring"), an initial workup (see section "Evaluation"), and/or referral to a HTN specialist. If at any point during this time the blood pressure normalizes, the patient can resume the standard screening regimen based on their individual risk. However, if their blood pressure worsens to the HTN category, follow-up measurements should occur more frequently as discussed below.

Stage 1 Hypertension

Patients with an initial blood pressure in the stage 1 HTN category should have their blood pressure rechecked in 1–2 weeks and, if still high, should include both upper extremities and at least one lower extremity. If stage 1 HTN persists, blood pressure should be rechecked in 3 months. If at the third blood pressure check, the patient has persistent stage 1 HTN, they should be referred to a HTN specialist for ABPM, further evaluation, and treatment. As before, if the blood pressure improves or worsens, the provider should follow the appropriate follow-up protocol.

Stage 2 Hypertension

Patients with an initial blood pressure value in the stage 2 HTN category require more urgent follow up and evaluation. The blood pressure should be measured in the bilateral upper extremities and at least one lower extremity at the first visit. A repeat blood pressure should be obtained within 1 week, or the patient should be referred to a HTN specialist to be seen within 1 week. If the second measurement remains in the stage 2 HTN category, the patient should be referred to and

seen by a HTN specialist within 1 week, in order to initiate a thorough evaluation, ABPM, and to determine if the patient warrants treatment.

Importantly, patients whose blood pressure at any point is at the stage 2 HTN category and who are symptomatic, have signs of target organ damage, or whose blood pressure is >30 mmHg above the 95th percentile for age, sex, and height (or >180/120 mmHg for adolescents), should be sent right away to the emergency department.

Ambulatory Blood Pressure Monitoring

ABPM has become a critical tool in the diagnosis and management of HTN. It more accurately predicts intermediate cardiovascular outcome measures [137] and development of future HTN [138] compared to other blood pressure measurement methods, may better distinguish primary from secondary causes of HTN [139], and is the only modality to formally evaluate for white coat HTN or masked HTN. It also has greater intra-individual reproducibility compared to in-office or out-of-office blood pressure measurement [140, 141]. The 2016 European Society of Hypertension (2016 ESH) guidelines and the 2017 CPG recognize the increasing importance of ABPM and provide specific recommendations for its use in children and adolescents at risk of HTN and as a screening tool in specific patient populations [4, 86].

Technical Considerations

The AHA has published detailed guidelines for ABPM in children and adolescents [2, 142]. The following is a brief summary, and the latest version of the AHA guidelines should be referred to for more detail.

To ensure that the data are properly collected and analyzed, ABPM should be administered by clinical staff who have sufficient training and expertise. Use of ABPM devices validated in children is essential [117, 123]. The cuff should be placed on the upper portion of the non-dominant upper extremity to minimize disruption of daily activities, unless medically contraindicated. However, if there is a significant discrepancy in office blood pressure measurement (e.g., approximately >10 mmHg) between the two upper extremities, the cuff should be placed on the upper extremity with the higher blood pressure. Proper cuff size is determined using the same guidelines that are used for office blood pressure measurement [4].

Prior to having the ABPM placed, the patient and family should receive education about the study. Patients should be instructed to keep their arm still during blood pressure measurements whenever possible [2]. Patients should record major activities in a provided diary, including the patient's sleep and awake times, episodes of physical activity, stress, or pain, and medication doses. The device should only be taken off during bathing or swimming. The monitor should be programmed to record blood pressures every 15–20 min while awake and every 20–30 min while asleep.

An ABPM study is considered adequate for interpretation if there is at least one valid reading every hour and at least 40–50 valid readings in the 24-h period [2]. Interpretation should be based on the recorded sleep and awake times as opposed to the preset times to decrease the risk of misclassification [143]. When interpreting the results, it is important to determine how well the patient tolerated wearing the cuff. Reported intolerance during both awake and sleep are common [144, 145], and may influence the results of the study [146]. Some monitors use actigraphy to measure patient activity at night, and this may be a more accurate method to determine the patient's sleep time and quality [147]. The provider should screen all recorded blood pressures to identify and exclude outlier values that are above the preset parameters for values that are likely out of the normal physiologic range; most software packages do this automatically.

Classifications Incorporating Ambulatory Blood Pressure Monitoring

ABPM classifications recommended by the AHA and the 2017 CPG are primarily based on blood pressure percentiles for age, sex, and height that are distinct from those based on manual blood pressure

measurement. However, important caveats remain regarding the available normative ABPM data in children. The generally accepted normative ABPM data in use are from a study of the German Working Group in 949 healthy individuals aged 5–20 years [148]. While this is widely used for ABPM interpretation, there are legitimate concerns regarding the data. The study was comprised of Caucasian children from Mid-Europe, and it is not clear how generalizable the data are to other populations. There have been few robust attempts thus far to address this issue [149], and it remains one of the most pressing issues for pediatric ABPM. There is also surprisingly little variability in the mean diastolic blood pressures among children of different heights, unlike that seen with casual blood pressures. The data also do not account for children under 120 cm in height, which may be problematic in young children with chronic conditions such as CKD in whom short stature is common.

As opposed to adult ABPM, which classifies blood pressure according to mean ambulatory blood pressure values, pediatric ABPM classification is based upon ambulatory blood pressure mean values (Table 48.3). The device software calculates and reports mean ambulatory blood pressure values for the 24-h period and for the awake and asleep periods. Mean values at or above the 95th percentile for sex and either age or height confirm a diagnosis of ambulatory HTN (Table 48.4). Adolescent patients who are tall—whose 95th percentile ambulatory blood pressure values are higher than the absolute values used in adults—are often categorized according to the adult criteria. Prior recommendations included the blood pressure load (the proportion of ABPM readings that are at or above the 95th percentile) in the diagnostic classification [2].

Table 48.3 Ambulatory blood pressure parameters

Variable	Definition	Abnormal threshold
Mean BP	Mean BP over each time period	≥95th %ile
% dipping	[Mean awake − mean sleep BP]/[mean awake BP] × 100	<10%
BP index	Mean BP/95th %ile per time period	≥1

BP blood pressure

Table 48.4 Ambulatory blood pressure classification. Adapted from [261]

Category	Casual (office) BP Age <13 years[a] Age ≥13 years	Mean ambulatory BP Age <13 years[a] Age ≥13 years
Normal BP	<95th %ile or <130/80 mmHg <130/80 mmHg	<95th %ile <130/80 wake, <110/65 sleep, <125/75 24 h
White coat hypertension	≥95th %ile or ≥130/80 mmHg ≥130/80 mmHg	<95th %ile <130/80 wake, <110/65 sleep, <125/75 24 h
Masked hypertension	<95th %ile or <130/80 mmHg <130/80 mmHg	≥95th %ile ≥130/80 wake, ≥110/65 sleep, ≥125/75 24 h
Ambulatory hypertension	≥95th or ≥130/80 mmHg ≥130/80 mmHg	≥95th %ile ≥130/80 wake, ≥110/65 sleep, ≥125/75 24 h

BP blood pressures

[a] Whichever is lower between the percentile of absolute blood pressure

However, more recent data suggest that blood pressure load does not provide prognostic value in children [150, 151], and it is no longer recommended to be included in the classification.

White Coat Hypertension

White coat HTN is a condition in which the patient's office blood pressure is in the HTN category but ambulatory blood pressure is normal (Table 48.4). White coat HTN is common in children, occurring in up to 30–50% of patients who are referred for HTN evaluation [152, 153].

Traditionally thought to be a benign condition, increasing evidence supports that white coat HTN may be associated with progression to sustained HTN [152, 154]. Although the prevalence of LVH between children who are normotensive and children with white coat HTN is not significantly different, there is evidence that patients with white coat HTN have higher LVMI [153]. The presence of obesity complicates the interpretation of these and similar data, as children with white coat HTN are more likely to have obesity, and obesity is associated with higher LVMI [155]. Studies of associations with other intermediate outcomes, such as increased carotid intima-media thickness,

have provided mixed results [152, 156]. In adults, white coat HTN is associated with increased risks of cardiovascular and all-cause mortality compared to patients with normal blood pressure [157, 158], although controversy exists as to whether this increased mortality is due to white coat HTN or is due to confounding bias from common comorbidities [159].

Given the uncertainty regarding the clinical implications of white coat HTN, the optimal approach to management of these patients remains undefined. The 2017 CPG recommend that children with white coat HTN have repeat ABPM in 1–2 years to assess for improvement or progression to ambulatory HTN [4]. Further investigation is warranted to better delineate these relationships and the risk white coat HTN confers and to develop evidence-based management strategies.

Masked Hypertension

Patients whose office blood pressure is normal but who have ambulatory HTN on ABPM are classified as having masked HTN (Table 48.4). Due to the fact that patients with normal blood pressures in the office, masked HTN is generally only diagnosed in high-risk patients that undergo ABPM screening. This ascertainment bias makes it difficult to accurately estimate masked HTN prevalence in children and adolescents; several studies have estimated an 8–10% prevalence [160–162]. Masked HTN is more strongly associated with target organ damage than white coat HTN [156]. It is more common in children with secondary HTN and may help in determining HTN etiology.

Isolated nocturnal HTN, a specific form of masked HTN in which ambulatory blood pressure is only in the HTN range during sleep and office blood pressure is normal, has been strongly associated with cardiovascular outcomes in adults [163, 164]. The few studies in children have shown associations with obesity, CKD, insulin resistance, and proteinuria [165–168].

Indications for Ambulatory Blood Pressure Monitoring

While ABPM is recommended for all children and adolescents who are being evaluated for HTN, certain patient populations who are at high-risk for HTN (including those with masked HTN) may benefit from more frequent ABPM screening (Table 48.5) [4]. In particular, the 2017 CPG recommends annual ABPM screening in patients with CKD and patients with coarctation of the aorta starting no later than 12 years post-repair.

Table 48.5 Indications for ambulatory blood pressure monitoring and associated hypertensive disorders

Clinical condition	Hypertensive disorder
Chronic kidney disease	Nocturnal HTN, masked HTN [71]
Kidney failure on dialysis	Masked HTN, worse HTN on non-dialysis days [262]
Solid-organ transplant recipient	Nocturnal HTN, masked HTN [263, 264]
Solitary kidney	Ambulatory HTN, non-dipping [265]
Type 1 or type 2 diabetes mellitus	Nocturnal HTN, masked HTN [266, 267]
Coarctation of the aorta	Masked HTN, post-repair HTN [268]
Sickle cell disease	Non-dipping [269]
History of prematurity	Ambulatory HTN, non-dipping [102, 270]

Evaluation

Once a diagnosis of HTN is established, careful and thorough evaluation, including a complete history and physical exam, is necessary to determine the etiology, detect target organ damage, and identify co-morbid conditions that may increase the risk of cardiovascular disease. In addition, emerging evidence suggests that children and adolescents with HTN may have specific cardiovascular phenotypes that stratify their risk of future cardiovascular disease. The history and physical exam in particular can detect causes of secondary HTN and can help avoid expensive and unnecessary testing.

History

With the widespread use of electronic health records, it is important to verify a patient's history recorded in their chart with what they and

their caregiver report. This includes reconciling records from other practices and hospital systems. The history should evaluate for risk factors for systemic disease that may cause secondary HTN as well as risk factors for primary HTN (see Table 48.6 and Chap. XX). These include, but are not limited to, acute kidney injury or CKD (gross hematuria, edema, poor growth), rheumatologic diseases (fever, weight loss, rashes, arthritis), hyper- or hypothyroidism/endocrine disease, including pheochromocytomas/paragangliomas, (weight changes, sweating, flushing, hair changes, palpitations, tachycardia, anxiety), and sleep-disordered breathing (snoring, daytime somnolence). A careful review of medications, supplements, and recreational substance use is important. Most patients with HTN are asymptomatic, but some patients describe nonspecific symptoms such as fatigue and sleep disturbances [169]. It is vitally important to detect symptoms associated with severe HTN, including headaches, visual changes, mental status changes, seizures, chest pain, shortness of breath, and edema (Table 48.7). In infants, severe, symptomatic HTN may present as irritability, poor feeding, or poor weight gain.

Table 48.6 Key components of a history relevant to pediatric hypertension. Adapted from [271]

History	Risk factor
Birth history	Gestational age and birth weight Preterm birth (<37 weeks' completed gestational age) Small for gestational age
	Fetal risk factors Intrauterine growth restriction Abnormal fetal ultrasound including oligohydramnios
	Maternal risk factors Chronic hypertension/gestational hypertension, preeclampsia, maternal diabetes/gestational diabetes, maternal medications (including antenatal corticosteroids), maternal recreational drugs, maternal tobacco or alcohol
	Birth risk factors: Cesarean section Asphyxia Resuscitation
	Postnatal risk factors: Neonatal Intensive Care Unit admission Umbilical catheters Intubation with mechanical ventilation
Medical history	Kidney disease Congenital anomalies of the kidney and urinary tract (including hydronephrosis and vesicoureteral reflux), solitary kidney Urinary tract infection, including pyelonephritis Acute kidney injury (including in neonatal period) Chronic kidney disease, kidney failure on dialysis
	Prior hypertension (including in neonatal period)
	Congenital and inherited conditions Congenital heart disease, including coarctation of the aorta Genetic variants and syndromes
	Bronchopulmonary dysplasia, chronic lung disease, asthma
	Growth history and trajectories, overweight or obesity
	Systemic disease Rheumatologic (systemic lupus erythematosus) Endocrinologic (diabetes mellitus of any type, hyperthyroidism, hypothyroidism) Hematologic (sickle cell disease)
	Malignancy (remission or active) Chemotherapy and which regimen Complications

Table 48.6 (continued)

History	Risk factor
	Transplantation: Solid organ, stem cell Medication regimen including immunosuppression Complications
	Mental/behavioral health Attention deficit hyperactivity disorder Anxiety Depression Post-traumatic stress disorder
	Sleep-disordered breathing
	Dyslipidemia, insulin resistance, hyperglycemia
Surgical history	Repaired congenital heart disease or coarctation of the aorta or vascular malformations
	Gender identity surgery
Medications/drugs	Decongestants (pseudoephedrine, phenylpropanolamine)
	Corticosteroids (short-term or chronic)
	Non-steroidal anti-inflammatory drugs
	Stimulants Methylphenidate Methylxanthines (caffeine, theophylline, aminophylline)
	Recreational drugs (marijuana, amphetamines, cocaine)
	Immunosuppressants (tacrolimus, cyclosporine)
	Tricyclic antidepressants
	Oral contraceptives
	Nicotine
Family history[a]	Hypertension (and cause)
	Overweight or obesity, dyslipidemia, diabetes mellitus of any type
	Cardiovascular disease[b] Coronary heart disease (myocardial infarction, angina pectoris, heart failure, and coronary death) Heart surgery Sudden cardiac death Cerebrovascular disease (stroke, transient ischemic attack) Peripheral artery disease Aortic atherosclerosis Thoracic or abdominal aortic aneurysm
	Chronic kidney disease, kidney failure on dialysis
	Congenital or inherited disease, including genetic variants and syndromes
	Systemic disease: rheumatologic, endocrinologic, hematologic, etc.
Nutritional history	Sodium intake
	Fruit and vegetable intake
	Fruit juice and sugar-sweetened beverages
	Caffeine, black licorice
Physical activity history	Organized sports or activities
	Access to physical activity resources (playground, gym, physical education in school)
Social history	More than one home and whose homes
	Who lives at home
	Who is (are) the primary caregiver(s)
	School environment (nurse available to check blood pressure)
	Unmet social needs Food insecurity Transportation insecurity Financial insecurity

[a] Immediate biological family members, including parents, siblings, grandparents, aunts, and uncles
[b] Especially in men before 55 years and women before 65 years

Table 48.7 Key signs and symptoms associated with hypertensive crisis

Symptoms	Physical exam findings
Visual changes	Papilledema
Headaches	Retinal hemorrhages or exudates
Mental status changes	Facial palsy
Shortness of breath	Tachypnea, crackles
Chest pains	Cardiac findings: gallop, new murmur
Gross hematuria	Peripheral edema
Seizures	Abdominal mass

Increasing and substantial evidence has demonstrated that a thorough antenatal and neonatal history should be obtained (see section "Screening Recommendations"), including maternal and fetal conditions, abnormal fetal ultrasounds (including cystic kidneys, hydronephrosis, oligohydramnios), gestational age and birth weight (including intrauterine/fetal growth restriction, small for gestational age), delivery mode and indication, and maternal medication exposure. A detailed review of any hospitalizations and medical conditions in the neonatal period is important, including admission to the Neonatal Intensive Care Unit, umbilical artery/vein catheter placement, intubation and mechanical ventilation, bronchopulmonary dysplasia, asphyxia, head or body cooling, antimicrobial exposure, nonsteroidal anti-inflammatory drug exposure, urinary tract infections, acute kidney injury, and HTN in the neonatal period.

Family history may give clues to the risk of primary HTN or select heritable forms of secondary HTN or CKD. Questions should center around family members who have HTN and at what age they were diagnosed, as well as for other conditions that are associated with HTN, such as CKD, diabetes, obesity, and sleep-disordered breathing. A specific surgical history should be obtained, with emphasis on surgeries involving the heart, intra-abdominal and retroperitoneal organs, or vasculature.

A general nutrition history should be obtained, focusing on aspects of the diet known to be associated with HTN. There is strong evidence in adults linking high dietary sodium intake with increased risk of HTN, and while the evidence in children is not as robust, numerous associations have been described, particularly in children with overweight and obesity [170]. Potassium intake is an important nutritional component, as higher potassium intake has been associated with lower blood pressures in adults [171]. This is thought to be related to the interplay between sodium and potassium, with potassium depletion increasing blood pressure sensitivity to sodium intake [172]. In children and adolescents, the relationship between potassium and blood pressure is less clear. Some studies have found an association between higher long-term potassium intake and lower risk of HTN, particularly in adolescent females [173, 174].

A comprehensive social history should be carefully obtained, as one can acquire important information about risk factors for HTN as well as barriers that may hinder the patient's ability to access and adhere to lifestyle counseling and medication. Providers should understand the patient's home and school environment, including who are the primary caregivers and if a school nurse is available to check blood pressure. Providers should assess a patient's current physical activity status, including organized sports and activities, physical education in school, and access to parks, playgrounds, and gyms. Increasing evidence in children and adults demonstrates that health disparities and unmet social needs—including limited access to health care, food, and transportation as well as financial insecurity—contribute to poor health outcomes in the short and long term [78, 175–182]. Importantly, these risk factors and barriers preferentially affect under-represented populations [183]. Providers should be cognizant of how systemic and implicit bias can affect patients' health, including HTN [184]. Further investigation into these important relationships is strongly needed, including mitigating barriers to equitable health care and social needs.

Physical Exam

The physical exam will be normal in the majority of children and adolescents with HTN. Blood pressures should be measured at all four extremi-

Table 48.8 Physical exam findings associated with secondary hypertension. Adapted from [4]

System	Exam finding	Associated condition
Growth	Overweight, obesity, central adiposity	Cushing syndrome, hypothyroidism
	Low body mass index for age and sex	Hyperthyroidism, neuroblastoma, pheochromocytoma, paraganglioma
	Short stature and poor growth velocity	Systemic disease, including chronic kidney disease, kidney failure on dialysis, inherited condition/syndrome
Dermatologic	Café-au-lait spots	Neurofibromatosis
	Neurofibromas	Neurofibromatosis
	Ash-leaf spots	Tuberous sclerosis complex
	Malar rash	Systemic lupus erythematosus
	Striae, acne	Cushing syndrome
	Flushing, diaphoresis	Pheochromocytoma, paraganglioma, neuroblastoma
	Acanthosis nigricans	Insulin resistance, type 2 diabetes mellitus, Cushing syndrome
	Spaced nipples	Turner syndrome
HEENT	Round/moon facies	Cushing syndrome
	Proptosis	Hyperthyroidism
	Adenotonsillar hypertrophy	Sleep-disordered breathing
	Elfin facies	William syndrome
	Thyromegaly	Hyperthyroidism
	Webbed neck	Turner syndrome
Cardiovascular	Tachycardia	Hyperthyroidism, neuroblastoma, pheochromocytoma/paraganglioma
	Decreased femoral pulses	Coarctation of the aorta
	Friction rub	Pericarditis (systemic lupus erythematosus, kidney failure)
	Murmur	Coarctation of the aorta
Abdomen	Mass	Wilm's tumor, pheochromocytoma/paraganglioma, neuroblastoma
	Palpable kidney	Polycystic kidney disease, hydronephrosis
	Hepatosplenomegaly	Infantile polycystic disease
	Bruit	Renovascular disease
	Edema	Kidney/renovascular disease, liver disease, heart disease, protein-losing enteropathy
Back/Flank	Flank tenderness	Pyelonephritis, obstruction, acute nephritis
Genitourinary	Ambiguous genitalia	Congenital adrenal hyperplasia
Extremities	Disparity in BPs	Aortic coarctation
	Edema	Kidney disease
	Joint swelling/stiffness	Systemic lupus erythematosus, collagen vascular disease
	Muscle weakness	Hyperaldosteronism, monogenic hypertension
	Rickets	Chronic kidney disease, X-linked hypophosphatemia

ties to assess for coarctation of the aorta and mid-aortic syndrome. Classically, coarctation is associated with systolic HTN in the upper extremities, low blood pressure in the lower extremities, and delayed or diminished femoral pulses (also called the brachial-femoral delay) [185]. Certain physical exam findings are associated with various causes of secondary HTN and may help with diagnosis (Table 48.8). In addition, the patient should be evaluated for potential signs of HTN-induced target organ damage (Table 48.7).

Secondary Causes and Target Organ Damage

Laboratory Workup

Laboratory evaluation is performed to investigate for secondary causes of HTN and to assess for HTN-induced target organ damage, most commonly in the heart and kidneys (Table 48.9). Up to 20% of all children with HTN have CKD [4] so generally all pediatric patients with HTN should have a chemistry panel to evaluate kidney function and electrolytes. Further laboratory

Table 48.9 Recommended laboratory evaluation in patients with hypertension. Adapted from [4]

Standard assessment	Secondary assessment
Blood	*Blood*
Metabolic panel, including phosphorus, AST, ALT	Uric acid
Complete blood count with differential	Vitamin D 25-hydroxy and vitamin D-1,25-dihydroxy
Lipid profile	Complements 3 and 4
Hemoglobin A1c	Antistreptolysin O antibody
Plasma renin activity and serum aldosterone	Anti-DNase B antibody
Thyroid stimulating hormone and free thyroxine	Antinuclear antibody
	Antineutrophil cytoplasmic antibodies with proteinase 3 and myeloperoxidase antibodies
	Serum cortisol and precursors
	Plasma fractionated metanephrine
Urine	*Urine*
Urinalysis	Drug screen
Albumin, protein, and creatinine	24-h stone profile
Sodium and potassium	24-h fractionated metanephrines and catecholamines
Calcium	Vanillylmandelic acid and homovanillic acid

ALT alanine aminotransferase, *AST* aspartate aminotransferase

Table 48.10 Laboratory abnormalities in monogenic forms of hypertension. Adapted from [271]

Condition	Pota	PRA	Aldosterone	ARR
Glucocorticoid remediable aldosteronism/Familial hyperaldosteronism type I	N or ↓	↓	N or ↑	↑
Familial hyperaldosteronism type II–IV	N or ↓	↑	↑	↑
Liddle syndrome	N or ↓	↓	↓	–
Gordon syndrome	N or ↑	↓	N or ↑	↑
Apparent mineralocorticoid excess	N or ↓	↓	↓	–
Congenital adrenal hyperplasia	N or ↓	↓	↓	–
Familial glucocorticoid resistance	N or ↓	↓	↓	–

ARR aldosterone-to-renin ratio, *PRA* plasma renin activity

evaluation will depend on the specific history, physical exam, and screening study results, but may include thyroid studies, plasma renin activity, serum aldosterone levels, neurohormones, and genetic testing.

Serum electrolytes are commonly normal in children with HTN, but abnormal results may assist in identifying secondary causes of HTN including primary or secondary hyperaldosteronism or monogenic HTN [186]. These can often be distinguished from each other via serum potassium levels, plasma renin activity, and serum aldosterone levels; genetic testing is usually necessary to confirm the diagnosis (Table 48.10, Chap. XX). It is important to note that serum potassium can be normal in aldosterone-mediated HTN and that these diagnoses should be considered if an adherent patient's blood pressure is poorly controlled on multiple anti-hypertensive medications that are optimally dosed [187].

A urinalysis with urine microscopy should be performed on all children and adolescents who have HTN to investigate for secondary causes, and it may play a role in identifying target organ damage. Microscopic hematuria, defined as at least six red blood cells per high-powered field, may indicate glomerular disease—including acute glomerulonephritis of various etiologies—particularly if it confirms dysmorphic red blood cells or red blood cell casts. Proteinuria is concerning for acute kidney injury or CKD and can be a sign of target organ damage to the kidneys. A spot urine sample to quantify urine protein is highly predictive of 24-h concentrations [188] and, if positive (>0.2 mg protein/mg creatinine), should be repeated on a first-morning urine sample to differentiate orthostatic proteinuria—a common and benign condition wherein the first-morning sample is normal [189]—from pathologic proteinuria that is persistently positive.

Albuminuria

Albuminuria is defined as >30 mg albumin/g creatinine in a spot urine sample. In adults it is considered a marker of HTN-induced target organ damage to the kidneys and predicts cardiovascular disease [190]. However, there is inadequate data in children to confirm a causal relationship between albuminuria and HTN [191], and the 2017 CPG does not recommended screening for albuminuria in youth with primary HTN. Thus, the role of urine albumin testing as a marker of HTN-induced kidney-specific target organ damage warrants further study.

Renin-Angiotensin-Aldosterone System

Of note, there may be increasing utility in measuring components of the renin-angiotensin-aldosterone system in circulation and in the urine in patients with HTN. Classically, plasma renin activity and serum aldosterone have been measured to assist in screening for renal artery stenosis and secondary and primary aldosteronism (which can occur in up to 15% of adults with HTN). In adults, a suppressed plasma renin activity, elevated serum aldosterone concentration, and aldosterone-to-renin ratio >20–30 (in [ng/dL]/[ng angiotensin I/mL/h])—even in the absence of hypokalemia—increase the likelihood of an aldosterone-mediated form of HTN [192–197]. Specific diagnostic criteria to screen for and diagnose primary aldosteronism in children do not exist, though some studies suggest an ARR >10 may have utility [198].

Baseline plasma renin activity and serum aldosterone are correlated with HTN severity, and higher values predict greater improvements in blood pressure and LVMI in response to treatment in youth with primary HTN [199]. Among 47 pediatric patients with HTN, higher values of baseline urine sodium-to-potassium ratio (a proxy measure of increased dietary sodium intake relative to potassium) were associated with lower plasma renin activity and higher aldosterone-to-renin ratio values [200]. These findings suggest that these measures of the renin-angiotensin-aldosterone system may distinguish emerging HTN phenotypes such as salt-sensitive blood pressure and renin-angiotensin-aldosterone system activation vs. suppression-mediated HTN.

However, renin and aldosterone measurements have limited clinical value in part because they only represent proximal and distal aspects of the renin-angiotensin-aldosterone system. It is crucially important to consider both pathways of the renin-angiotensin-aldosterone system: angiotensin-converting enzyme/angiotensin II and angiotensin-converting enzyme 2/angiotensin-(1–7) [201]. Emerging evidence supports the value of fully assessing both pathways of the renin-angiotensin-aldosterone system in individuals with HTN. Adults with untreated primary HTN had lower urinary angiotensin-(1–7) concentrations and 24-h excretion rates compared to control participants with normal blood pressure [202]. Children with primary HTN had higher plasma angiotensin-(1–7) levels compared to peers with normal blood pressure [203]. Adolescents born preterm with very low birth weight, who are at increased risk for HTN, had a higher ratio of angiotensin II to angiotensin-(1–7) in plasma compared to term-born peers, an association that was greater in individuals with obesity and in females [105, 204]. In addition, lower urinary angiotensin-(1–7) concentrations corrected for urine creatinine were associated with higher blood pressure in adolescents and adults and predicted higher blood pressure approximately 5 years later [106, 202]. However, accurate and reproducible measurement of the renin-angiotensin-aldosterone system depends upon adhering to rigorous methods [205, 206], and reliable normative data have not been fully defined for children or adults. Further research into the role of the renin-angiotensin-aldosterone system in pediatric HTN is ongoing.

Uric Acid

The utility of obtaining serum uric acid concentrations remains controversial. Observational studies consistently demonstrate that uric acid levels are associated with HTN in cross-section and predict development of HTN, CKD, and cardiovascular mortality over time, and that lowering uric acid (e.g., with allopurinol) reduces the risk of these outcomes [109, 207–216]. However,

data from clinical trials to lower uric acid levels remain conflicting [217, 218]. Evidence suggests that younger patients with shorter duration of HTN and better cardiovascular health may benefit from pharmacologic uric acid reduction [219, 220]. The reasons for these conflicting data are complex and include inadequate study design and variable patient populations/experimental disease models. Further, uric acid pathophysiology remains poorly described. The renin-angiotensin-aldosterone system likely mediates, in part, uric acid's deleterious effects, and uric acid can have anti-oxidant as well as pro-oxidant properties depending upon which tissue one investigates [109, 221–223]. The 2017 CPG concluded that there remains insufficient evidence to support or refute routine uric acid measurement when evaluating and managing youth with high blood pressure. This area remains an important area of further investigation, including the role of pharmacologic uric acid lowering.

Kidney Imaging

A **kidney ultrasound** should be considered when evaluating a patient for HTN, especially in those under 6 years of age or those who have an abnormal urinalysis or chemistry panel, have proteinuria, or who have a history of kidney abnormalities, acute kidney injury, urinary tract infections, or a family history of congenital anomalies of the kidney and urinary tract [4]. Ultrasonography can detect secondary HTN associated with CKD and aid in the diagnosis of renal artery stenosis; findings of note can include hypodysplasia, size discrepancy between both kidneys, solitary kidney or horseshoe kidney, cystic kidney disease, hydronephrosis, masses, increased echogenicity relative to the liver, and decreased corticomedullary differentiation.

For patients with a history of recurrent urinary tract infections (especially pyelonephritis), dimercaptosuccinic acid scintigraphy has historically been deemed helpful to identify scarring of the affected kidney, though it has well documented limitations [224]. To evaluate for scarring, it is recommended to wait at least 6 months after the most recent infection to allow for resolution of acute inflammation to avoid false-positive results [225]. HTN development may be delayed for years in patients who develop kidney scarring from urinary tract infections and vesicoureteral reflux [226].

Renovascular Imaging

Doppler ultrasonography can be used to screen for possible renal artery stenosis in normal-weight youth at least 8 years of age who are suspected of having renovascular HTN and can cooperate with the procedure [4]. Doppler studies are often the first-line imaging modality of choice to evaluate for renovascular HTN. However, sensitivity (64–90%) and specificity (68–70%) are low to detect or rule out renal artery stenosis and can be highly variable between sonographers and across institutions, particularly in patients with obesity and in younger children less than 8 years of age, and require extensive observer experience [227–229].

Further investigation is required when the Doppler study is normal but suspicion for renovascular disease remains high. **Computed tomographic angiography** (CTA) and **magnetic resonance angiography** (MRA) are commonly used non-invasive imaging modalities that have significantly higher sensitivity and specificity to detect renal artery stenosis compared to Doppler ultrasonography. Data in children are limited, but recent studies have estimated 88–100% sensitivity and 81–100% specificity for CTA [229–231]. For MRA, data are even more scarce, but one study estimated 81% sensitivity and 63% specificity [231]. Both CTA and MRA have additional advantages and limitations. CTA is less expensive and quicker to perform but involves significant radiation and contrast exposure, an important consideration in young patients. MRA is a longer, more expensive test that often requires sedation or general anesthesia in young children or patients with behavioral or developmental conditions that limit their ability to remain still during the test and involves exposure to contrast such as gadolinium.

The gold standard for diagnosis of renovascular HTN remains angiography [231]. Angiography may be therapeutic as well as diagnostic, but requires anesthesia, involves exposure to contrast and radiation, and is an invasive, higher risk pro-

cedure compared to CTA and MRA. A detailed description of the recommended diagnostic workflow for suspected renovascular hypertension is provided in Chap. XX.

Cardiac Imaging

Echocardiography is a useful and recommended test to diagnose cardiac causes of HTN—such as coarctation of the aorta—and HTN-induced target organ damage in the heart. The 2017 CPG recommends that echocardiography be performed when considering pharmacologic treatment of HTN [4], but many programs obtain echocardiograms for the majority of patients referred for HTN due to the fact that it is difficult to predict which patients have target organ damage. Recent evidence suggests that echocardiographic changes including LVH occur in youth with elevated blood pressure.

HTN can induce several deleterious changes to heart mass, structure, and function, including LVH, left ventricular remodeling, left atrial dilation, and, rarely, left ventricular systolic or diastolic dysfunction. Target organ damage in the heart occurs in approximately 40% of youth with HTN [5–7]. LVH is the most prominent evidence of target organ damage in children with HTN, and LVH should be defined by standardized left ventricular mass due to its correlation with body size [232]. Methods by which to calculate left ventricular mass are discussed in detail in Chap. 61.

Echocardiography should be repeated every 6–12 months to monitor for interval changes, including in patients with difficult-to-control HTN, concentric LVH, or reduced left ventricular ejection fraction. In patients with an initially normal echocardiogram, yearly repeated echocardiograms can be considered, especially for patients with stage 2 HTN, secondary HTN, or stable stage 1 HTN that is not well controlled.

While **electrocardiography** is low-cost and easy to perform, it has poor sensitivity and specificity for identifying LVH in children with HTN [233] and is therefore not recommended for use in the evaluation of pediatric HTN [4, 86].

Additional Considerations

Patients with a concern for HTN-related retinal findings should be referred to a pediatric ophthalmologist. The role of routine screening ophthalmologic exams by pediatric ophthalmologists in all patients with HTN remains unknown and warrants further study; however, availability of a pediatric ophthalmologist is a concern. Patients with HTN who have additional indications should undergo evaluation by a pediatric nephrologist for kidney biopsy; indications include presence of persistent proteinuria, hematuria, and acute kidney injury in addition to HTN. Patients with concern for or confirmed secondary causes of HTN should be referred to the relevant specialists for co-management with the HTN specialist (e.g., endocrinologist, cardiologist).

Co-morbidities

Patients with obesity or other risk factors for insulin resistance and diabetes mellitus should have a hemoglobin A1c assessed to screen for diabetes and liver enzymes (aspartate aminotransferase, alanine aminotransferase) to screen for non-alcoholic fatty liver disease, which is associated with HTN in children [4, 166, 234, 235]. A lipid profile should be obtained in all patients to evaluate for dyslipidemia; initial testing may be fasting or non-fasting [4]. Patients with obesity who are at higher risk should have a fasting lipid profile obtained.

Patients who have signs or symptoms of sleep-disordered breathing should be referred for polysomnography [4]. Potential symptoms include snoring, daytime somnolence, or reports of poor sleep quality. Adenotonsillar hypertrophy is a common cause of obstructive sleep apnea in children, and affected patients should be referred even in the absence of obvious symptoms. Unfortunately, access to centers with sufficient expertise in pediatric polysomnography and sleep medicine specialists is commonly limited and an area of pressing need in pediatrics.

Cardiovascular Phenotyping

There is increasing evidence that youth with HTN likely have a spectrum of cardiovascular abnormalities that may affect their HTN trajectory in the short term as well as their long-term

risk of cardiovascular disease across the life course [236, 237]. Newer, non-invasive imaging modalities are under investigation to assess cardiovascular target organ damage, including arterial structure and function, and to provide valuable normative data in children [238]. Measures of central arterial stiffness include pulse wave velocity and augmentation index. Pulse wave velocity estimates the speed at which the wave produced by ventricular systole propagates through the arterial circulation, while augmentation index is an indirect measure of central aortic pressure augmentation [239, 240]. Higher pulse wave velocity and augmentation index can indicate greater arterial stiffness associated with HTN; device-specific normative data exist for youth with and without HTN [241–244]. Carotid intima-media thickness—measured by high-spacial ultrasonography—quantifies the combined thickness of the intimal and medial layer of the carotid artery and is an established marker of subclinical arteriosclerosis [245]. Pediatric normative data are available [246]. Several pediatric studies have shown an association between HTN and higher carotid intima-media thickness [247], including in children with CKD [248, 249] (see Chap. 61 for a detailed review). Additional though less utilized studies include arterial flow-mediated dilation and distensibility [237].

Finally, abnormal autonomic function—characterized by abnormal heart rate or blood pressure variability and baroreflex sensitivity—associates with HTN in children and adults and predicts cardiovascular disease [108, 250–256]. At this time, however, these modalities are not yet recommended for routine use in the diagnosis or management of pediatric HTN [4, 86] and are not widely available in clinical practice, even to HTN specialists. More research is needed, including establishment of normative data and evidence-based cut-offs for abnormal values in diverse patient and healthy control populations.

Follow Up for Patients with Hypertension

All patients with HTN require close follow up with their HTN specialist and primary care provider to monitor their blood pressure and target organ damage response to lifestyle counseling and pharmacologic treatment. Youth treated with an anti-hypertensive medication should be followed up every 4–6 weeks until blood pressure is controlled and then every 2–6 months thereafter, while patients treated only with lifestyle counseling should be followed every 3–6 months. Follow-up periods and modality (HTN specialist clinic, primary care provider clinic, home, school) should be tailored to each individual patient and the resources available to them. ABPM has increasing importance in monitoring patients' response to treatment, especially in patients with CKD or kidney transplant recipients (see section "Ambulatory Blood Pressure Monitoring"). Specific recommendations for long-term follow up and transition of care when patients become adults remain undefined and are a major topic for further research.

Out-of-Office Measurement

Home

Home blood pressure monitoring with an oscillometric device or via manual measurement is not recommended to diagnose HTN in children, due in part to lack of normative data and heterogeneous technique [140], but may be a useful approach to blood pressure follow up to complement office and ABPM measurement [4]. Much like ABPM, home blood pressure measurement has the advantage of occurring in a familiar, calm environment that partially mitigates falsely high blood pressure readings and white coat HTN. Home blood pressure measurement often demonstrates better reproducibility compared to office-based blood pressure measurement [141].

School

Blood pressure measurements taken at school can be useful to monitor children with HTN. However, data on the accuracy of these measurements is limited, and universal protocols have yet to be developed. In addition, it is difficult to evaluate the skill and technique of the person taking the blood pressure. For these reasons, school blood pressure measurements are not recommended for use in the diagnosis of HTN [4].

As with office-based blood pressure measurement using oscillometric devices, it is crucial to use only those devices that are validated in children. Additional considerations include inter-device variation and difficulty in obtaining the correct cuff size [257].

Transition of Care

Health care transition from adolescence into adulthood is an underappreciated but crucially important aspect of care [258]. Exact transition recommendations and risk profiles for long-term outcomes for children with HTN remain undefined. Adolescents with HTN—and arguably those with other hypertension disorders such as elevated blood pressure and white coat HTN—regardless of whether they are receiving pharmacologic treatment should transition their care from a pediatric to an adult health care provider as they enter adulthood [4]. The specific age for transition can vary widely across centers and should be tailored to each individual patient based on their circumstances. The pediatric specialist managing their HTN should transfer all relevant information regarding etiology, target organ damage, co-morbidity evaluation and management history. Generally, adult primary care providers have sufficient experience to manage the majority of young adults with HTN, though certain populations may require adult specialist care, including patients with CKD or secondary HTN. It is extremely important, however, that the patients themselves and all adult providers caring for these transitioned patients be educated about the importance of pediatric HTN, especially the long-term cardiovascular risk conferred.

Conclusions and Future Directions

Pediatric HTN remains an important but underappreciated medical condition that has short and long-term implications for health during childhood and across the life course. Much progress has been made in recent years to better understand pediatric HTN risk factors, pathophysiology, detection, diagnosis, and related target organ damage. It remains critically important that primary care providers and HTN specialists—pediatric and adult providers alike—remain up-to-date on clinical care of youth with HTN and recognize its importance to long-term cardiovascular health. However, there are many areas that warrant further investigation to improve patients' cardiovascular health.

There is a pressing need for updated normative blood pressure data in youth of all ages and from diverse, international populations that can demonstrate intra-individual change over time as those individuals age and enter adulthood. This will allow for the transition of HTN definitions from more traditional, statistical/epidemiological-based normative blood pressure values to cardiovascular outcome-based approaches. Similarly, there is a need for robustly validated normative ABPM data from diverse populations that, ideally, will include cardiovascular outcome measures across the life course. This is especially true for populations with short stature or chronic medical conditions such as CKD. It remains unknown if ABPM data obtained during childhood is associated with increased risk of morbidity or mortality in later adulthood. There is no consensus regarding the appropriate blood pressure cutoffs for ABPM to confirm HTN, particularly in adolescents who are tall. The 2016 ESH guidelines recommend using adult ABPM values in cases in which pediatric thresholds exceed adult thresholds [86]. However, even the adult thresholds are not consistent, as different adult guidelines utilize different values to diagnose HTN [56, 259]. Clarification regarding the optimal thresholds is necessary for children and adolescents, as these competing guidelines can result in significantly different blood pressure classifications in pediatric patients [260]. Finally, rigorous validation and comparison of oscillometric and ABPM devices is a pressing need.

It is critically important to better understand how established and emerging early-life risk factors contribute to pediatric HTN and its short and long-term complications, including antenatal and neonatal exposures as well as social and health disparities. The long-term effects of the COVID-19 pandemic should be considered, including indirect effects from social/structural

changes and direct effects via severe infection and multisystem inflammatory syndrome in children. This new knowledge will allow for more targeted and appropriate blood pressure screening guidelines.

High-quality studies are required to determine if routine blood pressure screening practices can improve short and long-term outcomes. Further investigation is required to determine the optimal approach to defining cardiovascular phenotypes (e.g., pulse wave velocity, carotid intima-media thickness), the utility of biomarkers such as angiotensin-(1–7) and other components of the renin-angiotensin-aldosterone system, and how these studies could improve clinical care. Finally, definitive guidelines and best practices for the transition of care for youth with HTN who are entering adulthood is crucially important to answer the above questions.

Pediatric HTN remains a common and important medical condition with long-term health implications. Patients and health care providers alike should be aware of the importance of screening for, diagnosing, and evaluating patients who have HTN and the risk pediatric HTN confers on long-term cardiovascular health across the life course.

Renovascular Hypertension in Children

49

Agnes Trautmann and Kjell Tullus

Introduction

Renovascular disease is a rare but important cause of childhood hypertension. It accounts for 10% of secondary childhood hypertension [1–3]. Anatomic stenosis of the renal artery results in renal hypoperfusion with consequent release of renin and activation of the renin-angiotensin-aldosterone system (RAAS) developing a renin-mediated hypertension. Renal artery stenosis is important to accurately diagnose, as it is potentially amenable to curative treatment with several endovascular and surgical techniques in more than half of affected children.

Many children with renovascular disease have additional complex abnormalities of other major blood vessels including aorta, cerebral, intestinal or iliac arteries. Usually, children with complex renovascular disease require treatment provided by a specialised multidisciplinary team of paediatric nephrologists, cardiologists, neurologists, interventional radiologists, vascular and neurovascular surgeons.

Clinical Presentation

Renovascular hypertension is diagnosed at all ages with equally many cases found in all age groups.

Clinical Symptoms

The initial clinical presentation varies from asymptomatic to severe, life threatening symptoms including congestive heart failure or cerebral symptoms. The spectrum of cerebral symptoms is broad with headaches, visual disturbances, signs of acute hypertensive encephalopathy or cerebrovascular incident with convulsions, strokes with focal neurological deficits like facial palsy and hemiplegia. Young infants can also present with more unspecific symptoms and failure to thrive.

At time of diagnosis blood pressure is usually markedly increased, with predominantly stage 2 hypertension (blood pressure > 99th percentile + 5 mmHg). A systolic blood pressure of ≥160–180 mmHg is not uncommon. Target organ damage, in particular hypertensive left ventricular hypertrophy, may already be seen at initial presentation, depending on the stage and duration of hypertension.

Renovascular hypertension should also be suspected if there is inadequate blood pressure control with two or more antihypertensive drugs in the absence of any other identifiable cause.

Several rare genetic syndromes are associated with childhood renovascular hypertension, with neurofibromatosis type 1 (NF type 1) and Williams' syndrome being the most common. Infants and children with newly diagnosed renovascular hypertension should be carefully examined for syndromal signs (e.g. NF type 1: café au lait macules, axillary/inguinal freckles, neurofibromas, Lisch nodules; Williams' syndrome: facial dysmorphic features like "elfin" faces, cardiovascular disease). Although only a small fraction of children with these genetic syndromes will develop renovascular hypertension, blood pressure should be regularly monitored in these conditions.

Children presenting with non-specific clinical signs of inflammation and suspected large vessel vasculitis, in particular Takayasu's arteritis (TA), are also at risk of developing renovascular hypertension.

Children with new-onset hypertension post-renal transplantation should undergo screening for renovascular disease. An abdominal bruit in transplanted children reflecting the turbulent blood flow at the stenotic anastomosis. A bruit can also be heard over renal arteries in native kidneys especially in slim children. Clinical signs that may point to renovascular hypertension are summarized in Table 49.1.

Table 49.1 Suspicious signs for renovascular hypertension

Suspicious sign	Specification
Blood pressure level	Very high blood pressure (e.g. stage 2 hypertension)
Secondary symptoms of hypertension	Cerebral symptoms
	Cardiac failure
	Facial palsy
Control of hypertension	Difficult, not controlled with ≥2 or more drugs
Syndromal disease associated with vascular disease	Neurofibromatosis type 1 (NF 1)
	Williams' syndrome
	Tuberous sclerosis
Signs of vasculitis	Takayasu's vasculitis
Previous vascular insult	Renal artery thrombosis
	Umbilical artery catheterisation
	Previous trauma or radiation
Transplanted kidneys	New onset or worsening of hypertension post-transplant
Clinical examination	Bruit heard over renal artery or arteries
Laboratory diagnostic	Raised peripheral plasma renin
	Moderate hypokalemia

Laboratory Evaluation

Suspicious, but non-specific laboratory signs for renovascular hypertension include moderate hypokalemia in combination with hypochloremic metabolic alkalosis compatible with secondary hyperaldosteronism and a highly activated renin-angiotensin-aldosterone system. Typically, age-specific plasma renin, aldosterone and plasma-renin-activity (PRA) are increased. However, elevated plasma renin levels and PRA are not specific for renovascular hypertension as they do not allow a differentiation between renovascular and renoparenchymal disease. It is important to note that normal renin levels and PRA values do not exclude renovascular disease. Up to 15% of children with renal artery stenosis, confirmed by DSA, can have normal initial PRA values [4]. Therefore further investigations for renovascular artery stenosis should be performed in case of clinical suspicion (Table 49.1) even in the presence of normal age-specific PRA values.

Laboratory evaluation of renal function is also essential, as renal artery stenosis, especially if bilateral, can compromise renal function due to hypoperfusion.

Vascular Involvement

Renovascular disease in children is often complex with a wide spectrum of renovascular and other vascular involvement. All types of major renal arteries (main, branch and accessory arteries) as well as intrarenal small vessels (segmental, lobar and accessory arteries) can be affected. Bilateral renal artery disease is more common than unilateral disease. Twenty-five to thirty percent of patients are diagnosed with mid aortic

syndrome (MAS) combined with bilateral or unilateral disease [5, 6] (Fig. 49.3). MAS is often associated with stenotic lesions in the intestinal arteries, mainly the coeliac trunk and the superior mesenteric artery (SMA) which in many cases both are occluded. The inferior mesenteric artery (IMA) is much less involved and collaterals from the IMA maintain the intestinal blood flow [7]. Importantly, abdominal angina is nearly never seen in children and there is virtually never a need for treatment of the coeliac axis nor the SMA. At least 20% of children also show cerebrovascular involvement, which influences the extent of lowering the blood pressure by treatment without risking cerebral hypoperfusion.

Causes of Renovascular Disease in Childhood

Epidemiology

Renovascular disease is associated with a variety of diseases and pathologies (summarized in Table 49.2). The reported distribution of RVD aetiologies in children varies widely in different parts of the world. However, cross-cohort comparisons are hampered by limited information on the diagnostic criteria used.

In Europe and North America, fibromuscular dysplasia (FMD) accounts for 53–88%, neurofibromatosis type 1 for 10–25%, and Williams' syndrome for 5–10%, of cases (Table 49.2) [8–13]. Whereas Takayasu's arteritis is very rare in Western countries, this disorder has been reported in 73–89% of Indian and South African cohorts [14–18].

Table 49.2 Summary of causes of renovascular hypertension

Cause	Specified diagnoses
Fibromuscular dysplasia	Medial fibroplasia
Syndromal diseases	Neurofibromatosis type 1 (*NF1* gene)
	Williams' syndrome (deletion of chromosome 7q11.23, *Elastin* gene)
	Tuberous sclerosis (*TSC1*/*TSC2* gene)
	Alagille syndrome (*JAG1* gene)
	Marfan's syndrome (*Fibrillin 1* gene)
	Other syndromes associated with vasculopathies and mid-aortic syndrome
Vasculitis	Takayasu's disease
	Polyarterits nodosa
	Other systemic vasculitides
Extrinsic compression	Neuroblastoma
	Wilms' tumor
	Pheochromocytoma
	Other abdominal and perirenal tumors
Other rare causes	Abdominal radiotherapy
	Previous renal artery thrombosis
	Umbilical artery catheterisation with thrombosis
	Trauma with renal artery disruption
	Congenital rubella syndrome
Renal transplantation	Transplant renal artery stenosis

Fibromuscular Dysplasia (FMD)

FMD is a non-atherosclerotic, non-inflammatory vascular disorder affecting medium-size arteries. It occurs as unifocal or multifocal disease. The aetiology of FMD is unknown.

FMD can be classified into different types depending on the mainly involved part of the blood vessel (intima, media, adventitia) [19], with medial fibroplasia being the most common type. In childhood, FMD primarily affects the mid and distal renal artery leading to renovascular hypertension [20, 21].

The diagnosis of FMD is based on angiographic appearance and is mainly a diagnosis of exclusion when other conditions have been ruled out. A minority of children display the typical "string of beads" appearance on angiography [22] which is regarded as typical for FMD (Fig. 49.1).

Takayasu Arteritis (TA)

A similar angiographic appearance for renal artery stenosis has been described for vasculiti-

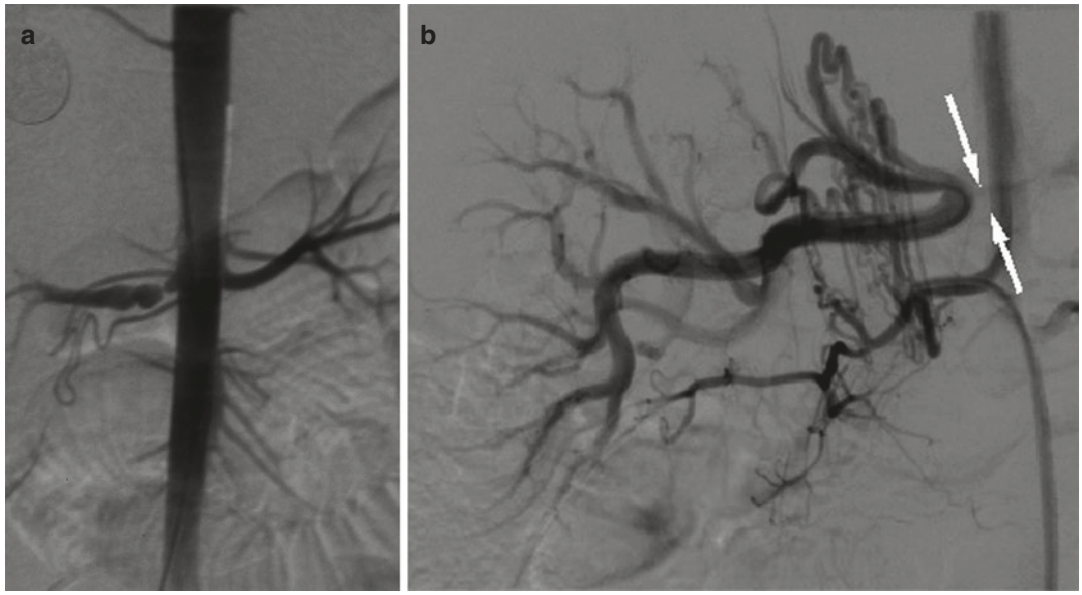

Fig. 49.1 (**a**) Fibromuscular dysplasia: Renal artery stenosis with "string bead" appearance in digital subtraction angiography (DSA) (image kindly provided by Great Ormond Street Hospital, London). (**b**) Obstructed right renal artery in digital subtraction angiography (DSA) (image kindly provided by Great Ormond Street Hospital, London)

des. The by far most frequent vasculitis is Takayasu's arteritis (TA). Rarely, polyarteritis nodosa, and other systemic vasculitides are associated with renovascular hypertension (Table 49.2). TA affects the aorta and its major branches and is mainly a disease of young women in their second and third decades of life. The age of onset is usually between 15 and 30 years [23]. TA has also been reported in young children presenting with malignant hypertension due to renal artery stenosis and cardiac failure [24–27]. However, the rate of misclassification of FMD as TA is suspected to be high in young children.

The aetiology of TA is still undefined. The vascular pathology is characterized by segmental and patchy granulomatous inflammation of all three layers of the aorta and major branches. Finally this inflammation leads to arterial stenosis, thrombosis and aneurysms. Thickened and acutely inflamed vessel walls can be often detected on MRA, CTA and/or PET scan [28] (Fig. 49.2).

The clinical features of TA can be divided into an early, acute and systemic phase, characterized by non-specific clinical features such as low-grade fever, malaise, night sweats, weight loss, arthralgia and fatigue, and a late occlusive phase [29]. Additionally, anaemia and a marked elevation of the erythrocyte sedimentation rate (ESR) can be found in most patients during the systemic phase. The early systemic phase is difficult to diagnose because only half of all patients show these symptoms. The late occlusive phase is characterized by progression from inflammatory into obliterative changes in the aorta and its main branches. In this late occlusive phase, the characteristic features of TA appear, in children predominantly hypertension secondary to renal artery stenosis, cardiac failure and neurological symptoms secondary to hypertension or ischemia [29]. Presentation with vascular bruits, absent or diminished pulses and claudication is less common in children.

The 2006 by EULAR/PRES (European League against Rheumatism/Paediatric Rheumatology European Society) defined consensus criteria for classifying TA are summarized in Table 49.3 [30, 31]. The classification criteria for TA imply that

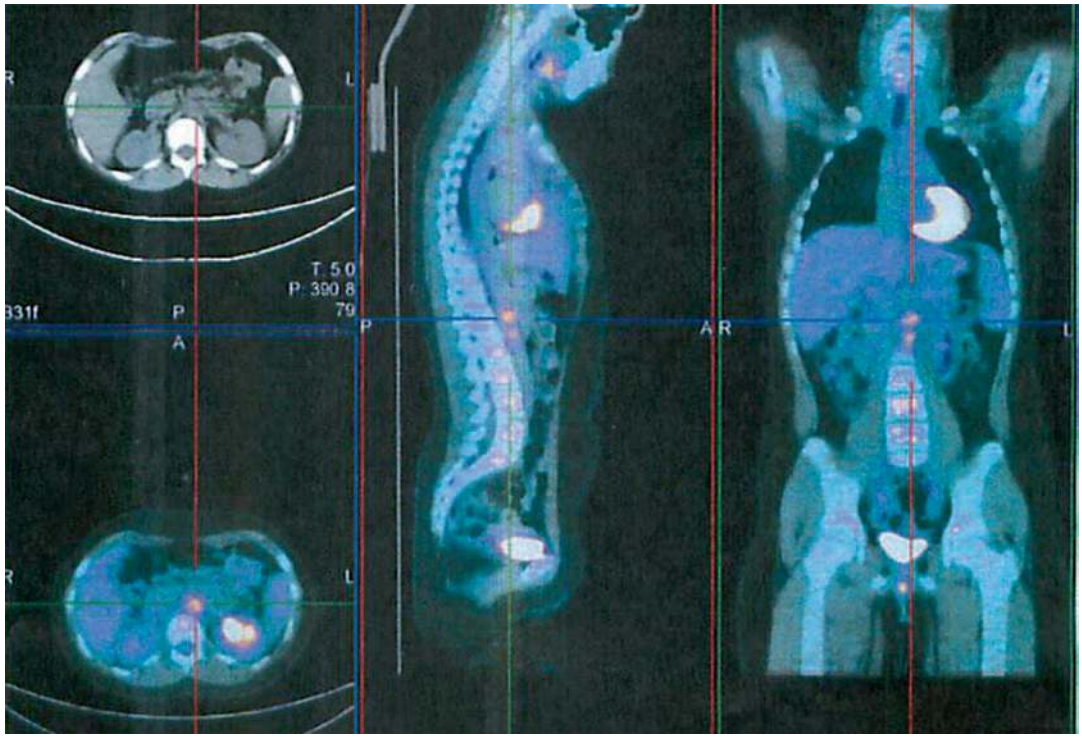

Fig. 49.2 Takayasu's arteritis: PET Scan with lightning of aorta reflecting thickened and inflamed arterial wall (images kindly provided by Great Ormond Street Hospital, London)

Table 49.3 Classification definition for Takayasu's arteritis according to EULAR/PRINTO/PRES (European League against Rheumatism/Paediatric Rheumatology International Trials Organisation/Paediatric Rheumatology European Society) Ankara 2008 consensus criteria (adapted from [31])

Requirement	Criterion	Specification
Mandatory	Angiographic abnormality	Angiographic abnormalities (conventional, CTA or MRA) of the aorta or its main branches and pulmonary arteries showing aneurysm/dilatation
+1 of the 5 following criteria	Hypertension	Systolic/diastolic blood pressure >95th percentile for height
	Pulse deficit or claudication	Lost/decreased/unequal peripheral artery pulse(s) Claudication: focal muscle pain induced by physical activity
	Four limbs blood pressure discrepancy	Discrepancy of four limb systolic blood pressure of >10 mmHg difference in any limb
	Bruits	Audible murmurs or palpable thrills above large arteries
	Acute phase reactant	Erythrocyte sedimentation rate (ESR) >20 mm per first hour or CRP any value above normal (according to local laboratory)

the diagnosis of any vasculitis was already made in the child. In such cases, the classification criteria have shown high sensitivity and specificity when being validated [31].

However, the difficulty is to diagnose vasculitis itself in children, especially if there is a lack of systemic inflammatory signs during the acute systemic phase as well as during the late occlusive phase of TA. Then the criteria are unspecific in diagnosing TA and overlap with features of FMD.

The evaluation of blood vessel wall thickness and inflammation by MR/CT angiography [32] and/or PET scan [28, 33] may help identifying

TA. A markedly thickened blood vessel wall reflecting oedema and inflammation strongly supports the diagnosis of TA (Fig. 49.2).

Differentiation Between Fibromuscular Dysplasia (FMD) and Takayasu's Arteritis (TA)

The differential diagnosis between FMD and TA seems to be difficult in many children. Children with obvious systemic inflammatory symptoms and raised inflammatory parameters (ESR, CRP) are likely to have TA. However, only a minority of children present in the inflammatory early phase of the disease. Inflammatory symptoms are missing during the late occlusive phase of TA. In the late phase of TA the mandatory criteria of angiographic abnormalities with hypertension are the same criteria as used to diagnose FMD. The typical "string of beads" pattern is not regularly seen on angiography in children with FMD.

In that case the evaluation of a thickened, inflamed vessel wall can help in the differential diagnosis, although systematic evaluations of this sign in MRA, CTA or PET scans have not been performed so far.

The ascertainment of the correct differential diagnosis is important for the indication for immunosuppressive treatment in the systemic phase of TA in order to control the active vasculitic process and in view of the timing of interventional or surgical procedures.

Genetic and Syndromic Causes

Several rare genetic syndromes are associated with childhood renovascular disease, with neurofibromatosis type 1 (NF type 1) and Williams syndrome being the most common (Table 49.2). All other associations of syndromes with renovascular disease are rare; these include tuberous sclerosis [34], Alagille syndrome [35, 36] and Marfan's syndrome with predominantly proximal aortic wall abnormalities [37].

To identify new monogenic causes for renovascular hypertension, two studies performed whole-exome sequencing in children with so far unexplained renovascular disease and mid-aortic syndrome [38, 39]. Both studies detected abnormalities in genes causing NF type 1, Williams syndrome, and Alagille syndrome that apparently caused a mild clinical phenotype. However, no new monogenic causes of renovascular disease were identified.

Neurofibromatosis Type 1 (NF Type 1)

The spectrum of NF type 1 associated vasculopathy is broad: Renal arteries are most frequently involved; the stenoses are usually located near the renal ostium. Unilateral and bilateral renal artery stenosis can occur in combination with mid-aortic syndrome by narrowing of the abdominal aorta and stenosis of its major branches (Fig. 49.3). Other common vascular manifestations in NF type 1 are abdominal aortic coarctation, internal carotid aneurysms and cervical vertebral arteriovenous malformations [40–42].

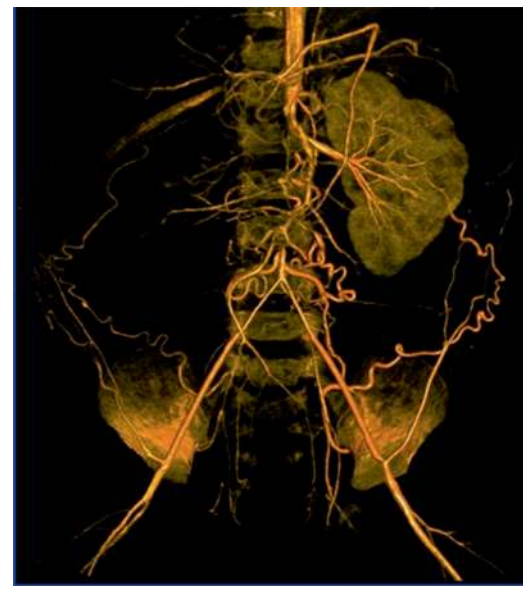

Fig. 49.3 Mid-aortic syndrome with occluded infrarenal aorta and right renal artery stenosis in two-dimensional ('volume-rendered') representation of a three-dimensional computed tomography dataset (image kindly provided by Great Ormond Street Hospital, London)

The real total incidence of secondary hypertension in NF type 1 and age-specific incidences remain unclear [43]; one study reported an incidence of 16%, with most cases involving renal artery stenosis followed by aortic coarctation and pheochromocytoma [44].

In general, blood pressure monitoring every 6–12 months is therefore recommended in all children with NF type 1 [43, 45].

Williams Syndrome

Williams syndrome is associated with cardiovascular abnormalities and a generalized arteriopathy focused on the aorta [46, 47] with consecutive development of mid-aortic syndrome. However, isolated stenoses of the renal and other arteries occur.

Since hypertension is a common feature of Williams syndrome, blood pressure screening is recommended. The reported prevalence ranges between 5% and 70% (summarized in [46]). In most children with Williams syndrome the aetiology of hypertension remains unclear; only in a minority of cases it can be attributed to renal artery stenosis, mid-aortic syndrome or aortic coarctation. It has been argued that arterial vascular stiffness due to defective elastin, resulting in decreased arterial elasticity, vascular smooth muscle cell proliferation and increased intima-media thickness, may contribute to hypertension in this condition [48].

Extrinsic Compression of Renal Artery

Extrinsic compression of the renal artery can mimick renal artery occlusive disease with renal hypoperfusion, activation of the renin-angiotensin-aldosterone-system and development of renin-mediated hypertension. This has been reported in different types of tumours, in particular Wilms tumour [49–51], neuroblastoma [52–54] and pheochromocytoma [55–58]. Mid-aortic syndrome and renal artery stenosis have also been reported after treatment of large tumours (Wilms tumour and neuroblastoma), usually associated with radio- and chemotherapy and postoperative fibrosis causing severe stenosis [59, 60] but also in patients without preceding radiotherapy [61].

Other Rare Causes

Umbilical artery catheterisation during the neonatal period can cause vascular endothelial disruption, thromboembolism with a completely or partially occluded aorta and renal hypoperfusion, renal artery thrombosis, or thromboembolism into the small renal vasculature with renal infarction [62–67].

Renal artery trauma can lead to renovascular hypertension due to surgical injury, disruption of the renal artery or from random accident.

Congenital rubella syndrome can also be associated with renovascular disease [65, 68, 69]. Due to the general recommendation for rubella vaccination, this association is very rarely seen nowadays.

Transplant Renal Artery Stenosis

Data from paediatric cohorts after renal transplantation with newly developed renal artery stenosis are very limited. To date, the prevalence of allograft renal artery stenosis is reported with 4–9% [70, 71]. Clinical presentation usually includes new onset of severe hypertension or significant worsening of pre-existing hypertension during the first few months after renal transplantation.

Imaging

Diagnosing renovascular disease in children is challenging due to the complex anatomical distribution of vascular involvement, the small size of renal arteries affected by age and size of the child and by the degree of arterial branching. Despite the development of non-invasive imaging, selective renal arteriography (digital subtraction angiography, DSA) is still the gold standard imaging

method in diagnosing renovascular disease. This might change with further technical developments in the future.

Non-invasive Imaging

For screening, several non-invasive imaging techniques are used in children although its role is still unclear due to the lack of high-quality evidence. The use of non-invasive imaging in children is based on small studies, clinical expert opinion and studies in adults. So far, non-invasive imaging methods cannot reliably diagnose renovascular disease in children, with at least 10–40% false-negative results as well as false-positive results. However, non-invasive imaging can be helpful to rule out extraparenchymal processes, to diagnose renoparenchymal disease, to plan surgery and to follow-up post-surgery.

Kidney Ultrasound and Doppler Studies

Kidney ultrasound combined with renal and abdominal vessel Doppler ultrasound is an important baseline investigation. It can exclude other renal pathologies (renoparenchymal disease, renal scarring), detect extrarenal processes, in particular tumours (e.g. neuroblastoma, Wilms' tumour) and show significant discrepancies of kidney volume and length (≥1 cm) as a possible indirect sign of renovascular hypertension.

Renal Doppler ultrasound can directly visualise a stenosis or be suggestive of renovascular disease when a *parvus et tardus* waveform pattern (Fig. 49.4) or pathologic age-dependent flow parameters (peak systolic flow >2 m/s [72, 73], acceleration time >80 ms, renal artery to aortic flow velocity ratio >3 and difference in resistive index) can be identified. The entire renal artery should be followed when possible from its origin in the abdominal aorta to the renal hilum and a screening for accessory renal arteries and the abdominal aorta is essential [74]. However, renal Doppler ultrasound in children requires advanced technical skills and experience and cooperative children to reliably suspect renovascular disease by Doppler ultrasound.

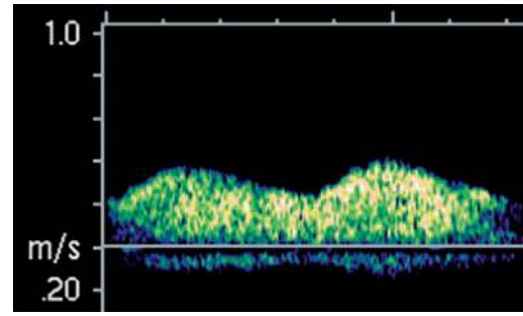

Fig. 49.4 Renal Doppler ultrasound suggestive for renal artery stenosis: *parvus et tardus* waveform pattern (image kindly provided by Great Ormond Street Hospital, London)

In general, the experience with renal Doppler ultrasound in children is limited apart from detecting renal artery stenosis in transplanted kidneys [75]. The sensitivity and specificity for Doppler ultrasound was reported in small paediatric cohorts at 63–88% and 73–99% [5, 72, 76–78]—significantly lower than in adult studies. In those small paediatric studies, Doppler ultrasound failed to detect stenoses located in small renal artery branches, segmental renal arteries as well as in main and accessory renal arteries.

CTA and MRA

Magnetic resonance angiography (MRA) or contrast-enhanced multidetector computer tomography angiography (CTA) can be used as next diagnostic steps in diagnosing renovascular disease in children. We do however advocate going directly to DSA in children with a strong suspicion of RAS. With the criteria given in Table 49.1, a majority of children will be shown to have arterial disease and MRA or CTA can never rule out RAS in these cases.

CTA and MRA are able to detect mid-aortic syndrome and sometimes stenosis of intestinal arteries and to assess non-vascular structures like occult renal or suprarenal neoplasms in addition to ultrasound [79].

The advantages of renal CTA versus MRA are a shorter examination time without the need for sedation or general anaesthesia in small children and an easy generation of high-quality 3D images. However, the disadvantage is the significant radiation exposure, even with low-dose protocols [80].

The spatial resolution of MRA has improved significantly with technological advancements and can evaluate renal parenchymal disease with high anatomical detail and improved diagnostic accuracy. However, there is a lack of data in children. To date, only small retrospective studies evaluated whether CTA/MRA can correctly predict renovascular disease, confirmed by DSA [5, 79]. MRA was less sensitive (80%) and specific (62%) than CTA (88% and 81%) and missed renovascular disease mainly in younger children [5]. Lee et al. described a sensitivity of CTA of 90% and MRA of 75% [81].

In summary, CTA and MRA are promising non-invasive imaging methods in diagnosing renovascular disease but currently cannot replace DSA. CTA seems to be more accurate than MRA in diagnosing renovascular hypertension in all age groups, but in particular in young children with small vessel size.

Renal Scintigraphy

Pre- and post-captopril renal scintigraphy with [99mTc] dimercaptosuccinic acid (DMSA) or 99m-Tc-mercaptoacetyltriglycine (MAG3) was initially thought to be a useful screening method for locating renal artery stenosis. However, paediatric studies could not reliably predict renovascular disease and showed low sensitivities of 47–73% [82–84]. Therefore, pre- and post-captopril renal scintigraphy cannot be recommended as a screening method.

DMSA scintigraphy can be informative by evaluating the relative function of each kidney and documenting focal ischemic deficits caused by renal artery stenosis and/or renal scarring. It is important to recognise that kidneys or renal segments with no initial DMSA uptake and suspected no function have the ability to recover after revascularization by angioplasty (Fig. 49.5), especially if the size of the kidney as measured on renal US is still good.

Invasive Imaging

Digital Subtraction Angiography (DSA)

DSA is the diagnostic gold standard in establishing the diagnosis of renovascular disease in children whereas all other non-invasive imaging methods have 10–40% false-negative and false-positive results. DSA provides the best spatial and temporal resolution producing excellent images of the renal arterial lumens and branches, especially if the sizes of the vessels are small.

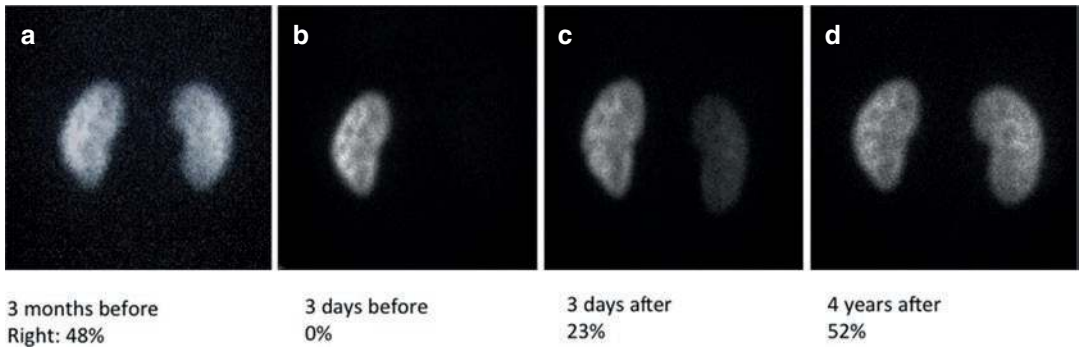

Fig. 49.5 DMSA scan with recovery of renal function after percutaneous transluminal angioplasty (PTA). (**a**) Right kidney with normal DMSA uptake 3 months before angioplasty (partial function 48%), (**b**) lacking uptake (0%) 3 days before angioplasty, (**c**) beginning recovery 3 days after angioplasty (23%) and (**d**) stable right partial function 4 years after invention (images kindly provided by Great Ormond Street Hospital, London)

Renal artery stenosis can be defined as a significant reduction of intraluminal diameter (e.g. >60%) and presence of collateral vessels.

DSA is an invasive diagnostic method with a mainly femoral artery approach, requiring general anaesthesia in children, and has a significant ionising radiation exposure. However, the main advantage of DSA is that potentially curative treatment with percutaneous transluminal angioplasty (PTA) can be performed during the same intervention. DSA and angioplasty are recommended to be performed only in clinical centres specialized in paediatric renovascular disease providing a multidisciplinary team including paediatric nephrologists, experienced interventional radiologists and vascular surgeons.

Renal Vein Renin Sampling

In case of bilateral renal artery disease and/or suspected location of stenosis in a segmental artery, renal vein sampling and measurement of plasma renin activity can be useful to identify the more relevant stenotic renal artery or to localize the segmental artery stenosis to a small area of one kidney. Usually, blood samples will be taken from the infrarenal vena cava inferior, the main renal veins and the larger intrarenal branches in order to perform renal vein renin studies during the diagnostic angiography.

Further Imaging

Cranial MR with Angiography

In case of neurological symptoms at initial presentation and suspected cerebrovascular involvement, a cranial MR evaluating cerebral parenchyma and vasculature is recommended.

Echocardiography

To evaluate cardiac function and left ventricular hypertrophy as target organ damage of severe hypertension, echocardiography should be performed in all children at initial presentation and on an annual basis.

Treatment

Treatment of renovascular hypertension is complex and requires input from a multidisciplinary team including interventional radiologists, vascular surgeons and nephrologists. In certain cases input from cardiologists, neurovascular specialists, anaesthetists and other specialists is needed. The goals of treatment are normalization of blood pressure and restoration or preservation of kidney function. Antihypertensive pharmacotherapy will nearly always be the first measure, but is almost never sufficient to control blood pressure. Angioplasty and sometimes open surgery will be needed in nearly all cases.

Pharmacological Treatment

The blood pressure in children with RVH is typically elevated very markedly. Antihypertensive medications usually improve blood pressure somewhat and many children receive combined therapies with multiple drugs [85]. It is however uncommon that blood pressure normalises by pharmacotherapy alone.

While there is no single most effective antihypertensive drug class in children with RVH, RAAS blockers are quite effective in selected individual cases. They do however bear a major chance of harming kidney function as they work by lowering the intra-glomerular pressure. These drugs are therefore contraindicated in children with renal artery stenosis. Selected cases where both angioplasty and surgery are technically unfeasible can benefit from renin-angiotensin blockade. This can often effectively reduce blood pressure but will also impair the function of the whole or part of a kidney (Fig. 49.6).

After successful angioplasty most children will acquire a much improved blood pressure and antihypertensive drugs can be weaned. It is however not uncommon that continued pharmacological treatment is required, albeit with much fewer drugs, to achieve total normalization of blood pressure.

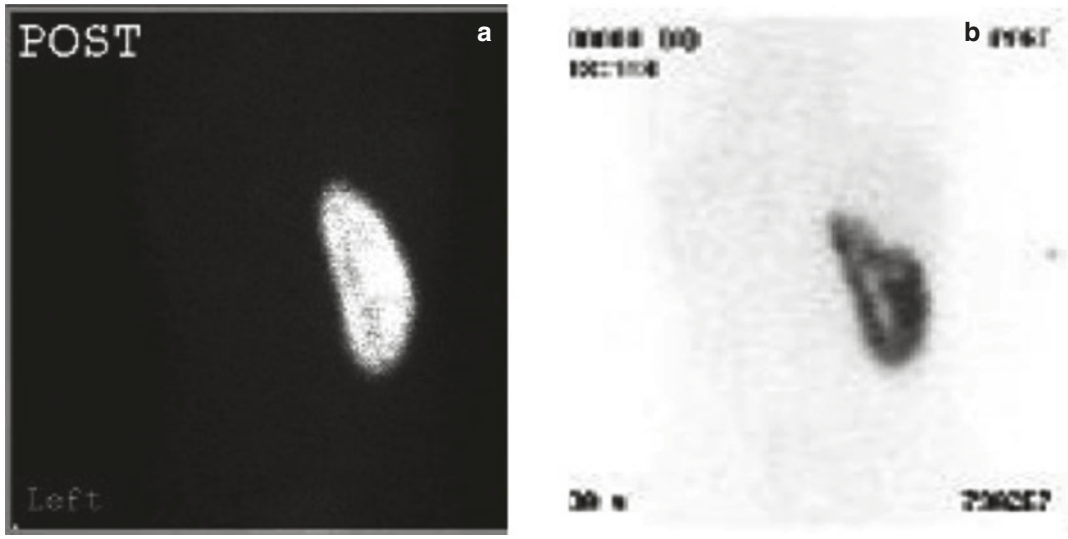

Fig. 49.6 Loss of upper pole after starting treatment with renin-angiotensin-blockade, shown in DMSA scan. (**a**) Normal left kidney in DMSA scan, (**b**) Missing upper pole of left kidney in DMSA scan (images kindly provided by Great Ormond Street Hospital, London)

Angioplasty

The vast majority of children will require interventional treatment. Percutaneous transluminal angioplasty (PTA) is the most commonly used procedure (Fig. 49.7). It is performed under general anaesthesia. The femoral artery is most commonly used for catheterization but in some cases an axillary or and radial approach is needed. The equipment used for adult coronary arteries are generally suitable. Mild to severe stenosis of the main renal arteries and sometimes also the aorta are most amenable to treatment [86]. Even completely occluded arteries can be re-canalized in many cases. Particularly in children with NF type 1 the stenotic tissue may be difficult to open up and a cutting balloon can be needed to reestablish a good-sized vascular lumen (Fig. 49.7).

Unfortunately, the artery can have elastic recoil and cause a residual stenosis after initially successful angioplasty [87]. In some of these cases a stent can be placed to keep the artery open [9, 88–90]. The lumen of the stent can however narrow in size with time. This can be due to intimal hyperplasia within the stent, stent thrombosis, or even stent fracture. Importantly, the fixed diameter of the stent may cause re-stenosis over time as children, and their arteries, grow in size. This is a particular issue in rapidly growing young infants. The use of a stent is therefore generally advised against in children.

A blood vessel that has had successful angioplasty can re-stenose with time and it is therefore not uncommon that a child needs to undergo repeated interventions to achieve optimal results [91].

Children with severe mid aortic syndrome can also benefit from angioplasty. We have seen cases diagnosed with an atretic aorta that have been possible to re-canalize and restore a reasonably wide aorta, normal blood pressure, and normal quality of life [92].

Some children with stenotic vascular lesions that are not amenable to angioplasty due to the small size of the blood vessel can be treated with ethanol ablation of a segment of a kidney [93, 94]. This is particularly useful in polar arteries supplying only a small part of the kidney.

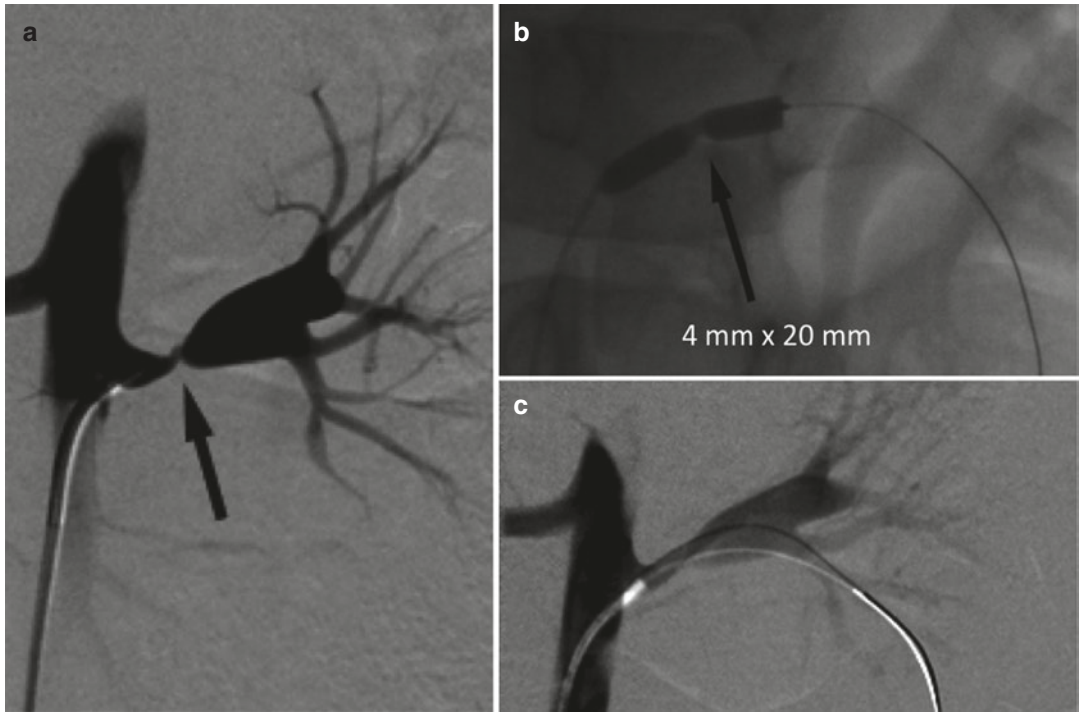

Fig. 49.7 Percutaneous transluminal angioplasty (PTA) of the left renal artery. (**a**) Left renal artery stenosis in angiography, (**b**) Positioning a cutting balloon catheter (4 mm × 20 mm) at the stenotic area, (**c**) improved vascular lumen of left renal artery directly after angioplasty procedure (images kindly provided by Great Ormond Street Hospital, London)

Complications to angioplasty include contrast-induced nephropathy, arterial spasm, thrombosis, arterial dissection and perforation. The risks for these complications vary from 0% to 43% in different publications [95, 96]. Haemodynamically insignificant dissections occur rather often and might be part of the remodelling process after angioplasty. Fatal complications are very uncommon for PTA but we and other centres recommend that vascular surgery should be readily available in case of arterial rupture or active extravasation of contrast [97].

Surgery

Surgery should be used in children where angioplasty has not achieved appropriate blood pressure control, and for aneurysmal disease that is not amenable to endovascular treatment. This assessment needs multi-professional consensus from interventional radiology, vascular surgery and nephrology. A variety of surgical revascularization procedures is available, including autologous or synthetic grafts [12, 13, 98, 99]. Autologous grafts can be the splenic or the gastro-duodenal artery that is pulled down to the kidney, or the use of a part of the saphenous vein or internal iliac artery can be used. Dacron is often used for synthetic grafts. Surgery on the renal arteries can be so complicated and time-consuming that it needs to be done outside of the child ("bench surgery", Fig. 49.8), with an ensuing auto-transplantation. In children with very complicated pathology, e.g., stenosis of both renal arteries and mid-aortic syndrome, a so-called trouser graft can be used. This extends

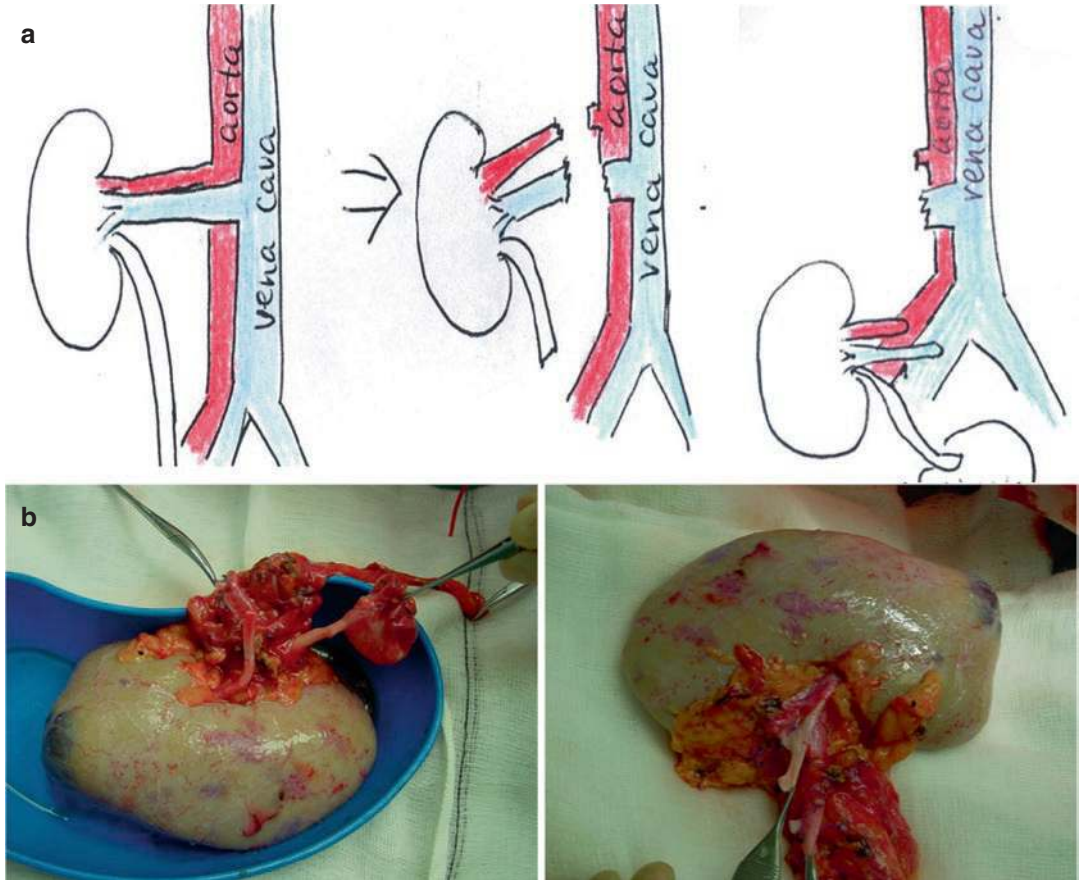

Fig. 49.8 Auto-transplantation: (**a**) Sketch and (**b**) bench surgery (images kindly provided by Great Ormond Street Hospital, London)

from the aorta above the MAS to the aorta below the stenotic lesion and to one or both renal arteries (Fig. 49.9).

In cases where no curative intervention is possible, nephrectomy can be an alternative option. This can be very successful and cure the blood pressure in children with unilateral disease and small non-functioning kidneys [100, 101]. A word of caution is, however, warranted; in some cases kidneys that show less than 10% function on a pre-treatment DMSA scan recover function after successful angioplasty or revascularization surgery, even up to 50% relative function (Fig. 49.4). These kidneys thus appear to survive on collateral circulation that does not give any relevant kidney function as measured with DMSA. We use the size of the affected kidney measured on ultrasound to decide when to try to recover function or to go directly to nephrectomy.

(**a**) Sketch of renal artery and mid-aortic stenosis and implementing a renal artery trouser graft in order to plan vascular surgery. (**b**) Complex vascular situation with renal artery trouser graft (images kindly provided by Great Ormond Street Hospital, London)

Outcome

Technical Results

Angioplasty will, in most cases, widen the lumen of the artery. In some cases e.g. with total occlusion of the blood vessel or with a very long and slender renal artery this will however not be possible. In 25–28% of children re-intervention with angioplasty was required [9, 97, 102, 103]. In some children the artery recoils very quickly despite several successful attempts with angioplasty. Some of these children are amenable to surgery. In a recent cohort, 18% of children underwent surgery after initial angioplasty [81].

Blood Pressure

Improvement of blood pressure is the most commonly reported treatment outcome. With the current techniques, PTA normalizes or improves blood pressure in 53–63% of children [9, 97, 103–105]. It typically takes some days before blood pressure settles down and medication can be weaned. Quite often there is a persistent need for one blood pressure drug even after successful intervention.

It is important to analyse the reason when blood pressure improvement is not achieved. Re-stenosis, occurring immediately or with temporal delay, can in many cases explain a failure to improve the blood pressure. In children with widespread renovascular disease, successful treatment of individual stenotic arteries might not be sufficient and the remaining disease continues to drive high blood pressure [9]. Notably, vascular disease in the contralateral kidney and involvement of small intrarenal branches occurs in 50–70% of those children [9, 103] that are not amenable to either PTA or surgery.

Kidney Function

Most studies have not systematically reported the short- and long-term effects of treatment on kidney function. Recovery or stabilization of kidney function is however a very important therapeutic goal. Some kidneys that display no function on DMSA scan regain up to normal function (50% partial function on DMSA) after successful revascularisation. The value of serum creatinine in monitoring kidney function before and after intervention is limited since a major loss of function in one kidney can be "covered up" by a normally functioning contralateral kidney.

Summary

Renovascular stenosis is an unusual but very important cause of severe arterial hypertension in children. It is important to suspect and to diagnose. DSA is the gold standard investigation and angioplasty can be performed at the same time. Surgery is needed in an important minority of cases. Most but not all children will eventually benefit from treatment.

Renal Hypertension: Etiology and Management

50

Elke Wühl and Franz Schaefer

Introduction

Blood pressure (BP) is regulated by several setting mechanisms and, apart from the cardiovascular system, the central nervous system and the adrenal glands, the kidneys are key players in BP control.

In 1836 Bright first described the association of a small contracted kidney with left ventricular hypertrophy (LVH) and linked hypertension to kidney disease [1]. In children and adolescents with chronic kidney disease (CKD), arterial hypertension is often the earliest and most prevalent complication of CKD [2]. Large cohort studies in pediatric CKD in Europe [3], Canada [2] and the US [4–6] found controlled or uncontrolled hypertension in more than 40% of children with CKD stage 1 and in up to 90% of those with CKD stage 3 to 5 [2, 6]. Even among patients receiving antihypertensive treatment, BP was uncontrolled in up to 50% of patients [6]. Evaluated by ambulatory BP monitoring (ABPM), the overall prevalence of uncontrolled hypertension ranged between 27% and 48%. The fraction of children with elevated BP not receiving antihypertensive treatment was between 21% and 45% [3, 7–9].

Because untreated or uncontrolled hypertension is an independent risk factor for kidney damage and kidney disease progression as well as for cardiovascular morbidity and mortality, BP control is of utmost importance, especially in patients with prevalent CKD.

This chapter will focus on the pathophysiology of hypertension in pediatric kidney disease and on the indications for antihypertensive treatment, therapeutic options and BP targets in childhood CKD.

The Role of the Kidney in Hypertension

Mechanisms of Blood Pressure Regulation by the Kidneys

The *Pressure-Natriuresis-Diuresis Hypothesis* plays an important role in BP control and the pathophysiology of hypertension. By this mechanism the kidneys regulate arterial pressure by adjusting blood volume. When arterial BP or renal perfusion pressure changes, blood volume is adjusted accordingly by altering the excretion or retention of sodium and water to return arterial BP to normal values [10]. This is accomplished by the interplay of angiotensin II, atrial natriuretic peptide, vasopressin, nitric oxide (NO),

kallikrein-kinin, prostaglandins, renal nerves, and other factors. Through this mechanism, the kidneys are even able to override other BP control mechanisms.

To protect the kidneys from BP peaks, transmission of elevated systemic pressure to the glomeruli and to periglomerular capillaries is prevented by preglomerular vasoconstriction [11]. This autoregulation of glomerular filtration rate (GFR) and renal blood flow (RBF) maintains RBF constant within a defined perfusion pressure ranging from approximately 80 to 200 mmHg.

Ideally, higher salt intake leads to an increase in natriuresis and diuresis but almost no change in arterial pressure. However, sensitivity to salt intake varies individually and subjects can be classified according to their arterial pressure response to changes in salt intake.

Subjects in whom arterial pressure is relatively insensitive to changes in sodium intake are so-called *salt-insensitive* individuals while those in whom arterial pressure is related to salt intake are called *salt-sensitive*. In salt-sensitive individuals the pressure-natriuresis relationship is shifted towards higher pressure levels needed to achieve increased sodium excretion; low salt intake results in normal BP but BP steadily increases with increasing salt intake [12].

Subjects with low nephron endowment, e.g., children born small for gestational age or preterm, are especially susceptible to salt sensitivity and increased BP level. Reduced nephron endowment may result in the histopathological finding of 'oligomeganephronia'. In a kidney biopsy study in adult patients with primary hypertension, the total number of glomeruli was reduced by 50%, while the size of the glomeruli was increased 2.3-fold [13].

In a neonate with low nephron number the kidney tries to adapt to the excretory overload by increasing the filtered sodium load per nephron and compensatory growth of the proximal tubule with a consequent increase in sodium reabsorption. A reduced flow at the macula densa induces an increase of glomerular pressure and filtration resulting in restoration of sodium delivery to the macula densa. Thus, extracellular fluid homeostasis is maintained by increased arterial pressure to excrete the sodium load [14]. However, the underlying pathophysiology is not yet fully understood. Pathophysiological mechanisms include genetic predisposition, kidney damage mediated by inflammation, the renin-angiotensin-aldosterone system, and neuronal alterations. After manifestation of salt sensitivity, an individual usually remains salt sensitive [15]. The prevalence of salt-sensitivity increases with age [16] and is associated with an increased risk for cardiovascular events over time [17, 18]. Supported by the observation that 50% of patients with essential hypertension are salt-sensitive, current hypertension guidelines recommend restriction of salt intake [19–21].

Also, dysfunctions of tubular ion transporters have a crucial role in the pathogenesis of hypertension. The Na^+/H^+-exchangers (NHEs), the Na^+-K^+-$2Cl^-$-cotransporter (NKCC), the Na^+-Cl^--cotransporter (NCC), the epithelial sodium cotransporter (ENaC), and the sodium-potassium-ATPase (Na^+/K^+-ATPase) play a major role in sodium homeostasis.

The *renin–angiotensin-aldosterone system* (RAAS) is one of the most powerful regulators of salt homeostasis and BP. The RAAS is activated by either the macula densa, baroreceptor activation, or the sympathetic nervous system. Activation of one of these sensors leads to stimulation of renin release by juxtaglomerular cells. Renin cleaves angiotensinogen to angiotensin I, and angiotensin I is rapidly converted to angiotensin II by the angiotensin-converting enzyme (ACE). Angiotensin II is the most effective component of the RAAS and plays a central role not only in the regulation of fluid volume but also in regulation of vascular resistance. Effects of angiotensin II are mainly mediated via the angiotensin (AT)-1 receptor, i.e., vasoconstriction, aldosterone and vasopressin release, salt and water retention through the kidney, and sympathetic activation, as well as important autocrine and paracrine effects on cell proliferation and migration, and on extracellular matrix formation. The AT-2 receptor-mediated effects of angiotensin II are mainly vasodilatory and anti-

proliferative and seem to antagonize the effect of angiotensin II at the AT-1 receptor [22]. Additionally, angiotensin II can directly stimulate the activity of ENaC in the collecting duct [23]. This subtle balance between salt homeostasis, BP and the RAAS changes with aging or with decreasing kidney function.

An important role in BP regulation and cardiac function has been ascribed to *renalase*, an amine oxidase mainly expressed by the kidneys [24]. Renalase expression and enzymatic activity are rapidly triggered by modest increases in BP and by brief surges in plasma catecholamines. The active enzyme degrades circulating catecholamines, causing a fall in BP.

Arginine-vasopressin (or *antidiuretic hormone* (ADH)), is a neuropeptide synthesized in the hypothalamus and released in response to increased plasma osmolality, decreased systemic BP, or reduced blood volume. Vasopressin regulates renal water excretion by increasing the osmotic water permeability of the renal collecting duct by activation of the vasopression-2 receptor. In addition, activation of the vasopressin-2 receptor induces NO production, attenuating vasopressin-1 receptor-mediated vasoconstrictor effects [25].

The *kallikrein–kinin system* (KKS) also contributes to the regulation of BP. Kinins, including bradykinin, are formed from kininogen by kininogenase and tissue kallikrein. Bradykinin is mainly degraded by ACE. In the tubular lumen bradykinin causes natriuresis, whereas interstitial bradykinin regulates medullary blood flow [26]. Bradykinin and kallikrein may also act in a paracrine manner on the preglomerular microvessels via release of nitric oxide and prostaglandins [27].

NO, involved in the renal regulation of BP, is produced in the renal medulla and mediates endothelium-dependent vasodilatation. It enhances arterial compliance, reduces vascular resistance and exerts an antiproliferative effect on vascular smooth muscle cells. NO antagonists (e.g. asymmetric dimethylarginine [ADMA]) induce endothelial dysfunction and lead to an increase of BP and decrease in RBF.

Endothelins (ETs) are vasoconstrictor peptides released by endothelial cells. In the kidney, ET-1 is expressed in the glomeruli and medullary collecting ducts. The renal hemodynamic effects are exerted by activation of ET-A and ET-B receptors, located in podocytes, glomeruli, afferent and efferent arterioles, the proximal tubule, the medullary thick ascending limb, and the collecting duct. ET-A is the dominant ET receptor on vascular smooth muscle cells and activation causes vasoconstriction, whereas ET-B receptor activation on endothelial cells results in vasodilation [28].

Atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP), C-type natriuretic peptide (CNP), and urodilatin have been named "*natriuretic peptides*" due to their ability to increase sodium and water excretion, resulting in reduction of intravascular volume and BP [29]. ANP and BNP decrease the secretion of renin and aldosterone, and antagonize the effects of angiotensin II on vascular tone and renal tubular sodium reabsorption. Natriuretic peptides are degraded in the lung and kidney by neutral endopeptidase [30].

Hypertension and the Kidneys

Patients with hypertension are at high risk for progressive kidney damage. The extent of the resulting nephrosclerosis depends on the individual susceptibility, degree of hypertension, the etiology of hypertension and the underlying kidney disease.

The pathogenic factors determining the degree of hypertensive kidney damage can be divided into systemic BP burden, pressure transmission to the kidney vascular bed, and local tissue susceptibility to damage. As long as BP remains within the upper limit of autoregulation, no severe changes occur. However, if this limit is exceeded, acute severe injury may occur. Autoregulatory responses can be compromised by hypertension-induced vascular injury, resulting in amplified kidney damage [31, 32]. Relevant reduction of kidney mass in CKD patients may additionally impair autoregulation [33–35] with consequent enhanced susceptibility to hypertensive injury and accelerated glomerulosclerosis [36, 37].

Pathomechanisms of Hypertension in Chronic Kidney Disease

Sodium retention and consequent *fluid overload* has long been recognized as a critical cause of hypertension in CKD patients. In contrast to patients with essential hypertension, plasma volume is elevated in CKD and correlates with BP. Also, extracellular fluid expansion is consistently found in hypertensive end-stage kidney disease (ESKD) patients. However, the correlation between interdialytic weight gain and BP is weak, suggesting additional volume-independent mechanisms in BP control [38–43]. Furthermore, the high prevalence of arterial hypertension in early CKD, when plasma and extracellular fluid volumes tend to be normal, supports a role of fluid independent mechanisms [44]. This is particularly seen in children with renal hypo/dysplasia, who tend to lose considerable amounts of sodium and water and yet are commonly hypertensive. Additional evidence for volume-independent mechanisms of hypertension in CKD comes from patients undergoing bilateral nephrectomy. In dialyzed children nephrectomy lowers mean BP despite causing anuria [45]. The removal of the native kidneys markedly reduces BP and total peripheral vascular resistance, suggesting an excessive vasopressor function of failing kidneys. Interestingly, previously hypertensive, but not normotensive patients respond to salt and water loading by an increase of BP. Hence, the vascular tone must be affected by kidney-related as well as kidney-unrelated mechanisms.

Activation of the RAAS plays a pivotal role in renal hypertension. Although plasma renin activity is typically significantly elevated in patients with isolated kidney artery stenosis, many patients with CKD have 'inappropriately normal' renin levels considering their degree of hypertension and fluid overload [46, 47]. Enhanced renin secretion by poorly perfused areas such as cysts, scars or due to microangiopathic damage or tubulointerstitial inflammation [48, 49] leads to angiotensin II mediated vasoconstriction and aldosterone-mediated salt retention, increasing both total peripheral resistance and blood volume. In addition, the local angiotensin tone in the diseased kidney is affected by multiple mechanisms, independently of plasma renin activity.

Additionally, *sympathetic overactivity* plays an important role in the pathogenesis of hypertension in CKD. Sympathetic nerve activity is increased in CKD and in dialyzed patients [50, 51], and persists even after kidney transplantation as long as the native kidneys are in place. After bilateral nephrectomy, sympathetic nerve activity and BP normalizes [50]. ACE inhibitor treatment, but not calcium channel blockers, normalizes sympathetic activity, suggesting an effect of renal angiotensin tone on afferent neural signaling [51]. Overactivation of the sympathetic drive is also observed in renovascular and polycystic kidney disease-related hypertension [52].

In addition, renalase expression and blood levels are directly correlated with glomerular filtration rate and are markedly reduced in patients with ESKD. Renalase deficiency may thus contribute to the sympathetic overactivation, hypertension and cardiac disease associated with CKD.

The *vascular endothelium* exerts important endocrine and paracrine functions, including active control of the vascular tone. In CKD, endothelium-dependent vasodilation is impaired [53, 54] and NO production is decreased [55, 56] as a result of impaired biosynthesis and bioavailability of L-arginine, reduced NO synthase (NOS) expression and increased circulating endogenous NOS inhibitors [56]. ADMA, a potent NOS inhibitor, accumulates in CKD due to impaired renal excretion and enzymatic degradation. ADMA independently predicts overall mortality and cardiovascular events in patients with ESKD as well as progression of CKD [57, 58]; however, these findings do not appear to be related to clinical differences in BP [59].

ET-1 is the most potent vasoconstrictor known to date. In ESKD patients, ET-1 plasma levels are

increased and correlate with BP level [60]; hence, circulating and possibly renal ET-1 may contribute to hypertension in CKD. With decreasing kidney function, activity of the sympathetic nervous system and oxidative stress are increasingly relevant for the risk of hypertension.

Pressure autoregulation is thought to be impaired in CKD [35], resulting in unrestricted transmission of systemic BP to the glomeruli and subsequent glomerular damage and reduction of renal mass. According to the *Brenner hypothesis*, any critical reduction of functional renal mass leads to *hyperfiltration and intraglomerular hypertension* in the remaining nephrons [61]. The increased filtration pressure causes or aggravates preexisting proteinuria. The exposure of tubular and mesangial structures to macromolecular proteins elicits a marked and persistent tissue response. In addition, proteinuria and enhanced angiotensin II formation stimulate the synthesis and release of several pro-inflammatory cytokines and chemokines, resulting in a local inflammatory and fibrotic tissue response and atrophy of the nephron.

A large body of evidence from epidemiological studies and clinical trials indicates that hypertension is an important driver of *CKD progression*. Numerous interventional trials have demonstrated that lowering BP preserves kidney function in hypertensive patients at risk for progressive kidney disease [62–74]. In addition to hypertension, proteinuria is a major risk factor contributing to CKD progression. Although hypertension aggravates proteinuria and the two risk factors are strongly interrelated, they independently influence kidney survival. Two prospective pediatric trials have demonstrated that hypertension and proteinuria are major independent risk factors for progressive kidney failure in children with CKD [63, 75, 76]. Detailed information on role of hypertension in kidney disease progression is provided in Chap. 55.

Various modifying risk factors, such as low birth weight, high fructose diets or obesity may increase the risk for hypertension [77] in CKD patients.

One potential factor influencing the risk of hypertension is hyperuricemia [78], which is often related to obesity or metabolic syndrome, but also to reduced kidney function. Uric acid levels correlate with endothelial dysfunction and higher BP [79]. Hyperuricemia is involved in the generation of reactive oxygen species (ROS), low NO levels, activation of the RAAS, and endothelial dysfunction. The resulting pro-vasoconstrictive conditions cause ischemia and chemokine release, local inflammation and intrarenal generation of vasoconstrictors that further promote ischemia and block pressure-natriuresis. Sodium retention leads to an increase in serum osmolality, activation of the sympathetic nervous system, constriction of vascular smooth muscle cells, and an increase in systemic vascular resistance. Increasing BP ameliorates tubular ischemia by shifting the pressure-natriuresis curve towards higher pressure and the salt-resistant state [77].

Secondary *hyperparathyroidism*, a complication of CKD, may be another contributor to the high prevalence of hypertension. A retrospective study in adults with CKD demonstrated higher systolic and diastolic BP in patients with elevated parathyroid hormone levels [80]. Since BP correlated highly with serum calcium levels, a mechanistic role of increased cytosolic calcium in patients with severe hyperparathyroidism has been postulated.

BP may also be increased due to *adverse effects of drugs* used in the treatment of CKD. For example, erythropoiesis stimulating agents (ESAs) might increase BP by increasing hematocrit. Hypertension may be secondary to the direct vasoconstrictive actions of steroids, calcineurin inhibitors and other immunosuppressive or anti-inflammatory drugs prescribed in acute or chronic immune-mediated kidney disease or after kidney transplantation.

Factors involved in the pathogenesis of hypertension in CKD are summarized in Fig. 50.1.

Hypertension in Specific Renal Conditions

Renoparenchymal hypertension is common in various forms of *acute and chronic glomerulonephritis*. The most common underlying histopathological entities associated with hypertension, even in the absence of kidney failure, are poststreptococcal, focal-segmental, membranoproliferative and crescentic glomerulonephritis. Persistent hypertension is also common in patients with glomerulonephritis secondary to systemic vasculitis, such as systemic lupus erythematosus, and in patients with hemolytic uremic syndrome (HUS).

Hypertension in Acute Kidney Injury

In acute kidney diseases, changes in BP usually mirror changes in disease activity.

In *acute glomerular disease*, e.g., poststreptococcal glomerulonephritis or nephrotic syndrome, patients are often volume expanded due to sodium retention by acute renal impairment [81]. BP increases due to fluid overload and even in subjects with subclinical volume overload the incidence of hypertension may already be increased. While in these conditions the release of atrial natriuretic peptide is enhanced by sodium retention, the RAAS is often suppressed. In contrast, in patients with acute vasculitis of the kidneys ischemia-induced activation of the RAAS is the main underlying mechanism.

In hypertensive patients with *HUS*, a difference in the pathophysiological mechanisms involved in the origin of hypertension between patients with shiga-toxin associated HUS (STEC-HUS) and patients with atypical, complement-disorder associated HUS (aHUS) is hypothesized. In patients with STEC-HUS, fluid overload and salt retention are supposed to play a major role, but in patients with aHUS complement activation and endothelial dysfunction are probably key players [82, 83]. Of note, while malignant hypertension may indicate aHUS and thrombotic microangiopathy (TMA), in patients with malignant hypertension extremely high BP per se can induce a thrombotic microangiopathy.

Hypertension in Chronic Kidney Disease

Chronic renoparenchymal hypertension is not limited to *glomerular disease*, but is also observed in patients with *congenital anomalies of the kidneys and urinary tract (CAKUT)* or with tubulointerstitial disorders leading to kidney scarring. Recurrent pyelonephritis, reflux nephropathy, obstructive uropathies or polycystic kidney disease, can all lead to activation of the local RAAS, tubulointerstitial fibrosis and tubular atrophy.

The risk of hypertension is more closely associated with the type of underlying kidney disease than with the degree of kidney dysfunction. At any given level of CKD (stage 1–5), children with acquired glomerulopathies or polycystic kidney disease tend to have higher BP than those with renal hypoplasia and/or uropathies. In a survey of the ESCAPE trial group in pediatric CKD patients with CKD 2 to 4, the prevalence of hypertension was 88% in patients with acquired glomerulopathies, 38% in children with hypo-/dysplastic kidney disorders and 57% in other congenital or hereditary kidney diseases [8, 9]. Renoparenchymal disorders are responsible for approximately 75% of cases of secondary hypertension in childhood [84].

A condition that can be associated with malignant hypertension in newborns or in early infancy is autosomal recessive polycystic kidney disease (ARPKD). Children with severe ARPKD may present with episodes of hypertensive crisis associated with high mortality risk, including sudden heart failure, cerebral ischemic or hemorrhagic stroke.

Autosomal dominant polycystic kidney disease (ADPKD), while becoming clinically symptomatic only in adults, has a high prevalence of hypertension in childhood when kidney function is still normal [85].

As described above, the pathophysiological mechanisms in renal parenchymal hypertension encompass an increased activity of the RAAS, sodium and water retention, enhanced activity of the sympathetic nervous system, oxidative stress and endothelial dysfunction.

Renovascular hypertension accounts for about 10% of pediatric patients presenting with secondary hypertension. Renovascular hypertension results from vascular lesions that impair blood flow to one or both kidneys or to kidney segments [86, 87]. Post-stenotic decreased renal perfusion results in stimulation of the RAAS. The most common causes of renovascular hypertension in childhood are idiopathic stenosis of the kidney artery, fibromuscular dysplasia, mid-aortic syndrome, and genetic or syndromic disorders such as neurofibromatosis type 1 (NF1, von Recklinghausen), which can affect not only the renal, but also intrarenal arteries, Williams-Beuren syndrome, and Alagille syndrome.

Kidney artery stenosis should be ruled out in children with very high BP (stage 2 hypertension), hypertensive complications (e.g., hypertensive crisis with cerebral symptoms, heart failure, facial neve palsy), uncontrolled hypertension on more than two antihypertensive drugs, worsening of kidney function after initiation of ACE inhibitor (ACEi) or angiotensin receptor blocker (ARB) therapy, or increased plasma renin activity with hypokalemia.

The preferred therapeutic intervention in childhood renovascular hypertension is revascularization of the stenosis. Detailed information on the management of kidney artery stenosis can be found in Chap. 49.

Hypertension in Pediatric Dialysis Patients

The prevalence of *hypertension in pediatric peritoneal or hemodialysis patients* (CKD stage 5D) is very high. At time of dialysis initiation, up to 80% of patients are hypertensive; out of these 60% are untreated or have uncontrolled hypertension despite antihypertensive drug therapy. After 1 year on dialysis more than 50% of patients remain hypertensive [88–90]. Hypertension may be maintained by the underlying kidney disease, especially in patients with glomerulopathies or PKD, but also by inappropriately high fluid and sodium intake.

In a survey of more than 1300 pediatric dialysis patients in the European ERA/EDTA registry, the overall prevalence of hypertension was similar in hemodialysis (HD; 69.7%) and peritoneal dialysis (PD; 68.2%) patients. However, the percentage of uncontrolled hypertension was higher in HD compared to PD patients (45% vs. 35%) [91]. These epidemiologic data were derived from casual BP measurements, with a single BP recording per patient reported to the registries. For the interpretation of these data, consideration of the time of BP measurement is important because pre-dialysis measurements are usually higher compared with post-dialysis measurements, resulting in a higher probability to be classified as hypertensive when only pre-dialysis measurements are considered.

The dominant factor contributing to hypertension in dialysis patients is volume overload; other contributing factors include, as in non-dialysis CKD patients, activation of the RAAS and the sympathetic nervous system, endothelial dysfunction, increased arterial stiffness, hyperparathyroidism and exposure to BP elevating drugs.

Contrary to the physiologically expected suppression of the RAAS in a state of salt or fluid overload, plasma renin activity was found to be significantly higher in a study comparing hypertensive to normotensive dialysis patients. These findings suggest that in ESKD patients with adequately controlled sodium balance, the RAAS is an important factor involved in the pathogenesis of hypertension [92]. Also, the significant decline in BP observed after bilateral nephrectomy [93] points to volume-independent mechanisms of hypertension in dialysis patients. A further factor contributing to arterial hypertension in ESKD might be the markedly decreased plasma levels of *renalase*. Renalase deficiency and the resulting increase of circulating catecholamine levels may also contribute to the high prevalence of hypertension and cardiovascular disease in ESKD [24, 94].

Hypertension in Pediatric Renal Transplant Recipients

In children and adolescents after kidney transplantation, hypertension is almost as common as in dialysis patients and constitutes a serious comorbidity [91, 95, 96], not only with respect to cardiovascular morbidity and mortality, but also for kidney transplant survival [97]. Posttransplant hypertension might be caused by the native kidneys, vascular stenosis of the transplant kidney artery, acute or chronic graft dysfunction, and recurrent or de-novo glomerulonephritis in the transplant kidney. In addition, medication side effects of immunosuppressive drugs (steroids, calcineurin inhibitors), including excessive weight gain with steroid treatment, have an important role in posttransplant hypertension.

Hypertension Associated with Disorders of Renal Tubular Sodium Handling

In rare cases, hypertension may be caused by autosomal dominant or recessive single gene mutations (***monogenic hypertension***) [98–100]. Characteristically, all hereditary forms of hypertension lead to suppression of the RAAS with low levels of renin concentration or renin activity (‘***low renin hypertension***’) due to expansion of plasma volume. In a broader sense, the pathophysiology of these disorders comprises alterations of renal tubular electrolyte handling due to mutations in genes regulating glucocorticoid synthesis or action effecting the mineralocorticoid receptor, or in genes regulating the sodium excretion in the distal tubule.

Apparent mineralocorticoid excess (AME) is an autosomal recessive disorder in which inactivating mutations in the *HSD11B2* gene, encoding the kidney isozyme of 11-β-hydroxysteroid dehydrogenase 2, lead to increased concentrations of cortisol in the kidneys and to activation of the mineralocorticoid receptor due to cross-reaction of cortisol with the non-selective mineralocorticoid receptor. This induces aldosterone-like effects in the tubule, typically causing hypokalemia, metabolic alkalosis, hypernatremia and hypertension.

Glucocorticoid remediable aldosteronism (GRA; familial hyperaldosteronism type 1) is an autosomal dominant disorder due to altera-

tions in the adjacent 11β-hydroxylase and aldosterone synthase genes on chromosome 8q24.3. Unequal cross-over between these genes results in ACTH-stimulated ectopic secretion of aldosterone from the adrenal zona fasciculata. Increased aldosterone secretion stimulates the mineralocorticoid receptor, resulting in suppressed renin levels and hypertension due to upregulation of potassium excretion and sodium reabsorption in the renal tubule.

Hypertension in congenital adrenal hyperplasia (CAH) is caused by autosomal recessive inherited defects in 11β-hydroxylase (Type IV) or 17α-hydroxylase (Type V), leading to overproduction of 21-hydroxylated steroids and overactivation of the mineralocorticoid receptor. The uncontrolled mineralocorticoid activity results in hypertension and hypokalemia. Additionally, in CAH type IV the enzyme block increases the production of sex steroids, with androgenic actions causing virilization in girls and precocious puberty in boys. In CAH type V, the synthesis of sex hormones is compromised, resulting in primary amenorrhea and delayed sexual maturation in girls and in ambiguous genitalia in boys.

Liddle's syndrome is caused by a dominant gain-of-function mutation in the amiloride-sensitive epithelial sodium channel (ENaC) located in the collecting duct. The overactive ENaC causes increased sodium reabsorption and intravascular volume expansion, which leads to hypertension. Moreover, these patients present with hypokalemia, metabolic alkalosis, and occasionally hypercalciuria.

Gordon's syndrome is characterized by familial hyperkalemia with normal kidney function, reduced renal sodium excretion, hypercalciuria and hyperchloremic metabolic acidosis due to dominant mutations in the WNK serine-threonine kinases WNK1 and WNK4 or in *KLHL3* or *CUL3*, associated with loss of inhibitory regulation of the NCC in the thiazide-sensitive distal convoluted tubule.

For accurate assessment of the different forms of low renin hypertension, analysis of serum renin, aldosterone, serum electrolytes and blood gas analysis, urinary potassium excretion and the urinary steroid profile is required. In addition, further hormonal studies and genetic testing for the disease-causing mutations may be required [98–100].

The etiology of hypertension in pediatric CKD is summarized in Table 50.1. For the diagnostic approach to renal hypertension see Table 50.2. Additional information on the diag-

Table 50.1 Etiology of pediatric renal hypertension

Etiology	Underlying kidney disease/ condition
Renoparenchymal	• Acute glomerulonephritis (e.g. post streptococcal glomerulonephritis, Henoch-Schönlein nephritis) • Chronic glomerulonephritis (e.g., FSGS, IgA nephropathy) • Hemolytic uremic syndrome • Interstitial nephritis • Congenital hypo- or dysplasia of the kidneys • Congenital anomalies of the kidneys and urinary tract • Cystic kidney disease (ARPKD, ADPKD) • Recurrent pyelonephritis with scarring • Acute pyelonephritis • Urological interventions • Kidney tumors • Kidney trauma • Chronic kidney failure • Status post kidney transplantation
Renovascular	• Kidney artery stenosis (e.g., fibromuscular dysplasia with neurofibromatosis, Williams-Beuren syndrome) • Vasculitis (e.g., periarteritis nodosa, Takayasu arteritis) • Compression of kidney artery by tumor, bleeding, abscess
Other renal conditions	• Fluid overload in dialysis patients (misjudgment of fluid status) • Side effects of drug treatment in immunosuppressed patients (e.g., steroids, cyclosporine, tacrolimus) • Forms of monogenic ('low-renin') hypertension

FSGS focal-segmental glomerulosclerosis, *ADPKD* autosomal dominant polycystic kidney disease, *ARPKD* autosomal recessive polycystic kidney disease

Table 50.2 Baseline diagnostic measures in suspected renal hypertension

Medical history	
Family history	Hypertension, cardiovascular disease, hereditary kidney disease
Perinatal history	Birth weight, gestational age, oligohydramnios
Current findings	Urinary tract infections, renal or urinary diseases/malformation
Potential renal findings	Dysuria, polydipsia, polyuria, nycturia, hematuria, edema, weight loss, failure to thrive
Indicators for target organ damage	Headache, nose bleeding, vertigo, dizziness, blurred vision, facial palsy, seizures, stroke, dyspnea
Medication	Antihypertensives, steroids, CNI (ciclosporine A, tacrolimus), …
Physical examination	
General	Height, weight, body mass index
Hypertension-associated syndromes	Neurofibromatosis, Williams-Beuren syndrome, …
Cardiovascular exams	Measurements of pulse rate and blood pressure at all 4 extremities Murmur, flow noise at heart, abdomen, flanks, back, neck, head, signs of heart insufficiency
Abdomen	Palpable mass → Wilms tumor, autosomal-dominant or recessive polycystic kidney disease, obstructive uropathy, hepatosplenomegaly → autosomal-recessive polycystic kidney disease
Virilization, ambiguous genitalia	Forms of monogenic hypertension
Basic diagnostics	*Finding → indicating …*
Creatinine, urea (serum)	Creatinine, urea increased → kidney insufficiency
Electrolytes (serum)	Hypokalemia → kidney artery stenosis Hyperkaliemia → kidney insufficiency
Blood gas analysis	Metabolic acidosis → kidney insufficiency
Urinalysis: erythrocytes, leukocytes, glucose, protein, albumin[a]	Hematuria, proteinuria → glomerulonephritis Leukocyturia → pyelonephritis Glucosuria → tubulopathy, diabetes mellitus
Ultrasound of kidneys and urinary tract	Enlarged hyperechogenic kidneys → glomerulonephritis, pyelonephritis Kidney cysts → polycystic kidney disease, cystic dysplastic kidney disease, multicystic dysplastic kidney disease Small, hyperechogenic kidneys → kidney hypoplasia, kidney dysplasia Side differences → unilateral kidney hypo/dysplasia, vesicoureteral reflux with scarring, indicating kidney artery stenosis Tumor
Ophthalmological	Hypertensive retinopathy → end organ damage
Echocardiography	Left ventricular hypertrophy → end organ damage
Further diagnostics	*Finding → indicating…*
Renin, aldosterone levels Renin activity Renin/aldosterone ratio	Hyperreninism → kidney artery stenosis, renoparenchymal hypertension Low-renin hypertension → monogenic hypertension
Urinary steroid profile	→ Forms of monogenic hypertension
Genetic testing	→ Forms of monogenic hypertension

nosis of hypertension and BP monitoring in CKD patients is provided in Chap. 49.

Antihypertensive Treatment Strategies in Acute and Chronic Kidney Disease

The main goal of BP control in acute kidney injury is to attain a BP level in the normal range and to avoid acute hypertensive damage to the kidneys and the cardiovascular system.

In CKD-associated hypertension, the growing understanding of the epidemiology, pathophysiology and target organ damage has promoted the search for effective long-term therapeutic strategies (for further information see also Chaps. 49 and 51). These relate to both BP targets and preferred antihypertensive drug choices.

Blood Pressure Target

The therapeutic goal in all CKD children with hypertension is long-term and consistent BP control irrespective of the underlying condition. Hypertension-related cardiovascular end-organ damage such as left ventricular hypertrophy, hypertensive retinopathy, and progressive kidney function deterioration has to be avoided and the risk of long-term cardiovascular sequelae and kidney failure should be minimized. While in children with primary hypertension a BP goal below the 95th BP percentile or below the adult thresholds, whichever is lower, is recommended and this target might be also applicable for hypertension in acute kidney injury, there is ample evidence for beneficial effects of lower BP targets in CKD patients.

In adult CKD patients with diabetic or non-diabetic kidney diseases, meta-analyses of antihypertensive trials showed an almost linear relationship between achieved BP and the annual GFR loss [101]: The better the BP control, the better was kidney survival. As a result, the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC7) published in 2003 recommended a BP goal of <130/80 mmHg in patients with CKD or diabetes, as compared to <140/90 mmHg in primary hypertension [102]. However, at that point in time the renoprotective superiority of very *strict BP control* had not yet been unequivocally demonstrated in adult nephropathies [103–108]. Thus, the usefulness of lower BP targets in adults with CKD had been questioned. Meanwhile, the findings of the SPRINT trial, published in 2015 [109], gave new impetus to the discussion on BP targets. In this prospective randomized controlled trial including more than 9000 participants aged 50 and older with increased cardiovascular risk (26% in CKD stage 3–4), patients with intensified BP control (systolic BP <120 mmHg) showed 25% lower fatal and nonfatal cardiovascular event rates, 27% lower all-cause mortality, and a 43% reduction of relative risk to die from any cardiovascular cause with the intensive intervention compared to standard treatment (systolic BP <140 mmHg). However, there was no difference in primary cardiovascular outcomes in CKD patients [109] and some methodological aspects of the study are critically discussed [110].

In children with CKD, the Efficacy of Strict Blood Pressure Control and ACE Inhibition on Renal Failure Progression in Pediatric Patients (ESCAPE) Trial has provided evidence for a nephroprotective effect of intensified BP control [63]. CKD children randomized to a target 24-h mean arterial pressure below the 50th percentile for age were 35% less likely to lose 50% GFR or progress to ESKD within 5 years than children with a more conventional BP target between the 50th and 95th BP percentile. The risk to attain the study endpoint was increased by 15% for each mm Hg above the 50th percentile, while a BP below the 50th percentile did not significantly affect renal risk [63]. The protective effect of low normal BP on kidney function seen in the ESCAPE trial was independent of RAAS inhibition since all subjects received the same dose of the ACE inhibitor ramipril. While the benefit was greatest in children with glomerular disorders, it was also significant in children with renal hypoplasia or dysplasia. Survival analysis stratified by the achieved 24-h BP suggested that any BP

exceeding the 50th percentile was associated with a compromised kidney outcome [63]. Also in this study, proteinuria was found to be an important modifier of the renoprotective efficacy of intensified BP control. Patients with significant proteinuria had a greater benefit from intensified BP control than non-proteinuric patients.

Based on the findings of the ESCAPE trial [63], the European Society of Hypertension (ESH) pediatric guideline recommends that antihypertensive treatment should be initiated if BP exceeds the 90th percentile and aim for a mean 24-h ambulatory BP target below the 75th percentile in non-proteinuric and below the 50th percentile in proteinuric children and adolescents with CKD [111]. In adolescents aged 16 years and older a BP below 130/80 mmHg should be aimed for in non-proteinuric and below 125/75 mmHg in proteinuric CKD [111]. For young adults with kidney disease, the guideline of the European Societies for Cardiology and Hypertension (ESC/ESH) recommends a BP target of 130–139/70–79 mmHg [21].

The American Academy of Pediatrics Practice Guideline for Management of Hypertension in Children and Adolescents [112] recommends that all children or adolescents with CKD be treated to lower 24-h mean arterial pressure to <50th percentile by ABPM, irrespective of the degree of proteinuria, whereas children with primary hypertension be treated by non-pharmacological or pharmacological intervention to a reduction in systolic and diastolic BP to below the 90th percentile (or below 130/80 mmHg in adolescents ≥13 years old).

Choice of Antihypertensive Drugs

Treatment of Hypertension in Children with Acute Kidney Injury

In view of the different etiologies of acute kidney injury, treatment of hypertension should be individualized. In patients with acute glomerulopathies and edema, such as those presenting with hypertension due to poststreptococcal glomerulonephritis or nephrotic syndrome, where fluid overload and salt retention play a major role, the initial therapy is diuretics. Loop diuretics should be prescribed in patients with severely reduced GFR since thiazides are ineffective when GFR falls below 30. RAAS antagonists can be effective as second line treatment for persistently elevated BP [113], although acute glomerulonephritis typically is a state of low-renin hypertension.

In patients with acute vasculitis, ACE inhibitors are recommended as first line antihypertensive therapy since activation of the RAAS due to renal ischemia is the main pathophysiological mechanism. Since STEC-HUS leads to RAAS activation, ACE inhibitors and angiotensin receptor blockers are the treatment of choice in this condition. In children with hypertension due to atypical HUS mediated by complement activation, treatment of the underlying complement disorder is essential to normalize BP in addition to acute antihypertensive therapy using either RAAS antagonists or calcium channel blockers [83].

Treatment of Hypertension in Children with CKD

The major recommended antihypertensive drug classes (ACEi, ARB, calcium channel blockers (CCB), β-blockers) exert comparable BP lowering effects in CKD patients. A list of antihypertensive drugs used in children with CKD is given in Table 50.3.

In view of the crucial role of the RAAS in kidney failure progression, *RAAS antagonists* (ACEis and ARBs) might confer specific nephroprotective properties beyond their antihypertensive action. RAAS antagonists reduce the intraglomerular pressure, thereby lowering proteinuria and suppressing local inflammatory processes, with subsequent reduction of glomerular hypertrophy and sclerosis, as well as tubulointerstitial inflammation and fibrosis. Most randomized clinical trials have demonstrated superior renoprotective efficacy of RAAS antagonists (ACEis and ARBs) in adults with diabetic and non-diabetic CKD. Several meta-analyses have confirmed the nephroprotective benefit of RAAS antagonists, although the effect size is quite variable [114, 115]. One analysis suggested that the nephroprotection conferred by ACEi might be partially independent of their antihypertensive

Table 50.3 Pharmacological treatment of renal hypertension in children

Class	Drug	Mode of action	Side effects
ACE inhibitors	e. g., Captopril Enalapril Ramipril Fosinopril Benazepril Lisinopril	Inhibition of the conversion of angiotensin I to angiotensin II → vasodilatation, reduction of sympathetic tone, decreased aldosterone dependent salt and water retention, nephroprotection	Cough, hyperkalemia, increase of serum creatinine, hypotension, dizziness, fatigue, headache, laryngioedema, neutropenia *Caveat*: contraindicated in bilateral severe kidney artery stenosis *Caveat*: pre-renal acute kidney failure in dehydration episodes *Caveat*: pregnancy (teratogenic)
Angiotensin-receptor blockers	e. g., Candesartan Valsartan Losartan Irbesartan	Blockade of angiotensin-II-type-1-receptors Nephroprotection (see also ACE inhibitors)	Side effects similar to ACE inhibitors, no cough Rhabdomyolysis, thrombocytopenia
Calcium channel blockers	e. g., Nifedipine Nitrendipine Amlodipine	Reduced influx of calcium into the cells → relaxation of the arterial vascular muscle cells, decrease of peripheral vascular resistance	Headache, flush, tachycardia/palpitations, peripheral edema, fatigue, hypotension, gingival hyperplasia
Diuretics	e. g., Furosemide, Torsemide Hydrochlorothiazide	Increase of renal sodium excretion, decrease of peripheral resistance	Hypokalemia, hyponatremia, alkalosis, extracellular volume depletion, hyperuricemia, diuretics enhance ACE inhibitor effect *Cave* acute kidney failure in dehydration episodes
β-Blockers	e.g., Atenolol Metoprolol Propranolol Carvedilol	Reduction of cardiac output, renin-aldosterone release and of sympathetic activity	Tiredness, dizziness, depression, reduced physical capacity, bradycardia, hypotension, nausea, bronchospasm, *Cave* β-blocker in diabetes mellitus or pulmonary obstruction/asthma
Alpha-blocker	e.g., Doxazosin Phenoxybenzamine	Relaxation of vascular smooth muscle cells, direct vasodilatory effect	Edema, dizziness, fatigue, headache
Centrally acting adrenergic drugs (alpha2-agonists)	e.g., Clonidine	Reduction of sympathetic outflow, decrease in peripheral vascular resistance, decrease of heart rate	Dizziness, headache, fatigue, xerostomia
Vasodilators	e.g. Minoxidil Hydralazine	Activation of gated potassium channels, vasodilatation, lowering of total peripheral resistance	Edema, fluid retention, salt retention, headache, hypertrichosis, leukopenia, nausea, palpitations/tachycardia

Examples of antihypertensives with (some) clinical experience in pediatric hypertension
ACE angiotensin-converting enzyme

and antiproteinuric actions [114]. Thus, RAAS antagonists are considered the first-line pharmacological therapy in hypertensive CKD patients.

For pediatric CKD, the Chronic Kidney Disease in Children (CKiD) Study found an increased prevalence of uncontrolled hypertension in children not receiving ACEi or ARBs, supporting the use of RAAS antagonists as preferred antihypertensive agents in pediatric CKD [5]. Both ACEi and ARBs have been shown to reduce systolic and diastolic BP efficiently [63] in a dose-dependent manner [116]. The drugs

were very well tolerated and side effects requiring ACEi or ARB withdrawal due to acute increases of serum creatinine, hyperkalemia or hypotensive episodes were rare [63, 116].

As expected, in patients with underlying CKD the prevalence of reported adverse events is higher, and increases in serum potassium, creatinine and blood urea nitrogen are more commonly reported compared to non-CKD patients. Approximately 25–30% of CKD patients experience an eGFR decline of more than 25% [117]. However, it has been hypothesized that the observed increase in serum creatinine after start of RAAS blockade is due to hemodynamic changes in the glomerulus, which does not reflect kidney injury and should thus be reversible at withdrawal of RAAS blockade [118].

In some patients, the RAAS is incompletely suppressed by ACEi alone, and the possibility of partial secondary resistance due to compensatory upregulation of ACE-independent angiotensin II production ('aldosterone escape') has been suggested [119–121]. Interestingly, in those patients with breakthrough proteinuria followed in the ESCAPE trial [63], BP was still well controlled. Thus, the doses required to achieve the maximal antiproteinuric effect of ARBs may be much higher than the maximally active antihypertensive doses. Significant additional proteinuria lowering was achieved without increased side effects in adults with 64 mg and even 128 mg of candesartan, which has only a minor additional BP lowering effect beyond daily doses of 16–32 mg [122]. Similarly, *dual RAAS blockade* by combined use of an ACEi and an ARB does not exert significant additional antihypertensive effects compared to the maximum recommended dose in monotherapy, but still might improve proteinuria. However, the risk-benefit balance of combining ACEis and ARBs in younger subjects is still debated [123–125].

Other drug classes inhibiting the RAAS exert antihypertensive effects. Aliskiren is a direct *renin antagonist*, blocking the conversion from angiotensinogen to angiotensin I. Its BP lowering effect is comparable to that of ARBs and a combination of aliskiren and valsartan at maximum recommended doses provided significantly greater BP reduction than the respective monotherapies [126]. However, combination therapy of aliskiren with ACEi or ARBs significantly increased the risk of cardiovascular events in adults with diabetes or CKD and is therefore not recommended [127, 128].

Mineralocorticoid receptor antagonists (MRA) also lower BP; however, their use is limited by the risk of side effects, including hyperkalemia, gynecomastia, impotence, and amenorrhea. These side effects are more common for the steroidal MRAs spironolactone and eplerenone. Due to the high risk of hyperkalemia, the combination of ACEIs and steroidal MRAs in CKD patients has not been recommended [129]. The novel nonsteroidal MRAs finerenone and esaxerenone have a higher potency and selectivity for the mineralocorticoid receptor and thus seem to have fewer side effects.

Because the antihypertensive effect of MRAs is not superior to ACEis or ARBs, they are not used as first line agents in renal hypertension. However, recent studies support a future role, especially of the nonsteroidal MRAs, in the prevention of cardiovascular disease and CKD progression by reducing oxidative stress, inflammation, fibrosis, endothelial dysfunction and proteinuria [130, 131]. MRAs play an important role in the treatment of some forms of monogenic hypertension (see Table 50.4).

In a substantial number of pediatric CKD patients with hypertension, multidrug antihypertensive therapy is required [3, 63]. The choice of additional antihypertensive drugs in children with CKD is largely arbitrary.

Dihydropyridine *calcium channel blockers* have no antiproteinuric effect and may actually promote proteinuria and more rapid CKD progression [132]. However, their combination with ARBs or ACEis provides powerful BP lowering and even conferred a patient survival advantage as compared to the combination of ARBs or ACEis with thiazide diuretics [133, 134]. Non-dihydropyridine calcium channel blockers (diltiazem, verapamil) are antiproteinuric and therefore potentially renoprotective, but have a weaker effect on BP [132].

The use of *β-receptor blockers* appears rational in view of the sympathetic overactivation in

Table 50.4 Dosing of antihypertensive medication in children with CKD (*modified from* [156], *Springer International Publishing*)

Class	Drug	Usual pediatric dosing range[a]	Dosing modifications in CKD stage 3–5 D[a]
Angiotensin receptor blockers	Candesartan	*1–6 years*: 0.2 mg/kg/day up to 0.4 mg/kg/day *6–17 years*: *<50 kg*: 4–16 mg QD *>50 kg*: 8–32 mg QD	No known recommended adjustment but clearance reduced if GFR <30 mL/min; not removed by dialysis; give 50% of usual dose; consider dosing after HD session
	Losartan	0.75 mg/kg/day to 1.4 mg/kg/day; maximum 100 mg daily	Not recommended if GFR <30 mL/min; not removed by dialysis
	Olmesartan	*20–35 kg*: 10–20 mg QD *≥35 kg*: 20–40 mg QD	Clearance reduced if GFR <20 mL/min; do not exceed 20 mg daily in such patients; not removed by dialysis
	Valsartan	*<6 years:* 5–10 mg/day up to 80 mg daily *6–17 years*: 1.3 mg/kg/day up to 2.7 mg/kg/day; maximum 160 mg daily	Clearance reduced if GFR <30 mL/min; not removed by dialysis
Angiotensin converting enzyme inhibitors	Benazepril	0.2 mg/kg/day up to 0.6 mg/kg/day; maximum 40 mg daily	No pediatric data. 20–50% removed by dialysis; give 25–50% of usual dose; consider dosing after HD session
	Captopril	0.3–0.5 mg/kg/dose TID up to 0.6 mg/kg/day; maximum 450 mg daily	No pediatric data. 50% removed by dialysis. Give 25% of usual dose in HD patients; consider dosing after HD session. Give 50% QD of usual daily dose in PD
	Enalapril	0.08 mg/kg/day up to 0.6 mg/kg/day; maximum 40 mg daily	Not studied in children with GFR <30 mL/min. 50% removed by dialysis. Give 50% of usual dose; consider dosing after HD session
	Fosinopril	0.1 mg/kg/day (up to 10 mg/day) up to 0.6 mg/kg/day; maximum 40 mg/day	No known adjustments; not removed by dialysis
	Lisinopril	0.07 mg/kg/day (up to 5 mg/day) up to 0.6 mg/kg/day; maximum 40 mg daily	Not studied in children with GFR <30 mL/min. 50% removed by dialysis. Give 25% of usual dose; consider dosing after HD session
	Quinapril	5–10 mg/day up to 80 mg daily	No pediatric data. For adults with GFR 10–30 mL/min, do not exceed 2.5 mg/day; no data for GFR <10 mL/min
	Ramipril	1.6 mg/m^2 BSA/day QD up to 6 mg/m^2/day; maximum 20 mg daily	No pediatric data. In adults with GFR <40 mL/min, give 25% of usual dose; 20% removal by dialysis. Consider dosing after HD session
α- and β-blocker	Carvedilol	0.1 mg/kg/dose BID (up to 6.25 mg) up to 0.5 mg/kg/dose; maximum 25 mg BID	No adjustment needed; not removed by dialysis
	Labetalol	2–3 mg/kg/day BID up to 10–12 mg/kg/day; maximum 1200 mg daily	No adjustment needed; not removed by dialysis

(continued)

Table 50.4 (continued)

Class	Drug	Usual pediatric dosing range[a]	Dosing modifications in CKD stage 3–5 D[a]
β-Blocker	Atenolol	0.5–1 mg/kg/day up to 100 mg daily	If GFR 15–35 mL/min, do not exceed 50 mg daily (reduction to 50% of usual dose); if GFR <15 mL/min, do not exceed 25 mg daily (reduction to 25% of usual dose). 50% removed by dialysis; consider dosing after HD session
	Metoprolol	Immediate release: 1–2 mg/kg/day BID up to 6 mg/kg/day; maximum 200 mg daily Extended release: 1 mg/kg/day up to 2 mg/kg/day; maximum 200 mg daily	No adjustment needed; not removed by dialysis
	Propranolol	1 mg/kg/day TID-QID up to 8 mg/kg/day; maximum 640 mg daily	No adjustment recommended but can accumulate in kidney impairment; not removed by dialysis
Calcium channel blockers	Amlodipine	0.06 mg/kg/day up to 0.6 mg/kg/day; maximum 10 mg daily	No adjustment needed; not removed by dialysis
	Diltiazem	1.5–2 mg/kg/day up to 6 mg/kg/day; maximum 360 mg daily	No adjustment needed; not removed by dialysis
	Felodipine	2.5–10 mg/day; maximum 10 mg daily	No adjustment needed; not removed by dialysis
	Isradipine	0.05–0.15 mg/kg/dose TID/QID up to 0.8 mg/kg/day; maximum 20 mg daily	No adjustment needed; not removed by dialysis
	Extended-release nifedipine	0.25–0.5 mg/kg/day up to 3 mg/kg/day; maximum 120 mg daily	No adjustment needed; not removed by dialysis
Central α-agonist	Clonidine	5–20 μg/kg/day BID up to 15 μg/kg/day; maximum 0.9 mg daily	No known adjustments; 5% removed on HD
Peripheral α-blockers	Prazosin	0.05–0.1 mg/kg/day TID up to 0.5 mg/kg/day; maximum 20 mg daily	No known adjustments; not removed by dialysis
	Doxazosin	1 mg QD up to 4 mg daily; maximum adult dose is 16 mg daily	No known adjustments; not removed by dialysis
	Terazosin	1 mg QD up to 20 mg daily	No known adjustments; 10% removed on HD
Vasodilators	Hydralazine	0.25 mg/kg/dose TID up to 7.5 mg/kg/day; maximum 200 mg daily	No known adjustments; 25–40% removed by dialysis. Consider dosing after HD session
	Minoxidil	0.1–0.2 mg/kg/day QD-BID up to 1 mg/kg/day; maximum 50 mg daily	No known adjustments
Diuretics	Chlorthalidone	0.3 mg/kg/day up to 2 mg/kg/day; maximum 50 mg daily	Avoid in oligoanuria or with GFR <10 mL/min

Table 50.4 (continued)

Class	Drug	Usual pediatric dosing range[a]	Dosing modifications in CKD stage 3–5 D[a]
	Furosemide	0.5–2 mg/kg/dose QD-QID up to 6 mg/kg/day; maximum 600 mg daily	Avoid in oligoanuria; not removed by dialysis
	Hydroclorothiazide	0.5–1 mg/kg/day; maximum 25 mg daily	Not effective in GFR < 30

BID twice daily, *GFR* glomerular filtration rate, *HD* hemodialysis, *kg* kilogram, *μg* microgram, *mg* milligram, *PD* peritoneal dialysis, *QD* once daily, *QID* four times daily, *TID* three times daily

Table 50.5 Advantages of specific antihypertensive combination therapies

Combination	Advantages
ACEi or ARB + diuretic	Enhanced antihypertensive effect of RAAS blockade by diuretic-mediated salt loss
	Decreased risk of RAAS-mediated hyperkalemia by diuretic-mediated potassium excretion
	Reduction of diuretic-mediated increase in plasma renin activity by RAAS blockade
ACEi or ARB + CCB	Attenuated CCB-mediated activation of the sympathetic nervous system by RAAS blockade
	Reduced risk of (dose dependent) CCB-mediated peripheral edema by RAAS blockade
ACEi + ARB[a]	Enhanced RAAS blockade (caveat: increased risk of hyperkalemia, increase in serum creatinine)
	Additional blockade of ACEi-independent pathways in the RAAS → reduced risk of aldosterone rebound phenomenon

ACEi angiotensin converting enzyme inhibitor, *ARB* angiotensin receptor blocker, *CCB* calcium channel blocker, *RAAS* renin-angiotensin-aldosterone system

[a] Combination therapy of ACE + ARB not recommended

CKD. Metoprolol and atenolol were the first antihypertensive drugs used to demonstrate nephroprotective effects by good BP control [135]. Newer β-blockers, such as carvedilol, exert a significantly greater antiproteinuric effect than atenolol at comparable BP reduction [136, 137]. Dosing recommendations for antihypertensive drugs in CKD are given in Table 50.5.

Combination of different drug classes might not only exert additive effects on BP control, but also might counterbalance or increase side effects of antihypertensive agents. Therefore, some antihypertensive drug combinations seem to be more favorable than others (Table 50.6).

In patients with advanced kidney impairment, refractory, multi-drug resistant hypertension usually indicates fluid overload and is an indication to start dialysis therapy.

Because renal hypertension is characterized by the loss of the physiological nocturnal decrease in BP (nocturnal BP dipping) in the majority of patients, the ***timing of antihypertensive drug administration*** should receive additional attention. For example, bedtime dosing of antihypertensive medication may reconstitute the circadian BP rhythmicity by a more marked effect during the nighttime hours. In a recent study in adult CKD patients randomly assigned to take either all antihypertensive medications in the morning or to take at least one drug in the evening, bedtime dosing improved overall BP control, and reduced significantly the risk for cardiovascular events [138].

In addition to pharmacological treatment, ***non-pharmacological interventions*** are generally recommended in all children with renal hypertension [21, 111, 139, 140]. These life-style interventions should comprise a reduction of dietary salt intake, high consumption of fruits and vegetables ('DASH' diet), maintenance of a normal body weight, regular physical activity and refraining from smoking. However, it should

Table 50.6 Risk profile and pharmacological treatment[a] of patients with monogenic, 'low renin' hypertension

Form of monogenic hypertension	Age at onset	Cardiovascular symptoms/risks	Recommended therapy	
Apparent mineralocorticoid excess (AME)	Early childhood	Severe hypertension with extensive target organ damage; hypercalciuria, renal failure; low birthweight, failure to thrive	MRA If MRA not effective add dexamethasone K-supplementation Low sodium diet	Spironolactone 1 mg/kg/day in 1–2 doses (max dose 100 mg/day) Eplerenone (adult dosing) 50 mg/day QD or BID Dexamethasone up to 0.01 mg/kg/day
Glucocorticoid remediable aldosteronism (GRA)	Infancy/ childhood	Severe hypertension, intracranial aneurysms, cerebral hemorrhage, high associated mortality rate (>50% at age 30)	Physiologic doses of a glucocorticoid (suppression of ACTH secretion) If not effective in reducing BP, then add MRA	Hydrocortisone 10–20 mg/m^2/day Prednisolone 0.1 mg/kg/day Dexamethasone up to 0.01 mg/kg/day Spironolactone 1 mg/kg/day in 1–2 doses (max dose 100 mg/day) Eplerenone (adult dosing) 50 mg/day QD or BID
Congenital adrenal hyperplasia (CAH) (11βhydroxylase deficiency)	Infancy	Hypertension		Hydrocortisone 10–20 mg/m^2/day Prednisolone 0.1 mg/kg/day Dexamethasone up to 0.01 mg/kg/day
Liddle syndrome	Late childhood to adolescence	Hypertension	Direct ENaC inhibition Low sodium diet	Amiloride 0.4–0.625 mg/kg QD (max 20 mg/day) Triamterene 0.5–1 mg/kg/dose BID (max 3–5 mg/kg/day)
Gordon's syndrome	Adolescence to adulthood	Hypertension	Low dose thiazide Low sodium diet	Hydrochlorothiazide 0.5–1 mg/kg QD or BID

ACTH adrenocorticotropic hormone, *BID* twice daily, *BP* blood pressure, *ENaC* epithelial sodium channel, *mg* milligram, *MRA* mineralocorticoid receptor antagonist, *QD* once daily

[a] Recommendations represent the authors' opinions although every effort has been made to confirm by consulting appropriate references. Manufacturers' prescribing information is frequently updated and should be consulted whenever possible

be noted that in children with advanced CKD a high potassium diet might not be feasible. Also, low-salt diets may not be possible in children with renal salt wasting, as often occurs in kidney hypodysplasia.

Treatment of Hypertension in Dialysis Patients

In dialysis patients, where fluid and salt overload play a major role in the pathogenesis of hypertension, *adjustment of dry weight* and *restriction of dietary sodium intake* are the primary measures to correct an elevated BP.

Dry weight is defined as the lowest body weight at the end of a dialysis session at which a patient can remain normotensive without antihypertensive medication until the next dialysis treatment, or the lowest weight a patient can tolerate without exhibiting symptoms of hypotension [141]. However, the determination of dry weight is challenging and often has to be achieved by trial and error. In clinical practice, dry weight is assumed to have been achieved when patients develop signs of intravascular volume depletion, such as drop in BP, cramping, yawning, headache, or abdominal pain (i.e. symptoms often

associated with unpleasant and traumatizing experiences for patients). Simple but rather unprecise methods to assess dry weight include monitoring of pre- and post-dialysis weight and clinical assessment of edema, jugular vein distension and crackles on lung auscultation. Bioelectrical impedance analysis, or bioimpedance, is a method that determines the electrical resistance of the body to the flow of an electric current and is correlated with tissue water content. Bioimpedance can be applied to both HD and PD patients and can facilitate the assessment and achievement of dry weight in infants, children and adolescents on dialysis [142]. Further information on the assessment and attainment of dry weight can be found in the chapters on PD, HD and adequacy of dialysis.

To attain dry weight in HD patients, adjusting the duration of dialysis therapy and or the concentration of dialysate sodium are the main strategies to improve fluid removal. There is increasing evidence that matching dialysate sodium with the patient's pre-dialysis serum sodium concentration leads to reduction in thirst, interdialytic weight gain and hypertension [143–145].

In PD patients, optimization of water and sodium removal can be achieved by optimizing osmotic potential (dialysate dextrose concentration, dwell time) and fill volume.

Controlling dietary sodium intake facilitates achievement of dry weight [146], and is associated with decreased thirst, lower interdialytic weight gain, improved BP control, lower left ventricular mass index and decreased mortality in adults [147–149]. Fluid restriction should always be combined with reduction of sodium intake, because increased sodium intake inevitably increases thirst, leading to greater interdialytic weight gain [150]. However, restriction of sodium intake is difficult to achieve given the high sodium intake of most children: while the recommended sodium intake in hypertensive children with CKD is 1500–2300 mg daily (corresponding to 3.8–5.8 g of salt) [151], children with CKD stage 2–4 have been shown to ingest more than 3–5 g of sodium on average [152].

Antihypertensive drugs should only be prescribed if the adjustment of dry weight and sodium restriction do not result in normalization of BP. The preferable drug class in hypertensive pediatric dialysis patients is still unclear. Calcium channel blockers, beta blockers and RAAS antagonists are frequently used; however, RAAS blockade may have an increased risk for hyperkalemia and loss of residual diuresis while calcium channel blockers might complicate fluid removal during dialysis. For dose adjustments of antihypertensive drugs in dialysis patients, see Table 50.5.

Native kidney nephrectomy is typically considered the last resort in the treatment of hypertension in dialysis patients refractory to antihypertensive treatment after optimization of dry weight and salt balance [153].

Treatment of Hypertension in Transplant Patients

Hypertension in *transplant patients* usually requires pharmacological treatment similar to pre-transplant CKD. While CCBs are favorable with respect to counteracting calcineurin inhibitor-induced vasoconstriction, RAAS blockers are also safe and effective and exert antiproteinuric and potentially also renoprotective effects on kidney allograft function. In adult transplant patients, BP control was associated with improved graft survival [154]. However, whether strict BP control is superior to conventional BP control in pediatric kidney transplant patients remains to be shown.

Like in non-transplant CKD patients, non-pharmacological lifestyle measures, including weight reduction in overweight children, a healthy, low-salt, low-sugar, high-fibre diet (DASH-Diet) and physical activity, should be encouraged.

In patients with stable graft function, steroid withdrawal has been shown not only to improve BP, but also to restore nocturnal BP dipping [155]. Treatment options in hypertensive kidney disease are summarized in Fig. 50.2.

Treatment of Patients with Monogenic 'Low-Renin' Hypertension

Because BP elevation in these forms of hypertension is related to functional disturbances of renal tubular sodium handling and to fluid expansion, specific therapies targeting the underlying disease should be prescribed as initial treatment [98–100].

In patients with apparent mineralocorticoid excess (AME), hypertension ameliorates with MRA

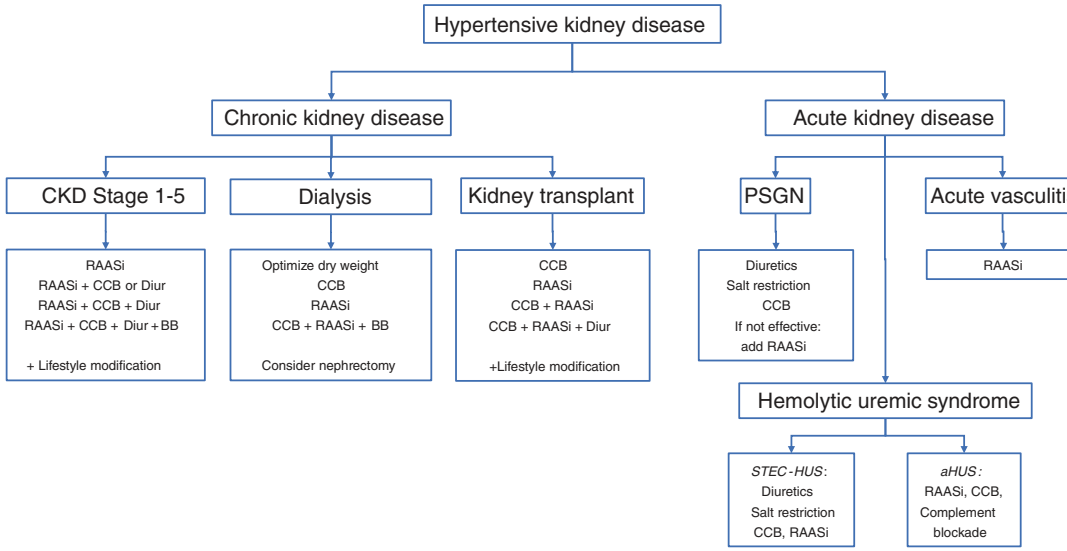

Fig. 50.2 Suggested treatment in hypertensive kidney disease and possible treatment escalation scheme. *CCB* calcium channel blocker, *RAASi* renin angiotensin aldosterone system inhibitor (i.e. ACE inhibitor or angiotensin type I inhibitor), *PSGN* poststreptococcal glomerulonephritis, *aHUS* atypical hemolytic uremic syndrome, *CKD* chronic kidney disease

treatment (spironolactone, eplerenone), along with potential potassium supplements and dietary sodium restriction. Persistently elevated cortisol levels may require glucocorticoid treatment to reduce ACTH-stimulated cortisol production and mineralocorticoid receptor activation.

In patients with *congenital adrenal hyperplasia (CAH type IV or type V)*, treatment consists of glucocorticoids to decrease ACTH secretion. Spironolactone, amiloride, and calcium channel blockers can additionally improve hypertension.

Hypertension in patients with *glucocorticoid remediable aldosteronism* (GRA) responds to treatment with glucocorticoids. If this is not effective to control BP, MRAs, and amiloride or triamterene can be added.

In patients with *Liddle's syndrome*, amiloride or triamterene, targeting the ENaC, are effective in lowering BP. MRAs are not effective in Liddle's syndrome because the ENaC activity is independent of mineralocorticoid regulation.

In Gordon's syndrome, hypertension should be treated with low-dose thiazide, which directly inhibits the underlying NCC overactivity.

Antihypertensive agents are usually of limited efficacy in monogenic forms of hypertension and are not the first-line therapy. For further information on recommended treatment of monogenic hypertension, see Table 50.4.

Monitoring of Patients with Renal Hypertension

Patients with CKD and renoparenchymal hypertension require long-term antihypertensive therapy and life-long monitoring of BP. In patients who recovered from acute kidney injury, BP should be monitored regularly since arterial hypertension and/or proteinuria may manifest years later in patients with subclinical residual kidney damage (e.g., after hemolytic uremic syndrome).

BP should be monitored at each medical appointment in all kidney patients. For further evaluation of BP control and to rule out masked or isolated nocturnal hypertension, conditions that are highly prevalent in CKD, *24-h ABPM* is recommended at least once a year [140]. In patients with insufficiently controlled hyperten-

sion at high risk for hypertensive end-organ damage, evaluation should be repeated at even shorter time intervals. Regular *home BP measurements* are recommended for monitoring of BP between outpatient appointments.

Echocardiographic examinations should be performed once yearly for timely diagnosis of left ventricular hypertrophy. If left ventricular hypertrophy is already present, echocardiographic follow-up should be performed every 3–6 months. Additional information on BP monitoring is given in Chap. 49.

Conclusions

Hypertension is a common condition in children with all stages of CKD and contributes to kidney disease progression by a variety of mechanisms, among which the RAAS plays a central role. Thus, RAAS antagonists are the drug class of first choice; other classes of antihypertensive agents should be added as needed until BP is controlled. In pediatric CKD patients, strict BP control is crucial to the preservation of kidney function and cardiovascular health. ABPM-guided treatment to achieve circadian BP control below the 50th to 75th BP percentile for age is the best currently known strategy to achieve maximal nephroprotection.

Part XI

Acute Kidney Injury and Neonatal Nephrology

51 Acute Kidney Injury: Pathophysiology, Diagnosis and Prevention

Prasad Devarajan

Introduction

Acute kidney injury (AKI) has been traditionally defined as an abrupt loss of kidney function leading to a rapid decline in glomerular filtration rate (GFR), reduction in urine output, accumulation of waste products such as blood urea nitrogen (BUN) and creatinine, and dysregulation of extracellular volume and electrolyte homeostasis. The term AKI has largely replaced acute renal failure (ARF) since the latter designation over-emphasizes the discrete event of a failed kidney. We now recognize that AKI embodies both the continuum of renal dysfunction that characterizes the clinical spectrum, as well as the diverse molecular, biochemical, and structural injuries to the nephron that occur well before the decline in function. Hence, AKI includes both structural injury and functional impairment. AKI is an increasingly common problem afflicting all ages, occurring in 10–30% of non-critically ill hospitalized children and >30% of children in critical care units. AKI is the leading reason to seek in-patient nephrology consultation and associated with serious short-term and long-term consequences, and therapeutic options are unsatisfactory. The etiology of AKI varies widely according to age, geographical region, and clinical setting [1–7]. Functional AKI induced by dehydration is usually reversible with early fluid therapy. However, the prognosis for patients with structural AKI in the intensive care setting remains guarded. Clinicians now recognize that critically ill patients are dying "of" AKI, and not just simply "with" AKI. Fortunately, the cellular and molecular tools of modern science are providing novel insights into the pathogenetic mechanisms of AKI. Newly discovered pathways are yielding early non-invasive biomarkers for the prediction of AKI and its consequences, as well as innovative strategies for the pro-active treatment and prevention of AKI.

Definitions, Staging, Risk Stratification

Traditionally, AKI has been defined as a rapid decrease in GFR, manifested by an elevated serum creatinine (or a rise from baseline serum creatinine), and/or a reduction in urine output. Based on these criteria, more than 35 different definitions of AKI have plagued the literature, resulting in a wide range of quoted incidence rates, risk factors, and outcomes in the pediatric literature [8]. Essential advances in the field have resulted from consensus AKI definitions, initially in the form of the RIFLE criteria (Risk, Injury, Failure, Loss and End-Stage Kidney Disease) in 2004 with pediatric modifications (pRIFLE) in

2007 [9]. The pRIFLE classification of AKI includes three graded levels of injury (*R*isk, *I*njury, *F*ailure) based upon the severity of reduction in estimated GFR or urine output, as well as two outcome measures (*L*oss of kidney function i.e., persistent failure for >4 weeks, and *E*nd-stage kidney disease i.e., persistent failure for >3 months). Another refinement was the addition of a 0.3 mg/dL serum creatinine rise in less than 48 h, as also embodied in the Acute Kidney Injury Network (AKIN) criteria [10], since studies have shown independent associations with poor outcomes at this creatinine threshold [8]. However, a systematic review of 12 pediatric studies that employed the RIFLE or pRIFLE classification showed continued wide variations in the relationship between RIFLE class and measures of morbidity and mortality [9]. More recently, the above definitions have been harmonized by the Kidney Disease Improving Global Outcomes (KDIGO) AKI Consensus Conference [11, 12] into a single definition of AKI:

- Increase in serum creatinine by ≥0.3 mg/dL [≥26.5 μmol/L] within 48 h, OR
- Increase in serum creatinine to ≥1.5 times baseline within the prior 7 days, OR
- Urine volume ≤0.5 mL/kg/h for 6 h

The KDIGO staging of AKI is shown in Table 51.1. Both the definition and staging include a 0.3 mg/dL serum creatinine increase criterion to specifically be applicable to pediatric AKI. The staging also allows for a child with eGFR <35 mL/min/1.73 m^2 to be included in Stage 3, in contrast with the adult criterion of ≥4 mg/dL serum creatinine (which would be unusual in infants and young children). The KDIGO AKI definition has now been extensively validated in both children and adults, and is therefore currently recommended to guide clinical care, and as a standardized inclusion and outcome measure in AKI studies. A neonatal modified KDIGO definition has recently been proposed with slight modifications to the KDIGO criteria, and is the recommended definition for clinical and epidemiological studies in neonates [1]. It is likely that validation and widespread clinical integration of the novel AKI biomarkers discussed later in this chapter will further improve our ability to define and stage AKI.

Table 51.1 The Kidney Disease Improving Global Outcomes (KDIGO) AKI criteria (Adapted from Ref. [11])

Stage	Serum creatinine	Urine output
1	1.5–1.9 times baseline, OR ≥0.3 mg/dL (≥26.5 μmol/L) increase	<0.5 mL/kg/h for 6–12 h
2	1.0–2.9 times baseline	<0.5 mL/kg/h for ≥12 h
3	3.0 times baseline, OR SCr ≥4.0 mg/dL (≥353.6 μmol/L), OR Initiation of renal replacement therapy, OR eGFR <35 mL/min per 1.73 m^2 (<18 years)	<0.3 mL/kg/h for ≥24 h, OR Anuria for ≥12 h

Some limitations with the KDIGO AKI definition and staging are well recognized, with respect to both the eGFR and the urine output criteria. First, the eGFR measurement is dependent on serum creatinine, which is imprecise for the clinical diagnosis of AKI (as detailed in section "Clinical Presentation"). Second, the definitions outlined above call for an increase in serum creatinine to ≥1.5 times baseline, and the baseline serum creatinine is often unknown. In previously healthy children, it is generally recommended to employ a presumed baseline of 120 mL/min/1.73 m^2 [13]. In children with available height measurements, the estimated baseline serum creatinine may be imputed by using currently proposed eGFR equations for children [14]. Alternatively, published normative values for serum creatinine based on age and gender can be used. Imputed age- and gender-based serum creatinine norms have been applied to determine baseline serum creatinine and the diagnosis of pediatric AKI in both the hospitalized [15] and the community settings [16]. Third, although a time-dependent reduction in urine output is an important component of AKI diagnosis, most of the published literature is based solely on serum creatinine changes since it is typically more commonly measured and more easily extractable from electronic health records (EHRs). Accurate urine output determination requires an indwell-

ing urinary catheter, which is usually restricted to the critical care setting. In addition, urine output is confounded by hydration status and the clinical use of fluids and diuretics. Finally, the majority of nephrotoxic AKI is non-oliguric. Despite these limitations, recent studies have illustrated that degree of oliguria is strongly associated with poor outcomes in pediatric AKI, and that exclusion of urine output in the definition results in underdiagnosis of AKI, especially in the critical care setting [17, 18].

A new criterion for pediatric AKI was reported, based on a change in reference value of serum creatinine [19]. This study defined pediatric AKI according to pediatric reference change value optimized for AKI in hospitalized children (pROCK) as creatinine increase beyond reference change value of serum creatinine, estimated as the greater of 20 μmol/L or 30% of the initial creatinine level. AKI incidence was lower using the pROCK criteria when compared with the pRIFLE and KDIGO definitions (5.3% versus 15.2% and 10.2%, respectively). In a subsequent study of critically ill children, the pROCK criteria outperformed KDIGO in predicting mortality [20]. However, at the present time, the use of pROCK criteria over the more extensively studied and validated KDIGO criteria is not widely recommended.

The duration of an AKI episode can be used to further refine the diagnosis. For example, transient or reversible AKI (lasting <48 h) portends an improved prognosis when compared to sustained AKI (typically of 2–7 days duration). A new definition of acute kidney disease (AKD) has been proposed for AKI that lasts beyond 7 days and up to 3 months (beyond which the condition is labelled as chronic kidney disease [CKD]). AKD represents a complex syndrome where recurrent bouts of acute injury interact with ongoing regeneration and repair processes. A recent consensus on the evolving definition, management strategies, and research priorities in AKD has been published [21]. AKD is now defined by abnormalities of kidney function and/or structure with implications for health and with a duration of ≤3 months. AKD may include AKI, but also includes abnormalities in kidney function that are not as severe as AKI or that develop over a period of >7 days. The cause(s) of and mechanisms underlying AKD should be actively sought and managed to prevent progression to CKD [21].

In the critical care setting, a simple bedside risk stratification system for AKI has been proposed, which can be incorporated into the real-time EHR for automated alerts. Termed the renal angina index (RAI), it is a composite of known clinical risk factors, including vasopressor use, invasive mechanical ventilation, percent fluid overload, estimated creatinine clearance, and the presence of bone marrow or solid organ transplantation. The RAI has been shown in prospective studies to improve prediction of severe AKI (KDIGO Stage 2 or 3) in critically ill children when compared to an increase in serum creatinine alone [22, 23]. Recent studies have demonstrated the ability of the RAI to predict AKI in children presenting to the emergency department [24] and in children with septic shock [25]. The RAI may be especially useful in identifying children who might benefit best from additional investigative monitoring, including novel biomarkers, and potential early intervention [26–28].

Epidemiology

The precise incidence and prevalence of pediatric AKI are not fully known. However, there is growing evidence to indicate that pediatric AKI is not only common but also rising in incidence globally. While the mounting AKI incidence rate may be attributed in part to increased awareness and better consensus definitions, it is also very likely a consequence of advancements in the non-renal care of otherwise critically ill children. The incidence varies based on the definition used, clinical setting, geographic location, available resources, and the underlying clinical risk factors, as outlined below.

Few data are available to define the incidence of pediatric AKI in the general community setting. In a diverse outpatient cohort of more than 1.5 million children who received care within

the Kaiser Permanente Northern California system from 2008 to 2016, the overall incidence of community-based KDIGO-defined pediatric AKI was about 1 per 1000 per year [29]. In contrast, the recent use of EHR systems has provided higher estimates of KDIGO-based AKI in non-critically ill hospitalized children in the 10–30% range. In a retrospective single center study from the United States that utilized EHR to identify AKI in a development and a validation cohort, the incidence of AKI in non-critically ill children was 722/2337 (31%) and 469/1474 (32%), respectively [30]. A prospective cohort study of hospitalized children from Wales used an electronic alert system to identify AKI in 77.3 cases per 1000 person-years [31]. A retrospective multicenter study from China identified AKI in the EHR of 20% among 101,836 hospitalized children [32]. A retrospective analysis from six hospitals in England revealed AKI in 11% of children using the National Health Services AKI e-alert algorithm [33]. In a single center retrospective EHR review in the United States, the incidence of AKI was 10.2% out of 8473 hospitalized children [34]. In the Kaiser Permanente cohort, the incidence of AKI in hospitalized children was 9% [29].

The incidence of AKI in critically ill children and neonates is even higher. In a recent prospective multinational study of 4683 children from 32 ICUs across North America, Europe, Asia, and Australia (AWARE), the overall incidence of AKI was 27% [35]. In a retrospective multicenter analysis of 2022 critically ill neonates from North America, Australia, and India (AWAKEN), the overall incidence of AKI was 30% [36]. This varied with gestational age, with the highest incidence (48%) noted in the 22–29-week gestational age group.

The incidence and etiology of pediatric AKI differs with geographic location and available resources. In resource-rich countries, the etiology has shifted in the past three decades to a hospital-acquired complication of other multisystem illnesses. The AKI is often multifactorial, frequently due to an underlying comorbid condition or its management, and often manifests in the context of multiorgan failure. Primary kidney diseases now account for only 7–10% of AKI in hospitalized children in high-resource settings. Thus, advances in critical care have increasingly rendered pediatric AKI a hospital-acquired disease, especially in developed countries. In contrast, in resource-limited countries, the most common causes of AKI remain in the community-acquired setting and include acute tubular necrosis (ATN) due to gastroenteritis or sepsis, and primary kidney diseases such as acute glomerulonephritis or hemolytic uremic syndrome [37]. In the Global Snapshot conducted by the ISN "*0by25*" AKI initiative, a prospective observational study of 341 children with AKI from 41 countries identified dehydration, infection, and primary kidney disease as the most common etiologies in low-income countries [38].

The primary risk factors for AKI include critical illness, comorbidities, and nephrotoxin use. The risk of AKI is greatest in critically ill children, in whom the incidence is about 30%. Major contributing factors include sepsis, multiorgan failure, hypotension, shock, congenital heart disease, nephrotoxins, and malignancy [35, 39–41]. Outcomes (including mortality and short- and long-term morbidity) in this population is directly related to AKI severity [42]. Critically ill neonates are also at high risk for AKI, in whom the incidence is also about 30% [36, 43]. Major contributing factors include very low birth weight, low gestational age, sepsis, congenital heart disease, and perinatal asphyxia [44, 45].

Nephrotoxin use is an important risk factor for pediatric AKI worldwide. Non-steroidal anti-inflammatory drugs (NSAIDs) are the most common culprits, accounting for up to 7% of AKI cases in hospitalized children. This risk is further increased in children with dehydration [46]. NSAIDs also cause sub-clinical AKI in children, as signaled by elevation of novel non-invasive biomarkers [47]. Other commonly implicated nephrotoxins include aminoglycosides, vancomycin, piperacillin-tazobactam, antiviral agents, angiotensin converting enzyme (ACE) inhibitors, and loop diuretics. Combinations amplify the risk [48, 49]. The overall risk of radiocontrast agents to cause AKI remains controversial but appears to be low in children with normal kidney function

and with the dominant current practice of using low osmolar contrast agents. In a retrospective study of hospitalized children with GFR ≥60 mL/min/1.73 m^2 who underwent contrast-enhanced CT scanning, the AKI rate was only 2.2% [50].

The global incidence of AKI is higher in pediatric populations with severe chronic illness or underlying comorbid conditions. For example, AKI incidence is high in children with congenital heart disease that requires surgical intervention [51–58], malignancies [59, 60], hematopoietic stem cell transplants [61, 62], liver transplants [63], nephrotic syndrome relapse [64], or sickle cell vaso-occlusive pain crisis [65].

The worldwide COVID-19 pandemic has now added an important new etiology and risk factor for AKI. While this is a rapidly evolving field, recent published data indicate that hospitalized children with COVID-19 infections are at high risk for developing AKI, with an incidence of 20–30% [66–69]. The incidence is even higher—up to 46%—in children with multisystem inflammatory syndrome [70]. The pathogenesis of AKI in COVID-19 infection appears to be multifactorial, including direct viral infection of podocytes and proximal tubular cells, cytokine storm, macrophage activation syndrome, endothelial dysfunction, hypercoagulability, rhabdomyolysis, and complement-mediated injury. AKI in children with COVID-19 infections is directly associated with increased morbidity and mortality, and residual renal impairment at discharge [68, 69].

Clinical Classification

Traditionally, AKI has been classified based on the anatomic location of the initial injury, as prerenal (functional response of structurally normal kidneys to hypoperfusion), intrinsic renal (involving structural damage to the renal parenchyma), or postrenal (congenital or acquired anatomic obstruction to the lower urinary tract). This classification remains convenient for understanding mechanisms as well as the approach to diagnosis and management. With the discovery and validation of novel AKI functional and structural biomarkers discussed below, the terminology is evolving to include functional, structural and even sub-clinical AKI to better depict the clinical situation and therapeutic response.

AKI may also be classified according to the clinical setting in which it occurs. Community-acquired AKI is more likely to be associated with a single insult, most commonly volume depletion, and is frequently reversible. The medical approach is often conservative, including discontinuing the insult, supportive fluid and electrolyte management, and awaiting spontaneous recovery of renal function. In contrast, hospital-acquired AKI, especially in the critical care setting, is frequently multifactorial, and often part of a more extensive multiorgan dysfunction. Management is more aggressive, with early initiation of renal replacement therapies to optimize the overall care of the patient. Recovery may be partial, and there are significant short- and long-term consequences.

AKI may also be classified according to the urine output, as being non-oliguric (urine output for greater than 6 h of >1 mL/kg/h in infants and >0.5 mL/kg/h in children), oliguric (urine output <1 mL/kg/h in infants, <0.5 mL/kg/h in children, or <400 mL/day in adults), anuric (no urine output), or polyuric (urine output >3 mL/kg/h). Measurement of urine output is especially useful in the critical care setting, since the degree of oliguria reflects the severity of the kidney injury, has important implications for fluid and electrolyte therapy, and provides prognostic information. However, even moderately severe forms of AKI due to nephrotoxins, and the majority of AKI seen in neonatal intensive care, are typically non-oliguric in nature. Furthermore, some children with AKI from ATN may present with polyuria due to a urinary concentrating defect, and polyuria is a characteristic of the recovery (diuretic) phase of AKI.

Functional AKI (Prerenal AKI, Volume-Responsive AKI)

Prerenal AKI is an appropriate functional response of structurally normal kidneys to hypoperfusion. It is the most common form of AKI encountered

globally, is often community-acquired, and accounts for 40–55% of all cases. The oliguria in this situation represents a renal mechanism for preserving intravascular volume and has colloquially been termed as "acute renal success". Prerenal AKI is often caused by true volume depletion (e.g., dehydration, bleeding, excessive intestinal or cutaneous losses), early sepsis, or other etiologies leading to effective kidney hypoperfusion (decreased cardiac output, decreased intravascular volume, decreased blood pressure, or "third-spacing"). When prerenal AKI is caused by dehydration, it is usually rapidly reversed by restoration of renal perfusion. However, it is critical to understand that prerenal AKI does not automatically imply fluid responsiveness. AKI due to sepsis or decreased blood pressure often requires the administration of vasoactive agents in addition to fluid resuscitation. In some situations leading to prerenal AKI, such as liver failure, heart failure and nephrotic syndrome, fluid restriction is a mainstay of treatment. The common causes of prerenal AKI are listed in Table 51.2.

Pathophysiology of Prerenal AKI

The kidneys normally receive 25% of the cardiac output, and any decrease in circulatory volume evokes a systemic response leading to the release of potent vasoactive agents (Fig. 51.1). These responses help maintain perfusion to other organs by normalizing circulatory volume and blood pressure, but at the potential expense of GFR. There is an intense baroreceptor-mediated activation of the sympathetic nervous system and renin-angio-

Table 51.2 Common causes of prerenal AKI

Mechanism	Etiology
Volume depletion	Dehydration, hemorrhage, diuretics, burns, shock, nephrotic syndrome, diabetes
Decreased cardiac output	Cardiac failure, arrythmias
Peripheral vasodilatation	Sepsis, anaphylaxis, anti-hypertensive agents
Renal vasoconstriction	Sepsis, non-steroidal anti-inflammatory drugs, angiotensin converting enzyme inhibitors, hepatorenal syndrome

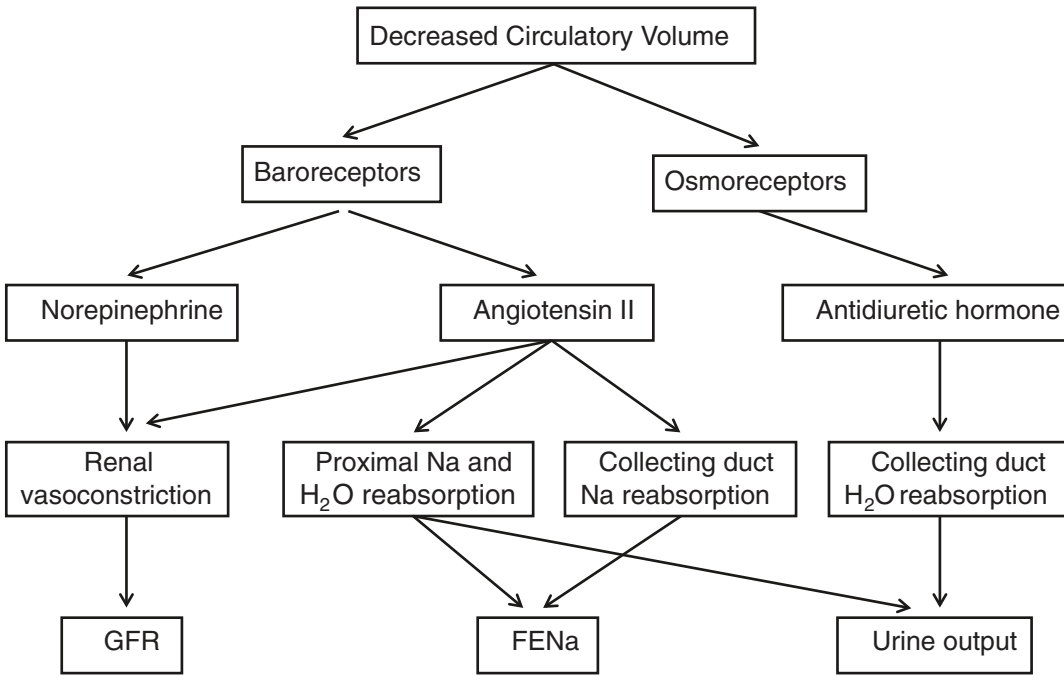

Fig. 51.1 Pathophysiology of prerenal AKI. These neurohormonal mechanisms are physiologically activated in the context of a reduction in effective circulatory volume, and result in an appropriate response by the kidney

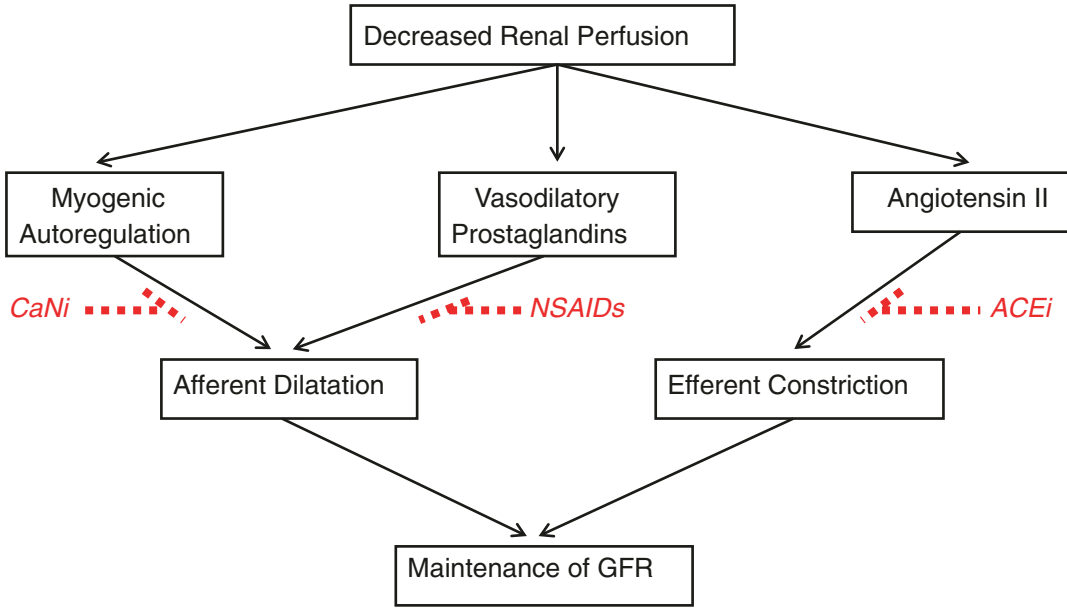

Fig. 51.2 Mechanisms that maintain GFR in prerenal AKI. Iatrogenic interference can precipitate a reduction in GFR. These include the use of calcineurin inhibitors (CaNi), non-steroidal anti-inflammatory drugs (NSAIDs), and angiotensin converting enzyme inhibitors (ACEi)

tensin axis, with resultant renal vasoconstriction mediated by angiotensin II and norepinephrine. Angiotensin II also promotes avid sodium and water reabsorption by the uninjured tubule cells, resulting in oliguria and a decreased fractional excretion of sodium that are the hallmarks of prerenal AKI. In addition, the release of anti-diuretic hormone in response to hypovolemia and a rise in extracellular osmolality results in enhanced water reabsorption by the intact collecting duct, which further contributes to the oliguria.

Concomitantly, at least three distinct intrarenal compensatory mechanisms are brought into play, which help maintain GFR in prerenal states (Fig. 51.2). Myogenic autoregulation refers to the rapid dilatation of the afferent arterioles in physiologic response to a reduction in lateral stretch following hypoperfusion. Calcineurin inhibitors such as tacrolimus and cyclosporine can interfere with the myogenic response and render the transplanted kidney more susceptible to prerenal azotemia. A more effective compensatory mechanism mediating afferent arteriolar dilatation involves the intrarenal production of vasodilatory prostaglandins [71]. Under normal physiologic conditions, the cyclooxygenase (constitutional COX-1 and inducible COX-2) enzyme systems catalyze the intrarenal production of prostaglandins that mediate afferent arteriolar dilatation. This system is dramatically upregulated by volume depletion. NSAIDs inhibit this response and can precipitate AKI, especially in the presence of decreased circulatory volume [72, 73]. For example, the use of postnatal indomethacin for patent ductus arteriosus closure in neonates results in AKI in as many as 40% of cases. When indomethacin is used to prevent preterm labor in pregnant women <32 weeks' gestation, the cumulative incidence of AKI within 15 days of life was 43.3% [74]. Another common pediatric scenario in which AKI might occur is the use of NSAIDs in febrile children with a dehydrating illness. In a recent meta-analysis, NSAIDs exposure was associated with an overall 1.6-fold rise in the odds of developing AKI in hospitalized pediatric patients [75]. A third mechanism for maintaining GFR involves the

differential effect of angiotensin II on the efferent arteriole. While angiotensin II tends to constrict both the afferent and efferent arteriole, this effect is more marked in the efferent arteriole, leading to increased hydrostatic pressure across the glomerulus and consequent preservation of GFR [76]. Interference with this compensation occurs following ACE inhibitor therapy. In clinical practice, the use of ACE inhibitors appears to increase the incidence of AKI in patients at risk, as has been documented for patients undergoing cardiac surgery, both pre-operatively [77, 78] and post-operatively [79].

It should be noted that compensatory mechanisms that maintain GFR in prerenal AKI are overwhelmed during states of prolonged reduction in renal perfusion pressure, and intrinsic AKI can ensue. Thus, prerenal and intrinsic AKI are along a continuum of renal hypoperfusion states and can co-exist in clinical situations. Furthermore, in some situations, prerenal AKI may be persistent and progressively detrimental, as exemplified by patients with heart failure and liver disease.

Structural AKI (Intrinsic AKI)

Intrinsic AKI is most frequently caused by prolonged ischemia, exogenous nephrotoxins (drugs), endogenous nephrotoxins (myoglobinuria and hemoglobinuria), or sepsis (Table 51.3). Primary kidney etiologies for AKI include vascular disease (e.g., typical and atypical hemolytic uremic syndrome, thrombotic thrombocytopenic purpura, and vasculitides), glomerular disease (e.g., acute glomerulonephritis), and tubulointerstitial disease (e.g., infections and allergic drug reactions). Intrinsic AKI can be associated pathologically with ATN. Consequently, it is common clinical practice to use the terms intrinsic AKI and ATN interchangeably. In the clinical setting, intrinsic AKI is frequently multifactorial, with concomitant ischemic, nephrotoxic, and septic components, and with overlapping pathogenetic mechanisms.

Table 51.3 Common causes of intrinsic AKI

Mechanism	Etiology
Acute tubular necrosis	Prolonged ischemia, nephrotoxins
Renal vascular diseases	Hemolytic uremic syndromes, vasculitis
Interstitial diseases	Interstitial nephritis, infections, infiltrations
Glomerulonephritis	Post-infectious, crescentic

Morphology of Intrinsic AKI

ATN is a misnomer since frank tubular cell necrosis is rarely found in human AKI. Even in patients with lethal sepsis and AKI, histopathological findings on post-mortem kidney biopsies taken immediately after death display only limited inflammation, coagulation and cell death. Biopsy findings in other forms of human AKI are also typically paradoxically mild when compared to the severe depression in GFR. There is effacement and loss of proximal tubule apical brush border, disruption of microvilli, patchy loss of tubule cells with exposure of denuded basement membranes, focal proximal tubular dilatation and distal tubular casts, and areas of cellular regeneration. Necrotic cell death is restricted to the outer medullary regions (S3 segment of the proximal tubule and medullary thick ascending limb (mTAL) of Henle's loop). On the other hand, patchy apoptotic cell death has been reported in both distal and proximal tubules, in both ischemic and nephrotoxic forms of human AKI. The relative contribution of damage to the distal tubule adjacent to the S3 segment of the proximal tubule remains controversial. An intense inflammatory response, with peritubular accumulation of leukocytes, is typical in experimental models of AKI but is less prominent in human AKI. In addition, peritubular capillaries in the outer medulla display a striking vascular congestion. The molecular, biochemical, and cellular mechanisms underlying these morphologic changes have uncovered several novel pathways in animal models. This is an extensively studied and rapidly advancing field, and only selected mechanisms that are currently providing promising therapeutic approaches [80] are outlined below.

Alterations in Hemodynamics and Microcirculation

Intrinsic AKI is characterized by persistent hemodynamic abnormalities (Fig. 51.3). Total renal blood flow is reduced to about 50% of normal due to persistent renal vasoconstriction in established AKI, a finding that resulted in the classical term of "vasomotor nephropathy". More importantly, there are regional alterations in renal blood flow, with marked congestion of the outer medullary region. Oxygen tensions are normally lowest in this region that ironically contains tubular segments with the highest energy requirements, namely the S3 segment of the proximal tubule and mTAL. The post-ischemic congestion worsens the relative hypoxia, leading to prolonged injury and necrotic cell death in these segments.

Mechanisms underlying these hemodynamic alterations relate primarily to renal microcirculatory and endothelial damage [81]. The renal microcirculation normally plays a crucial role in maintaining the kidney's functional and structural integrity. However, alterations in microcirculation and oxygenation due to endothelial damage can result in AKI regardless of systemic hemodynamic changes. At the sub-cellular level, AKI-induced mitochondrial damage is a prominent finding in endothelial injury [82]. This leads to a local imbalance of vasoactive substances, including enhanced release of the vasoconstrictor endothelin and reduced release of vasodilatory endothelium-derived nitric oxide (NO). There is substantial evidence from human AKI studies to indicate that endothelial dysfunction results in increased incidence, worsened severity, and prolonged duration of AKI. Plasma levels of endothelin, a potent vasoconstrictor, are increased (and NO levels decreased) in humans with septic AKI. However, while endothelin receptor antagonists ameliorate ischemic AKI in animals, human data are lacking. A human trial of an endothelin receptor antagonist for prevention of contrast-induced AKI resulted in a paradoxical exacerbation of nephrotoxicity. Several newer endothelin receptor blockers have recently been developed for potential use in hypertension and CKD and may hold promise in human AKI.

Similarly, carbon monoxide (CO) and carbon monoxide-releasing molecules have been shown to be protective in animal models of ischemic AKI, likely through vasodilatation and preservation of medullary blood flow as well as cytoprotective and immunomodulatory properties. However, much work is needed in translating these findings to humans, including determination of safe CO dosage, duration of treatment, and frequency of treatment for a given indication. NO, produced in renal endothelial and tubule cells from L-arginine by constitutive and induc-

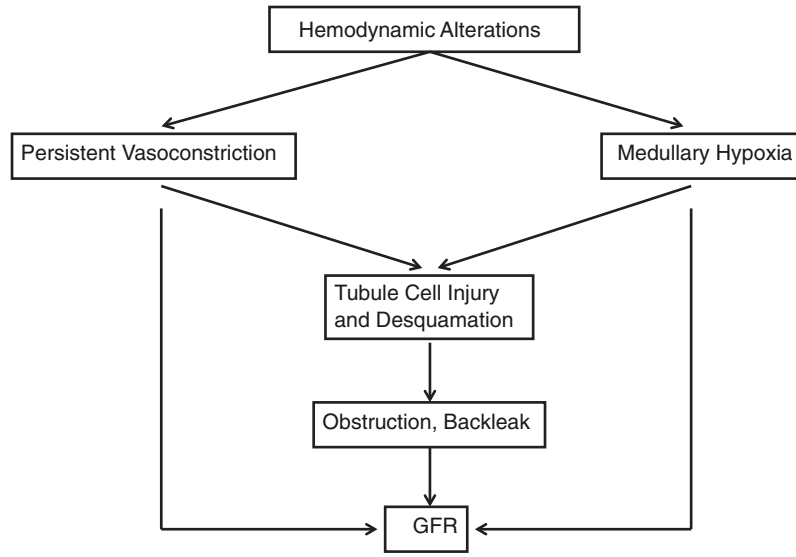

Fig. 51.3 Pathophysiology of intrinsic AKI—hemodynamic alterations and their consequences

ible NO synthetases (NOS), is also a known renal vasodilator. In a recent meta-analysis of five adult human studies, inhaled NO gas was associated with a reduced risk of AKI after cardiopulmonary bypass surgery with no adverse effects [83]. However, further studies are needed to determine the optimal dosage, timing and duration of NO administration in human AKI.

In the final analysis, it is now apparent that while hemodynamic abnormalities play an important role in the initial phases of AKI, they alone cannot fully account for the profound loss of renal function in established human AKI. Not surprisingly, several human trials of vasodilators have failed to convincingly demonstrate improvement in GFR in established AKI despite augmentation of overall renal blood flow. Persistent renal vasoconstriction may, in fact, represent an adaptive protective mechanism to minimize further cellular injury during the reperfusion period.

Alterations in Tubule Dynamics

Three well known derangements in tubular dynamics in intrinsic AKI include obstruction, back-leak, and activation of tubuloglomerular feedback. The consistent finding of proximal tubular dilatation and distal tubular casts in human AKI are indicative of obstruction to tubular fluid flow. The intraluminal casts stain strongly for Tamm-Horsfall protein, which is normally secreted by the thick ascending limb as a monomer. Conversion into a gel-like polymer is enhanced by the increased luminal sodium concentration typically encountered in the distal tubule in AKI because of impaired proximal tubule sodium reabsorption. This provides an ideal environment for cast formation along with desquamated tubule cells and brush border membranes. Cell death, most prominently noted in the highly susceptible outer medullary regions (S3 segment) of the proximal tubule, provides the sloughed cells and brush borders, with subsequent cellular cast formation and intratubular obstruction. However, it is unlikely that obstruction alone can account for the profound dysfunction in clinical AKI, since human studies using forced diuresis with furosemide or mannitol did not improve the renal recovery rate of patients with established AKI in most reported studies [84, 85]. Similarly, although movement of the glomerular filtrate back into the circulation has been shown to occur because of intratubular obstruction, this accounts for only a very minor component of the decrease in GFR in human AKI.

A role for activation of tubuloglomerular feedback has been proposed. By physiologic considerations, the increased delivery of sodium chloride to the macula densa due to abnormalities in the injured proximal tubule would be expected to induce afferent arteriolar constriction, mediated by adenosine via A1 adenosine receptor (A1AR) activation, and thereby decrease GFR. Thus, research efforts have focused on specific adenosine receptor antagonists as potential therapeutic agents, since tubuloglomerular feedback activation following ischemic injury may represent a beneficial phenomenon that limits wasteful delivery of ions and solutes to the damaged tubules, thereby reducing the demand for adenosine triphosphate (ATP)-dependent resorptive processes. The protective effects of adenosine inhibition on renal blood flow preservation may be mediated via more selective adenosine receptor activation, and the use of broad-spectrum adenosine receptor antagonists such as theophylline and caffeine is a subject of renewed clinical investigation [86–88].

Alterations in Tubule Cell Metabolism

The various cell types along the nephron display segment-specific susceptibilities to different types of injury, based on their metabolic requirements. The highly active proximal tubule cells need a steady oxygen supply to remain viable, whereas those in the thick ascending limb are relatively resistant to hypoxia. Epithelial cells in the straight segment (S3 segment) of the proximal tubule are most vulnerable to ischemic injury since they are highly dependent on oxidative phosphorylation for energy. The S1 and S2 segments are affected most by toxic nephropathy

because of their high rates of endocytosis. The mTAL is particularly vulnerable since it exists in a hypoxic precipice, with low oxygen tension but high oxygen consumption.

A profound reduction in intracellular ATP content is a hallmark of AKI that occurs very early after injury. Approximately 90% of renal intracellular ATP becomes depleted within 10 min of ischemic injury. With reperfusion, ATP levels recover in a bimodal fashion. There is an initial rapid but incomplete (up to 70% of normal) recovery phase, generated by re-phosphorylation of residual adenine nucleotides (ADP and AMP). This is followed by a second slower phase of ATP recovery, which requires resynthesis from purine nucleotide degradation products and salvage pathways. ATP depletion triggers several metabolic consequences in tubule cells. Events that provide insights into potential clinical interventions are detailed below, and their inter-relationship is illustrated in Fig. 51.4.

Alterations in tubule cell adenine nucleotide metabolism have been well documented. Oxygen deprivation leads to a rapid degradation of ATP to AMP and to hypoxanthine. These metabolites are freely diffusible, and their depletion precludes rapid re-synthesis of ATP during reperfusion. Provision of exogenous adenine nucleotides or thyroxine (which stimulates mitochondrial ATP regeneration) can ameliorate the cellular injury in animal models of ischemic AKI. However, a recent systematic review found a paucity of large, high-quality studies to inform analysis of thyroid hormone interventions for the treatment of humans with AKI. Current evidence suggests that thyroid hormone therapy may be associated with worse outcomes for patients with established AKI; therefore, its use for these patients should be avoided.

ATP depletion leads to impaired calcium sequestration within the endoplasmic reticulum, as well as diminished extrusion of cytosolic calcium into the extracellular space. The resultant increase in free intracellular calcium has been documented following AKI, but its role has remained controversial. Increased intracellular calcium could potentially lead to activation of proteases and phospholipases and cytoskeletal

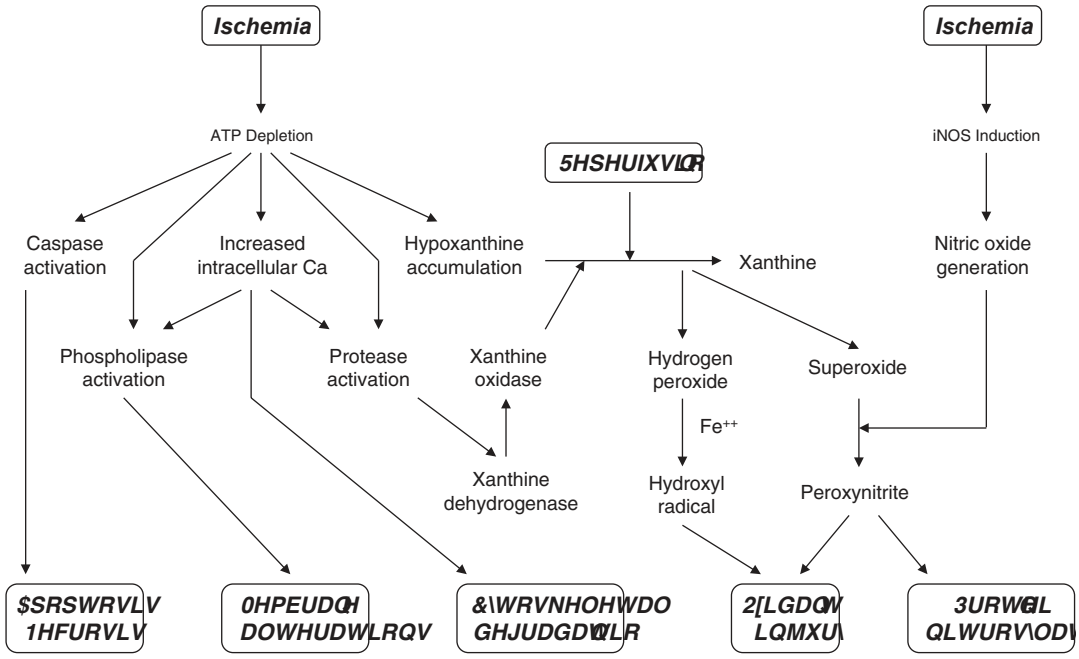

Fig. 51.4 Metabolic consequences of acute ischemia and reperfusion injury to kidney tubule cells. Inhibition of these pathways may provide novel therapeutic approaches to AKI

degradation. A previous meta-analysis suggested that calcium channel blockers may provide some protection from renal injury in the kidney transplant setting, but evidence for their efficacy in other forms of AKI is currently lacking. Any benefit from intracellular calcium blockade may be counterbalanced by the hypotension induced by these agents, with resultant worsening of AKI.

Abundant experimental, and to a lesser extent clinical data, now support a critical role for oxidative stress-related mechanisms in the early injury phase of AKI. Oxidative stress refers to metabolic disturbances, such as increased production of reactive oxygen species (ROS) that leads to the depletion of endogenous antioxidants with resultant cellular damage, dysfunction of proteins, and damage to DNA, lipids, and enzymes. Specifically, there is now substantial evidence for the role of ROS in the pathogenesis of intrinsic AKI. During reperfusion, the conversion of accumulated hypoxanthine to xanthine generates hydrogen peroxide and superoxide (Fig. 51.4). In the presence of iron, hydrogen peroxide forms the highly reactive hydroxyl radical. Concomitantly, ischemia induces NO synthase in tubule cells, and the NO generated interacts with superoxide to form peroxynitrate, which results in cell damage via oxidant injury as well as protein nitrosylation. ROS can cause renal tubule cell injury by oxidation of proteins, peroxidation of lipids, damage to DNA, and induction of apoptosis and autophagy. Studies have documented a dramatic increase in oxidative stress and autophagy, and reduction in antioxidant pathways, in experimental and human AKI. Several scavengers of ROS (such as superoxide dismutase, catalase, and *N*-acetylcysteine) protect against ischemic AKI in animal models, but human studies have been inconclusive or negative, except for prevention of contrast-induced AKI.

Free iron derived from red cells or other injured cells is one of the most potent factors in the generation of ROS, and the iron scavenger deferoxamine alleviates ischemia-reperfusion injury in animal models and in human clinical trials. However, the systemic toxicity of deferoxamine (hypotension and ocular toxicity) precludes its routine clinical use in human AKI. Several other molecules are under study for iron chelation [89]. Other potential approaches to minimize the nephrotoxic effects of iron and iron-containing proteins under investigation include administration of haptoglobin to facilitate sequestration of free hemoglobin, administration of hepcidin to prevent iron export from intracellular compartments into the circulation, and pharmacologic upregulation of heme oxygenase-1 (HO1) to accelerate the catabolism of toxic free heme.

Alterations in Tubule, Endothelial, and Glomerular Cell Structure

The cell biologic response of intrinsic kidney cells to ischemic or nephrotoxic AKI is multifaceted, and includes loss of cell polarity and brush borders, cell death, de-differentiation of viable cells, proliferation, and restitution of a normal epithelium, as illustrated in Fig. 51.5. While most prominently described in tubule epithelial cells, structural alterations in the endothelial and glomerular cell cytoskeleton are also of consequence. The major mechanisms underlying this morphologic sequence of events are summarized below.

Cellular ATP depletion results in an early, rapid disruption of the apical actin cytoskeleton and redistribution of actin from the apical domain and microvilli into the cytoplasm. This results in loss of brush border membranes, which contribute to cast formation and obstruction. Intracellular actin released from damaged tubule cells appears in the urine of patients with AKI. Similar changes in endothelial cells may potentiate vascular injury.

Disruption of the apical cytoskeleton also results in loss of tight (zonula occludens) junctions and zonula adherens junctions. Reduced expression, redistribution, and abnormal aggregation of several key proteins that constitute the tight and adherens junctions have been documented after ischemic injury in cell culture, animal models, and human studies. Loss of cadherin staining in the vascular endothelium also suggests that cadherin junctions are altered during injury.

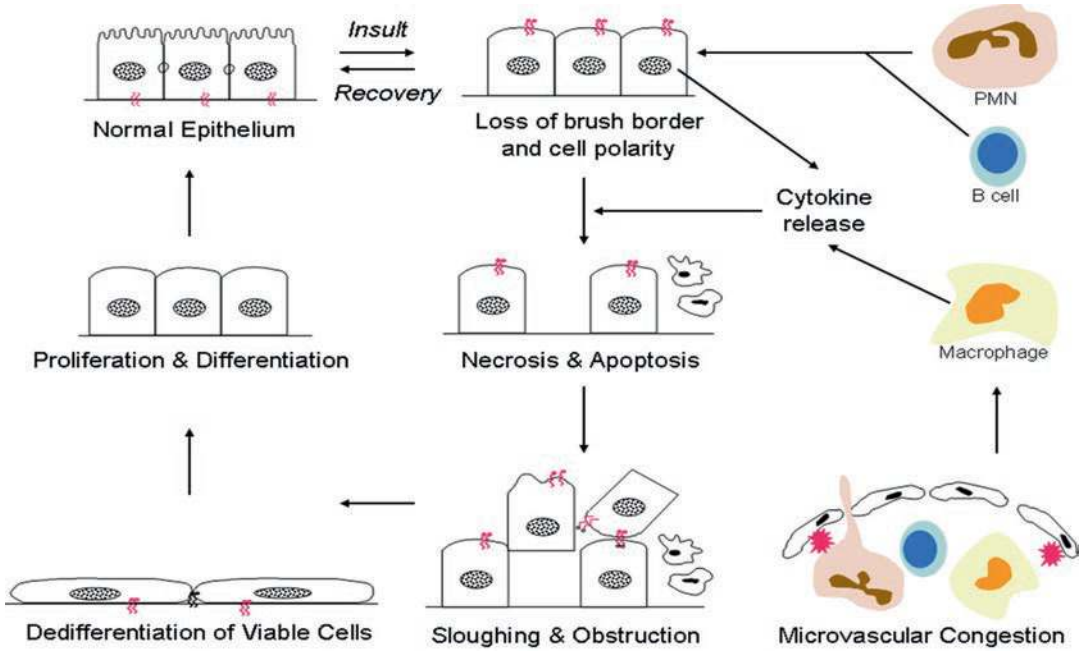

Fig. 51.5 Structural consequences of acute ischemia and reperfusion injury to kidney tubule cells. Novel therapeutic approaches in AKI have targeted prevention of cell death, inhibition of inflammation, and acceleration of the endogenous recovery process

The consequent loss of tight junction barrier function can potentially magnify the transtubular back-leak of glomerular filtrate induced by obstruction. Ischemic injury can also result in podocyte-specific molecular and cellular changes. In healthy podocytes, Neph1 (a component of the podocyte slit diaphragm) complexes with ZO-1 (an actin-related tight junction protein), to link tight junctions to the cortical actin skeleton, thereby providing a structural framework for the slit diaphragm. Slit diaphragms are an important component of the glomerular filtration barrier, and damage to slit diaphragms can lead to impaired filtration. Ischemia induces the dissociation of Neph1 from ZO-1, which results in podocyte effacement and loss of the Neph1-ZO-1 interaction. Although the interaction can be restored after reperfusion, the recovery of podocyte structure is often incomplete.

Other changes occur in the glomerulus during AKI. Podocyte foot processes coarsen during injury, and there is a decrease in heparin sulfate proteoglycan and sialic acid on the endothelial surface layer, which can lead to albuminuria and decrease GFR. Tumour necrosis factor-alpha (TNF-α) has been implicated as a mechanism mediating AKI via glomerular abnormalities. Mice deficient in TNFR1 have normal glomerular morphology and density with minimal cellular detachment, suggesting that TNF-α mediates damage to the glomerular endothelium and is a key determinant of AKI in sepsis.

Ischemic and nephrotoxic insults also result in the early disruption of at least two normally basolaterally polarized proteins, namely Na,K-ATPase and integrins. The Na,K-ATPase is normally tethered to the spectrin-based cytoskeleton at the basolateral domain via the adapter protein ankyrin, where it functions to pump intracellular sodium into the circulation. This provides the driving force for the normal reabsorption of salt and water by the proximal tubule via the apical membrane. A physiologic consequence of the loss of basolateral Na,K-ATPase is impaired proximal tubule sodium reabsorption and a consequent increase in fractional excretion of

sodium, which are diagnostic signatures of intrinsic AKI.

The β-1 integrins are normally polarized to the basal domain, where they mediate cell-substratum adhesions. Tubule cell injury leads to a redistribution of integrins to the apical membrane, with consequential detachment of viable cells from the basement membrane. This is followed by abnormal adhesion between these exfoliated cells within the tubular lumen, mediated by an interaction between apical integrin and the Arg-Gly-Asp (i.e., RGD) motif of integrin receptors. Administration of synthetic RGD compounds attenuates tubular obstruction and renal impairment in animal models of ischemic AKI, and the recent availability of orally active integrin antagonists as well as small-molecule peptidomimetics that inhibit RGD-binding integrins holds promise for clinical application in human AKI.

Alterations in Tubule Cell Death

Injured tubule epithelial cells may suffer one of several distinct cellular fates after AKI. Most cells remain viable, suggesting that they either escape injury or are only sub-lethally injured and undergo recovery. A subset of tubule cells displays patchy cell death resulting from at least five pathophysiologic mechanisms: necrosis, apoptosis, necroptosis, ferroptosis, and autophagy. Necrosis is an explosive, unregulated, chaotic process characterized by loss of membrane integrity, cytoplasmic swelling, and cellular fragmentation. Apoptosis is a quiet, regulated, orderly demise typified by cytoplasmic and nuclear shrinkage, DNA fragmentation, and breakdown of the cell into membrane-bound apoptotic bodies that are rapidly cleared by phagocytosis. Clearing dead cells and associated cellular debris is an integral part of tissue homeostasis. While diverse types of phagocytes remove various forms of dying cells during AKI, it remains unknown whether boosting removal of a specific form of dying cell would provide a benefit and which cell type should be targeted for phagocytosis-mediated therapy. Necrosis and apoptosis can coexist and are considered to present two ends of a spectrum. In AKI, the mode of cell death depends primarily on the severity of the insult and the resistance of the cell type. Necrosis occurs after more severe injury and in the more susceptible nephron segments and often is characterized by the activation of phospholipase A2, calpain, and eicosanoids. In contrast, apoptosis predominates after less severe injury, especially in the ischemia-resistant distal nephron segments. Apoptosis can be followed by "secondary necrosis," especially if the apoptotic cells are not removed rapidly.

Apoptosis is a major mechanism of early tubule cell death in contemporary clinical AKI, and considerable attention has been directed toward dissecting the molecular mechanisms involved. Several pathways, including the intrinsic (Bcl-2 family, cytochrome c, caspase 9) extrinsic (Fas, FADD, caspase 8), and regulatory (p53, NF-κB) factors, appear to be activated by ischemic and nephrotoxic AKI, as illustrated in Fig. 51.6. The extrinsic pathway functions by binding death ligands to cell-surface receptor, resulting in procaspase-8 activation, often through mediation with adaptor proteins such as Fas-associated protein with death domain (FADD) or TNF receptor 1-associated death domain. The role of the Fas-FADD pathway in animal models was suggested by demonstration of upregulation of these proteins in apoptotic tubule cells after ischemia and the functional protection afforded by siRNA duplexes targeting the Fas gene. However, convincing human data are lacking. On the other hand, growing evidence implicates an imbalance between the pro-apoptotic (Bax, Bid) and anti-apoptotic (Bcl-2, Bcl-xL) members of the Bcl-2 family in animals and humans so affected. Disequilibrium between Bac/Bcl-2 and Bad/Bid can lead to the formation of mitochondrial pores, which alters cell viability. The proapoptotic transcription factor p53 is activated by HIF-1α and induced at the mRNA and protein levels, and straddles both the intrinsic and extrinsic pathways. Inhibition of p53 by pifithrin-α suppresses ischemia-induced apoptosis by inhibiting transcriptional activation of Bax and mitochondrial translocation of p53. However, pifithrin-α is an unlikely candidate for therapeu-

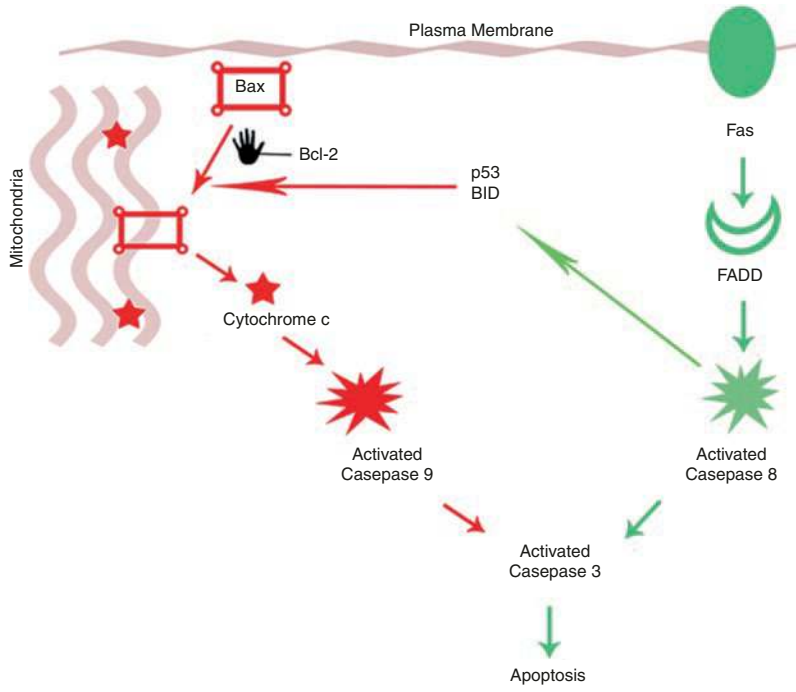

Fig. 51.6 Major tubule cell apoptotic pathways in human AKI. The extrinsic pathway (green) requires activation of Fas and TNF-R1, with subsequent signal transduction and activation of caspase 8. The intrinsic pathway (red) requires translocation of Bax to the mitochondria, thereby releasing cytochrome c and activation of caspase 9. Crosstalk between these pathways is provided largely by the regulatory molecule p53. Inhibition of the central regulatory molecule p53 and the terminal executor caspases hold promise in human AKI

tic consideration in humans because generalized inhibition of p53-dependent apoptosis is likely to promote survival of damaged or mutation-bearing cells in other organ systems. Studies have examined the efficacy of p53 si-RNA as a potential therapeutic agent, as administration of the treatment decreased serum creatinine and tubular necrosis in animal models. Clinical trials examining the effects of p53 si-RNA in human AKI are underway. A recent promising prospective, multicenter, double-blind, randomized, controlled phase 2 trial evaluated the efficacy and safety of a single 10 mg/kg dose of the p53 si-RNA teprasiran in reducing the incidence, severity, and duration of AKI after cardiac surgery in high-risk adult patients [90]. AKI incidence was 37% for teprasiran versus 50% for placebo-treated patients. AKI severity and duration were also improved with teprasiran: 2.5% of teprasiran versus 6.7% of placebo-treated patients had grade 3 AKI; 7% teprasiran versus 13% placebo-treated patients had AKI lasting for 5 days. No safety issues were identified with teprasiran treatment. Results of larger phase 3 studies, as well as investigations in other forms of AKI, are awaited.

Inhibition of other apoptotic pathways also hold promise for clinical application in human AKI. Caspase activation is by and large the final common "execution" step in apoptosis, and cell-permeant caspase inhibitors have provided particularly attractive targets for study. Currently available caspase inhibitors have largely been investigated only in animals, provide only partial protection, and are most effective when administered before the insult. A vast plethora of other agents, including mesenchymal stem cells, curcumin, erythropoietin (EPO), *N*-acetyl cysteine, thioredoxin, TNF-α antagonists, A1 adenosine receptor agonists, peroxisome proliferator-activated receptor ligands, NGAL, and poly(ADP-ribose) polymerase inhibitors (to name a few) have all provided encouraging struc-

tural and functional protection from experimental AKI, with inhibition of apoptosis and inflammation. Some of these agents are already widely available and have been used safely in other human conditions, and additional results with their use in human AKI should be forthcoming. Challenges for the future clinical use of apoptosis inhibition in AKI include determining the best timing of therapy, optimizing the specificity of inhibitor, minimizing the extrarenal side effects, and tubule-specific targeting of the apoptosis-modulatory maneuvers. The issue of timing is especially important, since inhibiting early cell death may be beneficial but interfering with late onset apoptosis is envisioned to interfere with the removal of dead and unwanted cells.

Necroptosis refers to a programmed cell death that is characterized by caspase-independent regulated necrosis resulting in plasma membrane rupture and subsequent release of damage-associated molecular patterns (DAMPs). Like apoptosis, necroptosis may be induced by multiple extracellular and intracellular stimuli, including tumor necrosis factor (TNF) family members, Fas ligands, interferon, and oxidative stress. However, the downstream mechanisms in necroptosis are distinct, independent of caspase activation, and the resultant cell death is characterized by several necrotic features, including a lack of chromatin condensation or DNA fragmentation. Several novel therapeutic agents that inhibit necroptosis pathways have already shown efficacy in experimental studies, and human translation appears to be promising.

Ferroptosis, a distinct form of iron-dependent cell death now well described in ischemia-reperfusion injuries in organs including the kidney, is characterized primarily by intracellular iron accumulation and lipid peroxidation. Morphologically, ferroptotic cells display mitochondrial changes, including reduced volume, increased membrane density, and decreased mitochondrial cristae and rupture of the outer mitochondrial membrane. The cell nucleus becomes devoid of chromatin condensation. Eventually, the cell membranes rupture and cell death occurs. Targeted regulation of ferroptosis and its signalling pathways are achieving promising results.

The study of autophagy as another mechanism of altered cell viability in AKI has been a topic of considerable recent attention. Autophagy is a physiologic process by which intracellular damaged macromolecules and organelles are degraded and recycled for the synthesis of new cellular components. The process of autophagy involves the formation of a double-membrane structure known as an autophagosome, which first sequesters the cellular constituents and subsequently delivers them to the lysosome for degradation. This results in the recycling of degraded products for the biosynthesis of new cellular components and for meeting the energy needs of the cell. The autophagy process uses lysosomal hydrolases to degrade large intracellular heterogeneous misfolded proteins, protein aggregates, damaged macromolecules, and even entire damaged organelles. Recent progress in identifying the interplay of autophagy, apoptosis, and regulated necrosis has revealed common pathways and molecules in this crosstalk during the pathogenesis of AKI. Autophagy and its associated pathways may pose potentially unique targets for therapeutic interventions in AKI.

The mechanisms whereby most tubule cells escape cell death and either emerge unscathed or recover completely after AKI remain under active investigation. HSPs have surfaced as potential mediators of this cytoprotection. Induction of HSPs is part of a highly conserved innate cellular response that is activated swiftly and robustly after ischemic AKI. The heat shock response is particularly robust in immature kidneys and may form the basis for the common observation that subsequent AKI is less likely to develop in premature infants than adults. Maneuvers that enhance the innate HSP response have potential benefit in human AKI, but clinical evidence is lacking.

Alterations in Tubule Cell Proliferation and Differentiation

Surviving renal tubule cells possess a remarkable ability to regenerate and proliferate after AKI. Morphologically, repair is heralded by the

appearance of de-differentiated epithelial cells that express vimentin, a marker for multipotent mesenchymal cells. These cells most likely represent surviving tubule cells that have de-differentiated. In the next phase, the cells upregulate genes encoding a variety of growth factors, such as insulin-like growth factor-1 (IGF-1), hepatocyte growth factor (HGF), and fibroblast growth factor (FGF), and undergo marked proliferation. In the final phase, cells express differentiation factors, such as neural cell adhesion molecule and osteopontin, and undergo re-differentiation until the normal fully polarized epithelium is restored. Thus, during recovery, renal tubule cells recapitulate phases and processes very similar to those during normal kidney development. Emerging data suggest that no pre-existing proximal tubule stem cell population exists, but rather all differentiated proximal tubule cells possess the capacity to proliferate during repair by de-differentiation and self-duplication.

In response to acute injury, animal studies have shown that the surviving, normally quiescent proximal tubule epithelial cells rapidly de-differentiate, proliferate, and enter the S-phase of the cell cycle. Understanding the molecular mechanisms of cell cycle re-entry may provide clues towards accelerating recovery from AKI. With mild injury, these endogenous repair mechanisms can result in the return to a normal structural and functional state. However, when the repair is more severe or dysregulated, the repair process can lead to fibrosis, which can facilitate progression to CKD. Recent experimental data have redefined the role of the surviving epithelial cells in fibrosis. After severe injury, the proximal tubule cell proliferative response is altered due to cell cycle arrest at the G2/M phase, resulting in generation of profibrotic factors including cytokines, growth factors and matrix proteins. Inhibition of the identified profibrotic factors may hold promise in preventing the AKI to CKD transition. For example, HGF is renoprotective and renotrophic in animal models of AKI, because of its proliferative, antiapoptotic, and anti-inflammatory actions. The use of HGF in humans, however, has been hampered at least in part by the widespread expression of its receptor, raising the possibility of extrarenal side effects. Recent studies have explored the effects of BB3/ANG3777, a small molecule with strong HGF-like activity, which, when first administered at 24 h after renal ischemia in rats, improved survival, augmented urine output, and improved kidney function. BB3/ANG3777 is currently being tested in renal transplant patients. In the case of IGF-1, enthusiasm for its renoprotective effects has been dampened by its exacerbation of inflammation and neutrophil infiltration in the post-ischemic kidney in animals. Human trials with recombinant IGF-1 have not demonstrated a beneficial effect. New growth factors have emerged as potential therapeutic targets that may accelerate renal recovery, including epidermal growth factor and α-melanocyte stimulating hormone (α-MSH), which likely acts via direct hemodynamic effects. α-MSH is an efficacious anti-inflammatory and antiapoptotic cytokine and protects from ischemic, nephrotoxic, and septic AKI in animal models. However, α-MSH therapy was not effective in human AKI trials.

Identification of the source of multipotent mesenchymal cells involved in the regeneration and repair process has been a matter of intense contemporary research. It is now established that renal tubule cells are capable of regeneration, instead of regeneration being driven by an extrarenal progenitor population. Current literature suggests that proximal tubule cells undergo transient de-differentiation after injury and then proliferate to repopulate the tubule. However, mesenchymal stem cells (MSCs) may have important autocrine, paracrine, and growth factor-like effects on kidney regeneration. MSCs are drawn to renal tubules that produce stromal cell-derived factor 1 and remain in the injured kidney for a short period of time. They secrete various growth factors that mediate kidney repair. Administered MSCs clearly enhance recovery from ischemic AKI in animals and recently were tested in clinical settings. Modified MSCs, which were modified to be immune privileged and genetically stable, were tested as a therapy for human AKI. In a cohort of adult patients with AKI after cardiac surgery, administration of allogeneic MSCs did not decrease the time to recovery of kidney function. Endothelial progeni-

tor cells (EPCs) are bone marrow-derived precursors that promote tubular regeneration in the kidney after ischemic injury. Microvesicles from EPCs can protect the kidney from ischemic injury, likely by delivering microRNA that reprograms resident renal cells to a regenerative program. Rats treated with EPC microvesicles had a reduced number of tubular lesions, improved kidney function, reduced apoptosis, and increased tubular proliferation. Six months after ischemic injury, rats showed less fibrosis and glomerulosclerosis, suggesting that EPC vesicles have long-term beneficial renoprotective effects in experimental animals.

Alterations in the Microvasculature

The role of endothelial alterations and endothelial dysfunction in the initiation and extension of AKI has received increasing attention. Morphologically, disruption of the actin cytoskeleton and junctional complexes, like those previously described in tubule epithelial cells, have been documented in endothelial cells in experimental AKI. Consequent endothelial cell swelling, blebbing, and death, with detachment of viable cells, have been observed, and circulating endothelial cells have been demonstrated in humans with septic shock. Sites of endothelial denudation are prone to prolonged vasoconstriction, and systemic or intrarenal administration of fully differentiated endothelial cells into post-ischemic rat kidneys results in functional protection. Furthermore, ischemic injury leads to a marked upregulation of angiostatin, a well-known antiangiogenic factor that induces apoptosis of endothelial cells. Collectively, these findings provide a rationale for the use of pro-angiogenic agents that can increase the pool of or mobilize endothelial progenitor cells. These agents include bone morphogenic protein (BMP), VEGF, statins, and EPO; their putative roles in AKI are currently under investigation. In particular, statins have been shown in pre-clinical studies to ameliorate AKI development via several microvascular mechanisms, including inhibition of vascular superoxide generation and restoration of endothelial derived NO synthase activity. The role of statins in clinical AKI remains controversial. In a recent large retrospective review of adult patients undergoing open cardiac surgery, preoperative statin exposure was a protective factor against all stages of postoperative cardiac surgery associated AKI as well as stage 3 AKI (OR, 0.671, 95% CI, 0.567–0.795), after adjusting for confounding factors [91]. These findings support the need for a larger prospective randomized controlled trial of AKI in adults and children, especially since several commonly available statins are approved for use in children over 8–10 years of age.

EPO is a well-known potent stimulator of erythroid progenitor cells and is commonly used to treat anemia in both children and adults with CKD. In animal models of ischemic AKI, EPO has protective effects via amelioration of microvascular injury as well as additional anti-apoptotic and anti-inflammatory mechanisms. However, several clinical trials in adults with AKI have yielded mixed results. In a meta-analysis of controlled trials in adult patients either at high risk for AKI or following kidney transplant, no reduction of incidence of AKI and no reduction in delayed graft function or improvement in 1-year graft survival after renal transplantation could be documented. Furthermore, in a recent study of extremely low gestational age neonates, EPO did not protect from any AKI or from severe AKI [92].

AKI also leads to increased endothelial expression of a variety of adhesion molecules that promote endothelium-leukocyte interactions. These include intracellular adhesion molecule-1 (ICAM-1), P-selectin, E-selectin, B7-1, vascular adhesion molecule-1 (VCAM-1), and thrombomodulin (TM). Endothelial cells are also involved with coagulation processes via interactions with protein C and TM. Derangements in the coagulation cascade, such as alterations in tissue-type plasminogen activator and plasminogen activator inhibitor-1 in the kidney, may account for the fibrin deposits characteristically found in the renal microvasculature after ischemic injury. The pathways and mechanisms that are involved in formation of interstitial fibrosis after AKI have

been examined. Impaired endothelial proliferation and mesenchymal transition processes contribute to vascular dysfunction after AKI. In contrast with tubule epithelial cells, cells of the renal vasculature lack an efficient regenerative capacity, which results in a persistent 30–50% reduction in vascular density after ischemic injury. Vascular dropout likely promotes hypoxia and impairs hemodynamic and sodium regulatory responses in the kidney after AKI and may augment the progression of CKD. Endothelial-to-mesenchymal transition may explain the loss of renal microvessels and the deposition of interstitial fibroblasts, which are seen during ischemic AKI recovery. Numerous genes and molecules have been identified as contributing to kidney fibrosis, including platelet-derived growth factor receptor-β (PDGFR-β), metalloproteinase inhibitor 3 (encoded by the TIMP-3 gene), a disintegrin and metalloproteinase with thrombospondin motifs 1 (encoded by ADAMTS1 gene), transforming growth factor β (TGF-β), and angiotensin II (Ang II).

Alterations in the Inflammatory Response

A growing body of evidence indicates that the inflammatory response plays a major role in ischemic AKI, including particularly in COVID-19 associated AKI [93]. The major components of this response include endothelial injury, leukocyte recruitment, and production of inflammatory mediators by tubule cells. Inflammatory cascades initiated by endothelial dysfunction can be augmented by the generation of several potent mediators by the injured proximal tubule (Fig. 51.5). These include proinflammatory cytokines (TNF-α, IL-6, and IL-1β) and the chemotactic cytokines (MCP-1, IL-8, RANTES). Human studies have shown that the plasma levels of the pro-inflammatory cytokines TNF-α, IL-6 and IL-8 are elevated in AKI and predict mortality. Toll-like receptors (TLRs) represent a major component of this pro-inflammatory response. TLRs are membrane-associated glycoproteins that primarily mediate the function of innate immunity upon induction with pathogen-associated molecular patterns, with resultant production of various pro-inflammatory cytokines and chemokines via intracellular activation of signalling cascades to eliminate the infective agents. TLRs also recognize endogenous host material released during cellular injury, rendering TLRs as crucial surveillance receptors to detect cellular injury. In the kidney, TLRs are expressed primarily in proximal and distal tubule cells. Renal tubular expression of TLR2 is enhanced after ischemic AKI, and TLR2 gene silencing by knockout and antisense treatment prevents ischemia-induced renal dysfunction, neutrophil influx, tubule apoptosis, and induction of MCP-1, TNF-α, IL-6, and IL-1β. Toll-like receptor 4 (TLR4) recently was suggested as another mediator of tubule cell injury. Activation of TLR4 supports the liberation of pro-inflammatory mediators, promotes leukocyte migration and infiltration, and triggers both innate and adaptive immune systems. Mice lacking TLR4 were observed to have reduced tubular damage and fewer proinflammatory cytokines after renal injury. Several compounds have been shown to offer renoprotection via inhibition of TLR4 in experimental animals. Many of these are safe for use in humans, rendering TLR4 inhibition as a novel therapeutic approach in clinical AKI.

Morphologically, several leukocyte subtypes have been shown to aggregate in peritubular capillaries, interstitial space, and even within the tubules after ischemic AKI, and their relative roles remain under investigation. These include neutrophils, macrophages, dendritic cells, B cells and T cells. Neutrophils are the earliest to accumulate in the postischemic kidney and often are found in the peritubular capillary network of the outer medulla, where they adhere to endothelial cells and can cause capillary plugging and congestion. Neutrophils also migrate into the interstitium and increase vascular permeability which aggravates tubular injury. Neutrophil depletion or blockade of neutrophil function provides partial functional protection in some but not all animal models. Furthermore, neutrophils are not a prominent feature of ischemic AKI in humans, casting doubt on the clinical significance of neutrophil infiltration.

Macrophages are the next to accumulate in animal models, classically thought to be largely in response to upregulation of MCP-1 in tubule cells and induction of its cognate receptor CCR2 on macrophages. There is recent evidence for the role of both resident macrophages as well as activated infiltrating macrophages after experimental AKI. Tubule cell injury results in increased expression of damage-associated molecular pattern (DAMP) molecules, Toll-like receptors (TLRs), and pathogen-associated molecular patterns (PAMPs). These signals rapidly recruit neutrophils, natural killer cells, activated macrophages, and resident macrophages to the site of injury. Macrophages recognize the initial damage signals through pattern recognition receptors (PRRs), a family of receptors that recognize DAMPs and PAMPs. This results in downstream stimulation of macrophage phagocytosis, phagolysosomes maturation, antigen presentation, and production of the proinflammatory cytokine, TNFα. Resident macrophages first act to engulf cellular debris as additional bone-marrow derived macrophages and monocytes are recruited. Resident macrophages further prolong inflammation by recruiting other leukocytes to the site of injury. The initial inflammatory macrophage events are subsequently followed by modulation and then inhibition of the inflammatory response. Macrophages have two distinct phenotypes during AKI; the first phenotype contributes to injury, whereas the second promotes kidney repair. Classically activated macrophages, which predominate in early ischemic injury, produce proinflammatory cytokines (such as IL-12). Alternatively activated macrophages, also known as M2 macrophages, are believed to modulate the inflammatory response and promote tissue repair and are prevalent during the recovery and repair phase of AKI.

Dendritic cells (DCs), like macrophages, have pro- and anti-inflammatory functions and work closely with other components of the immune system to respond to kidney injury. Dendritic cells help regulate immune effector cells, and present antigenic material to T cells. Macrophages and DCs share similar functions and have functional plasticity depending on the cues they receive from the microenvironment. There is a contiguous network of DCs, which are identified by presence of the chemokine receptor CX3CR1, in the kidney interstitium and mesangium. DCs are key initiators, potentiators, and effectors in the innate renal immune system. The role of DCs in renal injury is not fully resolved, because some experimental studies suggest that depleting DCs has protective effects while other findings suggest that deleting dendritic cells worsens injury.

CD4+/CD8+ T cells have been identified in animal as well as human models of ischemic AKI and often are observed to increase the production of proinflammatory molecules, such as TNF-α and IFN-γ. T cell depletion is protective in experimental AKI. Inconsistencies exist, however, and recent data suggest that the role of T cells in ischemic AKI may be complex, with the identification of both protective (TH2 phenotype) and deleterious (TH1 phenotype) subtypes of T cells. T helper lymphocytes enhance tissue injury by recruiting neutrophils and other inflammatory cells, while regulatory T cells conversely reduce renal injury and facilitate repair. Moreover, animals deficient in both T and B cells are not protected from ischemic AKI, and depletion of peripheral CD4+ T cells fails to bestow protection from ischemic AKI.

The potential role of B cells in ischemic AKI is intriguing. Compared with wild-type animals, B cell-deficient mice are protected partially from structural and functional ischemic renal injury, despite comparable neutrophil and T cell infiltrations. Wild type serum transfer, but not B cell transfer, into B cell-deficient mice was shown to restore susceptibility to ischemic AKI, implicating a soluble serum factor as a mechanism by which B cell deficiency confers renal protection.

Recent literature has focused on the proximal tubule's role in intra-renal cross talk. Crosstalk between the proximal tubule and the thick ascending limb (TAL) of the loop of Henle recently has been revealed, with TLR4 and Tamm-Horsfall Protein (THP) suggested as likely mediators of the process. THP, also known as uromodulin, is considered a protective molecule, and inhibits proximal tubule production of proinflammatory cytokines and chemokines. Crosstalk

between the TAL and proximal tubule suppresses tubular activation of innate immunity and reduces inflammatory injury. During the early phases of AKI, THP production is significantly diminished both at the RNA and protein level, in both experimental and human studies. However, THP is significantly upregulated within 48 h of ischemia in experimental models. The absence of THP in mice resulted in more severe inflammation, increased cast formation, reduced renal function, and diffuse tubular necrosis in the outer medulla. Neutrophil infiltration also was increased in THP-knockout mice, corroborating suggestions that THP functions as an anti-inflammatory and protective molecule during ischemic injury. There is now considerable evidence for a negative association between urinary THP and the development of human AKI [94]. Experimental administration of exogenous THP after AKI mitigates subsequent injury and hastens recovery.

Activation of the complement system in AKI, with resultant amplification of the inflammatory response in the kidney, has received widespread attention in recent years. Whereas ischemia-reperfusion injury in most organs activates the complement cascade along classic pathways, studies in animals and humans have implicated the alternative pathway in AKI. However, other reports have identified a role for the mannose-binding lectin pathway after animal and human ischemic AKI. Also controversial is the identification of the final active complement component. Although earlier studies pointed to the C6b-directed formation of a membrane attack complex, recent observations have identified a predominant role for C5a in ischemic AKI. C5a is a powerful chemoattractant that recruits inflammatory cells such as neutrophils, monocytes, and T cells. The kidney is one of the few organs in which the C5a receptor is normally expressed, in proximal tubule epithelial cells as well as in interstitial macrophages. C5a receptor expression in tubule epithelial cells is upregulated markedly after ischemia-reperfusion injury and sepsis. Inhibition of C5a generation using monoclonal antibodies was found to protect against renal dysfunction induced by ischemia, and in turn to inhibit neutrophil and macrophage influx in experimental models. Pre-treatment with orally active small molecule C5a receptor antagonists substantially reduced the histologic and functional impairment induced by ischemic AKI in animal models. Small molecule antagonists for C5a receptor represent promising agents for the treatment or prevention of ischemic AKI. In addition, the anti-C5 monoclonal antibody (eculizumab) ameliorates experimental ischemic AKI and is widely used in the AKI of atypical hemolytic uremic syndrome. Persistent systemic complement activation is also a hallmark of COVID-19 related AKI in humans, and eculizumab may be beneficial.

Alterations in Gene Expression

Attempts at unraveling the molecular basis of the myriad pathways activated by AKI have been facilitated by advances in functional genomics and transcriptome profiling technologies. Several investigators have used these techniques in human and animal models of AKI to obtain expression profiles of thousands of genes. When combined with bioinformatics tools, these studies have identified novel genes with altered expression, new signal transduction pathways that are activated, and even new drug targets and biomarkers in AKI [95–99]. A few clinically relevant examples are provided here.

One of the first induced molecules to be identified in the postischemic kidney using genomic approaches was kidney injury molecule 1 (KIM-1). KIM-1 protein subsequently was demonstrated to be upregulated in the postischemic animal and human kidney tubules, predominantly on the apical membranes of proximal tubule epithelial cells, where it may play a role in renal regeneration. An ectodomain is shed into the urine, making KIM-1 a promising non-invasive urinary biomarker of ischemic human AKI.

Another example is neutrophil gelatinase-associated lipocalin (NGAL), one of the most highly induced genes in the early postischemic kidney. NGAL protein is markedly upregulated in kidney tubules very early after ischemic AKI in animals and humans and is excreted rapidly in the

urine, where it represents a sensitive novel biomarker of early ischemic injury. In the postischemic kidney tubule, NGAL protein is highly expressed in tubule cells that are undergoing proliferation, suggesting its protective or regenerative role after AKI. Exogenous administration of NGAL in experimental models before, during, or even shortly after ischemic or nephrotoxic injury provides remarkable protection at the functional and structural levels, with induction of proliferation and striking inhibition of apoptosis in tubule epithelial cells. In this context, NGAL mitigates iron-mediated toxicity by providing a reservoir for excess iron and may provide a regulated source of intracellular iron to promote regeneration and repair. Exogenously administered NGAL also markedly upregulates HO1, a proven multifunctional protective agent in experimental AKI that works by limiting iron uptake, promoting intracellular iron release, enhancing production of antioxidants such as biliverdin and carbon monoxide, and inducing the cell cycle regulatory protein p21.

Gene expression studies have shown that extracellular signal-regulated kinases (ERK1 and ERK2) are activated 24 h after injury and likely alter cytoskeletal organization and focal complex assembly. ERK 1 and 2 are localized in damaged proximal tubule cells and are activated during renal reperfusion in response to ROS and Ras signaling. ERK1 and 2 have negative downstream effects by phosphorylating proteins that induce the dissolution and restructuring of focal adhesions. Synthetic ERK inhibitors, such as U0126 (already used in humans for chemotherapy), may be relevant in clinical settings as a method that preserves cytoskeletal structure during AKI.

Data mining of gene expression profiles from 150 microarray experiments performed in 21 different models of AKI (including mouse, rat, pig, and human models) identified novel upregulated genes that have now been well characterized—including *LCN2* (*encoding lipocalin 2 or NGAL*), *KIM-1* (kidney injury molecule-1), *CCL2* (*chemokine ligand 2 or MCP-1*), *HMOX1* (*heme oxygenase*), *TNF* (tumor necrosis factor), and *CLU* (Clusterin) [100]. More recent deep sequencing studies have identified significant differences in the responses between AKI subtypes. For example, there exists a remarkable diversity of changes in the kidney genomic response to ischemic and septic injuries [101]. In addition, a comparison of ischemic and volume depletion models of AKI, often considered to be a continuum and therefore predicted to have similar gene expression response, unexpectedly showed that less than 10% of expressed genes were differentially regulated in the two models despite identical elevations in the serum creatinine [102]. Volume depletion induced the metabolic pathways and anti-inflammatory molecules. By contrast, ischemic injury activated known and novel inflammatory, coagulation, and epithelial repair pathways, including *LCN2*, *KIM-1*, *CXCL1*, and *IL-6*, all of which were totally unchanged in the volume depletion model. For added complexity, different nephron segments responded with distinct signatures to different injuries. For example, volume depletion predominately affected the inner medulla, whereas ischemic changes were noted primarily in the outer medulla. Ischemic injury induces mRNA expression of *KIM-1* specifically in the proximal tubule and, in contrast, *LCN2* specifically in the distal nephron. Hence, different insults lead to diverse responses reflecting alterations in segment-specific pathophysiology.

Dramatic recent advances in single-cell RNA sequencing (scRNA-seq) and single-nucleus sequencing can now uncover the expression level of every gene in every cell type, enabling the rapid determination of serial gene expression changes in many thousands of cells, identification of previously unknown cell populations, and even novel heterogeneity within a given cell type. For example, scRNA-seq analysis of human kidney transplant biopsies has uncovered 16 distinct cell types and novel cell states within endothelial cells as well as proinflammatory parenchymal responses in the rejecting kidney. Single nuclear approaches have detected unique cell types and cell states within the human kidney, redefined cellular heterogeneity in the proximal tubule and thick ascending limb, and identified novel genomic signatures of fibrosis. Surprising recent data has begun to challenge the dogma that the fibrotic response of the kidney to injury is a late and final common pathway. In a murine bilateral ischemia-

reperfusion AKI survival model, early kidney sections at day 1 revealed surprising significant fibrosis adjacent to damaged S3 segments [103]. Single-cell profiling of AKI in mice has also revealed early activation of profibrotic transcriptional signatures [95]. Encouraging new experimental data suggest that this early fibrotic response can be prevented. In murine AKI due to ischemia-reperfusion, intraperitoneal administration of a peptide (pUR4) that binds fibronectin and inhibits fibronectin polymerization (an early event in the fibrotic cascade) soon after injury dramatically attenuated the early fibrotic response [104]. The pUR4 peptide was devoid of any adverse effects, rendering translational application to human AKI a realistic possibility. The NIH-funded Kidney Precision Medicine Project (KPMP) is analyzing human AKI kidney biopsies based on elevations in serum creatinine and a urinary biomarker. These single cell RNA-seq and other advanced deep sequencing studies are expected to yield a detailed molecular atlas of the human kidney, and potentially identify additional new pathways for future therapies.

One of the most remarkable and consistent finding from scRNA-seq studies is the rapid induction of an embryonic phenotype in injured tubule cells [95]. Specifically in injured proximal tubule cells, there is re-expression of genes normally present only in the developing kidney (e.g., *Sox4*, *Cd24a*). This switch to the embryonic state is likely critical for regeneration of tubule cells lost during AKI. The identified candidates that accelerate repair represent new future therapies.

Large-scale genome wide association studies (GWAS) can identify potentially pathogenetic genomic sequences that are statistically enriched in AKI cases compared to controls. A recent GWAS analysis of a discovery cohort of 1400 adults with critical illness (760 with AKI) followed by a separate replication cohort of 200 AKI cases [105] have yielded two single-nucleotide polymorphisms (SNPs) involving the transcription factor interferon regulatory factor 2 (*IRF2*), and an additional two SNPs close to the transcription factor T-box 1 (*TBX1*). The identification of SNPs near IRF2 suggests a potential role for the immune system in AKI, a concept with already strong biologic plausibility. TBX1 is expressed during kidney development, and this finding supports the intriguing concept that ontogeny recapitulates phylogeny after kidney injury, whereby genetic programs involved in nephrogenesis that become dormant after birth are once again reactivated and are essential for the recovery process after injury in post-natal life. Additional GWAS studies with even larger cohorts of control and AKI subjects are under way and may yield new AKI susceptibility genes of critical biological significance.

Alterations in Metabolomics

Recent metabolomic approaches have identified dramatic differences in the response of the kidney to injuries that were previously thought to be closely related. For example, experimental models of ischemia-reperfusion injury display the rapid appearance of alanine, leucine, and glucose in the urine, with a downregulation of urinary creatinine and nicotinamide [106]. In marked contrast, hypoxic injury rapidly induces the urinary excretion of benzoate and fructose, while citrate and isothionate are suppressed [107]. The differential appearance of these metabolites in the urine may hold important clues towards etiology-specific biomarkers and therapeutic targets in humans. Additional recent metabolomic studies in a mouse model of ischemic AKI have identified a deficiency in urinary and intra-renal nicotinamide adenine dinucleotide (NAD), an essential component of energy generation via glycolysis and the Kreb's cycle [108]. In a phase I study of oral NAM supplementation (which generates NAD via a salvage pathway) in adults undergoing cardiac surgery, the rise in serum creatinine was prevented compared to placebo [108]. Additional translational studies are under way.

Unique Aspects of Septic AKI

Although sepsis is one of the most common causes of AKI, the pathogenesis remains incompletely understood. Translational analysis of sep-

tic AKI has been limited by the fact that most animal models of this condition do not faithfully mimic the human condition. Kidney biopsies from humans with septic AKI have revealed only mild, nonspecific changes that do not correlate with the profound functional changes. Histological assessment of postmortem kidneys from non-survivors of septic AKI shows mild heterogeneous tubular injury with apical vacuolization, but with an absence of tubular necrosis and only minimal apoptosis. Studies have revealed the surprising finding that unlike in ischemic or nephrotoxic AKI, humans with early septic AKI demonstrate a paradoxical increase in renal blood flow despite a reduction in GFR. Thus, early septic AKI is a hyperemic injury that contrasts with the persistent vasoconstriction characteristic of ischemic and nephrotoxic AKI. In sepsis, at the glomerular level, there is evidence for afferent arteriolar vasoconstriction, efferent arteriolar vasodilatation, and shunting of blood flow via capillaries that bypass the glomerulus, resulting in decreased GFR and oliguria.

Recent evidence shows that microcirculatory dysfunction, inflammation, and metabolic reprogramming are the three fundamental mechanisms that may play a role in the development of septic AKI. Profound heterogeneous changes in microcirculatory flow have been demonstrated, including a decrease in the capillary density, a decrease in the proportion of capillaries with continuous flow and an increase in the proportion of capillaries with intermittent and stop flow. Multiple mechanisms may lead to microcirculatory alterations, including endothelial injury, autonomic nervous system response, shedding of the glycocalyx, and activation of the coagulation cascades.

During sepsis-associated AKI, a reprioritization of energy occurs that seeks to meet metabolic vital needs to ensure survival at the expense of cell function. Functions that consume ATP are downregulated, including protein synthesis and ion transport, especially in the proximal tubular epithelial cells. In addition, experimental studies have suggested that tubular epithelial cells may reprogram their metabolism by switching to aerobic glycolysis and oxidative phosphorylation to fulfill energy requirements during sepsis. Furthermore, mitochondria enter a series of quality control processes such as mitophagy and biogenesis to preserve the mitochondrial pool to confer protection and fulfill the necessary energetic requirements. Finally, an early response to septic AKI is cell cycle arrest in tubule cells, which may represent another defense mechanism to preserve energy. Approaches to enhance these survival mechanisms hold promise in human AKI.

AKI and Distant Organ Dysfunction

Substantial experimental and clinical evidence illustrates that AKI leads to dysfunction of other organs, including lung, heart, brain, liver, and intestine via aberrant organ-organ communication. This is clinically important, since the prognosis for patients who have AKI and another organ in a state of dysfunction is especially poor, with a morality rate of 60–80%. Interruption of normal immunological balance and generation of inflammatory mediators are important in AKI-induced distant organ crosstalk. Additional mechanisms include increased endothelial injury, cellular apoptosis, and oxidative stress.

Acute lung injury is a common complication of AKI, and manifests clinically as pulmonary edema and respiratory failure needing mechanical ventilation [109]. Fluid overload from decreased urine output and impaired cardiac function is the major cause of pulmonary edema. In addition, the integrity of alveolar-capillary barrier is impaired by systemic inflammation, oxidative stress, and uremia, causing fluid accumulation in the lung. Increased inflammatory cytokines in the plasma, such as IL-6 and IL-8, have been associated with prolonged ventilator weaning times and increased mortality in AKI patients with acute lung injury.

The term cardiorenal syndrome (CRS) refers to a complex pathophysiological disorder of the heart and kidneys whereby acute or chronic dysfunction in one organ may induce acute or chronic dysfunction in the other organ. In CRS Type 3, also called acute reno-cardiac syndrome, an abrupt worsening of renal function leads to acute cardiac disorder. Cardiovascular failure occurs in

about 60% of critically ill adults and is the second most common cause of death (after sepsis). Volume overload decreases myocardial contractility and induces maladaptive myocardial remodeling. Uremic toxin accumulation leads to cardiovascular toxicity and can increase risk for myocardial ischemia by compromising coronary vasoreactivity. Metabolic acidosis also diminishes myocardial contractility. Electrolyte imbalances can trigger arrhythmias.

Liver dysfunction can be observed in critically ill AKI patients and hepatic failure increases the in-hospital mortality in AKI patients. Several clinical studies have found development of hepatic dysfunction in AKI patients leading to alterations in protein synthesis and metabolism of lipid, protein, and drugs. During AKI, there are changes not only in renal drug metabolism, but also in non-renal metabolism, which can have considerable influence on clinical outcomes due to under- or over-dosing and related toxicity problems. The mechanisms by which AKI impacts liver drug metabolism may be related to uremic toxins, inflammatory cytokines, activated leucocytes, and other neuro-humoral factors. Drug dosing needs to be especially carefully monitored in AKI patients with hepatic dysfunction.

Clinicopathologic Correlations and Therapeutic Implications

The clinical course of AKI can be divided into four phases: initiation, extension, maintenance, and recovery. Clinical recognition of these phases can be facilitated using novel biomarker panels, as described later in this chapter (Fig. 51.7). Advances in our understanding of AKI pathogenesis now allow for postulation of temporal correlations between the clinical and cell biologic alterations. The *initiation phase* is the period during which initial exposure to the ischemic insult occurs, kidney function begins to fall, and parenchymal injury is evolving but not fully entrenched. Intracellular ATP depletion is profound, sublethal injury to the tubule epithelial and endothelial cells predominates, generation of reactive oxygen molecules is initiated, and activation of inflammatory mechanisms commences. Intrarenal protective mechanisms such as induction of HSPs in tubule cells also are brought to play during the initiation phase. If the injury is alleviated at this stage, complete restitution and recovery is very likely. Interventional approaches during this phase might include vasodilators, ATP donors, antioxidants, and iron chelators (Fig. 51.7).

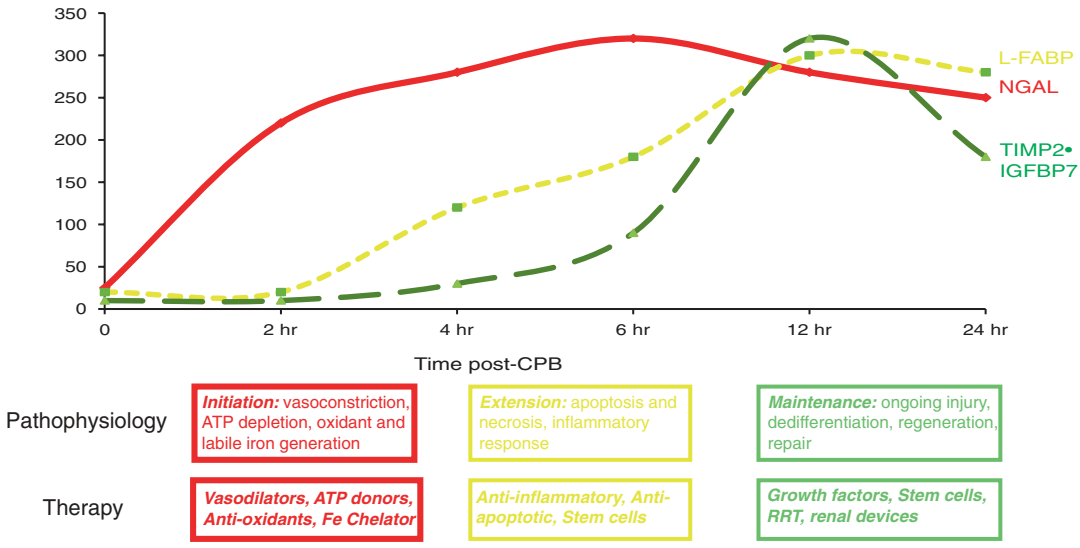

Fig. 51.7 Color coded correlations between time after the initiating insult (in this case, hours after initiation of cardiopulmonary bypass), appearance of non-invasive urinary biomarkers, phase of AKI and the underlying mechanisms, and suggested therapeutic approaches

Prolongation of the initial insult (including reperfusion after ischemia) ushers in the *extension phase*. Blood flow returns to the cortex, and tubules undergo reperfusion-dependent cell death but also commence the regeneration process. By contrast, medullary blood flow remains severely reduced, resulting in more widespread tubule cell death, desquamation, and luminal obstruction. Injured endothelial and epithelial cells amplify the raging inflammatory cascades, and the endothelial denudation potentiates the intense vasoconstriction. The GFR continues to decline. This phase probably represents the optimal window of opportunity for early diagnosis and active therapeutic intervention. Anti-inflammatory agents, anti-apoptotic measures, and stem cells are likely to be particularly efficacious during this phase.

During the *maintenance phase*, parenchymal injury is established, and the GFR is maintained at its nadir even though renal blood flow begins to normalize. Cell injury and regeneration occur simultaneously, and the duration and severity of this phase may be determined by the balance between cell survival and death. Repair of epithelial and endothelial cells appears to be critical to recovery. Measures to accelerate the endogenous regeneration processes may be effective during this phase. These include growth factors, stem cells, and kidney support therapies.

The *recovery phase* is characterized functionally by an improvement in GFR and structurally by reestablishment of tubule integrity, with fully differentiated and polarized epithelial cells. The origin of cells that replenish the damaged epithelial cells has been examined. Fate mapping studies have shown that bone marrow-derived cells do not make a significant contribution. Rather, it is the surviving tubule epithelial cells themselves that dedifferentiate and proliferate to repair the damaged tubule. The normally quiescent surviving proximal tubule cells proliferate by entering the cell cycle and activating cyclin-dependent kinases such as Cdk2 and Cdk4/6, resulting in adaptive repair. Re-expression of kidney developmental genes in injured tubule cells is likely critical for this process. However, the repair process may be incomplete or maladaptive, and AKI can progress to CKD.

Mechanisms Underlying Long-Term Sequelae of AKI

Several studies using large databases in both adults and children have now established the strong correlation between AKI and long-term sequelae, including CKD, hypertension, and end-stage kidney disease (ESKD). The cellular and molecular mechanisms that result in CKD after AKI have been intensely studied in animal models . The three primary morphologic findings include failed tubule recovery/maladaptive tubule repair, capillary rarefaction, and interstitial fibrosis.

The fate of tubule cells that do not regenerate and recover after AKI is variable. In severe AKI, tubule repair may not occur at all, leading to atrophic and fibrotic areas with disconnection of intact glomeruli from surviving tubules and subsequent decline in kidney function. Other surviving cells that undergo dedifferentiation become growth arrested in the G2 phase of the cell cycle and cannot engage proliferative pathways. Such abnormally dedifferentiated "failed-recovery" cells occur in small clusters along entire tubule segments. These senescent tubule epithelial cells acquire the senescence-associated secretory phenotype and actively secrete fibrogenic factors and pro-inflammatory cytokines, thereby creating microenvironments that promote fibrosis and inflammation. Mechanisms underlying this maladaptive repair are emerging.

Capillary rarefaction has been demonstrated after AKI in both animal models and in humans. Persistent hypoxia and resultant endothelial injury results in capillary disintegration. Failure of endothelial cells to regenerate leads to reduced capillary density. In addition, injury to pericytes, which are resident fibroblasts that normally support capillary structure and integrity, results in their detachment from capillaries and worsens capillary disintegration. The consequent persistent local tissue hypoxia drives secretion of profibrotic cytokines, inhibition of vascular repair, and endothelial-mesenchymal transition, all of which promote interstitial fibrosis. Loss of renal vasculature leads to renal VEGF deficiency, and administration of exogenous VEGF or VEGF-

derived chimeric molecules preserves capillary density and ameliorates CKD progression in animal models. As a strategy to combat tissue hypoxia, pharmacologic activation of hypoxia-inducible factor (HIF) prevented the development of fibrosis. Pharmacologic activation of Nrf2, a potent antioxidant, has also been effective in ameliorating the sequelae of AKI in animals. All three agents are available for human use and should be tested as ameliorators of the AKI to CKD transition.

The primary cellular drivers of interstitial fibrosis include activated fibroblasts, myofibroblasts derived from activated pericytes and/or endothelial-mesenchymal transition, and persistent influence of inflammatory macrophages and lymphocytes. Fibrosis typically occurs around damaged or atrophic tubules, and is not progressive *per se*. Indeed, the surrounding tubulointerstitium remains normal, and with time, fibrotic tissue shrinks as activated fibroblasts regress. However, fibrosis is progressive in the setting of repeated AKI episodes or if AKI occurs in the setting of previous CKD.

Postrenal AKI

Postrenal AKI is a result of obstruction to the outflow tract on both sides and is uncommon beyond the neonatal period. Postrenal AKI is usually reversed by relief of the obstruction but is accompanied by a very significant post-obstructive diuresis. The common causes of postrenal AKI are listed in Table 51.4. The pathophysiology and management of the obstructive nephropathy syndrome that can result from congenital anomalies are detailed in Chap. 45.

Clinical Presentation

AKI is largely asymptomatic, and its detection must begin with having a high index of suspicion and an awareness of the risk factors. AKI most commonly presents with a progressive accumulation of fluid and/or nitrogenous wastes, in a predisposed patient who has been exposed to one or more of the etiologic factors outlined in Tables 51.2, 51.3 and 51.4. Classic clinical presentations include edema, hypertension, hematuria, and oliguria. Less frequently, one encounters an increase in BUN and creatinine which is not readily explained. In all cases, the evaluation requires a complete history, physical examination, laboratory evaluation, renal imaging, and rarely a kidney biopsy. A diligent search for all drugs and medications ingested is especially important, even when another obvious cause for AKI is evident. The initial approach to a patient with known or suspected AKI should be directed towards (a) identifying the underlying cause, (b) distinguishing between pre-renal and intrinsic AKI, (c) discriminating between AKI and CKD, (d) determining the severity of AKI, and (e) considering a diagnostic fluid challenge.

Identifying the Underlying Cause

The initial history should be directed towards uncovering an obvious risk factor for AKI, such as those listed in Tables 51.2, 51.3 and 51.4. Additional relevant aspects of the AKI history and physical examination are outlined in Tables 51.5 and 51.6, respectively. These, in combination with a careful urinalysis with microscopy, will yield the etiology of AKI in most cases. A short duration of vomiting, diarrhea, or decreased oral intake associated with decreased urine output and typical physical findings of dehydration suggests prerenal volume-responsive functional AKI. Bloody diarrhea with oliguria is consistent with the hemolytic uremic syndrome. A history of pharyngitis or impetigo a few weeks prior to the onset of gross hematuria or edema suggests post-streptococcal glomerulonephritis. The presence of edema should

Table 51.4 Common causes of postrenal AKI

Acquired causes	Calculi, clots, neurogenic bladder, drugs that cause urinary retention

Table 51.5 History taking in patients with suspected AKI

• Fluid loss
– Diarrhea, vomiting
– Burns
– Surgery, shock
• Nephrotoxic agents
– Non-steroidal anti-inflammatory drugs
– Aminoglycosides
– Contrast agents
• Glomerular disease
– Streptococcal infection (Post-streptococcal glomerulonephritis)
– Bloody diarrhea (Hemolytic-uremic syndrome)
– Fever, joint complaints, rash (Systemic lupus erythematosus)
• Obstruction
– Complete anuria
– Poor urinary stream

Table 51.6 Physical signs in AKI

• Signs of intravascular volume depletion
• Signs of AKI (edema, hypertension)
• Signs of underlying renal disease
– Butterfly rash, joint swelling (Systemic lupus erythematosus)
– Purpuric rash (Henoch-Schonlein Purpura)
– Fever, macular rash (Interstitial nephritis)
– Palpably enlarged kidneys (Polycystic/multicystic kidney disease, Renal vein thrombosis)
• Signs of obstruction
– Poor urinary stream
– Palpably enlarged bladder
– Therapeutic catheterization

also prompt a search for nephrotic syndrome, cardiac failure, or liver failure, which would suggest prerenal AKI that should not be treated with fluid resuscitation. Fever, joint complaints, and a malar rash are indicative of systemic lupus erythematosus. In hospitalized patients, nephrotoxic medications or periods of hypotension are commonly associated with intrinsic AKI and should be diligently searched for.

The urinalysis is an important noninvasive test in the diagnostic evaluation. Typically, the urine in conditions that result in prerenal AKI is highly concentrated and contains little protein or blood. In contrast, proteinuria and hematuria are prominent in etiologies leading to intrinsic AKI. A heme positive urine by dipstick in the absence of RBCs in the sediment on microscopy suggests hemolysis or rhabdomyolysis. Characteristic findings on microscopic examination of the urine sediment can suggest certain diagnoses. Muddy brown granular casts and epithelial cell casts are highly suggestive of intrinsic AKI or ATN. The finding of red cell casts is diagnostic of glomerulonephritis. The concurrent findings of red cell casts, dysmorphic red cells, heavy proteinuria, or lipiduria are referred to as a "nephritic" urinary sediment. This is commonly associated with AKI due to glomerulonephritides. Pyuria with white cell and granular or waxy casts are suggestive of tubular or interstitial disease or urinary tract infection. White cells and white cell casts may also be seen in acute glomerulonephritis. The presence of renal epithelial cells, renal epithelial cell casts and granular casts are characteristic of ATN. In prospective studies of adults with AKI, when a renal epithelial cell, renal epithelial cell cast or granular cast was present, the sensitivity for discriminating no AKI versus AKI was low, but the specificity was very high at 91–95%. In another prospective study of adults with AKI, a urinary sediment scoring system created based on the number of renal tubular epithelial cells and granular casts was significantly associated with severity of AKI and with increased risk of worsening AKI. Urine microscopy is very inexpensive, readily available, noninvasive, and specific for AKI diagnosis and severity, and should therefore be a routine part of evaluating any patient who is suspected to have AKI [110].

Distinguishing Between Functional and Structural AKI

This determination is potentially important because (a) the treatment and prognosis are different, and (b) prompt identification and management of prerenal AKI can prevent the progression to intrinsic AKI. As noted above, the urinalysis with microscopy will often provide an initial differentiation between prerenal and intrinsic AKI. The further distinction is based on the principle that prerenal AKI is associated with maxi-

mal reabsorption of solutes and water by the intact proximal tubule, whereas the proximal tubule cell damage typical of intrinsic AKI results in impaired reabsorptive capacity. Urinary indices based on this principle are shown in Table 51.7. The fractional excretion of sodium (FENa) is a convenient bedside screening test for making this distinction. It is calculated from measured concentrations of sodium (Na) and creatinine (Cr) in the urine (U) and plasma (P), as follows:

$$\mathrm{FENa} = \left(\left[\mathrm{U}/\mathrm{P}\right]\mathrm{Na}\right)/\left(\left[\mathrm{U}/\mathrm{P}\right]\mathrm{Cr}\right)\times 100$$

A FENa below 1% suggests prerenal AKI, in which the reabsorption of almost all the filtered sodium represents an appropriate response to decreased perfusion. A FENa above 2% suggests intrinsic AKI with proximal tubule injury. A FENa between 1% and 2% is non-diagnostic. However, limitations to the utility of FENa should be noted. In neonates, the FENa is generally higher because of their decreased ability to reabsorb sodium resulting from immaturity of proximal tubule function. The FENa can be high following fluid resuscitation, or administration of diuretics.

The fractional excretion of urea (FEUrea) has been proposed as a more accurate determinant of prerenal AKI, especially in patients receiving diuretics and in patients with sepsis. FEUrea is typically <35% in patients with prerenal AKI, and >50% in those with established intrinsic AKI. In the setting of diuretic use, there can be an uncoupling of renal sodium handling from tubular function. FEUrea may represent an alternative diagnostic approach because urea transport is not directly linked to sodium transporters. However, recent studies have revealed that in patients with heart failure receiving intravenous loop diuretic therapy, FEUrea commonly and significantly increased above the pre-diuretic baseline [111].

Table 51.7 Urinary indices in AKI

Measurement	Prerenal AKI	Intrinsic AKI
Urine specific gravity	>1020	<1012
Urine/plasma creatinine	>40	<20
Urine Na (mEq/L)	<20	>40
FENa	<1%	>2%

Multicenter studies in the complex critically ill population have revealed limited utility of both FENa and FEUrea in distinguishing prerenal from intrinsic AKI. These studies raise fundamental questions about the pathophysiologic validity of the prerenal AKI paradigm and suggest that AKI in the critical care setting is a continuum of injury that should likely not be divided into functional (prerenal or transient) or structural (ATN or persistent) sub-types.

By the same principle of increased proximal tubule solute reabsorption, the BUN/creatinine ratio (both expressed as mg/dL) in the serum is often markedly elevated (>20) in prerenal AKI. This is because the intact proximal tubule can avidly reabsorb urea but is impermeable to creatinine. However, increases in BUN without AKI can be encountered in patients receiving steroids or total parenteral nutrition, in catabolic states, and those with gastrointestinal bleeding. In addition, a BUN/creatinine ratio >20 is a poor indicator of prerenal AKI in critically ill patients and should not be used in that setting. This is because of at least two confounding factors. One, critical illness is associated with increased protein catabolism and increased urea generation rate, and a higher severity of illness would be expected to result in a higher BUN and a greater risk for intrinsic AKI. Second, critical illness could result in decreased muscle mass, and a paradoxical reduction in serum creatinine. Indeed, animal studies have demonstrated decreased production of creatinine in sepsis, the most common cause of severe AKI. Thus, in critical illness, both the high BUN and lower serum creatinine are explicable by factors other than a prerenal state.

Distinguishing Between AKI and CKD

A kidney and bladder ultrasound are a sensitive, non-invasive modality that can differentiate not only between AKI and CKD but can also rule out a postrenal etiology. Typically, the kidneys in AKI are normal or enlarged, with increased echogenicity, whereas those in CKD are frequently small and shrunken. Other distinguishing features are shown in Table 51.8.

Determining the Severity of AKI

Estimating the baseline pre-illness serum creatinine can determine the severity of AKI and allow for classification based on the KDIGO criteria. This is best achieved when a previous serum creatinine level is available. If not, the baseline serum creatinine in children can be estimated using the Schwartz formula and a presumed baseline eGFR of 120 mL/min/1.73 m^2:

$$\text{Estimated creatinine clearance in mL/min} = 0.413^{*}\,\text{L/Pcr}$$

Where L = height (cm) and Pcr = plasma creatinine in mg/dL. The constant of 0.413 provides a good approximation of GFR in children of all ages and both genders [14]. However, it should be emphasized that this constant was derived in patients with CKD Stage 2 to 5 and has not been validated for use in AKI.

Another important index of AKI severity is the degree of fluid overload, which is especially useful in the assessment of the critically ill patient. Several recent pediatric AKI studies have demonstrated that increasing degrees of fluid overload are independently associated with mortality and adverse outcomes. Extent of fluid overload during a hospitalization period can be estimated by the following formula:

$$\%\text{Fluid overload} = \left[\text{Total fluid in}(\text{L}) - \text{Total fluid out}(\text{L})\right] / \text{Admission weight in kg} \times 100$$

The importance of assessing fluid overload was first demonstrated by the Prospective Pediatric Continuous Renal Replacement Therapy (ppCRRT) Registry Group, via analysis of its 340-patient cohort using a tripartite classification for percent fluid overload at CRRT initiation. Patients who developed >20% fluid overload at CRRT initiation had significantly higher mortality (66%) than those who had 10–20% fluid overload (43%) and those with <10% fluid overload (29%). The association between degree of fluid overload and mortality remained after adjusting for intergroup differences and severity of illness. When fluid overload was dichotomized to >20% and <20%, patients with >20% fluid overload had an adjusted mortality OR of 8.5 (95% CI, 2.8–25.7). In addition to impacting mortality, fluid overload can directly worsen kidney function and AKI due to increased renal venous pressure, interstitial edema, and abdominal compartment syndrome. Fluid overload also leads to hemodilution and a falsely reduced serum creatinine concentration, thereby delaying or masking the diagnosis and classification of AKI. Fluid overload at a threshold of 10–20% is independently associated with adverse outcomes in several critically ill pediatric populations [112].

Table 51.8 AKI versus CKD

Acute kidney injury	Chronic kidney disease
Progressive rise in BUN and Cr	Stable elevated BUN and Cr
History of AKI etiology	History of chronic hypertension
Normal growth	Stunted growth
Normal bones	Renal osteodystrophy
No broad urinary casts	Broad waxy urinary casts
Anemia usually mild	Anemia usually severe
Normal or enlarged kidneys	Small shrunken kidneys

Routine laboratory evaluation for the presence of metabolic complications can also assist in establishing AKI severity. AKI is associated with several life-threatening complications, which require diligent monitoring by the clinician. Fortunately, these complications are uncommon in patients who receive dialytic therapies. Common complications are listed in Table 51.9. Hyponatremia is usually dilutional (secondary to fluid retention and administration of hypotonic fluids). Less common causes

Table 51.9 Major complications of AKI

Metabolic	Cardiovascular	Gastrointestinal	Neurologic	Hematologic	Infectious
Hyperkalemia	Pulmonary edema	Nausea, vomiting, anorexia	Altered mental status	Anemia	Pneumonia
Metabolic Acidosis	Arrythmias	Malnutrition	Irritability	Bleeding	Sepsis
Hyponatremia	Pericarditis	Gastritis	Seizures		Infected IV sites
Hypocalcemia	Myocardial infarction	GI Bleeding	Somnolence		
Hyper-phosphatemia	Hypertension	GI ulcers	Coma		

of hyponatremia include sodium depletion (hyponatremic dehydration) and hyperglycemia (serum sodium concentration decreases by 1.6 mEq/L for every 100 mg/dL increase in serum glucose above 100 mg/dL). Hypernatremia in AKI is usually a result of excessive sodium administration (inappropriate fluid therapy or overzealous sodium bicarbonate administration). Hyperkalemia is due to the reduction in GFR, reduction in tubular secretion of potassium, increased catabolism, and metabolic acidosis (each 0.1 unit reduction in arterial pH raises serum potassium by 0.3 mEq/L). Hyperkalemia is most pronounced in patients with excessive endogenous production (rhabdomyolysis, hemolysis, and tumor lysis syndrome). A high anion gap metabolic acidosis is secondary to the impaired renal excretion of acid and the impaired reabsorption and regeneration of bicarbonate. Acidosis is most severe in shock, sepsis, or impaired respiratory compensation. Hypocalcemia is due to increased serum phosphate and impaired renal conversion of vitamin D to the active form. Hypocalcemia is most pronounced in patients with rhabdomyolysis. Metabolic acidosis increases the fraction of ionized calcium (the active form). Therefore, overzealous bicarbonate therapy can decrease the concentration of ionized calcium and precipitate symptoms of hypocalcemia, including tetany, seizures and cardiac arrhythmias. Hyperphosphatemia in AKI is primarily due to impaired renal excretion and can aggravate the hypocalcemia. During recovery from AKI, the vigorous diuretic phase may be accompanied by significant volume depletion, hypernatremia, hypokalemia and hypophosphatemia.

Considering a Diagnostic Fluid Challenge

A common clinical scenario is one where patients present with an increase in BUN and serum creatinine, with a history and physical exam findings consistent with a prerenal etiology, but the duration of the prerenal insult is unknown. Another common diagnostic dilemma occurs when a subject presents with an increase in serum creatinine, but the cause is unclear. In both these cases, a fluid challenge may be diagnostic as well as therapeutic. Typically, fluid challenges in children consist of normal saline in the dose of 10–20 mL/kg repeated once or twice until urine output improves. A reduction in BUN and serum creatinine would suggest a prerenal etiology, whereas an absence of improvement in these parameters (and/or the development of fluid overload) would confirm the diagnosis of intrinsic AKI. Fluid challenges should be avoided in children with pre-renal AKI due to volume-unresponsive states such as liver failure, heart failure and nephrotic syndrome.

Considering a Kidney Biopsy

A renal biopsy is rarely indicated in AKI but should be considered when noninvasive evaluation fails to establish a diagnosis. In pediatric AKI, it is most indicated in patients with suspected acute glomerulonephritis (to identify crescentic forms or specific vasculitides), with suspected lupus nephritis (to classify the disease

and establish the activity and chronicity), or with kidney transplant dysfunction.

Problems with Serum Creatinine Measurements in AKI

A progressive increase in serum creatinine (typically 1–2 mg/dL/day) is the hallmark of intrinsic AKI and has served as a biomarker of AKI for several decades. However, serum creatinine concentration is a flawed AKI biomarker for several reasons [113]. Serum creatinine does not differentiate the nature, type and timing of the renal insult. Changes in serum creatinine concentrations often lag changes in GFR until a steady state has been reached, which can take several days. Dialysis readily clears serum creatinine, rendering this marker less useful in the assessment for improving renal function once dialysis has begun. Even normal serum creatinine can vary widely with age, gender, diet, muscle mass, nutritional status, medications, and hydration status. In the acute setting, it is estimated that more than 50% of kidney function must be lost before the serum creatinine even begins to rise because of the concept of renal reserve. However, animal studies have shown that while AKI can be prevented and/or treated by several maneuvers, these measures must be instituted very early after the insult, well before the serum creatinine rises. The lack of early biomarkers of AKI in humans has hitherto impaired our ability to launch potentially effective therapies in a timely manner.

Serum Cystatin C as a Functional Biomarker

The use of cystatin C as an endogenous marker of kidney function in children is well established [114–119]. Cystatin C is a ubiquitous cysteine protease inhibitor protein that is produced by all nucleated cells at a constant rate, freely filtered by the glomerulus, catabolized by the proximal tubule, and does not undergo significant tubular secretion. These qualities make cystatin C a more ideal functional marker of GFR than serum creatinine. Its measurement has been standardized on a clinical laboratory platform. Serum cystatin C is not affected by gender, diet, hydration, muscle mass, and age (cystatin C levels are nearly identical in adults and children over 12 months of age). Cystatin C outperforms serum creatinine for estimation of GFR in adults and children in the steady state, but its ability to rapidly detect acute changes in GFR is still unclear. Some recent studies have demonstrated that serum cystatin C is an early predictive biomarker of AKI in children [119–121] and adults [122]. However, serum cystatin C measurements are not uniformly available, and the assay is more expensive than serum creatinine. Also, serum cystatin C levels are influenced by steroids and other immunosuppressive therapies, thyroid dysfunction, diabetes, acute inflammation, and high cell turnover. Serum cystatin C remains a functional marker, and not an early marker of structural kidney damage. Additional prospective studies are required to improve our understanding about cystatin C diagnostic cut-off values for prediction of AKI. There remain confounding variables such as method of measurement (standardized clinical laboratory measurements by nephelometry versus turbidimetry, international standardization of reagents) and different reporting equations. The creation of a calibrated reagent (IFCC) has recently allowed for standardization of cystatin C measurements across clinical laboratories and the development of universal GFR estimation equations. New CKD-EPI equations for cystatin C combined with creatinine have now become the preferred method for estimating GFR in adults. For use in children, the Full Age Spectrum (FAS) equations were developed using the assumption that the average GFR of children, adolescents, and young adults is 107.3 mL/min/1.73 m^2. The FAS cystatin C based equations performed as well as or better than the CKD-EPI equations and is currently the preferred mode of reporting eGFR in children and young adults [123].

Novel Early Biomarkers of Kidney Damage in AKI

In the clinical continuum of AKI, we are currently primarily operating in the "established AKI" stage, when the GFR is already reduced

and biomarkers of functional injury become apparent, as shown in Fig. 51.8. The genomic and proteomic tools of modern science have identified novel markers for the early stress response of the kidney, which serendipitously appear in the urine or plasma during the "subclinical AKI" phase, well before a change in serum creatinine is detected [124–126]. Thus, they detect structural kidney injury before any functional impairment may be apparent. Many are being developed and validated as early non-invasive structural damage biomarkers for the prediction of AKI and its clinical outcomes in humans. This is a rapidly evolving and expanding field, and the current status of only the most promising examples is summarized in Table 51.10.

The most widely studied and validated early biomarker of AKI in children is neutrophil gelatinase-associated lipocalin (NGAL) [124]. In a prospective study of 71 children undergoing cardiopulmonary bypass, levels of NGAL in the urine and plasma were significantly elevated within 2 h of bypass in those who subsequently developed AKI (defined as a 50% increase in serum creatinine) 1–3 days after surgery [51]. A subsequent prospective study of 374 infants and children undergoing cardiopulmonary bypass confirmed these findings, and additionally established cut-off thresholds as well as a strong association between early NGAL measurements and adverse clinical outcomes, including length of hospital stay and the duration and severity of AKI [54]. A prospective multicenter study of 311 children undergoing cardiac surgery has confirmed the early rise of plasma and urine NGAL concentrations (within 6 h after surgery) in subjects who developed an increase in serum creatinine 2 days later [127]. Early NGAL concentrations were also shown to be associated with longer hospital and ICU stays, and with longer duration of mechanical ventilation. Studies in the heterogeneous pediatric intensive care and emergency department settings have also demonstrated the ability of early NGAL measurements to predict subsequent AKI and its severity [128–130]. Furthermore, urine NGAL levels effectively discriminate between pre-renal AKI and intrinsic AKI [131, 132]. In many reported studies, the addition of NGAL significantly improved the risk prediction for AKI over clinical models alone. Since the widespread

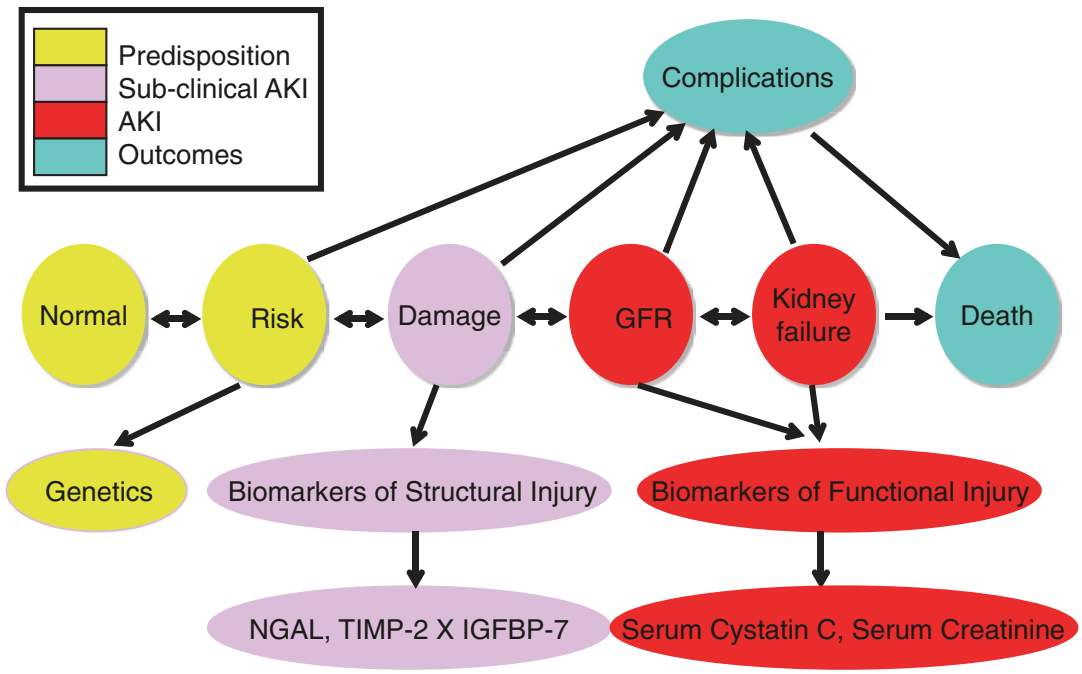

Fig. 51.8 Clinical continuum of AKI, showing the color coded correlations between phases of AKI, and the currently available laboratory methods for their detection

Table 51.10 Novel urinary biomarkers for the prediction of AKI and its outcomes

Biomarker	Source	Function	Cardiac surgery	Kidney transplant	ICU/ED
NGAL	Distal tubule and collecting duct	Regulates iron trafficking, promotes tubule cell survival	2 h post CPB 2 days pre-AKI Predicts AKI severity, dialysis, and death	6 h post-transplant 2–3 days pre DGF Predicts long-term graft loss	On admission 1–2 days pre-AKI Predicts AKI severity, dialysis, and death
IL-18	Proximal tubule	Promotes tubule cell apoptosis and necrosis	6 h post CPB 2 days pre-AKI Predicts AKI severity, dialysis, and death	6 h post-transplant 2–3 days pre DGF Predicts long-term graft loss	On admission 1–2 days pre-AKI Predicts AKI severity, dialysis, and death
L-FABP	Proximal tubule	Antioxidant, suppresses tubule-interstitial damage	6 h post CPB 2 days pre-AKI Not tested for outcomes	Fresh donor urine pre-transplant; predicts DGF	On admission 1–2 days pre-AKI Predicts AKI severity, dialysis, and death
KIM-1	Proximal tubule	Promotes epithelial regeneration, regulates apoptosis	12 h post CPB 1 day pre-AKI Not tested for outcomes	Fresh donor urine pre-transplant; Predicts DGF	On admission 1–2 days pre-AKI Predicts AKI severity, dialysis, and death
TIMP-2 X IGFBP-7	Proximal tubule	Biomarkers of G1 cell cycle arrest	12 h post CPB 1 day pre-AKI Not tested for outcomes	Not tested	12 h after admission; Predicts severe AKI

Times shown (in hours or days) are the earliest time points when the biomarker becomes significantly increased from baseline

AKI acute kidney injury, typically defined as AKIN Stage I or greater, *CPB* cardiopulmonary bypass, *DGF* delayed graft function, *ICU* intensive care unit, *ED* emergency department, *IL-18* interleukin-18, *KIM-1* kidney injury molecule 1, *L-FABP* liver-type fatty acid binding protein, *NGAL* neutrophil gelatinase-associated lipocalin

availability of commercial NGAL assays, there has been an explosion of studies validating the utility of NGAL as an early biomarker. Several multicenter pooled analyses of existing NGAL studies in children and adults have now confirmed the utility of this marker for the early diagnosis of AKI and its clinical sequelae in several clinical scenarios [133–143]. Collectively, these studies have identified proposed cut-offs for NGAL diagnostic thresholds. When urine or plasma NGAL is measured using standardized clinical laboratory platforms, a value of <50 ng/mL effectively rules out structural AKI (irrespective of the serum creatinine concentration). Measured NGAL values of >150 ng/mL are highly predictive of AKI, and values of >500 ng/mL strongly predict severe AKI [143]. These cut-offs still need to be rigorously validated using prospective, multicenter studies.

Studies have examined a combination of urinary biomarkers in children at risk for AKI, including following cardiac surgery [55, 144]. Urinary NGAL was increased in AKI patients within 2 h of bypass initiation, urine interleukin-18 (IL-18) and liver-type fatty acid binding protein (L-FABP) were increased within 6 h, and both urine kidney injury molecule-1 (KIM-1) and the cell cycle biomarkers (product of TIMP-2 and IGFBP-7) increased at the 12-h time point. All markers correlated with AKI severity and clinical outcomes and improved the risk prediction for AKI over clinical models. Thus, they represent temporally sequential markers, and a panel of such biomarkers may therefore help establish the timing of injury and plan appropriate therapies. This concept is illustrated in Fig. 51.7. Standardized clinical laboratory platforms for the measurement of urine and plasma NGAL as well as the cell cycle biomarkers are now available in most countries.

The concept of outcomes in "biomarker-positive, creatinine-negative" patients has been explored. Multicenter studies have enrolled cardiac surgical, critically ill or emergency department patients who were grouped according to their NGAL and serum creatinine status [133]. Studies found that measurement of the levels of NGAL complemented the information obtained by measurement of serum creatinine levels in establishing the diagnosis of AKI and predicting prognosis. A substantial proportion of patients (about 20%) had elevated NGAL levels even in the absence of loss of renal excretory function. This previously undetectable condition (which we now term "subclinical AKI") was associated with a two- to threefold increased risk of death or the need for renal replacement therapy compared to patients without elevations of serum creatinine or tubule damage markers. Notably, even in patients with significant loss of renal function, measurement of tubule damage biomarker levels still added prognostic information, as patients with increased levels of NGAL and serum creatinine levels displayed by far the worst prognosis. Overall, the data support that measurement of tubule damage markers such as NGAL results in a substantial added value to serum creatinine measurements.

Given the above considerations, NGAL and other tubule injury markers may complement a standardized diagnostic approach to AKI, and help clinicians improve their ability to make an early AKI diagnosis. Besides NGAL, other promising biomarkers of tubule damage currently include KIM-1, IL-18, L-FABP, and the cell cycle biomarkers (product of TIMP-2 and IGFBP-7), with additional candidates being continually discovered and verified in this area of intense contemporary research. However, markers of renal function will remain important even after tubule damage markers are fully established. Glomerular filtration markers such as serum creatinine or serum cystatin C are still valuable for the diagnosis and quantification of excretory function loss (e.g., for drug dosing) and prognosis (e.g., for development of CKD). Urine output will still represent a useful criterion for adjustments to fluid balance, and for the commencement or ending of renal replacement therapies. Structural AKI biomarkers may add substantively to our ability to detect AKI early, and to refine our ability to reliably classify AKI, as shown in Table 51.11.

Table 51.11 Biomarkers to refine AKI classification

Functional marker	Structural marker	Classification
–	–	Normal
+	–	Prerenal AKI
–	+	Subclinical AKI
+	+	Intrinsic AKI

Functional markers include serum creatinine, cystatin C, and other markers of GFR. Structural markers include neutrophil gelatinase-associated lipocalin, and others described in the text

Prevention of AKI

Proven measures for prevention of AKI include vigorous fluid administration in patients at high risk for developing AKI, adequate fluid repletion in those with hypovolemia, avoidance of hypotension in critically ill children by providing inotropic support as needed, and close monitoring of renal function and drug levels in children receiving nephrotoxic medications.

Hydration

Vigorous fluid administration (typically with isotonic crystalloid solutions) has been successfully employed to prevent AKI in patients at high risk, including hemoglobinuria, myoglobinuria, early tumor lysis syndrome, renal transplantation, other major surgical procedures, and use of nephrotoxic agents such as radiocontrast, cisplatin, and amphotericin. The efficacy of preoperative hydration strategies was demonstrated by a meta-analysis of 20 randomized controlled trials that investigated the reno-protective effects of perioperative hemodynamic optimization among 4220 adult surgical patients who were undergoing elective or emergent procedures [145]. Postoperative AKI was significantly reduced by perioperative hemodynamic optimization when

compared with the control group who did not receive similar goal directed therapy (OR 0.64, 95% CI 0.50–0.83). A more recent meta-analysis with an overall sample of 9308 patients indicated that goal-directed therapy by means of fluids and inotropes improves renal perfusion and oxygenation in high-risk patients undergoing major abdominal and orthopedic surgery [146].

Fluid Resuscitation

A child with a clinical history and physical examination findings consistent with hypovolemia and impending or established prerenal AKI requires immediate vigorous intravenous fluid therapy with normal saline (10–20 mL/kg over 30 min, repeated twice if necessary, until urine output is re-established). Isotonic crystalloids are most used for correcting extracellular volume depletion. Compared to crystalloids, colloids theoretically may result in a greater plasma expansion. However, the difference in required volumes for fluid resuscitation was minimal between crystalloids and colloids. Moreover, colloids carry the risks of hyper-oncotic reduction in glomerular filtration and osmotic tubular damage. It is recommended that serum chloride levels are monitored, since hyperchloremia can cause renal vasoconstriction. If urine output does not improve after restoration of intravascular volume, more invasive monitoring may be required to guide further therapy. In children not responsive to volume repletion alone, preservation of blood pressure and renal perfusion with appropriate inotropic agents is essential to prevent AKI. Patients with established intrinsic AKI require volume restriction to prevent worsening fluid overload. Such patients are best treated by maintaining current volume status by providing for insensible water losses and replacing any ongoing fluid losses.

Nephrotoxin Management

Nephrotoxins are an important risk factor and etiology for pediatric AKI. Monitoring kidney function and drug levels when possible are important for rational adjustment of drug dosing based on known alterations in pharmacokinetics and pharmacodynamics during AKI. It is crucial that clinicians caring for patients requiring potentially nephrotoxic drugs use appropriate drug dosing based on the knowledge of altered clearance rates in early AKI and be vigilant in monitoring for drug efficacy and toxicity. The importance of monitoring serum creatinine levels as a measure of kidney function in children receiving nephrotoxic drugs has been brought into focus in a retrospective single center study of 1660 non-critically ill, hospitalized children [147]. Children who developed AKI as defined by the serum creatinine-based pRIFLE criteria had significantly greater odds of exposure to one or more nephrotoxic medications than patients without AKI (OR 1.7; 95% CI 1.04–2.9). Both increasing dose and duration of nephrotoxin use were associated with increased development of AKI. A recent study demonstrated decreasing AKI duration when a systematic daily serum creatinine monitoring policy was put into practice for children who received multiple nephrotoxic medications. When a systematic daily serum creatinine monitoring program for all non-critically ill children receiving three or more nephrotoxic medications was put in place using an automated EHR-driven protocol in a single center, a 42% reduction in AKI days was observed [148]. This program has now been spread to multiple children's hospitals that could implement a systematic EHR-guided protocol, with excellent published results—follow-up studies have shown a nephrotoxin medication exposure rate decreased by 38% and a reduction in AKI incidence by 64% [149].

Additional quality improvement strategies in the prevention of AKI have been suggested [150]. Briefly, primary prevention at the community level includes raising awareness regarding AKI risk factors among health care professionals and patients by education and establishment of tools that measure these risk profiles. It is suggested that populations and patients at high risk for developing AKI should have a Kidney Health Assessment at least every 12 months to define

and modify their AKI risk profile. Primary prevention of AKI in hospitalized patients may be achieved by first screening for AKI risk factors, followed by at least an assessment of serum creatinine, urine dipstick analysis, and urine output. Once AKI has developed, secondary prevention may be directed towards early identification of AKI severity and complications (monitor serum creatinine, urine output, serum electrolytes), minimizing nephrotoxin exposure, ensuring optimal hemodynamic and nutritional status, and treating the underlying cause.

Unproven Pharmacologic Agents for Prevention of AKI

Unproven agents for prevention of AKI include mannitol, loop diuretics, low-dose dopamine, fenoldopam, atrial natriuretic peptide, N-acetylcysteine, and methylxanthines. Their potential use in AKI prevention is briefly discussed here.

Mannitol

Experimental studies suggest that mannitol might be protective by causing a diuresis (which minimizes intratubular cast formation), and by acting as a free radical scavenger (thereby minimizing cell injury). In the clinical setting, the efficacy of mannitol for prevention of AKI in high-risk patients is inconclusive. Indeed, its use may be detrimental, and can result in volume expansion, hyperosmolality, and pulmonary edema. Its use for prevention of AKI is not recommended.

Loop Diuretics

Loop diuretics such as furosemide induce a forced diuresis by reducing active NaCl transport in the thick ascending limb of the loop of Henle. The ensuing decrease in energy requirement may protect the tubule cells in the setting of a decrease in energy delivery. However, the available evidence from clinical studies in adults does not support the routine use of diuretics as prophylaxis for AKI. In some settings, the use of diuretics was harmful. In critically ill children, furosemide was found to be the most common nephrotoxin used and was associated with a twofold greater adjusted risk for developing AKI [151]. Therefore, the use of loop diuretics for prevention of AKI is not recommended. However, in certain select situations, such contrast induced AKI in susceptible populations, AKI prevention with loop diuretics can be associated with favorable outcomes if euvolemia is carefully maintained.

While controlled studies have demonstrated that the administration of diuretics to patients in the early stages of AKI does not significantly alter the natural history of the disease, furosemide can potentially convert AKI from oliguric to a non-oliguric form and therefore simplify fluid, electrolyte, and nutritional management. The concept here is to use diuretics in well-hydrated, diuretic-responsive patients (primarily furosemide, with sometimes the addition of thiazide diuretics) to maintain urine output, which would prevent fluid overload and allow for nutritional support, both of which would prevent worsening of AKI. In addition, a prospective assessment of a furosemide challenge, or furosemide "stress" test, was able to predict which patients would have worsening AKI based on a lack of response to furosemide within 2 h. In the setting of early AKI, low urine output following the furosemide stress test predicted progressive AKI, need for dialysis, and inpatient mortality [152]. Using a furosemide stress test in patients with increased AKI biomarker levels such as NGAL improves risk stratification and prediction of AKI progression [153].

Dopamine

The use of low "renal-dose" of the inotropic agent dopamine (0.5–3 μg/kg/min) is common in the critical care setting due to its renal vasodilatory and natriuretic effects. However, prospective randomized studies of adult patients at risk for AKI have not shown a beneficial reno-protective effect of "low-dose" dopamine. There are risks associated with even "low-dose" dopamine, including tachycardia, arrhythmias, and myocar-

dial, intestinal and even renal ischemia. Therefore, the routine use of dopamine for prevention of AKI is not recommended.

Fenoldopam

Fenoldopam is a potent, short-acting, selective dopamine A-1 receptor agonist that increases renal blood flow, increases natriuresis, and decreases systemic vascular resistance. Experience with fenoldopam in the pediatric age group is limited. A small, prospective, single center, randomized, double-blind, controlled trial of children undergoing cardiopulmonary bypass revealed a significant reduction in the urinary AKI biomarker NGAL at the end of surgery and 12 h after ICU admission in the group receiving fenoldopam [154]. Confirmation of the benefits of fenoldopam is required in a large, multicenter, randomized, controlled trial prior to routinely recommending this agent for the prevention of AKI.

Natriuretic Peptides

Atrial natriuretic peptide (ANP) and b-type natriuretic peptide (BNP) block tubular reabsorption of sodium and vasodilate the afferent arteriole. The reno-protective effects of these agents have been evaluated primarily in trials of adults undergoing cardiac surgery and with congestive heart failure. While initial data seemed promising, evidence from large, randomized trials have failed to show a conclusive clinic benefit from these agents. Pediatric data for the reno-protective effects of natriuretic peptides is limited. Pending further randomized controlled trial data, the routine use of natriuretic peptides for prophylaxis against AKI is not recommended.

N-Acetylcysteine

N-acetylcysteine (NAC) is a free radical scavenger antioxidant agent that counteracts the deleterious effects of ROS in the generation of tubule cell injury, and also has vasodilatory properties. Several recent meta-analyses have examined the efficacy of N-acetylcysteine in the prevention of AKI following cardiac and other major surgery as well as the prevention of contrast-induced nephropathy in adults. A recent meta-analysis evaluating the preventive effect of NAC on contrast-associated AKI in adults undergoing primary percutaneous coronary intervention suggested that NAC reduces the risk of AKI and all-cause in-hospital mortality [155]. NAC was also shown to prevent postoperative AKI in adults with pre-existing CKD undergoing cardiac surgery [156]. Given that the overall direction of the data is toward benefit and the agent is well tolerated and relatively inexpensive, the use of NAC in high-risk patients is generally recommended. While NAC is commonly used in children for treatment of acetaminophen toxicity and other forms of acute liver failure, data for its reno-protective effects in the pediatric population is limited. The routine use of NAC for AKI prophylaxis in children is not generally recommended, except for judicious use in children with CKD who are at high risk for contrast induced nephropathy. One approach is to use NAC in combination with IV hydration to prevent contrast induced nephropathy in children with CKD stage 3 or greater and a history of contrast-induced AKI in the past, or in children who are already on two nephrotoxins and contrast would be the third nephrotoxin to be used. The efficacy of this approach has not been systematically studied.

Methylxanthines

Methylxanthines are adenosine antagonists that act via A1 and A2A receptors in the kidneys. Previous human clinical trials using caffeine citrate, theophylline or aminophylline have suggested that methylxanthines may prevent AKI or improve renal function in special populations of high-risk neonates and infants, including those with perinatal hypoxia/ischemia or prematurity and undergoing cardiac surgery. In a recent multicenter in preterm neonates, caffeine administration in preterm neonates was associated with

reduced incidence and severity of AKI. In this retrospective analysis, for every 4.3 neonates exposed to caffeine, one case of AKI was prevented [86]. In two recent systematic reviews of prophylactic theophylline or aminophylline use for prevention of AKI in highly susceptible neonates with birth asphyxia, the pooled estimate showed a 60% reduction in the incidence of AKI and a significant improvement in fluid balance, with no increase in risk of complications [87, 88]. It should be noted that theophylline has wide variation in metabolism and a narrow therapeutic window, and it is therefore essential to monitor theophylline levels to avoid toxicity.

Prognosis and Outcome

In general, pediatric AKI has serious short- and long-term consequences. The outcome depends upon the etiology, age of the child, and comorbidities. The short-term outcomes of AKI include mortality and morbidity. Regarding mortality, retrospective analyses of large databases during the past decade in the United States showed that the overall in-hospital mortality rate of hospitalized children with AKI is approximately 15%. Mortality rates have ranged from 9.5% in non-critically ill children to 30% in children requiring intensive care. Even higher in-hospital mortality rates of 35–45% have been reported from other countries. The highest mortality rates are encountered in infants, those who have multiorgan failure, and those requiring renal replacement therapies. Data regarding long-term mortality after pediatric AKI is limited, although small studies have revealed a mortality rate of about 20% during a 2–5 year follow-up period. More recent multinational studies have revealed perhaps an encouraging improvement regarding in-hospital mortality. Both the AWARE study in critically ill children [35] and the AWAKEN study in neonates [36] reported an in-hospital mortality rate of approximately 10%. However, in the Global Snapshot study, children from low-income countries continue to experience a high mortality rate of 20% compared with only 1.2% in those from high-income countries [38].

Regarding short-term morbidity, it is quite clear that AKI is associated with adverse effects, including increased need for and longer duration of ventilatory support, as well as increased length of hospital stay [157]. The AWARE study demonstrated a stepwise increase in mechanical ventilation use as well as ICU lengths of stay (LOS), depending on AKI severity [35]. Critically ill children with stage 1, stage 2, and stage 3 AKI required mechanical ventilation 38.2%, 40.5%, and 50.2% of the time, respectively (vs. no AKI at 29.5%). In the AWARE study, patients with AKI (increase of 1.31 days) and severe AKI (increase of 3 days) had longer ICU LOS after adjusting for severity of illness [35]. These observations confirm previous findings of children who experienced AKI that had longer hospital LOS (36.6 days vs. 20.5 days) than those without AKI [9]. This association is also seen in neonates across all gestational ages. Two single center reports found that AKI increased hospital LOS among neonates by 3.4 days and 11.7 days, respectively. The association between AKI and LOS is evident even in non-critically ill children, including in the settings of nephrotoxin administration and the nephrotic syndrome [64].

Information regarding the long-term outcome of children after an episode of AKI is beginning to accumulate. In a multicenter pooled analysis of 3476 children with hemolytic uremic syndrome followed for a mean of 4.4 years, the combined average death and ESKD rate was 12%, and the combined average renal sequelae rate (CKD, proteinuria, hypertension) was 25%. Thus, long-term follow-up appears to be warranted after an acute episode of hemolytic uremic syndrome. Long-term follow-up of premature infants with neonatal AKI has shown a 45% rate of renal insufficiency. Prominent risk factors for progression include an increased random urine protein/creatinine ratio and a serum creatinine >0.6 mg/dL at 1 year of age. More recent long-term follow-up studies demonstrate that 40–60% of children surviving an AKI episode have a sign of CKD, including proteinuria, hyperfiltration, low eGFR or hypertension In the Translational Research Investigating Biomarker Endpoints in AKI (TRIBE-AKI) prospective study in children

after cardiac surgery, hypertension (17%), proteinuria (8%), and a eGFR <90 mL/min/1.73 (13%) were common 5 years later; however, these sequelae were not more common among the children who experienced perioperative AKI [158]. Similarly, the Assessment, Serial Evaluation, and Subsequent Sequelae in Acute Kidney Injury (ASSESS-AKI) prospective study followed children for 4 years after cardiopulmonary bypass [159]. The cohort prevalence of CKD was high (20%); hypertension prevalence was also high (30%). AKI was not significantly associated with the development of CKD or hypertension. However, a subsequently published retrospective study did find that cardiac surgery-associated AKI was associated with a greater risk for CKD stage 2 or greater [160]. The 5-year cumulative incidence of CKD for patients with cardiac surgery-associated AKI was 12%, in comparison with 3% in those without AKI (adjusted HR 3.8). In a longitudinal study of heterogenous critically ill children, AKI was associated with twofold higher odds for CKD or hypertension at 6 years of follow-up [161].

Beyond CKD, AKI episodes are also associated with ESKD. In a retrospective analysis of 1688 surviving children who required dialysis for an acute AKI episode, outcomes after a median of 9.6 years included death (7%), CKD (13%), ESKD (2.6%), and hypertension (12%) [162].

Collectively, these data strongly suggest that long-term follow-up is clearly warranted for children who survive an episode of AKI. Widely available interventions for hypertension and proteinuria hold promise for prevention of CKD progression after AKI, a concept that is especially pertinent to the pediatric population.

Concluding Remarks

AKI represents a very significant and potentially devastating problem in pediatric medicine, with dire immediate and long-term consequences. The incidence appears to be rising globally. Outstanding advances in basic research have illuminated the pathogenesis of AKI and have paved the way for several successful therapeutic approaches in animal models. However, translational research efforts in humans have yielded disappointing results. One reason for this is the lack of early markers for AKI, and hence an unacceptable delay in initiating promising therapies. Fortunately, several potential candidates are currently being developed and tested as sequential non-invasive early biomarkers for the prediction of AKI and its severity. It is likely that not any one biomarker but a collection of strategically selected proteins may provide the "AKI Panel" for the early non-invasive diagnosis of AKI and its consequences. Such a tool of biologically plausible sequential biomarkers would be indispensable for risk stratification, timely institution of potentially effective therapies, monitoring the response to therapies, and for prediction of adverse clinical outcomes. A judicious combination of clinical judgment, established functional markers, novel structural markers based on knowledge of underlying pathophysiology, and technical advances in therapies that counter the complex mechanisms holds the greatest promise for true progress in human intrinsic AKI.

Management of Pediatric Acute Kidney Injury

52

Lyndsay A. Harshman, Patrick D. Brophy, and Jordan M. Symons

Introduction

Acute kidney injury (AKI) affects an increasing proportion of critically ill patients who now survive medical and surgical complications that were once often fatal. Despite increased efforts to recognize and prevent AKI, progression to kidney failure continues to occur with alarming frequency. The treatment of AKI in critically ill and injured children requires understanding of medical management of disease with ready availability of renal replacement therapy (RRT) as well as adaptability for use in pediatric patients of all ages and sizes. In this chapter, we review medical management of AKI as well as traditional and emerging RRT modalities.

Medical Management of AKI

Medical management of AKI includes optimizing renal perfusion, preventing or reducing fluid overload, correcting electrolyte abnormalities and acid-base disturbances, supporting patient nutrition, and closely monitoring administration of nephrotoxic medications all while considering the patient's need for renal replacement if medical management proves ineffective [1–3]. The prevention of AKI is the foremost means of management. The clinician must pay close attention to subtle changes in serum creatinine and corresponding urine output as creatinine increase is a late marker of AKI [4]. Chapter 46 discusses this topic in detail.

Renal Perfusion

Intravenous (IV) fluid is used to treat hypovolemia in an attempt to maintain end organ perfusion, but overly aggressive resuscitation may lead to fluid overload. Both crystalloid and colloid (typically albumin) are utilized in fluid resuscitation; however, two major studies in adults have failed to demonstrate a clear benefit on AKI outcomes or survival difference for colloid versus crystalloid infusions [5, 6]. However, colloid may be advantageous over crystalloid in patients requiring large amounts of fluid resuscitation in the setting of sepsis or burn injury [7].

Vasopressors in conjunction with IV fluid resuscitation for vasomotor shock may improve kidney perfusion and are recommended in patients who have or are at risk of AKI [7]. Agents recommended are norepinephrine, vasopressin, and dopamine. Vasopressin and norepinephrine use has increased due to favorable side effect profiles versus the arrhythmic abnormalities noted with dopamine [8, 9].

The use of renal vasodilators to increase renal perfusion does not improve outcomes. Specifically, dopamine has been employed at low dosages in an effort to improve renal perfusion by promoting vasodilatation. Adult studies of "renal dose" dopamine show no benefit and may even suggest harm [10–13]. More recently the selective dopamine agonist fenoldopam has been utilized to augment renal blood flow. Adult literature from single-center studies suggests a decline in both mortality and the need for RRT [14]. Furthermore, meta-analysis of 16 trials of fenoldopam in adults concluded that fenoldopam decreased the incidence of AKI, the need for RRT, intensive care unit (ICU) stay and death from any cause [15]. To date, one available randomized controlled trial has suggested that use of high-dose fenoldopam in pediatric patients on cardiac bypass significantly reduced the use of diuretics and vasodilators during bypass [16]. Current Kidney Disease Improving Global Outcomes (KDIGO) recommendations are against the use of fenoldopam to prevent or treat AKI given the high risk for hypotension associated with its use in ICU patients in comparison to the relatively sparse data available regarding its efficacy [7]. Emerging data from randomized, blinded trials suggest that fenoldopam may be beneficial in complex cardiac surgeries to improve the quality of perfusion during cardiopulmonary bypass and prevent AKI in both adults and children [16, 17]. The role for fenoldopam in AKI requires further clarification.

Volume Status

Awareness of volume status is critical in a patient with AKI since patients may have hypovolemia, euvolemia, or hypervolemia (fluid overload). Volume status should be continually reassessed and correlated with patient intake and output as well as daily weights. Heart rate, blood pressure, capillary refill, and skin turgor are all key components of assessing volume status.

Hypovolemia should be addressed with isotonic fluid to restore intravascular volume, and if necessary, inotropic support. AKI secondary to prerenal azotemia is likely in a severely volume depleted child. Aggressive fluid resuscitation with 10–20 mL/kg normal saline boluses to reestablish intravascular volume is recommended, and if there is no urine output once volume status is restored, a significant dose of furosemide (2 mg/kg IV) may be given. It is important to recognize that administration of furosemide and subsequent diuresis may simply result in conversion of the AKI from oliguric to non-oliguric and will not alter the course of the renal injury itself [18]. If a furosemide trial is used, a single high dose should be administered with observation for response. Furosemide should not be continued if there is ongoing oliguria [19].

Fluid overload has been associated with increased morbidity and mortality in pediatric critical care patients; however, the pathophysiology leading to poor outcome is not fully delineated [20, 21]. Examples of AKI with hypervolemia include following aggressive fluid resuscitation in septic patients and in patients with left ventricular cardiac dysfunction. The use of excessive normal saline for fluid resuscitation is associated with hyperchloremia, which has been demonstrated to diminish renal sodium excretion [22, 23] and impair renal blood flow [24], thus heightening the risk for AKI. Congestive heart failure due to poor left ventricular function can result in poor renal perfusion secondary to deficits in forward flow, which further promotes edema formation through activation of the renin-angiotensin-aldosterone axis and subsequent sodium retention [25]. Diuretic use in the adult ICU patient with AKI is associated with heightened risk of both death and non-recovery of renal function [19]. A trial of high-dose furosemide may be used to relieve hypervolemia given evidence that persistent, positive fluid balance is

associated with increasing mortality in adult patients who develop AKI [26]. It is not advisable, however, to rely on diuretic therapy and fluid and nutritional restriction to avoid RRT given that such use of diuretics for either AKI "prophylaxis" or therapy does not improve outcomes [27, 28]. Patients with fluid overload not responsive to diuretics require consideration of RRT.

Cumulative percent fluid overload may be calculated as follows:

```
fluid input (liters) - fluid output (liters) / ICU admission weight (kg) * 100
```

Evaluation for RRT should occur in the setting of >10% cumulative fluid overload. Initiation of RRT is advised if cumulative fluid overload is >20% [29].

Critically ill pediatric patients presenting with euvolemia but oliguria that is unresponsive to fluid resuscitation may have intrinsic AKI. In this population, continued fluid resuscitation may be detrimental if the patient remains oliguric; thus, guidelines suggest restricting fluid to insensible losses plus replacement of urine output plus extra renal losses [30]. However, nutrition needs may require early RRT to prevent volume overload and electrolyte disturbances.

Electrolyte Abnormalities

Electrolyte abnormalities occur commonly in AKI and may develop rapidly, necessitating vigilant monitoring. Hyperkalemia is common, particularly in oliguric patients, and is potentially life-threatening due to ventricular tachycardia and fibrillation. Medical management of hyperkalemia is directed towards removal of potassium from the body (sodium polystyrene sulfonate, loop diuretic if responsive) and preventing arrhythmias via driving potassium into the cells (albuterol, sodium bicarbonate, insulin + glucose) and stabilizing the cardiac membrane (calcium), as summarized in Table 52.1. Dialysis may be necessary if moderate to severe hyperkalemia is refractory to medical management (Table 52.1).

Hyponatremia occurs more often than hypernatremia in AKI [30]. Hyponatremia is often due to water retention and may be exacerbated by intake of hypotonic fluids. Hyponatremia due to water retention secondary to volume depletion may respond to isotonic fluid. In contrast, fluid

Table 52.1 Medical agents utilized in the management of hyperkalemia

Agent(s)	Mechanism	Dose	Onset	Complications
Sodium bicarbonate	Shifts K+ into cells	1 mEq/kg IV over 10–30 min	15–30 min	Hypernatremia, change in ionized calcium
Albuterol	Shifts K+ into cells	400 μg by nebulizer	30 min	Tachycardia, hypertension
Glucose and insulin	Shifts K+ into cells	Glucose 0.5 g/kg, insulin 0.1 U/kg IV over 30 min	30–120 min	Hypoglycemia
Calcium gluconate 10%	Stabilizes membrane	0.5–1 mL/kg IV over 5–15 min	Immediate	Bradycardia, arrhythmias, hypercalcemia
Calcium chloride	Stabilizes membrane	10 mg/kg IV over 5–15 min	Immediate	Bradycardia, arrhythmias, hypercalcemia
Sodium Polystyrene Sulfonate (Kayexalate®, Concordia Pharmaceuticals, Oakville, Ontario, Canada)	Exchanges Na^+ for K^+ across the colonic mucosa	1 g/kg orally or PR in sorbitol	30–60 min	Hypernatremia, constipation, colonic membrane irritation if given PR

restriction is effective if due to free water excess. RRT may be necessary if renal dysfunction prevents excretion of excess free water. Sodium levels less than <120 mEq/L are associated with a high risk for cerebral edema and seizures. Sodium correction with hypertonic saline solution over several hours should be initiated. Further correction of hyponatremia can be achieved by free water restriction.

Hyperphosphatemia in AKI is secondary to reduction in glomerular filtration rate (GFR). Hyperphosphatemia may be treated with phosphate binders and dietary phosphorus restriction. Selection of a phosphate binder should consider the patient's calcium level. In patients with low ionized calcium, a calcium-containing phosphate binder (e.g. calcium carbonate) should be used; by contrast, in patients with hypercalcemia, a non-calcium phosphate binder, such as sevelamer, is recommended.

Hypocalcemia occurs in AKI secondary to high serum phosphorus. Both total and ionized calcium levels should be monitored since total calcium may be inaccurate due to decreased total calcium secondary to hypoalbuminemia and changes in calcium binding to albumin based on the patient's acid-base status. Initial treatment for mild hypocalcemia in AKI and phosphate retention is correction of hyperphosphatemia, typically using oral phosphate binders. Symptomatic hypocalcemia requires correction with IV calcium. This replacement should be provided with caution in the severely hyperphosphatemic patient given the possibility of systemic calcium phosphate precipitation, potentially worsening existing AKI with calcium phosphate deposition in the renal tubules. Inability to correct hypocalcemia in a symptomatic patient (e.g. tetany and/or seizures) secondary to severe hyperphosphatemia is an indication for dialysis.

For children who are not receiving RRT, several measures can prevent severe metabolic and electrolyte disturbances. First, no supplemental phosphorus or potassium should be provided to the patient unless symptomatic or there is significant hypophosphatemia or hypokalemia. Second, to prevent worsening hypertension and fluid overload, sodium should be restricted to 2–3 mEq/kg/day. Third, parenteral or enteral nutrition should be considered early in the patient's course, as described below, to replete electrolyte abnormalities. If adequate nutrition cannot be provided due to fluid overload, RRT should be initiated. Serum electrolytes, phosphorus, calcium, and albumin should be regularly monitored as dictated by the patient's clinical status.

Acid-Base Disturbances

Metabolic acidosis in AKI is due to renal dysfunction and systemic disease (e.g. sepsis, trauma, burns). Severe acidosis can be treated with IV or oral sodium bicarbonate, with careful monitoring for fluid overload and worsening of hypertension due to the sodium load. Patients with AKI who develop severe, refractory metabolic acidosis may require dialysis therapy, especially in the setting of oligoanuria. It is important to measure the serum total and ionized calcium prior to bicarbonate treatment due to potential for symptomatic hypocalcemia given increased pH-dependent binding of calcium to proteins, which decreases the ionized calcium.

Nutritional Interventions

Patients with AKI are in a hypercatabolic state and should have nutritional support to ensure full calorie, protein, and micronutrient delivery. Nutritional goals include preservation of lean body mass and avoidance of metabolic derangements. Potential benefits include improved wound healing, immune function, and scavenging of oxygen free radicals, with the goal of decreasing patient mortality [32].

Delivery

Adequate nutrition may require supplemental enteral and/or parenteral nutrition if oral intake cannot meet nutritional requirements. Enteral nutrition is preferred if the gastrointestinal tract is functioning given the ease of administration and lower rates of infection. Conversely, parenteral

nutrition should be employed when the gastrointestinal tract cannot be utilized and/or enteral feeding cannot provide sufficient nutrition [33]. See Fig. 52.1 for a decision tree illustrating mode of nutritional support in AKI [34].

Protein

Current evidence suggests that patients with AKI require increased protein, particularly when receiving RRT [35]. Protein-energy wasting (PEW) is loss of lean body mass and fat mass and may occur in patients with AKI d [36]. PEW is an independent predictor for patient mortality and is also directly associated with the length of hospital stay and risk of complications [37]. The adult literature recommends an increased protein intake goal of 1.5–2 g/kg per day for hypercatabolic patients or for patients receiving RRT that utilizes high-flux and/or highly efficient filters, which are associated with amino acid losses [38].

Calories and Lipid

General guidelines suggest that critically ill children should receive from 1 to 1.3 times basal metabolic needs in calories [39]; however, additional calories for hypercatabolic states should be provided given the patient's pre-existing state of nutrition. To optimize enteral nutrition, "renal-specific" formulas are an option for patients being medically managed with AKI or on RRT. These formulas may be beneficial given high caloric and protein density with low electrolyte levels [40]. Adequate caloric intake is needed to prevent catabolism, to promote protein synthesis and to offset heat-dependent caloric losses [41]. Parenteral nutrition, including IV lipids, is necessary if enteral nutrition cannot be provided [38, 41].

Nutrients

Levels of vitamin C and water-soluble vitamins, including thiamine and folic acid, may be low in patients with AKI [42]. Use of RRT can exacerbate nutrient and trace element losses due to the very efficient removal of small molecular weight substances [43]. Appropriate replacement is indicated.

Glycemic Control

Stress hyperglycemia is a notable feature of critical illness [44]. Several studies have investigated the impact of conservative versus intensive insulin therapy on patient mortality, with secondary analyses investigating impact of glycemic control on incidence of AKI [45–47]. Tight glycemic control has decreased the incidence of AKI in adults [48]. Insulin is recommended to correct hyperglycemia in AKI, with typical glucose goals between 110 and 150 mg/dL [49].

Avoidance of Nephrotoxins

Many commonly used medications are metabolized and/or excreted by the kidneys. Nephrotoxic medications in the ICU contribute to nearly 25%

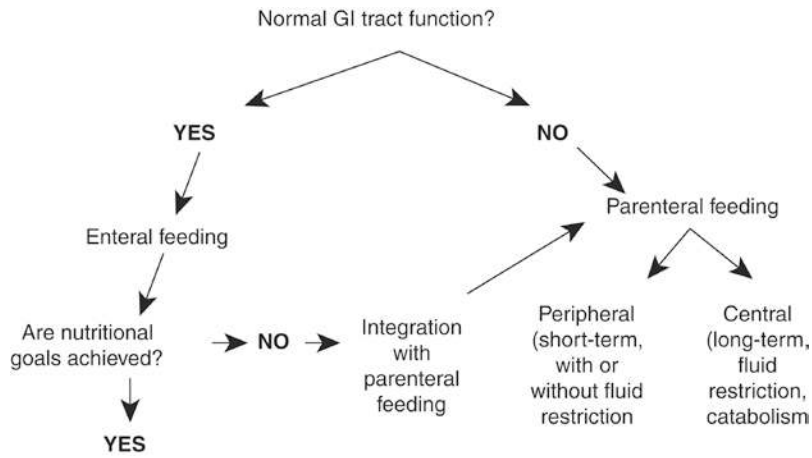

Fig. 52.1 Decision tree for nutritional support in AKI patients with protein energy wasting (PEW) or at risk of PEW. (Used with permission of John Wiley and Sons from Fiaccadori et al. [34])

of AKI cases [50, 51]. Prevention of drug-induced AKI is more effective than any available therapy; recognition of high-risk patients is therefore necessary. The dose and frequency of administration of any potentially nephrotoxic medication should be adjusted (or avoided) based on the patient's GFR.

Common nephrotoxins include aminoglycosides, nonsteroidal anti-inflammatory drugs (NSAIDs), contrast agents, and chemotherapeutic and immunosuppressant medications [52]. AKI induced by drugs occurs by two predominant mechanisms: direct toxicity to renal tubular epithelium, as is seen with aminoglycosides and amphotericin, and interference with autoregulatory mechanisms, leading to unrestricted vasoconstriction and reduced renal blood flow, as is seen with NSAID toxicity. NSAIDs are a common cause of AKI in children, even when ingested at recommended doses; the incidence of AKI may be underestimated both in the inpatient and outpatient settings [53]. Aminoglycosides are widely utilized in pediatric patients. Repeat administration of these agents may lead to renal interstitial and tubular epithelial cell accumulation, and as such, recommendations have been made to administer aminoglycosides every 24 h (or less) to minimize toxicity, with drug levels obtained daily [7].

Contrast-induced AKI (CI-AKI) in adults is associated with an increased risk of mortality in the year following the episode of AKI [54]. The incidence in children is not well-characterized. Patients with chronic kidney disease or diabetes are at increased risk of CI-AKI [54]. Volume and osmolality of contrast administered is directly associated with risk of AKI [55, 56], and non-ionic agents are thought to be safer, especially in patients with chronic kidney disease [57]. The pathophysiology of CI-AKI is still largely unknown. Severe vasoconstriction following contrast administration has been implicated [58, 59], as has direct cytotoxicity via oxygen free radical generation. Serum creatinine rises 1–2 days after the imaging procedure and is usually not accompanied by oligoanuria [60]. Dialysis is required in a minority of patients. No treatment exists other than support if CI-AKI occurs. However, in recent years, attention has focused on prevention [61, 62]. A meta-analysis of prevention strategies recommends pre- and post-contrast IV volume expansion with bicarbonate-containing fluids and use of low or iso-osmolar contrast agents in the smallest volume possible in patients with pre-existing kidney disease who are at increased risk. N-acetylcysteine and ascorbic acid have also been suggested for use as free radical scavengers in the higher risk populations [57]. N-acetylcysteine is indicated for the prevention of contrast-induced AKI per the 2012 KDIGO guidelines [7]. While older studies have suggested a benefit [63], controversy regarding its use remains as the effect of N-acetylcysteine to prevent AKI can be variable, and several studies have failed to show a significant benefit. There is no significant benefit of either N-acetylcysteine or bicarbonate infusion for prevention of AKI, even among populations at high risk for kidney complications [64]. There have been no randomized trials in children.

Other Medical Therapies

Growth Factors

Renal tubular injury is a major component in the pathogenesis of AKI, and renal tubular repair is a required step for recovery. Growth factors play an important role in the regeneration of epithelial cells. In animal models, several growth factors have been shown to accelerate recovery from renal injury such as erythropoietin, insulin-like growth factor, hepatocyte growth factor, and epidermal growth factor [65]. In cellular and animal models, erythropoietin appears to reduce necrosis and apoptosis in renal epithelial cells while also promoting cell proliferation [66]; however, human studies have failed to yield AKI-related benefit from use of erythropoietin for primary AKI prevention [67]. Similarly, hepatocyte growth factor and insulin-like growth factor-1 appear to limit apoptosis in animal models of renal injury [68, 69], but again, preliminary clinical trials with IGF-1 have not shown benefit to patients. The KDIGO work group recommends against use of IGF-1 to prevent or treat AKI [7].

Adenosine Receptor Antagonists

Theophylline is a non-selective adenosine receptor antagonist that is thought to increase renal blood flow at the level of the afferent arteriole [70]. KDIGO recommendations suggest a single dose of theophylline in high-risk neonates with perinatal asphyxia at risk of AKI [7]. Research to date supports an initial renoprotective effect following theophylline in asphyxiated infants; however, long-term impact on renal function is unclear [71, 72].

Renal Replacement Therapies in AKI

The lack of evidence-based guidelines regarding the definition of pediatric AKI (see Chap. 46) has resulted in much uncertainty and discussion regarding the indications and timing for initiation of RRT as well as the optimal modality to employ. Retrospective reviews in critically ill children demonstrate that those who develop AKI early in a hospital course have greater morbidity and mortality [73, 74]. Use of RRT may prevent and correct life-threatening complications of AKI refractory to medical management. Indications for initiation of RRT in pediatric AKI have traditionally been those used for end-stage renal disease (and are not necessarily easily juxtaposed in the acute setting), including metabolic/electrolyte abnormalities refractory to medical therapy, symptomatic fluid overload, and/or symptomatic uremia; however, metabolic derangement and fluid overload are often late findings in severe renal injury [75]. In the acute setting, consideration of RRT must account for the patient's clinical situation in the context of the aforementioned laboratory abnormalities.

Adult literature suggests that earlier initiation of RRT, for example before the appearance of florid metabolic derangements and symptomatic fluid overload, may yield better patient outcomes, including decreased risk of death, shorter duration of RRT, and shorter hospital stays [76, 77]. For example, volume overload in the setting of AKI refractory to medical management is an indication for RRT even without significant azotemia or elevation in creatinine. Additionally, the presence of multisystem organ dysfunction in the presence of AKI refractory to medical management is a strong indication for initiation of RRT.

More recently, the concept of renal angina [78] has been suggested whereby likelihood of developing AKI is informed by baseline and contextual factors as well as objective evidence to identify those patients at greatest risk for renal injury. Additionally, renal angina criteria stratify patients into moderate-, high-, and very-high risk categories for AKI based on their underlying clinical condition (Table 52.2). Renal angina can be thought of mathematically as "signs of injury" (i.e., fluid overload, estimated creatinine clearance) multiplied by presence of AKI and is comparable to assessment of risk for a myocardial infarction in an adult patient presenting with chest pain. Given that there are currently no reliable biomarkers for establishing the severity or

Table 52.2 Pediatric renal angina criteria

Hazard tranche	Renal angina threshold
Moderate-risk patients	Doubling of SCr
Patients admitted to PICU	OR
	eCrCl decrease >50%
	OR
	ICU fluid overload >15%
High-risk patients	Serum Cr increase ≥0.3 mg/dL
Acute decompensated heart failure	OR
Stem-cell-transplant recipient	eCrCl decrease 25–50%
	OR
	ICU fluid overload >10%
Very-high-risk patients	Any serum Cr increase
Receiving mechanical ventilation and one or more vasoactive medications	OR
	eCrCl decrease >25%
	OR
	ICU fluid overload >5%

prognosis of a patient's AKI, renal angina criteria may help the clinician to predict risk for AKI early in the clinical course and intervene, if needed, with RRT before reaching a state of fluid and metabolic derangement. In one study, the renal angina index obtained on Day 0 of pediatric ICU admission was predictive for progression to AKI on ICU Day 3 [79].

Greater than 20% fluid overload is a significant independent risk factor for increased morbidity and mortality [80]. Other less concrete indications for initiation of RRT include oliguria not responsive to diuretics, escalating ventilatory requirements (especially if pulmonary edema is secondary to fluid overload), need for a large volume of medications/blood products in a currently fluid overloaded patient (>10% overload), and/or when ability to provide adequate nutrition is compromised by fluid restriction secondary to fluid overload and oliguria.

Literature exists regarding when to stop RRT in the patient with AKI. In stopping RRT, the nephrologist may decrease the frequency of therapy from daily to every other day or change modality (e.g. conversion from CRRT to acute hemodialysis [HD]). The decision to stop should be based on evidence for improvement in the underlying disease pathology that led to RRT initiation and improvement in renal function (i.e., increased urine output, diminished azotemia, and decreased fluid overload).

Modality Choice

When initiating RRT for AKI, the clinician should first identify the goals of dialytic therapy. The patient's size, hemodynamic stability, and potential for vascular access also inform modality selection. Choice of therapy will also depend on clinician preference, available resources (e.g. dialysis equipment, nursing staff), and even capabilities for placement of dialysis access.

Acute Peritoneal Dialysis

Acute peritoneal dialysis (PD) provides gradual solute and water clearance through both convective and diffusion-based mechanisms. Although the use of continuous renal replacement therapy (CRRT) has dramatically increased in the past decade, there remains an important role for acute PD in preterm neonates with limited vascular access and patients admitted to the ICU following surgery for congenital heart defects [81, 82]. Acute PD is still the modality of choice in many countries, especially in the developing world [83–85] as it is a relatively inexpensive form of dialysis that does not require sophisticated technical expertise or equipment. It avoids the risks and complications associated with extracorporeal perfusion, including the possible need for blood-product exposure and systemic anticoagulation. Additionally, large volumes of fluid can be removed slowly over a prolonged period, maintaining hemodynamic stability. Due to the relatively slower solute clearance, including that of nitrogenous waste products, it is not associated with dialysis disequilibrium, which may occur in acute intermittent HD.

Initiation

An in-depth discussion regarding PD access is provided in Chap. 63. In brief, PD does not require vascular access, which can be a challenge in infants and small children, and provides a means for critically ill patients to be dialyzed with preservation of vascular access, thus allowing for rapid institution of therapy even in the less hemodynamically stable patient. Access can be obtained using semi-rigid stylet catheters requiring a trochar and canula method of insertion, the main advantage of which is the ease of bedside insertion by the pediatric nephrologist without surgical intervention and general anesthesia [86]. In patients who can tolerate a surgical procedure, placement of a tunneled permanent catheter is preferred to semi-rigid, temporary catheters to reduce technical complications such as leaks and catheter obstruction [87]. Newer acute placement techniques are performed with soft catheters, often where a Seldinger technique is utilized to insert the catheter over a guidewire (Fig. 52.2). This technique can be well-utilized in infants as it carries a minimal risk of dialysate leakage since no incision is required for the catheter insertion. Consequently, the risk of peritonitis is less, and

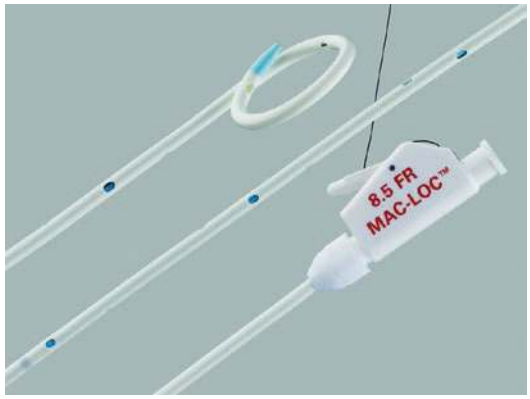

Fig. 52.2 Peritoneal dialysis catheter using Seldinger technique for insertion (8.5FR Mac-Loc™)

these catheters can be kept for up to 5 days without complications [87].

Prescription and Technique

The dialysis prescription for acute PD comprises four major components: the exchange volume, dialysate composition, individual cycle time, consisting of fill, dwell and drain, and total length of the dialysis session. For acute PD, the target exchange fill volume for adequate dialysis in terms of fluid and solute clearance, without the risk of leakage, is 30 mL/kg. However, smaller initial volumes of 10 mL/kg may be used for at least 24–48 h, if there is a risk of leakage from a wide incision site or if a tunneled cuffed catheter is used. Initially, short dwells (e.g. 30 min or hourly exchanges) for 48–72 h are required to remove accumulated solutes and excess fluid. Volume and metabolic control may best be achieved with exchanges performed around-the-clock. Subsequently, in maintenance dialysis, the dwell times can be extended, and total daily therapy time may be reduced, similar to chronic PD, with increasing volumes up to 40–45 mL/kg if a cuffed catheter has been used. PD should be continued until urine output improves, indicating recovering renal function.

Commercial dialysate solutions are available differing in osmolality, osmotic agent, and buffer. The osmotic agent is typically dextrose in a variety of pre-prepared concentrations. The hypertonic dextrose solutions utilized in PD provide a source of additional calories that may be beneficial in the critically ill child where IV access for nutrition and maintenance of glycemia may be limited; conversely, hyperglycemia may result from dextrose used in dialysate and insulin therapy may be required [88].

Complications

PD is contraindicated in patients with diaphragmatic defects, omphalocele, gastroschisis, and bladder exstrophy [89]. Complications with PD include catheter malfunction, peritonitis, and poor ultrafiltration. Neonates may have poor drainage due to catheter malposition or kinking, omental wrapping or a fibrin clot, which is exacerbated by the relatively small-bore peritoneal catheters required in the smallest patients. Inadequate drainage may also occur due to constipation. Bedside PD catheter placement with a semi-rigid trochar is associated with a risk of viscus perforation, especially in neonates, both at the time of insertion and with increasing dialysis duration. Severe abdominal pain and shock may occur, and the catheter must be removed for bowel repair and treatment of sepsis. The incidence of peritonitis is highest with the semi-rigid catheter, particularly if it has been kept in place for longer than 72 h [86]. In some cases, patients may develop a diaphragmatic pleuroperitoneal communication following cardiothoracic procedures, which results in a large pleural effusion once PD is initiated. Hypothermia is a complication of PD, particularly in neonates and small children, if dialysate is not warmed prior to infusion into the peritoneal cavity.

Poor ultrafiltration may occur, especially in critically ill infants due to the low fill volume with inadequate fluid reservoir intraperitoneally. Often it is difficult to increase the dwell to the desired volume in the setting of infant acute respiratory distress and low lung volumes as the increasing peritoneal fluid fill volumes results in splinting of the diaphragm. In some cases, during the inflow phase, critically ill infants may desaturate, and require transient compensation in ventilatory pressures. As a result, there is poor ultrafiltration, which increases the fluid retention, thus worsening the respiratory distress. These ill patients are often hypotensive requiring multi-agent inotropic and pressor support. The resultant

decrease in bowel perfusion due to vasoconstriction of the mesenteric vessels secondary to pressor support may also contribute to poor ultrafiltration. Additionally, in neonates there is a decrease in the osmotic gradient, because of increased absorption of dextrose from the dialysate, resulting in poor ultrafiltration. With the use of higher dialysate dextrose concentrations to facilitate ultrafiltration, hyperglycemia may occur and necessitate insulin administration.

Electrolyte abnormalities may occur with PD. Hypokalemia may occur, and if noted, potassium should preferably be added to the IV fluid if the patient is not feeding, rather than adding to the dialysate, to avoid frequent bag changes due to changing orders. Potassium can be added to the dialysate if the hypokalemia is severe enough such that the maximum safe concentration of potassium infusion will be exceeded.

Acute Intermittent Hemodialysis

In many countries, acute intermittent HD is the mainstay of dialysis for AKI, particularly in older children. Its main advantage is rapid ultrafiltration and solute removal. It is therefore indicated in AKI that requires rapid fluid removal (acute fluid overload) or rapid solute removal such as hyperkalemia, tumor lysis syndrome, toxic poisonings and other profound metabolic abnormalities. Acute intermittent HD is ideal for hemodynamically stable patients who can tolerate rapid fluid shifts. It is a versatile modality as it allows for ultrafiltration without solute removal, as well as adjustment of the dialysate bath to treat electrolyte abnormalities such as hypernatremia. Moreover, because of the intermittent nature of the dialysis, patients can be mobilized for other procedures. Systematic reviews have suggested that in hemodynamically stable adult patients the continuous forms of RRT do not appear to have a survival advantage over intermittent HD [90–92].

Initiation

When initiating acute HD, one must consider vascular access, HD prescription, and type of dialyzer membrane. Other factors include the patient's ability to tolerate rapid fluid shifts, the need for vasoactive substances to maintain blood pressure, and total fluid removal goals.

Vascular access for HD is discussed in detail in Chap. 65. As with all extracorporeal therapies, treatment success is dependent on the quality of the vascular access. Adequate blood flow (Qb) is essential to providing optimal therapy with minimal interruption. In pediatric patients, the choice of vascular access, catheter size, and insertion site is critical. Short, large bore catheters provide improved performance due to lower resistance to flow [93]; conversely, longer, smaller-bore catheters (e.g. Broviac catheters) are unsuitable due to their high flow resistance.

The HD prescription in AKI must be individualized to provide adequate solute clearance and fluid removal. The prescription for acute intermittent HD is comprised of the dialysis dose delivered per session and the frequency of the sessions. Additional factors affecting the individual HD prescription include the extracorporeal circuit volume, the dialyzer size, blood flow rate, dialysate flow rate, ultrafiltration required, dialysate composition, anticoagulation, and length of session. Blood flow rate is determined by vascular access and determines solute clearance, with higher blood flow increasing solute clearance by optimizing diffusion and convection. Dialysate flow rate is also a determinant of solute clearance [94]. Dialysate flow rate should be at least 1.5 times greater than the blood flow rate to maximize diffusion gradients of solutes. In pediatric patients, HD equipment and prescription require modifications for smaller children (i.e., infants less than 3 kg).

When initiating acute HD for AKI, dialysis dose delivered may change frequently with a need for greater renal support during initial therapy for AKI, as compared to the relatively stable initial dialysis doses provided in initiating chronic HD for end-stage renal disease [95]. Similarly, in patients receiving chronic HD, urea kinetic modeling (Kt/V) is utilized as a measure of dialysis adequacy; however, due to the rapidity of fluid shifts with therapy and frequently changing renal function, Kt/V may not be as reliable in the patient with AKI receiving HD [96]. A review of dialysis dosage in adults concluded that in AKI

a Kt/Vurea greater than 1.2 from thrice weekly intermittent HD is associated with improved survival in patients with intermediate severity of illness but does not influence outcomes in more severely ill patients [97]. Increased acute HD treatment frequency may be required despite reaching "adequate" Kt/V to achieve daily fluid removal goals. Although Kt/V recommendations exist, dialysis dosage must be individualized and higher doses of therapy for various metabolic derangements may be required in AKI [97].

The total volume of the extracorporeal circuit includes the volume of the tubing and the dialyzer and should not exceed more than 10% of the patient's blood volume, calculated as 75 mL/kg for older children and 80 mL/kg for infants. If the extracorporeal blood volume exceeds 10–15% of the patient's total blood volume, or the patient has a low hematocrit and/or hemodynamic instability, a blood prime is recommended [98]. When initiating a blood prime, using buffered packed red blood cells (PRBC) or transfusing the PRBC post-membrane in conjunction with a saline prime have been shown to reduce risk of "bradykinin release syndrome" (BRS) [99]. BRS, characterized by a precipitous decline in blood pressure 5–10 min after initiating both acute HD and continuous RRT, has been associated with the use of the AN-69 polyacrylonitrile membrane [99, 100]. Exposure of the primed blood to the negatively charged AN-69 membrane co-activates pre-kallikrein and Hageman factor, resulting in the release of bradykinin, a potent vasodilator. The reaction is potentiated by exposure to blood with an acid pH, which is typical of banked blood used for blood priming the circuit. Thus, the use of a blood prime with an AN-69 membrane can result in profound hypotension. PRBCs to be used in a blood prime should be diluted with normal saline to produce a hematocrit of approximately 35–40%. Buffering the banked blood for priming to physiologic pH prior to priming the circuit or infusing the blood post-filter at the same rate as a saline prime have been shown to be effective in minimizing the BRS, as has avoidance of the AN69 membrane [101, 102].

Dialyzer selection considers the type of membrane desired, the need for a blood prime, the dialyzer membrane surface area, and the ultrafiltration coefficient [103]. The membrane properties of the dialyzer, such as membrane thickness, pore size, and pore density affect dialysis efficiency, with varying clearances for small and middle molecular weight solutes. Dialyzer membrane biocompatibility should be considered when initiating acute HD. See Chap. 66 for additional information on this topic. The use of biocompatible synthetic membranes does not appear to confer any significant clinical advantage either in terms of mortality or AKI recovery when compared to substituted cellulosic membranes [104, 105]. High-flux membranes have larger pores resulting in greater clearances of higher molecular weight solutes but have the risk of back transport from the dialysate of water-borne solute contaminants. In a systematic review comparing the use of high-flux and low-flux membranes in AKI in adults, there was no difference in the risk of mortality or dialysis dependence in survivors [105]. However, in another meta-analysis, there appeared to be a significantly improved renal function recovery with the use of high-flux membranes [104]. High-cut-off-point membranes made from polyamide/polyarylethersulfone, polysulfone, or cellulose triacetate, have greater cytokine clearance and enhanced adsorption properties than conventional high-flux dialyzers [106], and have been developed for use in septic patients with AKI [107, 108]. Treatment using high-cut-off-point membranes has been shown in animal models of sepsis to have beneficial effects on immune cell function and survival [109]. Preliminary clinical studies show that use of these membranes in adult patients with AKI was associated with decreased need for vasopressor therapy, with no reports of serious adverse effects [108].

The smaller blood volumes in infants and young children place them at risk for blood loss due to clotting of the dialyzer; thus, anticoagulation is required with acute intermittent HD for pediatric AKI. Heparin is the most commonly used anticoagulant for intermittent HD. A loading dose of heparin may be given at the start of dialysis followed by intermittent bolus heparin doses. To monitor therapy, the activated partial

thromboplastin time (aPTT) or activated clotting time (ACT) may be used. The aPTT should be kept at 1.2–1.5 times the baseline, and the ACT between 120 and 180 s. When heparin is utilized, platelet count should be monitored frequently to assess for development of heparin-induced thrombocytopenia [110]. In coagulopathic patients, heparin-free dialysis can be performed by intermittently flushing the circuit with 0.9% saline; unfortunately, this method increases the ultrafiltration target and decreases dialysis efficiency [111–113]. When using saline anticoagulation, the filter pressure should be monitored, and dialyzer inspected for early clot formation. Regional citrate anticoagulation is also an alternative to systemic heparin anticoagulation in the coagulopathic patient [114] requiring HD for AKI.

Complications

HD in young children can be challenging due to the smaller patient blood volume. This problem is accentuated in the critically ill child, where pressor infusion may be required to support the systemic blood pressure. Moreover, these children may have acute respiratory distress syndrome with hypoxemia or other associated clinical problems such as congestive heart failure or cerebral edema. Therefore, maintenance of an adequate blood pressure in these children is critical to alleviate tissue hypoxia.

Rapid HD using dialyzers with larger surface areas in patients with very high plasma blood urea nitrogen (BUN) concentrations may result in the dialysis disequilibrium syndrome, characterized by neurological symptoms such as fatigue, headache, nausea, vomiting, altered consciousness, convulsions, and coma [115]. Patients with AKI may be at increased risk due to catabolism (high BUN) and pre-existing neurological compromise related to the acute illness. Measures to prevent the disequilibrium syndrome include decreasing the initial dialysis dose, increasing dialysate sodium concentration (143–146 mmol/L), and administration of osmotically active substances such as IV mannitol (0.5–1 g/kg) to prevent rapid osmolar shifts that can cause cerebral edema [116].

Hypotension is one of the most common complications with acute intermittent HD and occurs in part due to rapid fluid and solute removal. Technical advances in the delivery of HD have dramatically reduced the propensity for intradialytic hypotension. The use of volume-controlled dialysis machines and biocompatible synthetic dialysis membranes helped decrease the incidence of intradialytic hypotension. In adult studies, it has been demonstrated that priming the circuit with isotonic saline, discontinuing vasodilator therapy, keeping the dialysate sodium greater than 145 mmol/L and setting the dialysate temperature to below 37 °C result in lesser hemodynamic instability and better outcomes [117]. See Table 52.3 for a summary of recommendations to minimize hemodynamic instability with acute HD. Additionally, use of in-line noninvasive blood volume monitoring to minimize abrupt changes in extracellular volume is useful in young children with hemodynamic instability where large acute changes in extracellular volume are not well tolerated [118]. This method of performing intradialytic noninvasive blood volume monitoring indicates intravascular blood volume change during the dialysis session (Fig. 52.3).

Catheter site complications are possible in acute HD and include infection at the catheter exit site, catheter malfunction, and risk of

Table 52.3 Techniques to improve hemodynamic tolerance of intermittent hemodialysis

All patients:
Use only synthetic or modified cellulose membrane
Connect both lines of the circuit filled with 0.9% saline simultaneously to the central venous catheter
Set dialysate sodium concentration ≥145 mmol/L
Limit maximal blood flow to 150 mL/min with a minimal 4 h session
Set dialysate temperature at ≤37 °C
Advice for hemodynamically unstable patients:
Cool dialysate to 35 °C
Start session with dialysis and continue with ultrafiltration alone
Additional recommendations:
Stop vasodilator therapy

Used with permission of the American Thoracic Society from Schortgen et al. [117]

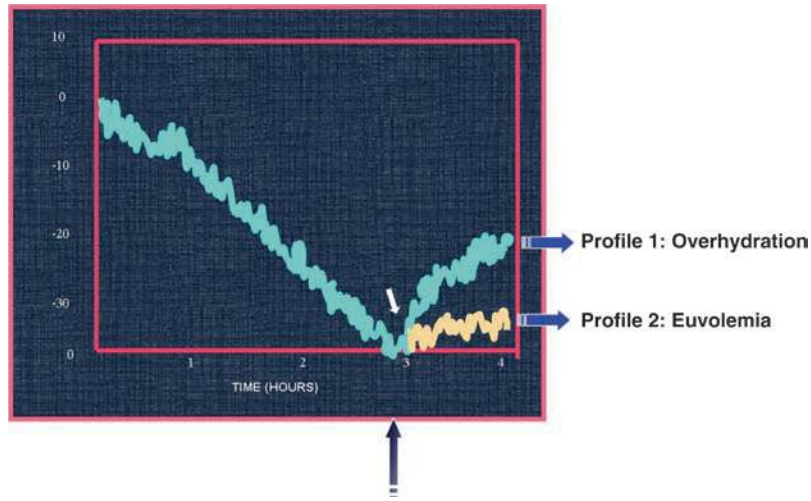

Fig. 52.3 Intradialytic noninvasive blood volume monitoring: Profile 1: overhydration. Profile 2: euvolemia

hematologic disturbance (e.g. bleeding, clot). In the event of signs of infection such as fever, line blood cultures should be obtained, and empiric antibiotics started. There is also risk for clotting of the extracorporeal system in acute HD; this can place patients at risk for acute blood loss if the blood is unable to be returned to the patient.

Continuous Renal Replacement Therapies

CRRT is now widely available in pediatric centers throughout the world, and in some has become the preferred method of RRT. CRRT in AKI offers several advantages over traditional dialysis methods when used in critically ill, unstable patients. Because CRRT is continuous, removal of solutes and modification of the volume and composition of the extracellular fluid occur gradually. Unstable patients, who are often intolerant of the abrupt fluid volume and solute concentration changes that accompany standard HD treatments, can be successfully treated with CRRT. The precision and stability with which fluid and electrolyte balance can be maintained using CRRT is unmatched by any currently available dialysis therapies, except perhaps the extended HD techniques mentioned in the following section.

The basic principles of CRRT are similar for adults and children. However, the application of these modalities in children requires attention to several important details unique to therapy in pediatric patients. For example, extracorporeal blood volume may be large compared to the patient blood volume, necessitating blood circuit priming in the very small child as described in the section on acute HD (see "acute intermittent hemodialysis," above). The most demanding considerations arising in pediatric CRRT are related to the need to adapt equipment and prescriptions designed for adult-size patients in order to meet the special needs of the smallest of pediatric patients requiring renal support.

Initiation

The indications for initiating CRRT in children and adults are similar and most often involve the treatment of AKI and fluid overload in a critically ill patient [20, 119]. CRRT may be combined with extracorporeal membrane oxygenation (ECMO) and plasmapheresis circuits.

CRRT refers to a variety of modalities that use one or both solute clearance mechanisms. In continuous venovenous hemofiltration (CVVH), blood flows through the hemofilter, generating large volumes of ultrafiltrate, which is replaced by a physiologic "replacement fluid," either before (pre-dilution) or after (post-dilution) the hemofilter (Fig. 52.4a). Clearance is thus exclu-

sively convective. If a dialysate is infused into the hemofilter, clearance is primarily diffusive, as in HD. Hence, this CRRT modality is called continuous venovenous HD (CVVHD, Fig. 52.4b). When both replacement fluid and dialysate are used, permitting convective and diffusive clearance, the therapy is known as continuous venovenous hemodiafiltration (CVVHDF, Fig. 52.4c).

Initiation of CRRT also requires adequate vascular access, as discussed previously and in Chap. 65.

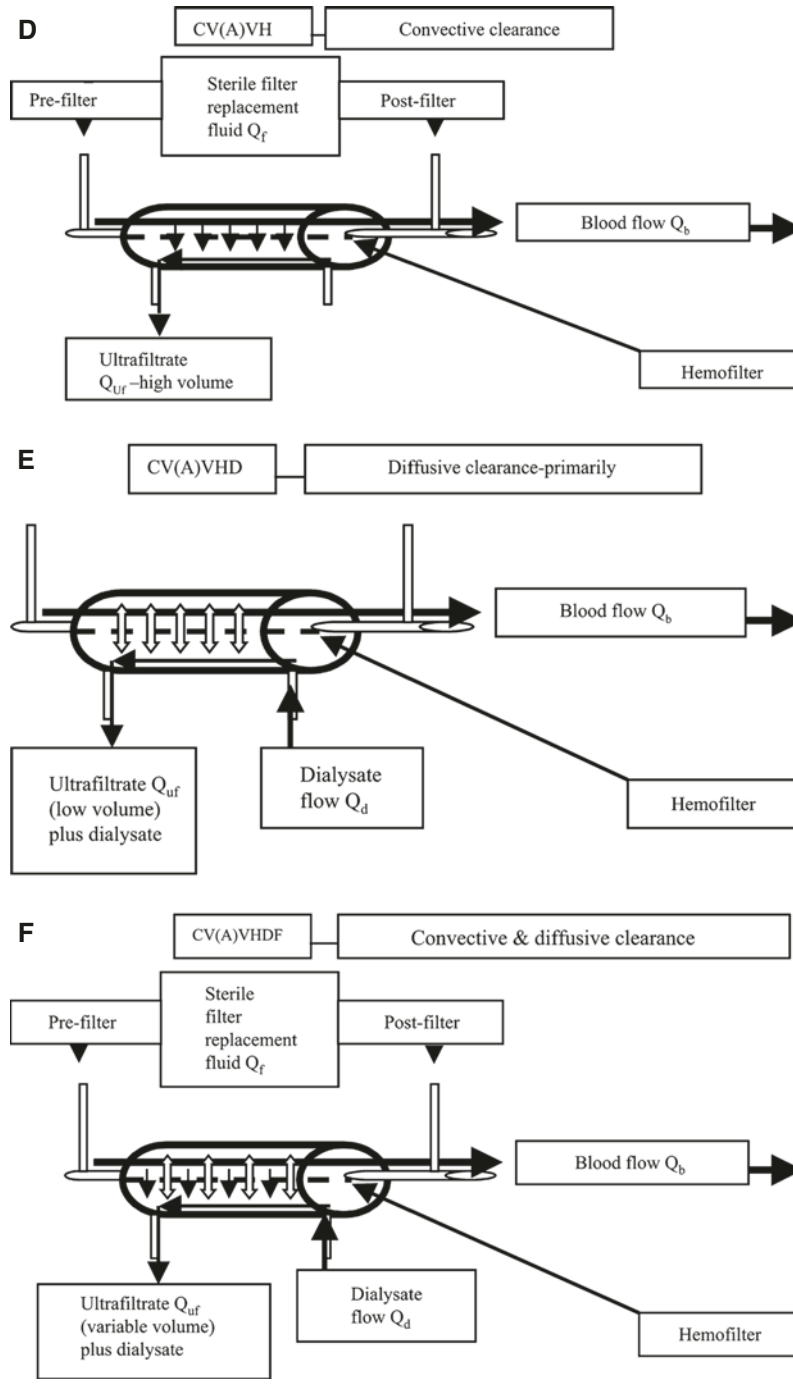

Fig. 52.4 (**a**) Diagram of a convective based (CVVH) continuous renal replacement therapy (RRT). Note use of either pre- or post-filter replacement fluid rather than dialysate. (**b**) Diagram of diffusion based (CVVHD) continuous RRT. Note use of dialysate rather than replacement fluid. Dialysate flow is countercurrent to blood flow. (**c**) Diagram of combined convective and diffusive based (CVVHDF) continuous RRT. Note use of both dialysate and replacement fluids

Blood Flow Rates

With a well-functioning vascular access, it is possible to adjust Qb based on to the size of the child and the clinical setting. Higher Qb may support longer filter life by reducing the likelihood of filter fiber clotting. Higher Qb also facilitates increased patient fluid removal by providing greater filter plasma flow rates and reduces the loss of clearance efficiency from pre-dilution mode CVVH or CVVHDF. However, not all patients will tolerate a higher Qb, especially at initiation of CRRT. Hence, we suggest initiating CRRT with lower Qb and advance to the targeted rate over the first 30 min of therapy as tolerated. In contrast to pediatric HD where initial Qb can be readily extrapolated from patient body weight, there are no true "body-weight" recommendations for Qb in any form of pediatric CRRT. The Qb chosen should provide adequate clearance for the size of the patient, with consideration of access limitations and device requirements. Recommendations for Qb range from 4 to 10 mL/kg/min; consequently, Qb may vary widely in CRRT. Depending on the patency of the access, the Qb may need to be higher to maintain flow. For example, 10–12 mL/kg/min may be necessary to accommodate technical requirements (access) and clearance in extremely low birth-weight neonates while 2–4 mL/kg/min may be appropriate in larger adolescents.

Solutions

The tolerability of CRRT has been greatly improved with the introduction of bicarbonate-based CRRT solutions. In the past, with lactate as the buffer, worsening lactic acidosis was common, leading to hypotension and depression of cardiac function [120]. A series of comparative clinical trials of lactate- and bicarbonate-based CRRT fluids in adults [121, 122] and children [123] have demonstrated the superiority of bicarbonate as a buffer; consequently, bicarbonate-based CRRT solutions are now the standard of care, although trace amounts of lactate may be used in solutions to maintain stability.

CRRT solutions also contain sodium, potassium, chloride, glucose, calcium, phosphate, and magnesium. Bicarbonate-based CRRT solutions are available from several manufacturers in a wide array of electrolyte formulations. Most hospital pharmacies stock only a single brand and in only a few formulations. A feature of CRRT, especially in small patients, is the tendency over time for the composition of the CRRT fluids to determine the electrolyte composition of the patient. A fluid low in potassium, phosphorous and magnesium may be appropriate at initiation of CRRT when concentrations of these electrolytes in AKI patients are often elevated. However, depending on the CRRT prescription, within a short time the patient may become deficient in these electrolytes, which can complicate management. Thus, while a "starter" fluid with reduced potassium, phosphorous and magnesium is needed, a fluid that includes these electrolytes in physiologic concentrations should follow. Rather than stocking multiple formulations, some pharmacies may prefer to add potassium, phosphorous, magnesium and even additional bicarbonate to the "starter" solutions as needed, a practice that may add the risk of pharmacy errors and increase costs. Calcium is always left out of solutions when phosphate is present to avoid precipitation. Calcium has usually, but not always, been left out of CRRT solutions used with citrate anticoagulation, as will be discussed below.

Prescription

The optimal "dose" of RRT is not known. Adult AKI studies by Ronco and colleagues using CVVH established a total convective clearance (replacement fluid plus patient fluid removal) target of 35 mL/kg/h as a threshold below which survival was significantly worse [124]. In a subset of these patients with sepsis, there was a trend in favor of improved survival with total convective clearance ≥45 mL/kg/h. Despite theoretical considerations that seemed to favor high clearance targets in cytokine-driven illnesses like sepsis [125] and preliminary results in septic adults treated with very high flow CRRT [126], available evidence does not support the use of clearance targets above 20–35 mL/kg/h. For pediatric patients, this translates to 2–3 L/1.73 m^2/h, rates that are reasonably easy to achieve.

Anticoagulation

Effective CRRT requires optimal anticoagulation. Activation of the clotting cascade occurs in CRRT circuits due to contact of the circulating blood with artificial surfaces. Low blood flow rates, turbulent flow, small catheters and high hematocrits hasten clotting. Anticoagulation regimens using mixed molecular weight heparin or sodium citrate are the most commonly used in pediatric CRRT, and either can be effective. An early comparison in pediatric centers showed equal filter life span with heparin and citrate, but more hemorrhagic events in the heparin group [127].

Heparin has been the mainstay of HD anticoagulation for decades. Many pediatric CRRT programs continue to rely on heparin. Heparin is infused in the CRRT circuit pre-filter and titrated to achieve a targeted post-filter activated aPTT 1.5–2 times normal, or an ACT between 180 and 220 s. This is usually accomplished by giving an initial heparin bolus of 20–30 units/kg, followed by a continuous infusion of 10–20 units/kg/h. Alternatively, the circuit may be rinsed and primed with 1–2 L of normal saline to which has been added 2500–5000 units/L of heparin, followed by the pre-filter heparin infusion.

Sodium citrate anticoagulation is widely used in pediatric CRRT programs due to its ease of administration and decreased bleeding risk [128]. By infusing citrate into the arterial limb of the CRRT tubing as it leaves the catheter, calcium ions are bound to the citrate, reducing available calcium and thereby inhibiting coagulation within the circuit, since normal coagulation is calcium-dependent. Systemic hypocalcemia is prevented by infusion of either calcium gluconate or calcium chloride into the patient at a central site. Thus, citrate anticoagulation achieves regional anticoagulation by affecting only the circuit, thereby eliminating the increased risk of bleeding with heparin. Since the original citrate protocol employing 4% trisodium citrate (440 mEq/L sodium), newer modifications utilize anticoagulant citrate dextrose "A" (ACD-A), a less-concentrated formulation, which is also commonly used as the anticoagulant in apheresis procedures.

Adverse effects of citrate anticoagulation include acid-base disturbances, citrate excess and hyperglycemia in infants when ACD-A is used. Patients receiving citrate anticoagulation may develop metabolic alkalosis; fortunately, citrate is readily cleared by dialysis [129]. Citrate excess may be diagnosed by monitoring the ratio of the total calcium to the ionized calcium levels [130]. If hepatic metabolism of citrate is insufficient, citrate accumulates; thus, patients with diminished liver function are at increased risk for citrate excess. Citrate excess can occur when citrate clearance is less than citrate delivery. Citrate is not inherently toxic, but citrate excess causes systemic hypocalcemia. Total calcium levels rise and the ratio of total calcium to systemic ionized calcium levels rises precipitously. As citrate accumulation progresses, it becomes more difficult to maintain the declining systemic ionized calcium levels within normal ranges. Monitoring of ionized calcium is the most sensitive way to detect citrate accumulation [131]. Treatment often requires increasing the removal of citrate by increasing clearance within the circuit (i.e., increased dialysate and/or replacement fluid rate); this assures ongoing anticoagulation while balancing the build-up of citrate in the patient. An initial citrate infusion rate of 50–70% of the usual rate is also recommended in patients with hepatic insufficiency who are at increased risk for citrate toxicity. A pediatric citrate anticoagulation protocol using bicarbonate dialysate has been published [132].

It is also possible in certain situations to use no anticoagulation, relying on periodic saline flushes of the circuit. This approach is typically considered in larger patients with evidence of a sustained coagulopathy due to disseminated intravascular coagulopathy or hepatic failure. However, many of these patients are receiving periodic fresh frozen plasma and platelet infusions to correct the underlying coagulopathy; these infusions will clot a CRRT system when no anticoagulation is used. Moreover, patients with hepatic failure may have a paradoxical hypercoagulable state. An uncontrolled study demonstrated that the no coagulation/saline flushes approach was associated with an inferior circuit life span compared to heparin or citrate anticoagulation [127].

CRRT Use in Combination Therapies

Extra-corporeal Membrane Oxygenation

The widespread use of ECMO in neonatal and pediatric critical care units along with the common occurrence of AKI in these patients with multi-organ dysfunction has led to the need to incorporate CRRT into the ECMO circuit. Fluid overload at CRRT initiation has been shown to be a consistent factor associated negatively with survival in ECMO and preventing the development of significant fluid overload at the outset of ECMO may be more clinically effective than attempting fluid removal later in therapy [133].

The ECMO circuit is fully heparinized, eliminating the need for anticoagulation of the CRRT circuit. Blood flow in the ECMO circuit is often 20–30 times that required for optimal CRRT. Newer ECMO circuits with multiple access phalanges allow the insertion of the CRRT circuit in an entirely pre-oxygenator location, avoiding shunt of oxygenated blood from the patient when the CRRT circuit is placed in a post- to pre-oxygenator position. Close collaboration between CRRT and ECMO teams is required to find the best location for the CRRT circuit and to coordinate therapy goals [134].

Plasma Therapy

Patients with AKI secondary to immune complex–mediated disease and sepsis-associated thrombotic microangiopathy may require both CRRT and plasma therapies (i.e., plasmapheresis, plasma exchange) [135]. CRRT is readily combined concurrently with plasma therapy procedures without interrupting the CRRT circuit. The placement of a three-way stopcock at both arterial and venous limbs of the CRRT circuit at the connection to the double lumen catheter allows diversion of blood through the centrifugation plasmapheresis machine [136].

Plasma exchange removes inflammatory mediators and replaces the volume with fresh frozen plasma in attempt to correct underlying homeostatic abnormalities; conversely, plasmapheresis removes plasma with inflammatory mediators, but replaces the volume with a non-plasma solution (usually albumin) [137]. Additionally, CRRT is believed to have an immunomodulatory effect on inflammatory cytokines in sepsis; however, the impact on patient outcome in sepsis remains unclear and the primary role remains management of fluid overload [138]. CRRT may downregulate the inflammatory response through nonselective extracorporeal removal, mainly by absorption, of cytokines and other mediators, restoring hemodynamic and immunologic homeostasis [139]. One retrospective study demonstrated benefit of isovolemic hemofiltration followed by conventional continuous venovenous hemofiltration in patients with septic shock and oliguric AKI with subsequent improvement in oxygenation and mean arterial pressure as well as significant improvement in survival at 28 days versus those receiving conventional supportive therapy [140].

Complications

CRRT requires the patient to remain relatively immobilized while connected to the CRRT circuit for prolonged periods. As a result, small children typically require sedation and occasionally even pharmacological paralysis to prevent small movements that may disrupt flow in the CRRT circuit. Additionally, a relatively large fraction of total circulating blood volume is in the extracorporeal circuit, placing the child at substantial risk for hypothermia during CRRT. Careful temperature monitoring is required during RRT, particularly when combination therapies are utilized. In-line fluid warmers can be used but increase priming volume. Line warmers that can be applied to the return line offer the best results.

Outcome

The Prospective Pediatric CRRT (ppCRRT) Registry reports an overall pediatric CRRT survival rate of 58% [80]. Survival of pediatric patients treated with CRRT has been reported in single center studies to vary widely by disease and modality [20, 141, 142]. A single center study initially demonstrated that the degree of fluid overload was an independent determinant of outcome in pediatric patients treated with CRRT [20], and that was confirmed by a large multicenter study from the ppCRRT Registry [80].

Patient survival was inversely correlated with percentage fluid overload at initiation of CRRT: survivors had a mean fluid overload of 14.2% while in non-survivors had a mean fluid overload of 25.4%, a difference that was highly significant and independent of diagnosis or severity of illness [20]. Further analysis of the ppCRRT Registry data demonstrated that 20% fluid overload was associated with four times the mortality of pediatric patients receiving CRRT when compared to patients with less than 10% fluid overload at initiation of CRRT [80]. These data suggest that earlier initiation of measures to control fluid accumulation, including CRRT, may improve survival.

Extended Hemodialysis Techniques

Extended hemodialysis techniques, also known as hybrid therapies, utilize intermittent hemodialysis machine technology while providing the slower solute and fluid removal associated with continuous RRT for use in less stable patients with AKI [143, 144]. The terms for these modalities include sustained low-efficiency daily dialysis (SLEDD) or extended daily dialysis (EDD) or slow continuous dialysis (SCD) [145].

SLEDD is a dialytic modality that allows for flexible options in treatment duration, prolonged or even continuous treatments, using conventional dialysis machines with varying pump speeds for 6–18 h daily [146]. Variants such as sustained low-efficiency daily diafiltration (SLEDD-f), aimed at improving clearance of middle molecular inflammatory mediators of the systemic inflammatory response associated with sepsis, have been developed for clinical use [92, 147]. Advantages of SLEDD-f over CVVHDF include faster clearance of small solutes and fluid removal yet maintaining hemodynamic stability [148]. It allows flexible therapeutic schedules so that patients are accessible and can be mobilized for other medical treatments.

Hybrid therapies also have lower heparin requirement than CRRT, but less frequent clotting. The reported incidence of clotting is 17–26% with heparin, while the reported incidence of circuit clotting without anticoagulation is 24–26% using single pass machines and lower using batch systems [149]. Hybrid therapies, with the high diffusive capacity for solutes, are able to correct alkalosis or hypernatremia, while at the same time removing the calcium chelated citrate complexes in citrate anticoagulation, an advantage in patients with liver failure [150]. With hybrid therapies, phosphate removal can be very extensive. Hypophosphatemia and metabolic alkalosis is easily induced in a critically ill patient, especially those on prolonged parenteral nutrition; therefore, preemptive fluid correction with phosphorous and reduction in dialysate bicarbonate are often warranted.

Conclusion

AKI is common in hospitalized children and associated with high risk of mortality and long-term morbidity. Recent advances in the understanding of the pathophysiology of AKI have pointed to newer diagnostic and therapeutic strategies that focus on early recognition and treatment. Exciting developments in technology have made RRT more accessible and more easily applied in the pediatric setting. Yet, despite these advances, mortality rates among children with AKI remain disturbingly high. Hopefully, future developments will improve outcomes for children with AKI.

Neonatal Kidney Dysfunction

53

Isabella Guzzo, Stefano Picca, and David Askenazi

Kidney Function in Neonates

At birth, the kidney replaces the placenta as the major homeostatic organ, maintaining fluid and electrolyte balance and removing harmful waste products. In a healthy term neonate, dynamic changes to renal blood flow occur which lead to alterations in glomerular filtration rate (GFR) over the first few months of life. Tubular development is intact such that conservation or elimination of electrolytes and water are efficient and adequate. Alternatively, the glomerular, tubular and vascular regulation of the kidney in premature infant are abnormal compared to the healthy term counterpart. Describing the "normal" renal physiology in preterm neonates is difficult (as one can argue they are all abnormal); understanding how a term neonate maintains renal blood flow, glomerular filtration and tubular function is critical to extrapolation of how the premature infant's underdeveloped/immature kidneys function. As we describe neonatal homeostasis, we will contrast the physiology of the "normal" healthy term infant to those of premature infants, understanding that the degree of immaturity and the neonatal course will affect the ability of premature infants "normal" homeostasis.

Healthy term infants are ready to maintain homeostasis of water, electrolytes, and acid/base. In addition, their kidneys function to metabolized drugs/toxins, and eliminate waste products. As the clinician has an integral role in prescribing fluids, electrolytes, and nutrition, proper homeostasis in sick term/near term newborns and premature infants depends on the clinicians' ability to appropriately prescribe fluids, nutrition and electrolytes. Infants who lack ability to remove uremic toxins and maintain appropriate electrolyte/fluid balance with medical management rely on nephrology teams to support the neonate with dialytic therapies designed to maintain homeostasis.

Renal Blood Flow in Newborns

Starting with delivery and umbilical cord clamping, major hemodynamic changes occur in renal blood flow which drive changes in neonatal glomerular filtration rate. The proportion of cardiac output distributed to the kidney changes abruptly. Fetal kidneys receive approximately 2.5–5% of cardiac output at birth [1], which increases to 6%

by 24 h of life [2, 3], steadily escalates to 10% at 1 week of life, and attains 15–18% at 6 weeks of life [4] as it approaches the fractional cardiac output to the kidneys observed in adults (approximately 20–30%). These dynamic changes in renal blood flow are driven by both increased systemic blood pressure and a substantial decrease in renal vascular resistance. The abrupt and significant drop in renal vascular resistance is due to a redistribution of renal blood flow within the kidney, changes in the number of vascular channels and changes in glomerular arterial resistance [5]. Initially, renal blood flow primarily extends to the outer cortex which gradually distributes to medullary sections over the first few months of life [6].

The auto-regulatory mechanisms which control renal blood flow are driven by both the myogenic reflex of vascular smooth muscles and the tubule-glomerular feedback system. These reflexes aim to maintain constant blood flow by sensing vascular endothelial stretch and distal tubular fluid flow respectively. Nitric oxide, angiotensin II, adenosine, bradykinins, and endothelin play a central role in maintaining adequate blood flow.

The renin angiotensin system is active throughout fetal development and contributes to normal fetal maturation. Congenital abnormalities (i.e., defects to angiotensin II receptors) and secondary abnormalities (i.e., maternal use of angiotensin converting enzyme inhibitor) can significantly affect kidney development. Prostaglandins (potent vasodilators) also serve to increase renal blood flow by active vasodilation of afferent arterioles. These agents are increased in times of stress and help counteract vaso-constrictive effects of angiotensin II and catecholamines. Prostaglandins and inhibitors of prostaglandins are commonly prescribed in neonatal medicine to maintain patency, or electively close patent ductus arteriosus; respectively. Such dynamic changes in renal blood flow, alterations in hemodynamics, and medications to promote vasoconstriction/ vasodilation will greatly affect glomerular filtration rate in neonates.

Glomerulogenesis

Kidney development commences during the 5th week of gestation with partially functional temporary organs (the pronephros and metanephros). The first nephrons are formed by about the 8th week of gestation and increase over time. Four glomerular generations are present after 14 weeks and 12–13 generations of glomeruli after 36 weeks of gestation [7]. The juxtamedullary nephrons develop initially, with superficial ones following. Nephrogenesis continues until 36 weeks of gestation at which time the number of nephrons, 1.6–2.4 million, approximates that of an adult [8]. Autopsy studies suggest that the extra-uterine environment is not amenable to neo-glomerulogenesis, leading to a low nephron number in premature infants [9]. Thus, the premature infant may be programmed for low nephron endowment, and subsequent chronic kidney disease.

In individuals with a lower number of nephrons, single-nephron hyperfiltration can increase total GFR to a similar level as attained by those with normal numbers of glomeruli. However, the impact of low nephron endowment may become problematic over time as single nephron hyperfiltration may cause glomerulosclerosis and ultimately progressive loss of kidney function, especially in the context of other risk factors for CKD such as acute kidney injury, hypertension, diabetes, and other primary kidney diseases.

Glomerular Function Rate (GFR)

GFR is the most useful measurement of kidney function. GFR is measured indirectly through the concept of clearance (the equivalent volume of plasma from which a substance would have to be totally removed to account for its rate of excretion in urine per unit time). Clearance is calculated by dividing the excretion rate of a substance by its plasma concentration ($C_x = U_x \times V$); where U_x and P_x are urine and plasma concentrations of substance x and V is urine flow rate. C_x is expressed as milliliters per minute and is usually normalized to 1.73 m^2, the idealized adult body surface area [10]. GFR is the best clinical test to estimate functional renal mass, which can assist the clinician in prescribing fluids/electrolytes, determine disease progression, and appropriately prescribe medications excreted by the kidney.

The gold standard method for GFR measurement is inulin clearance. Tables 53.1 and 53.2 summarize studies conducted to estimate GFR (measured by inulin clearance) in healthy term and preterm infants, respectively. Dependent on degree of prematurity, GFR steadily improves from 10–20 mL/min/1.73 m^2 during the first week of life to 30–40 mL/min/1.73 m^2 by 2 weeks after birth concomitant with alterations in renal blood flow. Thereafter GFR improves steadily over the first few months of life [11, 12]. Serum creatinine (SCr) is the most common method to estimate GFR and monitor kidney function but has significant shortcomings (see Chap. 3).

Table 53.1 Formal GFR measurements for term neonates during the first 2 years of life

Term infants	
Age	mL/min/1.3 m^2
1–3 days	21 ± 5
4–14 days	37 ± 7
1–3 months	85 + 35
4–6 months	87 ± 22
7–12 months	96 + 2
1–2 years	105 ± 17

Data from Schwartz and Furth [11]

Table 53.2 Formal GFR measurements for preterm neonates during the first 4 months of life

Premature infants	
Age	mL/min/1.73 m^2
1–3 days	14.0 ± 5.0
1–7 days	18.7 ± 5.5
4–8 days	44.3 ± 9.3
3–13 days	47.8 ± 10.7
1.5–4 months	68.4 ± 16.6

Data from Schwartz and Furth [11]

There are several specific problems with using SCr in neonates: SCr in the first few days of life reflects mother's and not the infant's kidney function. Moreover, GFR in term and preterm infants is generally very low and normal serum creatinine values vary greatly dependent on level of prematurity and age [13] (Fig. 53.1). Finally, bilirubin levels in premature infants rise in the first several days and return to normal after a few weeks. When the colorimetric Jaffe method of SCr is used this may impact SCr interpretation [14].

Attempts to estimate GFR using SCr in neonates have suggested the following formula for children who are <1 year of age [15]: Height (cm) * *k*/serum creatinine (mg/dL); where $k = 0.33$ for low birth weight and 0.45 for normal birth weight infants. However, caution should be used when applying this equation in clinical practice for several reasons. At best the formula represents a mean estimate and the true GFR may be off in either direction by 20% or more. In addition, the k coefficients were derived using the

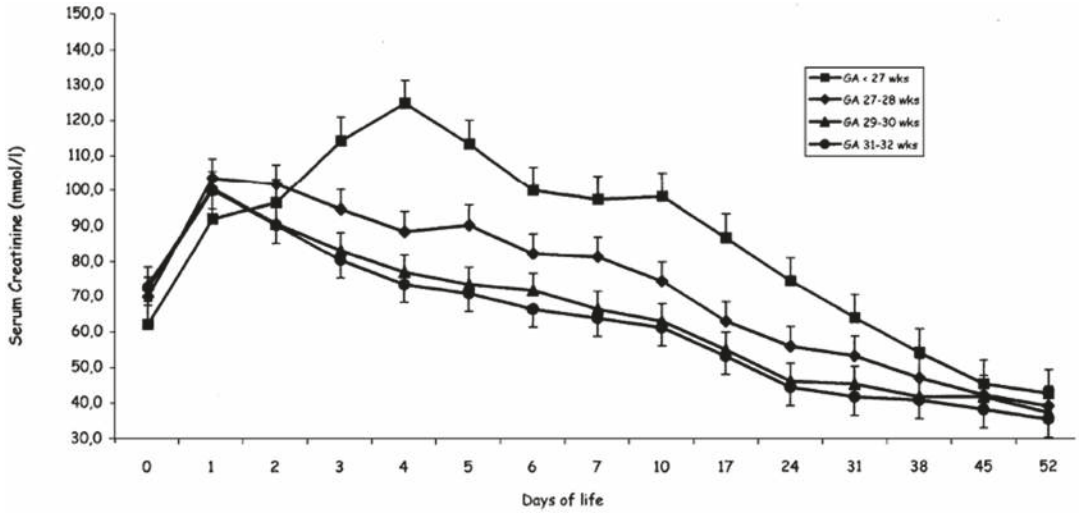

Fig. 53.1 Serum creatinine values over time by gestational age categories. (Used with permission from Gallini et al. [13])

Jaffe calorimetric method to measure SCr. As most hospitals now only use the enzymatic equation, the coefficients may no longer be applicable.

Cystatin C has been extensively studied as a measure of GFR and a marker of acute kidney injury. Since Cystatin C is not influenced by the maternal serum level and is highest at birth, it may be better suited than SCr to monitor kidney function in infants. Cystatin C concentrations significantly decrease during the first three days of life and are independent of gestational age, birth weight and maternal kidney function status in very low birth weight infants [16]. Cystatin C does not differ between males and females and is not influenced by gestational age. Thus, cystatin C seems to have many properties of an ideal marker of kidney function in this age group [17]. However, as only a few studies on this topic have been conducted so far and no studies have linked cystatin C levels with short and long-term outcomes in this population, further research is needed before adopting Cystatin C as a primary marker of kidney function in neonates.

Water, Electrolyte and Acid-Base Disorders in Neonates

Metabolic Acidosis

Neonates typically show a certain degree of acidosis depending on gestational and postnatal age [18]. In full-term neonates, after completion of nephrogenesis at the 34th week of gestation [19], the mechanisms devoted to maintain acid base (AB) equilibrium are still immature. This immaturity concerns both the capacity of H^+ excretion and the HCO_3^- reabsorption threshold [20, 21]. Moreover, the ability of excreting large amounts of acid through ammoniagenesis is impaired in the newborn baby, due to the decreased presence of enzymes necessary for ammoniagenesis, like glutaminase [22]. Finally, neonatal nutrition involves a two to three times higher protein load than older children with consequently higher acid production. In premature infants, this unfavorable condition is even worsened by the inability to efficiently acidify urine with further acid retention and consequently increased risk of metabolic acidosis. In fact, in preterm infants, plasma bicarbonate levels are lower than in full term neonates for the first 3 weeks of life due to the lower renal threshold for bicarbonate (see Chap. 36). This predisposes preterm neonates to condition known as late metabolic acidosis, which is further promoted by milk formulas containing casein, by parenteral nutrition (especially in TPN containing arginine HCl), and by withdrawal of milk alimentation (and consequently alkali intake), e.g., during episodes of diarrhea.

The acid-base disturbances seen in the NICU occur in an organism with immature homeostatic mechanisms. According to the classic metabolic acidosis classification based on the anion gap, we can take into account a number of clinical situations leading to metabolic acidosis. The anion gap attests the balance (or unbalance) between acid accumulation and loss of base equivalents. It is calculated by: $Na^+ - (Cl^- + HCO_3^-)$ in mEq/L. Metabolic acidosis with a normal anion gap (<16 mEq/L) is seen in neonates with intestinal or renal HCO_3^- losses, which can be due to either proximal or distal renal tubular acidosis (see Chap. 36). Also, the use of the carbonic anhydrase inhibitor acetazolamide in pregnancy has been associated with metabolic acidosis in preterm neonates [23, 24].

The most common conditions causing an anion gap >16 mEq/L in neonates are kidney failure, inborn errors of metabolism (IEM) or lactic acidosis [25]. In kidney failure, the impairment of acid load elimination increases HCO_3^- consumption while in IEM (in particular in organic acidurias [26]. HCO_3^- stores are depleted by the increased production of organic acids. Small bowel drainage following surgical procedures may also induce large HCO_3^- losses. In necrotizing enterocolitis (NEC) acidosis is associated with progressive systemic shock and lactic acidosis [27]. In VLBW infants, metabolic acidosis on the first day of illness is more common in infants with perforated NEC compared to infants without perforation [23].

The treatment of metabolic acidosis in neonates firstly relies on the diagnosis and treatment

of the underlying cause. The treatment of renal tubular acidosis with $NaHCO_3$ in critically ill children is controversial [28]. Only one randomized trial examining potential benefits of $NaHCO_3$ in asphyxiated newborn infants is available - it showed no influence on the outcome [29]. No benefit of bicarbonate supplementation has also been found in adult patients. In cardiac arrest, the administration of $NaHCO_3$ has been widely utilized in an attempt to correct acid overproduction caused by decreased tissue oxygenation. There are no available randomized trials demonstrating positive effects of $NaHCO_3$ administration in cardiac arrest in either adult and pediatric patients, including neonates. On the contrary, $NaHCO_3$ may induce CO_2 accumulation in poorly oxygenated districts and hypercarbia [30].

In 2013, a survey in Canadian NICUs showed that $NaHCO_3$ is most frequently administered in septic shock whereas its use is much less frequent in cardiac arrest [31]. With an analogous mechanism, CO_2 accumulation may occur also in ARDS if its elimination by the lungs is insufficient. In this case also, the addition of bicarbonate may induce only a transient rise of pH, usually followed by hypercarbia [32]. A different situation occurs when a net $HCO3^-$ loss or its excessive consumption take place. Examples are gastrointestinal losses and kidney failure. The ability of the neonatal kidney to reabsorb $HCO3^-$ is about one third of that of adult individuals [33] and a mature ammoniagenesis mechanism is lacking [20].

Potential hazards of $NaHCO_3$ supplementation in infants include risk of sodium overload and hypernatremia, hypokalemia and hypocalcemia. Moreover, the use of $NaHCO_3$ in infants has been associated with a number of adverse events like intracranial hemorrhage, deterioration of cardiac function and myocardial injury [34, 35]. In neonates $NaHCO_3$ should be given only after establishment of adequate ventilation and circulation and should be restricted to selected situations like severe acidosis with life-threatening hyperkalemia, massive GI losses, and tubulopathies. In neonatal resuscitation, a dose of 1–2 mmol/kg of a 0.5 mmol/mL solution may be given by slow intravenous push (over at least 2 min) after adequate ventilation and perfusion have been established [36]. In infants with kidney failure, titration of acid/base balance using sodium citrate is necessary to maintain appropriate metabolic control and growth.

Metabolic Alkalosis

Metabolic alkalosis is almost invariably accompanied by hypokalemia and can be classified on the base of chloride urine concentration. In critical infants, low urinary Cl^- concentration (expressed as $Cl^- < 10$ mmol/L or, more precisely, as Cl^-/Creatinine ratio < 10 in mol/mol) suggests that the kidneys are avidly holding on to chloride, thus, ruling out chloride loss from the kidneys as the etiology. Low urine chloride metabolic alkalosis may be present as a consequence of loss of gastric secretions (vomiting, nasogastric suction), secretory diarrhea or after rapid correction of hypercapnia, and chronic diuretic which cause low total body chloride). In contrast, metabolic alkalosis with high urine chloride suggests inappropriate losses of chloride from the kidney from primary chloride losing tubulopathies (Bartter syndrome, Gitelman syndrome) and, more frequently, the use of diuretics. If metabolic hypochloruric alkalosis is present in context of systemic hypertension, defects in regulation of aldosterone and renin should be sought (Fig. 53.2).

A peculiar low-chloride associated clinical situation is that of infants after cardiopulmonary bypass surgery. In these patients, metabolic alkalosis is associated with younger age, preoperative ductal dependency and hemodilution [37]. Volume and chloride depletion have been advocated as possible causes [38]. Metabolic alkalosis is also reported in up to 18% of infants referred to surgery for pyloric stenosis [39].

Hyperkalemia

Hyperkalemia may represent a life-threatening condition in the NICU. It is the most common electrolyte disorder associated to heart conduction problems [40]. Non-oliguric hyperkalemia

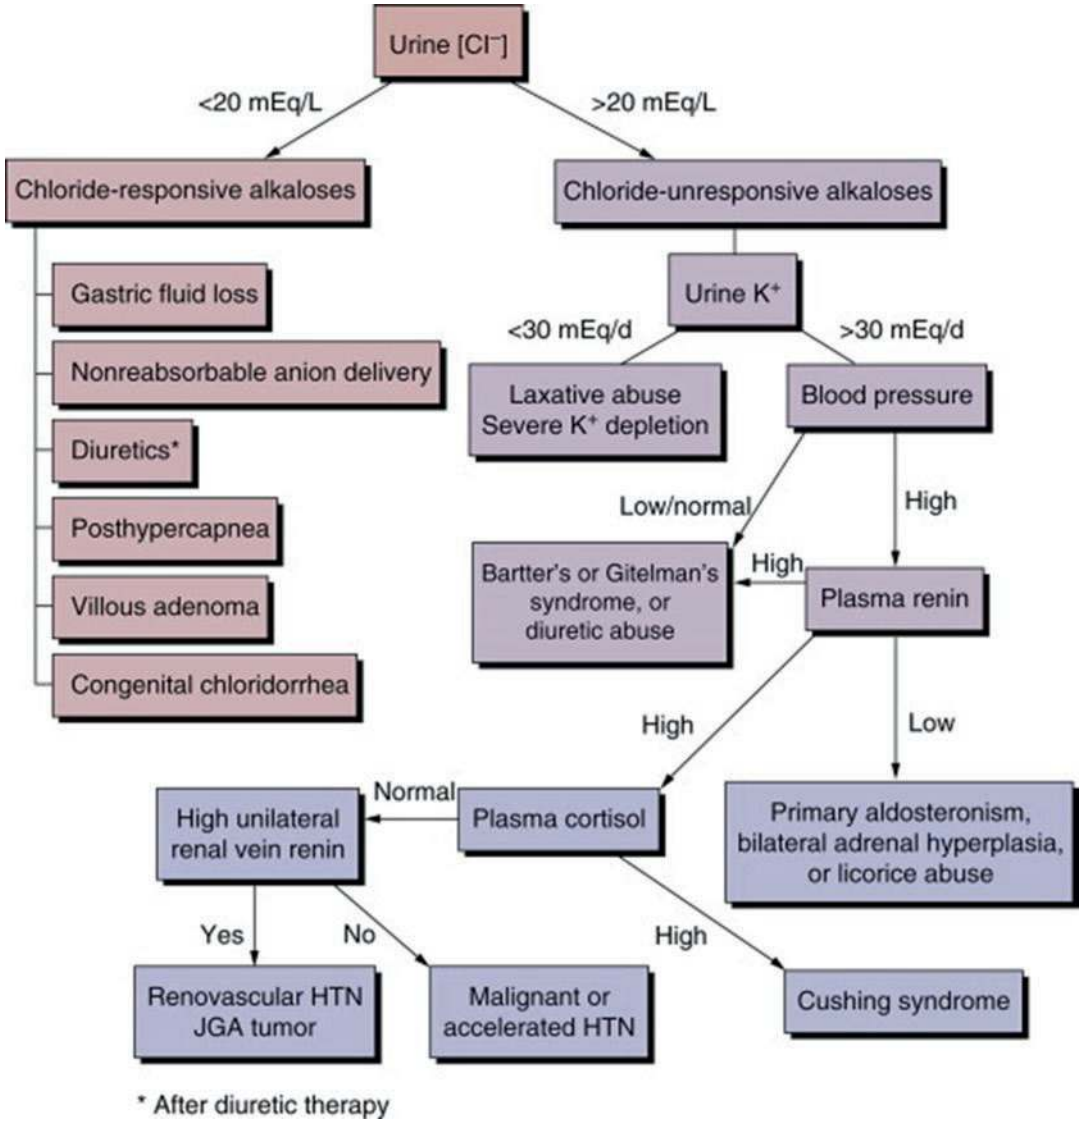

Fig. 53.2 Clinical decision tree diagram for metabolic alkalosis [1] used with permission

of the newborn is defined as a plasma potassium level >6.5 mmol/L in the absence of acute kidney failure [41]. In neonates, spurious hyperkalemia has to be initially excluded since mechanical trauma to red blood cells during venipuncture with consequent release of intracellular potassium is particularly frequent in neonates and prematures. The hemolytic Index is a measure of red color of serum which is due almost exclusively due to hemoglobin. This index (reported as 0 to 4 +) assist in detecting spurious hyperkalemia in infants [42]. Once spurious hyperkalemia is ruled out, a number of causes of true hyperkalemia have to be considered. Hyperkalemia may be induced by increased intake, intra-extracellular potassium redistribution and decreased elimination. Increased intake in critical infants may be seen with acute potassium load and blood transfusion. Acute load is infrequent in non-oliguric infants and it is usu-

ally consequent to dosing errors or the administration rate of intravenous potassium containing solutions. Potassium concentration in transfused blood may be as high as 50 mmol/L, so that even small amounts may induce severe hyperkalemia in small infants. This renders the use of fresh blood in newborns mandatory [43]. The most common cause of hyperkalemia due to intra-extracellular potassium redistribution in critically ill infants is metabolic acidosis. In this condition, potassium moves from the intracellular compartment in order to maintain electroneutrality after H^+ ions have accumulated in the intracellular space.

Hyperkalemia is frequent in preterm neonates. It presents as a sudden rise of serum potassium in the first 72 h of life of preterm neonates with a gestational age <28 weeks and may cause heart conduction impairment that may result in sudden death. This condition results from potassium loss from the intracellular space, together with the immature renal excretion of potassium and aldosterone unresponsiveness. Management of hyperkalemia is mandatory when symptoms and/or EKG alterations are present. The latter include tall, peaked T waves with narrow base, prolonged PR interval, decreased or disappearing P wave, widening of QRS, amplified R wave, ventricular fibrillation or asystole. There are three main approaches to the treatment of hyperkalemia: (1) antagonizing the membrane actions of hyperkalemia, (2) driving potassium into cells, and (3) removing potassium from the body. First, stabilization of myocardial function may be obtained by Ca^{2+} infusion. Calcium inactivates sodium channels and increases membrane excitability in 2–3 min. Its effect lasts for 30–60 min, so that an alternative therapy is required after that time. Calcium is given by slow intravenous injection over 5–10 min: 0.11 mmol/kg (0.5 mL/kg of calcium gluconate 10%). Potassium can be driven into intracellular space by insulin in exchange with sodium. I.v. insulin is used with glucose for emergency treatment of hyperkalemia at the dose of intravenous solution of insulin (0.1–0.6 units/kg/h in neonates) with glucose infusion of 0.5–1 g/kg/h (5–10 mL/kg/h of glucose 10%). The effect starts in 15 min and can last for hours. Blood glucose levels must be carefully monitored to avoid both hypo-and hyperglycemia [43]. Intravenous sodium bicarbonate reverses potassium ions from the extra- to the intracellular compartment to maintain electro-neutrality. A half correction of the base excess (0.3 × weight × BE) over 10–15 min can be administered and the rest given in the next 12–24 h. The main constraint of sodium bicarbonate use is sodium and volume overload, especially when kidney impairment is present. β-2 adrenergic agonists increase sodium-potassium ATPase activity and potassium is driven back into cells. Salbutamol or albuterol can be nebulised or given by intravenous infusions [44, 45]. Finally, removal of potassium is generally obtained by diuretics and cation exchange resins. Furosemide can be administered in 1 mg/kg dosage and repeated in case of need. Since the efficacy of diuretics depends on GFR, higher dosage may be required in kidney failure. Calcium or sodium polystyrene sulfonate (Kayexalate®, Concordia Pharmaceuticals, Oakville, Ontario, Canada) binds potassium by exchanging it with sodium in GI tract so that potassium is eliminated in the stool. In adult patients with life-threatening hyperkalemia, the role of exchange resins has been questioned [46]. In neonates, while potassium elimination can be enhanced by ion resins, gastro-intestinal obstruction and/or perforation can occur following oral or rectal administration of exchange resins [47]. Moreover, in a comparative study in hyperkalemic preterm neonates cation-exchange resin did not lead to a better outcome regarding all-cause mortality than glucose and insulin [48]. Given the above considerations, combined insulin/glucose infusion should be preferred over treatment with rectal cation-resin for acute hyperkalemia in preterm infants [49]. Low potassium formulas are available for children who have poor potassium elimination. In addition, premixing formula with sodium polystyrene sulfonate (Kayexalate®), allowing the resin to settle and providing the supernatant for nutrition, efficiently lowers the oral potassium load without risking bowel obstruction/perforation.

Hypokalemia

True, not alkalosis induced hypokalemia (<3.5 mmol/L) in critically ill infants may develop as a consequence of potassium loss due to intestinal problems (vomiting, nasogastric suction, diarrhea), kidney conditions (diuretic use, recovery from acute kidney injury) or insufficient potassium intake, mainly coming from unbalanced parenteral nutrition. Congenital conditions if untreated can be lethal during the first weeks or months of life. These include congenital chloride diarrhea (a rare autosomal recessive disease characterized by chronic secretory diarrhea), and some inherited conditions like Bartter syndrome, Gitelman syndrome, and related syndromes (see Chap. 33).

In neonates, potassium replacement must be managed with extreme caution, given the rapid change of kalemia induced by small amounts of potassium. Intravenous potassium treatment should only be given for immediately life-threatening emergencies over several minutes while severe hypokalemia may be treated with an infusion of 0.2–0.5 mmol/kg/h to a maximum of 1 mmol/kg. Non-emergencies are best treated using oral supplements if possible, otherwise as small dosages as low as 0.03–0.07 mmol/kg by slow injection. During potassium administration, very frequent monitoring of plasma levels has to be established as well as continuous EKG monitoring while correction occurs [50].

Hypernatremia

Changes in sodium concentration are common in critical neonates, due to the small patient volume and the body fluid changes occurring in the perinatal period. Hypernatremia (>145 mmol/L) must always be considered in relation to the water content and is traditionally classified as hypo-, normo- or hypervolemic. Hypovolemic hypernatremia is often seen when fluid restriction is required and water loss exceeds that of sodium. Other frequent causes of hypovolemic hypernatremia are losses through the gut or the kidney (like watery diarrhea, water loss in post-obstructive polyuria). Hypernatremia is more frequent in VLBW infants in which water loss through lungs and the immature skin may reach 150 mL/kg/day, thus exposing the preterm to hypernatremia due to free water deficit, especially in the first hours of life. Moreover, renal sodium handling is inversely related to creatinine clearance in the first 2 weeks of life. After 4–5 days from birth sodium balance becomes negative with a sudden decrease of fractional excretion, thus enabling the neonatal kidney to spare sodium. This occurs also in preterm babies [51]. A particular case is that of critically ill infants with severe hypoperfusion and acidosis requiring large amounts of sodium bicarbonate. In this case, often a capillary leak syndrome is present with leak of albumin, sodium and water to the interstitium in a mixed hypovolemic-sodium retaining situation in which sodium is in a third space. Hypervolemic hypernatremia in the NICU is frequently induced by administration of large amounts of sodium with drugs and blood products.

Management of hypernatremia in critically ill infants is usually an urgent treatment. Respiratory distress, necrotizing enterocolitis, and patent ductus arteriosus are associated with hypernatremia and volume expansion [52, 53]. Correction of hypernatremia basically consists in free water administration with correction velocity being the crucial issue. There is evidence that plasma both sodium changes and velocity of these changes are associated with neurological outcome [54]. The rule is to reduce natremia at a speed not >0.5–1.0 mmol/L/h. If plasma sodium is very high (>160 mmol/L), it is advisable to administer a 0.9% saline solution in order to reduce natremia slowly.

Hyponatremia

Hyponatremia (<130 mmol/L) is associated with cerebral edema and permanent neurologic sequelae especially in preterm neonates [55, 56]. In critical neonates, hyponatremia is most frequently seen as a consequence of diuretic use, surgical procedures, diarrhea/vomiting and third

space loss. A particular neonatal issue is hyponatremia during therapeutic hypothermia. In these patients, hyponatremia has been related to water loss as a consequence of cooling induced skin vasoconstriction [57]. Total body fluid overload will also cause hyponatremia.

Diuretics are commonly used to treat infants with oxygen-dependent chronic lung disease [58] and congenital heart defect [59]. In acute situations, high-dose diuretics may be required and this may cause hyponatremia which, in turn, hampers the response to the diuretic. Hypokalemia, alkalosis, and calcium wasting can be part of this picture. During surgery, standard neonatal intensive care guidelines recommending hypotonic i.v. infusions containing 20–40 mmol of sodium are often followed [60]. However, these guidelines may not meet metabolic and volume needs in the perioperative period and hyponatremia may result in up to 60% of patients [55, 60, 61]. Careful monitoring of sodium levels and the use of balanced sodium solutions are mandatory in these patients [61]. During neonatal sepsis, capillary leak may take place and large amounts of sodium together with water and albumin are displaced into the interstitium with severe edema poorly responding to diuretics [62].

Replacement of sodium loss in volume depletion must take into account the variation of sodium plasma levels since, if a patient is seizing with a serum sodium <120 mol/L, 3% saline can be given. In patients that are clinically stable, use of isotonic saline can improve sodium concentrations. Like in hypernatremia, correction velocity must not be >1 mmol/kg/h. Careful attention to fluid shifts and serial electrolyte monitoring is essential.

Hypocalcemia

Normal levels of serum calcium are normally achieved during the second week of life when PTH secretion from parathyroid glands can efficiently respond to hypocalcemic stimuli [63]. Before then, normal neonates spontaneously lean towards hypocalcemia. Actually, a physiologic fall in serum calcium concentration, occurs in the first 24 h of life due to the sudden stop of calcium supply from the placenta. PTH is then stimulated but its action becomes valid from 2 to 3 days of life onward [64] . The kidney plays a key role in calcium homeostasis and, although the timing of the action of PTH on renal calcium excretion in neonates is not certain, calciuria increases after the second week of life [65].

NICU infants may develop hypocalcemia (<8.8 mg/dL or ionized calcium <4.9 mg/dL) for a number of reasons. When PTH secretion from immature parathyroid glands is insufficient, a prolongation or a worsening of hypocalcemia occurs (early onset neonatal hypocalcemia) [63]. Under these circumstances, hypocalcemia is rarely symptomatic but EKG alterations (Q-T prolongation) may be present [63]. Preterm infants and children of diabetic mothers [66] are more exposed to the risk of hypocalcemia. Approximately 50% of infants of mothers who have diabetes show hypocalcemia [54].

The etiology of neonatal hypocalcemia is multifactorial. It is probably due to loss of calcium and magnesium with urine, resulting in reduced placental transfer and decreased neonatal secretion of PTH. Another risk factor for early onset hypocalcemia is maternal calcium ingestion during pregnancy, inducing inhibition of the neonate's PTH response and consequent hypocalcemia [67]. Hypocalcemia starting after 5–10 days of age is due to resistance of renal tubule cells to PTH leading to renal retention of phosphorus and hypocalcemia (late onset neonatal hypocalcemia) [63].

Overt hypoparathyroidism in neonates occurs in case of dysgenesis of the parathyroid glands. The most common cause is the DiGeorge syndrome. The phenotype is characterized by hypocalcemia caused by parathyroid gland hypoplasia, defective T-lymphocyte function and impaired cell-mediated immunity caused by impaired thymic differentiation and conotruncal defects of the heart or aortic arch. The syndrome is associated with microdeletions of chromosome 22q11.2. Some neonates may have isolated hypoparathyroidism. Also in the CATCH 22 syndrome (cardiac anomaly, abnormal facies, thymic aplasia, cleft palate, hypocalcemia), haploinsufficiency

for genes located in the 22q11 region is associated with contiguous gene deletion syndromes that include not only the DiGeorge syndrome but also the overlapping conotruncal anomaly and velocardiofacial syndromes [63, 68].

In NICU patients, acquired hypocalcemia is frequently drug induced. Aminoglycosides, often used in NICU, can increase renal calcium loss and induce hypocalcemia in neonates [69]. Anticonvulsants such as phenytoin or phenobarbital are potential inducers of cytochrome P450 (CYP450), causing increased vitamin D degradation. Also, the prolonged use of anticonvulsant in the mother during pregnancy can induce hypocalcemia in the newborn [70]. Renal excretion of calcium is notably enhanced during treatment with loop diuretics. This concerns particular populations like infants with heart problems or after cardiosurgery. Ionized calcium also can be reduced in infants treated with sodium bicarbonate, which increases calcium binding to albumin.

Urgent treatment of neonatal hypocalcemia is based on i.v. calcium supply. Calcium gluconate and calcium chloride are both available at 10% concentration. Both preparations have to be administered via a central vein. Although there is no proven superiority of one form over the other for the treatment of ionized hypocalcemia [71], calcium chloride appears to be more irritating for vessels and gluconate should be preferred in neonates. Calcium chloride contains three times more elemental calcium than gluconate (272 vs. 90 mg in 10 mL at 10%, respectively). Serum calcium levels should be corrected by continuous intravenous infusion of calcium (at 1–3 mg of elemental calcium/kg body weight per hour) under strict monitoring of ionized calcium levels, in order to avoid complications as such as bradycardia and arrhythmia or vessel necrosis.

Hypercalcemia

Neonatal hypercalcemia is much less frequent than hypocalcemia. Infants normally show higher total (8.8–11.3 mg/dL) as well as ionized calcium levels (1.19–1.40 mmol/L) than older children or [61]. Hypercalcemia is often asymptomatic. Hypercalcemic infants can show irritability, dizziness and arterial hypertension. It is not infrequent that hypercalcemia is discovered after diagnosis of nephrocalcinosis or lithiasis.

Hypercalcemia in NICU infants is almost always iatrogenic [63]. Vitamin D and calcium supplementation are a frequent cause of hypercalcemia. Hypophosphatemia is frequently seen in preterm neonates as a consequence of poor intake. Low phosphate levels stimulate PTH secretion which in turn increases intestinal calcium absorption and calcium resorption from the skeleton. Children on Extracorporeal Membrane Oxygenation (ECMO) experience hypercalcemia up to 30% of patients, probably due to aberrant vitamin D-PTH regulation [72].

Rare congenital conditions must be considered in the presence of neonatal hypercalcemia. The calcium-sensing receptor (CASR) is expressed in the PTH producing chief cells of the parathyroid gland and the cells lining the kidney tubule. Inherited abnormalities of the *CASR* gene can cause either hypercalcemia or hypocalcemia. This autosomal recessive condition affects neonates and induces neonatal severe hyperparathyroidism (NSHPT) [73]. Hypercalcemia is usually severe and can be life-threatening. Typically, PTH levels are normal to high and calcium urinary excretion is low.

Subcutaneous fat necrosis (SFN) can be the consequence of a difficult delivery and is characterized by necrosis of fat and a local macrophagic reaction to the necrotic fat. Hypercalcemia derives from the excess of calcitriol produced by macrophages and is associated with a 15% mortality rate [74]. Of interest, SFN with hypercalcemia has been recently associated with neonatal therapeutic hypothermia [75, 76]. Given the growing use of this therapy, blood calcium levels should be monitored in children undergoing therapeutic hypothermia.

Initial treatment of severe hypercalcemia in critical infants relies on hydration and loop diuretics. Calciuria can rapidly increase, which can worsen kidney function and/or nephrocalcinosis. Withdrawal of hypercalcemic agents such as calcium supplements or vitamin D supplements is mandatory. Treatment of neonatal hyperparathyroidism is an urgent requirement.

Steroids and bisphosphonates have been used with success [77]. More recently, the calcimimetic agent cinacalcet has been used successfully in neonatal hyperparathyroidism in combination with bisphosphonates [78].

Acute Kidney Injury (AKI) in Neonates

Definition and Epidemiology

Previously referred to as acute renal failure, acute kidney injury (AKI) is characterized by a sudden impairment in kidney function, which results in retention of nitrogenous waste products and altered regulation of extracellular fluid volume, electrolytes and acid-base homeostasis. The term "acute kidney injury" has replaced "acute renal failure" by most critical care and nephrology societies, primarily to highlight the importance of recognizing this process at the time of "injury" as opposed to waiting until "failure" has occurred [79].

Despite its limitations (as outlined above and in Chap. 46), SCr is the most commonly used measure to evaluate glomerular filtration in the clinical setting and is more specific than blood urea nitrogen (BUN). BUN is an insensitive measure of glomerular filtration rate (GFR) because it can be increased out of proportion to changes in GFR secondary to high dietary protein intake, gastrointestinal bleed, use of steroids and hypercatabolic states. If the BUN:SCr ratio exceeds 20, increased urea production or increased renal urea reabsorption that occurs in pre-renal azotemia should be suspected [80].

Historically the most common SCr cutpoint used to define neonatal AKI was set at an arbitrary cutoff of 1.5 mg/dL or greater, independent of day of life and regardless of the rate of urine output [81]. In 2009, categorical definition based on a rise in SCr to diagnose and define different stages of AKI [77] was applied to neonates [81]. Since then, we and others have used AKI definitions similar to those published by the 2007 AKIN and 2012 KDIGO guidelines [82–92]. A neonatal AKI definition has been adapted from the KDIGO definition (Table 53.3).

Table 53.3 Neonatal AKI definition

Stage	Serum creatinine (SCr) criteria	Urine output (UOP criteria)
0	No change or rise <0.3 mg/dL	UOP >1 cc/kg/h (over previous 24 h)
1	↑ SCr of ≥0.3 mg/dL or ↑ SCr to 150–199% × baseline	UOP >0.5 cc/kg/h and ≤ 1 cc/kg/h (over previous 24 h)
2	↑ SCr to 200–299% × baseline	UOP >0.1 cc/kg/h and ≤ 0.5 cc/kg/h (over previous 24 h)
3	↑ SCr to ≥300% × baseline or SCr ≥2.5 mg/dL or Receipt of dialysis	UOP ≤0.1 cc/kg/h (over previous 24 h)

Baseline SCr will be defined as the lowest previous SCr value

Table 53.4 Incidence and outcomes of neonates with AKI

Population	Incidence (%)	Mortality	Ref.
		AKI v no AKI	
VLBW[a]	18	55% vs. 5%	[82]
ELBW[b]	12.5	70% vs. 22%	[89]
Sick near-term/term	18	22% vs. 0%	[78]
Sepsis	26	70% vs. 25%	[90]
Asphyxiated Newborn	38	14% vs. 2%	[91]
ECMO[c]	71	72.7% vs. 20%[d]	[92]

[a]Very low birth weight (VLBW) infants <1500 g
[b]Extremely low birth weight (ELBS) infants <1000 g
[c]Extra Corporeal Membrane Oxygenation (ECMO)
[d]In group with highest stage of AKI

The following modifications have been made to account for specific neonatal issues:

- Because SCr normally declines over the first week of life [13], each SCr is compared to lowest previous value.
- As SCr of 2.5 mg/dL represents glomerular filtration rate <10 mL/min/1.73 m^2 in neonates, this cutoff is used to define Stage 3 AKI (as opposed to 4.0 mg/dL in adults).
- UOP criteria have been adapted to levels obtained over 24 h.

Table 53.4 shows the incidence and outcomes of neonatal AKI in different neonatal populations

using category AKI definitions similar to that presented here. However, more research is needed to develop, and validate this definition against hard clinical endpoints.

Risk Factors and Etiology

AKI is a common clinical condition in the NICU [93–96]. Up until 2013, limited data coming from small single-center studies identified premature infants, sick near-term or term infants, and infants who undergo cardiopulmonary bypass or ECMO at particular risk for neonatal AKI [88, 97–100]. Also, since there was a wide variation in the incidence of AKI according to the AKI definition used and the number of SCr values measured, a uniform understanding of the risk factors for AKI was difficult to ascertain [101–103]. In 2014, the Neonatal Kidney Collaborative was established and designed a multicenter study to evaluate AKI among critically ill neonates (the Assessment of Worldwide Acute Kidney Injury Epidemiology in Neonates (AWAKEN)) [104]. In AWAKEN, several risk factors have been evaluated according to gestational age and postnatal age [104]. In particular, perinatal risk factors are associated with early neonatal AKI (first perinatal week) and cardiac and kidney anomalies, surgery and nephrotoxin medications rather than perinatal factors are risk factors of late AKI (after the postnatal week) (Table 53.6) [105, 106]. Furthermore, nearly one third of neonates with late AKI had an episode of early AKI increasing the risk for CKD.

These conditions are important in identifying neonates at risk for development of AKI and because some of them are potentially preventable [107, 108]. The causes of AKI in newborns are typically divided into three groups: pre-renal failure, intrinsic renal failure and post-renal failure with pre-renal and intrinsic being the most frequently reported [109].

Pre-renal and intrinsic renal failure both include congenital and acquired causes of AKI (Table 53.7). The most common form of AKI in neonates is pre-renal failure which accounts for more than 80% of cases.

In numerous studies, **perinatal asphyxia and sepsis** are the most frequent associated conditions [110]. Asphyxia causes renal dysfunction secondary to redistribution of blood flow to more vital organs such as heart and brain at the expense of the others, especially kidneys and gut. The reported incidence of renal failure in asphyxiated neonates varies between 50% and 70% in infants not treated with therapeutic hypothermia [111–113] and 30–40% after introduction of therapeutic hypothermia for the treatment of perinatal asphyxia [114–116]. In asphyxiated newborns, renal outcome correlates with oliguria but also with clinical markers of the severity of asphyxia. In particular, Apgar score at 5 min <6, initial and 12-hour lactate concentrations, and hypoxic ischemic encephalopathy were much better predictors of adverse outcome than kidney function tests [113, 116]. The incidence of AKI among term and near-term neonates with encephalopathy in the AWAKEN cohort was more than 40% and analysis of data including antenatal risk factors selected among factors associated with AKI

Table 53.5 Time to dialysis start, fraction of patients reaching a negative fluid balance and survival rate of infants treated with PD after cardiopulmonary bypass surgery. Only in studies where all patients reached negative fluid balance survival exceeded 50%

Reference	*n*	Time to PD start	Patients with negative fluid balance (%)	Survivors (%)
Lowrie [179]	17	NA	35	24
Fleming [180]	21	2.5 days (1–6) after surgery	36	38
Golej [181]	116	NA, but 43% of pts. started on PD when CVP >10 mmHg	53	47
Werner [182]	23	2.6 ± 0.6 days	100	53
Dittrich [183]	27	In the OR or first hrs in ICU	100	73
Santos [184]	23	4.8 ± 16.8 h	100	57
Sorof [185]	20	22 h	100	80
Chien [186]	7	1.2 ± 0.4 days after AKI onset	NA	57

being outborn, low admission temperature, intrauterine growth restriction and the presence of meconium-stained amniotic fluid (MSAF) [117].

Among the neonatal population, **premature infants and low birth-weight** are particularly sensitive to asphyxia and hypoperfusion [97, 118, 119]. Very low birth weight (VLBW) and extremely low birth weight (ELBW) children are at increased risk for AKI because of prenatal fetal distress secondary to intrauterine growth retardation, placental insufficiency and maternal medications and a postnatal course frequently complicated by hypotension and hypoxia and the need for cardio-pulmonary support [97, 119, 120]. Studies focused on AKI in VLBW/ELBW reported an incidence of 12.5% and 18%, respectively [119, 120]. VLBW infants with AKI were more likely to have low birth weight, low gestational age and low Apgar scores and they frequently required umbilical arterial catheters, assisted ventilation and inotropic support. In another study, infants with AKI had a higher mean airway pressure, a lower mean arterial blood pressure and higher exposure to cefotaxime than non-AKI controls [119].

Given the high vulnerability of the neonatal kidney to the effects of hypoperfusion, **acute tubular necrosis** (ATN) commonly occurs. Pre-renal failure is due to renal hypoperfusion or ischemia in the presence of a normal kidney. Hence, irrespective of whether pre-renal failure is caused by total body volume depletion or decreased effective blood volume, renal function quickly returns to normal if perfusion is rapidly restored. Conversely, if the insult is severe and prolonged, acute tubular necrosis can occur [101]. During renal hypoperfusion many compensatory mechanisms are activated; in particular intrarenal vasodilatory prostaglandins are released. In order to help differentiate pre-renal failure from ATN, urinary indices have been proposed, in particular urine sodium concentration and the fractional excretion of sodium (FENa) [121] (Table 53.7). The assumption is that renal tubules work properly in pre-renal failure and are able to reabsorb solute and water while they are damaged and do not adequately conserve sodium in ATN. The urine samples for measuring indices must be obtained prior to a fluid and diuretic challenge. This could be difficult in oliguric neonates. Urine sodium less than 20 mEq/L and more than 50 mEq/L is suggestive of prerenal and intrinsic renal failure, respectively. FENa is calculated as urine sodium factored by serum sodium divided by urine creatinine factored by serum creatinine:

$$\text{FENa} = \text{urine sodium} \times \text{serum creatinine} / \text{serum sodium} \times \text{urine creatinine}$$

In term infants, a FENa above 3% indicates intrinsic renal failure. Preterm babies physiologically lose more sodium than term infants and a FENa of more than 6% can be used to define intrinsic AKI in infants between 29 and 32 weeks of gestation [121, 122].

Sepsis is the second most common condition associated with AKI after perinatal asphyxia [110]. AKI develops in 20–30% of neonates with sepsis [123–126]. In a series of 203 neonates with sepsis, 40 (20%) developed AKI. Increased baseline serum creatinine, vasopressor days, history of necrotizing enterocolitis (NEC) and ECMO requirement were good predictors of AKI in septic neonates. Most AKI episodes were detected within 2 days after sepsis evaluation; 23% of sepsis cases with AKI did not return to their serum creatinine baseline and all of them died [126]. In developing countries with limited resources, sepsis is more common than in developed countries [127, 128] and is the most common cause of AKI in neonates, occurring in 31% of newborns with a mortality rate of 65% [129]. The pathogenesis of AKI in sepsis is multifactorial, including shock, disseminated intravascular coagulation, haemorrhage, cardiac failure, and nephrotoxic drugs. All these conditions cause renal' hypoperfusion with resultant ischemic-reperfusion injury and cytokine- and oxidant-mediated kidney injury.

Administration of **nonsteroidal anti-inflammatory drugs** (NSAID) (for instance, indomethacin for patent ductus arteriosus closure) can inhibit this compensatory mechanism and precipitate AKI during renal hypoperfusion. In a multicenter Italian Study, ibuprofen treatment was identified as a risk factor correlated with impaired kidney function. Interestingly, maternal consumption of NSAID during pregnancy negatively influenced neonatal kidney function as well [130]. The risk of NSAID therapy-associated AKI is even higher when neonates concomitantly receive additional nephrotoxic drugs. Among neonates with patent ductus arteriosus who received gentamicin and NSAID, the rate of AKI was 14.8% compared to 9.1% for those not exposed to NSAID [131].

Antimicrobial agents are another major class of drugs associated with the development of AKI in preterm infants. Nephrotoxic AKI has been reported in association with aminoglycosides, vancomycin, piperacillin-tazobactam, acyclovir and amphotericin B [132]. In particular, aminoglycosides are widely used in pediatric patients. They accumulate in renal tubular cortical cells and exert nephrotoxicity causing damage to the proximal tubular epithelial cells secondary to lysosomal dysfunction [101, 133, 134]. Several studies have been performed to better understand the risk of nephrotoxicity associated with aminoglycoside therapy. A metanalysis of 16 trials involving 823 neonates comparing once daily aminoglycoside dosing with multiple doses per day found no difference in nephrotoxicity [135]. Similarly, in a Cochrane analysis of 11 studies and 574 neonates once daily dosing did not lead to more nephrotoxicity than twice-daily dosing, at comparable efficacy [136].

In a study that included 281 consecutive cases of AKI in preterm infants in NICU, multivariate logistic regression analysis showed that ceftazidime administration was associated with a greater risk of AKI compared to the other variables selected from univariate analysis including ampicillin, ibuprofen and furosemide [130]. Cephalosporin antibiotics have also been implicated in a case-control study involving 46 matched pairs of infants with and without AKI. Infants who developed AKI had a significantly higher prior exposure to cefotaxime, benzodiazepines, diuretics, and dopamine/dobutamine [119]. Globally, the AKI risk appears to increase with the number of nephrotoxic drugs [137] and the extended use of combination therapies [138].

Conservative Management of Neonatal AKI

Neonatal AKI is associated with a high morbidity and mortality [93]. Unfortunately, very few trials designed to test interventions have been per-

formed in the neonatal population. Management of AKI in newborns is therefore basically supportive and based on maintaining homeostasis until recovery of renal function [110, 122, 139, 140]. The first approach should be to carefully assess risk factors and to precisely define the cause of AKI. In particular, conditions that result in poor renal perfusion such as hypovolemia and sepsis should be promptly recognized and corrected [139, 140].

When and how to implement a fluid challenge continues to be an area of controversy and active investigation. In the resuscitative phase, hypovolemia can be initially corrected by the administration of a **fluid challenge** of 10–20 mL/kg of normal saline in bolus [141]. After active resuscitation has occurred, the goals of therapy should be to limit the degree of fluid overload, meanwhile providing adequate nutrition and medications necessary to promote recovery. Abnormalities in fluid balance are common among neonates and may impact patient outcome even in the absence of AKI. In a cohort of 645 critically ill neonates, a positive fluid balance was reported in more than 60% of patients during the first postnatal week [142]. Furthermore, the degree of fluid overload is an independent predictor of mortality [143, 144]. In a prospective study conducted on 58 neonates, those with AKI had more marked fluid overload and higher mortality rates over the first few days of life [143]. In a study of 154 newborns with AKI, fluid overload in excess of 7% was independently associated with a 13-fold mortality risk [141]. To prevent fluid overload, daily fluid input should not exceed insensible water losses (30 mL/kg/day) plus urinary losses. To guarantee adequate energy and nutrient intake while maintaining restricted fluid intake, concentrated solutions should be used. The volume required to apply drugs should be minimized by administration of pure or highly concentrated infusion volumes [139]. Body weight should be checked twice daily and the estimated fluid overload should be carefully assessed and tracked. Weight monitoring rather than cumulative fluid balance recording is, in fact, considered the most accurate method for measuring fluid balance in neonates and overcomes the problem of missed in and out measurements [142–145].

In order to maintain fluid balance and allow nutrition and drug infusions, diuretics are commonly used in patients with AKI. Studies in adult patients have not provided any evidence that diuretics improve survival or modify the course of AKI [146]. In young infants with AKI, furosemide use was an independent predictor of poor renal outcome [147] whereas data from AWAKEN suggested that diuretic administration was associated with a decreased risk of early-onset AKI [105]. Although controlled study evidence is lacking, furosemide has been used in neonates with AKI to facilitate clinical management by converting oliguric into non-oliguric AKI. Intravenous furosemide boluses (1 mg/kg) have been adopted for the treatment of oliguria in this setting given the challenges and risks associated with kidney replacement therapies in this difficult group of patients [139]. In addition to furosemide also bumetanide, a potent loop diuretic with similar pharmacologic characteristics as furosemide, was employed to increase urine output in preterm infants with oliguric AKI; while effectively increasing urine output the drug also caused a transient increase in serum creatinine levels, highlighting the nephrotoxic potential of loop diuretics in this vulnerable population [148, 149].

Low-dose **dopamine** has also been utilized to improve urine output in critically ill term and preterm neonates [110]. Dopamine is an endogenous catecholamine that influences different catecholamine receptors in a dose-dependent manner, and, in particular, has been claimed to induce selective renal vasodilation when administered at low dose. Dopamine administration is associated with increased cerebral blood flow and has been shown to be safe and effective for treating hypotension in preterm infants. In oliguric, non-hypotensive neonates, GFR and urine output increased significantly with dopamine infused at a rate of 2.5 μg/kg per min. Moreover, dopamine induced renal and mesenteric vasodilation without an effect on cerebral blood flow when started precociously in preterm neonates treated with indomethacin for the presence of a patent ductus

arteriosus. However, an assessment of dopamine use in 19 NICUs and PICUs together with a literature review failed to demonstrate an improvement in renal function and urine output in neonates and pediatric intensive care patients. Moreover, evidence emerged that dopamine may have detrimental effects by worsening renal perfusion in critically ill patients with AKI. More recently, **Fenoldopam**, a selective dopamine A1 receptor agonist that decreases vascular resistance and increases renal blood flow, improved urine output in neonates requiring cardiac surgery with positive fluid balance despite diuretics [150–156]. However, in 40 infants undergoing cardiac surgery with cardiopulmonary bypass, Fenoldopam infused at a low dose (0.1 μg/Kg/min) for 72 h soon after anesthesia did not exert any effects on urine output, fluid balance or AKI incidence [157]. The same authors treated 40 infants undergoing cardiac surgery with a higher dose of Fenoldopam (1 μg/kg/min) during cardiopulmonary bypass. They observed decreased urinary NGAL and cystatin C levels, but no difference in plasma creatinine and urine output between subjects receiving fenoldopam and placebo [158].

Perinatal asphyxia is the primary cause of AKI in neonates. During hypoxia and ischemia, adenosine is released and acts as a vasoconstrictive agent in the kidney contributing to a fall in glomerular filtration rate. In this setting, methylxanthines such as aminophylline and theophylline (non-specific **adenosine receptor antagonists**) can inhibit the vasoconstriction induced by adenosine [159]. Three independent randomized trials in severe asphyxiated term infants and one randomized trial involving preterm neonates have shown that a single dose of theophylline, given early after birth, was associated with decrease in serum creatinine and improved urine output [159–162]. Based on these findings, the KDIGO guidelines recommend a single dose of aminophylline for asphyxiated infants at risk for AKI [163]. More recently, a meta-analysis including 6 randomized trials enrolling 436 neonates treated with prophylactic theophylline as compared to placebo further confirmed the reno-protective effect of theophylline. A 60% reduction in the incidence of AKI and a decrease in serum creatinine over days 2–5 without significant difference in complications was reported [164]. However, because theophylline has some potentially harmful neurologic effects and because therapeutic hypothermia is now standard of care in these infants, further comparative trials are needed to determine whether these agents improve short-term and long-term renal and neurodevelopmental outcomes [165]. Recently, another methylxanthine, caffeine citrate, administered in the first 7 postnatal days, was associated with a reduced incidence and severity of AKI both in preterm neonates and in premature infants diagnosed with NEC [166, 167].

Few other studies have specifically addressed therapies for AKI in neonates. In an uncontrolled retrospective study of 7 infants with hyperuricemia secondary to AKI treated with intravenous **rasburicase** administration of a single bolus determined a significant decrease of uric acid and creatinine and an increase of urine output within 24 h [168].

As described above, drugs are common causes of AKI in neonates [130–138]. In the setting of AKI, an **evaluation of all medications** should be performed to eliminate nephrotoxic agents and to determine the proper dose of other medications in the context of reduced kidney function and drug clearance. Moreover, whenever possible blood levels should be measured in order to maintain the levels in the therapeutic range and reduce the risk of nephrotoxicity [140]. Involvement of a pharmacist is highly advised especially in those infants receiving nephrotoxic combination therapy for extended periods of time [138–169].

Electrolyte disorders and acidosis are common in neonates with AKI and may complicate the clinical course after AKI. For the management of electrolyte disorders we refer to the above sections of this chapter.

Finally, efforts should be made to provide adequate **nutrition** in NICU patients with AKI [122–170]. Trials in neonates are lacking but extrapolating data from critically ill children,

underfeeding is common in AKI and it is important to ensure adequate caloric intake in order to prevent catabolism [171]. Hyperglycemia should be avoided and may require treatment with insulin [137]. Protein intake should be adjusted to meet at least the basal growth requirements (1–2 g/kg/day). These goals could be challenging in oligo/anuric neonates and the risk of fluid overload should be carefully weighed against the risk of malnutrition. If nutrition cannot be provided due to risk of further fluid accumulation, initiation of kidney replacement therapy should be considered.

Dialysis in Newborns

Over the past decades, technological advances and increased expertise have made it possible to support very small infants with dialysis. Nowadays, infants with AKI can receive peritoneal dialysis, hemodialysis or continuous kidney support therapy (CKST) [143, 172, 173]. The **choice of dialysis modality** in critically ill neonates relies on the clinical goals, patient characteristics, and local expertise. Local expertise and facilities affect the dialysis modality choice. Different programs provide neonatal dialysis in one or more location(s) - neonatal ICU, pediatric ICU and/or cardiac ICU.

The **indications** for the different kidney support therapies for neonates and young infants generally resemble those in older children. Whatever the clinical context, general indications for therapy include severe hyperkalemia, intractable acidosis, uremia, fluid overload, prevention of fluid overload, inability to provide adequate nutrition due to concerns of fluid accumulation.

Although most programs that offer dialysis in neonates use peritoneal dialysis, it may not be possible to perform in certain situations; thus HD and/or CKST complements PD. CKST has increased as a form of treatment for children and neonates with AKI in the US [174] and Europe.

In the largest reported multicentric, multinational cohort of neonates with AKI (AWAKEN study), kidney replacement therapy (KRT) was required in 25/605 patients (4.1%). Eleven out of 25 of these patients needed CKRT + ECMO, 9 PD, 4 CKRT and 1 PD + CKRT. No patient was treated with intermittent HD. Although the survival of infants with AKI treated with KRT was higher than that previously reported (76% vs. 44%), the use of KRT was significantly associated with survival (76% vs. 90,9% in AKI patients not treated with KRT; $p < 0.01$) [175].

Peritoneal Dialysis

Peritoneal dialysis (PD) has been extensively used in infants given its simplicity, ability to perform without sophisticated machines, and its slow, continuous action. It is usually well tolerated in small infants [176]. PD has been successfully performed also in very low-birth weight and even extremely low-birth weight neonates, where extracorporeal dialysis faces anatomical barriers.

PD is performed after placement of straight or curled infant catheters. This can happen by percutaneous placement or by surgery. Although surgical implantation is considered the gold standard for PD placement in children, percutaneous placement is a valid alternative and may become essential in low income countries where surgery may not be available. The catheter can be placed by a trocar or, more safely, by Seldinger technique [177].

The most frequent complications include: leakage from catheter entrance, peritonitis, catheter obstruction, bleeding at catheter insertion, exit site infection, hyperglycemia and bowel perforation are the main PD complications [177].

PD prescription in critical neonates is based on frequent, continuous exchanges, with low volumes of dialysate. Regardless whether the catheter is placed percutaneously or surgically, initial loads should be in a low range of 10–20 mL/kg of body weight since larger loads may cause dialysate leakage and diaphragm lifting with respiratory complications [177]. Starting with a standard glucose concentration (1.5 g/dL) is recommended to avoid initial hyperglycemia. Subsequently ultrafiltration rate must be monitored and dialysate glucose concentration adapted according to ultrafiltration needs [177].

Dwell times are usually short, down to 30–40 min in neonates. When large volumes of ultrafiltration are obtained, excessive sodium loss in the ultrafiltrate may occur. This loss is related to patient size and is most marked in neonates. Oral, intravenous or intraperitoneal sodium supplementation may be needed [177].

Outcome data in neonates who undergo PD after cardiopulmonary bypass surgery suggest that early PD improves outcomes. Data on 146 infants who underwent cardiopulmonary bypass surgery, significantly better survival at 30 and 90 days was observed with "early" PD (started at the end of surgery or day after surgery) as compared with controls starting PD after the second day after surgery. The impact of fluid overload on outcome was analyzed in a prospective trial comparing two interventions in infants undergoing cardiac surgery. In the first study period, ascites was passively drained through a PD catheter placed at the time of surgery. In a second series of patients PD was initiated within 2 h of arriving at the cardiac ICU. The infants receiving active PD had significantly more negative net fluid balance, lower mean inotrope score, lower serum cytokine concentrations and earlier sternal closure compared to the infants who had only their peritoneal fluid drained [178].

Further analysis of these and other studies in infants undergoing cardiopulmonary bypass surgery confirmed that attainment of a negative fluid balance is associated with improved survival and other clinical outcomes. Taken together, early start of dialysis, avoidance of fluid overload and its consequent correction appear to favor a good outcome in critically ill infants and may be more important than the choice of treatment modality.

Hemodialysis (HD) can be performed in infants with good results, although poor vascular tolerance and the large extra-corporeal volume provide additional challenges [173].

Hemodialysis

Hemodialysis (HD) can be performed in infants with good results, although poor vascular tolerance and the large extra-corporeal volume provide additional challenges [173]. Although **Extracorporeal Dialysis** has been performed in neonates in the past five decades the main problems that have been limiting its widespread use are vascular access and cardiovascular tolerance. HD has mainly been used in metabolic crisis and intoxications, when urgent toxic compound removal is needed. There are few reports on the use of *intermittent hemodialysis* (*HD*) in neonates with AKI. In 1994, Sadowski described 33 acute infants weighing less than 5 kg treated with intermittent HD. A high rate of hypotensive episodes was reported (64%), and a 52% survival rate [173].

Blood flow is mainly dependent on vascular access performance. It is usually prescribed as 5–10 mL/kg body weight; in patients needing a high clearance rate (e.g. hyperammonemic crisis) the maximally achievable flow rate should be used and will be rate limiting for the efficacy of purification. Standard or even lower dialysate flows (300–500 mL/min) combined with low neonatal blood flows usually provide maximal solute extraction. Dialysate warming systems are provided by any HD monitor and preserve neonatal thermoregulation. Vascular access for extracorporeal dialysis is often troublesome in neonates due to the mismatch between vessel size and the diameter of the catheters minimally required to obtain adequate blood flow.

Continuous Kidney Replacement Therapy (CKRT)

Continuous Kidney Replacement Therapy (*CKRT*) may allow for achievement of the goals of therapy better than HD in neonates. Because it allows for 24 h metabolic and fluid control as opposed to the transient correction and shifts that occur between intermitten HD sessions.

The most commonly used catheters in neonates are dual-lumen, low resistance catheters. 6.5–8 F caliber. The length of the catheter will be depending on whether the catheter is tunneled or not, and whether the catheter is placed in the right internal jugular, left internal jugular, or femoral approach. As an alternative, two smaller single-lumen catheters have been used successfully [187].

Vascular access in children and infants on CKRT can be challenging. Results from the

ppCRRT Registry, 5-French catheters showed the poorest function, none of them lasting more than 20 h [188]. Catheterization of the internal jugular vein and the use of CVVHD was found to be associated with the best catheter survival introduction of latest-generation CKRT machines might change the choice of vascular access in neonates (see below).

Until recently, CKRT was performed using tubing, filters and consoles originally conceived for adults [189]. However, problems related to the fluid accuracy and large extracorporeal volumes compared to patient blood volume pose to the smallest neonates. The larger the extracorporeal volume the higher the risk of hemodynamic instability during start, hypocalcemia, acidosis and dilution effect of hemoglobin, platelets and coagulation factors. Blood prime procedures have been reported to minimize the blood exposures.

The creation of monitors and circuits specifically dedicated to neonates has profoundly changed the approach to the extracorporeal treatment of newborns with AKI. In Tables 53.6 and 53.7 list of filters and monitors available for neonates in 2022.

In 2012, Ronco et al. described the creation of the first CKRT monitor for infants <10 kg BW [190] and in 2014 the first patient was treated with this specific device [191]. This machine was approved by the US FDA in April 2020. It provides extraordinary accuracy in blood pump and fluid balance with a blood priming volume ranging 27–42 mL. The machine provides either CVVH and CVVHD (but not both). Blood flow can be set at 1–50 mL/min and dialysis flow from 1 to 10 mL/min, with a maximum effluent flow (net ultrafiltration + dialysate) of 20 mL/min. The maximum fluid removal is 1000 mL per day, with an accuracy of 1 mL per hour. Carpediem® works with such small catheters thanks to a three-roller blood pump that reduces the dead space of the pump tubing segment and the pulsatile profile of the blood flow as compared to conventional two-roller pump systems. This allows continuous aspiration even at very low blood flows through very small catheters [190]. 5F double lumen or combinations of 3.5F and 5F single lumen catheters were used in a series of 26 neonates treated with Carpediem® [192]. 25 of the children survived the CKRT period and 18 survived the NICU stay.

In 2014, Coulthard et al. showed the ability of a syringe-driven machine, the Newcastle Infant Dialysis and Ultrafiltration System (NIDUS®, Allmed, London, UK) to provide better clearance and more accurate ultrafiltration than peritoneal dialysis [193]. The device withdraws 5–12.5 mL aliquots of blood from a single-lumen central venous line, runs it across a dialysis filter and returns it back through a syringe pump. The I-KID study, a randomized clustered wedge study was conducted in England. Study results are expected to be shared in 2022 [194].

Askenazi et al. adapted the Aquadex® (CHF Solutions, Eden Prairie, MN) ultrafiltration system to provide CVVH to neonates [195]. Aquadex® was originally conceived for the treatment of edema in adult cardiac patients but its small priming volume was exploited to create a hemofiltration system in infants. The machine provides a blood flow of 10–40 mL/min; it is equipped with a 0.12 m^2 polysulfone membrane and a second pump that produces up to 500 mL/h ultrafiltrate in 10 mL/h increments. Reinfusion is provided by an infusion pump external to the circuit. In a 3-center retrospective study among 117 children treated with the Aquadex® system, 72 were under 10 kg body weight and 23 of these survived to discharge. Complications during therapy were seen in 15% of treatments and most were vascular access–related [196].

CKST Prescription for Neonates

No official recommendations for *adequacy* in critically ill infants exist. In neonates with AKI or congenital kidney failure, the daily clearance is potentially much higher than intermitten HD because clearance can occur continuously. The broader aims of metabolic and fluid control, hemodynamic stability, vascular access preservation, nutritional adequacy, and appropriate levels of essential drugs (i.e. anti-microbials) may be more important than waste product removal rates. Some programs aim for filtration rate of 2000 mL/h/1.73 m^2 others aim for a filtration rate of 20–25 mL/kg/h.

Given the immaturity of neonatal thermoregulation, CKRT induced heat loss could hamper the thermal protection adopted in NICU, especially in low birth weight neonates, with unpredictable consequences on vascular stability. Warming of fluids is needed and different approaches are available. Neonates are at an intrinsically high risk of hemorrhage, and extracorporeal treatment modalities are clearly fraught with an increased risk of hemorrhage. Safe and effective anticoagulation protocols are critical to the success of CKRT.

In the ppCRRT registry, small children <10 kg were more likely to receive heparin anticoagulation compared to citrate regional anticoagulation. In the overall registry, the rates of circuit survival was similar between groups, but the heparin group had higher rates of bleeding than the citrate group [197]. In those receiving heparin anticoagulation, some programs monitor aPTT (goal range 50–70) other target ACT rates of 160–180, while others target anti-Xa levels of 0.3–0.5. The use of citrate regional anticoagulation in smaller children can be more challenging for several reasons. First, traditional CKRT machines require a minimum blood flow, and the blood flow rate per kg is inversely related to body weight. Because the citrate dose depends on blood flow, the amount of citrate used in small children is therefore higher and may require higher clearance rates to achieve target levels. Furthermore, premature infants are born with immature liver function.

In critically ill children with a low body weight.

Management of Hyperammonemia with Kidney Support Therapy

A peculiar indication to KRT in the neonatal age group with metabolic crisis due to Inborn Errors of Metabolism (IEM), most often manifesting as neonatal hyperammonemia or leucinosis. Hyperammonemia is a severe clinical condition characterized by high ammonium levels, excess glutamine accumulation in astrocytes inducing cell swelling and brain edema. In most cases, it presents in full-term neonates with anorexia, seizures, lethargy, coma and death. Most frequently, it is caused by urea cycle defects (UCD) and organic acidurias (OA). The initial management of an undiagnosed hyperammonemia includes stopping protein intake, intravenous glucose, and initiation of first-line medications including L-arginine, nitrogen scavengers, carbamylglutamate, carnitine, vitamin B12, and biotin. When conservative treatment fails and whenever there is severe symptomatic hyperammonemia, dialysis has to be rapidly established in order to avoid permanent neurological sequelae or death [198]. In leucinosis (maple syrup urine disease; MSUD), deficiency in branched chain ketoacid dehydrogenase leads to the accumulation of branched chains aminoacids (BCAA) leucine, isoleucine, and valine in cells and body fluids. Given the poor renal clearance of BCAA, their accumulation can cause neurologic damage. Medical treatment consists in incorporation of BCAA into protein synthesis with nutritional support but, like in hyperammonemia, it may not be successful and dialysis must be started to clear excess BCAA [199]. In both cases, extracorporeal dialysis provides higher clearances than PD [198, 200]. HD provides highest ammonium clearance and it has been recommended as gold standard of therapy [201], although high volume CKRT (initially at 8 L/h/1.73 m^2) has been proposed as an alternative [198, 200, 202]. The practical application of CKRT in neonatal metabolic decompensation differs from that of AKI since it has been demonstrated in vitro that the clearance of ammonium and leucine achieved with CVVHD depend on dialysate flow rate, being substantially higher with increasing flow rates [200]. However, as in the case of AKI, there is no definite demonstrated association between a specific dialysis modality or of dialysis efficiency with survival. In the study of Schaefer et al. [200], out of nine patients, the five with fastest depuration survived with no or mild neurological impairment while the other four died or survived with severe sequelae. By contrast, in the study of Pela et al. [203], four out of seven neonates with organic acidurias treated with PD survived with no or mild neurological impairment. In a series of 12 neonates with metabolic crises from different IEM, all survivors showed plasma ammonia less than 300 μmol/L

after 8 h of KRT and significantly lower ammonia concentration than non-survivors at the same time of treatment. This difference was not related to dialysis modality [180]. In a systematic review of 90 reports on the impact of ammonium levels and dialysis on outcome in 202 infants with UCDs, a higher ammonium level was a determinant for starting dialysis but no significant influence of this treatment on outcome was observed [181]. In a series of 45 hyperammonemic newborns treated with KRT, predialysis ammonium levels were significantly associated with a composite end-point of death or neurological sequelae while the outcome was not related with dialysis modality. Interestingly, while the patients treated with HD had a shorter ammonium decay time compared with all other patients ($p < 0.05$), no significant difference in ammonium reduction rate was observed between patients treated with PD, CAVHD or CVVHD.

The above considerations raise the question if it is correct to evaluate dialysis efficiency by decay time. Under these circumstances, ammonium concentration is strongly dependent on the metabolic state and the majority of patients start dialysis with a medical therapy already under way. Dialysis is part of an overall treatment setting which includes variably efficacious pharmacological support and variably timed initiation of medical treatment and dialysis, with a major modifying influence of the type of underlying metabolic defect on final outcome.

In summary, while ammonium and leucine are small, unbound molecules and behave as such during dialysis (i.e.: best clearance by diffusion, most rapid depuration by HD, less rapid depuration by CKRT and by PD), the dialysis modality does not determine the outcome. A practical approach to the treatment of hyperammonemia in infants has been recently proposed [204].

Outcomes of Neonatal AKI

AKI is associated with significant mortality in critically ill children [205, 206] and adults [207–211], even after controlling for medical co-morbidities, severity of illness scores, and patient demographics. Epidemiological studies in several high-risk groups of neonates have been performed, including very low birth weight infants, near term/term infants with perinatal depression, neonates with severe asphyxia undergoing hypothermia, neonates receiving extra-corporeal membrane oxygenation and infants with cardio-pulmonary bypass—associated AKI. Using a categorical AKI frameworks the RIFLE classification systems [205, 207] allow for improved diagnosis and staging of AKI by severity, these studies have provided some evidence that AKI is independently associated with mortality in neonates and young infants even when controlling for potentially confounding demographics, co-morbidities, and interventions.

Critically Ill Neonates

In the multinational retrospective observational Assessment of Worldwide Acute Kidney injury Epidemiology in Neonates (AWAKEN) study using the KDIGO neonatal AKI definition, the incidence of AKI in NICU patients was about 30%, with gestational age following a "U"-shaped distribution (AKI incidence: < 29 week: 45%; ≥29–36 week: 14%; ≥36 week: 41%). Even after controlling for multiple potential confounders, neonates with AKI had 4.6 times higher adjusted odds of death and 8.8 more adjusted hospital days [175]. These associations held true for all gestational age groups [175]. A full account of all studies conducted in this population is beyond the scope of this chapter. Review of outcome studies in premature neonates [212–214], neonates with perinatal asphyxia (REF), those who receive extra-corporeal membrane oxygenation [215] those who undergo cardio-pulmonary bypass surgery have been recently published [216].

Outcomes of Neonates Treated with Kidney Support Therapy (KST) for AKI

The interpretation of outcome of infants treated with dialysis is hampered by several problems. First, the reasons to start KSTt for AKI or not based on AKI diagnosis/criteria. Rather, most pediatric patients initiate kidney support for fluid

overload or a combination of fluid overload and AKI. Secondly, the timing of support and the treatment choices are made according to local availability, clinician preference and expertise. Thirdly, the modality, dose and approach are set to institutional practice. Finally, programs will provide kidney support (or choose not to support) neonates based on the severity of illness. Programs that provide kidney support for neonates of higher severity of illness would be expected to have higher mortality rates. Furthermore, most of the studies are retrospective studies at risk for reporting bias.

With this in mind, the overall survival rates of critical ill neonates treated with dialysis are generally poorer than those reported for older children. In the Prospective Pediatric Continuous Renal Replacement Therapy (ppCRRT) Registry, the cohort of children <10 kg (n = 84) had lower survival rates than children >10 kg (n = 166) (43% vs 64%). Not differently from older children, fluid overload, high PRISM2 score and urine output at dialysis initiation were found associated with mortality. In particular, patients with fluid overload >20% at the time of CKRT initiation had an almost five times higher odds ratio of death than those who initiated CKRT with <10% fluid excess. Survival was better in neonates who were able to achieve dry weight during CKRT. This suggests that fluid overload predisposes to a poor outcome but its correction may reverse this association [143]. Recent studies using novel and adapted machines with small extra-corporeal volumes suggest better outcomes [196, 217].

Long-term Effects of Prematurity and Neonatal AKI on Chronic Kidney Disease

Links between prematurity/low birth weight and chronic kidney disease in adulthood become increasingly apparent [218]. Figure 53.3 depicts the possible etiology of chronic kidney disease in premature and low birthweight infants. Pre-term delivery disrupts nephrogenesis, which is not complete until around 34–36 weeks gestation. A small number of autopsy studies have suggested that nephrogenesis continues for only a short time after birth [9, 219, 220]. The remaining nephrons hypertrophy to compensate for decreased nephron mass and, according to Brenner's hypothesis, the resultant "hyperfiltration" eventually becomes deleterious and leads to glomerulosclerosis with sodium retention, systemic hypertension, proteinuria and progressive chronic kidney disease [221]. Thus, premature birth may 'prime' infants for kidney injury and chronic kidney disease. Indeed, premature infants with a birthweight less than 2500 grams have nearly twice the odds of having low glomerular filtration rate, microalbuminuria, end-stage kidney disease and hypertension than their term counterparts [222].

Moreover, the impact of additional AKI events in the NICU on long-term kidney and health outcomes is not yet known. Previously, it was assumed that subjects who survive an episode of AKI would recover kidney function without long-term sequelae; however, recent data from animals [223], critically ill children [224, 225] and adults [226–238] suggest that AKI survivors are indeed at risk for development of CKD. A meta-analysis in adults with AKI showed an

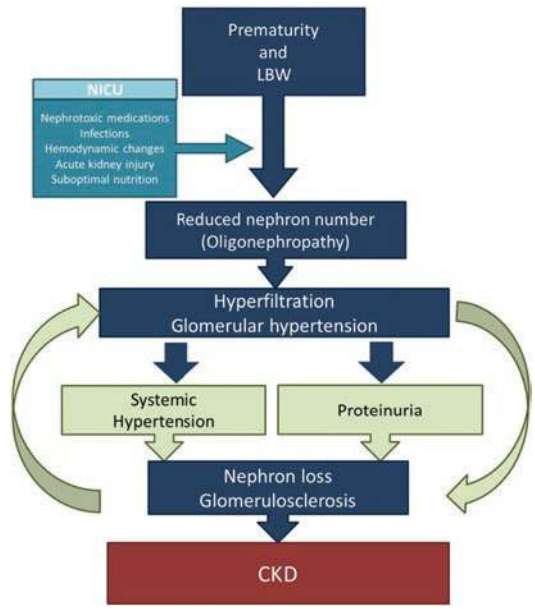

Fig. 53.3 Possible etiology of chronic kidney disease in premature and low birthweight Infants [218] (from Carmody et al. Pediatrics 2013)

almost ninefold risk to develop incident CKD, a threefold risk to progress to end-stage kidney disease and a doubled mortality risk compared to patients without AKI [239].

The role that AKI plays in the development of CKD in the infant population is still unknown. Several small single center retrospective reports have suggested that CKD can develop in infants who had AKI [101, 240]. Human autopsy and animal studies suggest that AKI affects post-natal nephron development. Premature infants who suffer AKI were shown to have fewer layers of nephrons and abnormally configured glomeruli compared to term neonates [9, 220]. Large prospective cohort studies designed to determine risk factors for long-term CKD are needed to define the most appropriate surveillance protocols and identify the subjects at greatest risk.

Future Directions in Neonatal AKI

Our understanding of neonatal AKI has improved and we now have clear epidemiological evidence suggesting that AKI is common and associated with mortality in this age group. New AKI definitions based on SCr, urine output, Cystatin C and emergent urinary biomarkers promise to improve our ability to reliably define neonatal AKI. Studies in VLBW neonates [241, 242], infants undergoing cardiopulmonary bypass surgery [243–251], and other sick NICU patients suggest that these biomarkers can predict a subsequent rise in SCr as well as mortality [84]. However, large comparative studies will be required to determine which functional and kidney injury biomarkers can best predict hard clinical outcomes. Importantly, the normal ranges of urine biomarkers in premature neonates will require careful validation since excretion varies by gestational age, probably due tubular immaturity [241]. With better definitions and earlier indicators of AKI, we will be able to better understand the risk factors, develop preventive strategies, and timely apply appropriate management to improve outcomes in those at risk for AKI.

Another emerging breakthrough regards the provision of extracorporeal treatments for neonates. Thanks to major technological advances, dialysis machines miniaturized for the specific needs of neonates have become available. Machines such as the CARPEDIEM, Aquadex and NIDUS are making important differences in the ability to provide safe and effective therapies in small infants. The main advantage of these machines is the low extra-corporeal volume which drastically lowers the rates of hemodynamic instability at circuit initiation. Furthermore, smaller circuits allow for smaller catheters to be used, enabling extracorporeal therapy even in very small neonates. Maximizing the efficiency and safety of kidney support therapies with these devices will change our approach to the neonate with AKI. One day soon, any infant who could benefit from kidney support therapy will no longer be left without an appropriate and safe treatment option.

Part XII

Chronic Kidney Disease

Demographics of CKD and ESRD in Children

54

Julien Hogan and Karlijn J. van Stralen

Introduction

Irreversible kidney damage or so-called chronic kidney disease (CKD) has become a major public health problem worldwide. The adult population has been the subject of extensive epidemiological research [1, 2] but fewer data are available about CKD in children [3]. Despite major scientific advances resulting in substantial improvement in the care of children with CKD, some will still progress and require kidney replacement therapy (KRT). ESKD is a devastating disorder causing substantial mortality and morbidity (most notably cardiovascular, cancer and infection), but this is compounded by specific problems which occur in children such as impaired growth and psychosocial adjustment [4], all of which severely impact upon quality of life [5]. Understanding of the epidemiology of CKD in children is required in order to make a precise and early diagnosis, identify preventable or reversible causes of progression, predict prognosis, and aid the counseling of children and their families.

Part I: CKD (Stages I–4)

Definition of CKD

Precise data on the epidemiology of CKD in children allowing the evaluation of the incidence and prevalence of CKD and the comparison between countries is lacking. This was in part due to the lack of a universal definition of CKD. For example, the ItalKid Project and North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) defined CKD as having a glomerular filtration rate (GFR) of below 75 mL/min/1.73 m^2 [6, 7]. Others based their definition on serum creatinine levels themselves or on other thresholds of GFR [8–10]. In 2002, the National Kidney Foundation's Kidney Disease Outcomes Quality Initiative (NKF-K/DOQI) published a classification of CKD applicable to children [11]. CKD was defined by the persistence for more than 3 months of morphological, histological or biological abnormalities of the kidneys and/or a glomerular filtration rate (GFR) below 90 mL/min/1.73 m^2. This classification grades CKD in five stages from stage 1 with normal GFR to end-stage kidney disease (ESKD, stage 5). The K/DOQI classification was revised in 2012 by the KDIGO (Kidney Disease: Improving Global outcomes) to reflect the risk of progression to ESKD and is based on both GFR and albuminuria [12]. Of note, some pediatric specificities need to be considered when using this classification: a) the criteria for duration >3 months

does not apply to newborns or infants <3 months of age, (b) the criteria of a GFR <90 mL/min/1.73 m^2 does not apply to children <2 years of age as neonates are born with lower GFR, which increases to normal values in the first 2 years of life, (c) a urinary total protein or albumin excretion rate above the normal value for age may be substituted for albuminuria ≥30 mg/24 h. A similar classification based on the same GFR cut-offs and on the urine protein-creatinine ratio and specifically validated in two large pediatric cohorts (CKID in the USA and ESCAPE in Europe) has been developed recently (Fig. 54.1; Table 54.1) [13].

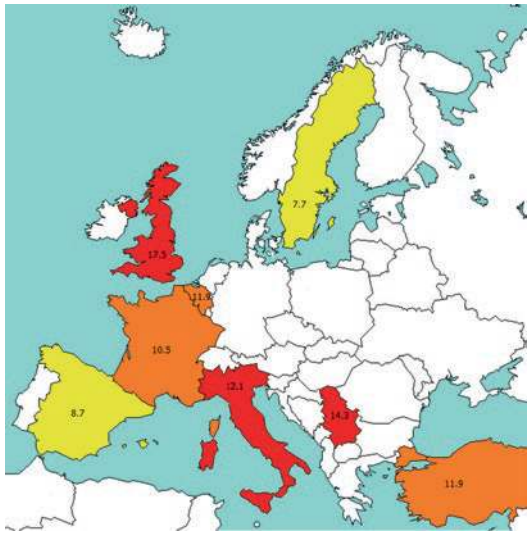

Fig. 54.1 Reported incidence (pmarp) of CKD in children in Europe

The new classification was widely adopted after its introduction; however, its limitations and possible modifications have been a matter of extensive discussions. Moreover, despite efforts to standardize creatinine measurement (by using enzymatic methods instead of colorimetric methods) and GFR estimation, there are still ongoing debates on which eGFR equation should be used in various clinical conditions particularly in early stages of kidney injury [14–17]. In 2009, the bedside Schwartz formula using height and serum creatinine and a unique k coefficient was developed and remains frequently used in clinical practice [18]. Since then many equations have been published using serum creatinine or cystatine C or a combination of both. Recently, papers focused on developing formulas that perform consistently over the whole range of GFR from infants to young adults (FAS [19], CKID U25 [20]).

Screening for CKD

CKD screening and surveillance in adults, either population-based or targeted at risk populations, has become widely advocated and implemented in many countries worldwide, in an attempt to prevent ESKD and the progression of CKD. However, the benefit of screening for early-stage CKD is uncertain [21]. The benefit of such programs in children is even more uncertain [22]. Tests used for CKD screening in children

Table 54.1 CKD classification and estimated risk of progression adapted from (Furth et al. AJKD)

			Baseline UPCR		
			<0.5	[0.5, 2.0]	>2.0
Baseline GFR	I	≥ 90	IR = 2.3 (0.7, 7.0) per 100p-y	–	–
	II	[60–90)	IR = 1.5 (0.8, 2.6) per 100p-y	IR = 8.1 (4.8, 13.8) per 100p-y	IR = 14.2 (6.4, 31.6) per 100p-y
	IIIa	[45–60)	IR = 3.6 (2.5, 5.0) per 100p-y	IR = 6.4 (4.5, 9.1) per 100p-y	IR = 22.8 (13.7, 37.8) per 100p-y
	IIIb	[30–45)	IR = 5.9 (4.4, 7.8) per 100p-y	IR = 10.7 (8.1, 14.1) per 100p-y	IR = 32.0 (23.5, 43.6) per 100p-y
	IV	[15–30)	IR = 17.4 (12.8, 23.6) per 100p-y	IR = 24.8 (19.5, 31.6) per 100p-y	IR = 58.4 (44.5, 76.6) per 100p-y
	V	<15			

Based on baseline GFR and UPCR patients are classified in 6 groups (colors) based on their risk of progression. Incidence rates (IR) of 50% GFR decline or GFR < 15 mL/min/1.73 m^2 are reported

are usually limited to urinary dipstick protein instead of urine albumin/creatinine ratio or on creatinine-based calculation of estimated GFR as recommended for adults. There is also a large variation in the methods used and approaches taken by the different countries, and the findings have shown poor reproducibility [22].

The main studies about screening for CKD in children are summarized in Table 54.2 [23–34]. Mass screening programs to detect CKD in children have been undertaken for many years in several Asian countries such as Japan, Taiwan and Korea [23–25]. Conversely, screening programs have not been adopted in Europe or Australia but screening using urine dipsticks have routinely been performed in healthy children for decades in the United States. In 2000, the recommendations from the American Academy of Pediatrics were to screen the urine of preschool children and adolescents [35]. This policy has been revised in 2007 and this practice is no longer recommended [36]. Although a decrease in the incidence of ESKD has been observed in Japan and Taiwan, there is only limited evidence that early detection of kidney injury in children may lead to effective interventions to slow progression of CKD and further reduce the risk of developing ESKD [22]. Furthermore, some studies suggest that a urine dipstick is not a cost-effective strategy for screening in children [37] given the high prevalence of transient proteinuria in this population. Although some population-based studies assessing CKD epidemiology by GFR estima-

Table 54.2 Results from studies reporting screening programs from chronic kidney disease in children

Country [Reference]	Study period	Study population	Screening criteria	Main findings
Japan [23]	1974–2002	Population-based 6–14 years old	2 positive urine dipsticks	Prevalence of Pu: 0.07% in 6–11 years 0.35% in 12/14 years old
Taiwan [24]	1992–1996	Population-based 6–15 years old	Pu > 100 mg/dL CKD (SCr >1.7 mg/dL)	Prevalence Pu 0.06% Prevalence CKD 0.002%
Korea [25]	1998–2004	Population-based 6–18 years old	2 positive urine dipsticks	Prevalence Pu 0.2%
Australia [26]	2004–2008	Population-based (57% Arboriginal) 4–14 years old	Single assessment Urine dipsticks uACR≥3.4 mg/mmol	Prevalence of albuminuria at baseline 11.5%
India [27]	2013–2016	Population-based 8–18 years old	Single assessment Urine dipsticks	Prevalence of Pu 1.9% Prevalence of hematuria 5.2%
USA [28]	2009–2014	Population-based 12–18 years old	Albuminuria (uACR) eGFR (bedside Schwartz)	Prevalence of albuminuria: 13.7% Prevalence of persistent albuminuria 3.29% Prevalence of eGFR<60: 0.91%
Singapore [29]	1999–2000	Population-based 12 years old	Urine dipstick	Prevalence of Pu 1.3%
China [30]	2003–2005	Selected population School age children	2 positive urine dipsticks	Prevalence of Pu and/or Hu in 2 specimens: ~1%
Finland [31]	NA	Selected population 8–15 years old	4 urine samples (2 morning, 2 evening. Dipstick and measured Pu	Prevalence of Pu: 10.7% on at least 1 specimen 2.5% on 2 specimens 0.1% on 4 specimens
Iran [32]	NA	Selected population 6–7 years old	Urine dipsticks	Prevalence of Pu: 3.6% Prevalence of persistent Pu: 1.3%
Mexico [33]	2006–2007	Selected population 0–18 years old	Single assessment urine dipstick eGFR (Schwartz)	Prevalence of Pu 16.1% Prevalence of hematuria 17.5% Prevalence of eGFR<60: 1.7%
UK [34]	1967–1969	Selected population 5–16 years old	2 positive urine dipsticks	Prevalence of persistent proteinuria 0.8% on 2 specimens

tion have been performed and indicate that a certain proportion of asymptomatic children have CKD, no systematic national screening program based on GFR assessment in children is currently ongoing.

Demographics of CKD

There is limited information on the epidemiology of early stages of CKD in children. As CKD is usually asymptomatic in its early stages, providing precise epidemiological data is difficult so CKD in children is likely to be underestimated and underreported. Although some pediatric CKD registries using the K/DOQI classification are beginning to emerge, only a few reports on the epidemiology of CKD stages 2–5 in children are available. Due to lack of resources and national renal registries, we know even less about the incidence and prevalence in low income countries. For these countries, data are mostly obtained from reports of major tertiary care referral centers, but the validity of this data is variable.

Europe

The largest population-based study in Europe on the epidemiology of pediatric CKD is the ItalKid project. This study in Italy has been collecting data since 1990 on the epidemiology of childhood CKD, describing the natural history of the disease, and identifying factors that influence its course [6]. So far, nearly 1198 patients have been registered. Other nation-wide European studies are the Serbian CKD registry [38], collecting data on over 336 patients since 2000, the Belgium CKD registry which started in 2001 and has over 143 patients [39], and the data from the Swedish Pediatric Nephrology Association [40]. Also regional studies have taken place in Spain [41], the South-East of the UK [42] and Lorraine in France [8].

Several pediatric nephrology societies from European countries have provided data on the early stages of CKD. Even though age categories and definition of CKD differed between countries, incidence in Europe was consistent, ranging from 8 to 14 per million age-related population (pmarp) for CKD stages 2–5, and being around 8 pmarp for CKD stage 4–5 (Fig. 54.1). The incidence was highest (17.5 pmarp) in a report from the United Kingdom but the study was hospital-based leading to potential referral filter bias and there may be some uncertainty about the covered geographical area [42].

While an increase in incidence since the 1970s was seen in France [8], this was not seen when comparing two time periods in Sweden [9, 40]. Two studies from Serbia and the UK also suggested an increase in incidence in the past 10 years [38, 42]. Prevalence ranged from about 55–60 to 90–95 pmarp in Spain, Italy, UK and Serbia, depending on the clinical definition of CKD that was used in each study.

In Turkey, the CREDIT study reported a prevalence of CKD stage 3–5 of 2600 pmarp in children aged 5–18 years old in 2007 [43].

North America

In Northern America most of the information on CKD in children derives from two large sources of information namely the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) [44] and the Chronic Kidney Disease in Children Prospective Cohort Study (CKiD) [45]. Both studies are collecting data on a voluntary basis and are not population based.

Population-based data are available in adolescents since the NHANES study investigated albuminuria and GFR in a nationally representative sample of the US population including 9225 adolescents aged 12–18 years over 3 study periods. They found a prevalence of 0.91% [95% CI 0.58–1.42%] for CKD stage 3–5 and a prevalence of persistent albuminuria of 3.29% [95% CI 1.94–4.63%] in the 2009–2014 survey [28].

Latin America and the Caribbean

In Chile, a national survey of pediatric nephrologists estimated an incidence of CKD (GFR <30 mL/min/1.73 m^2) in children aged less than 18 years of 5.7 pmarp and a prevalence of 42.5 pmarp in 1996 [46]. Among these patients, half were on conservative treatment and the others were on KRT. Very similar results were found in Argentina, with an incidence of 6.5 pmarp, but with a lower prevalence

(15.4 pmarp) [47]. Fifty-eight percent of this population had ESKD and started with dialysis. In Jamaica, the estimated incidence of CKD was 4.6 pmarp and 28% of them were already in ESKD, without having access to KRT [48].

A study on the epidemiology of CKD conducted in several Latin American countries (Argentina, Brazil, Chile, Colombia, Mexico, Uruguay, and Venezuela) has shown a wide variation in incidence that ranged from 2.8 to 15.8 new cases pmarp [49]. Also an indirect estimation of the incidence of CKD in Mexico suggested a very high incidence, between 24 and 39 per million inhabitants, for which the differences within Mexico were explained by the level of social deprivation [50].

Asia

The estimated prevalence of CKD stage 3–5 among Japanese children in 2010 was 29.8 pmarp [51]. This lower prevalence of pre-dialysis CKD in Japan than in Europe was consistent with the lower prevalence of pediatric ESKD in Japan. Two reports from Vietnam and one from Thailand have suggested an annual incidence of hospitalization for CKD around 5 pmarp, most of patients had already reached ESKD [52–54]. Very little is known about pediatric CKD epidemiology in India and China. A survey conducted in 91 Chinese hospitals found a total of 1658 children aged <15 years with CKD stage 3–5 between 1990 and 2002 which suggests a very low incidence of treated CKD <0.5 pmarp [55]. Patients were referred late with advanced CKD or ESKD in 80% and in-hospital mortality was as high as 72%. Similarly, in India 58% of children had ESKD at the time of CKD diagnosis suggesting that children with CKD are underdiagnosed and referred late [55].

Middle East

The referral center for pediatric kidney diseases in Kuwait provided data on children aged 0–15 years with a GFR <50 mL/min/1.73 m^2 [10]. The mean incidence was found to be as high as 38 pmarp whereas the prevalence increased from 188 in 1996 to a rate as high as 329 pmarp in 2003. The marked difference in incidence between Kuwaiti children and non-Kuwaiti residents suggested the role of genetic factors. An incidence of 12 pmarp was found in a Turkish survey including children with a GFR <75 mL/min/1.73 m^2 [56]. An incidence of 11 pmarp and a prevalence of 51 pmarp have been reported in Jordanian children [57].

Africa

Single center studies from sub-Saharan Africa showed very low incidence of CKD estimated at 1–4 pmarp in Nigeria, Sudan, and South Africa [58–61]. Another single center report from Nigeria, however, found an annual incidence of CKD stage 1–5 of 11 pmarp and a prevalence of 48 pmarp [62], which was much higher than the 1.7 pmarp reported in 2004 [63].

Causes of CKD

Type 2 diabetes and hypertension are the leading causes of CKD in adults. The distribution of the causes of CKD in children are very different with major variations between countries. Indeed, congenital abnormalities of the kidney and the urinary tracts (CAKUT) account for 50–60% of CKD cases in children in Europe [6, 38, 39, 42], Japan [51] and the USA [44]. In Turkey and in the Middle East, CAKUT remains the first cause of CKD with often a higher proportion of hereditary nephropathies related to higher rates of consanguinity [10, 56, 57, 64]. Higher proportions of glomerular diseases are found in developing countries such as India, Southeast Asia [52–54], Latin America [48, 49] and Sub-Saharan Africa [58]. The latter may be related to the high prevalence of bacterial, viral and fungal infections in these regions.

Whereas CAKUT predominates in younger patients, glomerulonephritis is the leading cause in children older than 12 years of age. Causes of CKD vary across races, for example, focal segmental glomerulosclerosis, the main cause of glomerular disease, is three times more common in blacks than in whites (19 compared with 6%) and especially among black adolescents (35%) [65].

In general, there is a predominance of male gender (male/female ratio ranging from 1.3 to 3.0). This partly reflects the higher incidence of CAKUT in boys than in girls, but has also been reported in the regions with a high rate of glomerulonephritis.

Part II: KRT (CKD Stage 5D and 5 T)

Epidemiological data on ESKD treated by dialysis or transplantation is more robust thanks to the development of several national and international registries. Unfortunately not every country has such a registry, not all children are reported to the relevant registry, and some countries with registries do not regularly publish reports. Also, as KRT is expensive not all countries are able to offer KRT to children with ESKD. Approximately 80% of the children on KRT live in Europe, Japan or the United States. Dialysis and transplant registries only collect data on treated ESKD; untreated children with ESKD are not captured. However, at least in the developed world, the proportion of children with ESKD who do not receive KRT is likely to be very low [1].

Incidence

The incidence of KRT in children varies greatly between countries but can be estimated between 5 and 10 pmarp [66–70] with extreme values ranging from 0 (Malta) to 17 pmarp (Kuwait) [71]. However, given that pediatric KRT is extremely rare, numbers in smaller countries are subject to random error. Moreover, variations in incidence may reflect variations in the incidence of CKD, differences in pre-ESKD care or differences in access to KRT. Among large countries with universal access to KRT, the US incidence is consistently high at around 12.9 per million population [72]. In Japan, incidence of pediatric KRT (4.0 pmarp) was consistently much lower than in other high income countries (Table 54.3).

Among lower income countries the incidence is typically lower, as was shown for the Eastern European countries in the ESPN/ERA-EDTA registry [73]. In developing countries where KRT is unaffordable for all but the very wealthy, incidence rates are either not available or were extremely low (<1 pmarp in Bangladesh and Nepal). Some of the variation in incidence may be due to differences in the timing of KRT initiation. In Europe, KRT was generally started at a median GFR of 10.4 mL/min/1.73 m^2 whereas mean GFR ranged from 11.3 to 13.6 mL/min/1.73 m^2 in the United States [72, 74] (Fig. 54.2).

Within-country variations occur by racial group. For example African American in the US, arboriginal children in Australia and New Zealand or children from South Asian origin in the UK [72, 75, 76] have a significantly higher incidence of ESKD than their white counterparts, although differences in the prevalence of other ESKD risk factors such as obesity or disparities in access to medical care may account for at least

Table 54.3 Incidence, prevalence and KRT modality distribution among children with ESKD

	Countries	Year	Age	Incidence/ prevalence	Treatment modality distribution

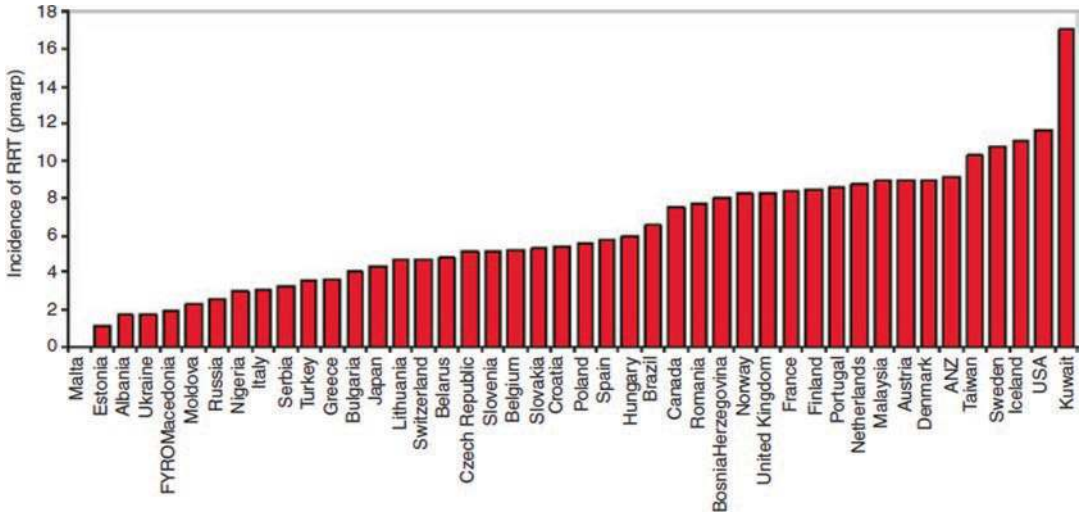

Fig. 54.2 Incidence of KRT in children aged 0–14 between 2008 and 2014

part of these differences. There are also large differences between age groups. The incidence has a typical U-shape distribution, with the highest incidence in the preschool children and in adolescents. Therefore, registries that include patients up to 20 years of age report higher incidence and prevalence data compared with registries excluding those over the age of 15.

Around 20% of patients receive a pre-emptive kidney transplant. In patients starting on dialysis, dialysis modality is strongly dependent on age; while peritoneal dialysis is the treatment of choice in the majority of young children, this pattern decreases with age, with typically higher rates of HD from the age of 10 onwards [75]. Finally, the relative proportion of HD and PD is quite variable between countries and between centers presumably reflecting differences in clinician preference and funding models [77].

Prevalence

The prevalence of treated ESKD is completely dependent on access to KRT in each country. In countries with available data on KRT, the IPNA global registry reports prevalences ranging from less than 1% in some African and Asian countries to 98.7 pmarp in the United States [72, 78]. Indeed, 80% of prevalent ESKD patients live in Europe, North America and Japan, while the prevalence of treated ESKD remains very low in many countries with the highest CKD burden [79]. Within Europe, there are also large differences, with high income countries reporting prevalence rates over 55 pmarp similar to Australia/New Zealand with 56.7 cases per million population [69], while middle income European countries report prevalences around 40 pmarp (Fig. 54.3).

In many countries the prevalence is rising due to the combination of a fairly steady incidence and improved patient survival on KRT. In the United States, the adjusted annual incidence of ESKD in the pediatric population rose slowly during the 1980s then increased marginally from 14 to 15 pmarp between 1990 and 2011 [80]. In contrast, the adjusted prevalence increased from 60 to 85 in between 1990 and 2011. Similar trends were observed in Australia and New Zealand, where the incidence has remained constant at about 8 pmarp over the past 25 years, while the prevalence of KRT increased from approximately 30–50 pmarp [69]. A report from the ERA-EDTA registry on patients aged 0–19 years starting KRT between 1980 and 2000 in 12 Western European countries showed that the incidence of KRT rose from 7 pmarp in 1980–1984 to 10 pmarp in 1985–1989 and remained stable thereafter [81], while the preva-

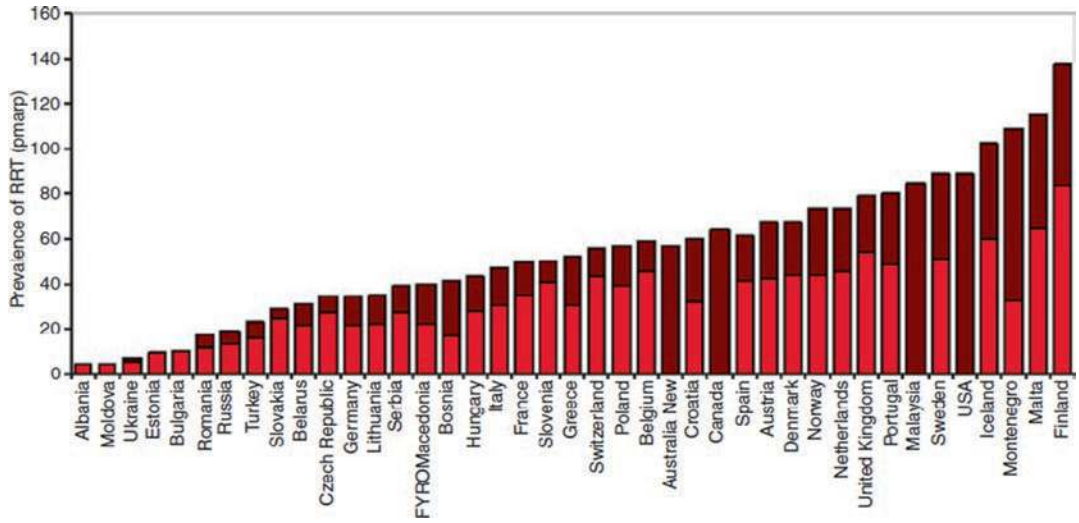

Fig. 54.3 Prevalence of KRT in children on 31st of December 2011 (2012 for Australia and New Zealand and Malaysia). The light bar corresponds to the prevalence in children aged 0–14 years, the sum of the light and the dark bars corresponds to the prevalence in children aged 0–19 years

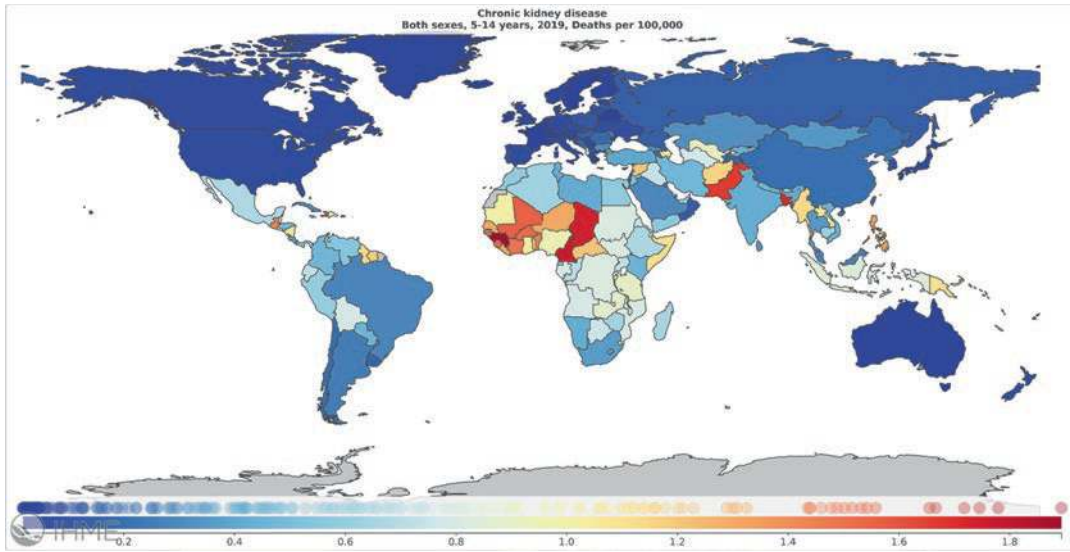

Fig. 54.4 CKD-related death rates in children aged 5–14 years (Global Burden of Disease [83])

lence increased from 22.9 pmarp in 1980 to 62 pmarp in 2000. The increases in prevalence were explained by improved survival and treatment of younger children, while the prevalence was relatively constant for the pubertal age groups.

In developing countries, a lower prevalence of children with ESKD is explained by a low access to KRT [78] and by lower patient survival. Figure 54.4 presents the death rates per country caused by CKD in children aged 5–14 years old in 2019. As expected, this map perfectly matches maps reporting access to KRT by countries [82].

Transplantation is by far the most common treatment modality in most countries, accounting for 60–80% of patients receiving KRT (Table 54.3). Here again, differences among

countries are substantial. For example, fewer than 10% of children on KRT are maintained with a kidney transplant in Belarus, compared with over 90% in Japan and Finland [84]. Recent data show that differences among countries were explained by factors such as the deceased donor rate, the pediatric priority from deceased donor programs, the living donation rate, and healthcare funding models [85]. Compared to adults, children are much more likely to be treated by transplantation due to a combination of fewer comorbidities, higher availability of living donors and, in some cases, preferential allocation of deceased donor kidneys.

Causes of ESKD

the distribution of primary kidney diseases in children reaching ESKD is different than the distribution in children with CKD. Although CAKUT is the most prevalent cause also in children with ESKD, a relatively higher proportion of ESKD cases is caused by glomerular diseases reflecting the faster progression and higher risk of ESKD of this disease group. However, a recent large cohort study from Israel demonstrated that young adults (16–25 years old) with a medical history of kidney disease in childhood but with normal serum creatinine, blood pressure and no proteinuria presented a four-fold increased risk of ESKD over a 30 year follow-up [86]. This underlines the impact of kidney diseases in childhood on ESKD in adulthood and supports long-term follow up of these patients.

There are also very specific local factors. For example, congenital nephrotic syndrome of the Finnish type, explains the very high prevalence of childhood KRT in Finland. Finally, the difference in the distribution of the causes of ESKD in children vs. adults and especially the absence of diabetes or hypertension induced ESKD explains the moderate increase in the prevalence of ESKD in children (+16.6%) in contrast with the major growth experienced by the entire ESKD population (+77%) between 2000 and 2017 in the US [72].

Conclusion

CKD and ESKD in children is a significant public health burden worldwide. Despite significant effort to collect data on children with CKD, the incidence and prevalence of CKD are underestimated in many parts of the world and further studies aiming at improving early CKD diagnosis and at developing effective strategies to slow down CKD progression are needed. For children reaching ESKD, the main challenge is the access to KRT and especially transplantation that remain unavailable to the majority of children with ESKD worldwide.

55 Progression of Chronic Kidney Disease and Nephroprotective Therapy

Elke Wühl and Franz Schaefer

Progression of kidney malfunction towards end-stage kidney disease (ESKD) is common in patients with chronic kidney disease (CKD), and once significant impairment of kidney function has occurred CKD tends to progress almost irrespectively of the underlying kidney disorder.

It was first shown in the 1930s that removal of three quarters of the kidney mass in rats leads to progressive glomerulosclerosis and functional deterioration of the remaining nephrons [1]. The glomerular lesions of the remnant kidney were associated with abnormal glomerular permeability and proteinuria. At that time, proteinuria was considered a mere marker of the extent of glomerular damage, despite the findings of Volhard and Fahr in 1914 [2] and von Mollendorf and Stohr [3] in 1924 demonstrating that kidney damage was globally related to pathological amounts of protein excreted in the urine. In 1954 Oliver et al. recognized protein droplets in the cytoplasm of tubular cells. It was proposed that proteinuria could lead to structural and functional nephron damage [4]. In the late 1960s Brenner and coworkers described the pathophysiology of the adaptation processes to nephron loss in the rat remnant kidney model. They found that after removal of nephron mass, arteriolar resistance lowers and plasma flow increases in remnant glomeruli [5]. The tone of afferent arterioles was found to drop by a greater degree than those of the efferent arterioles, increasing glomerular capillary pressure and leading to increased filtration rate per nephron. Brenner also demonstrated that therapies attenuating these changes reduce decline of glomerular function and structural alterations.

Today, there is clear evidence from clinical studies that both hypertension and proteinuria are key players in the pathophysiology of CKD progression in humans [6–8]. The renin-angiotensin system is intrinsically involved in this process, and other potential contributors include genetic background, altered mineral homeostasis, dyslipidemia, renal anemia, inflammation and oxidative stress as well as general cardiovascular risk factors such as obesity, smoking and diabetes. The phenomenon of kidney failure progression following kidney injury or maldevelopment is a current focus of research in adults and children.

This chapter summarizes the current state of knowledge regarding the pathophysiology of kidney disease progression and discusses the evidence base of renoprotective strategies in pediatric CKD.

Natural Course of Chronic Kidney Disease Progression in Children

Information on the natural course of CKD progression in children is still limited. The prospective, population-based ItalKid registry was started in 1990 and over the first 10 years 1197 children with various kidney disorders were registered, including 23% suffering from severe impairment of kidney function [9]. The incidence of kidney replacement therapy (KRT) was 7.3% per year with a 68% cumulative risk of developing CKD Stage 5 by age 20. The decline of kidney function was not linear, but rather characterized by a sharp decline during and after puberty. The probability of kidney survival decreased with lower glomerular filtration rate (GFR) at baseline. This finding supports the general clinical impression that in many children with hypodysplasia of the kidneys, the deterioration of kidney function accelerates around the time of puberty. However, it is still speculative whether this may be due to an increasing discrepancy between body size and functional nephron mass or whether the emerging production of sex steroid hormones at this age may influence kidney survival.

In a retrospective analysis of 176 patients with hypodysplasia of the kidneys, it was suggested that the natural course of kidney function in patients with congenitally reduced renal mass can be divided into three periods: an initial 'hypertrophy' phase characterized by improving kidney function (+6.3 mL/year on average during the first 3 years of life), a subsequent period of stable kidney function attained by 50% of the patients and lasting for a mean of 8 years, and a pattern of kidney function gradually deteriorating towards CKD Stage 5 (Fig. 55.1) [10]. The progression phase started just after infancy in 48% and around puberty in 23%. In 30% of patients kidney function remained stable even beyond puberty. Correlates of deteriorating kidney function were proteinuria, hypertension, past febrile urinary tract infections and lower GFR at onset [10].

An accelerated decline of kidney function was observed during the last 18 months before start of KRT in the Chronic Kidney Disease in Children (CKiD) cohort [11].

In an analysis of 4700 patients with congenital anomalies of the kidneys and the urinary tract followed in the ERA-EDTA Registry, more than two thirds of the patients attained ESKD at adult

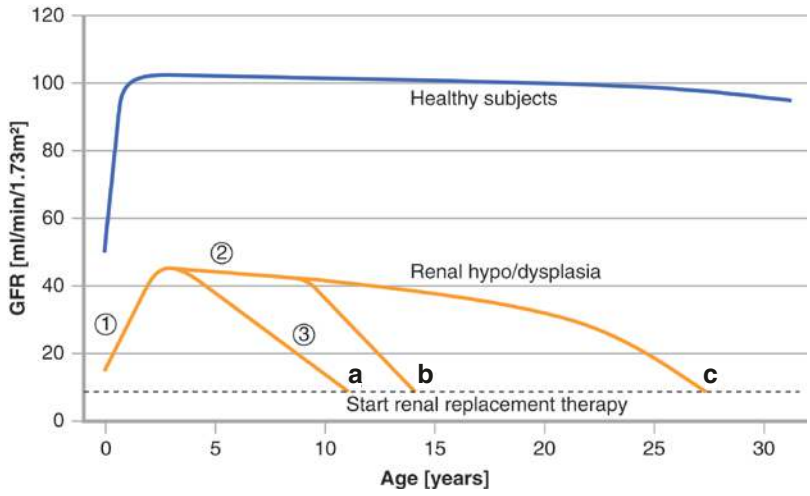

Fig. 55.1 Natural time course of kidney disease progression in children with renal hypodysplasia. ① denotes period of improving kidney function during infancy, ② period of stable kidney function, ③ period of kidney function deteriorating toward ESKD. Third phase is characterized either by rapid decline soon after infancy (**a**) or at early pubertal age (**b**), or by steady slow decline of renal function (**c**). Modified from Celedon et al. [10]

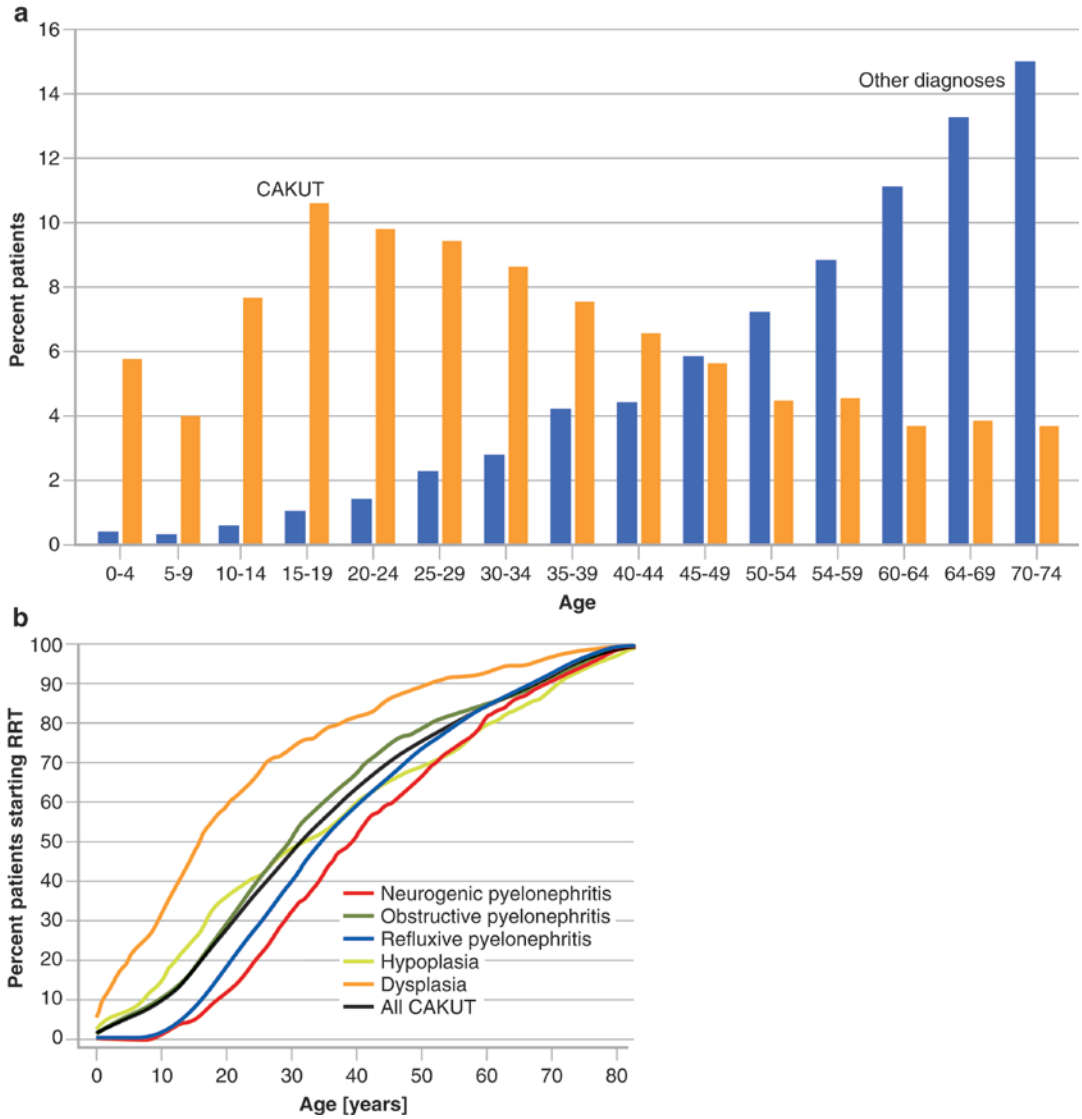

Fig. 55.2 Age distribution at onset of kidney replacement therapy in patients with congenital anomalies of the kidneys and the urinary tract (CAKUT) compared with non-CAKUT patients (**a**) and cumulative percentage of patients starting kidney replacement therapy by CAKUT subcategory (**b**). Data from the European Renal Association – European Dialysis and Transplant Association Registry. Used with permission of American Society of Nephrology from Wühl et al. [12]

age. The mean age at start of kidney replacement therapy was 34 years [12] (Fig. 55.2a, b). These findings support the concept that in patients with a congenital reduction in nephron mass, CKD progression due to ongoing loss of remnant nephrons is a lifelong process.

Mechanisms of Kidney Failure Progression

According to the Brenner hypothesis, any critical loss of functioning kidney mass, irrespective of the nature of the initial injury, leads to glomerular

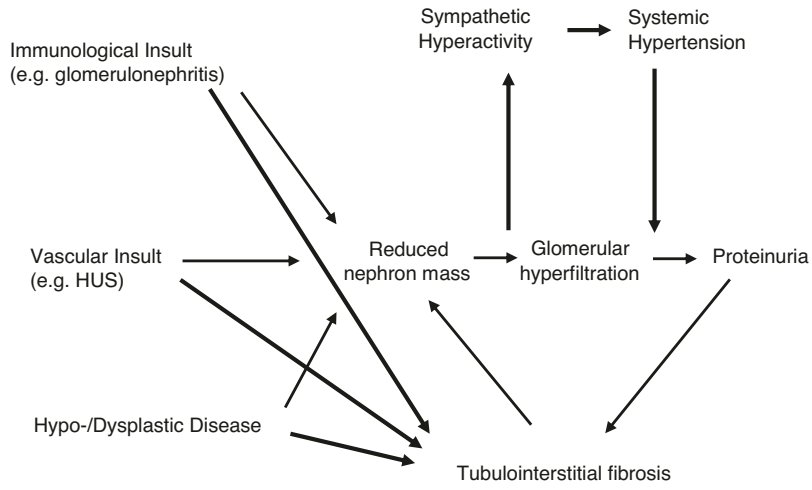

Fig. 55.3 Mechanisms of kidney disease progression in pediatric nephropathies

hyperfiltration with an increased single-nephron GFR (Fig. 55.3). The remaining nephrons lose their ability to autoregulate glomerular pressure, resulting in transmission of systemic hypertension to the glomerulus. Increased intraglomerular pressure induces proteinuria, which is the pathophysiological link between glomerular, interstitial [13] and tubular damage [14]. The degree of proteinuria in glomerular diseases correlates with the rate of CKD progression [15].

Recent research has attributed a central role to the podocytes, which are terminally differentiated and unable to respond to injury by proliferation and repair [16]. The key role of this glomerular cell type in the pathophysiology of CKD progression has been demonstrated by a growing number of specific genetic disorders specifically affecting the development, terminal differentiation and postnatal function of the podocytes, which result in congenital or infantile nephrotic syndrome inevitably leading to glomerulosclerosis and progressive kidney failure. The loss of lesioned podocytes may lead to focal and segmental adhesions of the denuded basement membrane to the Bowman capsule, with spreading of the ultrafiltrate into the tubulointerstitial compartment where it causes inflammatory injury ('misdirected filtration').

The formation and maintenance of the glomerular filtration barrier requires a complex interaction between podocytes and glomerular capillary endothelial cells. Vascular endothelial growth factor (VEGF) overexpression by podocytes has been noted in proteinuric states, and VEGF blocking antibodies prevent glomerular hyperfiltration, hypertrophy and proteinuria. Endothelial cell injury, resulting from disease-specific and/or from non-specific uremia-associated vasculotoxic and inflammatory insults, is frequently involved in progressive glomerular damage [17]. Vascular endothelial cells release endothelin, platelet derived growth factor (PDGF) and fibroblast growth factor (FGF) in response to fluid shear stress [18]. Moreover, injured endothelial cells express increased angiotensinogen and transforming growth factor β (TGFβ) [19], factors causing inflammation and fibrosis. In chronic glomerular injury, endothelial cells lose part of their anti-coagulant properties and intensify their pro-coagulant activity by increased expression of plasminogen activator inhibitor 1 (PAI-1). By release of adhesion molecules such as intracellular adhesion molecule 1 (ICAM-1), endothelial cells facilitate macrophage infiltration and attraction and proliferation of inflammatory cells. In addition, damage to endothelial cells may denude the glomerular basement membrane, all resulting in induction of local platelet aggregation and activation of coagulation with fibrin deposition and microthrombi formation.

Reabsorption of filtered proteins by the tubular epithelial cells can induce direct injury to intracellular lysosomal pathways, oxidative stress

and increased local expression of growth factors [20, 21] such as insulin-like growth factor 1 (IGF-1), TGFβ and hepatocyte growth factor (HGF). Moreover, stressed epithelial cells release an array of chemotactic factors including monocyte chemoattractant protein 1 (MCP-1), RANTES, connective tissue growth factor (CTGF), fibronectin and endothelin-1 (ET-1), which promote tubulointerstitial inflammation and fibrosis through recruitment and activation of macrophages [22–28]. Macrophages infiltrating the renal parenchyma in turn perpetuate the production of further cytokines and growth factors. The proteins of the complement system represent another component of proteinuria that may cause tubular damage, and once tubular cells are injured, they may vice versa activate the alternative complement pathway.

Both in the glomerulus and in the tubular apparatus, chronic inflammatory processes promote cell transdifferentiation towards a fibroblast phenotype, driven by a high tone of TGF-ß (epithelial mesenchymal transformation; EMT). Myofibroblastic transformation is characterized by the release of proteinases, cytokines and oxidants [29, 30]. Moreover, myofibroblasts and local fibroblasts begin to deposit fibronectin and laminin, the molecular framework for interstitial collagen deposition [31], and secrete extracellular matrix components including type IV collagen and collagens I, III, and V ('scar' collagens) resulting in scar formation [32]. In addition, the activity of matrix degrading enzymes is inhibited by overproduction of inhibitory peptides (PAI-1, tissue inhibitors of metalloproteinases (TIMPs)) [33, 34]. As a result of increased synthesis and reduced degradation, excessive tubulointerstitial collagen accumulation occurs. The fibrous masses in the tubulointerstitium are believed to compromise oxygen supply to the tubular cells, thereby further contributing to tubular atrophy and nephron loss.

Glomerular sclerosis, tubulointerstitial fibrosis and tubular atrophy result in a further loss of functioning renal mass, closing a vicious circle by further increasing intraglomerular pressure and hypertrophy of the remaining glomeruli (Figs. 55.3 and 55.4).

Angiotensin (Ang) II**,** the primary effector of the renin angiotensin system, is mechanistically involved in most of the mechanisms described above. Ang II is produced both systemically and locally in the kidney and exerts multiple endocrine, intercrine, autocrine and paracrine effects. Intrarenal Ang II concentrations are a thousandfold higher than in the circulation. The major source of intrarenal Ang II is auto/paracrine synthesis by tubular, juxtaglomerular and glomerular cells [35–37]. Renin release from the juxtaglomerular apparatus drives systemic Ang II generation and is involved in blood pressure upregulation, but has probably little relevance for intrarenal Ang II action. Most of the intrarenal effects of Ang II are mediated via the Angiotensin II type 1 (AT1) receptor [38]. Ang II is a potent vasoconstrictor that augments intraglomerular pressure by preferentially increasing the efferent arteriolar tone. Ang II also increases intracellular calcium in podocytes [39, 40], inducing cytoskeletal changes and altered podocyte function with resultant protein ultrafiltration even in the absence of structural glomerular damage [41, 42]. Moreover, Ang II increases the proliferation of smooth muscle cells and increases the glomerular and tubular expression of various growth factors, cytokines and chemokines, most importantly of the TGF-β/CTGF system, but also of tumor necrosis factor α (TNFα), PDGF, FGF and vascular cell adhesion molecule 1 (VCAM-1).

Ang II also stimulates oxidative stress, which perpetuates the up-regulation of cytokines, adhesion molecules, and chemoattractants [43, 44]. Finally, intrarenal Ang II stimulates afferent neurons, which are believed to activate central nervous structures regulating sympathetic tone. Hence, Ang II is pathophysiologically involved in the state of sympathetic hyperactivation which is characteristic of CKD and constitutes another important mechanism of renal disease progression and cardiovascular morbidity [45, 46].

In addition, uremia-induced deficiency of nuclear factor erythroid 2-related factor 2 (Nrf2), a transcription factor for the antioxidative stress response and activator of an array of cytoprotective genes, may enhance the susceptibility to kidney injury [47, 48].

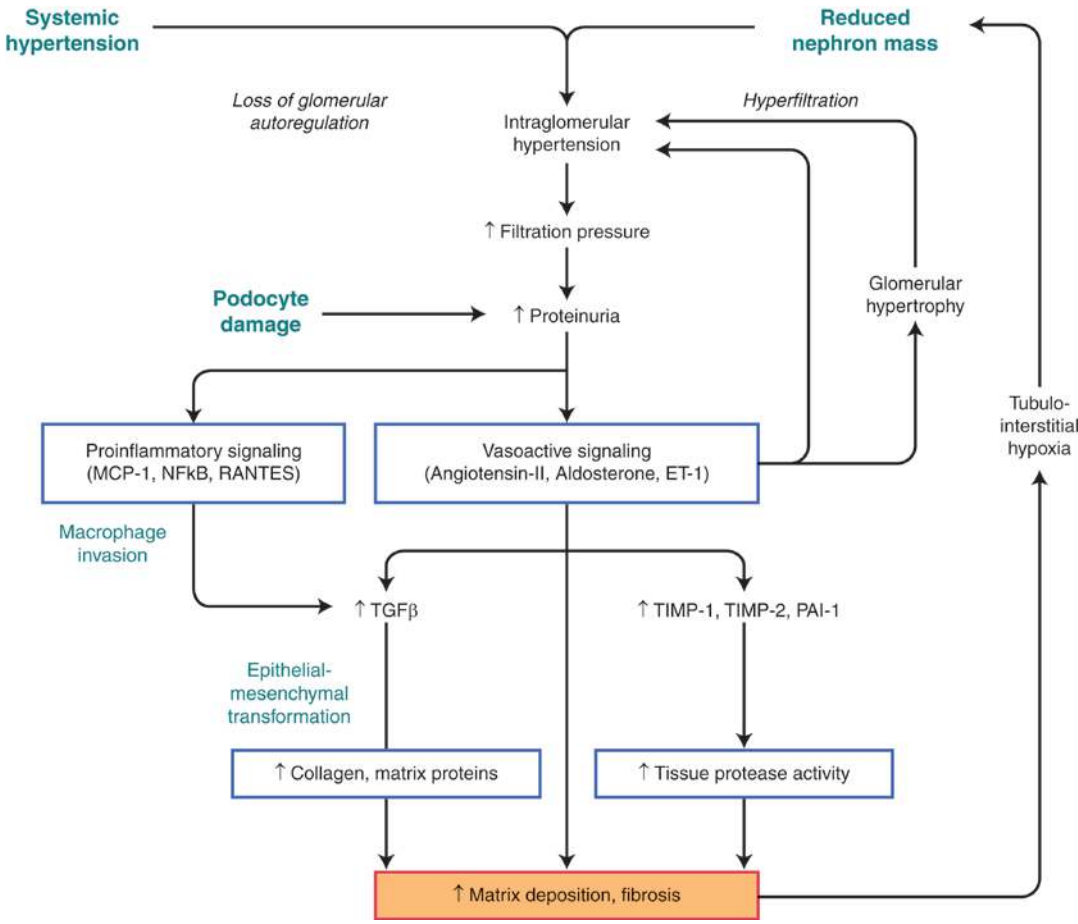

Fig. 55.4 Pathophysiological consequences of hypertension and proteinuria in chronic kidney disease

In patients with reduced nephron mass and anemia, hypoxia of tubular cells may occur due to increased oxygen consumption by tubular cells of the remaining nephrons, a decreased number of interstitial capillaries [49] and accumulation of extracellular matrix between interstitial capillaries and tubular cells, which hampers oxygen diffusion. In turn, hypoxia stimulates the production of profibrotic molecules such as TGFβ and ET-1 by tubular cells, further increasing the synthesis of extracellular matrix by fibroblastic cells and ultimately leads to tubular epithelial cell loss with formation of atubular glomeruli [50, 51].

In addition, hypoxia enhances the local production of reactive oxygen species (ROS). Oxidative stress also induces the release of pro-inflammatory and pro-fibrotic molecules, thereby enhancing the production of extracellular matrix by fibroblasts and favoring cell death.

Factors Modifying the Risk of Kidney Disease Progression

Age at Attainment of Kidney Mass Deficit

The age at which a significant loss of kidney mass occurs may influence the degree of glomerular hypertrophy and the long-term prognosis of kidney function. Patients born with unilateral kidney agenesis are at greater risk for proteinuria, hypertension and CKD than subjects undergoing unilateral nephrectomy by trauma or kidney

donation in later life, suggesting that the number of functional nephrons in congenital solitary kidneys might be decreased (possibly by hypogenesis) [52, 53].

Most patients with a solitary functioning kidney experience compensatory kidney growth of the remnant kidney. After unilateral nephrectomy for Wilms' tumor, compensatory renal growth was most marked in patients who underwent surgery at very young age. Marked kidney growth was associated with microalbuminuria in more than 30% of these patients [54]. The possibility that nephrons in infantile solitary kidneys are subject to greater hypertrophic stress is supported by quantitative morphometric studies showing glomerular volumes 5–6 times greater than normal [55].

However, most long-term follow-up studies of congenital solitary kidneys included heterogenous patient populations. Of note, patients with a congenital solitary kidney due to unilateral multicystic-dysplastic kidney disease (MCDKD) appear to have better functional outcomes over time than patients with unilateral kidney agenesis. In the long-term follow-up study by Sanna-Cherchi, 5% of MCDKD cases but 30% of unilateral kidney agenesis cases required dialysis after their second decade of life (HR 2.43) [53]. In addition, MCDKD patients had a lower prevalence of hypertension (3% vs. 19%) and proteinuria (3% vs. 12%) than patients with unilateral kidney agenesis [56]. It is tempting to speculate that the natural history differences observed with these single-kidney disorders may be related to different underlying pathogenic mechanisms variably affecting the long-term function of the remaining kidney.

Gender

Among adult patients with CKD, women have a higher overall prevalence of pre-dialysis CKD than men, possibly due to the longer life expectancy of women and to CKD overdiagnosis by use of estimated GFR equations. However, decline of kidney function in men is faster, maybe due to unhealthier lifestyles and hormonal differences, resulting in a higher rate of kidney replacement therapy in men [57].

A kidney survival advantage of females has been suggested by meta-analysis of patient cohorts with autosomal dominant polycystic kidney disease (ADPKD), IgA nephropathy and membranous nephropathy [58]. The advantage seems to be lost in post-menopausal women, suggesting a nephroprotective effect of female sex steroids; however, some confounding by lipid levels or the prevalence of smoking cannot be ruled out. In addition, at all levels of pre-dialysis CKD mortality is higher among men, whereas mortality on KRT is similar for men and women.

Data on a potential sexual dimorphism of kidney survival in children with CKD are scarce. A recent analysis of data from the CKiD Study was able to identify different trajectories of CKD progression in children. However, while females with glomerulopathies showed faster CKD progression than males, no significant sex differences were found in patients with non-glomerular disease. The differences in progression seem likely explained by sex differences in the underlying primary kidney disease and in baseline GFR rather than by a direct effect of sex on progression [59].

Underlying Kidney Disease and Genetic Pathology

Although the pathophysiological principles of CKD progression described above generally apply to all chronic kidney diseases, the time course of deterioration of kidney function for individual disease entities is highly variable. It is evident that patients with aggressive, incompletely controlled immunological nephropathies will have a more rapid progression of CKD than subjects with hypoplasia of the kidneys. However, even within groups of patients suffering from pathogenetically homogeneous hereditary kidney diseases, the rate of CKD progression can vary markedly between individuals. In a growing number of these entities, the progression phenotype can be linked to the underlying genetic defect. In disease entities caused by defects in

more than one gene, progression patterns may differ according to the gene involved. For instance, in adults with ADPKD, individuals with mutations in the PKD1 typically have a more severe disease course with earlier need for renal replacement therapy than those with mutations in the PKD2 gene. A gene-phenotype correlation is also obvious in children with the nephronophthisis complex. In children with mutations in the NPHP1 gene, CKD stage 5 is attained at a mean age of 13 years, compared to 8 months in NPHP2 and 19 years in NPHP3 mutation carriers [60]. Even within the same gene, the localization and type of the causative mutations is a key determinant of the renal prognosis. The highly variable times of disease onset and progression to ESKD in steroid resistant nephrotic syndrome caused by different mutations in the NPHS2 gene [61], and in Alport syndrome related to COL4A5 gene mutations [62] are classic examples for genotype-phenotype correlations in recessive and dominant forms of hereditary kidney disorders.

In addition to the causative role of genetic disorders in many if not most pediatric kidney diseases, common polymorphic variants in various genes may determine an individual's susceptibility for kidney injury, kidney disease progression and the response to renoprotective treatment. One of the first common variants studied in the context of CKD progression was the insertion/deletion polymorphism of the angiotensin converting enzyme (ACE) gene. The DD genotype has been shown to predispose for progressive renal failure in IgA nephropathy [63, 64]. Some, though not all studies, found an increased risk for parenchymal damage with the DD genotype in children with congenital urological abnormalities, particularly vesicoureteral reflux [65–67] and an increased risk for poor kidney survival in children with CKD due to kidney hypodysplasia [65].

In adults with non-diabetic proteinuric kidney diseases, the ACE polymorphism has been claimed to predict the nephroprotective efficacy of ACE inhibition. Proteinuria, the rate of GFR decline and progression to CKD stage 5 were lowered by ACE inhibitors in patients with the DD genotype, but not in those with the II or ID genotype [68, 69].

Also, common variants exist in various genes encoding cytokines, growth factors and regulatory peptides involved in CKD progression.

Recent and ongoing meta-analyses of genome-wide association studies (GWAS) are aiming to identify loci associated with incident CKD or the risk of KRT in general population based cohorts [70, 71], as well as in cohorts of adult and pediatric CKD patients [72]. An increasing number of common risk variants in genes related to nephrogenesis (e.g. *ALMS1*, *VEGFA*, *DACH*), glomerular filtration barrier formation and podocytes function (e.g. *DAB2*, *PARD3B*, *VEGFA*), angiogenesis (e.g. *VEGFA*), and renal function (e.g. *UMOD*, *SHROOM3*, *STC1*) have been identified [71]. For example, common variants in the region of the *UMOD* gene encoding uromodulin (Tamm-Horsfall protein) associate with CKD and GFR. Elevated urine uromodulin concentrations, which are associated with a common polymorphism in the *UMOD* region, precede the onset of CKD [73].

Genome-wide association studies may also allow identification of variants related to known CKD risk factors as hypertension or proteinuria in adults [74–76] as well as in children [77].

Epigenetics and Fetal Programming

Fetal programming describes the effect of environmental cues experienced during fetal development on an individual's susceptibility to diseases later in life through epigenetic changes that may be additionally modified postnatally.

Fetal programming may have direct consequences on kidney development and function. Barker and colleagues first demonstrated a correlation of low birth weight with the incidence of cardiovascular disease (CVD) in later adulthood [78]. Subsequent studies suggested that low birth weight is correlated with decreased kidney mass and nephron number, which in turn predisposes to adult hypertension [79]. In line with these findings, a recent study in more than 400 Japanese children born with very low birth weight showed a significant contribution of intrauterine malnutrition to chronic kidney damage [80]. Conversely,

higher estimated weights in utero, at birth and at 6 months post-gestational age were found to be associated with higher kidney volume and higher GFR at age 6–7 years [81].

Thus, in interaction with an existing congenital or acquired kidney disease, prenatal programming by epigenetic mechanisms may influence the course of CKD progression [82].

Hypertension

Hypertension is an independent risk factor for renal failure progression in adults [6–8]. While the degree of hypertension is a marker of the underlying renal disease severity, interventional studies have provided evidence that high blood pressure actively contributes to renal failure progression in human CKD. This has been confirmed by hypertension registry data of more than 40,000 adult patients demonstrating an association of systolic blood pressure with incident CKD. Each 10 mmHg increase of baseline or time-varying systolic blood pressure above 120 mmHg was associated with a 6% increase in the risk of developing CKD [83].

In pediatric nephropathies, renal hypertension is common, although typically less severe than in adult kidney disorders. Hypertension prevalence estimates in children with CKD range from 20% to 80%, depending on the degree of renal dysfunction [84]. However, even children with CKD stage 2 or renal hypodysplasia, conditions usually not strongly associated with hypertension, may present with elevated blood pressure [85]. In a large prospective study of children with CKD, systolic blood pressure greater than 120 mmHg has been associated with a faster GFR decline [86] (Fig. 55.5). Among CKD children included in the CKiD Study, time-varying blood pressure ≥ 90th percentile (compared to <50th percentile) was associated with an odds ratio of 3.75 in non-glomerular and of 5.96 in glomerular disease for the risk of losing 50% of GFR or progressing to ESKD [87].

Investigations on the physiological diurnal variation of blood pressure by ambulatory blood pressure monitoring have revealed that the integrity of the nocturnal fall of blood pressure ('dipping' pattern) plays a significant role in renal failure progression, in addition to and independent of the absolute blood pressure level.

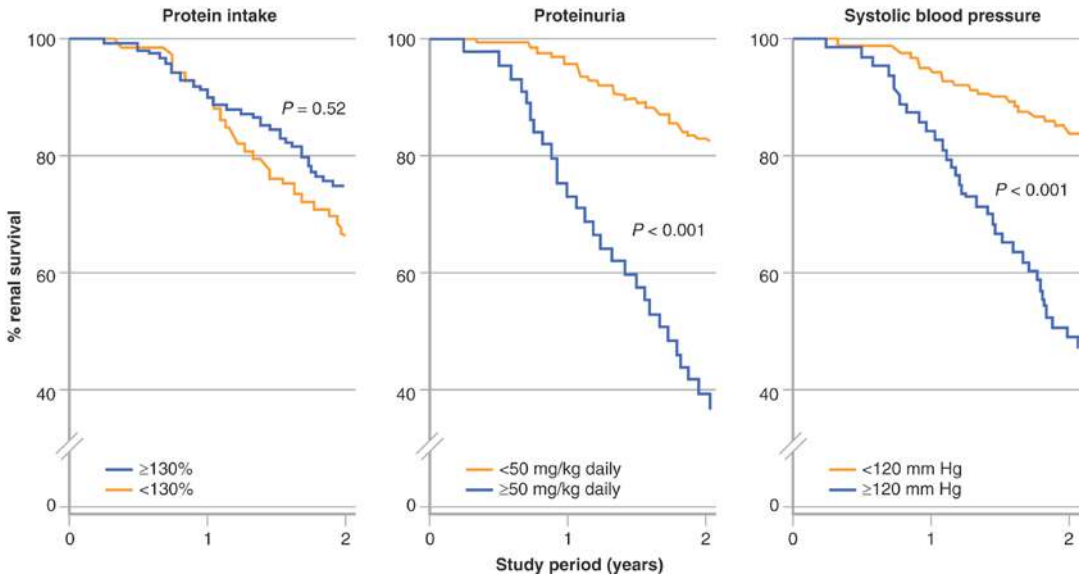

Fig. 55.5 Proteinuria and Hypertension predict the risk of disease progression in children with CKD. Used with permission of Elsevier from Wingen et al. [86]

Non-dipping, a well-known independent cardiovascular risk factor and common characteristic of renoparenchymal hypertension, is associated with more rapid progression towards kidney failure in adult CKD patients [88–91].

Similarly, elevated night-time blood pressure is correlated with an increased risk of CKD in the general population [92] and with a faster decline of GFR in CKD patients [93]. Overactivation of the sympathetic nervous system and endothelial dysfunction may contribute to the dysregulation of nocturnal blood pressure and circadian pattern [89].

Proteinuria

Population based studies in healthy individuals have demonstrated that proteinuria is an independent risk factor for CKD, KRT and overall mortality [94–96]. In adults with diabetic and non-diabetic kidney disorders, proteinuria is clearly predictive of the renal prognosis [15, 97, 98]. In the Ramipril Efficacy in Nephropathy (REIN) trial [99], urinary protein excretion was the only baseline variable correlated with GFR decline and progression to KRT.

In children, the spectrum of underlying kidney disorders markedly differs from adults. Congenital renal hypodysplasia with or without urinary tract abnormalities is the leading underlying pediatric kidney disorder, accounting for more than 60% of CKD cases. The European Study Group for Nutritional Treatment of Chronic Renal Failure in Childhood first demonstrated in 200 children with CKD stages 3–4 that proteinuria and hypertension are also major predictors of GFR decline in pediatric kidney disease [86] (Fig. 55.5). The ItalKid Project confirmed that proteinuria predicts renal disease progression in children with renal hypodysplasia [100]. In the ESCAPE (Effect of Strict Blood Pressure Control and ACE Inhibition on Progression of Chronic Renal Failure in Pediatric Patients) trial, baseline proteinuria and residual proteinuria during ACE inhibition were quantitatively associated with CKD progression [101, 102].

In a joint analysis of 1200 children with CKD stages 2–4 from the CKiD Study and the ESCAPE Trial, patients with glomerular disease showed a 43% shorter time to ESKD or 50% GFR loss than children with non-glomerular disease [103]. The average time to reach this endpoint was more than 10 years in non-proteinuric children with mild to moderate CKD as compared to 1.3 years in those with CKD stage 4 and nephrotic range proteinuria [103] (Fig. 55.6).

Metabolic Acidosis

In the Cardiovascular Comorbidity in Children with CKD Study (4C Study), pediatric patients with CKD stage 3–5 with time-averaged serum bicarbonate below 18 mmol/l had a significantly higher risk of CKD progression compared to those with a serum bicarbonate of 22 mmol/L or more [104]. These findings are in keeping with findings in interventional trials in adult CKD patients suggesting that *metabolic acidosis* is associated with faster decline in eGFR [105–107] (Table 55.1).

Dyslipidemia and Insulin Resistance

Abnormalities of lipid metabolism are a common complication in CKD. In the CKiD Study, 45% of children had *dyslipidemia*, with an increased risk in children with GFR < 30. Obese and overweight children in the cohort had significantly higher odds ratios of having dyslipidemia, with the highest risk in the most obese subjects. Dyslipidemia was also independently associated with nephrotic–range proteinuria. [108].

Epidemiological studies give some evidence that dyslipidemia is an independent risk factor not only for CVD but also for progressive chronic renal failure [109]. The dyslipidemic pattern differs between the major renal disease entities [110] and the degree of dyslipidemia parallels the degree of renal function impairment. Underlying mechanisms of uremic dyslipidemia include insulin resistance [111], obesity, hyperparathyroidism [112], malnutrition, acidosis [113] and impaired catabolism of triglyceride-rich lipoproteins by decreased activity of lipoprotein lipase and hepatic triglyceride lipase.

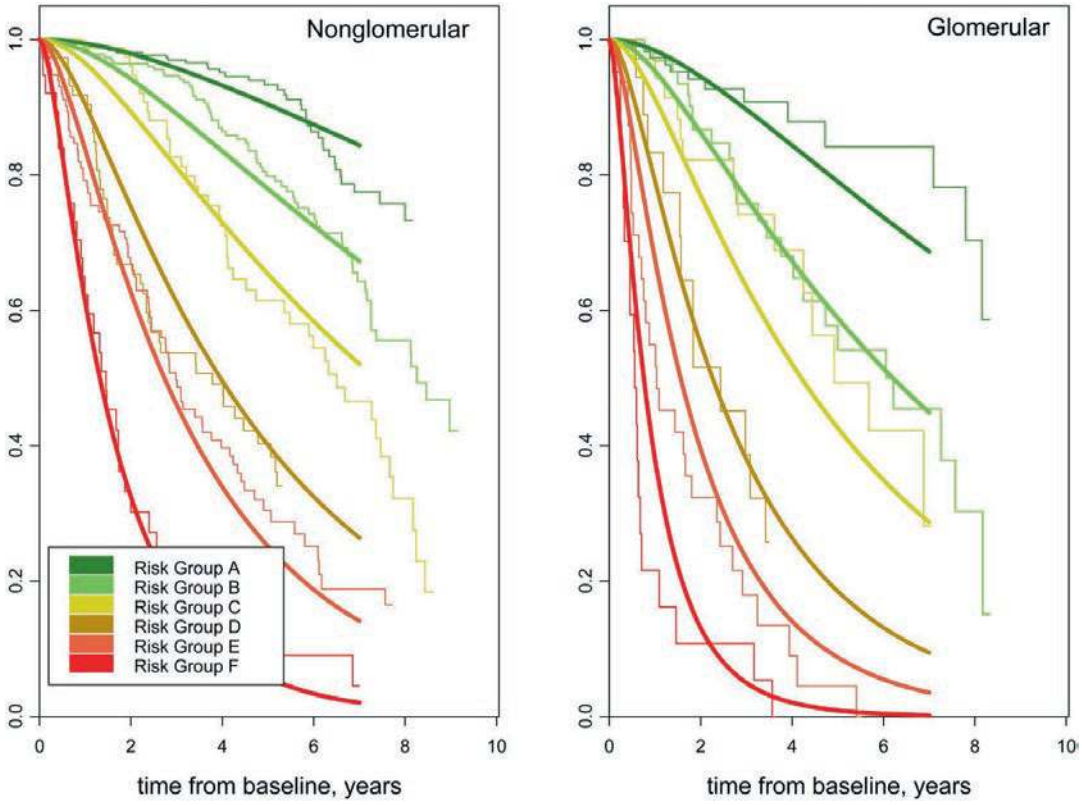

Fig. 55.6 Survival curves for the time from assessment of CKD (baseline) to a composite clinical event (50% GFR decline, kidney replacement therapy, or GFR less than 15 mL/min/1.73 m^2) stratified by CKD diagnosis and risk group. Used with permission of Elsevier from Furth [103])

In animal models, hypercholesterolemia accelerates the rate of progression of kidney disease [114]. A link between dyslipidemia and oxidative stress in the pathogenesis of renal damage was shown in unilaterally nephrectomized rats, in which hyperlipidemia increased glomerular and tubulointerstitial infiltration and aggravated glomerulosclerosis [115].

There are also observations in humans that the *insulin resistance syndrome* may underlie or mediate the association between lipids and loss of renal function. A strong relationship between the *metabolic syndrome* and the risk for CKD and microalbuminuria was found in a large, adult, non-diabetic general population [116]. A relationship between serum cholesterol and GFR decline was also shown in adult patients with type 1 diabetes and overt nephropathy [117]; patients with a total cholesterol level > 7 mmol/L showed an at least three times faster decline in GFR than subjects with lower cholesterol levels.

Table 55.1 Potential therapeutic strategies for prevention of kidney disease progression

Therapeutic target	Agents	Action	Treatment aim
Renin-angiotensin-aldosterone system	ACE inhibitors Angiotensin receptor blockers Aldosterone antagonists Renin inhibitors	RAAS blockade: antiproteinuric, antihypertensive, anti-fibrotic, and anti-inflammatory effects	Blood pressure control Reduction of proteinuria Attenuation of glomerular sclerosis and tubulointerstitial fibrosis
Hypertension	All antihypertensive drug classes	Antihypertensive Additional antiproteinuric effect by blood pressure control	Strict blood pressure control [101, 135, 136, 239, 240]: – BP target <75th Pct in non-proteinuric children – BP target <50th Pct in proteinuric children
Proteinuria	ACE inhibitors, some CCBs (non-dihydropyridines) and ß-blockers (e.g., carvedilol)	Antiproteinuric	Minimization of proteinuria: urinary protein excretion <300 mg/m^2/d [143, 144]
Metabolic acidosis	Bicarbonate	Renoprotective	Serum bicarbonate level > 22 mmol/L [107]
Inflammation	e.g., Endothelin A receptor antagonist, Pentoxifylline, Neprilysin, bardoxolone	Anti-inflammatory and antifibrotic action	Reduction of inflammation and fibrosis, attenuation of glomerular sclerosis and tubulointerstitial fibrosis
Dyslipidemia	Statins	Lipid lowering	Normalization of lipid profile
Anemia	Erythropoietin	Improved oxygen supply, reduced oxidative stress, direct protective effects	Normalization of hemoglobin levels
Mineral metabolism, Hyperparathyroidism	Phosphate binders (Calcium-free) Vitamin D Calcimimetics	Renoprotective Anti-fibrotic (vitamin D) Reduction of proteinuria, blood pressure, glomerular sclerosis (calcimimetics)	Calcium, phosphate, PTH and vitamin D levels within target range for CKD patients [241]
Hyperuricemia	Allopurinol	Renoprotective	Normalization of serum uric acid levels [229]
Renal disease progression	Low Protein Diet (0.8–1.1 g/kg/d)	Reduction of serum urea levels	Reduction of serum urea levels, delay of end-stage renal disease

RAAS renin-angiotensin-aldosterone-system, *ACE* angiotensin converting enzyme, *ACEi* ACE inhibitor, *ARBs* angiotensin receptor blockers, *CCBs* Calcium channel blockers, *BP* blood pressure, *Pct* percentile, *CKD* chronic kidney disease

Additionally, *obesity* appears to be a negative prognostic factor for both diabetic and non-diabetic nephropathies and an independent risk factor for accelerated progression [118, 119]. As adipose tissue generates high levels of circulating free fatty acids (FFA) and FFA uptake and oxidation in CKD are reduced by hypoadiponectinemia, leptin resistance, and increased cytokine release from adipose tissue and macrophages, intracellular FFA accumulate [120]. This may cause renal mesangial and epithelial cell injury and renal disease progression as a consequence of FFA-induced lipotoxicity.

However, the evidence for dyslipidemia as an independent risk factor for renal disease development and/or progression is not as strong in clinical studies as it is in experimental settings. It is unclear whether dyslipidemia independently increases the renal risk in those without other risk factors for kidney disease because most studies have been performed in patients with pre-existing renal disease or patients with associated renal risk factors such as hypertension or diabetes.

Hyperuricemia

Data regarding the role of hyperuricemia in the progression of CKD are conflicting. While in the Modification of Diet in Renal Disease (MDRD) study [121] a single elevated uric acid level was not predictive of future kidney failure in adults, a retrospective cohort study from Taiwan suggested that higher uric acid levels are associated with a more rapid eGFR decline and higher risk of kidney failure, particularly in patients without proteinuria [122]. In line with the latter findings, data from the CKiD Study indicated that hyperuricemia may also be an independent risk factor for faster CKD progression in children and adolescents [123].

Bone Metabolism

Disturbances of the *bone mineral metabolism* also may influence CKD progression. Phosphorus accumulation [124], elevated serum alkaline phosphatase [125] and low 25-hydroxyvitamin D levels are associated with progression, potentially via their relation to fibroblast growth factor 23 (FGF23), which has been identified as an independent risk factor for CKD progression in adults and children [126].

Environmental Factors

Additionally, environmental effects may affect progression of CKD, such as exposure to *smoking*. Smoking has been associated with an increased risk of renal disease progression in adults [127]. In the CKiD cohort, second hand smoking exposure was independently associated with nephrotic range proteinuria [128].

Treatment Strategies in Kidney Disease Progression

Based on the current understanding of the mechanisms of kidney disease progression, several principal nephroprotective strategies have emerged in recent years. These are based mainly on clinical evidence established in adult patients, but growing evidence also supports their efficacy in children. Efficient control of blood pressure and minimization of proteinuria are the two most important measures to preserve residual kidney function. Other approaches, such as the prevention and treatment of CKD-associated anemia, dyslipidemia and mineral metabolism disorder, have an experimental basis whereas their clinical importance is still less clear. The level of clinical evidence in support of the various nephroprotective strategies will be discussed below and is summarized in Table 55.2.

Blood Pressure Control

Numerous studies in adults have shown that antihypertensive therapy slows the rate of kidney failure progression [129]. There seems to be a linear relationship between the blood pressure level achieved by antihypertensive treatment and the rate of annualized GFR decline in CKD patients [129]. This relationship appears to persist well into the normal range of blood pressure [15, 130], although interventional trials comparing different blood pressure targets yielded somewhat conflicting results.

In children with CKD, the ESCAPE Trial provided evidence that intensified blood pressure control targeting for a 24-h mean arterial pressure below the 50th percentile provides superior long-term nephroprotection compared to a higher target range (50th to 95th percentile) [101]. In this randomized clinical trial, the ACE inhibitor ramipril was administered at a fixed dose in 385 children with CKD. Subsequently, the patients were randomized for conventional or intensified blood pressure control to be achieved by administration of additional antihypertensive drugs not affecting the renin-angiotensin-aldosterone system (RAAS). Within 5 years of observation, the risk of losing 50% of eGFR or progressing to KRT was reduced by 35% (from 42.7 to 29.9%) in the strict blood pressure control arm [101] (Fig. 55.7).

Intensified blood pressure control effectively improved kidney survival in children with an

Table 55.2 Evidence levels for efficacy of nephroprotective treatment strategies in adults and children with CKD

Renoprotective treatment	Evidence in adults	Evidence in children	Effect of Intervention		Drugs licensed for … in …
Antihypertensive treatment (RAAS blockade/CCBs/ß-Blockers)/**Strict BP control**	Multiple RCTS, meta-analyses	One RCT; few observational studies	+	BP control reduces risk of CKD; evidence for beneficial effect of strict BP control especially in proteinuric CKD	Hypertension in adults and children
RAAS blockade – antihypertensive + antiproteinuric treatment					
ACEi/ARBs	RCTs	RCTs	++	Antihypertensive + antiproteinuric	Hypertension in adults and children
Aldosterone antagonists	RCTs	RCT underway (finerenone)	+	Antihypertensive + antiproteinuric, reduced risk of CKD (finerenone)	Spironolactone: hyperaldosteronism in adults and children; eplerenone: left ventricular dysfunction in adults; Finerenone: diabetic and non-diabetic CKD in adults
Renin antagonists	RCT	None	+	Antihypertensive + antiproteinuric	Hypertension in adults
Combined RAAS blockade (ACEi + ARB or ACEi/ARB + aldosterone / renin antagonist)	RCTs	None	+	Antihypertensive + antiproteinuric; increased risk of side effects, combined RAAS blockade not recommended	NA
SGLT2 inhibitors	RCTs	None	++	Antihypertensive, antiproteinuric, anti-inflammatory, reduction of CKD progression rate	Diabetic / non-diabetic CKD in adults
Bicarbonate	RCTs	Observational studies	+	Reduced risk of CKD progression	Metabolic acidosis
Tolvaptan (in ADPKD)	RCTs	RCT	+	Retardation of cyst growth and CKD progression	Progressive ADPKD in adults
Antihypertensive chronotherapy	RCTs	None	+?	Nephroprotective effects reported, but quality of studies questioned	NA
Anti-inflammatory agents					
Endothelin receptor antagonists	RCTs	RCT underway (sparsentan)	+?	Antihypertensive + antiproteinuric, but unfavourable side effect profile for some compounds	Sparsentan: FSGS in adults

(continued)

Bardoxolone	RCTs	None	+?	Inconclusive findings	Not licensed
Pentoxifylline	RCTs	None	?	Inconclusive findings	Peripheral arterial disease in adults
Neprilysin	RCTs	None	?	Inconclusive findings	Heart failure in adults
Statins	RCTs	None	+?	Reduced risk of CKD progression in some studies	Dyslipidemia
Allopurinol, Febuxostat	RCTs	None	+?	Inconclusive findings	Hyperuricemia
Vitamin D	Observational studies	Observational studies	+		Vitamin D deficiency, rickets, CKD
Erythropoiesis stimulating agents	Observational studies	None	?	Inconclusive findings	Anemia
Low protein diet	RCTs	One RCT	+?	Inconclusive findings	NA

RCT randomized, controlled trial; + positive effect; ++ strong positive effect; +? Positive effects reported, but findings still inconclusive;? effect unknown; *NA* not applicable, *ADPKD* autosomal dominant polycystic kidney disease, *FSGS* focal segmental glomerulosclerosis, *BP* blood pressure, *ACEI* angiotensin converting enzyme inhibitor, *ARB* angiotensin receptor blocker, *CCB* calcium channel blocker

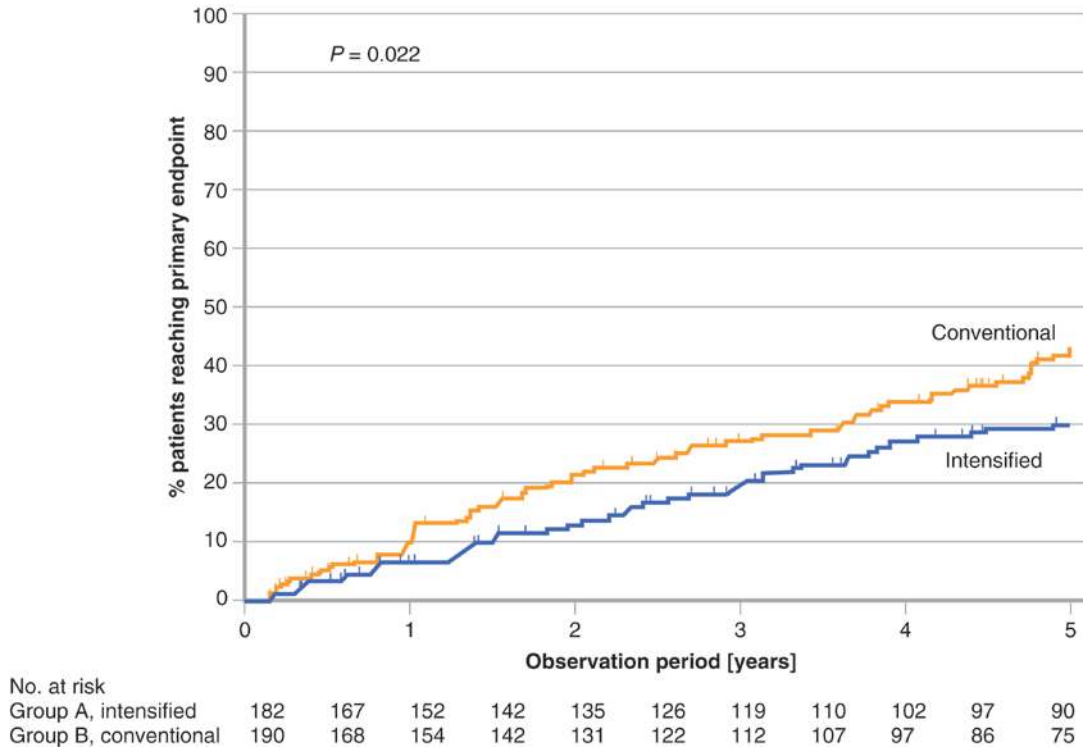

Fig. 55.7 Progression of chronic renal disease in children with CKD according to blood pressure control. The cumulative probability of reaching the primary composite end point of a 50% decline in the GFR or progression to end-stage renal disease is shown for patients randomized to either conventional or intensified blood pressure control in the ESCAPE Trial Used with permission of Massachusetts Medical Society from Wühl et al. [101]

underlying glomerulopathy as well as renal dysplasia or hypo-dysplasia, albeit not in other congenital or hereditary nephropathies [101].

The kidney survival benefit of intensified blood pressure control demonstrated by the ESCAPE Trial is in partial contrast to findings in other studies in adult CKD populations (MDRD Trial, ABCD Trial, AASK Trial, REIN-2 extension trial [131–133] in which no significant benefit was demonstrated for the cohorts as a whole. These partially discrepant findings may be explained by methodological and population differences. Patient age, ethnicity, pharmacological treatment protocols, duration of follow-up and dropout rates varied markedly between the mentioned studies. Furthermore, the use of ambulatory blood pressure monitoring may have enabled more sensitive monitoring of achieved blood pressure level in the pediatric ESCAPE Trial than in the adult trials, in which casual blood pressure readings were exclusively used. Remarkably, for all adult CKD studies mentioned above, patients with proteinuria were more likely to benefit from intensified blood pressure control. This is consistent with the results of a meta-analysis of nearly 10,000 CKD patients in which intensified blood pressure control in patients with proteinuria appeared to protect against renal failure [134].

In the ESCAPE trial [101], strict blood pressure control was tolerated very well in the vast majority of children. Since the absolute risk of cardiovascular events in children is very low, the "J curve" phenomenon, i.e., an increase of cardiovascular events in patients achieving a very low blood pressure level, seems to be largely confined to elderly patients with advanced atherosclerosis.

The findings of the ESCAPE Trial [101] have been adopted by the most recent pediatric guideline published by the European Society of

Hypertension, which recommends a blood pressure target (for casual blood pressure and for ambulatory blood pressure monitoring) below the 75th percentile in non-proteinuric children with CKD, and below the 50th percentile in those with proteinuria [135]. The AAP Clinical Practice Guideline for Screening and Management of High Blood Pressure in Children and Adolescents, published in 2017, recommends a blood pressure goal below the 50th percentile for all children with CKD [136].

For adults and adolescents above age 15, the latest European hypertension guideline recommends a systolic target blood pressure of 130–140 mmHg [137], while the US guideline recommends a target blood pressure of <130/80 mmHg for adults with CKD [138] and the most recent KDIGO guideline suggests a systolic target blood pressure of <120 mmHg by standardized office readings [139]. For further information, please see also Chap. 50.

Proteinuria Control

In line with the experimental evidence given above, multiple clinical studies have confirmed that proteinuria is not only a marker, but also an important mechanism of kidney disease progression. Its reduction is associated with a slowing of GFR loss in the long term [15, 140–142].

In the ESCAPE trial, the level of residual proteinuria during antiproteinuric treatment was negatively associated with kidney survival in children with CKD [101, 102]. In a post-hoc analysis of the trial data, the initial antiproteinuric effect of the pharmacological intervention predicted the long-term preservation of kidney function [102]. The maximal effect was observed in children who achieved a proteinuria reduction of more than 60%. In the MDRD and REIN trials in adults with CKD, each 1 g/d reduction in proteinuria achieved within 3–4 months of antiproteinuric therapy slowed the subsequent GFR decline by 1–2 mL/min per year [15, 143]. Hence, the goal of antiproteinuric treatment is to reduce proteinuria as much as possible, ideally to <300 mg/m^2/day [144, 145].

Pharmacological Treatment Options

Antihypertensive and Antiproteinuric Pharmacotherapy

While the different classes of *antihypertensive agents* are comparable with respect to their blood pressure lowering efficacy, they differ markedly regarding their effects on proteinuria and CKD progression [141, 142, 146, 147].

By virtue of their pharmacological properties, *ACE inhibitors* (ACEis) and *angiotensin II type I receptor blockers* (ARBs) are the first options in both adults and children with CKD. These RAAS antagonists have an excellent safety profile, which is almost indistinguishable from placebo. In adults with essential hypertension, treatment with RAAS antagonists has been associated with the best quality of life among all antihypertensive agents.

RAAS antagonists suppress the local angiotensin II tone (ACEis) or action (ARBs). This results in a reduction of intraglomerular pressure and proteinuria, diminished local release of TGF-ß and other growth factors, cytokines and chemokines, with consequently attenuated glomerular hypertrophy and sclerosis, tubulointerstitial inflammation and fibrosis [85]. They also normalize central nervous sympathetic tone by reduced renal afferent nerve stimulation.

Several randomized trials in adults with diabetic or non-diabetic kidney disease have demonstrated a more effective reduction of proteinuria, usually by 30–40%, by ACEis as compared to placebo and/or other antihypertensive agents [144]. In the long term, this is associated with a reduced rate of renal failure progression [140, 144, 148–156].

Very similar results were obtained in randomized comparisons of ARBs with placebo or conventional antihypertensive agents in diabetic nephropathy [147, 157, 158]. It has been reasoned that ACEis might have a specific renoprotective advantage by inducing accumulation of vasodilatory and antifibrotic bradykinins, but the course of GFR was similar in clinical trials comparing ACEi and ARB therapy [159, 160]. However, a recent network meta-analysis suggested that ACEis are superior to ARBs and other antihyper-

tensive agents in reducing adverse renal events in patients with non-dialysis CKD 3–5, but are not superior to ARBs in lowering odds of kidney events in patients with advanced CKD [161].

Prescription of RAAS antagonists typically reduces the risk of doubling serum creatinine or attaining ESRD by 30–40%, but the superiority of RAAS antagonists is related to the prevailing degree of proteinuria. In adults, the superior nephroprotection of ACEis over other antihypertensive agents has been most clearly shown in patients with proteinuria exceeding 500 mg/day.

While the maximal antiproteinuric effects of RAAS antagonists occur at doses exceeding those providing maximal antihypertensive action [162], regulatory authority approval is usually available only for the doses used to treat hypertension. Therefore, it is generally recommended to administer these drugs, after confirming tolerability in a short run-in period, at their highest approved doses [141, 163].

Early pediatric studies showed stable long-term renal function with ACE inhibition in children following hemolytic uremic syndrome [164], stable GFR during 2.5 years of losartan treatment in children with proteinuric CKD [165], and attenuated histopathological progression in children with IgA nephropathy receiving combined RAAS blockade [166]. The ESCAPE trial demonstrated efficient blood pressure control and proteinuria reduction by the ACE inhibitor ramipril [101, 167]. Subsequently, several randomized clinical trials demonstrated efficient, dose-dependent antihypertensive and antiproteinuric efficacy of ARBs in children [168–171]. One comparative trial suggested superior 24-h blood pressure lowering with the ARB valsartan relative to the ACEi enalapril, without any difference in antiproteinuric efficacy [168].

In the EARLY PRO-TECT Alport study, ramipril treatment significantly reduced the risk of disease progression in children and young adolescents with Alport syndrome by almost half and diminished the slope of albuminuria progression and the decline in GFR [172]. Early ACEi treatment is not curative, but may delay, or even prevent, the need for dialysis and kidney transplantation until relatively late in life for substantial numbers of patients with Alport syndrome due to hemizygous missense variants and even truncating variants [173].

The CKiD study has provided observational evidence that children with moderate to severe CKD benefit from ACEi and ARB use by a KRT risk reduction of 21–37% [174].

The antiproteinuric response within in the first 2–3 months of administration is predictive of the long term renoprotective effect [102, 143] and may be utilized to individualize the appropriate drug dose. The specific glomerulodynamic effects of RAAS antagonists induce an immediate drop of the GFR, usually by approximately 10–15%, when these drugs are first administered. In patients with CKD, this may cause a significant increase in serum creatinine. It is important to know that a marked initial GFR decline is actually a positive predictor of the long-term nephroprotective effect [175]. Rapid acute renal failure soon after administration of a RAAS antagonist is a very rare event and usually related to concomitant volume depletion or previously unidentified bilateral renal artery stenoses.

Notably, a gradual rebound of proteinuria after the second treatment year during ongoing ACE inhibition was observed in the ESCAPE trial [101]. This effect was dissociated from a persistently good blood pressure control (Fig. 55.8), and may limit the long-term renoprotective efficacy of ACEi monotherapy in pediatric CKD. In several adult studies, subsets of patients developed partial secondary resistance to ACE inhibitors (‘aldosterone escape’ by compensatory upregulation of ACE-independent angiotensin II production) [176–179]. Such patients might benefit from the use of ARBs, which should not be affected by aldosterone escape.

Combined RAAS blockade using ACEi and ARB concomitantly has only a minor effect on blood pressure (3–4 mmHg vs. monotherapy), but increases the antiproteinuric effect of ACEi or ARB monotherapy by 30–40% [180, 181]. However, the findings of the ONTARGET in adult populations with high cardiovascular risk (CKD and diabetes) do not support the concept of

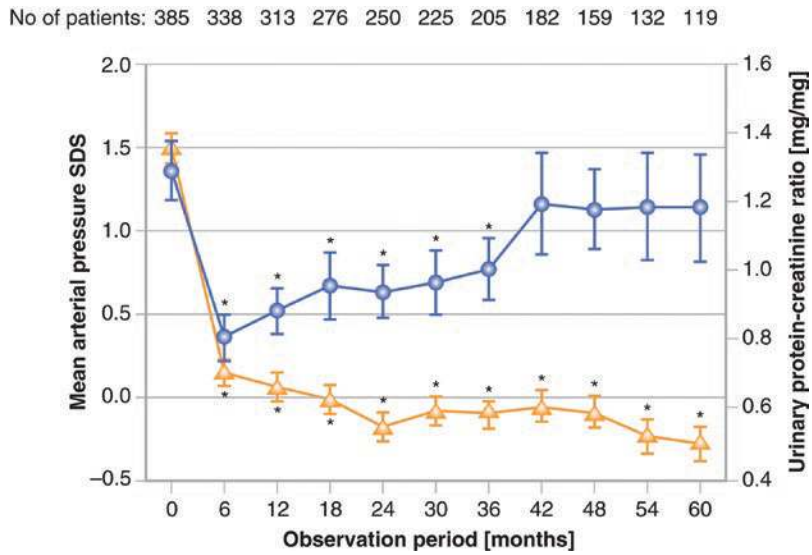

Fig. 55.8 Dissociation of antihypertensive and antiproteinuric effects of ACE-inhibition in children with CKD and fixed ramipril treatment (6 mg/m^2/day) participating in the ESCAPE Trial. Used with permission of Massachusetts Medical Society from Wühl et al. [101]

dual RAAS blockade in patients with low GFR or albuminuria [182, 183]. However, it is questionable whether these findings in a high-risk adult population with diabetes and established CVD can be extrapolated to pediatric CKD patients [184].

Aldosterone antagonists also act by RAAS suppression resulting in reduced blood pressure. While the use of spironolactone is limited by its endocrine side effects, the newer aldosterone antagonist eplerenone has minimal affinity for progesterone and androgen receptors; apart from the risk of hyperkalemia, reported side effects were similar to placebo [185]. Combined therapy of eplerenone and an ACEi increased patient survival in adults with congestive heart failure. However, the combination therapy of both compounds is limited in CKD patients by the potentiated risk of hyperkalemia. A Cochrane review analyzing the results of 44 studies on the use of aldosterone antagonists in combination with ACEi or ARB found uncertain effects of aldosterone antagonists when added to ACEi or ARB (or both) on the risk of death, major cardiovascular events, and kidney failure in patients with proteinuric CKD [186]. Aldosterone antagonists may reduce proteinuria, eGFR, and systolic blood pressure in patients who have mild to moderate CKD but may increase the risk of hyperkalemia, acute kidney injury and gynecomastia when added to ACEi and/or ARB.

In contrast, finerenone, a novel nonsteroidal selective mineralocorticoid receptor antagonist, has been shown in animal studies to block inflammation and fibrosis in both the heart and kidneys with only minor effects on serum potassium. In the placebo-controlled Fidelio-DKD trial involving >5700 adults with CKD and type 2 diabetes, finerenone significantly lowered the risk of CKD progression and cardiovascular events [187]. A clinical trial assessing the antiproteinuric efficacy of finerenone in pediatric CKD is currently underway.

The simultaneous use of novel, well-tolerated oral potassium binders may improve the tolerability of combined RAAS blockade, including aldosterone antagonists, in patients with increased risk for hyperkalemia [188].

The *renin-antagonist* aliskiren, which blocks the conversion from angiotensinogen to angiotensin I, has been shown to effectively reduce blood pressure. Preliminary data showed a blood pressure lowering effect comparable to that of ARBs and the combination therapy of aliskiren and valsartan at maximum recommended doses provided significantly higher reductions in blood pressure than did monotherapy [189]. However, due to the higher risk

of cardiovascular complications found in the ALTITUDE study, the combination therapy of aliskiren with ACEis or ARBs in patients with CKD is not recommended [190].

Calcium channel blockers (CCBs) are safe and can achieve blood pressure goals in patients with CKD. However, CCBs of the dihydropyridine type (amlodipine, nifedipine) fail to reduce progression of CKD. Although being excellent antihypertensive agents, dihydropyridine calcium channel blockers have no antiproteinuric effect and may actually promote proteinuria and more rapid CKD progression [142]. This is in contrast to non-dihydropyridine calcium channel blockers (diltiazem, verapamil), which have some antiproteinuric effect [142]. Therefore dihydropyridine CCBs should be avoided in proteinuric patients unless administered in combination with RAAS antagonists to improve blood pressure control [163], and may be acceptable as first-line antihypertensive monotherapy only in non-proteinuric patients.

CKD is often a state of overactivation of the sympathetic nervous system, and antiadrenergic drugs play an important role in its management. *β-blockers* are effective in lowering blood pressure in CKD patients; metoprolol and atenolol were the first antihypertensive agents for which beneficial effects on the decline of kidney function in CKD patients were demonstrated [149]. In the AASK trial, the beta-blocker metoprolol had an antiproteinuric effect almost comparable to ramipril, in marked contrast to amlodipine [141]. The antiproteinuric action may be due to sympatholytic effects. Newer β-blockers such as carvedilol have even better antiproteinuric effects compared to atenolol [191, 192].

Antihypertensive Combination Therapies

Because hypertension is a multifactorial disorder, monotherapy is often not effective in lowering blood pressure to the target range. Treatment with a single antihypertensive agent typically controls blood pressure in less than half of the patients.

Although most patients can be started on a single-drug regimen, consideration should be given to starting with two drugs of different classes for those with stage 2 hypertension. In addition, other patient-specific factors, such as age, concurrent medications, drug adherence, drug interactions, the overall treatment regimen, and comorbidities, should be considered. However, of those patients started on a single agent, many will subsequently require ≥2 drugs from different pharmacological classes to reach blood pressure goals. Drug regimens with complementary activity should be considered to maximize lowering of blood pressure. In addition, use of combination therapy may also improve adherence [137, 138].

In the ESCAPE trial [101], one third of patients required combination therapy to attain a blood pressure level in the normal range (<95th percentile), and 40% to reach a blood pressure in the lower normal range (<50th percentile). Likewise, 41% of the more than 700 patients participating in the European Cardiovascular Comorbidities in Children with CKD (4C) study were on two or more antihypertensive drugs [193], and 35% of the CKiD Study participants received combination therapy at baseline [194].

In CKD patients, RAAS antagonists are most commonly combined with a diuretic or with a calcium channel blocker, whereas their combination with a β-blocker usually does not exert an additive effect on blood pressure control. Fixed-dose combinations ('single pill') preparations are becoming increasingly popular in antihypertensive therapy, and may help maximize treatment adherence and efficacy [137, 138].

Antihypertensive Chronotherapy

In view of the fact that nocturnal blood pressure non-dipping is an independent risk factor for CKD progression, the timing of antihypertensive drugs may be relevant. Even with long-acting agents with recommended once daily administration, evening dosing lowers night-time blood pressure more efficiently, thereby partially restoring the physiologic nocturnal dipping pat-

tern. However, these effects seem to differ for individual antihypertensive drug classes. Whereas bedtime administration of calcium channel blockers and ACE inhibitors tends to restore the dipping pattern, evening dosing of β-blockers has no effect on the circadian blood pressure rhythm [195].

While antihypertensive 'chronotherapy' has not yet been demonstrated to affect CKD progression, in a study randomly assigning hypertensive CKD patients to either take all prescribed hypertension medications in the morning or at least one of them at bedtime, bedtime dosing was associated with improved blood pressure control and significant reduction of cardiovascular risk [196].

SGLT-2 Inhibition

Several drugs developed to enhance glucose control in patients with diabetes mellitus type 2, such as metformin, glucagon-like peptide 1 (GLP-1) agonists, dipeptidyl peptide 4 (DPP-4) antagonists, and specific *sodium-glucose cotransporter 2 (SGLT2) inhibitors***,** have recently been demonstrated to not only improve metabolic control but to exert additional beneficial effects on the cardiovascular system and the kidneys. Among these medications, SGLT2 inhibitors (gliflozins) have emerged as a particularly promising novel drug class. Apart from their glucose lowering effect, SGLT2 inhibitors decrease blood pressure, body weight, and albuminuria. The nephroprotective effects are based on a decrease of sodium delivery to the distal tubule and reduced glomerular blood flow leading to reversal of glomerular hypertension and hyperfiltration [197]. Large clinical outcome trials with the SGLT2 inhibitors dapagliflozin, canagliflozin, and empagliflozin in adult CKD patients with diabetic nephropathy have demonstrated a potent long-term nephroprotective effect of SGLT2 inhibition, with proteinuria reduction by 30–50% and impressive beneficial effects on hard renal outcomes such as doubling of serum creatinine, eGFR decline, need for KRT, and death from renal disease [198–200]. These nephroprotective effects have been confirmed in non-diabetic CKD patients [201]. To date, based on the results of the clinical trial programs, the SGLT2 inhibitors have been approved for the treatment of diabetic nephropathy. Unfortunately, pediatric trials with these novel compounds are currently not planned.

Due to the complementary effects of SGLT2 inhibitors and RAAS antagonists on glomerular perfusion and intraglomerular pressure (vasoconstriction of the afferent vessel by the SGLT2 inhibitor and vasodilatation of the efferent vessel by RAAS inhibition), combined therapy with these two drug classes might further reduce intraglomerular pressure and exert additive nephroprotective effects [202].

Anti-inflammatory Drugs

While RAAS antagonists exert indirect anti-inflammatory and antifibrotic properties via blockade of RAAS-dependent profibrotic and inflammatory pathways as outlined above, other non-specific *anti-inflammatory and antifibrotic drugs* may decrease fibrogenesis by reducing macrophage infiltration and subsequent recruitment of fibroblasts or generation of ROS. For example, pirfenidone, exerting anti-fibrotic, antioxidant, and anti-inflammatory properties, interfering with the expression, secretion and the effect of TGF-β, improved kidney function and proteinuria and reduced kidney scarring in animal models; however, in clinical trials in FSGS or diabetic nephropathy patients, pirfenidone showed conflicting results, failing to prevent proteinuria or GFR decline particularly in patients with renal dysfunction [203, 204].

Endothelin$_A$ (ET_A) receptor mediated inflammation, fibrosis and proteinuria can be reduced by *endothelin A receptor antagonists* (ERAs). ERAs have been shown to reduce albuminuria and blood pressure, but also cause sodium and fluid retention and anemia. A large randomized controlled trial in patients with diabetes mellitus type 2 and CKD using the relatively unselective ERA avosentan was terminated early because of an increased frequency of heart failure [205]. Atrasentan, a more selective endothelin receptor

antagonist, reduced the risk of renal events compared with placebo in pre-selected patients with diabetes and CKD [206]. Combined ET_A and angiotensin II blockade by sparsentan, a drug comprising moieties of irbesartan and atrasentan, achieved significantly greater reductions in proteinuria compared to irbesartan in patients with primary FSGS [207].

Despite their relevant side effect profile, the large body of pre-clinical data supporting a beneficial effect of ERAs, as well as encouraging results from clinical trials in IgA nephropathy, FSGS, Alport syndrome, sickle cell nephropathy, and resistant hypertension, hold promise that ET_A receptor antagonists may ultimately have a beneficial effect on a wide range of kidney disorders [208].

It has been shown that Nrf2 expression is consistently downregulated in CKD [209] and that activation of Nrf2 may prevent or attenuate fibrosis. Interventions that increase Nrf2 system components have been already described, but their effectiveness and clinical relevance require further clinical studies [209]. One pharmacological promotor of Nrf2 activity is *bardoxolone.* Initial phase 1 studies showed that bardoxolone increased GFR; however, subsequent phase 3 studies in patients with CKD and diabetes type 2 were prematurely terminated due to an increased risk of heart failure, elevation of transaminases, hypomagnesemia and muscle cramps. Worryingly, bardoxolone seems to increase urinary albumin excretion, indicating ongoing or even worsening glomerular damage. This might explain why after an initial increase GFR declined over 24 weeks in patients allocated to bardoxolone in the BEAM study [210]. Studies to further elaborate whether bardoxolone effectively retards kidney fibrosis and progression in specific kidney diseases such as Alport syndrome (CARDINAL trial) or ADPKD are underway.

Pentoxifylline (PTF), a non-specific phosphodiesterase inhibitor, has anti-inflammatory, antiproliferative, and anti-fibrotic properties. So far, the small clinical trials evaluating PTF in patients with CKD yielded conflicting data. A meta-analysis of 11 studies on PTF in combination with ACEi or ARB treatment including 705 adult patients suggested that combination therapy may lead to a greater reduction in proteinuria and attenuate the decline in eGFR in patients with CKD stages 3–5 [211].

Neprilysin (neutral endopeptidase or membrane metallo-endopeptidase) degrades numerous peptide hormones, including bradykinin, endothelin, and atrial and brain natriuretic peptides (ANP, BNP). Thus, *neprilysin inhibition* (NEPi) may be a therapeutic strategy enhancing the activity of the natriuretic peptide system, inducing natriuresis, diuresis and inhibition of the RAAS and the sympathetic nervous system. Sacubitril/valsartan, the first *angiotensin receptor-neprilysin inhibitor* (ARNI), has been shown to substantially improve not only cardiovascular outcomes in adults with heart failure, but also to delay CKD progression in this population. However, ARNIs have not shown similar effects on kidney function in the short-to-medium term in CKD patients [212].

In patients with ADPKD, *tolvaptan*, an oral selective antagonist of the vasopressin V2 receptor, has demonstrated beneficial disease-modifying properties in adults. Tolvaptan reduced total kidney volume and the decline of kidney function in adults with relatively early-stage ADPKD and high likelihood of rapid disease progression [213, 214] and also in those with more advanced disease [215]. Preliminary results of a placebo-controlled trial in pediatric ADPKD patients have shown efficient lowering of urine osmolality and a nominal reduction of total kidney volume after one-year of exposure to the drug [216].

Other Supportive Treatment Strategies

Metabolic acidosis is common in patients with CKD and may contribute to the development and worsening of proteinuria and tubulointerstitial fibrosis, accelerating the rate of decline in renal function. In a randomized controlled trial evaluating the renoprotective potential of oral bicarbonate supplementation in adult patients with CKD, only 4 of 67 patients receiving bicarbonate progressed to dialysis as compared to 22 of 67 patients in the untreated control group [107]. CKD progression

rate was reduced to 1 mL/min/year in patients with serum bicarbonate levels ≥22 mmol/L compared to >2.5 mL/min/year in patients with uncorrected low bicarbonate levels [107]. In adults with hypertensive nephropathy and relatively preserved GFR (mean GFR 75 mL/min/1.73 m^2), 5 years of oral sodium bicarbonate substitution (0.5 mEq/kg lean body weight daily) provided effective kidney protection when added to blood pressure reduction and ACE-inhibition [106]. Therefore, tight control of metabolic acidosis may become an important component of renoprotective therapy in patients with progressive CKD.

Treatment of uremic *dyslipidemia* is another component of renoprotective therapy. General measures to prevent dyslipidemia in CKD patients include prevention or treatment of malnutrition and correction of metabolic acidosis, hyperparathyroidism and anemia, all of which may contribute to dyslipidemia [112, 217, 218]. In addition, based on evidence from the general population, therapeutic life style modification (diet, exercise, weight reduction) is recommended for adults and children with CKD related dyslipidemia by the KDIGO Clinical Practice Guideline for Lipid Management in Chronic Kidney Disease [219]. Experimental evidence suggests that statins may retard kidney disease progression not only by their lipid lowering, but also by lipid-independent pleiotropic effects, inhibiting signalling molecules at several points in inflammatory pathways. Anti-inflammatory effects and improved endothelial function are thought to be partially responsible both for CVD risk reduction and improved kidney function [220]. Lipid lowering pharmacological treatment is common in adults with CKD, based on the benefit of this approach for primary and secondary prevention of CVD in the general adult population. However, in children with CKD, treatment of hypercholesterolemia is not recommended and treatment for hypertriglyceridemia should focus on severe cases due to lack of clear benefits coupled with safety concerns related to long-term use in children [219].

A meta-analysis including 10 studies on the impact of statin therapy on CKD progression suggested that high-dose, but not low-dose statin use, may be nephroprotective in CKD patients [221]. In addition, the degree of CKD and proteinuria may influence the effect of statin therapy on CKD progression. A study in almost 3500 adults with CKD demonstrated significant effects on GFR decline in patients with CKD stages 3b to 5 or proteinuria >1000 mg/d, whereas no significant effects were seen in mild to moderate CKD and non-proteinuric patients [222].

Several studies in adults with CKD suggested that dietary phosphorus restriction may stabilize kidney function [223]. However, no conclusions were possible from studies in children [224]. Experimental studies have suggested a PTH-independent beneficial effect of *phosphate restriction* on CKD progression. A high calcium phosphorus product may be detrimental to renal survival by aggravating intrarenal vasculopathy as well as by causing tubulointerstitial calcifications, which may stimulate tubulointerstitial inflammation and fibrosis. In view of these pathophysiological associations, it is currently discussed whether calcium-free phosphate binders may have some renoprotective potential in patients with CKD.

Sevelamer or colestilan may prove beneficial beyond phosphate lowering due to their pleiotropic effects, which include lipid lowering and anti-inflammatory properties. A lower all-cause mortality was found in patients with CKD stage 3–5D treated with sevelamer compared to patients on calcium-based phosphate binders [225].

Treatment with non-hypercalcemic doses of active *vitamin D* attenuates renal failure progression in uremic rats. This effect may be due to the immune modulatory and antifibrotic properties of vitamin D in combination with inhibitory actions on the RAAS [226]. In children with CKD, 25(OH)D levels >50 nmol/L were associated with better preservation of renal function, even in the presence of concomitant ACEi therapy [227].

In addition, there is increasing evidence for interactions between vitamin D, FGF23, and klotho regulating calcium phosphate homeostasis. Alterations of this endocrine axis may contribute to kidney disease progression by activation of the RAAS, vitamin D deficiency, reduced renal production of klotho and reduced FGF23

signaling [228]. FGF23 levels are independently associated with progression of CKD and may serve as a biomarker and mechanism of CVD [126]. These findings provide further arguments for close monitoring and early intervention to maintain mineral, vitamin D and PTH homeostasis in CKD.

Another biomarker of progressive CKD is serum uric acid. While allopurinol treatment improved renal outcome in CKD patients compared to placebo without a change in blood pressure level [229], and febuxostat treatment slowed down kidney disease progression [230], the CKD-FIX Trial could not demonstrate a beneficial effect of *uric acid lowering treatment* on kidney disease progression in stage 3–4 CKD patients [231].

Historically, *low protein diet* was prescribed for prevention of renal progression. However, the effects and consequences of this diet on CKD progression and delay of ESKD are inconclusive. A large randomized trial in adults failed to demonstrate efficacy of a low protein diet on the progression of non-diabetic kidney disease [232], whereas, in a recent review, protein restriction was associated with a risk reduction of kidney death [233]. Thus, though the progression rate was not significantly influenced by protein restriction, kidney replacement therapy could be postponed.

In children reduced protein intake to the minimal acceptable lower limit did not slow CKD progression [86, 234]. Further reductions may be effective but not acceptable for patients. Furthermore, a low protein diet may increase the risk of low-calorie intake, which may jeopardize the preservation of adequate statural growth. Therefore, it does not seem to be justified to prescribe a low protein diet in children with CKD.

Recently, studies in ADPKD patients have identified a chronic shift in energy production from mitochondrial oxidative phosphorylation to aerobic glycolysis as a contributor to cyst growth, making the cyst cells particularly sensitive to the availability of glucose. Therefore, low calorie or ketogenic diets may be a potential intervention to delay ADPKD progression [235]. A clinical trial evaluating the effect of a ketogenic diet on cyst growth and CKD progression in adult ADPKD patients is underway (NCT04680780).

Erythropoiesis stimulating agents (ESA) have emerged as a tissue-protective survival factor in various non-hematopoietic organs [236]. It has been suggested that normalizing hemoglobin in CKD patients might attenuate renal disease progression by increasing oxygen supply to the kidneys, preventing tubular atrophy and interstitial fibrosis. In addition, erythropoietin might counteract oxidative stress and apoptosis and may have direct protective effects on tubular cells [237] and podocytes [238]. However, this concept has not been substantiated in clinical trials on CKD progression to date.

Conclusions

Progression of childhood CKD towards kidney failure is common and once a significant impairment of kidney function has occurred it progresses irrespectively of the underlying kidney disease. Onset of CKD and progression rate in defined disease entities may be influenced by genetic factors. Hypertension and proteinuria are the most important independent risk factors for CKD progression. RAAS antagonists preserve kidney function, not only by lowering blood pressure, but also by their antiproteinuric and anti-inflammatory properties. Intensified blood pressure control exerts additional renoprotective effects in pediatric CKD; therefore, therapeutic strategies to prevent progression should comprise blood pressure control aiming for a target blood pressure below the 50th to 75th percentile. Furthermore, there is increasing evidence that treatment with SGLT2 inhibitors contributes to preservation of kidney function in adults with CKD. Other factors contributing in a multifactorial manner to CKD progression include anemia, metabolic acidosis, dyslipidemia and disorders of mineral metabolism. Measures to preserve renal function should therefore also comprise the maintenance of hemoglobin, serum bicarbonate, lipids and mineral metabolism in the normal range.

56 Growth and Puberty in Chronic Kidney Disease

Dieter Haffner and Lesley Rees

Introduction

Maintaining optimum growth is one of the most challenging problems in the management of children with chronic kidney disease (CKD): reports published in 2013 showed that approximately 50% of children requiring kidney replacement therapy (KRT) before their 13th birthday had a final height below the normal range [1–4]. Short stature is a marker for increased mortality and hampers the psychosocial integration of pediatric CKD patients [5–7]. There is, however, evidence that, alongside advancements in the medical and technical management of CKD and kidney replacement therapy (KRT), height prognosis has substantially improved over the past decades [1, 2, 4, 8–11]. In 799 pre-dialysis children with mostly mild to moderate CKD (median age 11 years, estimated glomerular filtration rate (eGFR) 50 mL/min/1.73 m^2) followed in the Chronic Kidney Disease in Children (CKiD) Study, the median height standard deviation score (SDS) was −0.55. Among 594 patients from 12 European countries with CKD stage 3–5 (median eGFR 30 mL/min/1.73 m^2) who were followed prospectively in the 4C Study, mean height SDS was −1.57, with 36% of patients having a height below the third percentile. In 1001 children in the International Pediatric Peritoneal Dialysis Network (IPPN), the mean height SDS at initiation of dialysis was −1.97 [10]. Hence, these data from contemporaneous large cohort studies demonstrate that growth failure progressively occurs with decreasing eGFR. In the 2020 USRDS report the percentage of incident end-stage kidney disease (ESKD) patients with short stature was lowest in the oldest patients age groups, being 20.3% at 18–19.9 years, 25.8% at 14–17, 20.1% at 10–13, 38.8% at 5–9 and 51.9% at 0–4 years of age [11, 12].

There appears to be a positive trend over time: e.g. in Germany, the mean standardized height in children on KRT has increased over the past 20 years from −3.0 SDS to −1.8 SDS [1]. Yet this is not the case in all parts of the world, particularly in those with inadequate local resources, where height prognosis remains dismally low [2, 13]. Even across Europe, the 4C Study observed growth failure to vary widely between countries, from 7% to 44% [9].

There is no single cause of failing growth in children with CKD (Fig. 56.1). The two most important influences are the severity of CKD and young age at its onset, so that children with CKD due to congenital kidney abnormalities manifest-

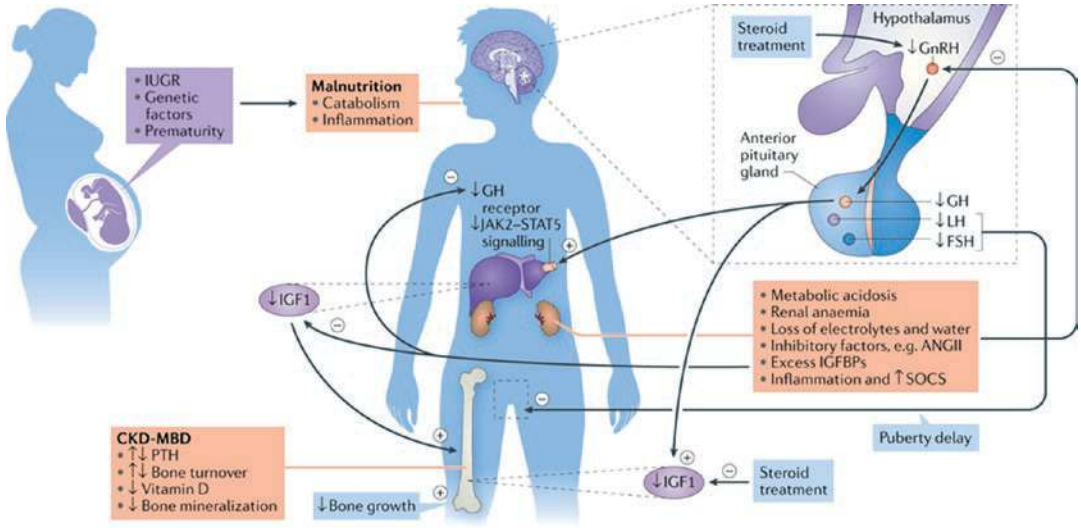

Fig. 56.1 The etiology of growth failure in CKD is multifactorial and includes intrauterine growth restriction (IUGR), genetic factors such as parental height and primary renal disease, prematurity, and malnutrition which especially limits growth in children with congenital CKD. Mineral and bone disorder (CKD-MBD), metabolic acidosis, anemia, loss of electrolytes and water, and disturbances of the somatotropic and gonadotropic hormone axes are additional factors. CKD is a state of growth hormone (GH) insensitivity, characterized by deficiency of functional insulin-like growth factor I (IGF-I), to reduced GH receptor expression in target organs like the liver, disturbed GH receptor signaling via the Janus kinase - signal transducers, activators of transcription (JAK2-STAT5) due to inflammation induced SOCS (suppressor of cytokine signalling), and increased IGF-binding capacity due to excess of IGFBPs. Finally, reduced release of hypothalamic gonadotropin-releasing hormone (GnRH), due to uremia-related inhibitory factors such as angiotensin II (AngII), and steroid treatment may result in decreased circulating levels of bioactive luteinizing hormone (LH), hypogonadism and reduced pubertal growth spurt. PTH, parathyroid hormone; FSH, follicle stimulating hormone; IGFBP, insulin-like growth factor binding proteins. [Reproduced with permission of [30]]

ing in infancy are usually more severely affected than those with acquired conditions developing in later childhood. This review summarizes the current knowledge of the phenotype, pathophysiology and therapeutic options for children with failing growth resulting from CKD.

Normal Growth

The physiological growth pattern can be divided into fetal, infantile, mid-childhood and pubertal phases (Fig. 56.2) [14]. During fetal life, nearly 30% of final height has already been achieved, so low birth weight and prematurity can substantially influence subsequent growth and final height attainment: although many otherwise normal infants born prematurely grow normally, and those who are small for gestational age (SGA) catch up in the first 6 months of life, around 10%, particularly if SGA, remain below the normal range for height into adulthood. A further one third to one half of total postnatal growth occurs during the first 2 years of life, and 20% during the pubertal phase. Throughout each postnatal phase the predominant influences on growth are different. Whereas in infancy, growth mainly depends on nutritional intake, growth in mid-childhood is driven by the somatotropic hormone axis. During puberty, the gonadotropic hormone axis stimulates growth via increased proliferation of growth plate chondrocytes and modulation of growth hormone (GH) secretion from the pituitary gland, resulting in the pubertal growth spurt (Fig. 56.2) [14].

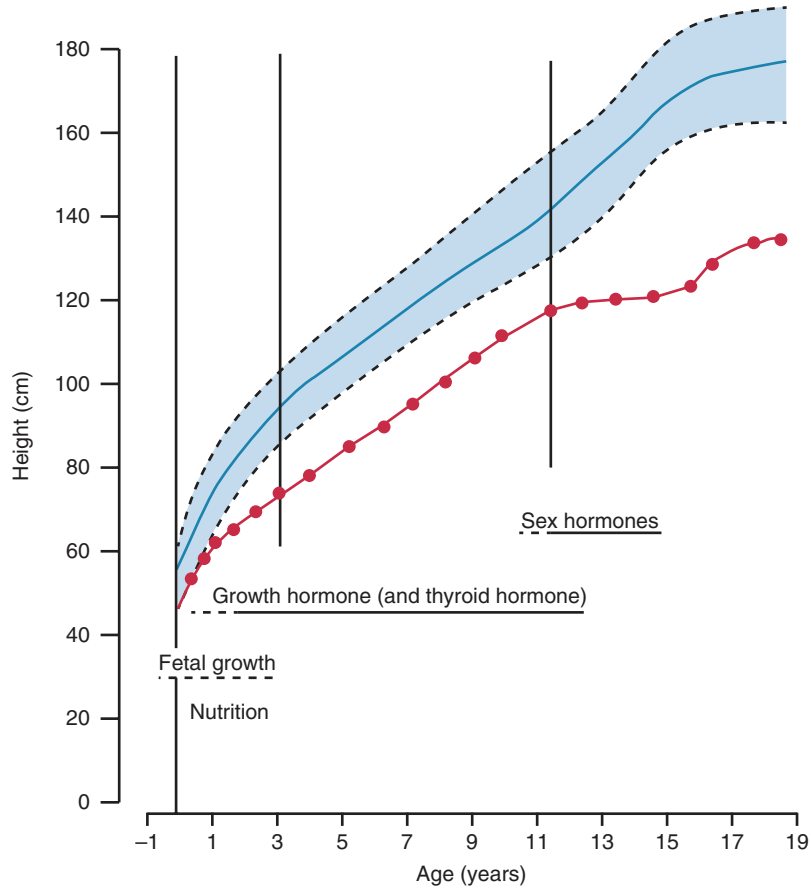

Fig. 56.2 Typical growth pattern in congenital chronic kidney disease. Relative loss in the nutrient-dependent infantile and gonadal hormone-dependent puberty phases, and percentile-parallel growth in the mainly GH-dependent growth period in mid-childhood are shown. The shaded area represents the normal range, third to 97th centiles. (Reproduced with permission of [14])

Effect of CKD on the Phases of Growth

The classical growth pattern for a child born with CKD was described in 1974 [15]. Length at birth is usually already below the mean (Fig. 56.2) [16]. As with any chronic disease, height velocity is most affected during periods of rapid growth. Marked growth retardation occurs during the first 2 years of life, followed by percentile parallel growth in mid-childhood, but catch-up growth is unusual. In the pre-pubertal years, the appearance of secondary sexual characteristics is delayed and the growth rate again decreases disproportionately [17, 18]. The pubertal growth spurt is later than normal and its magnitude impaired, resulting in further loss of growth potential and reduced final height (Fig. 56.2) [14]. Over the last 20 years, although these basic principles remain, this classic description has been reassessed as there have been new concepts and treatments for most patients in all postnatal phases of growth.

The Fetal Phase

Reduced fetal growth was described as a feature of the classic growth pattern of the child with CKD in 1994, and has been demonstrated in several studies since [16, 19–22]. Both prematurity and low birth weights are common. The incidence is particularly high in infants on dialysis but perhaps more surprisingly is high in children with less severe CKD as

well [23]. Registry data do not always distinguish between infants who do or do not have co morbidities (such infants often have below normal mean birth weight and length) but it has been shown that of just over 400 children with a mean eGFR of around 40 mL/min/1.73 m^2 in the US CKD registry, low birth weight (LBW, <2500 g) occurred in 17%, prematurity (gestational age < 36 weeks) in 12% and small for gestational age (SGA, birth weight < tenth percentile for gestational age) in 14%. It has been hypothesized that poor intrauterine growth conditions, e.g. maternal malnutrition and smoking, could cause both intrauterine growth retardation and kidney dysplasia [24, 25]. Likewise genetic abnormalities, e.g. dysregulation of Wilms' tumor suppressor gene, could cause both short stature and renal hypodysplasia [26]. Interestingly, in the US CKD registry 40% of patients had needed intensive care (ICU) at birth. The comparable overall incidence of abnormal birth history in the US population is 7–8%. Low birth weight, prematurity, SGA and requirement for ICU were all risk factors for poor growth outcomes, independent of renal function [21]. Likewise, intrauterine growth retardation, neonatal distress and parental height were shown to be important independent predictors of poor growth outcome in a cohort of 509 German children with CKD stage 3–5 [27].

The Infantile Phase

It is not surprising that adverse effects on growth are most intense during the infantile phase, and in particular the first 6 months of life, as the rate of growth is as high as 25 cm per year at birth, 18 cm per year at 6 months of age, and still 12 cm per year at 12 months of age. These figures are higher than at any other time during childhood and adolescence. Such growth challenges require nutrient intakes that are relatively higher than at any other age. As the infantile phase is predominantly dependent on nutrition, inadequate intake at this time can have a dramatic influence on growth. Indeed, any circumstances leading to decreased growth rates in this phase result in severe growth retardation and a potentially irreversible loss of growth potential [28, 29]. The decrease in mean standardized height can amount to 0.6 SD per month in infants with CKD stage 5. In recent years the increasing acceptance of KRT for all infants, including those with associated comorbidities, has increased the challenge to achieve normal growth in this age group [20]. Malnutrition in young children with CKD is due to inadequate nutritional intake and frequently recurrent vomiting as well. In addition, catabolic episodes due to infections, loss of water and electrolytes, and CKD-mineral and bone disorder (CKD-MBD) are major contributing factors to growth impairment in this period. If these disturbances are adequately controlled, severe stunting can be avoided in the majority of patients without untreatable comorbidities [19, 20, 30]. However, most infants suffering from severe CKD need supplementary feeding in order to provide adequate nutrient, water and electrolyte intake [31].

The Childhood Phase

During this phase, the somatotropic hormone axis becomes the most important influence on growth. Growth is closely correlated with the degree of kidney dysfunction in this period. Although there is no critical threshold, growth patterns are typically stable if the GFR remains above 25 mL/min/1.73 m^2 and tend to diverge from the percentiles below this level [23]. Sequels of CKD such as anemia, metabolic acidosis and malnutrition seem to be less important in mid-childhood. However, even a growth rate that parallels the centiles may not be 'normal', as children with good renal function and steroid-free immunosuppression following transplantation exhibit significant catch-up, compatible with the concept of continued suppression of an intrinsic catch-up growth potential in the uremic state [32, 33].

The Pubertal Phase

Pubertal Development

Delayed onset and progression of pubertal development was a common feature when KRT programs for children started [17]. Studies of the timing of pubertal onset have been hampered by the fact that bone age is only a crude marker for

assessment in CKD. Indeed, the distribution of bone age at pubertal onset varies at least as much as the distribution of chronological age in these patients. However, data from the late eighties demonstrated a delay of pubertal onset by 2–2.5 years in children with ESKD [17]. Menarche occurred after the upper limit of the normal age range (i.e. 15 years) in almost half of the girls treated by dialysis or transplantation [34]. Moreover, despite the achievement of pubertal stage IV or V, a substantial proportion of dialysis patients presented with permanently impaired reproductive function [35]. Fortunately, in the last twenty years most children requiring KRT before pubertal age present with normal or only slightly delayed pubertal onset. In two recent studies, mean age at pubertal onset as well as age at menarche did not differ between children on KRT and healthy children; and the serum levels of pubertal reproductive hormones were normal in the great majority of patients [1, 36]. Bone maturation in patients on KRT continues to be delayed by approximately 1.4 years compared to healthy children, although this does not negatively impact on pubertal development [1]. The age at onset of puberty has been positively correlated with the age at transplantation. Thus, early renal transplantation is a prerequisite for prevention of pubertal delay in children with stage 5 CKD [18, 36]. A recent analysis of the CKiD cohort including children with CKD stage 3–5 revealed delayed menarche in 10% of adolescent patients which was associated with African American race, lower eGFR, ever corticosteroid use, and longer duration of CKD [18, 37]. Delayed menarche was strongly associated with reduced height (<−2.0 SDS). Thus, delayed puberty is an important contributor to short stature in female patients even prior to dialysis. Patients who show delayed puberty—defined in boys by a testicular volume < 4 mL at the age of 14 years and in girls by a breast stage <B2 at age 13.5 years—should undergo work up by a pediatric endocrinologist including potential induction of puberty [30].

Pubertal Growth

During the last two decades in parallel with the improvement in sexual maturation has been an improvement in pubertal height gain [1, 2, 17, 18]. Longitudinal growth in 384 German children on KRT who were followed between 1998 and 2009 was compared with 732 children enrolled in the European Dialysis and Transplant Association (EDTA) Registry between 1985 and 1988 (Fig. 56.3) [1]. In line with previous

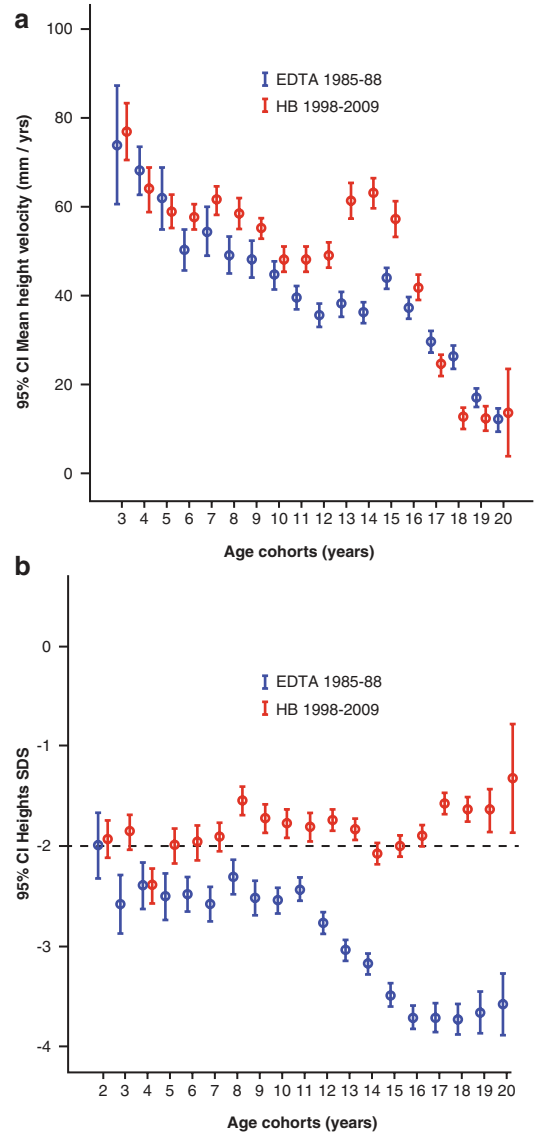

Fig. 56.3 (**a**) Mean height velocity of European children with renal replacement therapy in the EDTA study 1985–1988 (blue lines) versus the Hannover/Berlin (H/B) pediatric population cohort 1998–2009 (red lines) in different age cohorts. (**b**) Age-dependent height standard deviation score of European children on kidney replacement therapy 1985–1988 (EDTA study, n = 732, blue error bars) and in the HB group (n = 384, red error bars). EDTA European Dialysis and Transplant Association, CI Confidence interval. Reproduced with permission of [1]

studies, the pubertal growth spurt in the EDTA patients was delayed by approximately 2.5 years. In many patients no clear pubertal growth spurt was present, and consequently standardized height decreased during pubertal age. In contrast, a clear pubertal growth spurt was present and the onset of the pubertal growth spurt was within the normal range in the majority of the patients followed-up more recently. Consequently, standardized height even improved during puberty and until adult height. A strong negative correlation between total pubertal height gain and age at transplantation was reported in two studies a [18, 36]. Thus, whereas 20 years ago a loss of about 1.0 SD was expected during puberty, nowadays normal or only slightly reduced pubertal growth spurt can be expected if long-term dialysis is avoided.

Segmental Growth

It has been postulated that during malnutrition there is preferential preservation of growth of vital organs at the expense of less vital tissues such as the limbs, so that malnutrition during childhood results in disproportionate stunting with impairment of leg growth, and preserved trunk and head growth [38]. Consequently, relative leg length is increasingly used as a biomarker of childhood nutrition in epidemiological studies [39, 40]. Information pertaining to segmental growth has been collected in the CKD Growth and Development Study, in which more than 800 pediatric CKD patients before and after transplantation have been enrolled since 1998 [41–43]. Patients with a long-term history of CKD and KRT showed an age related disproportionate growth pattern [41–43]. Growth impairment and disproportionality was most obvious in early childhood. Sitting height was mostly preserved, whereas growth of the legs and arms was most severely affected. This resulted in a markedly elevated sitting height index (ratio of sitting height to total body height). Leg length was more affected in prepubertal patients. Consequently, body disproportion was less pronounced in pubertal patients. In addition to transplant function and steroid exposure, congenital CKD, smallness for gestational age, young age, and use of recombinant human growth hormone (rhGH) in the pre-transplant period were significantly associated with growth outcome (stature and degree of body disproportion. Catch-up growth after kidney transplantation is mainly related to improved trunk growth in children aged less than 4 years and stimulated leg growth in older children resulting in complete normalization of body proportions until attainment of adult height in the vast majority of patients [42, 44].

Adult Height and Height Prediction

When interpreting the adult heights of patients treated for CKD in childhood, it has to be remembered that the data obtained at any time will reflect treatment practices spanning the previous two decades. Furthermore, most reports of adult heights do not or incompletely discriminate according to patient characteristics (e.g. diagnoses, ages of onset of CKD, types and durations of KRT), and in particular registries do not separate out children with co morbidities that affect growth in their own right. With that in mind, reduced adult heights have been reported in up to 50% of CKD patients, although there has been a trend for improvement over the past decade [1–4, 17, 18, 45]. Mean adult heights vary from 148–158 cm for females and 162–168 cm for males (second centiles 151 and 163 cm respectively).

The ESPN/EDTA registry has shown that, after adjustment for age and period of start of KRT, final height increased significantly from −1.93 SDS in children who started KRT before 1990, to −1.78 in children in 1990–1999, and to −1.61 in those starting KRT after 1999 ($p < 0.001$). While 55% of patients attained an adult height within the normal range between 1990 and 19,995, this figure had risen to 62% between 2006–2011 [2]. The improvement in adult height over time was independent of age at the start of KRT (Fig. 56.4). Poorest growth outcomes were associated with earlier start and longer duration of dialysis or a diagnosis of a metabolic disorder such as cystinosis and hyper-

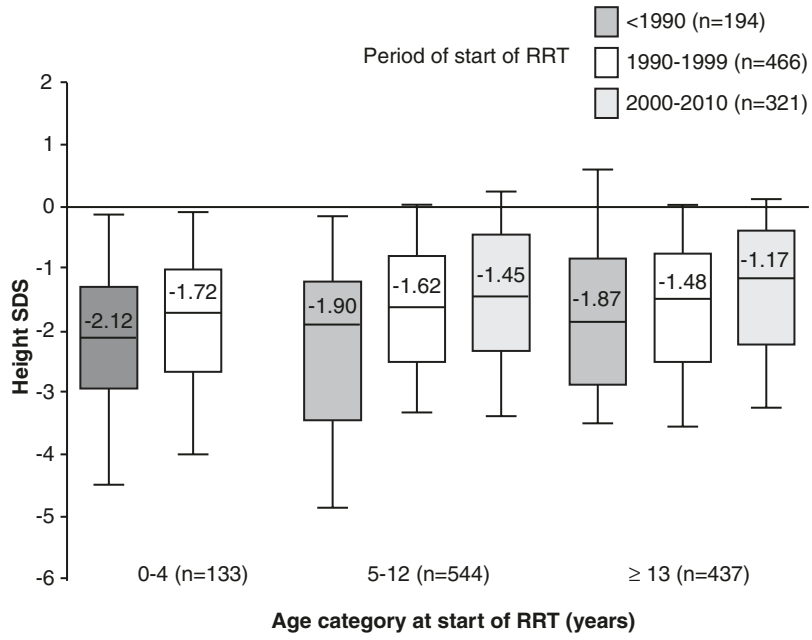

Fig. 56.4 Changes in final height SDS over time according to age and period of start of KRT (n = 981). (Reproduced with permission of [2])

oxaluria; whereas those with a longer time spent with a renal transplant and those treated with rhGH did the best [2–4, 46–49].

There is evidence that over the years, final height post transplantation is improving [3]. This is likely to be due to a combination of factors such as better growth attained pre transplant, e.g. by adequate nutrition and rhGH therapy, preemptive transplantation thus avoiding dialysis, and to the development of protocols that minimize the use of corticosteroids. European data show an improvement in final height from −2.06 SDS in children who reached adulthood in 1990–1995 to −1.33 SDS in 2006–2011[2]. In the 2014 NAPRTCS report, the mean height SDS of those >19 years of age was −1.37. Twenty-five percent of these patients had a height SDS of −2.2 or worse, and 10% were more than 3.2 SD below the mean. This has improved considerably as adult height SDS was −1.93 with the 1987–1991 cohort, −1.51 for 1992–1996 cohort; −1.06 for the 1997–2001 cohort, −0.98 for the 2002–2006 cohort and −0.89 for the most recent cohort (https://naprtcs.org/system/files/2014_Annual_Transplant_Report.pdf).

Older age at start of KRT, starting KRT more recently, cumulative time with a transplant, and greater height SDS at initiation of KRT were independently associated with a higher adult height SDS. Most impressively, recent results of the avoidance of steroids post transplant altogether are excellent, with mean final heights of 177 cm and 175 cm in males transplanted prepubertally and postpubertally respectively, with similar figures of 165 cm and 162 cm for females [4].

The application of adult height prediction methods in children suffering from CKD is not recommended. In several validation studies final height was overpredicted by 3–10 cm [17, 18, 46]. Most likely this reflects the complexity and thus unpredictability of growth and development under the conditions of chronic uremia, with highly variable and dynamic impacts of disease progression, medications, bone disease, KRT modalities, skeletal maturation, and pubertal timing [18, 46].

Causes of Growth Failure in CKD

Growth failure in CKD is due to a complex interplay of many different factors, with varying effects at different ages and stages of CKD (Fig. 56.1). While some factors, such as nutri-

tional and hormonal abnormalities, and hematological and metabolic derangements such as acidosis, electrolyte imbalance, and CKD-MBD are potentially correctable, the effects of others, such as birth parameters, associated syndromes, race and parental heights, are not [27]. There is a substantial global variation of the degree of growth failure in children on KRT which is at least partly explained by differences in economics. In a recent survey of the IPPN network gross national income was a strong independent predictor of standardized height, adding to the impact of other well-known factors, e.g. congenital CKD, anuria, and dialysis vintage as outlined below [50]. Likewise the country of residence was an independent predictor of growth outcome in a large European cohort of children with CKD stage 3–5, which may be related to differences in the timing of diagnosis and/or referral to a center specialized for children with CKD—which in turn may have economic causes [9].

Cause of Renal Disease

Congenital Abnormalities of the Kidneys and Urinary Tract (CAKUT)

Renal tubular sodium and bicarbonate losses are common in children with CAKUT, and can cause salt depletion and acidosis both of which can contribute to growth failure [51]. Supplementation with salt and bicarbonate may be necessary, along with free access to water.

Glomerulopathies

Growth may be affected in children with glomerulopathies, even in early CKD [52]. The nephrotic state per se and glucocorticoid treatment are known risk factors. Prolonged high corticosteroid doses lead to severe growth failure. Although partial catch-up growth can be seen after cessation of glucocorticoid treatment, this is usually restricted to young (prepubertal) patients [53]. Congenital nephrotic syndrome is often associated with severe growth retardation during the first months of life, even in patients with preserved kidney function, and seems to be secondary to persistent edema, recurrent infections, losses of peptide and protein-bound hormones in the urine, and/or protein-calorie malnutrition [54, 55]. In the Finnish-type nephrotic syndrome adequate nutritional support is vital and bilateral nephrectomies and initiation of dialysis may be necessary to stabilize growth. In less severe types of congenital nephrotic syndrome, unilateral nephrectomy and/or treatment with prostaglandin synthesis inhibitors and RAS antagonists can reduce proteinuria and thereby stabilize growth and the overall clinical condition [54–56].

Tubular and Interstitial Nephropathies

Tubular dysfunction characterized by losses of electrolytes, bicarbonate, and water can lead to severe growth failure even in the presence of normal glomerular function. The growth suppressive effects of isolated tubular defects are illustrated by the severe growth failure typically seen in patients suffering from renal tubular acidosis, Bartter syndrome, and nephrogenic diabetes insipidus [57]. Supplementation with electrolytes, water and bicarbonate may be able to prevent growth failure or even induce catch-up growth [58].

The most severe growth failure, which may be very difficult to treat, occurs in patients suffering from complex tubular disorders such as Fanconi syndrome [58–61]. In these patients, only partial catch-up growth can usually be achieved even with vigorous water and electrolyte supplementation. Systemic metabolic disorders (such as cystinosis, primary hyperoxaluria and mitochondrial cytopathies) resulting in complex tubular dysfunction, progressive loss of kidney function, and involvement of other vital organs (e.g. liver, bone, and brain) also lead to severe growth failure [61–63]. In children with nephropathic cystinosis, growth failure occurs already in infancy when glomerular function is typically not yet compromised. Progressive growth failure is further sustained by generalized deposition of cystine crystals altering the function of the growth plate, bone marrow, hypothalamus, and pituitary and thyroid glands. Early initiation of treatment with cystine depleting agents (cysteamine) results in an improvement of

growth rates and substantial delay in the development of ESKD [61, 64]. Nevertheless, in a recent European study mean standardized height in children suffering from nephropathic cystinosis with CKD 2–5 was 1.0 SDS lower compared to that in children with other causes of CKD at comparable age and degree of CKD, compatible with an additional impact of an underlying osteoblast defect in this disease [65, 66]. In patients with primary hyperoxaluria, supplementary treatment with citrate and pyridoxine can delay the progression of CKD in some patients, and possibly improve longitudinal growth [62]. However real catch-up growth after combined liver-kidney transplantation is rarely observed even in prepubertal oxalosis patients [48]. New ribonucleic acid interference (RNAi) therapies are expected to become the standard of treatment in these children, so that end-stage kidney disease, KRT and consecutive growth failure may be avoidable in the vast majority of cases in the future [67].

Stage of CKD and Dialysis

Even moderate reduction of GFR has been reported to result in impaired growth. The principal registry providing data on the epidemiology of growth in conservatively managed CKD is the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS). The 2006 report covers the 10 years between 1994–2004 and includes a very large cohort of over 5000 children with GFRs of up to 75 mL/min/1.73 m^2. As expected, the most growth retarded were the youngest children, with a mean standardized height for under 2 years of age of −2.3 SD, but mean height SDS was reduced at all ages (−1.7, −1.4, −1.0 at 2–6, 6–12 and > 12 years respectively), with over one third overall being below the third centile for height. Standardized height worsened with progression of CKD, so that there was a strong correlation between creatinine clearance and height SDS (−3.2, −1.9, −1.5, and −0.9 for GFR <10, 10–25, 25–50 and > 50 mL/min/1.73 m^2 respectively) [68]. This means that many children, and particularly the very young, are already short at the time of entry to KRT programmes [69]. This has been confirmed more recently in a cohort of 42 children followed during the first 6 years of life, when the mean height SDS was normal at CKD stage 1–2, approximately −0.5 at CKD stage 3–5 and much less, at −1.5 SDS, for those on dialysis [70].

That short stature becomes more common in children on dialysis has been confirmed by the United States Renal Data System (USRDS), a registry collecting data on patients on KRT programs in the US. The 2007 report shows that the height and weight of approximately half of children on dialysis were below the 20th centile for the normal population [71]. Comparison of 2007 and 2016 data demonstrates that the prevalence of short stature in the incident pediatric ESKD population has not improved over the past 10 years [12]. The British Association for Paediatric Nephrology (BAPN) report for height SDS of prevalent patients on dialysis at the end of 2017 was −2 with interquartile range of −1 to −3, having been −1.3 (−0.3 to −2.4) SDS at the start of KRT (UK Renal Registry (2021) UK Renal Registry 23rd Annual Report – data to 31/12/2019, Bristol, UK. Available from renal.org/audit-research/annual-report). Children on dialysis were shorter than their transplanted peers whose mean Height SDS was −1.0 (−0.2 to −2), although both groups are below the heights of the normal age matched population. The International Pediatric Dialysis Registry collects data from more than 3000 children on peritoneal dialysis (PD) from around the world, and is, therefore, able to provide comparisons of all aspects of PD according to region in the largest cohort of children on PD to date. Currently, the mean standardized height on commencing PD is −2.35 SDS, and is below normal worldwide, but there is a large variation, ranging in 21 countries from −1.3 in the UK, to −3.5 in Brazil. Regional variations in resources are likely to contribute to these differences [31]. Given our knowledge that in the majority of reports standardized height declines with increasing time on dialysis, the obvious key to prevention of growth deterioration is pre-emptive transplantation [72].

Protein-Calorie Malnutrition

Anorexia is a common symptom of CKD, due to a combination of altered taste sensation, decreased clearance of cytokines that affect appetite and satiety, obligatory losses of salt and water leading to a preference for salty foods and large volumes of water, and the need for multiple medications. Vomiting is also common, particularly in infants, whose diet is liquid and therefore high volume, and because gastro-esophageal reflux is frequent and elevated polypeptide hormones result in abnormal gastrointestinal motility. PD results in raised intra-abdominal pressure, which may affect both appetite and cause vomiting and constipation, and dietary and fluid restrictions may result in an inadequate diet. Peritoneal dialysate losses of protein and sodium may be high. Finally, co-morbidities may cause poor feeding in their own right [31, 73]. Nutritional deficiency is, therefore, one of the most frequent and important factors contributing to growth failure. The Pediatric Renal Nutrition Taskforce has produced guidelines for the nutritional management of children with CKD stages 2–5 and on dialysis (*vide infra*) [74, 75].

Protein-Energy Wasting

Protein-energy wasting (PEW) is characterized by maladaptive responses including anorexia, elevated basic metabolic rate, wasting of lean body tissue, and under-utilization of fat tissue for energy [76]. It differs from malnutrition in which appetite is maintained, and weight loss is associated with protective metabolic responses such as a decreased basic metabolic rate and preservation of lean body mass at the expense of fat mass. Malnutrition can usually be overcome by nutritional supplementation or changes in the composition of the diet, whereas PEW can only be partially reversed by increased nutrition. Why some children develop PEW is unknown, but inflammation is likely to play a role [77]. However, growth failure is one of the main manifestations of PEW in children with CKD. New understandings of the pathophysiology of PEW in CKD have the potential for novel therapeutic strategies such as ghrelin agonists and melanocortin antagonists [31].

Obesity

At this stage it is important to mention obesity, which is emerging as a growing problem for children with CKD. In the ESPN/ERA-EDTA registry including 25 countries, of 5199 patients below the age of 18 years the prevalence of underweight was 4.3%, while 19.6% and 11.2% were overweight or obese respectively [78]. Receiving steroid therapy and living with a kidney transplant were independent risk factors for overweight. The incidence of obesity parallels that around the world in the normal population. The IPPN database demonstrates this regional variation, with BMI-SDS ranging from a mean of 0.8 in the US to −1.4 in India in children of all ages [31]. Twenty six percent of infants were obese in the US and 50% malnourished in Turkey [31, 58]. In North America, the frequency of obesity is increasing in the CKD population both before as well as at CKD stage 5 [79]. Obesity is a particularly a problem after kidney transplantation. This has been studied in the NAPRTCS database in a retrospective cohort study of 4326 children transplanted between 1995 and 2006, and followed up to 2007. Median BMI increased by 11% at 6 months but with no substantial changes thereafter [80]. In Europe, children with the lowest BMI and those over 5 years of age at transplant showed the greatest increases in BMI post-transplant [78]. UK 2017 data shows that the mean BMI of transplanted children was 1 SDS (0–1.8), whereas it was 0 (−0.8–1.1) for children on dialysis (UK Renal Registry (2021) UK Renal Registry 23rd Annual Report—data to 31/12/2019, Bristol, UK. Available from renal.org/audit-research/annual-report). The use of steroid sparing regimens may mitigate post transplant obesity [4]. Important to note, among transplanted recipients, a very short stature (OR: 1.64, 95% CI: 1.40–1.92) and glucocorticoid treatment (OR: 1.23, 95% CI: 1.03–1.47) were associated with a higher risk of being overweight/obese. Hence, at least in post-transplant patients, obesity is also a risk factor for poor growth.

Metabolic Acidosis

Metabolic acidosis (serum bicarbonate <22 mEq/L) usually begins when the GFR falls below 50% of normal, and is associated with decreased longitudinal growth and increased protein breakdown [81, 82]. Metabolic acidosis is also associated with endocrine consequences: in experimental uremia there is increased glucocorticoid production, increased protein degradation, and profound effects on the somatotropic hormone axis. The latter is characterized by down regulation of spontaneous GH secretion by the pituitary gland, decreased expression of the GH-receptor and insulin like growth factor I (IGF-I) receptor in target organs, and decreased IGF I serum concentrations [83]. Hence, metabolic acidosis induces a state of GH insensitivity, which is likely to contribute to impaired longitudinal growth in CKD patients.

Disturbances of Water and Electrolyte Balance

Although the relationship between salt loss and growth failure has not been formally proven in CKD, children with isolated tubular disorders resulting in urinary salt and water losses show severe growth retardation which can be at least partly resolved by adequate salt and water supplementation. The same applies to patients with a reduced chloride diet or with familial chloride diarrhea [84]. Growth impairment in diabetes insipidus supports the concept that polyuria may also contribute to growth failure in CKD patients [85].

CKD-Mineral and Bone Disorder (CKD-MBD)

It is widely accepted that skeletal deformities due to CKD-MBD contribute to uremic growth failure [86, 87]. Pronounced secondary hyperparathyroidism can interfere with longitudinal growth by destruction of the growth plate architecture, epiphyseal displacement and metaphyseal fractures. Severe destruction of the metaphyseal bone architecture may result in complete growth arrest. Treatment with 1,25-dihydroxyvitamin D_3 ($1,25(OH)_2D_3$) improves growth in uremic rats, but this not been demonstrated in children with CKD [88, 89].

PTH levels primarily reflect osteoblast activity. Therefore, it has been speculated that low PTH levels may be associated with poor bone and statural growth, and conversely high PTH levels might be expected in well growing children; and similarly, that poor growth might be expected with adynamic bone disease and better growth in its absence. Information on this issue is conflicting. Diminished growth rates have been shown in four dialyzed patients who had adynamic bone disease on bone biopsy, and PTH levels were positively correlated with the annual change in standardized height [90]. However, the proportion of patients showing adynamic bone disease in this population, where all subjects received high-dose intermittent calcitriol treatment, was rather high (25%). Therefore, this does not represent patients treated nowadays [91]. Indeed, low bone turnover was noted in only 4% of pediatric patients on dialysis in a recent study. In addition, there was no relationship between PTH levels and growth rates in 35 prepubertal children on dialysis for more than one year. Moreover, stable growth was seen with PTH levels only slightly above the normal range, and even catch-up growth occurred in children younger than 2 years [92]. In addition, one well-designed direct histomorphometric assessment in children on dialysis revealed no association between low bone turnover and body growth [93]. The IPPN offers the most up to date information from the largest cohort of PD patients: the annual prospective change in standardized height tended to correlate inversely with time-integrated mean PTH levels: patients with mean PTH levels >500 pg/mL (i.e. > 9 times upper limit of normal (ULN)) showed a significant loss in height SDS as compared to children with lower PTH levels (−0.28 versus −0.05 SDS per year; $p < 0.05$) [94]. Thus, dialyzed children with normal or only slightly elevated PTH levels have the potential for normal growth, whereas patients with high PTH levels (>500 pg/mL) are at increased risk of growth failure.

Anemia

Longstanding anemia in CKD patients has profound systemic consequences including anorexia and catabolism due to altered energy turnover, and multiple dysfunctions of organ systems. Retardation of growth and development is a hallmark of untreated chronic anemias of non-renal origin, such as thalassemia major. Theoretically, anemia may interfere with growth via mechanisms such as poor appetite, undercurrent infections, cardiac complications and reduced oxygen supply to cartilage. The advent of recombinant human erythropoietin in the late 1980s permitted study of the effects of anemia correction on longitudinal growth in CKD. Although short-term stimulatory effects of erythropoietin on longitudinal growth have been reported anecdotally, no persistent catch-up growth could be demonstrated in several multicenter clinical trials [95, 96] Partial correction of anemia has, though, improved exercise capacity and decreased heart rate and resting oxygen consumption [95, 97].

Endocrine Changes

Uremia interferes with the metabolism and regulation of various peptide hormones. This leads to inappropriate concentrations of circulating hormones and/or altered hormone action on target tissues (Fig. 56.1). Distinct alterations of the somatotropic and gonadotropic hormone axes have been identified, which are believed to play an important role in uremic growth failure [98].

Gonadotropic Hormone Axis

Gonadal Hormones

Low or low normal total and free testosterone (T) as well as dihydrotestosterone (DHT) plasma concentrations due to decreased synthesis and/or increased metabolic clearance have been reported in adolescents and adults with longstanding uremia [99]. The reduced conversion of T to DHT secondary to diminished 5α-reductase activity might contribute to the delayed pubertal development seen in some boys on dialysis [100]. Likewise, plasma estradiol levels in women tend to decrease in parallel with GFR reduction, and some adolescent girls show low-normal or decreased estradiol levels in relation to pubertal age [100, 101]. However, these observations were all made more than 20 years ago. At least in transplanted children this issue seems to be resolved nowadays. In a recent study, the majority of transplanted children without prior long-term dialysis had normal estradiol and testosterone levels [36]. This may at least partly explain the improvement of pubertal development in patients on KRT during the last decades [1].

Gonadotropins

Increased plasma concentrations of LH and FSH in combination with decreased or low-normal gonadal hormones suggest a state of compensated hypergonadotropic hypogonadism in patients with CKD stage 5 [102]. However, in patients on dialysis, gonadotrophin secretion may be inadequate relative to the degree of hypogonadism. This is compatible with an additional defect of pituitary gonadotropin release and the analysis of spontaneous pulsatile LH secretion has provided insights into the underlying pathophysiology [103, 104]. In dialyzed patients mean LH plasma levels are elevated despite significantly reduced pituitary LH secretion, due to the markedly impaired kidney metabolic clearance of LH. When kidney function is restored by kidney transplantation, pulsatile LH secretion normalizes and hypergonadotropic FSH and/or LH levels are only rarely observed [36, 103]. Animal studies suggest that a primary hypothalamic defect may contribute to the delayed onset of puberty in patients with uremia. The observed reduced release of hypothalamic gonadotropin-releasing hormone (GnRH) is due to uremia-related inhibitory factors and/or to an increased tone of the inhibitory neurotransmitter gamma-aminobutyric acid [105, 106].

Beyond the quantitative alterations of gonadotropin release, uremia also affects the biological quality of circulating gonadotropins. In pubertal and adult dialysis patients the proportion of bio-

active LH in relation to the total immunochemically measurable amount of LH is reduced. This might be due to altered glycosylation and/or accumulation of less active isoforms [105–107].

In summary, insufficient activation of the hypothalamic GnRH pulse generator, likely mediated via circulating inhibitors, appears to be the key abnormality underlying delayed puberty and altered sexual functions in patients with CKD stage 5. However, kidney transplantation is able to completely normalize all these alterations in the majority of patients if long periods on dialysis treatment are avoided.

Somatotropic Hormone Axis

Growth Hormone Secretion and Metabolism

In both pediatric and adult CKD patients fasting GH concentrations are normal or even increased, depending on the stage of CKD. GH, a 22-kilodalton protein, is almost freely filtered by the glomerulus (sieving coefficient ~0.82) and thereby ultimately cleared from the circulation [108]. Indeed, a linear relationship between GFR and the metabolic clearance rate of GH has been shown; GH clearance is reduced by approximately 50% in patients with CKD stage 5 [108, 109]. The prolonged plasma half-life of GH, rather than increased endogenous secretion, explains the increased circulating GH concentrations in uremia. Pituitary GH secretion is unaltered in prepubertal patients but decreased in adolescents with CKD, suggesting insufficient stimulation by gonadal steroids during puberty [110, 111]. In addition, malnutrition and metabolic acidosis negatively impact GH secretion rates in children with CKD [112].

Growth Hormone Receptor and GH Signaling

Experimental studies have advanced our understanding of uremic GH resistance. Both, the GH-induced hepatic as well as the growth plate cartilage IGF-I synthesis is diminished, due to either decreased expression of the GH receptor (GH-R) and/or a postreceptor signaling defect [113, 114]. Whereas reduced expression of the GH-R encoding mRNA in liver and growth plate chondrocytes was seen, hepatic and growth plate cartilage GH-R protein levels were comparable in uremic and non-uremic animals when corrected for uremia-associated anorexia by pair feeding [113–115]. Thus, whereas a decreased GH-R abundance in the liver and the growth plate cartilage is questionable, a postreceptor GH signaling defect was identified as cause of the diminished hepatic IGF-I secretion upon GH stimulation. In fact, aberrant GH-dependent JAK-STAT signaling has been noted in experimental animals [116]. Binding of GH to its receptor leads to activation of the JAK-STAT cascade by tyrosine phosphorylation, and transcriptional activation of IGF-I synthesis and proteins of the suppressor of cytokine signaling (SOCS) family. The latter are responsible for dephosphorylation of the GH-activated cascade and as such provide a GH-regulated negative feedback loop. However, under the conditions of chronic uremia the equilibrium between GH-induced transcriptional activation of IGF-I and SOCS is shifted towards SOCS overstimulation. Recent studies suggest that the chronic inflammatory state associated with CKD contributes to GH resistance, as SOCS are also induced by inflammatory cytokines [117, 118].

In humans, GH binding protein (GHBP), which enters the circulation by proteolytic cleavage of the extracellular receptor domain, is taken as a measure of GH receptor expression. In line with animal experiments, GHBP plasma levels in CKD patients are decreased and are related to residual kidney function [119].

Insulin-Like Growth Factor Plasma Binding and Tissue Action

Apart from GH resistance, insensitivity to IGF-I is also found in patients with advanced CKD [120–122]. While serum concentrations of IGF-I and IGF-II are usually within the normal range in children with CKD stage 1–4, IGF-I levels are slightly reduced and those of IGF-II mildly increased in dialyzed patients [123]. In contrast to the unchanged total amount of circulating immunoreactive IGF, somatomedin bioavailabil-

ity is reduced in advanced CKD pointing to the existence of circulating inhibitors [124]. A low-molecular weight somatomedin inhibitor (~1 kDa) was reported to circulate in uremic serum in an early study, but this has not been characterized further. Later studies focused on the accumulation of the specific high-affinity IGF-binding proteins (IGFBP1–6), which are normally cleared by the kidneys and are considered the main cause of diminished somatomedin bioactivity in uremia. In particular, the concentrations of IGFBP-1, −2, −3, −4 and − 6 increase as kidney function declines and IGFBP-1, -2 and -6 have been shown to inhibit IGF I bioactivity in-vitro [125, 126]. In contrast, the serum concentration of IGFBP-5 is normal and IGFBP-5 proteins undergo intense proteolytic cleavage in chronic uremia [126]. Likewise, the elevated level of IGFBP-3 is mostly due to the accumulation of proteolytic fragments whereas intact IGFBP-3 is markedly diminished [127]. The molar excess of IGFBPs over IGFs is approximately 150% in children with CKD and 200% in children on dialysis as compared to 25% in children without CKD. An inverse correlation between growth retardation and IGFBP-1, -2, and -4 serum concentrations has been described [128]. Reduced IGF bioactivity can be normalized by removing unsaturated IGFBP [124]. These data are in favor of the concept that serum IGFBPs increase with progression of CKD, and that the greater excess of IGFBPs by CKD stage 5 contributes to the more severe growth failure and reduced response to rhGH therapy in these children. In addition, cellular IGF signaling is impaired in the uremic state; it remains to be elucidated whether a postreceptor mechanism similar to the one observed for GH signaling is responsible for this phenomenon [118, 122, 124].

In summary, the marked deficiency of IGF-I synthesis, the modest elevation of GH levels due to decreased metabolic clearance, and increased IGF plasma binding capacity, strongly support the concept of a multilevel homeostatic failure of the GH-IGF-I system.

Corticosteroid Treatment

Long-term glucocorticoid treatment in patients after transplantation leads to diminished longitudinal growth by impairment of the somatotropic hormone axis. High-dose glucocorticoid treatment suppresses pulsatile GH release from the pituitary gland mainly by reduction of pulse amplitude [129]. The physiologic increase in GH secretion during puberty is reduced in allograft recipients receiving glucocorticoid treatment ($\geq$ 4 mg/m^2 per day) and the association between sex steroid plasma concentrations and GH release observed in healthy adolescents is blunted [129]. These changes are mainly due to increased hypothalamic somatostatin release.

In addition to reduced GH release, corticosteroids suppress GH-R mRNA and protein in animals and most likely also in humans [130]. Consequently, hepatic IGF-I mRNA levels are reduced in animals receiving glucocorticoids. However, plasma concentrations of IGF-I in patients treated by glucocorticoids are normal or only slightly reduced. In individual children on corticosteroid treatment impaired longitudinal growth occurs despite normal GH secretion and plasma IGF-I levels, suggesting insensitivity to GH and IGF-I at the level of the growth plate. Indeed, a direct growth inhibiting effect of dexamethasone on the growth plate was shown by local injection in rabbits [131]. In cultured growth plate chondrocytes glucocorticoids decreased DNA synthesis and cell proliferation in a dose-dependent fashion, associated with reduced expression of the GH receptor and diminished paracrine IGF-I synthesis [132]. In addition, pharmacological doses of glucocorticoids also impaired the proliferative response to the calciotropic hormones calcitriol and PTH [132]. This is at least partly related to a diminished release of paracrine IGF-I secretion by these hormones. IGF-I modulates its own activity in cultured rat growth plate chondrocytes by the synthesis of both inhibitory (IGFBP-3) and stimulatory (IGFBP-5) binding proteins. This is modified by

glucocorticoid treatment. Therefore, glucocorticoid treatment not only interferes with the somatotropic hormone axis with respect to GH secretion and GH / IGF-I receptor signaling, but also by modulation of paracrine IGF-I synthesis and binding by IGF binding proteins. Even more important, based on *in vivo* studies in rabbits catch-up growth after glucocorticoid exposure may remain incomplete in general [131]. Consequently, all efforts must be undertaken to reduce steroid exposure in children with CKD before and after kidney transplantation [133].

Treatment of Growth Failure in Chronic Kidney Disease

General Measures

The main measures for prevention and treatment of growth failure in children with CKD are summarized in Table 56.1. Close growth monitoring with intervals depending on previous growth, age and stage of CKD is essential. Early referral to a pediatric nephrology center followed by careful nutritional and metabolic management is vital in the prevention of growth retardation [134]. Growth retardation is clearly correlated to the degree of CKD. Therefore, adequate measures should be undertaken to preserve GFR, and to provide adequate dialysis in those children who require maintenance dialysis [72]. Preservation of kidney function requires treatment of elevated blood pressure, aiming for blood pressure values below the 50th and 75th percentile in proteinuric and non-proteinuric children, respectively [135]. Renin-angiotensin aldosterone system inhibitors, preferentially angiotensin-converting enzyme inhibitors or angiotensin receptor inhibitors, should be used to treat high blood pressure and ameliorate proteinuria in children with CKD [136]. Nephrotoxic medication should be avoided, and urinary tract infections in children with congenital abnormalities of the kidneys and urinary tract (CAKUT) should be treated. Finally, disease specific treatment, e.g. treatment with cysteamine in patients with nephropathic cystinosuis, may be required.

Table 56.1 Main measures for prevention and treatment of growth failure in pediatric CKD

Prevention:
• Close growth monitoring with intervals depending on previous growth, age and stage of CKD
• Preserve kidney function by:
– treating elevated blood pressure and reducing proteinuria, preferrably using RAAS inhibitors
– avoiding nephrotoxic medication
– prompt treatment of urinary tract infections
• Provide adequate energy and protein intake and consultation with a renal dietician.
– Consider enteral feeding by gastrostomy or nasogastric tube in cases of persistent insufficient oral intake
• Substitute water and electrolyte losses and correct metabolic acidosis
• Keep PTH levels in the recommended CKD stage-dependent target range and substitute native vitamin D in cases of low vitamin D levels
• Aim for early (preemptive) kidney transplantation with minimal steroid exposure in patients with end-stage CKD
• Provide adequate dialysis in patients requiring maintenance dialysis
Treatment:
• Consider use of growth hormone treatment in cases of persistent growth failure, i.e. height < third percentile and height velocity < 25th percentile, excluding patients who have received a transplant within the last 12 months
• Consider intensified dialysis or hemodiafiltration in in patients requiring maintenance dialysis presenting with persistent growth failure
• Consider use of rhGH therapy in pediatric kidney transplant recipients for whom expected catch-up growth cannot be achieved by steroid minimization, or for patients where steroid withdrawal is not feasible due to high immunological risks, particularly in children with suboptimal graft function (eGFR <50 mL/min/1.73 m^2)

CKD chronic kidney disease, *RAAS* renin-angiotensin aldosterone system, *PTH* parathyroid hormone, *eGFR* estimated glomerular filtration rate

Adequate **nutritional management** is crucial in infants and young children, who frequently need supplementary feeding via nasogastric tube or, preferably, gastrostomy [75, 137]. In a retrospective analysis of growth in 101 infants and young children with severe CKD it could be demonstrated that persistent catch-up growth can be achieved in the majority of patients when there is good metabolic control and enteral feeding is commenced at the first sign of growth delay (Fig. 56.5) [20]. However, spontaneous growth as well as catch-up growth after initiation of enteral feeding is limited in patients with comorbidities [20, 138]. The use of enteral feeding varies around the world, as has been clearly demonstrated by the IPPN report of 153 infants on PD: gastrostomies are most commonly used in the US, where 80% of infants on PD are gastrostomy fed; 20% have gastrostomies in Europe, but there are very small numbers or none in the rest of the world [13]. Nasogastric feeding is commonest in Europe and Latin America. Gastrostomy feeding, rather than demand or nasogastric tube feeding, is associated with better preservation of linear growth in the infants in the IPPN database (Fig. 56.6)) [13]. This may be related to decreased vomiting with gastrostomies as compared to nasogastric tubes. Catch-up growth in children started on enteral feeding after the age of 2 years may be substantial but is markedly reduced in those on dialysis and strongly negatively correlated with age [139]. The assurance of adequate caloric and energy intake requires the patient and families to be advised by a kidney dietician, especially when supplementary feeding via nasogastric or gastrostomy tube is required [74, 137] In general, the initial prescription for energy intake in children with CKD should approximate that of healthy children of the same age (suggested dietary intake, SDI) [74]. To optimize growth in children with suboptimal weight gain and linear growth, energy intake should be adjusted towards the higher end of the SDI [74]. Caloric intake should account for growth failure and be related to "height age" rather than to chronological age if the child's height is below the normal range. Calorie intake in excess of 100% of SDI may not improve catch-up growth but rather results in obesity and may thereby negatively contribute to long-term cardiovascular morbidity in CKD patients [140, 141]. If there is excessive weight gain dietary energy intake should be reduced for children on PD to compensate for the energy derived from dialysate glucose, estimated at 8–12 kcal/kg per day. In addition; to promote optimal growth, target protein intake in children with CKD should be at the upper end of the SDI [74]. In patients on PD, a slightly higher intake (+0.2 g/kg/day) is recommended to compensate for dialytic protein losses. The aim is to maintain a normal serum albumin and a urea below 20 mmol/L as far as possible. High protein intakes should be avoided since, despite many attempts, anabolizing or growth promoting effects of high-protein diets have neither been demonstrated in animal models nor in children with CKD. On the contrary, high protein diets may be detrimental by aggravating metabolic acidosis and augmenting the dietary phosphorus load.

Metabolic acidosis should be vigorously treated by alkali supplementation aiming for serum bicarbonate levels equal or above 22 mEq/L. This can be assured by treatment with sodium bicarbonate and/or the use of HCO_3-based or lactate based dialysis solutions in patients on dialysis [11]. In addition, supplementation of water and electrolytes is essential in patients presenting with polyuria and/or salt losing nephropathies. Supplementation of sodium chloride is also important in young children on PD, since significant amounts of sodium chloride (i.e. 2–5 mmol/kg body weight) may be eliminated via ultrafiltration.

Dialysis and Intensified Dialysis

Although dialysis attenuates the uremic state, longitudinal growth is not usually improved and long-term PD or HD are associated with a gradual loss of standardized height in children and adolescents, and can be as high as 1 SD per year in infants [9, 142–144]. Children on dialysis who maintain some residual kidney function have the best growth; indeed residual kidney function may be a better predictor of longitudinal growth than dialytic clearance [145, 146]. However, a recent

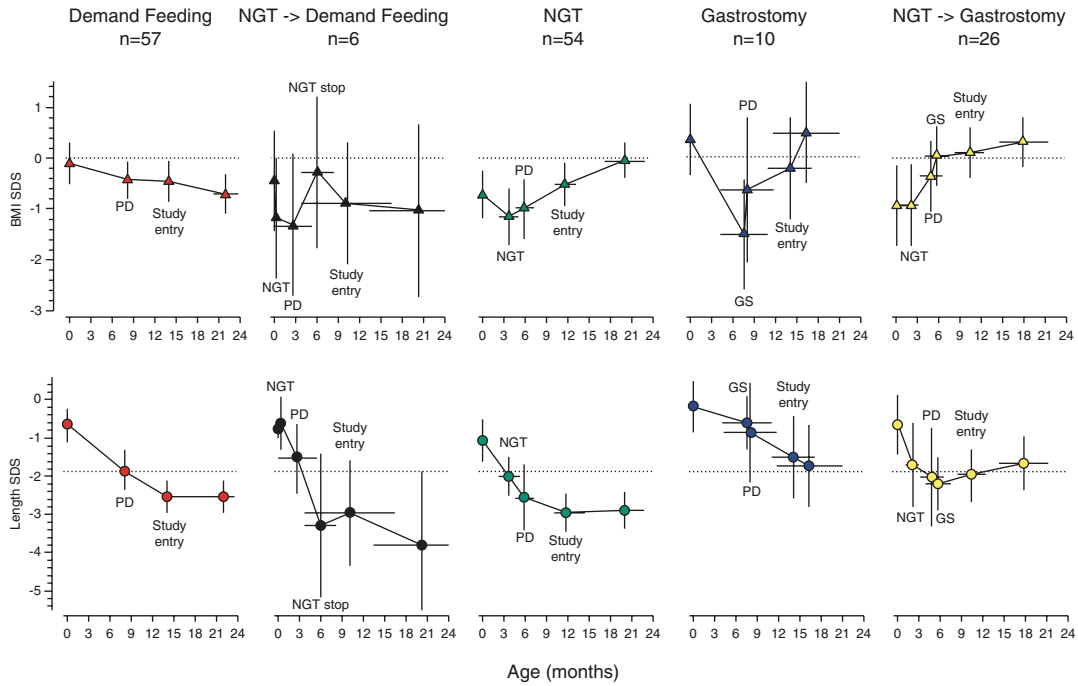

Fig. 56.6 Whereas both nasogastric tube (NGT) and gastrostomy (GS) feeding improve nutritional status, only GS feeding associates with stabilized linear growth in young infants undergoing CPD. The data points represent mean estimates at key time points of postnatal development, (i.e., birth, commencement of CPD, initiation and discontinuation of nasogastric tube or gastrostomy feeding, enrollment to IPPN [study entry], and last available observation). Two-dimensional error bars denote the 95% confidence intervals to mean age and SDS at the respective time point. [Reproduced with permission of [13]]

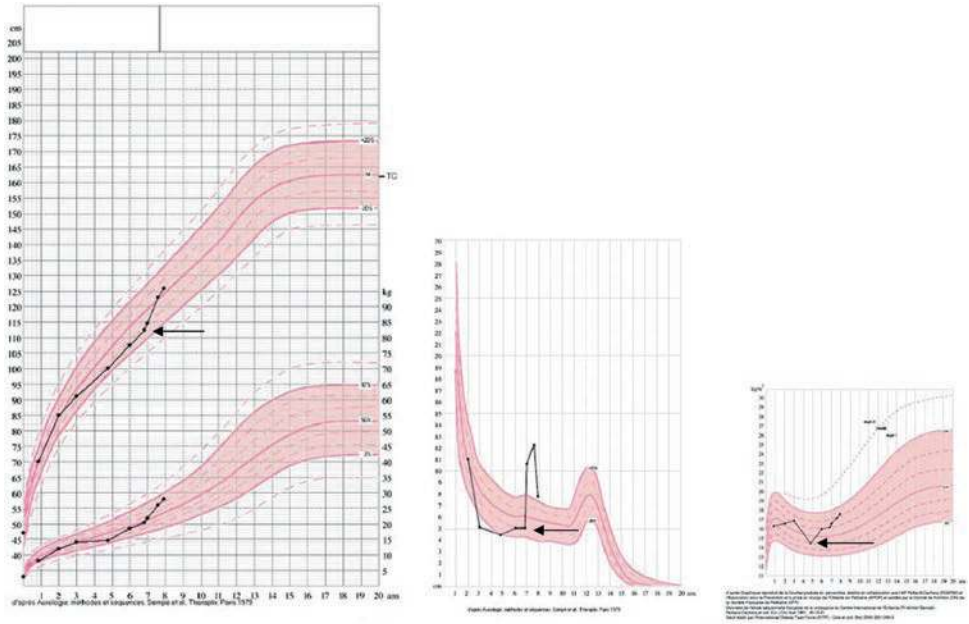
Italian study in infants on chronic PD reported catch-up growth in 50% of patients [147]. High peritoneal transporter status, a condition associated with increased morbidity and mortality in adults, is associated with poor longitudinal growth in children on chronic PD [148]. This might be due to the putative association of high peritoneal transport with inflammation, which can suppress statural growth by interference with GH signaling (*vide supra*), or excessive losses of proteins and amino acids important to growth.

It has been suggested that intensified dialysis, achieved by either extended thrice-weekly sessions, daily nocturnal or short daily sessions, might be able to induce catch-up growth [148–150]. According to a French study, catch-up growth can be maximized when intensified hemodiafiltration (3 h, 6 times a week) and rhGH therapy are combined [148, 149, 151–154]. Using this approach in 15 mainly prepubertal children for an average observation time of 21 months, there was an average increase in growth velocity from 3.8 cm/year at baseline to 8.9 cm/year (Fig. 56.7). This resulted in a mean of 1.7 SDS gain of standardized height, representing complete catch-up growth according to the attainment of the target height SDS [153]. A recent non-randomized study demonstrated superior growth in children treated with hemodiafiltration compared to those with conventional hemodialysis (HD) (Fig. 56.8) [155]. From a pathophysiological point of view, intensified hemodiafiltration (HDF) is a better substitute for physiological kidney function and may allow substantially better clearance of uremic toxins, e.g. middle-molecular weight compounds [155]. As a result, microinflammation and metabolic acidosis may be abolished, leading to improved appetite and tissue anabolism. The improved removal of inflammatory cytokines might reverse



Patient 14, a girl on daily on line hemodiafiltration

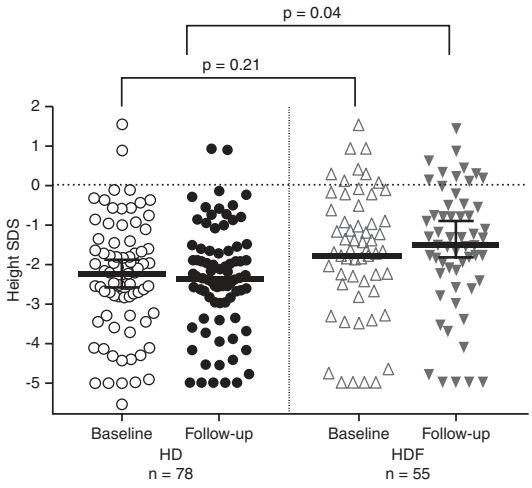

Fig. 56.8 Improved height SDS in children on hemodiafiltration (HDF) compared to hemodialysis (HD). The figure shows change in height SDS in the HD and HDF arms at baseline and 1-year follow-up. Data are shown as median and interquartile range. Within-group analyses performed by Wilcoxon matched-pairs signed-rank test and HD versus HDF cohorts compared by Mann–Whitney U test. At 12 months the height SDS in the HDF group was higher than in the HD group (P = 0.04). (Reproduced with permission of [155])

GH resistance enabling the full therapeutic potential of rhGH [152]. The positive effects of intensified dialysis, particularly home HD, usually outweigh the potential impact on psychosocial integration and treatment costs. Prospective randomized trials appear required to provide definite proof to this promising concept. In particular, the relative contribution of concomitant rhGH therapy to the growth improvement observed with intensified dialysis remains to be defined.

Transplantation

Although many of the metabolic and endocrine disorders contributing to uremic growth failure are resolved by kidney transplantation, post-transplant catch-up growth is usually restricted to young children and occurs far from regularly [3, 156]. As well as transplant function, age, severity of stunting at time of transplantation and glucocorticoid dosage are inversely associated with longitudinal growth. One retrospective study found that while standardized height was comparable at time of transplantation, it was significantly higher among living-related donor (LRD) than deceased donor transplant (DDT) recipients 5 years later [157]. This benefit of LRD grafts was independent of GFR arguing for preferential LRD in children with respect to post-transplant growth.

It must be stressed that even low-dose glucocorticoid treatment (<4 mg/m^2/day) results in growth suppression in children after transplantation. While complete steroid withdrawal has been associated with unacceptably high rejection rates in children with azathioprine and/ or cyclosporine A medication, withdrawal or even complete steroid avoidance appears much safer with the currently preferred immunosuppressants [158]. In a randomized trial of late steroid withdrawal in patients on treatment with cyclosporine A, mycophenolate mofetil steroid-free patients showed improved growth compared to controls (i.e. change in height SDS; 0.6 ± 0.1 versus −0.2 ± 0.1) within 27 months [159]. However, catch-up growth in pubertal patients was rather limited compared to that in prepubertal patients. It seems logical

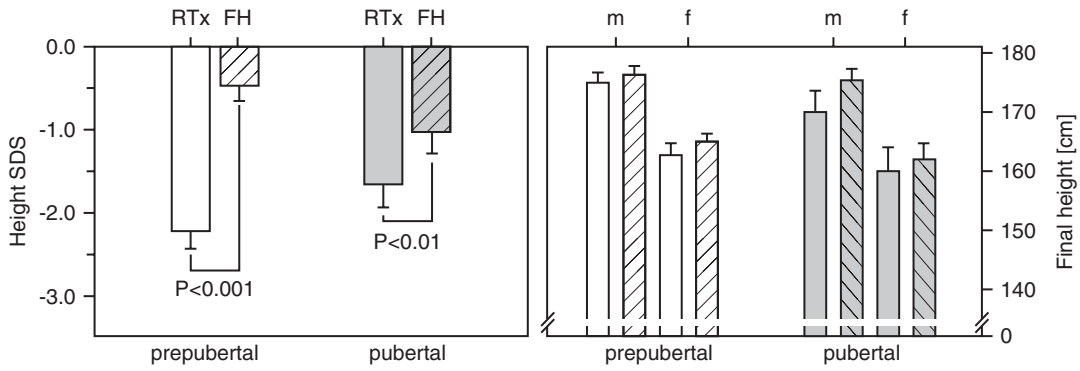

Fig. 56.9 Mean standardized height at time of renal transplantation compared to adult height and comparison of adult height with genetic target height in patients with steroid-withdrawal during month 4–6 after transplantation Mean standardized height at the time of transplantation and final height in prepubertal (n = 36) and pubertal (n = 24) patients. (d) Mean adult height (open bars) and genetic target height (hatched bars) in boys (n = 25) and girls (n = 17). Data in (c) and (d) are given as mean ± SEM. (Reproduced with permission of [4])

that if steroids are withdrawn at an early stage, or even completely avoided, a better growth outcome will be observed. Indeed, a retrospective analysis of longitudinal growth in a cohort of 74 children who had been weaned off steroids within 6 months of transplantation showed remarkable results [4, 159]. Mean adult height was −0.5 ± 1.1 SDS and −1.0 ± 1.3 SDS in prepubertal and pubertal patients and was within the normal range (>−2 SD) in 94% and 80% of them respectively (Fig. 56.9). Likewise, early steroid-withdrawal (< 6 weeks) and complete steroid avoidance improved standardized height by approximately 1.0 SDS within 3–5 years post-transplantation [32, 33, 160, 161]. Although experimental data indicate that mTOR inhibitors may interfere with chondrocyte proliferation and/or gonadal hormone synthesis, recent case control studies in transplanted children revealed similar growth rates in patients with and without mTOR inhibitor treatment [162].

In summary, efforts to avoid a height deficit before transplantation, early (preemptive) kidney transplantation, and immunosuppressive strategies characterized by the early withdrawal or even complete avoidance of steroids can improve adult height and normalize body proportions in children after successful transplantation.

Endocrine Therapies

Vitamin D

Calcitriol deficiency is a major cause of secondary hyperparathyroidism and CKD-MBD. Although calcitriol supplementation reverses the biochemical, radiographic, and histological signs of high turnover bone disease, neither experimental nor clinical studies demonstrate consistent improvement in longitudinal growth [89, 162–164]. These conflicting results might be due to differences in the mode of administration and to the pleiotropic calcitriol-specific effects on growth plate chondrocytes. In addition, only a week association between parathyroid hormone (PTH) levels and linear growth was reported in children with advanced CKD [94]. In general, minimal PTH suppressive active vitamin D analogues dosages should be used in order to keep PTH levels in the desired target range [165]. Finally, supplementation with cholecalciferol or ergocalciferol should be initiated in children with serum 25-hydroxyvitamin D concentrations below 75 nmol/L (<30 ng/mL) [166].

Calcimimetics

Uncontrolled and controlled studies provide evidence that calcimimetics are an effective therapy for secondary hyperparathyroidism in pediatric

dialysis patients [167]. Calcimimetics suppress PTH secretion by activating the calcium-sensing receptor (CaR). The CaR is expressed by epiphyseal chondrocytes; its stimulation stimulates chondrocytic proliferation and differentiation. Thus, calcimimetics may affect longitudinal growth in uremia as well. In fact, the calcimimetic cinacalcet improved food efficiency and body weight gain in uremic rats, but no effects on growth plate morphology and/or longitudinal growth were seen [168]. Likewise, no beneficial or adverse effect on longitudinal growth was noted during calcimimetic treatment periods of up-to three years in children on dialysis [167]. A comprehensive European guideline on the use of cinacalcet in children on dialysis was published recently [169].

Growth Hormone

Pharmacological treatment of children with CKD and growth delay with rhGH actually predated the elucidation of the pathomechanisms that underlie chronic uremic alterations of the GH-IGF-1 axis [114, 169–171]. Administration of rhGH markedly stimulates IGF-I synthesis with only a modest effect on IGFBPs, thereby normalizing somatomedin bioactivity and promoting longitudinal growth [172]. The efficacy and safety of long-term treatment with rhGH in children with CKD before and after kidney transplantation is well established and clinical practice recommendations on this topic were recently published in 2019 [30].

Efficacy of rhGH in Prepubertal Children

In prepubertal children with pre-dialysis CKD, rhGH therapy typically doubles height velocity during the first treatment year [173]. Catch-up growth continues asymptotically during extended treatment [174–176]. In dialyzed children, the treatment response is significantly attenuated compared to children with pre-dialysis CKD (0.8 SD vs. 1.3 SD) [177]. RhGH responsiveness is similarly poor in children on peritoneal dialysis and standard hemodialysis, but as noted previously, can be markedly improved when dialytic clearance is augmented by daily HDF [153].

Based on the current experience with rhGH in pediatric CKD patients, a model to predict growth response was developed [178]. The prediction model was developed using a cohort of 208 prepubertal children with CKD stage 3-5D followed in a pharmaco-epidemiological survey (KIGS), and validated in an independent group of 67 CKD patients registered at the Dutch Growth Research Foundation. The height velocity during the first rhGH treatment year (PHV) was predicted by the following equation: PHV (centimeters per year) = 13.3 – [age (years) × 0.38 + (weight SDS × 0.39)] – [hereditary renal disorder (0 when absent or 1 when present) × 1.16] + [Ln rhGH dose (milligrams per kilogram per week) × 1.04] + [GFR (milliliters per minute × 1.73 m^2) × 0.023]. This equation explains 37% of the overall variability of the growth response. The SE of the estimate or error SD of the prediction model was 1.6 cm and non-responders in the validation group were correctly identified. This model may help in predicting non-responders and in tailoring treatment strategies for growth retarded children with CKD.

Several RCTs have shown the benefit of rhGH therapy in short prepubertal renal transplant recipients. A meta-analysis of five prospective RCTs involving a total of 401 patients showed that patients receiving rhGH therapy had a significantly higher growth velocity 1 year after the initiation of therapy than the control group, with a mean height SDS difference of 0.68 (95% CI 0.25–1.11) [173].

Effects of rhGH on Pubertal Growth and Adult Height

In a study following patients with CKD and ESKD from late prepubertal age to final height, the average height increment in rhGH treated patients was twice that seen in a matched control group [46]. The main benefit for total growth and final height was achieved before the onset of the pubertal growth spurt, whereas no overall effect on pubertal height gain was observed (Fig. 56.10).

Data on adult height are available from 11 non-randomized trials in which rhGH was administered for at least 2 years, comprising a total of 836 patients on various modes of KRT [30]. In

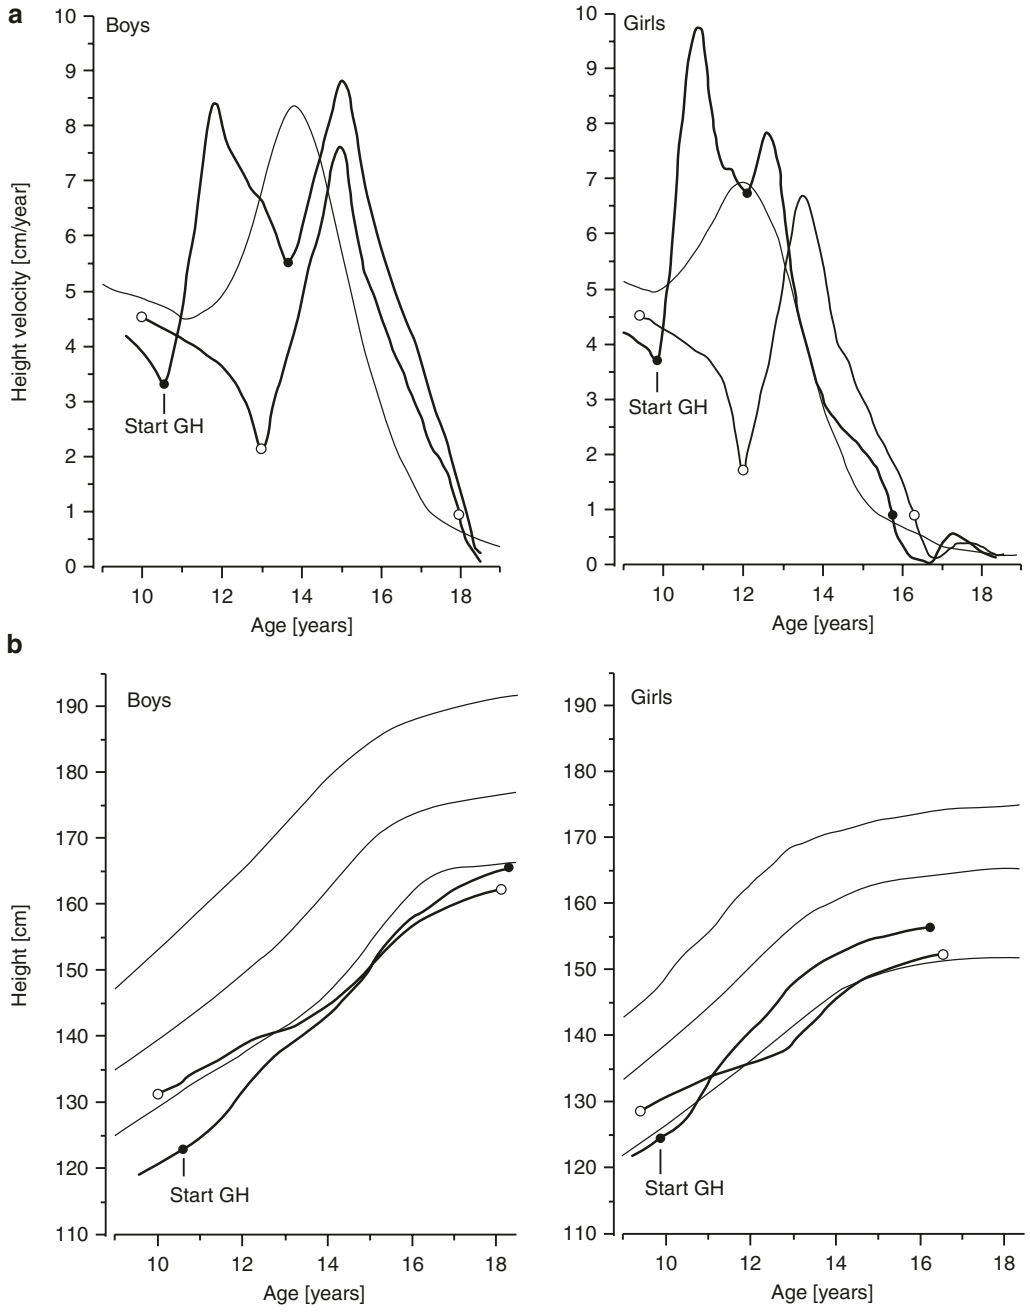

Fig. 56.10 (**a**) Synchronized mean height velocity curves of 32 boys (left panel) and 6 girls (right panel) with CKD during rhGH Treatment (closed circles), as compared with 50 children with CKD not treated with rhGH (open circles) and 232 normal children (thin lines). The dots indicate the time of the first observation, which corresponds to the start of rhGH treatment in the growth hormone-treated children, minimal prespurt height velocity, and the time of the end of the pubertal growth spurt. (Reproduced with permission of [46]). (**b**) Synchronized mean height curves of 32 boys (left panel) and 6 girls (right panel) with CKD during rhGH treatment (closed circles), as compared with 50 children with CKD not treated with rhGH (open circles). Normal values are indicated by the third, 50th, and 97th percentile. The dots indicate the time of the first observation, which corresponds to the start of rhGH treatment in the growth hormone-treated children, and the time of the end of the pubertal growth spurt. (Reproduced with permission of [46])

five studies a matched historical control group was included. The median change in standardized height until attainment of adult height amounted to 1.1 SDS (range 0.2–1.6 SDS) in rhGH treated patients ($p < 0.05$ for each final height measurement versus initial height measurement). This change corresponded to a median absolute increase in rhGH treated patients by 7.4 cm (range 1.4–10.8 cm) in boys and 7.0 cm (range 1.3–10.1 cm) in girls, based on European reference values. However, this calculation may underestimate the rhGH effect since in the non-rhGH treated controls adult height was significantly below the initial standardized height indices in all except one study. Height attained at the start of rhGH and throughout the duration of rhGH treatment were positively associated with final height, whereas time spent on dialysis, age at puberty onset, and age of start of rhGH were negatively associated with final height [46, 47]. Taken together, the available studies suggest that rhGH improves adult height in short prepubertal and pubertal CKD patients prior to and after kidney transplantation.

Efficacy of rhGH in Infants

According to standard concepts of the pathophysiology of uremic growth failure, malnutrition and fluid and electrolyte imbalances have a much greater impact on infant growth than alterations of somatotropic hormones. Consequently, correction of the nutritional status has been considered the primary measure to restore normal growth in growth retarded infants, postponing the option of endocrine therapeutic intervention to beyond the second year of life. This concept has been challenged by several reports of initiating rhGH in growth retarded infants with CKD [179–181]. A randomized controlled study involving 30 growth retarded infants (mean age: 16 months) with moderate CKD (mean eGFR: 25 mL/min/1.73 m^2) revealed excellent catch-up growth from from −3.0 to −1.1 SDS within 24 months of treatment, in contrast to no significant change in controls [179]. Another study reported an increase in height SDS from −3.3 to −2.2 within 12 months in 8 infants with a mean age of 22 months and CKD stage 3–4 [180]. In a randomized study of 16 infants with stage 3–4 CKD who were receiving at least 80% of the recommended daily allowence for calories and of whom seven were enterally fed, those randomized to rhGH showed significantly higher length gains (14.5 versus 9.5 cm/year; delta height SDS +1.43 versus −0.11) [181]. Hence, the results of these studies lend further support to the previous observation that the relative efficacy and cost efficiency of rhGH is actually best when initiated at young age, i.e. during infancy and early childhood [30]. While the provision of adequate nutrition is certainly vital to growth and development of infants with CKD, some children show growth failure despite adequate nutrition. In these patients, any further increases of energy intake typically lead to fat deposition, but not catch-up growth. Early rhGH therapy appears to be an attractive option to accelerate length and weight gain in such infants. The fact that the enhanced growth also helps the infant achieve the body size required for kidney transplantation more expeditiously is another substantial benefit [30].

General rhGH Treatment Strategies

Children from 6 months of age with stage 3–5 CKD or on dialysis should be candidates for rhGH therapy if they have persistent growth failure, defined as a height below the third percentile for age and sex and a height velocity below the 25th percentile, once other potentially treatable risk factors for growth failure have been adequately addressed, and provided the child has growth potential (open epiphysis on X-ray of the wrist) [30]. RhGH therapy should also be considered for children older than 6 months with stage 3–5 CKD or on dialysis who present with a height between the third and tenth percentile but persistent low height velocity (<25th percentile), once other potentially treatable risk factors for growth failure have been adequately addressed. Such early, preventive therapy is probably more cost-effective than starting at a more advanced age when growth retardation has become more evident and higher absolute rhGH doses are required.

Children suffering from nephropathic cystinosis often show severe growth retardation despite somewhat mild reductions in GFR, which is

thought to be related to the deleterious effects of Fanconi syndrome, resulting in hypophosphatemic rickets and malnutrition and/or an underlying obsteoblast/osteoclast defect [61]. Therefore, rhGH treatment is recommended in short children with nephropathic cystinosis at all stages of CKD [30].

The growth response to rhGH treatment is positively associated with residual kidney function, target height, initial target height deficit and duration of rhGH treatment, and inversely correlated with the age at start of treatment [46, 47, 174, 177, 178]. Daily dosing is more effective than three doses per week and the optimal dose is 0.045–0.05 mg/kg body weight per day by subcutaneous injections in the evening [30]. Parents and physicians should encourage children from about 8 to 10 years of age to do the rhGH injections on their own if adequate training and adherence can be assured, because this may ultimately improve patient adherence and self-esteem [30]. Whereas discontinuation of rhGH results in catch-down growth in approximately 75% of CKD patients this phenomenon is rarely observed when rhGH treatment is discontinued after kidney transplantation, highlighting the close relationship between kidney function and growth [182]. Furthermore, although the absolute height gain achieved by rhGH is independent of age, the reference range increases with age. Thus, rhGH treatment should be started as early as growth retardation becomes evident (i.e. height below third percentile) [30]. If height velocity in the first year of rhGH treatment is less than 2 cm per year over baseline, it is recommended to assess patient adherence to rhGH therapy through the measurement of serum IGF-I levels and/or the use of an injection pen with downloadable memory function, ensuring administration of the correct weight-adjusted GH dose, and addressing any, possibly subclinical, nutritional and metabolic issues [30].

The primary treatment target should be to return the child's height into her/his individual genetic percentile channel. Treatment may be suspended once this target is reached, but growth should be monitored closely as outlined above. In patients receiving rhGH while on conservative treatment rhGH should be continued after the initiation of dialysis, but stopped at the time of kidney transplantation. RhGH therapy should, however, subsequently also be considered for pediatric kidney transplant recipients for whom expected catch-up growth cannot be achieved by steroid minimization or for patients in whom steroid withdrawal is not feasible due to high immunological risk, particularly in children with suboptimal graft function (eGFR <50 mL/min/1.73 m^2). Growth should be monitored for at least 1 year post-transplantation before rhGH therapy is considered, in order to allow for spontaneous catch-up growth without need for rhGH therapy [30].

Potential Adverse Events Associated with rhGH Therapy

The safety of long-term rhGH treatment in CKD has been evaluated in several clinical studies and registries [30]. RhGH therapy in short children with CKD stage 3–5D and after kidney transplantation was not associated with an increased incidence of malignancy, slipped capital femoral epiphysis, avascular necrosis, glucose intolerance, pancreatitis, CKD progression, acute allograft rejection or fluid retention. Intracranial hypertension (ICH), manifesting in 3 out of 1376 CKD patients, was the only adverse event significantly associated with rhGH therapy [183]. However, in all three instances ICH occurred after discontinuation of rhGH. Due to the potentially increased risk of ICH in CKD, baseline fundoscopy is recommended prior to therapy initiation [30]. Furthermore, hydration should be carefully monitored in CKD patients receiving rhGH since overhydration may be a predisposing factor for ICH. In the presence of symptoms like headache or vomiting, an immediate workup for ICH including fundoscopy should be performed.

Although insulin secretion increases during the first year of rhGH treatment and hyperinsulinemia persists during long-term therapy, normal glucose tolerance is preserved during up to 5 years of rhGH administration in CKD patients on conservative treatment, dialysis, and after kidney tansplantation. Hyperinsulinemia is most pronounced in transplanted patients on con-

comitant glucocorticoid therapy. Hyperinsulinemia may, at least in theory, contribute to the development of atherosclerosis or induce diabetes mellitus by exhaustion of ß-cells. However, up to now this has not been observed in CKD patients receiving rhGH [183].

Aggravation of secondary hyperparathyroidism has rarely been reported in CKD patients on rhGH treatment, and the underlying pathomechanisms remain to be elucidated [184]. RhGH might have a direct stimulatory effect on the parathyroid gland and/or might have subtle effects on calcium homeostasis which in turn stimulate PTH secretion. Finally, increased longitudinal bone growth by rhGH treatment may unmask preexisting renal osteodystrophy. Therefore, bone metabolism should be evaluated carefully in candidates for rhGH therapy and severe hyperparathyroidism and renal osteodystrophy should be adequately treated before initiation of such therapy in CKD patients. Likewise, rhGH therapy should be stopped in patients with persistent severe secondary hyperparathyroidism (PTH > 500 pg/mL). RhGH may be reinstituted when PTH levels return to the desired PTH target range [30].

Future Perspectives

Despite attention to nutrition and the availability of rhGH therapy, the problem of CKD associated growth failure has not been resolved in the majority of dialysis patients. If early kidney transplantation is not possible, the concept of intensified hemodiafiltration combined with rhGH may be a promising option for patients suffering from growth retardation and GH insensitivity on conventional dialysis therapy. Independent of concomitant rhGH therapy, hemodiafiltration appears to allow improved growth rates than conventional hemodialysis and, if available, should be the preferred extracorporeal dialysis modality in all growing children.

Self-reported nonadherence to rhGH is associated with poorer growth velocity in children with CKD. Therefore, monitoring and optimizing adherence to rhGH therapy is key to satisfactory growth outcomes [185]. Another promising avenue of clinical research may be the provision of recombinant IGF-I administered as monotherapy or in combination with rhGH, as well as targeting of the SOCS2 signaling pathway [186].

A particular challenge is the management of severely diminished pubertal height gain seen in some adolescents with CKD. In such adolescents, pharmacological inhibition of epiphyseal closure may allow an extended duration of the remaining growth period. Since the closure of the epiphyseal growth plate is induced by local estrogen action, inhibition of estrogen synthesis is a principal therapeutic option. Whereas gonadotropin-releasing hormone analogues arrest pubertal progress, the potential growth benefit would come at the psychological disadvantage of delayed sexual maturation. In boys, aromatase inhibitors, which suppress local conversion of testosterone to estradiol, might extend the growth phase without affecting pubertal development and thereby increase the time window for the use of rhGH therapy. Indeed, the combined use of armomatase inhibitors and rhGH was associated with modest increases in adult height in boys with idiopathic short stature.

[187, 188]. However, some important questions about their long-term safety exist which at the moment prevent this from being generally recommended [189]. It would be fascinating to study its efficacy in adolescents on long-term dialysis. Nevertheless, successful early (preemptive) kidney transplantation with minimal steroid exposure is ultimately the best current measure to improve growth and final height in children with CKD stage 5.

57 Neurodevelopment in Chronic Kidney Disease

Rebecca J. Johnson and Lyndsay A. Harshman

Introduction

Neurodevelopmental outcomes for young children with end-stage kidney disease (ESKD) historically were poor [1, 2]. As medical and surgical management of the disease have improved, cognitive and developmental outcomes have improved as well [3, 4]. However, our understanding of how the biochemical and hormonal milieu of kidney failure affects the growing brain remains incomplete. We also recognize that the treatments for kidney failure and their complications affect neurodevelopment, although the full effects may not be recognized for years.

Critical brain growth occurs *in utero* and throughout infancy [5], and it continues into young adulthood as well [6]. Early experiences and environment can affect vision, hearing, language, and responses to social cues [5, 7]. Structural maturation of specific neural pathways occurs throughout childhood and adolescence, which presumably corresponds to maturation of cognitive abilities and suggests that sensitive periods for neuronal architecture and function of discrete regions of the brain occur throughout these stages of life [8]. Thus, infancy, childhood, and adolescence are characterized by growth in cognition, memory and comprehension, and the long duration of childhood chronic kidney disease (CKD) has the potential to influence or interrupt brain development over an extended span of time.

The psychology literature is concordant with the observations of neuroscientists. Armstrong and Horn [9] presented a model of late effects that outlines how childhood chronic illness can impact neurodevelopment and neurocognitive function. They noted that most childhood chronic health conditions and their treatments affect the growth and development of children's brains. Brain structures, processes, and functions that develop prior to onset of disease are likely to be less affected, although exceptions such as toxic exposures or cerebral infarction may still have an impact. Secondly, the age of the child over the course of the disease determines the scope and severity of neurocognitive effects. Brain structures, functions, and processes that develop after the age of disease onset are likely to be most affected; thus, the younger the child is at onset of disease and treatment, the more global and severe the effects on development may be. We can synthesize this into a model for a given child who is treated for a chronic illness: the course will be an interaction between the age at diagnosis, the extent of disease

and treatment intensity, whether the disease is successfully managed, the time since the treatment, and the age of the child when neurodevelopmental function is assessed [10–12].

This model of disrupted neurocognitive development is particularly relevant to childhood CKD and offers a useful paradigm for understanding the range of possible consequences on cognition [13]. CKD is a lifelong condition that differs from some insults originally envisioned by Armstrong and colleagues [11, 12]. Approximately 50% of all pediatric CKD diagnoses are due to congenital, non-glomerular anomalies [14] and *half* of all CKD patients with congenital disease will progress to kidney transplantation [15]. Some of these children will have a history of preterm birth and a complicated neonatal course with early hypoxia and mechanical ventilation, hypotension or hypertension, anemia, potential stroke, multiple surgical procedures with general anesthesia, and exposure to a wide range of drugs. Any of these exposures can adversely affect neurodevelopment.

Even children who develop kidney disease at a later stage of life may experience a prolonged course of disease with comorbidities. A large proportion of children with CKD will require chronic dialysis therapy prior to receiving a kidney transplant. While such treatment is lifesaving and more refined than decades ago, it provides far less clearance than normal kidney function and does not fully normalize the biochemical and hormonal milieu. In this chapter, we will review the effects of dialysis on brain structure and function. Patients, families, and the nephrology team often expect a great deal from kidney transplantation, including dramatic amelioration of the metabolic abnormalities associated with advanced CKD/dialysis. Yet transplantation requires exposure to a range of drugs known to have neurologic effects, including glucocorticoids, calcineurin inhibitors, cytotoxic agents, and monoclonal/polyclonal antibodies. These effects will be discussed at greater length later in the chapter.

Children with CKD experience frequent interruptions in schooling and may have a consequent lack of engagement in their education. School absences may have a higher than anticipated impact on future educational attainment, employment, and social adjustment. In fact, the social and emotional cost of chronic disease has a substantial impact on children with CKD, draining energy from the important work of cognitive and social growth and development. This is discussed in detail in Chap. 63.

This chapter will provide readers with both a summary of literature and an in-depth analysis of current knowledge. Tables 57.1, 57.2, and 57.3 provide a comprehensive listing of publications of cognitive and developmental testing in children with CKD: assessments of children diagnosed before 24 months of age (Table 57.1), assessments of children diagnosed after 24 months of age (Table 57.2), and comparisons of different treatment groups (e.g., pre- vs. post-transplant and dialysis vs. transplant) (Table 57.3). We have highlighted selected findings from these core studies in the sections below.

[a]Age at diagnosis presented as mean (range) unless otherwise indicated

Early Development

Several studies have described developmental outcomes for children who were diagnosed with CKD during infancy. These studies have either assessed children shortly after their diagnosis or have reported developmental progress during the period of early childhood using broad measures (cognitive, motor, language) such as the Bayley Scales of Infant Development (BSID) or the Griffiths Mental Development Scale. Davis et al. [16] assessed 37 children younger than 30 months of age who were undergoing kidney transplant, and again an average of 14 months post-transplant, utilizing either the BSID or the Stanford-Binet Intelligence Scales (SB), depending on the child's age. Prior to transplant, most patients had significantly delayed psychomotor development and 18 patients had mental development scores classified as delayed. Post-transplant psychomotor performance improved, with the group mean reaching the low average range, and many of the patients with cognitive delay (12 of 18) improving their scores to the average range. Persistently abnormal cognitive function was associated with the earliest onset of kidney failure. In a similar study, 28 patients diagnosed with ESKD before three months of age [4] were assessed at a mean age of 5.9 years (the majority post-transplant), using a range of instruments, including the Modified Developmental Assessment Test (MDAT) and the Wechsler Intelligence Scale for Children, Third edition, (WISC-III) as well as the BSID and SB. Overall, 22 of the 28 children (79%) had general mental development that placed within the broad range of average.

Hulstijn-Dirkmaat et al. [17] prospectively evaluated 31 young children (mean age of 2.5 years) with a broad range of CKD, using the BSID and the McCarthy Scales of Children's Abilities. In this sample, 32% of patients had comorbid conditions or disease (cerebral complications or unexplained neurological impairment, visual/hearing disorder, congenital heart disease); children with comorbid conditions were evenly distributed between dialysis and non-dialysis groups. Overall, the patients had significantly delayed cognitive development, with a mean developmental index of 78.5 (SD 19.5), and a distribution of scores skewed below that of the normal population. Children *without* comorbidities who did not yet require dialysis had a group mean in the average range, compared to those on dialysis, whose group mean placed in the borderline range for cognitive functioning. Among children *with* comorbidities, those with CKD who did not yet require dialysis scored in the borderline range for cognitive development, while those on dialysis had a mean score in the impaired range. Thus, comorbid disease and more advanced CKD (i.e., need for dialysis) were independently associated with lower neurodevelopmental scores.

Other studies have found the developmental outcomes of very young children with CKD to be linked to comorbid medical conditions or risk factors. Shroff et al. [18] evaluated a group of 11 children who began kidney replacement therapy between 0 and 24 months of age; six achieved age-appropriate developmental milestones. The remaining five had significant special education needs, with developmental outcomes linked to medical co-morbidities including VACTERL association (e.g., vertebral defects, anal atresia, Cardiac defects, tracheoesophageal fistula, renal anomalies, and limb abnormalities), infantile hemiplegia, deafness, congenital hypothyroidism, transposition of the great vessels, and an undiagnosed syndrome that included dysmorphism, developmental delay, and non-functioning kidneys. Laakkonen et al. [19] examined neurodevelopmental outcomes for 21 patients who began kidney replacement therapy with peritoneal dialysis (PD) before 24 months of age and were at least 5 years of age. A comprehensive battery of tests was used (see Table 57.1) which targeted development, cognition, sensory and motor function, memory and learning. Six of these patients were considered to have normal neurodevelopment; the remaining 15 had some degree of neurodevelopmental impairment, ranging from minor (n = 9) to major (n = 6). Those

with major impairment all had documented predialysis risk factors (e.g., perinatal asphyxia, severe hypotension, alcohol exposure, severe neonatal respiratory distress).

In contrast to studies that have evaluated young children with more advanced stages of CKD, Hooper et al. [20] reported on preschool children with mild to moderate CKD. Measures of developmental level/IQ were administered to 124 children 12–68 months who had a mean estimate glomerular filtration rate (eGFR) of 50 ml/min per 1.73 m^2. While all mean scores placed in the average range in this group with mild disease, the authors noted that an unexpectedly high percentage (27%) had developmental/IQ scores that placed in the at-risk range, defined as scores more than 1 SD below the mean of a normal distribution.

To summarize, children diagnosed with CKD in infancy are at risk for delayed neurodevelopment; the magnitude of the delay is influenced by medical and neurological comorbidities, as well as the age of onset and severity of disease. There is some evidence that transplant early in life benefits neurodevelopmental catch-up.

Intellectual Function (IQ)

ESKD Onset in Infancy and Early Childhood

Many studies in pediatric CKD have specifically examined intellectual function (IQ). The most used measure to assess IQ is the Wechsler Intelligence Scale for Children (WISC); its most current version is the Fifth Edition (WISC-V). The WISC includes a Full-Scale IQ (FSIQ) and five index scores: Verbal Comprehension (VCI), Visual Spatial (VSI), Fluid Reasoning (FRI), Processing Speed (PSI), and Working Memory (WMI).

A few studies have looked at long-term intellectual functioning of children diagnosed with ESKD as infants or early in life. The previously noted study by Warady et al. [4] assessed IQ in 28 patients who were diagnosed with ESKD before 3 months of age. Using the WISC-III, they showed a divergence in verbal (acquired knowledge and verbal reasoning) and nonverbal (ability to understand and manipulate nonverbal stimuli such as colors, patterns, and shapes) performance at a mean age of 5.9 years: 72% of the children had average verbal scores, whereas only 56% reached average nonverbal scores. In a similar study, Madden et al. [21] assessed the IQ of 16 patients with ESKD who initiated dialysis during the first year of life. These subjects were also studied at a mean age of 5.8 years. The IQ range for the sample was 50–102 with an average IQ of 87 for the ESKD group (approximately 1 standard deviation below the mean). Ten children had IQ scores within one standard deviation of the mean. This average and distribution of scores were clearly abnormal (i.e., average IQ = 100) with a distribution that skewed lower.

Johnson and Warady [22] built on the above studies by adding a sibling control group. They assessed late neurocognitive outcomes for 12 patients diagnosed with ESKD as infants (mean age at testing: 10 years). All but one had functioning transplants, and for those with transplants mean eGFR was consistent with mild to moderate CKD. Mean WISC-IV index scores ranged from 80 to 82 (borderline to low average) and the mean FSIQ score was 76.8. The distribution of FSIQ scores ranged from 55–102 and are strikingly similar to those reported by Madden et al. [21] noted above. Nine of the patients were compared to their healthy siblings and these participants had FSIQ, Processing Speed Index (PSI), and Working Memory Index scores significantly lower than siblings. For example, only one-third of patients had an FSIQ in the average range or above, in contrast to 6 of 9 siblings. For the patient group, higher FSIQ and the VCI were associated with older age at start of dialysis; higher FSIQ and the PSI were associated with fewer months on dialysis, and higher PSI was associated with younger age at transplant. The Test of Nonverbal Intelligence (TONI-2), a test of intellectual functioning that does not require verbal responses, was utilized in another study of 62 children with CKD that included sibling controls [23]. While these subjects were diagnosed later in life, the pattern of intellectual functioning was

very similar: patients' mean percentile ranks for nonverbal intelligence ranged from the 27th to the 35th percentile, regardless of whether they were on dialysis or post-transplant, while siblings' mean percentile ranks ranged from the 32nd to the 56th percentile.

Popel et al. [24] found similar results using data from a longitudinal, prospective study to evaluate predictors of developmental outcomes for children who received a transplant before the age of 5 years. These patients started dialysis in the first 2 years of life (73% initiating dialysis in the first year of life), with a mean age of 30 months at transplant. At a mean age of 56 months (all post-transplant), mean scores on FSIQ, visual-motor integration, and adaptive skills were approximately one SD below the population normative mean. Hartmann et al. [25] assessed the neurocognitive and neuromotor outcomes of 15 patients with severe congenital CKD who received a kidney transplant at a mean age of 2.8 years and were evaluated a mean age of 8.3 years. Six of these patients received a pre-emptive kidney transplant and the other nine underwent dialysis for a mean of 11 months (±8.6 months). Neuromotor function was assessed as abnormal for eight patients. Performance IQ (PIQ) was lower (m = 89) than the normative mean of 100, and lower PIQ was associated with abnormal neuromotor function. Time on dialysis was inversely correlated with verbal IQ. Pre-emptive kidney transplant and duration of dialysis less than 3 months were protective; participants meeting these criteria demonstrated better neurocognitive outcomes.

Existing data indicate that children diagnosed with ESKD as infants or very early in childhood achieve intellectual outcomes which vary depending on comorbidities. Many achieve normal or near normal intellectual function, but with a distribution that is skewed below normal. Patients tend to perform less well than their unaffected siblings. Younger age at transplant and shorter duration of dialysis appear to benefit neurocognitive outcomes. These are impressive outcomes given the complexity of ESKD with onset in infancy, yet they indicate a substantial risk for learning impairment and academic difficulties.

Mixed Age Groups Including Mild to Moderate CKD

Children with onset of ESKD before school-age and those with mild-to-moderate CKD demonstrate IQ impairment that is similarly skewed below the population mean, although the effect is less striking than those diagnosed with ESKD as infants or in early childhood, and more children perform in the average to above average range. Fennell et al. [26–28] published some of the earliest data regarding associations between standardized neuropsychological tests and CKD. Compared to a healthy control group matched for age, sex, and ethnicity, a group of children with a range of eGFR, from moderate CKD to post-transplant, performed more poorly on selected indices of non-verbal IQ (Wechsler subtests Similarities, Digits Forward, and Digits Backward).

Gipson et al. [29] studied children and adolescents with advanced CKD (a mix of dialysis-dependent patients and patients being treated conservatively) and included a comparison group of healthy children. This sample of 20 children with CKD had an average age at diagnosis of 7 years and an age range of 7.5–19 years at the time of assessment. Patients with CKD scored significantly lower than the healthy controls on a measure of intelligence (Wechsler Abbreviated Scale of Intelligence [WASI] Full Scale IQ).

Using a sibling control group, Bawden et al. [30] evaluated 22 patients who were listed for transplant and either receiving dialysis or approaching dialysis. Intelligence was assessed via the WISC-III. Those with CKD/ESKD had a group mean score that was average to low average. Overall, the group scored significantly lower than the sibling group on measures of VIQ, PIQ, and FSIQ.

Qvist et al. [31] assessed children diagnosed in early childhood with ESKD secondary to congenital nephrotic syndrome. At a mean age of 8 years, this group had an average IQ of 87 (low average range) on the WISC-Revised, and 6–24% of patients were characterized as impaired based on the results of neuropsychological tests (NEPSY).

Hooper et al. [32] used a cross-sectional analysis of the Chronic Kidney Disease in Children (CKiD) study to describe cognitive function in 368 school-age children with mild to moderate CKD. While the group had mean IQ scores in the average range, the number of subjects whose scores placed one or more SDs below the mean on a measure of nonverbal ability (WASI block design) was more than twice that of the normative group. Several risk factors for low scores were identified in this study, including proteinuria, low birth weight (LBW), and history of seizures.

Duquette et al. [33] examined 30 patients (mean age = 12.7 years) with childhood-onset CKD, half on dialysis and half with pre-dialysis CKD, and compared them to a healthy control group. The two groups differed significantly on some key variables: the control group had higher maternal education and a larger proportion of children who identified as Caucasian. Nonetheless, after controlling for maternal education and race, the control group scored significantly higher on measures of VIQ, PIQ, and FSIQ than patients with CKD. Fifty-seven percent of the CKD group had FSIQ scores below the 25th percentile, compared to only 15% of the control group. Kidney function (eGFR) was a significant predictor of intellectual functioning, while age of CKD onset and duration of CKD were not associated with IQ in this study.

Groothoff et al. [34] obtained estimates of cognitive functioning in a group of 126 adults (mean age = 29.4 years) who began kidney replacement therapy between the ages of 1.9 and 14.9 years. The majority had a functioning transplant; 16 and 12 were on hemodialysis (HD) and PD, respectively. Groups mean scores for Verbal, Performance, and FSIQ placed in the average range. Compared to a matched control group, however, IQ scores and educational attainment were significantly lower for the CKD group.

Executive Function

Executive functioning (EF) is a term used in the field of psychology that refers to the management of complex cognitive processes, including planning, organization, problem solving, working memory, and attention. These skills are required for optimal performance on tests of intellectual functioning (IQ), but are assessed more directly with EF-specific cognitive tasks. A number of researchers have examined attention and memory abilities in children with CKD, believing these abilities may be particularly susceptible to effects of the disease. The early work of Fennell et al. [26–28] sought to examine the relationship between EF and CKD. Their subjects, a group of children receiving a range of kidney replacement therapies (HD, PD, transplant), scored worse than healthy controls on a variety of measures of EF (e.g., working memory, attention). The NEPSY was administered by Qvist et al. [31] to children with congenital nephrotic syndrome to assess attention, concentration, and memory skills. Results indicated that impairment was more frequent in children with a history of major central nervous system (CNS) infarcts, hemiplegia, and/or those with a seizure disorder or an abnormal EEG.

Gipson et al. [35] included measures of memory and executive function in their study of children and adolescents with CKD and compared them to healthy controls. Patients scored significantly lower on all of the memory indices and on the "initiation" and "sustaining" EF domains, which assess task initiation and ability to sustain attention. Memory and EF findings persisted even after the authors controlled for IQ and age. Of note, the severity of memory deficits was positively related to the age at onset of CKD.

In Johnson and Warady's (2013) long-term follow-up of patients who had been diagnosed with ESKD as infants, EF findings were similar to those for IQ: better verbal ability and memory were associated with older age at start of dialysis and fewer months on dialysis, and younger age at transplant was associated with higher overall memory scores. Shorter time on dialysis and younger age at transplant were also associated with better scores on the Metacognitive Index of the parent-report BRIEF. When compared to their healthy siblings, the patients scored significantly worse on the Wide Range Assessment of Memory and Learning, Second Edition Verbal Memory Index (but not the Visual Memory

Index), the BRIEF Metacognition Index, and the BRIEF Global Executive Composite score.

The CKiD study is the largest study to examine EF, but unlike many of the other studies discussed, included only children with mild to moderate CKD and without history of kidney transplant [32]. Mean scores were in the average range for a variety of attention-related measures (Conners' Continuous Performance Test, Second Edition) and parent ratings of executive functioning (BRIEF). However, on several of the BRIEF measures (Metacognition Index, Working Memory and Planning subscales, and the Global Executive Composite score) a larger than expected proportion of patients scored one or more SD below the mean ("at risk" for lower EF). If we consider these results broadly, 33–40% of children with early-stage CKD would be considered at risk for some impairment in EF. CKD-associated risk factors including low birth weight, proteinuria, hypertension, and history of seizures were associated with slightly worse scores on several measures. Conversely, higher eGFR appeared protective, as it was associated with a lesser chance of scoring in the "at risk" range. Older subjects had slightly worse scores, suggesting that EF growth was diverging from their peers. It is important to emphasize that overall mean scores were average and group findings were statistically, but not necessarily clinically, significant. In another study of CKiD participants, Johnson et al. [36]examined parent ratings of attention problems using the Behavior Assessment System for Children, Second Edition (BASC-2) Parent Rating Scales. Parents rated 28% of the sample as at risk for attention problems. Persistent hypertension and unresolved proteinuria predicted rating of attention problems. Taken together, these findings suggest that even mild to moderate CKD is associated with increased risk for sub-optimal neurocognitive functioning, which may be relevant for some patients. The CKiD study also collected parent ratings of attention and executive functioning for preschool participants with mild to moderate CKD. Thirty percent of the participants had parent ratings that placed in the "at-risk" range (ratings higher than 1 SD above the mean [worse]) for overall executive functioning [20].

Executive functioning was examined by the Neurocognitive Assessment and Magnetic Resonance Imaging Analysis of Children and Young Adults with Chronic Kidney Disease (NiCK) Study, a cross-sectional study of youth with CKD stages 2–5 [37]. This study compared 90 participants with CKD to 70 controls. Those with CKD scored significantly worse than controls in several areas of executive functioning, including attention, memory, and inhibitory control. In addition, performance was associated with eGFR: participants with CKD exhibited lower performance on tests of executive functioning as eGFR declined. Using ambulatory blood pressure monitoring, the authors also found that blood pressure abnormalities, including increased diastolic load and decreased diastolic dipping, were associated with neurocognitive impairment.

Lande et al. [38] also found an association between blood pressure variability (BPV) and executive functioning. They assessed 650 children 6+ years old with mild to moderate CKD enrolled in the CKiD study and had a mean follow-up period of 4 years. Children with systolic visit-to-visit BPV in the upper tertile obtained lower scores on a measure of executive functioning (D-KEFS Category Switching) than those with BPV in the lower tertile. This association remained significant in multivariate analyses that controlled for mean BP, demographic characteristics, and CKD-related variables.

Academic Achievement and Educational/Vocational Outcomes

There are limited data to describe academic achievement outcomes for children with mild to moderate pediatric CKD. An initial evaluation of academic achievement data collected as part of the Chronic Kidney Disease in Children (CKiD) multicenter prospective cohort study [39] suggested that general academic achievement scores were skewed toward the lower end of the normal range in CKD. The group's mean performance on the Wechsler Individual Achievement Test, Second Edition, Abbreviated (WIAT-II-A) was in

the average range, but across all academic domains more patients were "at risk" (scoring one or more SDs below the normative mean for age) than would be expected given a normal distribution. One third of subjects scored "at risk" on the WIAT-II-A Numerical Operations subtest, which is more than twice the expected rate. CKD-related characteristics including eGFR, proteinuria, hypertension, and anemia were not associated with low achievement. Among children evaluated in the CKiD cohort, ADD/ADHD was self-reported for 9% of the sample; however, this was not significantly associated with risk for academic underachievement. Children displaying lower total achievement scores had significantly more school absence (5.5 days versus 3 days). Use of an IEP or 504 plan was reported by 29% of the CKiD sample and children with lower total achievement scores had a higher rate of IEP or 504 plan usage (51% versus 17%).

When we consider the study by Duquette et al. [33], which compared 30 patients with CKD or ESKD to a group of 41 age and gender-matched healthy controls, we must keep in mind differences in key variables: the control group had higher maternal education and a larger proportion of children who identified as Caucasian. In addition, the CKD participants had more previous grade retentions, use of specialized educational plans, and more school absences. Allowing for these caveats, the patients scored significantly lower than the controls on the WIAT-II Word Reading and Math Reasoning domains. Higher eGFR was positively correlated with all academic scores, suggesting that less advanced disease causes fewer adverse educational consequences. The authors also examined whether children in either group met criteria for a learning disorder, using three different formulas: an ability-achievement discrepancy formula, which requires an academic standard score to be at least 15 points lower than FSIQ; a regression formula, which statistically adapts the discrepancy formula using achievement scores predicted by FSIQ; and a low achievement formula, which defines learning disability as a standard score below the 25th percentile for age. The two groups differed significantly only when the low achievement formula was used. Using this approach, 43%, 37%, and 40% of the CKD group met criteria for a learning disorder in reading, math, and spelling, respectively, compared to 7%, 2%, and 5% of the control group. Thus, for children with CKD, for whom the disease process may depress both cognitive performance and academic achievement, discrepancy formulas (which require a significant discrepancy between cognitive and achievement scores) may be of limited use. The authors also noted that children with CKD had a 40% rate of grade retention, compared to 2.4% of the control group, suggesting that current educational services are not meeting the needs of these patients.

Brouhard et al. [23] compared 62 dialysis and transplant patients (average age 13.7 years, roughly half with disease onset prior to 10 years) to a healthy sibling control group, using the Wide Range Achievement Test (WRAT), a brief measure of academic achievement that assesses three areas: spelling, arithmetic, and reading. There were no significant differences between the dialysis and transplant groups. When compared to siblings, the combined patient group scored significantly lower across all domains, with sibling mean scores placing in the average range and patient mean scores placing in the low average range. Using available data for approximately half the study sample, 85% percent of sibling participants were in regular education classes full-time while only 64% of patients were in a regular setting. Over half (56%) of the patients had missed 21 or more days of school in the last semester, compared to only one sibling (4%). The percentage of a patient's life with ESKD was negatively correlated with the WRAT Arithmetic score.

Early onset of disease, type of disease (e.g., congenital nephrotic syndrome), and associated comorbidities confer risk to academic achievement. Studies have historically varied in terms of whether those with significant CNS risk factors are included in analyses. When Johnson and Warady [22] compared the performance of nine children diagnosed with ESKD in infancy to that of their healthy siblings, patients with major neurological risk factors, including stroke or

asphyxia, Galloway Mowat syndrome, and Joubert syndrome, were excluded. Healthy siblings outperformed patients across all domains of the WIAT-II-A, including Word Reading, Spelling, and Numerical Operations, as well as the Total Achievement score. Mean scores for siblings placed in the average range; in contrast, all patient mean scores placed in the low average range. Based on parent report, only one of the siblings had ever been diagnosed with a learning or attention disorder, while three patients (33%) had been diagnosed with a learning disorder, and one with an attention disorder (11%). In another study that excluded patients with syndromes known to influence neuropsychological functioning, and that also included a sibling control group [30], 22 patient-sibling pairs participated in academic assessment and no significant differences were found on measures of achievement. These patients ranged in age from 6 to 16 years, were on a transplant waiting list, and were approaching or receiving dialysis. The average age of onset of ESKD was not reported. These results are more consistent with those from the CKiD study and suggest better academic achievement outcomes for children diagnosed later in childhood compared to those diagnosed in infancy.

In a more severely affected cohort, Qvist et al. [31] examined educational outcomes for children diagnosed with ESKD early in life. In this sample, a large proportion (88%) of children had a diagnosis of congenital nephrotic syndrome (severe Finnish type), many with comorbid events in early infancy including history of stroke. Thirty-three children who underwent transplant before 5 years of age were followed prospectively. The authors reported outcomes an average of 6 years post-transplant, when the patients were 7–12 years of age. Twenty-six patients (79%) attended a regular school, although six of these children required remedial education services. The remaining seven children attended a specialized school, two of them to accommodate hearing impairment rather than intellectual impairment. Risk factors for requiring a specialized educational setting included: longer time on dialysis, more hypertensive crises (the majority of which occurred during dialysis), more seizures (which occurred for some patients during dialysis and for others post-transplant), and major infarcts/hemiplegia. While major cerebral infarcts were more common in those requiring special education (3/7), watershed infarcts and abnormal EEGs were also seen among those in remedial and regular classes.

A small number of studies have examined much longer-term educational and vocational outcomes for patients who had ESKD as children. Having ESKD as a child appears to be associated with lower educational attainment, lower socioeconomic class, and higher rates of unemployment [34, 40], although at least one study reported more positive outcomes [40]. Offner et al. [41] described 124 adults with a mean age of 25 years who had received a kidney transplant between 1970 and 1993, when they were a mean age of 12.1 years. Mean eGFR had declined over the years, from 76 to 45 ml/min/1.73 m^2, and 80% of the sample had maintained or developed hypertension. Education and employment levels were roughly the same as the general German population at that time (9% unemployed in general population, versus 14% in the sample), although 45% lived with their parents. In contrast, a large study of 126 Dutch adults by Groothoff et al. [34] reported that only 42.2% of patients completed intermediate or advanced vocational training compared to 72.2% of the general population. Reynolds et al. [40] examined long-term outcomes for patients who underwent dialysis or transplant during adolescence (at a mean age of 14.4 years) and found that (1) the social distribution of kidney patients was lower than that of a healthy comparison group; (2) kidney patients had lower educational achievement; (3) significantly fewer were employed full-time, although two-thirds were employed in some capacity; and (4) that more kidney patients were receiving social security benefits compared to the control group (42% vs. 15%). Seventy-one percent of patients in this study reported that their disease and its treatment had significantly affected their education. The authors reported that onset of illness before 11 years of age and current self-reported low energy were associated with unemployment.

Qualitative research exploring educational and vocational outcomes have produced similar themes. Kerklaan et al. [42] interviewed 30 young adults 18–35 years of age who were diagnosed with CKD during childhood. These participants described long-term impact of school absences and reduced participation in social activities, including social anxiety, feelings of inferiority, and falling behind peers with activities and accomplishments. Longer duration of dialysis during childhood seemed to be related to more negative impact on friendships and participation in recreational activities. Participants described limitations to school, work, and social/leisure activities secondary to treatment burden; challenges with independence (e.g., moving out of parents' home); and difficulty forming adult relationships. Some described reorienting their plans and goals, being inspired to pursue certain professions (e.g., nursing, counseling), and unique, positive opportunities that arose secondary to the diagnosis of CKD.

The available data examining academic and vocational outcomes are consistent with what we know about the impact of CKD on cognitive and intellectual functioning. Children with CKD are at risk for lower academic achievement and poorer educational and vocational outcomes. The age of onset of CKD, disease severity, and comorbid conditions all influence the degree to which academic achievement is affected. The available evidence suggests that the academic achievement of children with CKD will be significantly below that of their siblings if kidney replacement therapy is required early in life. It is important to consider that in addition to the medical effects of CKD (such as uremia, acidosis, hypertension, and fatigue), children with CKD miss more academic instruction, and often have less time and energy to complete homework. The emotional and financial strain of kidney replacement therapy, as well as the time commitment, may also result in fewer opportunities for enrichment activities (music lessons, field trips) all of which also may impact a child's learning and achievement.

Pediatric nephrologists and allied health professionals have an opportunity to reduce the impact of CKD on academic achievement, particularly for children receiving chronic outpatient dialysis. This might include provision of school services in the dialysis unit, adjusting dialysis schedules to accommodate the school day, and working with families and schools to develop individualized education or remediation plans. Children who are struggling academically should be referred early for cognitive and psychoeducational evaluation.

Cognitive Outcomes and Kidney Transplantation

Kidney transplantation is a central goal in the management of children with advanced CKD, promising improved survival and quality of life. A substantial body of literature indicates that both cognitive performance and academic achievement are improved among children with kidney transplant when compared to those receiving dialysis. The available literature indicates that, in general, children with kidney transplant have improved performance on a range of tests of cognitive abilities and achievement post-transplant, although not full normalization. This is supported by more recent meta-analytic data from over thirty pediatric studies demonstrating that, in general, children with kidney transplant have intelligence equivalent to children with mild/moderate CKD and significantly better intelligence assessment than children receiving dialysis [43].

Icard et al. [44] reported results for six patients with advanced CKD who received a transplant. Compared to a control group of children with CKD being treated conservatively, children who received a transplant demonstrated a meaningful increase in their intellectual and developmental functioning. In fact, children receiving a transplant had, on average, a 12-point increase in their standard intelligence scores from pre- to post-transplant. Mendley and Zelko [45] obtained baseline intellectual assessment (WISC-III or WAIS-R) and performed within-subject comparisons of nine patients just prior to and 1 year after kidney transplant, using a wide range of neuropsychological tests. At baseline,

intelligence scores placed within the broad range of average, although skewed slightly lower than a normal distribution. All were attending regular education classes full-time with excellent attendance. After transplant, there was significant improvement in specific aspects of neurocognitive performance. Mental processing speed and decision-making speed (as assessed by the computerized Cognitive Abilities Test) improved from pre- to post transplant and subjects showed more consistent performance after transplant. Sustained attention (assessed by the Connors' Continuous Performance Test Signal Detection Index) and working memory (assessed by the Paced Auditory Serial Addition Test) also improved after transplant.

A study of an early cohort of infants (diagnosed and treated between 1978 and 1985) demonstrated how successful kidney transplantation has the potential to ameliorate developmental deficits [46]. All nine children had significant improvement in head circumference Z-score after transplant even as linear growth lagged. Performance on developmental assessment improved in most infants, with post-transplant Bayley cognitive and motor development scores placing within the broad range of average for most children. Seizures noted while children were on dialysis were not present after transplant.

Falger et al. [47] evaluated the intellectual functioning of 27 patients who had transplants in childhood (mean age at transplant was 9 years); evaluations took place an average of 6 years post-transplant (average age at assessment was 14 years). Median FSIQ was 97, but the range was wide (49–133). Five patients had neurological comorbidities, and their mean FSIQ score was 81, with a range of 49–101 (encompassing severe impairment to normal function). Twenty-one subjects had an FSIQ score > 85, and two were in the high average range (>115). The VIQ was significantly higher than the PIQ, which was significantly lower than a control population. The patients also scored significantly lower than a control group on 5 of 11 WISC-III subtests, even when excluding subjects with neurologic morbidity.

The assessment of long-term intellectual and metacognitive functioning and academic achievement for a group of 12 children transplanted in early life is described previously in this chapter [22]. Performance on some indices was related to younger age at transplant and fewer months on dialysis; however, post-transplant evaluation showed persistence of IQ and achievement gaps when a subgroup of patients was compared to their unaffected siblings. Molnar-Varga et al. [48] also examined how age and duration of dialysis impact later cognitive functioning. They compared 35 kidney transplant recipients who were a median of 28 months post-transplant to 35 healthy controls on a measure of intelligence (Woodcock-Johnson International Edition). The mean FSIQ score placed in the broad range of average, but greater than 1 SD lower than control participants (mean score 85 versus 107). Earlier age at onset of dialysis and longer time on dialysis were associated with lower scores in the transplant group, as was cumulative days hospitalized (standardized for age).

We must also consider how the introduction of a range of new medications at the time of transplantation has the potential to affect the CNS. While high dose glucocorticoid therapy is almost always of short duration, many children continue to receive lower dose glucocorticoids for years or even decades. The hippocampus has high concentrations of glucocorticoid receptors and neurochemical and electrophysiologic changes occur in the presence of these hormones [49]. Prolonged supraphysiologic exposure can accelerate neuronal loss in the hippocampus and increase the severity of other neurologic insults. Cellular toxicity, dendritic atrophy, and damage to hippocampal structure have been shown in a primate model of chronic exposure [50]. The effects of low doses over longer duration are unknown [51].

Calcineurin inhibitors are a mainstay of lifelong immunosuppression, but our knowledge of the neurocognitive effects of chronic use of this class of medications in children is limited. Acute neurotoxicity has been described in a subset of patients and can include headache, tremor, insomnia, paresthesia, mental status changes, visual and auditory hallucinations, cortical blindness, seizures and memory loss [52, 53]. These

side effects are more often observed in patients undergoing bone marrow or liver transplant, likely because of the greater intensity of immunosuppression required. In a study of 14 pediatric kidney recipients receiving calcineurin inhibitors, 86% reported myalgias, tremor, fatigue and headache, and half of the group had symptoms most of the time [54]. Acute, reversible encephalopathy with MRI findings was reported in two children, ages 7 and 17 years, after kidney transplant who were treated with tacrolimus at levels of 10–11 ng/ml [55]. Both subjects recovered completely and tolerated lower tacrolimus levels of 6–7 ng/ml.

Many potential mechanisms have been proposed to explain calcineurin inhibitor neurotoxicity, and these hypotheses are relevant to our concerns regarding brain development in young children with CKD. Calcineurin represents >1% of total brain protein, and intracellular binding proteins for cyclosporine and tacrolimus are found throughout the CNS. Both drugs may interfere with the activity of excitatory (N-methyl-D-aspartic acid [NMDA]) and inhibitory (γ-aminobutyric acid [GABA]) amino acid receptors through calcineurin, which may impact memory formation [52]. Intra-cranial injection of cyclosporine to day-old chicks disrupts memory formation [56]. Further, cyclosporine is toxic to glial cells in culture in a manner that appears to correlate with the white matter changes which are seen by CT and MRI in affected transplant recipients [52]. Cyclosporine has also been shown to induce apoptosis of oligodendrocytes and neurons in culture [57]. It is only possible to speculate to what degree these observed changes affect the normal dendritic pruning, myelination, and formation of complex connections which characterize infant and early childhood brain development.

Clinical observations suggest that sirolimus may not have independent neurologic toxicity [58]. However, it appeared to enhance the toxic effects of cyclosporine on brain mitochondrial glucose metabolism in a rat model [59]. In contrast, mycophenolate mofetil is not thought to have a neurotoxic profile.

Genetics of Neurodevelopment and Kidney Development

While only a fraction of adult CKD is caused by genetic disorders, genetic forms of kidney disease are common in pediatric CKD, representing approximately 40% of all cases. Single gene mutations explain an array of kidney diseases [60], yet there can be no doubt that there is much more to learn about genetic etiologies. A few genetic disorders are known to be associated with both CKD and mental retardation, but the full spectrum of neurodevelopmental abnormalities associated with genetic CKD has not been clearly defined. Causative genes have been identified in approximately half of kidney diseases with classic Mendelian inheritance [60], but we recognize other organ systems are affected in addition to the kidneys and urinary tract.

We now know that copy number variants (CNVs) are common in the human genome and can be identified and analyzed using array-based technologies [61]. Certain rare CNVs appear etiologic in developmental disorders, including schizophrenia, attention deficit disorder, developmental delay, behavior abnormalities and learning disability [62–64]. In a study of 522 patients with congenital kidney malformations, including kidney aplasia, agenesis, hypoplasia and dysplasia, rare CNVs were more likely in cases than controls, and large CNVs and gene-disrupting events were strikingly more frequent [65]. Among the genomic disorders associated with kidney developmental disturbance were those previously recognized to be associated with neuropsychiatric traits (e.g., DiGeorge, Wolf-Hirschhorn, Kallman, Potocki-Lupinski syndromes). Further, there were novel CNVs spanning genes having murine orthologs associated with kidney and neurodevelopmental defects.

These findings may change our understanding of the relationship between developmental and neurocognitive abnormalities and childhood CKD. Rather than attributing neurodevelopmental delay exclusively to uremic metabolic disturbance, we must consider that defects in pleiotropic genes involved in the morphology of brain and kidney may play a causative role in neurodevelopmental delays.

Neuroimaging

Neuroimaging provides a noninvasive opportunity to examine brain structure and function. Given the observed neurocognitive findings in the pediatric CKD population, research has more recently moved to defining the neural mechanisms for cognitive dysfunction. Neuroimaging studies in children with CKD and ESKD are few and are limited by broadly defined inclusion criteria including age at the time of evaluation, age at diagnosis, type of therapy, and underlying disease. In seeking a deeper understanding of the documented cognitive deficits in CKD, it is critical to ask: (1) is there a structural or functional brain basis for the observed neurocognitive deficits in this population; and (2) are there specific regions of the brain that are most associated with these deficits?

Imaging data can largely be reviewed by modality: computerized tomography (CT), structural magnetic resonance imaging (sMRI), and functional magnetic resonance imaging (fMRI). Twenty neuroimaging studies that include pediatric CKD patients have been published in the literature between 1977 and the present. Of these studies, 13 utilized CT-based neuroimaging and 7 utilized MRI. Most early studies on the topic of neuroimaging in pediatric CKD used CT. Within the more modern pediatric MRI subset, six have evaluated structural MRI and only one has examined brain function through use of regional cerebral blood flow. Study populations in the published literature vary widely in sample size, age, and primary disease etiology.

Contemporary neuroimaging data available from CT are available from 1997 to 2006. Nine of the thirteen published studies in the pediatric CKD literature using CT as a neuroimaging modality were case-control or prospective in nature. CT-based studies focused on pediatric populations with ESKD or post-transplantation without inclusion of less severe disease CKD phenotypes. In general, CT data from these studies demonstrate higher risk for global cerebral atrophy, silent white matter infarcts, and ventriculomegaly [3, 66, 67]. Cerebral atrophy is well-described in pediatric nephrology literature dating prior to 1990, with reports of up to 60% of patients having atrophy that was not associated with type of renal disease, hypertension severity, or corticosteroid therapy [68]. Cerebral atrophy in ESKD, however, has been correlated with age of onset of renal disease [66] and dialytic modality [69, 70]. Qualitative imaging also shows that lower cerebral density [69, 71] and ventriculomegaly secondary to brain atrophy [72] are more often associated with requirement for and duration of pediatric HD compared with receipt of PD [70].

The use of MRI can provide high-resolution qualitative and quantitative assessment of the brain. sMRI provides information related to volumes within and between regions of the brain. Additionally, if the MRI is performed in a research-based scan sequence, it is often possible to obtain sequences that evaluate white and gray matter as well as blood flow within the brain—the former representing sMRI and latter representing functional fMRI.

Data from the Neurocognitive Assessment and Magnetic Resonance Imaging Analysis of Children and Young Adults with Chronic Kidney Disease (NiCK) Study performed volumetric brain assessment using sMRI in youth with CKD compared to normal controls [73]. Although the sample size was adequately powered to detect a statistical difference between populations (N = 90), the CKD sample was very heterogenous with regard to chronological age, stage of disease, disease etiology, and inclusion of dialysis/transplant patients. Statistical analyses, including corrections for multiple comparisons and adjustments for age and sex, did not support any specific brain regional differences between CKD patients and controls. Furthermore, there were no CKD-related clinical predictors to link differences in brain regions of interest to neurocognitive performance. Single-center data by Solomon et al. [74] evaluated 18 males with mild to moderate CKD due to congenital anomalies of the kidney and urinary tract in comparison to matched, healthy peers. Cerebellar gray matter volume was significantly smaller in children with CKD compared to peers (Fig. 57.1). In contrast, cerebral gray matter volume was increased in CKD participants. Reduced

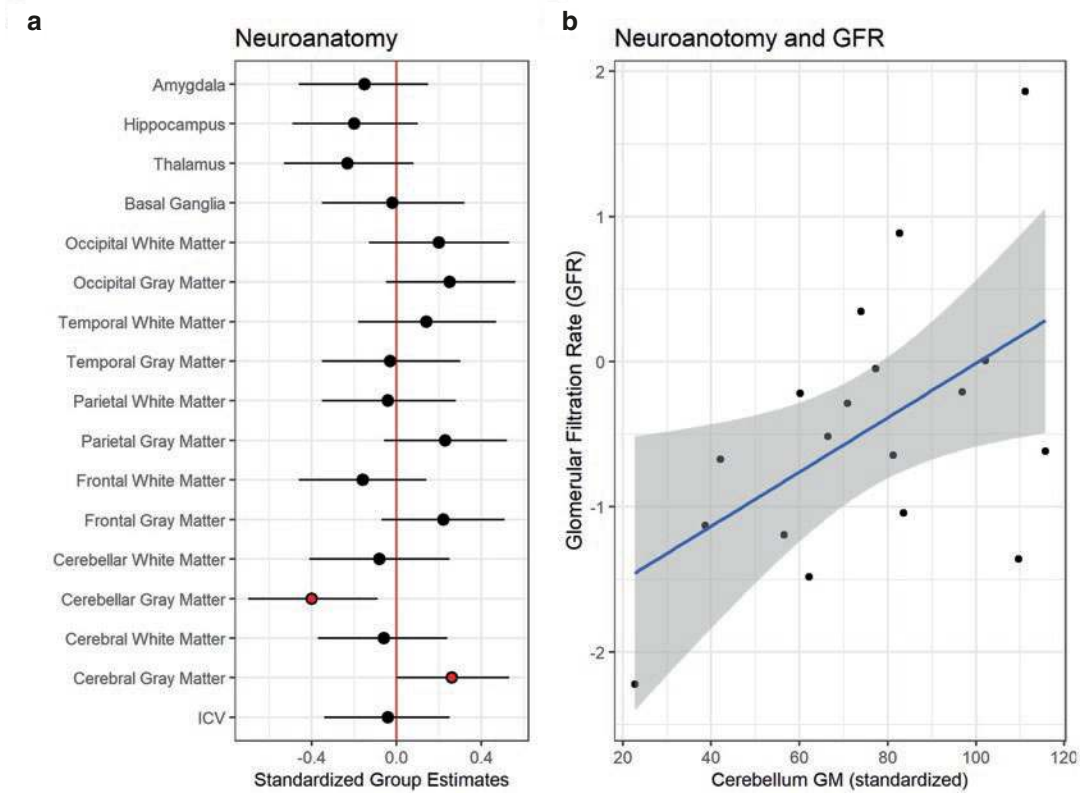

Fig. 57.1 Neuroanatomical differences between controls and pediatric chronic kidney disease [74]. Panel A shows the standardized group estimates (x-axis) and 95% confidence limits of the estimates for each of the regions of interest (ROI) included in the analysis (y-axis). Estimates are adjusted for age, socioeconomic status, and maternal education. The red (vertical) line marks 0, or no significant effect of group on ROI. Red circles mark significant group estimates. Panel B shows the relationship between estimated glomerular filtration rate, eGFR, (x-axis) and standardized cerebellum gray matter volume (y-axis) in the CKD group

cerebellum gray matter volume was associated with disease severity, operationalized as eGFR and predicted lower verbal fluency scores in the CKD sample. Enlarged cerebral gray matter in the CKD sample predicted lower scores on mathematics assessment.

sMRI also serves to inform the microstructural white matter integrity of the brain via diffusion tensor imaging (DTI). DTI is an MRI modality that allows for examination of white matter integrity—i.e., axonal or white matter microstructural changes that disrupt the diffusive property of water in the axon. These microstructural changes have been shown in diseases such as hypertension, diabetes mellitus, and atherosclerosis [75, 76]. The result of this microstructural disruption is a change in a physical diffusive property of the axon called decreased fractional anisotropy. Matsuda-Abedini et al. [77] conducted a quantitative white matter analysis utilizing a heterogenous sample of patients with varying CKD etiologies (including patients on PD and post-transplant) and control patients. This demonstrated the presence of decreased white matter integrity, specifically decreased fractional anisotropy, within the anterior limb of the internal capsule. It is possible that the entirety of the white matter integrity difference within the sample was not captured given the multisite nature of the study; specifically, MRI sequences are highly scanner dependent and statistically significant differences can emerge (or be lost) due to differences in magnet strength or brand of scanner utilized. Lastly, the sample did not have

parallel neurocognitive data to further inform the significance of white matter changes within the anterior limb of the internal capsule finding.

fMRI studies examine the use of oxygen within the brain or rate of arterial cerebral blood flow with specialized scan sequences called 'resting state' or 'arterial spin labeling,' respectively. Additional analysis of data from the NiCK Study lends evidence for regional cerebral blood flow abnormalities that may underlie cognitive changes in pediatric CKD [78]. In a study by Liu et al. [78], patients with CKD, including dialysis and transplant patients, showed higher global cerebral blood flow compared to control subjects. Perhaps of most interest, one area showed regional cerebral blood flow differences between patients and control subjects—including a region called the "default mode" network (Fig. 57.2). Neuroscience literature supports that the brain is organized into functional networks, and the

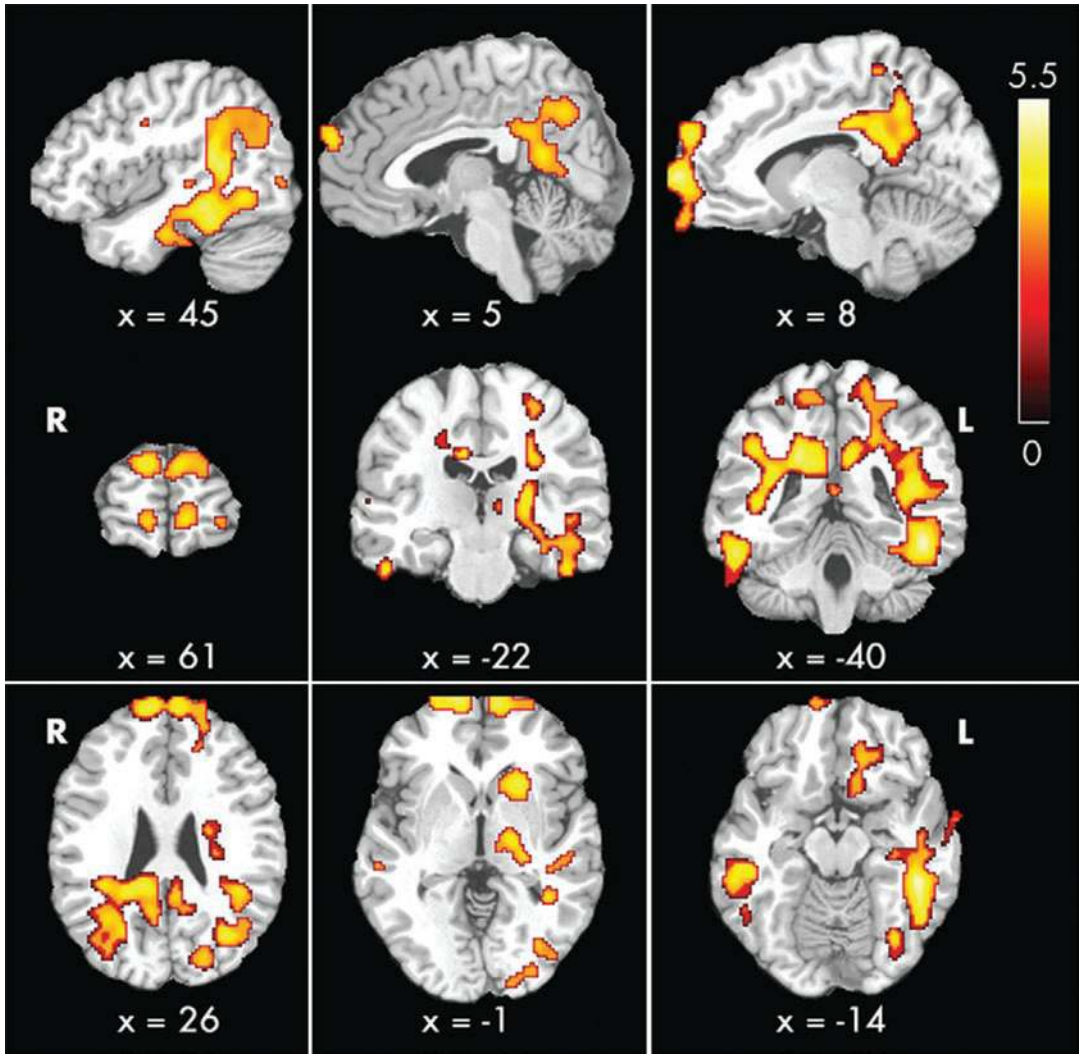

Fig. 57.2 From Liu et al. [78], reprinted with permission: demonstration of voxel-wise group comparison of cerebral blood flow after removal of effects of hematocrit level, age, and sex. Contrast shown here demonstrates the regions where those with CKD have greater cerebral blood flow than controls. Of note, there were no regions in this analysis where controls had greater regions than those with CKD. Color bar indicates *t* scores. *x, y, z* = coordinates in Montreal Neurological Institute (MNI) space

default mode network is a critical loop for attention regulation and, perhaps, EF processes [79–82]. Hematocrit-related effects explained most of the observed group differences in cerebral blood flow. Thus, Liu et al. hypothesized that chronic anemia experienced in pediatric CKD could be a potential cause of vascular endothelial damage due to increased compensatory blood flow to meet demands for deficits in tissue oxygen delivery.

More Frequent Hemodialysis and Neurocognitive Functioning

There were improvements in blood pressure, phosphate control and health-related quality of life in a prospective controlled trial of daily or nocturnal HD in adults [83, 84]. One cohort was studied with an expanded battery of cognitive tests; executive function and global cognition were not affected, but memory and verbal fluency were improved [85]. The subjects who received daily HD saw improvement on the Rey Auditory Verbal Learning Test Immediate Recall and the Controlled Oral Word Association Test after 12 months. The frequent nocturnal HD group did not see a benefit in cognition and had poorer performance on one test of attention. A smaller longitudinal study of 14 adults showed benefits to attention and working memory, psychomotor efficiency and processing speed, and learning efficiency when subjects were converted from thrice weekly HD to nocturnal treatments 5–7 times per week [86].

Reports of frequent HD and nocturnal dialysis in children have focused on improvements in growth and metabolic control, rather than on cognition. There remains interest in expanding these treatment choices to more children. Improvement in blood pressure control and middle molecule clearance coupled with reduction or removal of dietary restrictions could benefit both cognition and quality of life. Nonetheless, it is recognized that these treatment schedules are burdensome. In one of the largest series reporting patient outcomes for more frequent dialysis, daily in-center hemodiafiltration required 3-hour treatments six times per week [87]. Home nocturnal HD performed 6–7 nights per week provides improved metabolic control and elimination of dietary restrictions [88] but increased perceived treatment burden for the family. The NxStage System is most often used for home HD but is only appropriate for those over 30 kg; we do not have an alternative to PD for the smallest patients. These preliminary observations in selected dialysis programs have engendered enthusiasm for alternative regimens for HD in children and it has been recommended that pediatric nephrologists consider ways to implement more frequent HD and strategies for supporting families who wish to pursue it [89, 90].

Conclusion

The cognitive deficits observed in pediatric CKD patients represent a potentially under-recognized consequence of pediatric CKD in day-to-day clinical practice. The findings presented in this chapter demonstrate that our pediatric CKD patients are most at risk for cognitive dysfunction in the domain of executive functions; specifically, attention and working memory. Cognitive and academic performance may be associated with features on neuroimaging including differences in gray matter volume. These cognitive, academic, and neuroimaging differences likely emerge in early childhood and can be detected during the early stages of CKD. This signals a need for greater attention to the developing brain in the midst of a life-long, chronic disease process. Current data represent a limited understanding of the medical determinants of cognitive dysfunction in CKD and an even more minimal understanding of the genetic and epigenetic drivers of cognitive development and performance in CKD. Certainly, research efforts to understand cognition in CKD may be better served through parallel inclusion of a chronic disease control model that includes healthy controls. Nephrologists should remain aware of the burden of managing chronic disease at a young age and how that differs from the experience of adults who develop CKD later in life.

When treating children with CKD, it is important that nephrology care incorporate a psychologist as part of the treatment team to provide understanding for families and patients regarding the impact of CKD progression on neurodevelopment and neurocognitive performance and available academic accommodations and interventions. This will allow patients and caregivers to obtain more comprehensive information about the potential for cognitive rehabilitation and learn how best to support children and adolescents with CKD as they navigate educational and vocational endeavors.

Acknowledgments The authors wish to acknowledge Susan R. Mendley, MD for her contributions to the previous edition of this chapter.

Nutritional Challenges in Pediatric Kidney Disease

58

Rayna Levitt and Caitlin E. Carter

Introduction

Provision of adequate nutrition is a cornerstone of optimal management and improvement of outcomes for children with chronic kidney disease (CKD). Nutrition impacts short-term outcomes, including renal disease progression, growth, and development as well as long-term outcomes, including cardiovascular risk. Presently, the majority of guidelines for the nutritional management of children with CKD are based on consensus opinions and practice-based evidence.

Important considerations include the provision of adequate energy and macronutrients, the achievement of fluid and electrolyte balance, the provision of adequate micronutrients, and the prevention of metabolic bone disease. Extremes of body mass index, representing under-nutrition and over-nutrition are associated with poor outcomes and should be addressed when designing nutritional care plans for children with CKD. Promoting optimal nutrition for children with CKD necessitates multidisciplinary collaboration, including input from registered dietitians, physicians, nurses, and social workers.

Nutrition Assessment

In 2009, in recognition of the growing population of children with CKD, the National Kidney Foundation published the Kidney Disease Outcomes Quality Initiative's (KDOQI) Clinical Practice Guidelines for Nutrition in Children with CKD [1]. These practice guidelines expanded upon guidelines that were published by KDOQI in 2000 by setting out evidenced based nutrition recommendations for pediatric patients with CKD, including patients receiving dialysis and those who have received kidney transplants. The guidelines were recommended as a starting point for those providing medical nutrition therapy to this complex patient population [2]. In 2019, the Pediatric Renal Nutrition Task Force, a team of pediatric nephrologists and pediatric renal dietitians from eight countries in Europe and North America, was established to develop clinical practice recommendations (CPRs) to update the 2009 KDOQI guidelines in areas where new evidence has become available [3]. This group conducted an in-depth review of evidence for current practices along with consensus opinion to establish updated practice guidelines.

The primary goal of evaluating nutrition status of children with CKD is to support growth and development, while preventing protein-energy wasting (PEW) and its well documented negative effects on patient outcomes [4, 5]. Provision of medical nutrition therapy in this population also

aims to ensure that vitamin and mineral needs are met. There is a risk posed by over-nutrition as well, illustrated by obesity resulting from factors such as overzealous tube-feeding and the frequent use of corticosteroid therapy. Nutrition assessment in this patient population should involve the use of multiple measures of nutrition status as no single measure can provide an accurate picture. Children with CKD require more frequent monitoring of their nutrition status than their healthy counterparts, and the collection and comparison of measures over time can be used to form a more complete picture. The recommended components of assessment include anthropometric measures, evaluation of dietary intake, and review of biochemical data.

Anthropometric Measures

Height, weight and head circumference are the most easily attained measures used in nutrition assessment. They should be accurately measured using calibrated equipment and standardized techniques [1].

- Weight should be assessed at every clinic visit and weight gain or loss trends should be noted.
- Height should be evaluated in order to give context to the weight assessment. For children under 2 years of age, recumbent length should be measured. Standing height can be measured for those over 2 years who are able to stand. In order to determine if the height achieved is appropriate given a child's genetic potential, mid-parental height should be assessed. While anecdotal data can be used for this, it is best if the heights of both biological parents can be measured [6].

Mid-Parental Height Calculation:	
Boys:	[(mother's height + 13 cm) + father's height]/2
Girls:	[mother's height + (father's height-13 cm)]/2

(chart adapted from KDOQI 2009)

- Head circumference should be measured for children under 2 years of age.

These measures are plotted on percentile charts. In the U.S., the recommendations of the Centers for Disease Control and Prevention (CDC) are to use the World Health Organization growth charts to monitor growth for infants and children ages 0–<2 years of age and to use the CDC growth charts to monitor growth for children ages 2 years and older [7]. These values can also be expressed as standard deviation scores (number of standard deviations from the mean for a normal population of the same age). If an applicable underlying genetic disorder is present, it is appropriate to utilize a disease specific growth charts to assess growth parameters.

- Weight for length (for children <2 years) or BMI (for children ages 2–20 years) should be calculated every time weight and height are measured and plotted on percentile charts.

When evaluating BMI in children with CKD, it may be preferable to express their BMI relative to height age (the age at which the child's height would be at the 50th percentile). Children with CKD commonly experience poor linear growth and delayed skeletal maturation. Comparison of BMI to other children with the same chronological age may result in an underestimation of that child's BMI percentile. It is therefore more appropriate to compare BMI to those of children with similar height and maturation [1, 4, 5]. When evaluating weight or using weight to calculate BMI, it is important to first evaluate whether edema is present. For dialysis patients, estimated dry weight should be used when calculating weight for length or BMI.

In addition to anthropometric measurements, nutrition-focused physical exam (NFPE) can be included as part of the patient assessment as it can identify muscle wasting, subcutaneous fat loss, edema and macronutrient deficiencies [8]. The value of NFPE has been noted in the general pediatric population as it can identify malnutrition that has a negative impact on growth and

development. Since children with CKD are known to be at risk of poor growth, it may add value to the assessment of this patient population as well.

Dietary Assessment

It is recommended that dietary intakes of children with CKD be assessed with a minimum frequency of annually, or as often as every 2 weeks depending on the age of the child and stage of disease. More frequent assessments are recommended for younger children and children with advanced stages of CKD. Children who depend solely on enteral feeding should have more frequent monitoring. This is especially true of enterally fed infants who may benefit from feeding adjustments as often as weekly [6, 9]. The dietary intake assessment should either take the form of a prospective 3-day diet diary or a 24-h diet recall. A 3-day diary should include one weekend day to represent variation in the diet due to change in schedules on weekends. The 24-h diet recall may be better suited to adolescents who, may not be compliant with completion of a food diary. Either technique can be utilized by a registered dietitian to estimate daily intake of energy, macronutrients, vitamins and minerals. They can provide information about diet adequacy and, over time, can highlight changes in appetite that may lead to weight loss or increased risk of malnutrition. If dietary assessment reveals that the diet is inadequate, in addition to other considerations, the dietitian should evaluate whether food insecurity is a contributing factor. In 2018, one in seven U.S. households with children was affected by food insecurity, which can be exacerbated by families facing increased medical expenses [10].

Assessing Protein Status: Normalized Protein Catabolic Rate vs. Serum Albumin

Lower serum albumin is associated with increased morbidity and mortality [11]. The 2000 KDOQI Nutrition Guidelines recommended albumin be used as a marker of nutritional status in pediatric dialysis patients [2]. There are several shortfalls, however, in the use of albumin levels as a measure of nutritional status in children with CKD. Serum albumin concentrations decrease for various non-nutritional reasons, such as the presence of fluid overload, urinary and dialysate protein losses, inflammation, infection and liver disease [4]. In addition, it is possible for serum albumin to be normal in patients who are known to have a poor oral intake and who appear malnourished with a decrease in lean body or fat mass. Despite these limitations, hypoalbuminemia has been associated with mortality in children initiating dialysis therapy and albumin levels above 4 g/dL in adolescent patients on hemodialysis (HD) have been associated with a reduced risk of death and decreased hospitalizations [6]. For this reason, serum albumin levels continue to be monitored and are interpreted in the context of other assessment data.

Normalized protein catabolic rate (nPCR) has been validated as an objective tool that may assist in the nutritional assessment of adolescent HD patients. The calculation of nPCR is based on the increase in the level of blood urea nitrogen between the end of one HD treatment and the beginning of the subsequent treatment and it is theoretically more accurate than food diaries or diet recalls. Calculations using BUN values from the end of one dialysis treatment and BUN values at the start of a subsequent treatment may more accurately reflect protein intake than calculations using BUN values from the start and end of a same day HD treatment [12]. Higher nPCR in adolescents has been found to be a good predictor of weight gain, whereas lower nPCR has been shown to predict weight loss.

Normalized protein nitrogen appearance (nPNA) is a similar measure of estimated protein intake that can be calculated for patients on peritoneal dialysis (PD). It is calculated by determining the total daily excretion of urea in the dialysate and urine, as well as the daily dialysate protein losses. These values are entered into an estimating equation and are normalized for body size.

Equations for Calculation of Normalized Protein Catabolic Rate (nPCR) and Normalized Protein Equivalent of Nitrogen Appearance (nPNA)
nPCR
1. Calculate urea generation rate (G, mg/min):
G = [(C2 × V2) − (C1 × V1)/t
C1 = post-dialysis BUN (mg/dL)
C2 = pre-dialysis BUN (mg/dL)
V1 = post-dialysis total body water (dL; V1 = 5.8 dL/kg × post dialysis weight in kg)
V2 = pre-dialysis total body water (dL; V2 = 5.8 dL/kg × predialysis weight in kg)
t = time (minutes) from the end of one dialysis treatment to the start of the next dialysis treatment
2. Calculate nPCR:
5.43 × estG/V1 + 0.17
nPNA
1. **Calculate total nitrogen appearance (TNA, g/day):**
0.03 + 1.138 urea-Nurine +0.99 urea-Ndialysate +1.18 BSA + 0.965 protein-Ndialysate
2. Calculate protein equivalent of nitrogen appearance (PNA, g/day):
TNA × 6.25
3. Normalize PNA to body weight (nPNA):
PNA/weight (kg)

N = nitrogen, BSA = body surface area, BUN = blood urea nitrogen

Adapted from: National Kidney Foundation KDOQI Clinical Practice Guideline for Nutrition in Children with CKD: 2008 Update. Am J Kidney Dis. 2009; 53(3 Suppl 2):S1-S123 [1] and from Roman B. Nutrition Management of Pediatric Chronic Kidney Disease. Support Line. 2013 April;35(2):12–21 [4]

nPCR and nPNA are expressed in grams of protein per kilogram body weight per day (g/kg/day). The target nPCR or nPNA should be equivalent to the protein goal for age, which is based on the dietary reference intake (DRI) plus an allowance for dialytic protein and amino acid losses. Because nPCR fluctuates on a daily basis depending upon what is eaten, a single nPCR value does not give a good picture of protein intake; the observation of trends from month to month provides more information [1]. Among the shortfalls of nPCR are that it may overestimate protein intake in severely catabolic patients and underestimate protein intake in growing children, and has not been shown to have predictive value in infants and young children. For these reasons, like other assessment tools, it should be used in conjunction with other data to provide a complete picture of nutritional status.

Nutrition Management

Health care teams have moved away from prescribing "renal diets" as the standard diet for all children with CKD. Dietary modifications should be individualized based upon disease state and biochemical data as well as factors such as the child's age, development and food preferences. Children with CKD may require modifications to their intake of calories, protein, fat, phosphorus, calcium, sodium, potassium and fluid. In order to promote growth and development and facilitate adherence to diet recommendations, restrictions should be kept as liberal as possible. The diet can then be liberalized or tightened depending on the response in the relevant parameter. The nutrition care plan should be monitored frequently. Adjustments should be made over time in response to changes in the child's nutritional status, age, development, anthropometrics, food preferences, renal function, biochemistries, need for and mode of renal replacement therapy, medications and psychosocial status. Diet instructions should begin with a simple explanation of the role of the nutrient in the body, the rationale for the diet modification, the desired outcomes to be achieved (e.g., specific amount of weight gain, normalize serum phosphorus levels) and what happens if the modifications are not made. Guidelines for change should be practical, individualized to the patient's and the family's lifestyle, cultural food preferences and eating habits, and should be positive in that they emphasize the foods that the child can eat to replace those that need to be limited or avoided. Food models, pictures of foods from supermarket advertisements, and food containers with labels and ingredient lists can be used to make teaching sessions more interesting and relatable. During follow up, food records and diet histories can be used to assess the child's and family's understanding of and adherence to the diet to identify problems that may exist with modifying dietary intake. Nutritional counseling is recommended on an ongoing basis in order to address the dynamic nature of a child's development, food preferences, residual renal function and medical condition. Caregivers outside of the family (grandparents, school staff, daycare providers,

and babysitters) should be aware of diet modifications and should be provided with copies of teaching materials to use as reference guides to ensure consistent adherence to diet modifications. Adolescents should receive sufficient education to allow them to independently make appropriate choices when they are at restaurants, with friends, or at school.

Energy

Energy Requirements

Adequate energy intake can lead to increases in body weight and improvement in linear growth. Meeting caloric requirements is important to avoid using protein as an energy source through gluconeogenesis. There is no evidence that children with CKD have different energy requirements than their same-aged healthy counterparts. For this reason, the KDOQI 2009 guidelines and the Pediatric Renal Nutrition Task Force (PRNT) agree that initial energy goals for children with CKD 2–5D be the same as those for healthy children of the same chronological age [1, 3]. The PRNT utilizes the terminology suggested dietary intake (SDI) (see Table 58.1 from PRNT paper) as the guideline rather than estimated energy requirements used by KDOQI. The SDI provides a range of values. These SDI for energy can be adjusted for physical activity level and BMI [1, 3]. If weight gain and linear growth are poor, energy intake should be adjusted towards the higher end of the SDI. Weight and linear growth

Table 58.1 Energy and protein requirements for infants, children and adolescents with CKD2–5D aged 0–18 years

SDI for energy and protein: birth[a] to 18 years				
Month	SDI[b] energy (kcal/kg/day)	SDI protein (g/kg/day)	SDI protein (g/day)	
0	93–107	1.52–2.5	8–12	
1	93–120	1.52–1.8	8–12	
2	93–120	1.4–1.52	8–12	
3	82–98	1.4–1.52	8–12	
4	82–98	1.3–1.52	9–13	
5	72–82	1.3–1.52	9–13	
6–9	72–82	1.1–1.3	9–14	
10–11	72–82	1.1–1.3	9–15	
12	72–120	0.9–1.14	11–14	
Year	**SDI energy (kcal/kg/day)**		**SDI protein (g/kg/day)**	**SDI protein (g/day)**
–	Male	Female		
2	81–95[c]	79–92[c]	0.9–1.05	11–15
3	80–82	76–77	0.9–1.05	13–15
4–6	67–93	64–90	0.85–0.95	16–22
7–8	60–77	56–75	0.9–0.95	19–28
9–10	55–69	49–63	0.9–0.95	26–40
11–12	48–63	43–57	0.9–0.95	34–42
13–14	44–63	39–50	0.8–0.9	34–50
15–17	40–55	36–46	0.8–0.9	Male: 52–65 Female: 45–49

For children with poor growth, reference to the SDI for height age may be appropriate. Height age is the age that corresponds to an individual's height when plotted on the 50th centile on a growth chart

[a]Thirty-seven/40 weeks gestation. Premature infants have higher energy and protein requirements. The increased need for these and other nutrients (sodium, potassium, calcium, and phosphorus) must be balanced against the nutritional interventions to control the effects of CKD. This is outside the scope of this CPR

[b]Suggested Dietary Intake (SDI) is based on the Physical Activity Level (PAL) used by the international bodies: 1–3 year PAL 1.4; 4–9 year PAL 1.6; and 10–17 year PAL 1.8. Where guidelines have given a range of energy requirements for different levels of PAL, the lowest PAL has been taken for SDI energy in consideration that children with CKD are likely to have low activity levels

[c]Scientific Advisory Committee on Nutrition [13] reports energy requirements as kcal/day: male 1040 kcal/day; female 932 kcal/day

should be monitored over time and calorie goals should be adjusted according to the child's weight gain or loss and needs for catch-up growth.

There are many factors that can contribute to inadequate caloric intake in children with CKD. Decreased appetite is common. This may be related to alterations in taste perception that can decrease spontaneous intake of food [14]. High fluid intake requirements in polyuric patients or the requirement to take multiple medications can also diminish appetite. Other factors impacting intake include vomiting and gastroesophageal reflux, delayed gastric emptying and elevation of cytokine levels, including tumor necrosis factor [15]. Changes in hormones that regulate appetite such as leptin and ghrelin can also contribute to decreased intake. Frequent hospitalizations, multiple surgeries, nasogastric tube use and developmental delays impacting feeding with or without the factors previously listed can lead to oral aversion or delayed development of oral feeding skills. Nutrition supplementation should be initiated promptly if a downward trend in weight percentile is noted [3].

Obesity is increasing both in the population of healthy children around the world as well as in the population of children with CKD. In 2015–2016, the prevalence of obesity in the U.S. was 13.9% among preschool-aged children (2–5 years of age), 18.4% among school-aged children (6–11 years of age) and 20.6% among adolescents (12–19 years of age) [3, 16].

The International Pediatric PD Network (IPPN) registry found that children starting chronic peritoneal dialysis (PD) therapy had an overweight/obesity prevalence as high as 19.7% [3, 16, 17]. Nasogastric and gastric tube feeds have been found to be an independent predictor of overweight/obesity, which suggests that there may be over-utilization of supplemental feeds through NG/GT tubes in some patients, leading to an imbalance between caloric intake and energy expenditure [18]. The Chronic Kidney Disease in Children (CKiD) study found the median energy consumption of children with CKD to be higher than recommended in all age groups [19, 20]. With recognition that the epidemic of obesity in the general pediatric population has been linked to increased rates of hypertension, hypercholesterolemia, impaired glucose tolerance, insulin resistance, type 2 diabetes, sleep apnea and asthma, the potential adverse impact of these co-morbidities on children with CKD should be investigated. Future prospective studies should examine any potential link between obesity and poor outcomes, especially with respect to cardiovascular events, so that appropriate dietary and lifestyle modifications can be defined.

Appetite Stimulants

When patients are not meeting nutritional needs, nutrition counseling and calorie supplementation provide the first line of defense; however, complementary strategies for improving appetite and treating or preventing malnutrition have been examined. Megestrol acetate (MA), a synthetic progesterone derivative with appetite stimulating properties, has been studied in the pediatric CKD population. In a retrospective cohort study, Hobbs et al. followed 25 patients with a mean age of 8.9 ± 5.4 years who had demonstrated decreases in BMI and poor weight gain [21]. The mean duration of therapy was 5.4 ± 6.3 months. During treatment, there was a significant increases in BMI ($P < 0.0001$) and weight ($P < 0.0001$). Linear growth continued to improve. MA was well tolerated with the exception of one patient who experienced a side effect of cushingoid features. The authors conclude that MA may provide a safe short-term strategy to improve nutritional status in children with CKD. Possible side effects of MA such as diarrhea, headaches, dizziness, hyperglycemia, hypertension, adrenal suppression, adrenal insufficiency and thromboembolic events have been cited as causes for taking caution in its use in infants with CKD [22]. Cyproheptadine is an antihistamine that increases appetite by exerting an anti-serotoninergic effect on the brain. It has been studied as a potential appetite stimulant in underweight children who are otherwise healthy, children with cystic fibrosis and those with cancer-related cachexia, and has been found to significantly increase caloric intake and height velocity [23, 24]. The appetite stimulating effects of the gut hormone ghrelin suggest that it could be

an effective treatment for anorexia in adult CKD patients. This hormone is felt to potentially play a key role in the pathogenesis of protein-energy wasting, inflammation and cardiovascular complications in CKD [25–27]. Ghrelin has been found to acutely induce lipolysis and insulin resistance and could potentially increase the risk of diabetes [28]. Though further studies demonstrating the long-term efficacy of ghrelin are needed, along with evaluation of its use in children, it appears possible that administration of long-acting ghrelin mimetics holds the promise of improving appetite and nutrition in patients with CKD.

Nutritional Supplementation

When voluntary oral intake is low, calories can be maximized by adding concentrated sources of carbohydrate and fat to the diet, choosing calorie dense foods, and limiting calorie-free foods and fluids such as water. Calories can be added to foods using heart-healthy margarines or oils, cream and other fats, sugars, syrups, or commercial carbohydrate modules. Commercial calorie supplements such as milkshakes or energy bars may be useful; however, their phosphorus and potassium content should be taken into consideration. Standard pediatric enteral supplements have fairly high calcium and phosphorus content to support bone growth. These products are contraindicated in children with hyperphosphatemia and/or hyperkalemia. Standard products may be used in combination with low mineral and electrolyte pediatric renal products for these patients. Adult renal products can be used for older children and teens.

For infants with CKD, breastfeeding is the preferred method of feeding. If breastfeeding is not possible or breastmilk is not available, whey-based infant formulas are recommended. If a low potassium, low phosphorus formula option is needed, a low renal solute load infant formula such as Similac PM 60/40®(Abbott Laboratories, Chicago, IL, USA) can be used either to fortify or supplement breastfeeding or on its own. Breastmilk and infant formula should be fortified for infants who require fluid restriction or for those who require more energy or nutrient dense feeds.

To meet requirements, commercial glucose polymer powders, liquid fat products or powdered fat and carbohydrate combination products can be added to infant feedings to increase their standard energy density (20 kcal/oz., 0.67 kcal/mL) as high as 60 kcal/oz. (2 kcal/mL) without significantly increasing electrolyte and mineral content. The choice to add a carbohydrate module, fat, or a combination of both should be made after considering serum glucose and lipid profiles, the presence of malabsorption or chronic respiratory disease (carbohydrate metabolism increases carbon dioxide production), and the cost to the caregivers. When making more than two or three increases in energy density, the distribution of calories from carbohydrate and fat should be kept similar to the base feeding. Unless fat malabsorption is present, "heart-healthy" oils such as corn or canola oil can provide a low-cost option, especially for infants on PD who have hypertriglyceridemia as a consequence of absorbing excess glucose from the dialysate. Powdered products may be preferred over oils, however, due to the difficulty of blending oil with formula and the tendency of the oil to adhere to feeding bottles and feeding tubes. Increasing the caloric density of powdered formulas by concentration (i.e., adding more formula powder or liquid concentrate and less water) is typically not recommended because of the accompanying increase in sodium, potassium, and phosphorus concentrations. If concentration of feeds or if dietary supplements are required, they should be introduced in a gradual manner to optimize acceptance and tolerance. Increases in energy density of 2–4 kcal/oz. are generally better tolerated than larger increases.

If using adult formulas, clinicians should evaluate the protein and electrolyte content of the formula to ensure its safety and appropriateness based on the child's age and weight. Serum magnesium levels require monitoring when using adult renal formulas because their magnesium content is significantly higher than breast milk, infant and pediatric formulas. The acceptance of these products can be improved by mixing them with fruit, and/or ice to make shakes or slush-type drinks.

For children undergoing PD, energy contribution resulting from glucose absorption from peritoneal dialysate solutions may provide an additional 8–26 kcal/kg [2]. The amount of glu-

cose absorbed can vary depending on the mode of dialysis (time on dialysis, cycles and dwell times), the glucose concentration of the dialysate and the characteristics of the peritoneal membrane [3, 5] For underweight children on PD therapy, clinicians need not calculate the calories absorbed from dialysate as this might compromise the nutritional quality of the diet. These calories should be considered as "bonus" calories to help promote weight gain. However, for children on PD who are exceeding weight gain goals, it may be important to take the estimated calorie contribution from PD fluid into account.

Infant, Pediatric and Adult Renal Formula Options

Formula	Distributed by	Used for
Similac PM 60/40®	Abbott Laboratories, Chicago, IL, USA	Infant formula for infants requiring low renal solute load, low electrolyte formula Can be used alone or to supplement breast milk Can be used in combination with other formulas to achieve desired mineral and electrolyte balance
RenaStart®	Vitaflo, USA	Intended for children ages 1 and up For children requiring formula low in protein, calcium, chloride, potassium, phosphorus and vitamin A Can be used in combination with other formulas to achieve desired mineral and electrolyte balance Not intended for use as a sole source of nutrition
Suplena®	Abbott Nutrition	Calorie dense adult nutrition supplement for patients with potassium and phosphorus restrictions
Nepro®	Abbott nutrition	Calorie dense adult nutrition supplement for patients with potassium and phosphorus restrictions who require additional protein
NovaSource Renal®	Nestle nutrition	Calorie dense adult nutrition supplement for patients with potassium and phosphorus restrictions
Renalcal®	Nestle nutrition	Calorie dense adult nutrition supplement for patients requiring minimal additional electrolytes and minerals. Can be used in combination with other formulas to achieve desired mineral and electrolyte balance Not intended for use as a soul source of nutrition

Despite efforts to provide adequate calories through oral nutrition supplementation and formula concentration, many factors such as gastroesophageal reflux, vomiting, medication taste, uremia and thirst for large volumes of water due to polyuria can contribute to inadequate oral intake and poor weight gain. For children who are not able to meet their nutrition requirements orally, enteral feeding is recommended.

Enteral Feeding

Nasogastric, gastrostomy, gastrojejunostomy, and jejunostomy tubes have all been used successfully to provide additional nutrition, fluids and/or medications by intermittent bolus or continuous infusion. Nasogastric tubes are a good option for short-term enteral feeding or may be used as a bridge until a long-term tube can be placed, but they are not recommended for long-term use as they are associated with an increase in emesis. Although oral feeding is preferred when possible, tube feeding should be considered for children who are unable to meet their energy needs despite dietary intervention and who are underweight and/or growth delayed. In addition to the benefits of promoting weight gain and growth, enteral feeding can help relieve the stress that many caregivers experience when efforts to provide adequate oral nutrition are failing. If oral intake is limited or absent and enteral feeding is provided, oral stimulation is encouraged in order to promote

development of feeding skills and prevent the development of food aversion [1]. Oral stimulation and nonnutritive sucking opportunities should be provided to infants who are completely dependent on tube feeding to help smooth their transition to oral feeding after successful transplantation. Limiting practice with oral feeding can have a significant negative impact on oral motor skill development. Occupational therapists or speech therapists are central in facilitating the development and strengthening of oral feeding skills and preventing or extinguishing oral aversion. Using a multidisciplinary approach, the prospects for a transition to oral feeding post-transplant are good. Even if oral intake improves after transplant, some children will benefit from retaining the G-tube to help ensure adequate hydration and adherence to recommended medications.

The choices of formula and feeding plan are guided by age, serum chemistries, gastrointestinal function, and fluid allowance. In addition, caregiver related factors, including the ability of caregivers to mix and measure formula recipes and financial barriers to accessing ingredients, must be considered. Feedings are initiated and advanced according to pediatric guidelines and tolerance [29]. Volumes and rates that are based on body weight help to avoid intolerance in patients who are underweight or small for their age**.** Whenever possible, the volume of feeds should be minimized to optimize tolerance and keep the hours of feeding manageable within the child's daily schedule. Infants should be given intermittent bolus feeds to maintain normal blood sugars. Continuous overnight feeds are generally avoided for infants due to an increased risk of aspiration resulting from vomiting and gastroesophageal reflux associated with uremia. Continuous feedings may be required if the patient's tolerance of bolus feedings is poor. Continuous overnight feeds are generally preferred for children and adolescents to facilitate daytime hunger and optimize oral intake. Reported complications of enteral feeding include tube blockage, tube displacement emesis, leakage around the gastrostomy exit site, skin irritation and itching, exit site infection, hemorrhage and peritonitis [30], When vomiting and gastroesophageal reflux are not responsive to medical therapy, jejunal feeding or a fundoplication may be warranted. To decrease the risk of peritonitis, the placement of gastrostomy, gastrojejunostomy, and jejunostomy tubes should occur before or concomitant with insertion of a PD catheter, whenever possible [31–33]. In particular, percutaneous endoscopic gastrostomy insertion after PD initiation carries a high risk for fungal peritonitis and potential PD failure. Suggested precautions for lowering the risk of peritonitis include antibiotic and antifungal prophylaxis, withholding PD for 2–3 days, and gastrostomy placement by an experienced endoscopy team [9, 33].

Age	Initial hourly infusion	Daily increases	Goal
Continuous feedings			
0–1 year	10–20 mL/h or 1–2 mL/kg/h	5–10 mL/8 h or 1 mL/kg/h	21–54 mL/h or 6 mL/kg/h
1–6 years	20–30 mL/h or 2–3 mL/kg/h	10–15 mL/8 h or 1 mL/kg/h	71–92 mL/h or 4–5 mL/kg/h
6–14 years	30–40 mL/h or 1 mL/kg/h	15–20 mL/8 h or 0.5 mL/kg/h	108–130 mL/h or 3–4 mL/kg/h
>14 years	50 mL/h or 0.5–1 mL/kg/h	25 mL/8 h or 0.4–0.5 mL/kg/h	125 mL/h
Bolus feedings			
0–1 year	60–80 mL every 4 h or 10–15 mL/kg/feed	20–40 mL every 4 h	80–240 mL every 4 h or 20–30 mL/kg/feed
1–6 years	80–120 mL every 4 h or 5–10 mL/kg/feed	40–60 mL every 4 h	280–375 mL every 4 h or 15–20 mL/kg/feed
6–14 years	120–160 mL every 4 h or 3–5 mL/kg/feed	60–80 mL every 4 h	430–520 mL every 4 h or 10–20 mL/kg/feed
>14 years	200 mL every 4 h or 3 mL/kg/feed	100 mL every 4 h	500 mL every 4 h or 10 mL/kg/feed

Parenteral Nutrition

When oral and/or enteral nutrition intake is not sufficient or not tolerated, parenteral nutrition (PN) may be necessary to provide adequate nutrition. When delivering PN in fluid restricted patients, concentrated solutions of amino acids, dextrose, and lipids are required. Energy requirements during PN are 10% lower than enteral requirements because there is no thermal effect of feeding. Standard amino acid solutions (i.e., both essential and nonessential amino acids) are generally used and provided according to daily enteral protein recommendations specific to the child's age and renal replacement therapy. Amino acids, dextrose, and lipids can be advanced according to normal pediatric PN guidelines and serum urea, glucose, and triglyceride concentrations should be monitored. Mineral and electrolyte content should be adjusted to maintain acceptable serum concentrations, and acetate and chloride content should be adjusted to maintain normal acid-base balance. Standard pediatric dosages of parenteral multivitamins and trace elements can be used; the risk of toxicity, especially for vitamin A, is minimal with a daily injectable multivitamin provided that the child has no other exogenous source of vitamin A (i.e., oral diet is minimal).

Intradialytic Parenteral Nutrition (IDPN)

Intradialytic PN (IDPN) is a non-invasive method of delivering supplemental nutrition to malnourished patients on HD. It can be delivered using the HD access during treatments, allowing the volume of fluid to be removed through ultrafiltration. The KDOQI guidelines recommend a trial of IDPN for children receiving maintenance HD who are unable to meet their nutritional requirements through oral or enteral feeding [1]. IDPN is only supplemental and cannot be used as a sole source of nutrition, but it can be used to augment inadequate oral and/or enteral intake in malnourished children. It can provide a significant amount of protein, but will only meet a small percentage of overall caloric needs [34].

There have been several studies of IDPN use in children. Goldstein et al. demonstrated that IDPN could reverse weight loss and promote weight gain within 6 weeks of its initiation in three teenage patients who had experienced a $\geq$ 10% weight loss over a 3 month period [35]. In this study, IDPN provided 40% of the weekly prescribed protein intake. Orellana et al. examined IDPN in teenaged patients who had lost 10% of their body weight in a 3 month period and were below 90% of their ideal body weight [36]. Of the nine patients studied, seven patients who had organic illness demonstrated an improvement of weight or BMI during the first 5 months of IDPN therapy. The other two patients had psychosocial associated malnutrition and did not demonstrate similar improvement of weight or BMI. The lack of weight gain in these patients was postulated to be due to issues such as depression or inadequate access to food after initiation of IDPN, which may have limited their ability to improve their oral or enteral intake [37].

The optimal composition of IDPN has not been defined, but it is typically designed to provide amino acids in amounts to meet the estimated daily protein needs along with dextrose and 20% or 30% lipid components to increase calorie provision [1]. The goal infusion rate provides optimal caloric intake while avoiding hyperglycemia and hyperlipidemia. It is important to monitor for hyperglycemia, hypokalemia, hypophosphatemia and hyperlipidemia. It has been suggested to limit the glucose infusion rate to $\leq$9 mg/kg/min. This can help minimize hyperglycemia and prevent refeeding syndrome. Lipid infusions should be limited to no more than 1–2 g/kg/day, starting as low as 0.5 g/kg/day. It is recommended to hold or reduce intralipid (IL) infusions if triglycerides exceed 250 mg/dL [34]. It is also important to be aware of the additional fluid contribution in patients who routinely present with fluid overload between dialysis treatments. As critics of PN, Dudley et al. point to potential problems such as disorders of glucose homeostasis, acid-base, fluid and electrolyte disturbances, impaired renal function, metabolic bone disease and nephrolithiasis. They state that IDPN is not more beneficial than enteral supplements in patients who are compliant with supplementation and have adequate intestinal function.

They do, however, recommend a minimum 3 month trial of IDPN for malnourished children on HD in whom enteral support has not demonstrated benefits or is not viable [38]. Although IDPN is costly, it is recommended for patients who have experienced a weight loss of >10% for three consecutive months and who are below 90% of their ideal body weight (or who have a BMI for height age that is below the fifth percentile) and who have not responded to oral and/or enteral supplementation [1, 34, 37].

The use of IL infusion alone has been studied in children receiving HD as a method of sparing protein degradation and supporting positive nitrogen balance. Hasken et al. found that the provision of 0.5–1 gram/kg IL therapy during each dialysis session could contribute to improvements in serum albumin, predialysis BUN, and nPCR in malnourished pediatric HD patients [39]. The cohort exhibited a 5% weight gain without any changes in cholesterol or triglyceride levels. One benefit from this approach is a reduction in cost compared to delivering full IDPN.

Limiting Energy Intake

Increased appetite and excessive energy intake are common in children treated with high-dose corticosteroid therapy for conditions such as nephrotic syndrome, vasculitis, and renal transplantation. Children and caregivers should receive early education about the potential for overweight and obesity and be provided with strategies for controlling caloric intake, optimizing dietary balance and increasing physical activity to maintain a healthy weight. Overweight is sometimes seen in infants and children on PD as a result of significant dialysate glucose absorption, which is usually greater in young infants because of the enhanced permeability of their peritoneal membrane for small molecules. To help control weight gain in these patients, dialysate calories should be considered when estimating energy intake. Icodextrin dialysate, which contains a poorly absorbed, high-molecular-weight, starch-derived glucose polymer to provide the osmotic force for ultrafiltration, can be used to lower the caloric load without sacrificing clearance of metabolic waste or fluid removal.

Protein

Protein Requirements

Children need to be in positive nitrogen balance to support growth. Along with providing adequate protein, the diet must also provide adequate non-protein calories from fats and carbohydrates in order to prevent protein from being utilized to meet energy needs. It is also critical that the correct balance of amino acids be provided. The PRNT suggests a range for the SDI for protein that is designed to represent the daily amount of protein considered to meet the needs for 97.5% of the population (see Table 58.1) [3]. They suggest that the target for protein intake should be at the upper end of the SDI in order to support optimal growth. The lower end of the SDI is considered to be the minimum safe intake. Children treated with HD or PD may need to have protein intakes above the SDI in order to compensate for protein losses into the dialysate. During periods of peritonitis, there may be an increase in peritoneal protein losses that necessitates a further increase in protein intake. Protein needs may increase due to proteinuria, glucocorticoids, acidosis, other infections and catabolism. In contrast, children who have a persistently high BUN level that is believed to be associated with dietary intake may need their protein intake adjusted towards the lower end of the SDI. If protein intake is excessive, patients may experience increased accumulation of nitrogenous waste products and increased symptoms of uremia. For children following a lacto-ovo vegetarian or vegan diet, it is recommended that the SDI be increased by a factor of 1.2 (lacto-ovo vegetarian) to 1.3 (vegan) to compensate for the lower bioavailability of non-animal protein. The restriction of dietary protein in the early stages of CKD is not recommended as it may increase the risk of malnutrition, protein-energy wasting and poor growth. A high intake of protein may also be detrimental to health as it may negatively impact acid-base balance and urea levels as well as increase phosphorus intake [3]. During the immediate post-transplant period, protein needs are increased by approximately 50% in association with surgical stress and the catabolic effects of

steroids. Needs are decreased back to normal recommendations approximately 3 months after transplantation [1].

Modifying Dietary Protein Intake

Despite anorexia and decreased appetite, voluntary protein intake usually exceeds recommendations, which can be acceptable as long as serum urea and phosphate levels are within acceptable limits. Occasionally, protein intake may be inadequate as a result of anorexia, oral-motor problems, low meat intake, or a low phosphorus diet that limits protein-rich dairy foods. Persistently low urea levels (i.e., <50 mg/dL or <18 mmol/L) may be a sign of overall inadequate protein and caloric intake in children receiving dialysis. KDOQI guidelines recommend the use of protein supplements to augment poor oral and/or enteral protein intake [1]. Powdered protein modules (see Table 58.2) can be added to expressed breast milk, infant formula, beverages, pureed foods, cereals, or other moist foods to boost their protein content. Minced or chopped meat, chicken, fish, egg, tofu, or skim milk powder can be added to soups, pasta, or casseroles. High levels of phosphorus often accompany high protein diets and this should be considered when making efforts to increase dietary protein content. Renal nutrition supplements that are rich in protein can also be given orally or enterally to increase protein intake.

Carbohydrates

Prescribed oral, enteral and/or parenteral diets for children with CKD should include a balance of calories from carbohydrates and unsaturated fats within the physiological ranges recommended as the acceptable macronutrient distribution ranges of the DRI [5]. Recommended carbohydrate intake should account for 45–65% of total daily caloric intake, with less than 10% coming from added sugars. In addition, children on PD may receive up to an additional 8 ± 2.8 calories/kg/day from absorption of intraperitoneal dextrose [40, 41]. Diets with excess simple carbohydrates or fats may lead to potential increased risk of chronic diseases such as coronary heart disease, obesity and diabetes. Cardiovascular disease (CVD) is the leading cause of morbidity and death in children with CKD. After transplantation, glucocorticosteroids and immunosuppressive agents such as tacrolimus may cause impaired glucose tolerance, glycosuria, and a relative resistance to insulin that may lead to diabetes. The management of children who have or who develop diabetes should follow the recommendations of the American Diabetes Association, including the avoidance of simple carbohydrates, weight control, and physical activity [42].

Table 58.2 Examples of modular protein additives

Beneprotein powder	Nestle nutrition	Contains 6 g of protein, 25 kcal per 7 g scoop
Complete amino acid mix	Nutricia	Contains 7.8 g protein, 31 kcal per TBSP
Liquid protein fortifier	Abbott nutrition	Contains 1 g protein, 4 kcal per 6 mL

Fiber

Obtaining an adequate intake of dietary fiber has traditionally been difficult for patients following a renal diet, but with a shift towards recommending fewer processed and packaged foods, and more whole and plant-based foods, it is easier to include fiber in the diet of children with CKD. Among the benefits of consuming adequate dietary fiber are the reduction of constipation and improvement of hypercholesterolemia with a reduction in total and LDL cholesterol levels as well as a decrease in overall risk of CVD. Recent literature has promoted the benefits of dietary fiber in improving the composition and metabolism of gut microbiota, which has been linked in adults with reducing obesity, diabetes and dyslipidemia [43]. An increased intake of high fiber foods may require an increase in the use of phosphate or potassium binders or an adjustment of the potassium content of the dialysate, but it is important to avoid restricting fiber for the sole purpose of controlling labs. For children who have difficulty meeting their fiber needs from food, fiber supplements can be used to increase fiber intake; however, care should be

taken to ensure that these supplements do not contain potassium. For patients following a fluid restriction, fiber intake may need to be limited to prevent the hardening of stools and subsequent constipation.

Fat

Dietary fat is an important source of calories for growing children, but high fat diets are also associated with an increased risk of CVD events, a major contributor to morbidity and mortality in patients with kidney disease. The KDOQI guidelines recommended that fat intake account for 25–35% of caloric intake in children above age 4, with slightly higher intake of 30–40% in younger children. [1] Less than 10% of fat intake should come from saturated fats. In the CKiD cohort, while overall energy intake was higher than recommended, the median percentage of caloric intake from fat was within this range [19]. Supplemental fats can be used for children with poor weight gain and fat intake can be safely restricted to the lower end of this range in circumstances of excessive weight gain of dyslipidemia.

CVD is the leading cause of death in adults with childhood onset CKD [44, 45] and dyslipidemia is one of many factors that increase the risk of CVD. Lipid metabolism is disrupted in CKD, with up to 45% of children with in the CKiD cohort having dyslipidemia and dyslipidemia is more prevalent and more severe in children with lower glomerular filtration rate (GFR) and nephrotic range proteinuria [46]. Dyslipidemia in children with CKD has not been directly associated with increased CVD events; however, higher triglyceride levels and lower LDL have been associated with increased carotid artery intima-media thickness and reduced brachial artery flow-mediated dilation, both of which are associated with atherosclerosis [47]. There is consensus that lipid profiles should be monitored annually in children with CKD and that diet and lifestyle modification is warranted for children with dyslipidemia. These modifications include increased physical activity to achieve 5 h of moderate to vigorous physical activity and increasing dietary fiber, fruit, and vegetable intake while decreasing intake of saturated and trans fats. Increased intake of monounsaturated and polyunsaturated fatty acids (e.g. oils from canola, corn, flaxseed, safflower, soy, olives, and peanuts) should be encouraged as total and LDL cholesterol are decreased with increased intake.

Because CVD events are rare, even in high-risk children, there have not been sufficient data to show a decrease in CVD risk with statin therapy in children. However, while KDOQI/KDIGO guidelines do not recommend lipid lowering pharmacotherapy for children with CKD [48], the American Heart Association (AHA) [49] recommends that children with increased risk of CVD have target triglyceride level <150 mg/dL and LDL <100 mg/dL for highest risk, which includes end-stage renal disease (ESRD), and <130 mg/dL for moderate risk, which includes CKD. The AHA recommends initiation of lipid lowering therapy if these targets cannot be achieved with 3 months of diet and lifestyle modification.

Consumption of omega-3 fatty acids (ALA, EPA, and DHA) can have beneficial effects on cardiovascular risk factors including inflammation, thrombosis, triglycerides, vascular and cardiac hemodynamics and arrhythmias [50]. Omega-3 fatty acids can be found in fatty fish such as tuna mackerel, trout, salmon, herring, sardines, and anchovies. Adequate intake of omega-3 fatty acids is 0.5 gm for children less than 1 year and rises to 1.6 g for males and 1.1 gm for non-pregnant females by age 14. Most individuals meet this level of intake through dietary ingestion, and there has not been sufficient evidence to recommend supplementation in treatment of hypertriglyceridemia.

Omega-3 fatty acid supplementation has been shown to result in modest improvement in lipid profile in children on dialysis, but there has not been convincing evidence that supplementation mitigates CV risk in adults or children with CKD [51, 52]. A recent meta-analysis of studies evaluating the effects of omega-3 polyunsaturated fats in adult patients with CKD showed a modestly reduced risk of CV events in patients on dialysis, but no benefit in regards to reduction of CV events, progression to ESRD, mortality, or graft rejection in patients with pre-dialysis CKD [53].

Potassium

The PRNT recently provided updated recommendations for management of potassium intake in children with CKD 2–5 [54], recognizing that there are limited data to support many of the recommendations. Maintenance of normal serum potassium levels depends on potassium intake, urinary potassium excretion and transcellular shifts of potassium, which can happen rapidly in response to increased potassium intake, acid-base disturbances, and insulin. Because 98% of total body potassium is intracellular, even small transcellular shifts can result in significant changes in serum potassium levels. Dyskalemias are associated with cardiac arrhythmias and muscle dysfunction and can be fatal if severe and not treated emergently. Urinary potassium excretion decreases as GFR decreases, and with the use of medications such as calcineurin inhibitors and renin-angiotensin-aldosterone inhibitors. Daily dialysis (either HD or PD) will typically provide sufficient potassium clearance to permit a diet without potassium restriction; however, children with more standard HD prescriptions or with CKD 4–5 not yet on dialysis often require dietary potassium restriction. High dietary potassium has been associated with increased mortality in adult patients on dialysis [55]. Recommendations for dietary potassium intake should target normal serum potassium levels and must account for all of these contributing factors. The KDIGO recommended potassium restriction is 30–40 mg/kg/day for older children and 40–120 mg/kg/day for younger children, but there are minimal data to support this recommendation [1].

Sources of dietary potassium intake can be difficult to identify on dietary history and bioavailability of ingested potassium varies widely. Most dietary potassium comes from breast milk, infant formula, milk, potatoes, tomatoes and other fruits and vegetables. Providers must also ask about salt substitutes, which are commonly used to avoid high sodium intake. A food is considered to have high potassium content if it contains >200 mg/serving. Restricting high potassium foods or soaking high potassium foods and rinsing them prior to ingestion reduces potassium intake. For infants or children on enteral formula, specific renal formulas with low potassium formulas can substitute for standard formula. In older children, high potassium foods such as oranges, bananas, potatoes and potato products, tomatoes and tomato products, legumes, lentils, yogurt and chocolate should be limited. Additional carbohydrate or fat additive may be required to achieve adequate caloric intake while limiting potassium intake [21]. If dietary restriction is insufficient to control elevated serum potassium levels, potassium binders such as sodium polystyrene sulfonate or patiromer can be used to prevent hyperkalemia; however, both binders have gastrointestinal side effects that must be monitored. These binders can be given orally or enterally. Alternately, fluids such as nutritional supplements and formulas can be pre-treated with the binder to reduce their potassium content. The insoluble resin is allowed to sit in the formula for 30 min and potassium is exchanged for sodium (SPS) or calcium (patiromer). The potassium-depleted formula can then be decanted from the sediment at the bottom of the container. Along with the decrease in potassium content, the decanted portion of formula may also affect concentration of other electrolytes and minerals [56, 57].

Hypokalemia occurs in children who have excessive potassium losses due to frequent dialysis or high urinary potassium excretion due to renal tubular dysfunction. Severe hypokalemia requires emergent intravenous (IV) supplementation to avoid cardiac arrhythmia. Dietary increases in potassium intake and cessation of binders is usually sufficient to correct the hypokalemia chronically.

Sodium

Recommendations for sodium intake depend on the specific cause and severity of CKD. Serum sodium cannot be used to differentiate between sodium excess and sodium depletion because it reflects water balance rather than total body sodium. For children with salt-wasting syndromes and associated polyuria, including obstructive uropathy, renal dysplasia, tubular disease, and polycystic kidney disease, urinary sodium losses commonly exceed dietary sodium intake, result-

ing in need for sodium supplementation. Conversely, for children with glomerular disease or oliguria/anuria, high sodium intake is associated with fluid overload and hypertension.

Salt restriction in adults with CKD is associated with lower blood pressure and proteinuria, both risk factors for CKD progression and CV mortality, but studies evaluating the relationship between sodium intake and those outcomes have been variable [58]. For children who are pre-hypertensive, hypertensive or edematous, restriction of daily sodium intake to 1500 mg/day for children aged 2–3 years, 1900 mg/day for children aged 4–8 years, 2200 mg/day for children aged 9–13 years and 2300 mg/day for adolescents aged ≥14 years is recommended [1]. This can be difficult to achieve, but families can start by limiting processed foods, canned foods, and fast foods, which are all high in sodium. Families should be taught to read nutritional labels and strategies to increase consumption of fresh foods that are flavorful and appealing to the child.

For children with excessive sodium losses in the urine or through PD, sodium supplementation is required to prevent sodium depletion, volume depletion, and impaired growth. Supplementation should begin with a goal of providing at least the age related DRI of sodium and chloride and can be adjusted as needed [1]. Supplements can be given separately or added to breast milk or infant formula, provided that the infant reliably receives the full volume of breast milk of formula. As infants transition to table food, dietary sodium intake increases and adjustments to sodium chloride supplementation should be made accordingly.

For patients with calcium-based kidney stone formation, decreased sodium intake has been shown to decrease urinary calcium excretion, but has not definitively been proven to reduce the risk of calcium-based stones [59].

Salt and Sugar in Hypertension

Regulation of total body sodium content is an important homeostatic mechanism for maintaining normal blood pressure—as blood pressure rises, urinary sodium excretion increases. The underlying mechanisms resulting in the presumed causal relationship between higher dietary sodium intake and higher blood pressure have not been fully described. In studies in adults, lower dietary sodium intake is associated with lower blood pressure and lower CVD risk. Higher sodium intake is associated with higher systolic blood pressure and risk for pre-hypertension and hypertension in U.S. children and adolescents [60] and reduction in sodium intake over time was temporally associated with a decreased incidence of hypertension among children participating in the NHANES study [61]. A meta-analysis of studies assessing the effect of sodium restriction for 2 weeks or longer on children with elevated blood pressure showed reduction in blood pressure on a lower sodium diet [62]. Based on these data and consistent data from adult studies [63] indicating improved outcomes at lower sodium intake, the CDC recommends that dietary intake of sodium should be restricted to 2300 mg for adults and 1500 mg for children with hypertension. Epidemiologic studies have linked fructose intake with hypertension and elevated uric acid [64]. Reduction in sugar-added beverages consumption is strongly associated with reduction in blood pressure [65]. Indeed, an important component of the DASH (dietary approaches to stop hypertension) diet is limitation of added sugar (fructose).

Fluid Intake

Similar to sodium intake, recommendations for target daily fluid intake should be adjusted based on the child's clinical condition, taking into account the underlying cause of CKD, the volume of urine output, the GFR, and the presence of edema and hypertension. Infants and children with polyuria due to nephrogenic diabetes insipidus or salt losing nephropathy, typically have high obligatory fluid output and require high fluid intake to prevent chronic dehydration, malaise, and poor growth. High fluid intake may also be recommended for children with nephrolithiasis or urinary tract infections to prevent recurrence. There is currently a study underway to evaluate the potential benefit of prescribed increase in fluid intake on progression of renal disease in adult patients with autosomal dominant polycystic kid-

ney disease [66]. After kidney transplantation, high fluid intake is prescribed to maintain adequate perfusion of the transplanted kidney, to replace high urine volume, and regulate intravascular volume. For all of these conditions, water and calorie free fluids are encouraged to prevent excessive weight gain and hyperglycemia.

Once CKD progresses to oliguria or anuria, fluid limitation is often required to avoid fluid overload, hypertension, and subsequent cardiac, cerebrovascular, renal and respiratory complications. Children on PD may not need fluid restriction because higher glucose concentration dialysates can increase ultrafiltration to maintain euvolemia. Fluid limits are more often needed for patients on HD to limit interdialytic fluid gain to less than 5% of dry weight between dialysis sessions. The prescribed total fluid intake is based on insensible fluid losses, urine output, ultrafiltration capacity, other losses, and current amount of fluid overload. Insensible water losses for children and adolescents are 20 mL/kg/day or 400 mL/m^2 with maximum estimates of 800 mL/day in adults [1], and can be 1.5–2 times higher in neonates and preterm infants. In anuric children, fluid intake above this threshold can lead to hypervolemia. Higher interdialytic weight gain is associated with higher blood pressure and left ventricular mass index in children on dialysis [67] and higher ultrafiltration rates is associated with increased mortality for adults on HD [68]. These data emphasize the importance of fluid restriction between dialysis treatments.

Limiting fluid intake can be difficult for children and their families and requires careful education about reducing sodium intake and about the water content of many fruits and vegetables.

Calcium and Phosphorous

Calcium and Phosphorous Intake

Appropriate calcium and phosphorous management is critical to maintaining normal bone health and growth while reducing the risk of extraosseous calcification in the kidneys and vascular system. Elevated serum phosphorus levels occur early in CKD and can lead to elevated levels of parathyroid hormone (PTH) and FGF23, which are associated with high bone turnover calcium deposition in organs and arteries. The PNRT and KDOQI recommend daily intake of calcium and phosphorous within age adjusted ranges for healthy children, with a goal of maintaining normal serum calcium and phosphorous levels [68]. Periodic food frequency questionnaires and/or a 3-day food diary can be used to assess dietary phosphorous intake in children with CKD. Absorption of calcium and phosphate varies by food source and vitamin D status.

Calcium

Children have higher calcium requirements than adults due to increasing skeletal mass, particularly during the periods of most rapid growth including infancy and puberty. Suggested dietary intake of calcium, including from dietary and calcium based phosphate binders, should be 1–2 times the standard daily intaking, ranging from 220 mg/day in infancy to 1300 mg/day in adolescence [69]. Most dietary calcium comes from breast milk, formula, cow's milk, other dairy products and cereals. Absorption of calcium is affected by bioavailability. Abnormal bone mineralization is seen at all stages of CKD, with increasing frequency at lower GFR [70, 71]. Increased calcium intake in childhood is associated with increased bone density [72–74] and phosphate binder usage (primarily calcium containing), was found to be protective for incident fracture in the CKiD cohort [71].

Patients with insufficient calcium intake should be encouraged to consume food with high endogenous calcium content (such as dairy products) as well as calcium-fortified foods. This must be balanced with the goal of limiting phosphorous intake, which is also high in many dairy products. If dietary intake alone cannot meet the SDI, calcium supplementation should be recommended, and should be taken between meals to maximize absorption. Salts of calcium such as calcium gluconate, lactate, acetate, or carbonate are usually well tolerated by children and can be given in doses of less than 500 mg at a time to optimize absorption. Calcium chloride should not be used to supplement patients with CKD as it may cause metabolic acidosis, and calcium

citrate should be avoided due to concerns for increased aluminum absorption [1].

Serum calcium should be maintained in the normal range for age. When hypocalcemia is present, vitamin D supplementation should also be considered to increase intestinal calcium absorption, as low vitamin D levels impair calcium absorption [75]. Patients with hypocalcemia and persistently elevated PTH levels may require calcium intake above the 200% SDI upper limit, and this should be monitored closely to avoid hypercalcemia. Hypercalcemia should also be avoided as it can lead to extraosseous calcification. In general, mild to moderate hypercalcemia can be treated with serial reduction in calcium supplementation, calcium-based phosphate binders, and vitamin D supplements. A variety of calcium-free phosphorous binders (i.e. sevelamer) are available as substitutes. In addition, synthetic vitamin D analogues such as paricalcitol and doxercalciferol may have less hypercalcemic effect. For patients on HD or PD, dialysate calcium content can be decreased.

After transplantation, glucocorticoid therapy can induce osteoporosis; therefore, calcium supplementation may be needed for children who are unable to meet the SDI for calcium through dietary intake alone.

Phosphorous

Elevated serum phosphorous levels occur relatively early in CKD progression due to decreased urinary phosphorous excretion. This stimulates higher levels of the phosphaturic hormones PTH and FGF-23, which results in high bone turnover with bone calcium loss. This leads to calcium deposition in organs and small vessels.

Targeting a normal serum phosphorous for age and decreasing dietary phosphorous intake, even prior to onset of hyperphosphatemia, can help prevent both elevated serum phosphorous and PTH levels. Dietary phosphorous intake should be limited to the SDI for age starting early in CKD, with more strict limitations to the lower limit of SDI as CKD progresses, or in the setting of ongoing hyperphosphatemia or hyperparathyroidism [69]. For infants and formula fed children, whey based infant formulas and specific renal formulas with low phosphorous content can be used to reduce phosphorous intake. For children who are not formula fed, attention to sources of dietary phosphorous is particularly important, as intestinal phosphate absorption is affected by the source of phosphorous. Inorganic dietary phosphorous, found in processed foods, has much higher absorption (up to 100%) compared to phosphorous found in meats, fish, dairy, vegetables, and other plant-based foods.

For many children, dietary restriction is insufficient to control serum phosphate levels, and mealtime phosphate binders are required to impair intestinal phosphorous absorption to achieve normal serum phosphorous levels. Calcium-based binders (calcium carbonate and calcium acetate) are preferred in infants and young children due to their higher calcium requirements. Non-calcium based binders (e.g. sevelamer carbonate) can be added if calcium based binders are insufficient to achieve normal phosphorous levels. Sevelamer carbonate may also be used to pre-treat breast milk, infant formula or cow's milk in order to reduce phosphate content [76].

Despite the importance of normalization of serum phosphorous, achieving control of serum phosphorous levels is particularly challenging. For example, the majority of subjects in the CKiD study ingest more phosphorous than recommended, especially in the younger age group [19].

For children with renal tubular disorders and associated urinary phosphorous wasting or those with intensified dialysis regimens resulting in hypophosphatemia, phosphorous supplementation is often required as hypophosphatemia is associated with morbidity, mortality, and poor growth.

Acid Load

Progressive renal dysfunction resulting in decreased urinary ammonia excretion despite stable acid generation leads to increased prevalence of acidosis in children with impaired renal function. In the CkiD cohort, 25% of children with CKD had serum bicarbonate <22 mEq/L [77]. Children with tubular dysfunction from dysplasia or inherited tubular defects are at higher

risk for acidosis. In the 4C cohort, 43–60% of children had serum bicarbonate <22 mmol/L [78]. Normalization of acid-base status in children with glomerular disease has been associated with reduced progression of kidney disease [79]. While dietary acid load is more difficult to quantify, increased urinary acid excretion, a correlate of dietary acid intake, has been associated with CKD progression and hypertension in small pediatric studies [80, 81]. Reducing dietary acid load by increasing intake of fruits and vegetables may improve acidosis, minimize requirement for alkali supplementation, and slow kidney disease progression.

Vitamins, Minerals and Trace Elements

Children with CKD and ESRD are at increased risk for vitamin and mineral deficiencies due to multiple nutritional factors, including anorexia, poor intake, dietary restrictions, abnormal renal metabolism, drug-nutrient interactions, and poor intestinal absorption. In addition, there are concerns about potential losses of water-soluble vitamins during dialysis. Thiamine (B1), pyridoxine (B6), folate (B9), and vitamin C are all small to middle-sized molecules that are easily cleared on HD. PD is thought to result in less diffusive clearance of these molecules, but higher protein losses may result in greater losses of protein bound vitamins and trace elements [82]. A recent study of adults on thrice weekly HD and typical doses of vitamin B and C supplementation (given after dialysis), showed that almost all patients had high vitamin B levels at baseline, while over 80% of patients had normal vitamin C levels. When the dose of supplementation was reduced by 50%, vitamin B levels generally stayed normal; however, there were significant losses of B vitamins into the dialysate effluent [83]. While vitamin C clearance during dialysis is hypothesized, no difference in vitamin C levels over time were seen in adult patients receiving three times weekly versus six times weekly in the Frequent Hemodialysis Network Study [84]. Children with protein energy malnutrition may be particularly susceptible to thiamine deficiency because it is extensively protein bound.

Current practice, consistent with KDOQI guidelines, is to provide vitamin and trace element supplementation for children on dialysis to achieve DRI for healthy children, with the goal of avoiding complications of vitamin insufficiencies. There are minimal pediatric data available to support this recommendation [82]. Thiamine deficiency is rare in children, but can lead to severe lactic acidosis and neurologic complications in the acute phase; therefore, supplementation to avoid deficiency is recommended [82]. Folate (B9), pyridoxine (B6), and cobalamin (B12) supplementation may mitigate hyperhomocysteinemia, which potentially reduces cardiovascular risk [85]. In addition, folate deficiency can result in erythropoietin resistant anemia that can be corrected with supplementation [86].

Vitamin C is thought to be low in patients with CKD due to decreased intake to accommodate low potassium and low oxalate diets, low dose vitamin C supplementation due to concern for conversion to oxalate, and clearance of vitamin C during dialysis. Scurvy has been reported in a pediatric PD patient.

There are no pediatric renal vitamins available in the US. Adult B and C vitamin formulations can be used in older children and adolescent patients. Younger children can be prescribed liquid adult vitamins or can be offered split doses of adult renal vitamins or every other day dosing. These preparations contain no more that 6–100 mg of vitamin C to avoid oxalate retention.

Trace Elements

Trace elements are important components of many enzymatic pathways and proteins. Deficiencies of these micronutrients may have major adverse effects in growing children. Dialysis can lead to the accumulation of trace elements either because of insufficient elimination or because of contamination. It can alternately lead to excessive removal of trace elements. Zinc and selenium contents vary by formula type and, for breast-fed infants, are largely determined by maternal diet [82].

Low dietary intake of copper has been noted in children receiving dialysis and the KDOQI

guidelines recommend monitoring intake every 4–6 months [1]. Copper deficiency can cause anemia and neutropenia. Clinical signs of copper overload should also be assessed, as excess copper is associated with CKD [1].

Selenium acts as a cofactor for oxidation and reduction enzymes such as glutathione peroxidase. Low serum selenium levels have been found in patients with CKD and those receiving dialysis, although it is not removed by dialysis. Selenium depletion appears most likely in critically ill patients on continuous renal replacement therapy.

Zinc deficiency is relatively common in adult dialysis patients, resulting from poor dietary intake and removal by HD because it is not protein bound [82]. Zinc deficiency can present as failure to thrive, dermatitis, and inflammatory disease in children. Monitoring of trace elements in dialysis may be warranted, but there are no specific recommendations for children.

Supplemental oral or IV iron is usually required by all children on erythropoietin-stimulating agents to avoid depletion of iron stores and to maintain target hemoglobin concentrations. Current KDIGO guidelines recommend iron administration during erythropoietin therapy to maintain transferrin saturation greater than 20% and serum ferritin greater than 100 ng/mL to ensure adequate iron stores [87]. Iron stores in patients with kidney disease may be depleted by frequent blood draws and chronic blood loss in the gastrointestinal tract and HD circuit. In addition, iron metabolism is disrupted in patients with advanced CKD and other chronic inflammatory conditions due to increased levels of the regulatory protein hepcidin. Hepcidin prevents duodenal iron absorption and movement of iron into the circulation, making iron unavailable for erythropoiesis. This is thought to explain resistance to enteral iron supplementation for patients with CKD.

Enteral or parenteral iron supplementation are options. Oral supplementation at a dose of 3–6 mg/kg of elemental iron daily is often successful, particularly for patients with lower serum ferritin levels and who are earlier in their CKD course. For patients with significant iron losses on dialysis and with hepcidin mediated iron deficiency (i.e. those with normal or high ferritin levels), IV iron supplementation is preferred. There are several formulations of intravenous iron available, with the more recently developed formulations less likely to result in hypotension [88]. IV iron can be given as a loading dose with serial infusions or as maintenance therapy on a weekly to monthly basis depending on patient need. There are limited data on the use of IV iron in children with CKD and ESRD. Studies including adults on HD, demonstrated higher dose IV iron supplementation was non-inferior, with a statistical trend towards superiority for a composite endpoint of mortality and cardiovascular morbidity ascribed to lower exogenous erythropoietin dose [89]. In this population, higher dose IV iron supplementation was also found to be safe, without an increased risk of infection [90].

Vitamin D

Vitamin D is obtained from the diet (D2, ergocalciferol) and exposure to ultraviolet light (D3, cholecalciferol). The liver hydroxylates the vitamin D precursors to form 25-hydroxy vitamin D (25[OH]D). A second hydroxylation occurs in the kidney, leading to the formation of 1,25 dihydroxyvitamin D (1,25(OH)2D), calcitriol). Calcitriol regulates intestinal calcium absorption, bone resorption and renal excretion of phosphate and calcium. As GFR declines, plasma concentrations of calcitriol decrease. This leads to a decrease in intestinal calcium absorption and reduced renal phosphate excretion. The result is hypocalcemia and hyperphosphatemia, which stimulate PTH and FGF-23 secretion, leading to mineral bone disorder.

Clinical practice guidelines focused on optimizing bone health in children with CKD recommend defining sufficient 25[OH]D levels as >75 nmol/L (>30 ng/mL) and supplementation with vitamin D (cholecalciferol or ergocalciferol) for children with CKD who have levels below this threshold [90]. This is based on data demonstrating that children with CKD who were treated with ergocalciferol have longer time prior to developing hyperparathyroidism [91]. In addition, Stein et al. [92] reported 100 pediatric CKD patients and

found a high prevalence of hyperparathyroidism early in CKD which was associated with lower 25[OH]D levels, independent of calcitriol level. There may also be a relationship between vitamin D deficiency in CKD and CVD as measured by arterial stiffness and LVMI [93, 94].

Low 25[OH]D levels have been documented in patients with nephrotic syndrome and can be at least partially attributed to loss of vitamin D binding proteins in the urine. Supplementation with vitamin D3 in 43 children with nephrotic syndrome showed improved 25[OH]D vitamin D level. There was no change in bone mineral content or bone mineral density at 6 months [95]. There is a risk of nephrocalcinosis and urolithiasis with excess vitamin D supplementation, so levels should be monitored periodically.

For children with PTH elevated above target range for CKD stage, treatment with vitamin D analogs such as calcitriol [96] reduce PTH levels; however, the effect on bone outcomes including, fracture and growth is less clear. Daily calcitriol, at the lowest effective dose, with monitoring for hypercalcemia, is recommended.

Other Fat-Soluble Vitamins

Vitamin A is best known for its effects on vision. Vitamin A toxicity can cause dry skin, pruritus, weight loss, anorexia, taste disturbances, bone and joint pain, hypercalcemia, and neuropsychiatric symptoms [97]. Vitamin A is not removed by dialysis and patients with CKD and ESRD have been found to exhibit elevated serum levels without supplementation [1]. The total intake for vitamin A should be limited to the DRI and supplementation should only be used in patients with very low dietary intake. Vitamin K and E, the other primary fat soluble vitamins, are not removed by dialysis and intake should be limited to the DRI to avoid toxicity, which is less common for these fat soluble vitamins than for vitamin A.

Transplantation

When caring for children after kidney transplantation, it is important to view the post-transplant period as a dynamic phase of CKD. Factors such as electrolyte balance, linear growth, and weight gain remain important components of nutrition assessment. The primary goal of medical nutrition therapy post kidney transplant is to promote optimal nutrition status while helping patients offset or minimize the side effects of immunosuppressive medications. These side effects may include protein catabolism, hypertension, hyperglycemia, hyperkalemia, dyslipidemias, hypophosphatemia, hypomagnesemia, osteoporosis, increased infection risk and gastrointestinal disturbances. Patients should be closely monitored for changes in kidney function resulting from recurrence of disease, rejection episodes, lapses in taking medication, and gradual decline in graft function.

Immediately post-transplant, patients may require restrictions of sodium, potassium, phosphorus and/or fluid until full graft function is established. Assuming the kidney is functioning well, a balanced, heart healthy diet is recommended. Intake of saturated, trans-fats and sodium should be limited, although some toddlers may require sodium supplementation. For children receiving tube feeds, formula can typically be changed to a standard pediatric variety. Energy needs should be established based on age and gender, starting at 100% estimated energy requirement and adjusting for activity and body size [1]. Protein needs are increased for the first 3 months post-transplant to allow for healing of the surgical site. Subsequently, needs should be based on DRI or recommended daily allowance for age and gender.

Hydration is critical after transplant to ensure adequate perfusion of the graft. For infants and toddlers, 2500 mL/ 1.0 m^2 body surface area is recommended. For older children and adolescents, 1.5–4 L/day may be required [98]. Sugar-free, caffeine-free beverages should be encouraged. It is important to educate patients and families on strategies for ensuring that fluid goals are met. Cell phone apps, water bottles, watch alarms or incentive charts may all be helpful in reminding patients to drink throughout the day. Tube fed patients who are able to transition successfully to taking nutrition orally may continue to require the g-tube in order to meet fluid goals.

Children will benefit from a nutrition assessment to evaluate if their diets are balanced. Children who lack variety in their diets should be encouraged to take a daily multivitamin. Phosphorus and magnesium supplementation are often required immediately post-transplant as these minerals are often wasted in the urine. Calcium intake should be evaluated, and supplements should be encouraged if dietary intake is poor, particularly for children taking corticosteroids as part of their immunosuppressive protocol. Vitamin D levels should be evaluated routinely as supplementation should be provided if insufficiency or deficiency is present.

Weight management can be particularly difficult for children who are taking steroids as part of their post-transplant immunosuppressive regimen. The steroid-induced increase in appetite along with the liberalization of diet restrictions that may have been present prior to transplant can lead to rapid weight gain and obesity. Education on diet and lifestyle modification should be provided and repeated in order to help prevent this outcome.

Food safety and hygiene are important in order to prevent food borne illness in this immunosuppressed population. Families should be specifically instructed about washing hands and food preparation surfaces, separating foods to avoid cross-contamination, prompt refrigeration of foods and heating foods to the proper temperatures to kill pathogens. Additionally, foods such as grapefruit and pomegranate should be avoided because they can alter the absorption of certain medications, including some immunosuppressants and calcium-channel blockers.

Potential side effects of common transplant medications	Nutrition therapy
HTN/edema	Low-sodium diet
Hypotension	Encourage increased fluid intake, sodium if appropriate
Hyperkalemia/ hypomagnesemia/ hypophosphatemia	Adjust mineral intake with diet and/or with supplementation
Hyperglycemia	Carbohydrate control/ Insulin
Diarrhea/constipation	Add fiber/fluid/physical activity Polyethylene glycol/Docusate Sodium prescribed when needed
Nausea/vomiting	Small frequent meals/ medication if needed
Anemia	Supplement with iron
Growth suppression	Ensure adequate intake of protein, calories Growth hormone may be warranted but is typically note used within the first year post transplant
Osteoporosis	Calcium/Vitamin D, weight bearing exercise
Increased appetite	Calorie control, exercise
Hyperlipidemia	Low fat diet, exercise, Omega-3 supplementation
Anorexia	Small frequent meals

Larry A. Greenbaum

Abbreviations

CKD	Chronic kidney disease
CRP	C-reactive protein
DA	Darbepoetin alpha
ESA	Erythropoiesis stimulating agent
FDA	Food and Drug Administration
GFR	Glomerular filtration rate
Hb	Hemoglobin
HD	Hemodialysis
HIF	Hypoxia inducible factor
IL-6	Interleukin-6
IV	Intravenous
KDIGO	Kidney Disease: Improving Global Outcomes
Kg	Kilogram
LVH	Left ventricular hypertrophy
MCV	Mean corpuscular volume
PD	Peritoneal dialysis
PEG	Polyethylene glycol
PHD	Propyl hydroxylase domain
PHIs	Prolyl hydroxylase inhibitors
PTH	Parathyroid hormone
rHuEPO	Recombinant human erythropoietin
SLE	Systemic lupus erythematosus
TIBC	Total iron binding capacity
TSAT	Transferrin saturation

Introduction

Anemia is one of the most common problems in children with chronic kidney disease (CKD); it is almost universal in children with stage 5 CKD. The development of recombinant human erythropoietin (rHuEPO) revolutionized the treatment of anemia in CKD, but anemia management remains challenging. Many management issues remain uncertain, including the ideal target hemoglobin (Hb). There are guidelines for the management of anemia in CKD [1–3].

Pathophysiology of Anemia

A variety of factors contribute to anemia in CKD (Table 59.1). The principal etiology is decreased production of EPO by the kidneys. However, many children are still anemic despite administration of erythropoiesis stimulating agents (ESAs) [4, 5], emphasizing the multifactorial etiology of anemia in children with CKD.

Erythropoietin Deficiency

The kidneys produce EPO and kidney damage leads to decreased EPO production. In children with CKD, EPO levels are inappropriately low for the degree of anemia [6]. The degree of EPO deficiency generally worsens as the glomerular

filtration rate (GFR) decreases, but the level of GFR at which inadequate EPO causes anemia varies between patients, partially due to the nature of the underlying kidney disease [7]. On average, a GFR below 43 mL/min/1.73 m^2 is associated with a decline in Hb in children with CKD [8].

Blood Loss

Excessive blood loss may directly cause anemia, or it may lead to iron deficiency (see below). Causes of blood loss in children with CKD include phlebotomy, blood lost in the dialyzer and tubing during hemodialysis (HD) [9], gastrointestinal losses [9], and increased menstrual bleeding due to the acquired platelet function defect of CKD. Children receiving HD have increased intestinal blood loss when compared to other children with CKD [9] and have lower Hb values than children receiving peritoneal dialysis (PD) [5]. Increased blood loss is associated with rHuEPO resistance in pediatric HD patients [10].

Decreased Red Blood Cell Survival

Red blood cells in children with CKD have a decreased lifespan [9]. This may be partially due to carnitine deficiency (see below) [11], and a direct consequence of EPO deficiency, since red cell survival increases in CKD patients after starting rHuEPO [12]. Red blood cells in patients receiving HD have an increased osmotic fragility. Hemolytic anemia may occur due to a child's primary disease [e.g. systemic lupus erythematosus (SLE)].

Bone Marrow Suppression

In an in vitro assay, serum from children with CKD directly suppressed red blood cell production [6]. The specific inhibitory substances have not been identified, but dialysis appears to effectively remove some of these molecules, allowing for decreased doses of rHuEPO [13]. In a study of teenagers receiving HD, the children with Hb less than 11 g/dL had a slightly lower Kt/V_{urea} (1.46 v.s 1.53), but dialysis adequacy did not predict anemia in the multiple regression analysis, perhaps due to the high overall Kt/V in this patient population [14]. Severe bone marrow suppression may occur in children after renal transplantation due to medications [15] or infections, especially parvovirus B19 [16].

Iron Deficiency

Iron deficiency is a significant cause of anemia in patients with CKD; it is multifactorial (Table 59.2). In a study of older children, a serum transferrin saturation (TSAT) less than 20% was an independent predictor of anemia [14]. However, serum ferritin was not predictive of anemia, perhaps because ferritin is often elevated in CKD patients with concurrent inflammation, which may inhibit red cell synthesis (see below). This is supported by a study of children receiving PD where Hb was inversely related to serum ferritin [17].

Table 59.2 Causes of iron deficiency in children with CKD

Hemodialysis
Menses
Gastrointestinal
Surgical procedures
Dietary iron deficiency
Poor absorption of enteral iron
Inflammation
Medications (phosphate binders, gastric acid inhibitors)
Iron depletion during ESA therapy

ESA erythropoiesis-stimulating agent

Iron deficiency often develops after initiation of an ESA because the increase in red blood cell synthesis depletes iron stores. In some patients, there is a functional iron deficiency following ESA treatment; there are adequate supplies of iron, but the transfer of iron from ferritin is not fast enough to meet the high demand for red blood cell synthesis.

Inadequate Dialysis

In adults receiving dialysis, there is evidence that anemia is associated with inadequate dialysis. An increase in dialysis dose leads to an improvement in Hb. In addition, there is an inverse relationship between Kt/V and ESA dose. Resistance to ESAs was associated with a lower Kt/V in a study of pediatric HD patients [10]. Dialysis is effective at removing hepcidin (see below) [18], suggesting a possible mechanism for the relationship between dialysis dose and anemia.

Malnutrition

Malnutrition may be another factor contributing to anemia in CKD. In one pediatric study, low albumin was one predictor of anemia [14]. There are many possible explanations for the relationship between malnutrition and anemia. Generalized malnutrition may be a marker for nutritional iron deficiency or for deficiency of other nutrients that influence red cell production or survival. Another possible explanation for this observation is the relationship between markers of malnutrition and markers of inflammation [19]. As described below, inflammation is another mechanism of resistance to rHuEPO. It is possible that inflammation causes malnutrition, and this directly causes resistance to ESAs. An alternative explanation is that inflammation directly causes rHuEPO resistance, and that malnutrition is a surrogate marker of inflammation. A malnutrition inflammation score predicted ESA resistance in a study of pediatric HD patients [10].

Inflammation

Acute and chronic inflammation are well-known causes of decreased red blood cell synthesis. Inflammation is one of the mechanisms of the anemia of chronic disease and of the decreased erythropoiesis that occurs during infections. Markers of inflammation are commonly increased in CKD patients. There are a variety of putative mechanisms. Surgical procedures and acute infections are more common in CKD patients, especially those who are receiving dialysis or have a kidney transplant. The impaired immune system in uremia may lead to an increase in nonspecific inflammation [20]. CKD patients may have underlying systemic diseases, such as SLE or granulomatosis with polyangiitis. HD may induce inflammation via complement activation, direct activation of inflammatory cells by the dialysis membrane, and diffusion of endotoxin into the patient from the dialysate. Use of ultrapure dialysis in HD patients decreases inflammatory markers, increases Hb levels, and decreases ESA use [21].

Hepcidin is an important mediator of ESA resistance [22]. Hepcidin, which is produced in the liver, inhibits intestinal absorption of iron and release of iron stores from the reticuloendothelial system. This is accomplished through downregulation of ferroprotein, the principal trans-

membrane transporter of iron. Hepcidin is normally down-regulated in anemia, increasing absorption of iron and release of iron stores. In contrast, hepcidin increases when iron stores are adequate. Hepcidin is also up-regulated by inflammation. Interleukin 6 (IL-6) induces production of hepcidin and is risk factor for ESA resistance [23, 24]. Hepcidin's effect on release of iron stores explains inflammatory block, a condition where body stores of iron are adequate, but there is ineffective delivery of iron to the bone marrow. Findings in patients with inflammatory blockade may include elevated C-reactive protein (CRP) levels, resistance to ESAs, high serum ferritin levels, and low levels of serum iron and TSAT [25]. This mechanism is common to the anemia of many chronic diseases.

Hyperparathyroidism

Hyperparathyroidism may decrease bone marrow production of red blood cells [26] and rarely causes pancytopenia [27]. Elevated parathyroid hormone (PTH) levels are associated with ESA resistance in pediatric HD patients [10] and PTH is inversely related to Hb in pediatric dialysis patients [5]. Treatment of hyperparathyroidism via parathyroidectomy may lead to an increase in Hb.

B12 or Folate Deficiency

Patients with CKD may rarely develop a megaloblastic anemia due to folate or vitamin B12 deficiency. Poor nutritional intake combined with dialytic losses may predispose CKD patients to deficiencies of these water-soluble vitamins. There is some evidence that routine folate supplementation improves the response to rHuEPO, even in the absence of low serum levels of folic acid [28].

Aluminum Toxicity

Aluminum overload may cause a microcytic anemia in patients with CKD [29]. Currently, aluminum overload is an uncommon cause of anemia due to the recognition of the dangers of aluminum-containing phosphate binders.

Carnitine Deficiency

Carnitine deficiency may occur in CKD, principally due to removal of carnitine by dialysis, although decreased dietary intake and endogenous synthesis may also contribute [11]. Renal losses of carnitine are significant in children with Fanconi syndrome. Carnitine deficiency may decrease red blood cell survival by reducing the strength of the red cell membrane [11]. Intravenous (IV) carnitine may reduce rHuEPO dose requirements in adults receiving HD, but there is disagreement regarding the strength of the evidence; carnitine should not be used routinely in children, if at all, outside of a research setting [1, 11, 30–32]. Oral carnitine should not be used in patients receiving HD [11].

Medications

A variety of medications can inhibit erythropoiesis, especially certain medications used in renal transplant recipients [15, 33]. Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers are especially pertinent in CKD patients because of their widespread use [34].

Summary

Erythropoietin deficiency and iron deficiency are the most common causes of anemia in children with CKD. Inflammation and hyperparathyroidism are important mediators of ESA resistance.

Epidemiology of Anemia in Pediatric CKD

Anemia is common in children with CKD, even in patients with stage 3 CKD [5, 35]. In one study, anemia was more common in children

greater than 2 years old, males, and patients receiving antihypertensive medications [35]. In another cohort, African American race was associated with an increased risk of anemia in children with CKD [4].

In children receiving PD, anemia is quite common and varies by region [17]. Risk factors for anemia include inflammation, decreased residual urine output and hyperparathyroidism [17].

Anemia is common in children after kidney transplantation [36]. The principal cause of anemia is allograft dysfunction, although current immunosuppressive medications appear to be responsible for the increased prevalence of anemia in these patients. Iron deficiency is common in children who are anemic after renal transplantation.

Clinical Effects of Anemia

There are a variety of clinical effects of anemia (Table 59.3). The clinical consequences of anemia in patients with CKD are difficult to discern because anemia identifies patients with co-morbidities such as inflammation and malnutrition. A variety of studies demonstrated an association between anemia and morbidity and mortality, but these conclusions may be biased by co-morbidities.

Studies in adult CKD patients have shown an association between anemia and increased mortality and hospitalization rates [37–40]. In a pediatric analysis, anemia 30 days after initiation of dialysis was associated with a significant increase in mortality and hospitalization rate [41]. In analysis of children receiving PD, anemia was associated with increased mortality, hypertension, and left ventricular hypertrophy (LVH) [17], suggesting that in patients with ESKD low Hb may partially reflect fluid overload ("dilutional anemia"). In children with CKD, anemia was associated with an increased risk of hospitalization [42].

In a group of children receiving dialysis, treatment of anemia with rHuEPO was associated with an elevated cardiac index in 6 months and a significant reduction in left ventricular mass index by 12 months [43]. In one study [44], children with severe LVH had significantly lower Hb values than children without LVH. However, anemia did not predict LVH in the final multiple regression model.

There is uncertainty regarding the direct deleterious consequences of a lower Hb in adults with CKD. These include observational studies that have corrected for a variety of co-morbidities [45]. More importantly, randomized studies using ESAs to target different Hb levels have failed to demonstrate a benefit of higher Hb targets on morbidity or mortality [46, 47]. In fact, a higher Hb target has resulted in a significant increase in morbidity and mortality in randomized studies [48, 49].

In randomized studies in adults, a higher Hb improves quality of life [47], although this is not a consistent finding [48, 50]. In a placebo-controlled trial, randomization to rHuEPO resulted in less fatigue, improved exercise tolerance and improved scores of physical symptoms and depression [51]. There is evidence of the deleterious effects of anemia on child development. There is an association in children with CKD between anemia and lower scores of health-related quality of life [52]. Studies of the effect of rHuEPO in children with CKD have shown improvement in quality of life, exercise tolerance, appetite, peak oxygen consumption and treadmill time during exercise testing, Wechsler intelligence score, and ventilatory aerobic threshold [53–55]. There does not appear to be a beneficial effect of anemia correction on the growth retardation associated with CKD [56].

Decreased exercise tolerance
Impaired cognitive function
Loss of appetite

Clinical Evaluation of Anemia

Initial Evaluation

Alternative causes of anemia should be evaluated prior to treating patients with an ESA (Table 59.4). The diagnosis of anemia in children should be based on age and gender specific normal ranges.

The initial evaluation of children with CKD and anemia should include a complete blood count, reticulocyte count, ferritin, iron, total iron binding capacity (TIBC) and a TSAT. The TSAT is calculated by dividing the serum iron by the TIBC. Measurement of EPO levels generally does not have clinical utility. A cost-effectiveness analysis in adults argues against routine screening for aluminum overload or deficiencies of folate or B12 [57]. EPO deficiency causes a normocytic anemia; macrocytosis or microcytosis should lead to consideration of other etiologies (Table 59.4).

Table 59.4 Indications for additional evaluation in children with chronic kidney disease and anemia

Indication	Response
Macrocytosis	Consider B12 or folate deficiency, unless due to brisk reticulocytosis
Decreased platelets and/or white blood cells	Consider malignancy, acute infection, SLE, severe hyperparathyroidism or medications
History of using aluminum-containing phosphate binders or other symptoms of aluminum overload	Consider aluminum toxicity
Anemia despite adequate reticulocytosis	Consider excessive blood loss or hemolysis
Microcytosis	Consider iron deficiency, hemoglobinopathy, or inflammation
Iron deficiency prior to starting an ESA	Evaluate for causes of iron deficiency (see Table 59.2)
Low reticulocyte count and falling hemoglobin in a patient being treated with an ESA	Consider non-adherence, anti-erythropoietin antibodies, parvovirus B19 infection

ESA human erythropoiesis stimulating agent, *SLE* systemic lupus erythematosus

A low mean corpuscular volume (MCV) occurs with iron deficiency, thalassemia and in up to 50% of patients with anemia of chronic disease. A high MCV suggests the possibility of B12 or folate deficiency. Measurement of serum levels of B12 and folate is indicated if there is an elevated MCV or if there is anemia without an alternative explanation. RBC folate is useful when a serum folate level is inconclusive or if recent intake of folate may lead to a falsely normal serum folate level.

Concomitant depression of white cells or platelets raises the specter of malignancy, although an isolated low white blood cell count may be due to a transient viral infection or a medication. SLE may cause depression of the white blood cell count, platelet count and an autoimmune Coombs positive hemolytic anemia. EPO deficiency causes an inappropriately low reticulocyte count, and the presence of an adequate reticulocytosis suggests alternative explanations, such as blood loss or hemolysis. An elevated CRP, indicating inflammation, may provide an explanation for anemia refractory to ESAs.

Iron deficiency is common in children with CKD, even prior to starting an ESA. There are a variety of explanations for iron deficiency in children with CKD (Table 59.2). All children with CKD should be queried about gastrointestinal blood loss and, when appropriate, menstrual losses. A more aggressive work-up (e.g. testing stool for occult blood or endoscopy) is appropriate in children with significant, unexplained iron deficiency prior to receiving ESA therapy. Along with low serum ferritin and TSAT, children with iron deficiency typically have a low MCV. Because it is a marker of inflammation, serum ferritin may be misleadingly normal in children with CKD despite iron deficiency.

Evaluation of the ferritin and TSAT establishes a baseline, since iron deficiency is likely to develop during ESA treatment. In addition, while all patients starting an ESA should receive oral iron supplementation unless iron overload is present, iron deficiency prior to starting ESA therapy may significantly attenuate the response to therapy. Such patients are candidates for IV iron.

Chronic Monitoring

Routine monitoring in children with anemia due to CKD includes periodic assessment of Hb, MCV, and iron stores. The development of macrocytosis in a patient after starting an ESA is usually due to the expected reticulocytosis; an increasing Hb, arguing against a nutritional deficiency anemia, supports this explanation. Iron overload may also cause an increased MCV [58]. Microcytosis is usually due to iron deficiency.

A decrease in Hb is expected during acute infections [59] or after surgical procedures [60]. ESA dose requirements increase following blood loss that causes a fall in Hb; this persists until the Hb returns to the target range. Depleted iron stores are the usual explanation for a poor response to ESA therapy. Some children have a functional iron deficiency, and may respond to IV iron, even though the ferritin levels are adequate. Additional evaluation is indicated in children who have an unexplained increase in ESA dose requirement, need unexpectedly large doses of ESA, or have a decreasing Hb (Table 59.4).

A reticulocyte count is the usual first step in evaluating unexplained anemia or an excessive ESA requirement. An appropriately elevated reticulocyte count (corrected for the degree of anemia) argues that the patient is anemic due to blood loss or hemolysis. Blood loss is also suggested by a minimal increase in ferritin and TSAT despite the use of multiple doses of IV iron. The child should then have stool tested for occult blood; an evaluation for hemolysis may also be appropriate. Inadequate reticulocytosis suggests that there is a defect in red cell production. This may be due to poor adherence or technique failure in a patient receiving home ESA. There may be a readily identifiable explanation, such as severe secondary hyperparathyroidism. Alternatively, additional testing may be necessary. A serum aluminum level is an appropriate test in the child with a history of using aluminum-containing phosphate binders. One of the most common causes of a poor response to ESA is an inflammatory block due to acute or chronic inflammation. An elevated CRP supports this diagnosis [20]. Other testing, depending on the patient, may include screening for anti-EPO antibodies (see below), and serum levels of folate and B12. A hematologist should evaluate refractory anemia with no identifiable explanation [31, 61].

Treatment of Anemia

Treatment with an ESA is necessary in many children with CKD, including children with chronic allograft dysfunction [62]. Almost all children receiving dialysis are treated with an ESA. In addition, almost all treated patients require oral or IV iron. Other underlying causes of anemia should be corrected (Table 59.1). Blood transfusions should be reserved for children with symptomatic anemia or with worsening anemia due to blood loss, hemolysis, or unresponsiveness to ESAs [1].

Target Hemoglobin

A number of randomized studies in adult patients with CKD have demonstrated that targeting higher Hb levels leads to increased morbidity and mortality [46, 48, 49, 63]. In one study, targeting a higher Hb led to a decrease in dialysis adequacy and a higher use of IV iron [46]. The TREAT trial compared placebo and darbepoetin alpha (DA) in adults with CKD. The risk of stroke was almost doubled in the patients randomized to receive DA to achieve a Hb of 13 g/dL, although there was a modest improvement in fatigue in the DA group [49]. Stroke was also increased when adult HD patients were randomized to a higher Hb target [63]. In the CREATE trial, the group randomized to a higher Hb had more episodes of hypertension and headache [47]. In the CHOIR trial, the group randomized to a higher Hb had an increased risk of death or cardiovascular event and there was no difference in quality of life between the groups [48]. In a retrospective cohort study of adult kidney transplant recipients, patients receiving an ESA with a Hb level above 12.5 g/dL had an increase in mortality [64].

The reason for the increased morbidity and mortality associated with a higher Hb target is

unresolved. It could be attributed to a higher Hb level or to the need for higher doses of ESAs, which have been postulated to have untoward effects beyond increasing the Hb. High ESA dose is associated with increased morbidity and mortality, but this appears to be partially related to resistance to ESAs due to co-morbidities [65–67]. However, in studies that randomized CKD patients to ESA or placebo, the groups receiving ESAs had an increased risk of stroke [49] and access clotting [51]. Moreover, in a randomized study of rHuEPO in patients with ischemic stroke, the group receiving rHuEPO had significantly increased mortality [68]. Dialysis patients who have high Hb levels without the use of ESAs do not have increased mortality [69]. A higher Hb target could lead to more variation in Hb levels, which has been associated with increased mortality [70].

The negative consequences of targeting higher Hb concentrations in the trials of ESAs has led the US Food and Drug Administration (FDA) to recommend that ESAs be given at the lowest dose possible to avoid blood transfusions and that ESAs should be reduced or withheld if the Hb exceeds 11 g/dL and withheld if the Hb exceeds 12 g/dL. Moreover, all ESAs have a black box warning and patients must receive education regarding the possible adverse effects of ESAs. A combination of these concerns, and possibly a change in the payment structure for ESAs, has led to a decrease in the dose of ESAs and Hb levels in US dialysis patients [71].

There are no data on the ideal target Hb in children or whether the target should be adjusted based on age and gender. Kidney Disease: Improving Global Outcomes (KDIGO) recommends an upper limit Hb of 11.5 g/dL in adults, but recommends targeting pediatric CKD patients between 11–12 g/dL. The British NICE guidelines recommend a target of 10–12 g/dL for all patient 2 years and older, with a target of 9.5–11.5 g/dL in children less than 2 years [2, 3]. The Canadian Society of Nephrology recommends a target of 10–11 g/dL for adults, but considers 9.5–11.5 g/dL an acceptable range [72]. The US KDOQI commentary on KDIGO advocates the FDA-recommended upper cutoff of 11 g/dL for adults, but a range of 11–13 g/dL for children [73]. There are clearly clinical situations that require different target Hb values. For example, specific children may require a higher target Hb (e.g. a child with underlying cyanotic heart disease) or a lower target (e.g. a child with sickle cell disease).

Some patients remain anemic or develop refractory anemia despite ESA therapy and correction of other etiologies of anemia. This is especially common in patients who have inflammation. Ongoing escalation of ESA dose in these patients has been associated with adverse outcomes in adults [49], suggesting that ESA dose should not be increased without limit in patients who are hyporesponsive. Patients who do not respond to an ESA or stop responding to an ESA should have an evaluation of possible etiologies of anemia (Tables 56.1 and 56.4).

Hemoglobin Monitoring

Hb monitoring is preferred over hematocrit because Hb measurements are more standardized and consistent. For patients receiving HD, blood samples should be taken immediately prior to dialysis. This may lead to a falsely low Hb value due to hemodilution from fluid gain between dialysis sessions. Hence, this should be considered in children with significant interdialytic weight gain. It is reasonable to measure Hb prior to a HD session after a short interdialytic period (2 days) since the effect of hemodilution on Hb is generally less significant [31].

The frequency of monitoring varies depending on the patient. Children who are being given a stable dose of ESA and within their target Hb can have a Hb level performed as infrequently as monthly in a dialysis patient, and even less often in a predialysis patient (minimum of every 3 months). After the initiation of ESA or after a dosing change, a Hb should generally be obtained at least monthly until the Hb has stabilized within the target range. Protocols that use less frequent monitoring and dose adjustments may reduce costs and minimize Hb cycling, large variations in Hb values that are associated with increased morbidity in adults [74, 75].

Erythropoiesis Stimulating Agents

rHuEPO was the first ESA, but a number of other preparations are now available. Two preparations, DA and methoxy polyethylene glycol (PEG)-epoetin beta, are modified forms of EPO. The main advantage of other preparations is a longer half-life, which permits less frequent dosing. This is especially advantageous in children who require subcutaneous dosing given the discomfort and fear associated with injections. Less frequent dosing may also decrease provider burden in a dialysis unit and provide cost savings [76]. Hypoxia-inducible factor (HIF) prolyl hydroxylase inhibitors (PHIs) have a different mechanism of action than the other ESAs, including both stimulation of EPO production and increasing iron bioavailability. HIH-PHIs have the advantage of oral administration, but regulatory approval has been slow due to safety concerns; they have not been systematically studied in children.

There are no studies directly comparing different ESAs in children, and limited studies in adults except for comparisons of the HIF-PHIs with other ESAs. Availability of the different preparations varies by country.

Recombinant Human Erythropoietin

Multiple studies in adult patients demonstrated the efficacy of IV and subcutaneously administered rHuEPO for correcting the anemia of CKD. A placebo controlled trial demonstrated that rHuEPO is effective in children with CKD [55], and studies in adults demonstrate that use of ESAs decreases the need for transfusions [49, 51, 77].

Pharmacokinetics

The pharmacokinetics of rHuEPO in CKD has been studied in children and adults. There are clear differences based on the route of administration, with less complete absorption of subcutaneous rHuEPO, but a significantly longer half-life when compared to IV administration. In studies of children with CKD, the measured mean half-life of rHuEPO is 5.6–7.5 h for IV dosing and 14.2–25.2 h for subcutaneous dosing. For IV dosing, there is evidence in adults that the half-life of rHuEPO increases as the dose increases.

Dosing

There are dramatic differences in the dosing needs of children with CKD who are receiving rHuEPO, even when adjusted for patient size [78, 79]. Some have recommended dosing children independent of weight and utilizing "adult" dosing [80]. A variety of variables influence the dosing needs of patients (Table 59.5), but it remains difficult to predict the dosing needs of an individual patient. Factors affecting the necessary dose per kilogram (kg) of rHuEPO in children with CKD include the stage of CKD (higher in stage 5), the mode of dialysis (higher in HD due to increased blood loss) [81, 82], the age of the patient (higher in younger patients) [78, 79, 82], the route of administration (higher with IV versus subcutaneous) [79], and the dosing frequency (higher with less frequent dosing regimens). Concurrent causes of poor response to rHuEPO, such as iron deficiency, inflammation, or hyperparathyroidism, often result in higher doses. Blood loss, due to HD, blood draws, and other sources, increase the need for rHuEPO. Blood draws can be especially problematic in the youngest patients, because they often need more frequent monitoring and the relative losses per kg of body weight tend to be higher. Finally, residual renal production of EPO can decrease the need for rHuEPO.

In children receiving PD or predialysis patients, an appropriate starting dose for subcutaneous rHuEPO is 100 units/kg/week divided into two doses, although once weekly dosing may be appropriate in a child with mild anemia. Children less than 5 years are likely to need a higher dose,

Table 59.5 Factors influencing erythropoietin dosing

Presence of other causes of anemia (see Table 59.1)

and a starting dose of 150 units/kg/week may be appropriate in such patients, especially if severe anemia (Hb < 8 g/dL) is present. Alternatively, a study of children receiving PD demonstrated that the average weekly dose of EPO was 4300 IU/m^2 independent of age [17], suggesting that body surface area can be used to dose EPO in children independent of age or weight. For children receiving HD and IV rHuEPO dosing, a starting dose of 150 units/kg/week divided into theree doses is reasonable, again with the caveat that higher doses are likely necessary in children less than 5 years. A starting dose of 200–300 units/kg/week may be more appropriate in such patients, especially if there is concomitant severe anemia.

In children receiving chronic subcutaneous dosing of rHuEPO, the majority can be maintained on weekly dosing to minimize the number of painful injections. However, some patients require more frequent injections. Less frequent dosing regimens of rHuEPO are effective in adults with pre-dialysis CKD [83].

When children receive IV dosing during HD, it is important to inject rHuEPO via the bloodlines. Use of the venous drip chamber may result in reduced drug delivery due to "trapping" of rHuEPO, although this appears to be somewhat machine dependent.

For children receiving subcutaneous dosing, the site of injection should be rotated. The discomfort of subcutaneous dosing can be reduced by utilizing the multidose vial, which contains the local anesthetic benzyl alcohol as a preservative.

Frequent dose adjustments are typically necessary in patients receiving rHuEPO. This is probably due to variations in the factors that cause anemia (Table 59.1) and that influence rHuEPO dosing (Table 59.5). In addition, more active erythropoiesis is needed to increase a patient's Hb. Hence, the dose that patients need to increase their Hb level into the target range is often more than the dose needed to maintain a stable Hb. Patients may need higher doses of rHuEPO at the start of therapy or after a decrease in Hb due to blood loss or a transient illness.

Most children, when they initiate HD, are converted to IV dosing of rHuEPO, which should then almost always be given thrice weekly. Based on adult studies, the total weekly dose of rHuEPO should be increased by 50% when a patient changes from subcutaneous to IV dosing. Similarly, patients changing from IV dosing to subcutaneous dosing should have their weekly dose decreased by 33%. However, most pediatric patients who convert between IV and subcutaneous dosing are also changing dialysis modality. Given the higher needs for rHuEPO in children on HD [78], patients changing to IV dosing because they are initiating HD may need an additional increase in their dose. In children less than 10 years and certainly those less than 5 years, rHuEPO dosing requirements during HD are very high [79]. This suggests that these patients may need an increase in their rHuEPO dose after beginning HD, irrespective of any change in route of administration. Young children should have careful monitoring of the Hb when initiating HD, increasing the dose of rHuEPO further if necessary. Even in older children, there is extreme variability in the dose requirements when converting to IV dosing; dose requirements may increase or decrease. The ability to more aggressively treat iron deficiency in children receiving HD (see below) may result in a decrease in rHuEPO requirements.

The goal of rHuEPO therapy is to maintain patient Hb within a desired target range. Overly rapid increases in Hb can be associated with hypertension, and should be avoided. In patients with a Hb below the target, the goal is to increase the Hb by 1–2 g/dL per month. The dose of rHuEPO should be increased by 25% if the patient is below the target Hb and has not increased at least 1 g/dL over the last month. The dose should be reduced by 25% if the Hb is greater than the target Hb or the Hb has increased by more than 2 g/dL over the last month. The rHuEPO should be temporarily held if the Hb is more than 1 g/dL over the target Hb or the Hb has increased by more than 2 g/dL over the last month and is above the target Hb.

Complications

An increase in blood pressure after starting rHuEPO therapy may occur in children [55, 84].

This appears to be more common in children who receive higher doses of rHuEPO, and have a consequent more rapid increase in Hb [85]. Hence, rapid increases in Hb should be avoided. While the increase in red cell mass appears to be one mechanism of the hypertension, there also appears to be a direct effect of rHuEPO on the vasculature.

An increase in vascular access clotting following rHuEPO treatment has been attributed to the increase in Hb. There may also be a small negative effect on dialytic clearance, but this is not clinically significant.

Iron deficiency may develop in children treated with rHuEPO [55, 84]. This is secondary to iron utilization for red blood cell synthesis. Consequently, unless iron overload is present, all patients treated with rHuEPO should receive iron supplementation and be screened for iron deficiency before and during therapy.

A rare complication of rHuEPO is the development of anti-EPO antibodies [86]. These antibodies neutralize both endogenous EPO and rHuEPO, resulting in red cell aplasia. Immunosuppressive therapy, including after renal transplantation, results in hematologic recovery in many patients [87]. Patients with undetectable anti-EPO antibodies may subsequently respond to rHuEPO [87].

Darbepoetin Alpha

DA (Aranesp™) is a genetically engineered molecule with a longer half-life than rHuEPO, permitting less frequent administration. The longer half-life of DA is due two additional N-glycosylation sites.

Efficacy

Studies in adults demonstrate comparable efficacy of rHuEPO and DA, despite less frequent dosing of DA [88, 89]. One study demonstrated that many CKD patients do well when receiving DA subcutaneously as infrequently as once every 3–4 weeks [90].

In a prospective study, children receiving rHuEPO were randomized to rHuEPO or DA at a less frequent dosing interval (0.42 μg of DA per week for each 100 units/week of rHuEPO). There was no significant difference in Hb or side effects between the groups at the end of the 20-week study; the median weekly dose of DA was 0.41 mcg/kg, with 25th and 75th percentiles of 0.25 and 0.82 mcg/kg, respectively [91]. A small prospective study evaluated the response to converting seven children receiving HD from thrice weekly rHuEPO to weekly DA (1 mcg of DA per week for each 200 units/week of rHuEPO). Especially in the younger children who were receiving high doses of rHuEPO, there were problems initially with elevated Hb levels and associated hypertension. This was corrected by reducing the dose of DA, suggesting that this dose conversion ratio may be inappropriate in younger children, and that careful monitoring of the initial response is necessary when converting to DA. The mean steady-state dose of DA after 3 months was 0.51 mcg/kg/week [92].

In a large prospective study, children with CKD and anemia were given DA at a starting dose of 0.45 μg/kg/week. There was a significant improvement in Hb and it was sustained during the 28 weeks of the study. By the end of the study, slightly more than half the patients were receiving DA at dosing intervals of at least 2 weeks [93]. A small study has described the successful use of DA in infants, with a starting dose of 0.5 μg/kg/week [94]. The dose was able to be reduced and the dosing interval was increased to 3–4 weeks in some of the infants [94]. In another study in children, the initial dose in naïve patients was 0.45 mcg/kg and patients previously treated with rHuEPO were converted using a dose of 1 mcg of DA per 200 IU of rHuEPO [95]. The final dose was higher in the patients converted from rHuEPO, perhaps because most of these patients were receiving dialysis and none of the naïve patients were dialysis patients [95]. In a prospective registry study in children, including dialysis and pre-dialysis patients, the geometric mean dose range was 1.4–2.0 mcg/kg/month (0.3–0.5 mcg/kg/week) [96].

Pharmacokinetics

One study evaluated the half-life of DA in pediatric patients with CKD [97]. Each patient received one

dose of DA (0.5 mcg/kg) intravenously and subcutaneously. The half-life of DA with IV administration was 22.1 h (SD = 4.5 h). The half-life was 42.8 h (SD = 4.8 h) with subcutaneous administration. The pharmacokinetics were comparable to a similarly designed study in adults except for increased bioavailability (54% vs. 37%) and an earlier T_{max} (36 h vs. 54 h) in the pediatric patients when DA was administered subcutaneously [97, 98]. Hence, DA may be absorbed more rapidly in pediatric patients [97]. More rapid absorption was also seen in pediatric studies of rHuEPO [99].

Dosing

Based on protein mass, 1 mcg of DA is equivalent to 200 units of rHuEPO. Nevertheless, the recommended DA dose by the manufacturer when converting patients from rHuEPO to DA is not a direct conversion based on the 1 mcg of DA to 200 units rHuEPO ratio (Table 59.6). The recommended conversion ratios are based on an analysis of the dose conversion clinical trials [100]. This analysis indicates that proportionally less DA was needed in patients who began the trial on higher doses of rHuEPO [100]. The explanation for this observation is unclear. It is possible that the efficacy of DA increases at higher doses. Alternatively, there may simply be a "regression to the mean" in those patients who were on very high doses of rHuEPO. These patients may have had a transient reason (e.g. inflammation) that led to high ESA dose requirements that subsequently resolved, allowing lowering of the DA dose during the study.

One challenge with DA administration in children is the lack of a multidose vial. First, many small pediatric patients are likely to need less than 25 μg, the smallest available single-dose vial. This results in wasting of the unused medication. Second, pediatric patients may not tolerate the discomfort of 1 mL injections or may require multiple injections in order to tolerate the full 1 mL volume of the single-dose vials. A useful alternative is to utilize DA in more concentrated single-dose prefilled syringes. Thus, dosing of DA necessitates knowledge of the available preparations (Table 59.7), and requires creative adjustments of doses and dosing intervals to minimize wasting of medication.

Recommendations for converting patients from rHuEPO to DA based on adult data are available (Table 59.6). Patients who are receiving rHuEPO twice or thrice weekly should receive DA weekly, and patients who are receiving weekly rHuEPO should receive DA every other week.

Based on the pediatric literature, a reasonable starting dose of DA in ESA naïve patients is approximately 0.5 mcg/kg given weekly. Alternatively, the same total dose could be given every 2 weeks (i.e. 1 mcg/kg every 2 weeks). Every 2-week dosing at initiation should be

Table 59.6 Starting dose of darbepoetin alpha based on previous dosing of rHuEPO

reserved for patients with a Hb that is only mildly below target. Close monitoring of the Hb is essential for all patients due to the variable response to DA.

As occurs with rHuEPO, frequent dose adjustments of DA are often necessary [88]. Since DA has a long half-life, it is important not to increase the dose too quickly to avoid overshooting the target Hb. Many patients require lower doses after their Hb reaches the target range. When adjusting DA dosing, it is desirable to round doses based on the available preparations (Table 59.7) to avoid excessive wasting of the medication. Nevertheless, excessive rounding is not appropriate; some patients will need to discard some of their medication. Table 59–8 presents one system for dose adjustment. It is unclear whether the DA is evenly distributed in the prefilled syringes. Hence, gentle mixing of the medication and transfer to a 1 mL syringe has been recommended for patients who do not need a full dose [94].

Dose frequency of DA can be gradually reduced from weekly to every other week to every 3 weeks to every 4 weeks [101]. Not all patients will tolerate decreased dose frequency, especially beyond every 3 weeks. The dose frequency can be reduced whenever the patient has a Hb level that would normally mandate decreasing the dose. Alternatively, the dose frequency can be reduced in patients who are on a stable DA dose and have a Hb in the target range. The total weekly dose should remain the same. For patients receiving DA less often than weekly, consideration should be given to increasing the dose frequency if a patient requires more than 1 dose increase, especially if the total weekly dose is relatively high.

Complications

Side effect profiles have been similar in studies comparing IV DA with IV rHuEPO [88, 89]. In one study, there was a statistically significant increase in pruritus in the DA group [89]. Injection site pain is more severe in children with subcutaneous DA than with rHuEPO [102]. There have been cases of antibodies developing to DA leading to pure red cell aplasia [103].

Methoxy Polyethylene Glycol-Epoetin Beta

Methoxy PEG-epoetin beta is made by linking EPO with a large polymer chain via amide bonds between amino acids and methoxy PEG butanoic acid. Methoxy PEG-epoetin beta is also called Continuous Erythropoietin Receptor Activator (C.E.R.A.). A long half-life permits less frequent dosing [104].

Efficacy

A number of studies have demonstrated the effectiveness of methoxy PEG-epoetin beta in adult patients with CKD [105–111]. In a direct comparison with DA in adult HD patients, methoxy PEG-epoetin beta was superior at maintaining Hb at the prescribed target [112]. Methoxy PEG-epoetin beta given either every 2 weeks or every 4 weeks was comparable to rHuEPO in adult dialysis patients [107, 109].

Methoxy PEG-epoetin beta is effective in adult kidney transplant recipients [113, 114]. In a randomized study, once-monthly methoxy PEG-epoetin beta was compared with every 1–2 weeks DA, with similar efficacy and side effect profiles [115].

Two clinical trials have demonstrated that methoxy PEG-epoetin beta is effective in children with CKD [116, 117]. Children with stable anemia undergoing HD were converted from EPO or DA to methoxy PEG-epoetin beta, and Hb remained stable [116]. Similar efficacy was seen in a clinical trial that included children with pre-dialysis CKD and children receiving PD or HD [117].

Pharmacokinetics

The half-life of methoxy PEG-epoetin beta was 134 h and 139 h in adult PD patients following IV and subcutaneous dosing, respectively [118]. The peak reticulocyte count occurred at a mean of

8 days in both groups. Injection site location does not influence the pharmacokinetics, with half-lives between 160 and 164 h [104].

Dosing

For adults, the starting dose is 0.6 mcg/kg every 2 weeks, with conversion to monthly dosing once the Hb is within the target range. The every 2 week dose is doubled to calculate the monthly dose. An initial dose of 1.2 mcg/kg every 4 weeks was effective and comparable to DA every 1–2 weeks in a randomized clinical trial in ESA naïve non-dialysis patients [110]. In one study, the dose conversion ratio for HD patients converted from DA to methoxy PEG-epoetin beta was 1.21 mcg of methoxy PEG-epoetin beta for each 1 mcg of DA [119]. In a small study of pediatric kidney transplant recipients, the patients received a median dose of 2.5 mcg/kg every 4 weeks [120]. In a study of children 6–17 years receiving HD, a conversion factor of 4 mcg every four weeks of methoxy PEG-epoetin beta for each weekly dose of 125 U of EPO or 0.55 mcg of DA maintained a stable Hb [116]. In a registry study of patients receiving HD or PD, monthly doses per kg/month were much higher in younger children than older children, although the difference was minimal when analyzed using body surface area (approximately 100 mcg/m^2/month) [121].

Methoxy PEG-epoetin beta is available in single use vials and single use prefilled syringes in a variety of doses. The prefilled syringes are more concentrated and hence preferable in patients who require subcutaneous injection.

Complications

In adult HD patients, conversion from DA to methoxy PEG-epoetin beta led to more transfusions [119]. No safety concerns have been noted in the pediatric studies [116, 121].

Hypoxia-Inducible Factor Prolyl Hydroxylase Inhibitors

Hypoxia-inducible factor (HIF) prolyl hydroxylase inhibitors (PHIs) have a different mechanism of action than the other ESAs, and they have the advantage of oral administration. HIF-PHIs activate the normal response to hypoxia. HIF-α is constitutively produced; however, in the absence of hypoxia, HIF-α is degraded via the actions of propyl hydroxylase domain (PHD) enzymes (PHD1, PHD2 and PHD3), which are oxygen sensors. These PHD enzymes hydroxylate proline residues in HIF-α, leading to ubiquitylation and proteasomal degradation of HIF-α [122, 123].

Hypoxia or HIF-PHIs decrease the degradation by PHD enzymes of HIF-α, which can then combine with HIF-β, and translocate to the nucleus, where the resulting heterodimer increases transcription of a variety of hypoxia-responsive genes, including EPO in kidney and liver cells, glycolytic enzymes, angiogenic factors, and proteins involved in iron metabolism, absorption, mobilization and transport [122, 123]. The induction of EPO in liver cells permits effective use in anephric patients, though it is unknown whether such patients will require higher doses.

Theoretically, HIF-PHIs could also increase Hb levels by increasing the availability of iron for red blood cell synthesis, especially in patients with decreased iron availability due to inflammatory blockade. HIF decreases synthesis of hepcidin, which is increased by inflammation and decreases iron availability for red blood cell synthesis. Moreover, HIF directly increases ferroprotein, which increases the release of absorbed and stored iron into the circulation, and transferrin, which transports iron to the bone marrow [122, 123].

There are multiple HIF-PHIs, including daprodustat, roxadustat, molidustat, vadadustat and enarodustat. They have different pharmacologic and pharmacodynamic properties [122, 123]. Roxadustat, daprodustat and enarodustat are primarily metabolized by cytochrome P450 enzymes, while molidustat and vadadustat are primarily metabolized by uridine 5′-diphosphoglucuronosyltransferases. Roxadustat is administered thrice weekly; the others are given daily [123].

The HIF-PHIs have been studied in predialysis and dialysis-dependent adult patients.

These studies demonstrate dose-dependent increases in Hb when compared to placebo, and generally equivalent hematologic responses when compared to other ESAs [122, 123]. There is not yet compelling evidence for a clinical benefit of HIF-PHIs on iron metabolism in patients with CKD (e.g. decreased need for IV iron). There is also a hope that patients with inflammation may respond better to HIF-PHIs than other ESAs. There remains concern regarding the multiple actions of HIF-PHIs beyond stimulating erythropoiesis could lead to adverse effects (e.g. upregulation of vascular endothelial growth factor could theoretically enhance tumor growth or worsen retinal disease), though there is also the possibility of beneficial effects (e.g. improved lipid metabolism). One study suggested a cardiovascular safety concern with vadadustat when compared to DA in non-dialysis-dependent adults with CKD [124]. Both positive and negative effects may differ by preparation [122, 123].

Monitoring Iron Stores

Serum ferritin and TSAT are the most widely used tests for monitoring iron stores. However, the United Kingdom National Institute for Health Care Excellence (NICE) guidelines recommend initiating iron therapy based on the measurement of either the percentage of hypochromic red blood cells (iron if >6% unless ferritin >800 mcg/L) or the reticulocyte Hb count (iron if <29 pg unless ferritin >800 mcg/L) [3, 125], though pediatric reference ranges may be needed [126, 127]. Per these guidelines, ferritin and TSAT should only be used if these tests are not available or the patient has thalassemia or thalassemia trait [3]. There is some information on the use of these measures in children, but studies are quite limited [128, 129]. Test availability remains a barrier in many settings, especially since samples may need to be processed relatively quickly (<6 h for percentage of hypochromic red blood cells).

Per KDIGO, TSAT and serum ferritin should be measured at initiation of ESA therapy in all children with CKD [1]. Subsequent monitoring should be at least every 3 months [1]. More frequent monitoring is appropriate in a variety of clinical situations, including after initiation of ESA therapy, when there is a poor response to ESA therapy, after a course of IV iron, or during administration of chronic IV iron therapy. Children receiving IV iron doses of more than 1.5 mg/kg or more than 100 mg should have a delay of at least 1 week before checking serum iron parameters.

Diagnosis of Iron Deficiency

The gold standard for diagnosing iron deficiency in patients with CKD is bone marrow assessment of iron stores, a test that is impractical on a routine basis. An alternative definition is the response to IV iron. An increase in Hb or a decrease in ESA dose after receiving IV iron suggests that the patient was iron deficient. This definition is not perfect—the "response" to IV iron may be coincidental or the patient may not respond for other reasons—but it has been widely used in clinical research and clinical practice.

The traditional criterion for iron deficiency, the combination of a low serum ferritin and a low TSAT, are not applicable in patients with CKD. The serum ferritin is especially problematic because ferritin is an acute phase reactant, and it is therefore often elevated in CKD patients because of infection and non-specific inflammation. Moreover, treatment with an ESA can induce functional iron deficiency. This occurs because the high rate of red blood cell synthesis depletes the readily available iron, even though total body iron stores may be adequate. Patients with functional iron deficiency due to rapid erythropoiesis may have a normal ferritin, but a low TSAT. Often the ferritin level decreases in these patients, yet it remains in the normal range, and it is therefore not as useful a predictor of iron deficiency as the TSAT.

A TSAT below 20% and a serum ferritin below 100 ng/mL is consistent with an absolute iron deficiency. A TSAT below 20% and a serum ferritin above 100 ng/mL suggests a functional iron deficiency. This same scenario can also

occur with an inflammatory block, a condition where inflammation prevents effective delivery of iron for erythropoiesis. Clinical signs of infection, a low serum iron, an elevated CRP, and an increasing ferritin support a diagnosis of an inflammatory block.

KDIGO recommends treating adult CKD patients with IV iron when the TSAT is <30% and the ferritin is <500 ng/mL, assuming there is an indication (desire to increase the Hb or decrease the ESA dose). It is clear that some patients respond to IV iron despite an elevated ferritin [130]. This has led to controversy regarding the upper limit of ferritin in the KDIGO guidelines, with some suggesting that there is no evidence base for an upper limit for ferritin of 500 ng/mL [72, 73]. There has been an increase in the use of IV iron worldwide [131], and in the US the mean serum ferritin in HD patients increased to close to 800 ng/ml [71].

The KDIGO cutoffs for initiating IV iron in pediatric patients are a TSAT <20% and a ferritin <100 ng/ml. This is quite conservative and many pediatric nephrologists treat patients with TSATs <20–30% despite ferritin values >100 ng/ml. The upper limit of ferritin for holding IV iron for pediatric patients varies among clinicians, with some practitioners using cutoffs of 500–800 ng/ml. This variation is due to the lack of evidence supporting a specific cutoff.

Iron Therapy

After EPO deficiency, iron deficiency is the leading cause of anemia in children with CKD. Treatment of iron deficiency often allows achievement of the target Hb with a lower dose of ESA. Iron therapy should not be given to patients who have iron overload, which is commonly defined as a ferritin greater than 800 ng/mL or a TSAT>50%.

Oral Iron

Only a small percentage of oral iron is absorbed, limiting its efficacy in patients who have high iron requirements due to blood loss, such as children receiving HD [9]. Adherence to therapy may be problematic due to problems with gastrointestinal side effects, including abdominal discomfort and constipation [132]. In HD patients, oral iron appears to be of limited benefit and is poorly tolerated [133].

There is an up-regulation in oral iron absorption in patients who have a low serum ferritin or decreased marrow iron stores. However, HD patients have decreased absorption of oral iron when compared to normal controls; inflammation, which is common in HD patients, decreases iron absorption. This is partially mediated by hepcidin, which inhibits iron absorption from the intestines, and is increased by inflammation [22].

Oral iron absorption is decreased when given with food; hence, iron should be given either 1 h before or 2 h after a meal. Calcium carbonate and calcium acetate decrease iron absorption; oral iron should not be given at the same time as these phosphate binders. Sevelamer seems to have little effect on oral iron absorption [134]. H2-receptor antagonists and proton pump inhibitors may also adversely affect iron absorption.

Oral iron may be adequate therapy in children who are not receiving HD. In children receiving HD, oral iron is often not sufficient to correct absolute or functional iron deficiency [135, 136]. Children receiving chronic IV iron should not receive oral iron given the limited benefits and high rate of side effects of oral iron.

Ferrous sulfate, an iron salt, is the most commonly prescribed oral iron preparation; other iron salts include ferrous fumarate, ferrous gluconate and polysaccharide iron complex. Iron salts rapidly release iron ions, which increases the risk of gastrointestinal side effects. The iron salts are inexpensive options. Children should receive a dose of 3–6 mg/kg/day of elemental iron (maximum dose: 150–300 mg/day).

There are a variety of alternative options to iron salts, but many are expensive, with prices that range from 20 to more than 500 times the cost of ferrous sulfate. The possible advantages include increased effectiveness due to increased bioavailability, and improved tolerability with some preparations.

Ferric citrate was originally approved as a phosphate binder, but has been shown to be effective in treating iron deficiency, though gastrointestinal side effects are common [137–139]. In a randomized study in adults with CKD, ferric citrate was superior to ferrous sulfate for correcting iron deficiency [140]. There is limited pediatric experience with ferric citrate as a phosphate binder [141].

Ferric maltol is an oral iron preparation that was approved by the FDA and European Medical Agency for iron deficiency based on studies of patients with inflammatory bowel disease and CKD [142, 143]. It is better tolerated than iron salts [142]. Because of its improved bioavailability, doses of 30 mg twice daily are effective in adults. A randomized study in adult inflammatory bowel disease patients showed comparable 26 and 52 week efficacy when compared to IV ferric carboxymaltose [144]. There is no published pediatric experience.

Sucrosomial® iron has improved bioavailability and gastrointestinal tolerance compared to iron salts [144]. It is effective in adults with CKD at a dose of 30 mg daily, and had comparative long-term efficacy in increasing hemoglobin in adult CKD patients not on dialysis when compared to 125 mg of IV iron gluconate given weekly, though iron stores improved more with IV iron gluconate [145]. It is much less expensive than the other alternatives to iron salts (ferric citrate and ferric maltol) and is cost-effective when compared to IV iron preparations [146]. It is available over the counter in the US, though only via on-line sources. There is no published pediatric experience.

Intravenous Iron

IV iron is more effective than oral iron in correcting anemia in adult patients with CKD, although the benefit is relatively small in pre-dialysis patients [132, 147, 148]. IV iron is believed to be cost effective in HD patients due to decrease ESA utilization [149, 150]. Studies in children, including a meta-analysis [151], have shown the efficacy of IV iron in correcting iron deficiency, improving Hb levels, and reducing rHuEPO dose requirements [135, 136, 152–155]. There is limited experience using IV iron in pediatric kidney transplant recipients [156].

Acute dosing of IV iron is used for patients who have evidence of iron deficiency, which is most commonly defined based on measures of iron stores. The dose given is relatively large. Chronic dosing utilizes smaller doses to maintain iron stores and provide a regular source of iron for erythropoiesis. Acute dosing results in a more significant change in Hb and iron stores [157]. For children receiving PD or who are predialysis, the goal is usually to minimize the need for IV line placement by maximizing the dose given during a single infusion. A chronic dosing strategy is generally only utilized in patients receiving HD due to the burden of IV placement.

Preparations

There are a variety of IV iron preparations available (Table 59.9). The European Pediatric PD Working Group recommended not using iron dextran due to concerns about life-threatening anaphylactic reactions [30]. These preparations have different side effect profiles. In addition, there is no preparation that is ideal in every situation. Iron sucrose and ferric gluconate have limitations on individual doses and must be given over an extended period when higher doses are utilized. This somewhat limits their utility in patients who are not receiving HD. In contrast, ferric carboxymaltose, ferric derisomaltose and ferumoxytol can be given more rapidly at higher doses. However, ferric carboxymaltose, ferric derisomaltose and ferumoxytol are not designed to be given in a chronic dosing strategy due to product packaging in very high doses.

Ferric gluconate is generally well-tolerated [158, 159], and an effective treatment for CKD patients with iron deficiency [130, 160–163]. Ferric gluconate is available in 62.5 mg vials. Acute dosing in adult HD patients is typically 125 mg administered over 10 min given over 8 consecutive HD sessions (total dose = 1000 mg). The recommended acute dose in children receiving HD is a maximum of 1.5 mg/kg over 10 min. In adults, ferric gluconate doses of 250 mg, over
