disorders are a group of mental disorders whose common feature is preoccupation with food that leads to somatic, emotional, and behavioral problems (Sambol and Cikac 2015). According to the DSM-V classification, three diagnostic categories of eating disorders are listed: anorexia nervosa (AN), bulimia nervosa (BN), and eating disorder not otherwise specified (ED-NOS) (APA 2013). They are usually transient conditions in the period of adolescence but also part of the clinical features of numerous other mental disorders, such as affective disorders, schizophrenia, and others. They usually occur between 10 and 20 years of age. Anorexia nervosa begins earlier, usually in childhood or early adolescence, when bodily changes occur very rapidly and require extra effort for the young person to accept, process, and incorporate them into his/her physical appearance and identity (Fairburn 1997). Bulimia nervosa usually occurs later in middle and late adolescence when the person enters the adult world (Jurcic 2004). The main characteristic of anorexia nervosa is self-starvation and increased physical activity, while the main characteristic of bulimia nervosa is overeating and self-induced vomiting (Vulic-Prtoric and Cifrek-Kolarcic 2011). The origin of anorexia and bulimia has not been sufficiently studied yet; however, it is known that it is a combination of factors that lead to destabilization of the young person's emotional state. Researches confirm that adolescents with bulimic disorder are pathologically preoccupied and dissatisfied with their body, which affects the emergence of anxiety, depression, and low self-esteem (Halvorsen

and Heyerdahla 2006). Low self-esteem, as a crucial part of identity, is related to other aspects of optimal functioning – self-efficacy, relationship with others and oneself, moral actions, academic success, and attitude toward work and responsibilities (Skoro 2009). Researches have shown that body and weight dissatisfaction affects early pubertal maturation, and negative comments from parents and peers affect the young person in the most vulnerable period of growth and development (Berk 2005). Therefore, the adolescent suffering from this disorder needs professional assistance and adequate nutritional, pharmacological, and psychological treatment. Only in this way one can resolve the problems related to eating habits, binges, vomiting, starvation, dieting, or increased physical activity, but also educating how to regulate negative emotions and the impulses that precede the diet, binges, and/or vomiting (Grilo et al. 2005; Barakat et al. 2017).

Mini-Dictionary of Terms

- **Overeating.** Intake of large amounts of food within a short period of time, followed by reduced self-control
- **Bulimic behavior.** Behavior followed by concerns about the weight and body shape, restrictive diet, overeating, and self-induced vomiting
- **Diet.** An unhealthy and ineffective way to regulate weight, which is followed by a strict and low-calorie diet that, if followed regularly, contributes to weight gain and increases the risk of overeating
- **Perfectionism.** A multidimensional concept that has its own non-adaptive, but also adaptive, desirable functions that are manifested by an increased aspiration for perfection for personal growth and development
- **Negative affect.** A general factor of subjective discomfort, decreased mood, fear, and negative emotions that additionally affect the cognition, worldview, and quality of life
- **Emotional eating.** A pattern of behavior characterized by the intake of increased amounts of food to reduce unpleasant emotions such as depression, anxiety, or loneliness

Key Facts of Bulimia Nervosa

Bulimia nervosa is a developmental disorder that has its latent period that begins in childhood and a manifest, clinical period, which under the influence of precipitating factors manifests itself in the period of adolescence.

Sociocultural, psychological, biological, and genetic factors are part of the genesis of bulimia nervosa.

The young person in the period of adolescence has high criteria related to the index of their own appearance and body shape and weight; therefore, the person satisfies the failure to meet high goals with an increased desire to eat and overeat,

which encourages the psychological patterns of behavior in relation to food, such as bulimia nervosa.

Adolescents with a disturbed self-image develop irrational thoughts about their own body appearance and the importance it has in forming a self-image, which further affects their thoughts, emotions, and behavior.

Low self-esteem and self-assessment, anxiety, and depression are present in the background of bulimia nervosa.

Overeating, self-induced vomiting, and increased physical activity are part of the inner self-harming behavior of a young person with bulimia nervosa.

The main goal in the treatment of bulimia is to enable the person to understand, perceive, and change his/her thoughts that will contribute to setting a new and normal, balanced pattern of a diet and change of personal appearance and food, body, and health.

Summary Points

- The changes from a somatic, mental, and psychological aspect that occur in a young person during the period of adolescence affect the person's bulimic behavior.
- Difficulties with self-esteem, affective self-limitation, impulsivity, perfectionism, inadequate image of one's own body, and reduced social abilities of interaction and communication are the main psychological catalysts for the development of bulimia nervosa.
- The dissatisfaction with the image of one's own body leads to negative attitudes toward a diet, weight concerns, dieting, or overeating, which contributes to the development of bulimia nervosa.
- Low self-esteem in adolescence is a result of the conflict that occurs between the ideal and the real self-image, and the person strives for perfection; however, the person satisfies the failure to meet highly set goals by increasing the desire to eat and overeat.
- Cognitive distortion followed by dysfunctional thoughts contributes to the emergence of concerns, anxiety, depression, overeating, or vomiting in the young person, which are a part of the bulimic behavior.
- Bulimia is a result of increased negative emotional affect, and it affects the self-control of the individual, which contributes to overeating and self-induced vomiting.
- The treatment of a person with bulimia nervosa is a long and complex process; therefore, adequate prevention programs should be implemented by means of which the young person will develop a healthy attitude to food, will learn to control unpleasant emotions and thoughts, and will apply a healthy and appropriate way in relation to the care of his/her health and body.

Abstract

A consistent body of research reports reduced ability in visuospatial processing in the eating disorder population. It has been hypothesized that this neurocognitive alteration may be a consequence of the eating disorder *per se* or an underlying

trait-marker. Visuospatial difficulties, in particular weak central coherence (a bias towards detail-focusing thinking style), along with executive dysfunctions, have been proposed as endophenotypic traits for anorexia nervosa individuals. In particular, anorexia nervosa patients and their unaffected relatives show a specific detail-focused information processing bias along with a central coherence weakness, with limited ability to gain and integrate contextual information. In bulimia nervosa individuals' visuospatial profile appears less compromised, and, if a dysfunction is present, it seems to characterize specifically bulimia nervosa individuals with a prior history of anorexia nervosa. Visuospatial abilities should be detected and addressed in specific treatment programs due to their potentially negative role in both treatment outcome and body image disturbance, which typically affect individuals on the whole eating disorders spectrum.

Introduction

A growing number of studies in the past few years have identified visuospatial difficulties as one of the core features for eating disorders (EDs), especially in the case of anorexia nervosa (AN) and bulimia nervosa (BN). Individuals suffering from AN present a moderate degree of cognitive dysfunction in the visuospatial spectrum, at least partially mediated by specific clinical variables such as BMI, education, and severity of eating symptomatology (Stedal et al. 2021). Indeed, in studies specifically including patients in the acute phase of the illness, clinical severity and lower BMI are factors both associated with poorer visuospatial memory (Zuchova et al. 2013).

AN is one of the most severe mental illnesses. It is a condition characterized by drastic caloric restriction and food avoidance as to induce extreme weight loss or failure to gain weight, along with body weight and shape overestimation (considered

one of the key symptoms) that leads to both meaningful concerns for one's body image, continuous efforts to lose weight, and an intense fear of gaining weight, despite being extremely underweight. Similarly, BN is usually characterized by a radical food-restriction behavior interrupted by episodes of binge eating in turn followed by dysfunctional compensatory behaviors (i.e., vomiting, laxative/diuretic misuse, etc.), more restrictive self-imposed dietary rules, and a very intense "emotional breakdown" increasing the likelihood of running into (i.e., vulnerability of) a new loss of control on food and eating. Lastly, in binge eating disorder (BED), patients exhibit binge eating and very troubled body weight and shape concerns without compensatory behaviors. Usually, as the disease progresses, there is a surge in body weight which, although it is not a diagnostic criterion, takes the role of core symptom for diagnosis, as sufferers express both great distress and pain in dealing with their body weight. Body dissatisfaction and emotional dysregulation are both factors associated with greater vulnerability of incurring in dysfunctional behaviors and of getting stuck in the restriction binge eating loop. Some authors conceptualized body size overestimation characterizing not only AN individuals but also those who are affected by BN and BED, as a direct outcome of visuospatial failure (Lang et al. 2014, 2016). In the non-clinical sample, body size overestimation is associated with poor visual memory (Thompson and Spana 1991). Several authors speculated on the link between body image alteration and a detail-focusing thinking style characterizing AN individuals (Madsen et al. 2013; Urgesi et al. 2012). In particular, it has been proposed that an enhanced attention to local information along with a weakness in the ability to reach global features may predispose to disproportionately focus on detailed body areas, leading to greatest dissatisfaction (Madsen et al. 2013).

Moreover, visuospatial alterations can tie with poor set-shifting, another very peculiar cognitive style observed in ED conditions, leading to a strong cognitive and behavioral rigidity and an extreme need for repetitiveness and keeping to routines (Shott et al. 2012; Steinglass et al. 2006).

Diagnosis, differential diagnosis, clinical classification, and treatment of EDs have traditionally focused on pathological behaviors (i.e., food intake restriction, physical hyperactivity, vomiting, etc.) and typical thoughts and beliefs associated with ED (i.e., fear of gaining weight despite being underweight, body weight overestimation, etc.), while it is only in the last few years that a growing interest towards phenotypic and endophenotypic traits has been observed (Kanakam et al. 2013). This relatively recent focus on cognitive functioning of EDs, in particular on set-shifting and visuospatial abilities, is at least partly supported by some considerations, such as:

- EDs are conditions which are very difficult to treat; to date, elective psychological interventions are very few and for some cases far from effective. Specifically, about half of patients with AN diagnosis recover completely, and 20% remain ill for the rest of their lives (Amianto et al. 2017). Furthermore, relapse rates tend to rise at longer follow-up intervals and appear highly variable (i.e., 9–52%) (Khalsa et al. 2017). Regarding BN, in a recent meta-analysis, over 60% of patients failed to fully overcome eating symptoms despite receiving gold standard treatments (Hagan and Walsh 2021). The long-term outcome studies on the BED population suggest a chronic course of the disorder characterized by a succession of recovery

and relapse phases, with fewer diagnostic migrations than observed in AN and BN (see Hilbert 2019 for a complete overview).
- Neurocognitive weaknesses can have a role in increasing both the vulnerability and the risk of maintaining core symptoms of ED (Connan et al. 2003; Schmidt and Treasure 2006).
- Neuropsychological features can have a negative impact not only on the course of the illness (prognosis) but also on the response to treatment (in terms of both motivation to change and treatment outcome) and, in line with previous considerations, may contribute to maintaining the disorder itself (Harper et al. 2017; Smith et al. 2018).

Studies on cognitive abilities in the ED population are not in line with each other. Alongside those who found a clear visuospatial affection (Lopez et al. 2008a; Tenconi et al. 2010; Weider et al. 2015), there are those who failed to find any cognitive malfunctioning in ED individuals (Jones et al. 1991; Thompson 1993; Øverås et al. 2017), perhaps due to methodological heterogeneity such as experimental design, sample sizes, cognitive tasks employed, and age of the sample (Smith et al. 2018). Moreover, among the studies that found poor visuospatial functioning in the field of ED, it is still unclear whether and to what extent this cognitive alteration represents a premorbid and stable trait-marker rather than a state-characteristic, due to the acute state of the illness. Longitudinal studies on adults (especially in AN) found that visuospatial inefficiencies still persist after recovery (Tchanturia et al. 2002) supporting the trait nature of these inefficiencies. Nevertheless, looking at the duration of the illness, poor cognitive functioning could be considered a consequence of prolonged malnutrition rather than a true trait-marker of the illness (Stedal et al. 2021). Especially in the adolescent population, illness recovery induces cognitive improvement (Lang and Tchanturia 2014; Lozano-Serra et al. 2014; Hemmingsen et al. 2021). The same pattern has been observed with regard to the weak central coherence construct: superior local information processing along with a poorer global thinking style seems to persist despite ED recovery, indicating that both aspects may be stable traits than temporary effects of symptoms, specifically malnutrition and low BMI (Lopez et al. 2009). Furthermore, stronger local processing and weakened global integration appear as relatively independent dimensions (Lopez et al. 2009).

Visuospatial Abilities and Mental Rotation

A promising theoretical framework sees ED individuals enabled in integrating specifically egocentric (vs allocentric) multi-sensory cues, including visuospatial information (Riva 2012). The body image is conceptualized as a construct stored in long-term memory and influenced by implicit and explicit perceptions continuously updated by the perceptual system. The egocentric frame is linked to first-person experiences, perceptions, and short-term memories, with the individual (the body) as the center point of reference, while the allocentric frame refers to a third-person point

of view and relies on long-term memory and schematic representations of space, with spatial orientation gained by external landmarks not associated with the location of the individual's body. This framework conceptualizes AN as a result of a biased perception along with an inability to update the perceptual information in long-term memory. One study found difficulties in processing specifically spatial stimuli from an egocentric perspective in both AN and BN individuals (Serino et al. 2015). Studies which used both mental rotation and object perspective-taking tasks found that AN patients did not perform differently from controls in allocentric perspective tasks, indicating a preserved ability to process the body as an object in the same way as other objects in the environment, while the egocentric perspective tasks (object perspective-taking test) appeared affected. In the object perspective-taking tasks, the task request is a re-estimation of our own position in relation to other objects in space. AN participants show difficulties in updating new locations and a specific difficulty in taking a first-person (egocentric) perspective suggesting an impaired neuronal activity underlying this task (i.e., left inferior parietal lobule and the left somatosensory cortex) (Cipolletta et al. 2017; Lander et al. 2020). Moreover, among individuals with acute AN, measures of detail processing and global integration correlated with connectivity of the left parietal cortex within the somatosensory network, which is involved in the long-term multimodal spatial memory and representation (Favaro et al. 2012). Although perceptual abilities in AN appear to be intact when it is the external world to be processed, things do not work in the same way when it is one's own body that needs to be processed. Egocentric alterations of one's body image would be involved in the body image distortion observed in EDs and may potentially contribute to the development and maintenance of the disorder itself. AN individuals show abnormal egocentric representations along with spared allocentric visual abilities, and the former has been hypothesized to be worsened by visual perception and cognitive flexibility difficulties (Lander et al. 2020).

Central Coherence

Utah Frith in 1989 introduced the term "central coherence" in the context of autism spectrum disorder (ASD) to indicate the natural predisposition to process environmental information integrating features progressively to gain the whole gestalt. Frith named this tendency "weak central coherence" highlighting how at this level information is processed piece by piece, in an extremely detailed way, as opposed to whole perception. Individuals with ASD show a specific cognitive style characterized by strong local processing strategies that keep information fragmented hindering their integration into a meaningful whole (Muth et al. 2014). This phenomenon was already known in the middle of the last century, named field-dependence and field-independence, for individuals with a stronger global and local bias respectively (Witkin et al. 1971). It is the same as that already observed by Navon who found that in the general population, perception is affected by a natural bias from a global to a local processing where the global elements take

precedence over local details (i.e., "a scene is decomposed rather than built up"; Navon 1977, 2003). Weak central coherence is thought to underlie a broad spectrum of skills at both high (i.e., conceptual, abstract, and strategic thinking) and low levels of processing (i.e., visual and perceptive) (Happé and Frith 2006). This pattern of information processing seems to fit the broader autism phenotype well, accounting for the cognitive processing pattern usually adopted in both individuals affected by autism and their relatives (Happé et al. 2001). Lopez et al. (2008a) following Happé and Frith's model of weak central coherence (i.e., poor global processing) in ASD individuals (Happé and Frith 2006) proposed a similar bias towards details in ED individuals. In line with these findings, in the last 20 years, there has been a growth of studies investigating the overlap between EDs, especially AN and ASD (Nickel et al. 2019). The cognitive profile of the two disorders shows some close overlaps, such as both cognitive and behavioral rigidity, the need for repetitiveness, withdrawal from social contacts, and an extreme detail-focused cognitive style at the expense of the contextual information (i.e., global picture). Performance across visuospatial tasks showed an alteration in central coherence in both AN and BN, not only in individuals affected but also in recovered patients and in their unaffected relatives (Lopez et al. 2009; Tenconi et al. 2010; Roberts et al. 2013). The first studies on central coherence found that people affected by an ED show difficulties in global processing, but their superiority in local processing appeared more controversial (Lopez et al. 2009). In particular, its seems that AN individuals and their relatives display high piece-by-piece information processing style (local), while BN patients and their relatives display just a weak central coherence profile, without a local advantage. In line with this, in visuospatial tasks requiring global processing strategies (i.e., the Object Assembly subtest of WISC and WAIS, the Rey-Osterrieth Complex Figure Test, the Bender Gestalt Test), AN individuals perform worse than controls, while in tasks requiring detail-focused strategies (i.e., Block Design, the Matching Familiar Figures Test, the Overlapping Figures Test), their performance appears to be average, if not even above average. In these cases, the better performance has been attributed to a piece-by-piece information processing proneness characterizing both ASD and AN individuals. Regarding the Rey-Osterrieth Complex Figure (ROCF), poor organizational and planning strategies adopted to copy the picture affect copy performance (accuracy score) and immediate (3′) and delayed (10′, 20′, 30′) figure recall (visual memory). Lang et al. (2014) in their systematic review confirmed the involvement of the weak central coherence hypothesis in the ED population.

Anorexia Nervosa

The visuospatial abilities in AN appear altered in both perception and memory. Individuals with current AN perform the copy condition of ROCF, assessing perception and visuospatial planning and organization, significantly worse than healthy controls (Lopez et al. 2008a; Kim et al. 2011), whereas fully recovered AN individuals show improved perception and planning (Lindner et al. 2013). Their ability to

identify the perceptual structure of the complex figure appears preserved, but elements are organized in a fragmented way as a result of a detail-focused thinking style, leading to poor construction abilities. Spatial memory skills also appear deficient in acute AN people (Lopez et al. 2008b), and some authors proposed that a poor visual memory may be a result of the bias towards detail-focused processing (Lopez et al. 2008a; Stedal et al. 2012). As already mentioned, AN individuals show a general weakness in their central coherence, with an information processing style characterized by a strong focus on details along with difficulties in global integration (Smith et al. 2018). This pattern is more evident in the adult population but less consistent in studies on adolescents (Lang et al. 2014). In AN there is some evidence suggesting that the recovered individuals show a higher detail processing along with a better visual coherence (on the ROCF) than acute patients. Therefore, weight loss and malnutrition seem to negatively affect both detail processing and global integration (Lopez et al. 2009). Nevertheless, the literature on these aspects does not appear to be in agreement; indeed, a very recent systematic review reports that factors such as BMI, anxiety, and depression do not affect central coherence abilities in AN (Fuglset 2021).

Bulimia Nervosa

Although BN and AN are clearly distinct disorders, with specific diagnostic criteria (DSM-5), there is a strong overlapping between them in "core" ED distinctive symptoms, such as body weight and shape concerns, overevaluation of one's one body size, and the close interdependence between self-esteem and body weight. This tight bond between BN and AN diagnoses is also highlighted by the very frequent diagnostic migrations within the ED spectrum, particularly from AN to BN, suggesting some biological and psychopathological common processes (Eddy et al. 2008). Studies on BN found poor visuospatial functioning in both visuospatial memory and central coherence (Lopez et al. 2008c). In particular, BN patients showed lower accuracy scores on the copy trial of the ROCF and impaired visuospatial memory (Bosanac et al. 2007). Investigations on information processing approaches in ED found a greater difficulty in global integration (weak central coherence) in BN individuals, whereas a higher detail-focused processing characterizes those with AN diagnosis (Roberts et al. 2013). A weaker performance in tasks which benefit more from a global strategy (i.e., the ROCF) along with a superior detail-focused processing (e.g., shorter times for completing the Embedded Figure Test, lower Central Coherence Index, and a trend for a smaller advantage from Block Design segmentation) appeared to characterize BN individuals. In light of these data, BN shows weak central coherence and some overlaps with the visuospatial profile of individuals with current AN (Lopez et al. 2008b). Both the presence of high levels of anxiety and the severity of BN psychopathology in acutely affected individuals negatively impact the accuracy performance of the ROCF and the CCI (Lopez et al. 2008c); even so it seems to be an aspect that persists at the remission of anxiety symptoms (Lopez et al. 2009). Nevertheless, cognitive impairment in BN

(visuospatial as well as that regarding executive abilities) appears to be less severe and more heterogeneous than in AN (Weider et al. 2015, 2016; Darcy et al. 2014; Lopez et al. 2008c). A possible explanation of this milder cognitive profile characterizing the BN population may be the presence or not of a prior history of AN in individuals with a current BN. The very few studies that differentiated BN patients with "pure" BN (without a prior diagnosis of AN) from those with prior AN found a significative difference compared to healthy controls exclusively in this latter group and specifically for executive abilities, but no differences in visuospatial skills were found (Degortes et al. 2016; Strumila et al. 2020). The only prior investigation on visuospatial functioning in BN that considered the presence or not of a prior diagnosis of AN (in this study the authors assessed 24 "pure" BN and 18 BN with prior AN) found a greater local processing in BN/AN patients than in the "pure" BN (Lopez et al. 2008c), supporting the hypothesis of some impact of prior AN on the thinking style of current BN. The presence of a previous history of AN in BN individuals may have affected cognitive and physical functioning differently from those patients who have never experienced malnutrition and a very low BMI. All these studies support the hypothesis of a residual detrimental role of having had prior AN. In line with this, a poor ICC in the AN study of Weider et al. (2016) no longer differs from controls once it is adjusted for nadir BMI. Although for BN cognitive behavioral therapy is a gold-standard treatment with ample proof of a good efficacy, about one-third of BN patients show poor treatment outcomes. The presence of a prior history of AN implies a greater involvement of physical and cognitive aspects that should receive proper attention, as well as requiring specific care (Strumila et al. 2020).

Binge Eating Disorder

With respect to cognitive functioning, individuals with BED show specific eating disorder-related difficulties and a relative saving of general cognitive abilities. As noted above, the BED condition is usually strongly associated with overweightness and obesity, and some lines of research in both animals and humans support the association between a high-fat and a high-sugar diet, as well as a poor-quality diet and a reduced neural plasticity also associated with alterations in spatial memory (Cordner and Tamashiro 2015; Francis and Stevenson 2011). In a study using the Zoo Map task, in which participants are asked to produce a plan to navigate among a series of positions on a visual map, obese BED individuals made a higher number of errors than non-BED obese participants, providing the first evidence of the link between BED and poor spatial processing (Duchesne et al. 2010). Moreover, there are also insights about relationships between visual memory deficit and being overweight or having binge eating (loss of control) (Calvo et al. 2014; Prickett et al. 2015). Two studies on the obese population found poor performance not only in memory trials but also in the copy trial of the ROCF, a perceptual task usually considered preliminary to the memory test (i.e., the delayed recall part of the ROCF) (Boeka and Lokken 2008; Roberts et al. 2007). In the BED population, visual

memory appears to be deficient, regardless of BMI. According to some studies, as happens in overweight people, also in this population, in addition to poor memory recall, patients reported poorer accuracy scores in the copy trial, again indicating perceptual difficulties (Aloi et al. 2015). Moreover, in a more controlled (i.e., the study considered both normal-weight and overweight BED patients and weight-matched controls) and recent study, BED individuals showed a saving in perceptual skills (i.e., good performance on the coping trial), as well as good visuospatial recognition abilities, along with poor performance on both immediate (3′) and delayed (30′) recall trials compared to controls indicating visual memory deficiency (Eneva et al. 2017). The latter study found an association between BED diagnosis and visual memory difficulties regardless of body weight. It is possible that visuo-spatial memory alterations may affect body size estimations. Future studies of BED using the ROCF should examine central coherence measuring the organizational and perceptive approach strategies for drawing the complex figure.

Tasks Description

Visuospatial abilities are multiple and complex skills consisting in the perceptual analysis of the visual environment by structuring the local elements (details) into a coherent and meaningful perceptual configuration. The literature suggests that the development involves a progressive shift from a local perceptive processing to a global decoding of visuospatial information facilitating global information processing as compared to detail processing. The different but related visuospatial abilities include more "pure" visuospatial functions, such as spatial construction, spatial analysis, and manipulation and visuo-motor coordination, but also the superior executive functions. Spatial analysis consists in the ability to visually perceive the external environment, break it down into sub-elements (local processing), and then integrate details into a coherent whole (global processing). All of these functions lead to organizing and integrating details to perceive a spatial configuration by reproducing spatial patterns. Usually, constructional abilities are assessed by a complex drawing and/or block assembling. The most widely used tasks for spatial construction are the Rey-Osterrieth Complex Figure Test and the Block Design Test. For example, the ROCF is usually employed to assess visuospatial perception and memory but also organizational strategies such as planning and a more local or global cognitive approach. In psychiatry there is a lack of cognitive tests specifically developed and tailored to cognitive alterations characterizing major psychiatric disorders. Neuropsychological tasks were originally conceptualized to detect the effects of focal injury due to brain damage or trauma, and they are not entirely suitable for the psychiatric population, characterized by a different type of damages, usually widespread and enduring. Perhaps, for these reasons they may not be (or not always be) sensitive enough to detect also minor cognitive difficulties (Keefe 1995), which sometimes characterize those who suffer from a psychiatric disorder, especially in the first stages of the illness. A good alternative might be to consider process scores (i.e., considering behaviors and reasoning employed to solve the task) more

Table 1 Visuospatial tests divided according to their local vs global properties

Tasks whose performance benefits more from:	
LOCAL processing	GLOBAL processing
Embedded Figures Test/Group Embedded Figures Test	Rey-Osterrieth Complex Figure test
Matching Familiar Figures Test	Object Assembly
Block Design	Overlapping Figures test
Unsegmented Block Design	Segmented Block Design

than the outcome scores themselves (Stedal et al. 2019). A good example of process scores may be the Central Coherence Index (CCI), an outcome score ranging from 0 to 2 which represents the individual's local vs global natural predisposition (i.e., the bias for detail-focused versus global-synthesis approach in information processing) in copying the ROCF, which appears to well (with a large effect size) differentiate AN individuals from controls.

The tests most commonly used for assessing visuospatial abilities in the field of ED (see Table 1 for a classification of tasks on the basis of their local/global task demand strategies) are:

- The Rey-Osterrieth Complex Figure (ROCF) (Osterrieth 1944), which is no longer regarded as a purely visuospatial test, but is now considered a good task also for the assessment of higher executive functions. Savage et al. (1999), assessing the ROCF performance of obsessive-compulsive individuals, proposed that visual memory deficit could be at least partially explained by difficulties in cognitive planning and organizational strategies activated during the copy trial of the complex figure. The ROCF assesses a variety of cognitive processes such as visual perceptual organization, spatial planning, problem-solving, spatial memory, and motor function. The task consists of two parts: the first assesses perceptual abilities, and participants are asked to copy the complex figure as closely as possible to the template. Successively, without prior warning, they are asked to recall the figure after a temporal delay that may vary from 3 to 30 min (implicit visual memory). The task gives two outcome measures, the perceptual accuracy score and the visual memory accuracy score. The former consists in the correct placement and reproduction of 18 details composing the complex figure, and the latter is the correct placement and production of the same 18 details from memory, after a longer or shorter time interval. In both cases higher scores are indicative of a better performance (range 0–36). The most used scoring system is that proposed by Taylor (1969), adapted from Osterrieth, but there are a lot of different alternatives. Process scoring for organizational strategy and drawing style specifically in the ED population have been developed by Booth (2006). This score system allows us to obtain the CCI, derived from both the order of construction index (the first six global or local elements drawn in the copying trial) and the style index (the degree of continuity of drawing). A higher CCI (the closer the scores are to a score of 2) is indicative of a more coherent drawing style. In

general, a weak central coherence cognitive style (low ICC score) in copying the complex figure adversely impacts on the quality of recall (Lopez et al. 2008a).

- The Object Assembly (a subtest of the Wechsler Adult and Children Intelligence Scales – WAIS and WISC), which is a test assessing the ability to solve five small jigsaw-type puzzles reproducing familiar objects (e.g., a hand, a mannequin). Participants have a time limit to complete and build each object starting from single pieces. Both the time taken to complete the puzzle and the number of pieces correctly assembled are outcome measures. A shorter time suggests a better ability to create an integrated global representation from its parts, indicating stronger global processing.
- The Overlapping Figures Test (Lezak et al. 2004) evaluates the ability to discriminate figures from the background (visual interference), spatial exploration, and denomination abilities. The task consists in a set of overlapping lines which, on closer analysis, hides different types of meaningful shapes (e.g., animals, fruits, words, numbers, etc.). The participant is asked to recognize and correctly denominate the greatest number of figures within a 4 min time limit. Differently from the EFT, in this task the overlapping lines configure many meaningfulness stimuli, and a unified meaningful shape is more difficult to be interpreted in terms of local parts. In this task, a weak central coherence (i.e., difficulties in global processing) is thought to reduce performance (i.e., the detection of as many figures as possible).
- The Block Design (subtest of the WAIS and WISC), which is a construction test assessing the ability to reproduce a complex geometric figure by putting together sets of blocks to replicate the block-design depicted on a two-dimensional template. The outcome score considers both the time taken and the number of block designs correctly reproduced. A higher performance on this task is considered to be indicative of a better detailed visual processing (i.e., higher ability to segment the figure into its constituent elements). Some studies (Tenconi et al. 2010) used a modified version of the Block Design Test, the Unsegmented/Segmented version developed by Shah and Frith in 1993. In the Segmented trials, templates are not presented as a whole (in this case the participants have to split the design into its component elements to solve the task), but are already divided into smaller portions slightly separated from each other. Higher scores in both speed and accuracy are indicative of a better local processing approach, and people usually benefit more from the segmented (vs unsegmented) version. People with weak central coherence should benefit less from segmentation (i.e., should show no difference in performance between unsegmented and segmented trials) (Lopez et al. 2008b).
- The Embedded Figures Test (EFT)/Group Embedded Figures Test (GEFT) (Witkin et al. 1971). This perceptual test measures the time taken to locate and trace 12 (or 18 in the GEFT) simple shapes embedded in complex designs. Scores are expressed in seconds and represent the time taken to locate the hidden shapes and number of errors and false claims. A shorter time and fewer errors/false claims suggest stronger local processing.

- The Matching Familiar Figures Test (MFFT) is a visuo-perceptual test designed to measure reflection-impulsivity. The participant is asked to select from eight very similar alternative items the exact match of a template. The time required to complete all the matches and the number of errors are outcome scores. People who record above-median response times and below-median errors are classified as reflective; people with below-median response times and above-median errors are impulsive. In this task a more detail-focused processing results in better efficiency (i.e., a reduction in both time and errors).

Clinical Implications

The natural tendency to process detail-focused information better in EDs may impact on clinical psychopathology, treatment involvement, and outcome. In particular, the bias towards local processing may prompt and/or maintain maladaptive pattern behaviors as well as make individuals unable to see both the situation as a whole (bigger picture) and the negative effects/outcomes of dysfunctional choices. In line with these considerations, the difficulty in integrating all the data in a bigger picture (context) may limit seeing the long-term consequences of the dysfunctional behaviors triggered by the ED, along with a limitation of the ability to learn from the experience. The strong need observed in EDs for both everything to appear perfect and under strict individual control, combined with an extremely detailed information processing style, may affect eating behavior and other aspects of patient's life (i.e., academic, work, personal and interpersonal life). The extreme detail-focusing processing style risks getting the patient stuck in them, exacerbating core cognitive and behavioral ED symptoms (i.e., perfectionism, rigidity, fears). This bias towards local information over the whole body perception may limit the integration of bodily perceptions and feelings contributing to body image disturbance and distortion, resulting in the overestimation of one's own body size (the peculiar phenomenon of feeling and perceiving oneself as fat despite being severely underweight), or the amount of food intake.

Treatment Implications

The visuospatial difficulties along with the central coherence deficit characterizing information processing in EDs in general, and AN in particular, represent quite stable disorder traits that could contribute to illness onset and maintaining and should be addressed in treatment programs. In particular, some authors developed a specific cognitive treatment (i.e., cognitive remediation therapy) that addresses these aspects directly, helping patients to increase self-awareness about their own thinking style (i.e., the attention is more on the ways than on the contexts of thinking) and stimulating patients to criticize and overcome this specific thinking style promoting the assumption of a broader view (Lindvall and Rø 2014).

CRT is a manualized program, usually employed as an add-on treatment, which addresses the cognitive style underlying both the development and maintenance of AN and other EDs. CRT is a metacognitive intervention considered, with a few exceptions (van Passel et al. 2020), able to increase the effectiveness of traditional treatments and to improve cognitive abilities and quality of life, and in some cases it has also reduced ED symptoms and treatment dropout (Lindvall and Rø 2014; Leppanen et al. 2018). CRT aims to help patients to adopt a new cognitive style through stimulating and engaging in new activities avoiding issues and emotions relating to all that concern the usual eating disorder aspects (e.g., food avoiding, fasting, fear of gaining weight). The key items of CRT are that practicing a determined cognitive skill is thought to improve both the performance itself and the sense of self-efficacy. Moreover, practicing a new cognitive process may increase the neural network (via brain plasticity) involving and activating less-used brain areas. In particular, CRT comprises exercises focusing on enhancing visuospatial abilities and reducing central coherence weakness/extreme attention to detail encouraging patients to "see the wood from the trees," to move on to the whole context by reducing the natural tendency to focus attention on details. CRT also has the key role of indirectly preparing and motivating patients to a more general and eating-addressed psychotherapy. For example, one of the aims would be to help the patient to become more able to manage a full meal without pausing on each single food (e.g., calorie counting or rumination). See Fig. 1 for an example of a CRT exercise in adopting a broader view.

- Task demand: the patient verbally describes the complex figure so that the therapist can draw it without being able to see it. At the end the therapist's drawing is compared with the template, and a metacognitive style discussion follows.
- Reflection questions on the task (e.g., what the patient thinks about the task, which kind of thinking did he/she use, etc.)

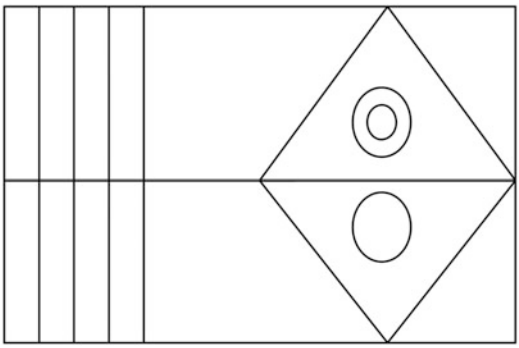

Fig. 1 Complex picture task (Tchanturia et al. 2010 CRT Manual, https://www.katetchanturia.com/_files/ugd/2e1018_f71866481f9f44e5a342fb068b891a8c.pdf)

Conclusion

The literature supports the idea that neurocognitive anomalies characterizing EDs are not a mere consequence of illness state (such as malnutrition, underweight, or purging behaviors) but rather represent a specific and relevant feature to support the diagnosis, involved in the onset, maintenance, and vulnerability to relapse, after a period of recovery. If cognitive alteration can be involved in the maintenance of the illness, it should be specifically addressed in planning treatment interventions, according to the specific processing style shown by the specific patient.

Application to Other Areas

In this chapter, we have dealt with visuospatial abilities and disabilities across the whole spectrum of eating disorders. Anorexia nervosa patients present the greatest impairments in this cognitive area, followed by bulimia nervosa individuals with a previous history of anorexia nervosa (Lopez et al. 2009; Tenconi et al. 2010; Roberts et al. 2013). The "pure" bulimia nervosa patients appear to have slight difficulties, while binge eating patients show deficiencies mainly when the stimuli are specific eating disorder-related (vs. neutral stimuli), although there is growing evidence of some visuospatial fragility (Degortes et al. 2016 for BN and Duchesne et al. 2020; Kittel et al. 2015 and Eneva et al. 2017 for BED). Visuospatial alterations appear to persist after clinical improvement in both anorexia nervosa and bulimia nervosa patients (Tchanturia et al. 2002; Lopez et al. 2009; Tenconi et al. 2010) and seem slightly mediated by psychopathology (i.e., low BMI, illness severity, etc.) (Stedal et al. 2021). The adolescent population needs deeper attention because there are insights of some improvement after initial recovery (Hemmingsen et al. 2021). We should consider visuospatial functioning as a broader construct, as it appears involved not only in eating disorders but also in other psychiatric populations, such as autistic spectrum disorders and schizophrenia. Especially in the latter condition, visuospatial deficiencies already appear to be present in the first episodes and, worsening as the disorder progresses, they seem to worsen the prognosis and it would be very important to disentangle them from the hypothesized negative impact of antipsychotic medications (Happé et al. 2001; Stirling et al. 2003).

Mini-dictionary of Terms

- Visuospatial abilities are multiple and complex skills consisting in the perceptual analysis of the visual environment by structuring local elements (details) into a coherent and meaningful perceptual configuration.

- Central Coherence is the natural predisposition to process environmental information (not only perceptual data) progressively integrating features to gain the whole gestalt (the context, or big picture).
- Weak central coherence indicates a personal tendency to process information piece by piece, in an extremely detailed way, as opposed to processing information as a whole.
- Visuospatial tests are specific tasks employed to both assess and quantify visuospatial skills.
- The Complex Picture Task is an exercise belonging to the Cognitive Remediation Therapy program, designed to address weak central coherence and promote a more global cognitive thinking style.

Key facts of Visuospatial Abilities in Eating Disorders

Visuospatial Abilities

- Visuospatial difficulties affect the eating disorder population.
- Visuospatial difficulties have been proposed as endophenotypic traits for both anorexia and bulimia nervosa.
- Both patients and unaffected relatives may show some visuospatial inefficiencies.
- Weak central coherence is a specific visuospatial alteration and characterized by a bias toward detail-focusing thinking style.
- Clinical improvement does not seem to significantly improve visuospatial cognitive style.

Summary Points

- *Individuals affected by an eating disorder show a reduced ability in visuospatial processing.*
- *Anorexia nervosa patients show a specific detail-focused information processing bias along with a central coherence weakness.*
- *Cognitive alterations consistently associated with AN were less present in BN, especially in those individuals without a previous history of AN.*
- *BED individuals show altered retrieval of a complex visual stimulus, independent of their BMI.*
- *Memory abilities may be negatively affected by unhealthy diet, and memory may affect food intake behavior.*
- *Visuospatial abilities may further affect and worsen body image disturbance observed in the whole eating disorder spectrum.*
- *Visuospatial abilities should be detected and addressed in specific treatment programs due to their role in the development and maintenance of the disorder itself.*

Androgens and Their Role in Bulimia Nervosa and Eating Disorder Not Otherwise Specified of Purging Type (EDNOS-P)

39

Contents

Abstract

The sex steroid hormones, estrogen, progesterone, and androgens, play an essential role in the pathophysiology of bulimia nervosa (BN). The importance of androgens has also been recognized recently. However, the research on androgens' role in bulimic disease, and its psychopathology and comorbidity, is scarce.

Androgens exert direct action on the CNS but also in conjunction with estrogens, and progesterone.

APABulimic women of normal body weight have disturbances in the hypothalamic-pituitary-thyroidal axis and are at increased risk of developing physiologic and endocrine disturbances, including menstrual irregularities. Polycystic ovarian syndrome (PCOS), with features of biochemical hyperandrogenism, menstrual disturbances, and polycystic ovarian morphology, can

be seen in women with BN. Antiandrogenic oral contraceptives appear to reduce bulimic symptoms, meal-related appetite, and bulimic behavior. Maybe BN is a hormonal rather than primarily a psychiatric illness in some cases.

In a recent study, it has been found that women with BN and the subgroup of Eating Disorder Not Otherwise Specified of Purging type (EDNOS-P) had different origin of androgens, despite similar androgen levels. A direct ovarian testosterone (T) secretion was found in women with EDNOS-P, and peripheral conversion of circulating androstenedione (A2), and dehydroepiandrosterone sulfate (DHEAS) in women with BN.

These findings can perhaps be interpreted as a transition between EDNOS-P to BN and vice versa; the results may also indicate endocrine and psychoendocrine differences between the two groups of bulimic women.

These implications of sex steroid hormones' involvement in the pathophysiology of BN are yet to be understood.

PMS	Premenstrual syndrome
T	Testosterone
VLDL	Very-low-density lipoproteins

Introduction

This chapter deals with androgens' role in women with bulimia nervosa (BN) based on studies in the field. There are several proposed biological mechanisms thought to cause and perpetuate BN pathology. However, this chapter will only address the effect of sex steroid hormones' association with BN.

Most of the recent findings concerning androgen's role in BN includes the subgroup of Eating Disorder Not Otherwise Specified (EDNOS), based on the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) (APA 2000).

The sex steroid hormones, testosterone (T), 5α-dihydrotestosterone (DHT), and 17β-estradiol (E2) influence, among many other factors, the development of eating disorders. Therefore, a background of these hormones' mechanisms of action will be addressed here.

Androgens and Their Mechanism of Action

Cholesterol is the precursor for all steroid hormones, including gluco- and mineralocorticoids, sex hormones, and vitamin D. The production of cholesterol takes place in the liver but most of the supplies come from plasma low-density lipoproteins (LDLs) derived from dietary cholesterol (Gwynne and Strauss 3rd 1982) (Fig. 1).

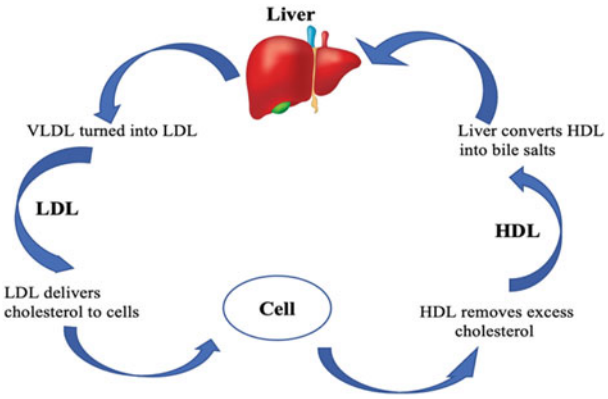

Fig. 1 Production of cholesterol and triglycerides in the liver

Pregnenolone is the main steroid synthesized from cholesterol, which is converted to steroid hormones after a series of enzymatic processes. The biologically active androgens, testosterone (T), and 5-α- dihydrotestosterone (DHT) are formed by de novo synthesis in the ovaries and the adrenal cortex, but the main part arises through peripheral conversion of the adrenal androgens 4-androstene-3,17-dione (A-4), dehydroepiandrosterone (DHEA), and its sulfate (DHEA-S) in the liver, kidneys, muscles, fat, and skin and in the CNS (Miller and Auchus 2011).

Consequently, peripheral testosterone can cross the blood-brain barrier and have various effects on the brain (Melcangi et al. 2008). Dihydrotestosterone has a higher molar potency because of its higher affinity for the androgen receptor, and the androgenic action is diversified by the aromatase (CYP19) mediated conversion of testosterone to estradiol.

The testosterone production in the gonads follows the pulsatile release of luteinizing hormone, and circulating testosterone concentrations result in suppression of gonadotropin (LH and FSH) secretion (Dabbs Jr and La Rue 1991) (Fig. 2).

In the ovaries, androgen formation is performed in LH-stimulated thecal cells, with the synthesis of DHEA and A4. Most of these precursors will be converted to estrogens by granulosa cells, but ovaries will also directly secrete androgens in the circulation, mainly as A4 and T (Burger 2002).

The secretion of testosterone from the ovaries is stimulated by luteinizing hormone, with estradiol exerting negative feedback, while in the adrenal cortex, the secretion of testosterone is stimulated by adrenocorticotropic hormone with negative feedback by cortisol.

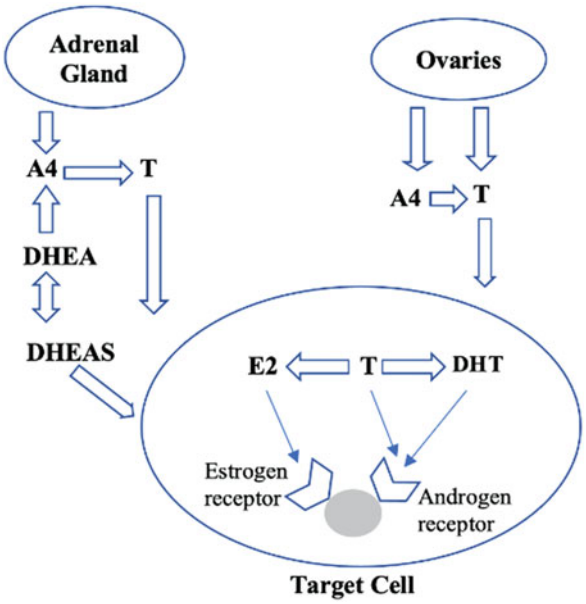

Fig. 2 Testosterone production in women

Testosterone production in premenopausal women is approximately 0.1–0.4 mg per day (Burger 2002), and the circulating testosterone concentrations are stable and not subject to negative feedback by exogenous testosterone (Rothman et al. 2011).

In the circulation, testosterone is specifically bound to sex hormone-binding globulin (SHBG) (∼66%) and to albumin (∼32%), leaving only a small fraction free (∼2%). SHBG is produced and secreted by the liver, binds to testosterone with high affinity, and regulates their bioavailability. In addition, the hepatic production of SHBG is raised by estrogens, and suppressed by androgens.

Testosterone is predominantly bound to SHBG; however, various terms are used to explain the degree of binding grades. *Total testosterone* refers to the sum of the concentrations of protein-bound and unbound testosterone in circulation. The fraction of circulating testosterone that is unbound to any plasma protein is referred to as the *free testosterone fraction* (Manni et al. 1985).

The term *bioavailable testosterone* refers to the fraction of circulating testosterone that is not bound to SHBG and largely represents the sum of free testosterone plus albumin-bound testosterone. However, recent data shows that the bioavailable testosterone also includes SHBG-bound testosterone, which seem to mediate the cellular uptake and biological actions of testosterone (Hammes et al. 2005). One of the most abundant proteins in plasma is albumin. Although it binds testosterone with lower affinity than SHBG does, its high binding capacity and high concentration allow it to buffer fluctuations in testosterone levels (Hammond 2016).

In addition, the hepatic production of SHBG is regulated positively by estradiol, while androgens decrease its production. The androgen DHEAS is the most abundant circulating steroid hormone in the body. It enters the ovarian follicle and can be an important source of ovarian testosterone (Burger 2002). The serum concentrations of androgens in descending order are DHEAS, DHEA, A-4, T, and DHT, though only the latter two bind the androgen receptor (Burger 2002). Both DHEA and DHEAS can be converted in peripheral tissues to androstenedione (A2), testosterone (T), and dihydrotestosterone (DHT), and both are aromatized to estrogens. Compared to T, the daily production rates of DHEA and DHEAS are much higher, approximately 6–8 mg/day and 3.5–20 mg per day, respectively, and both circulate in micromolar concentrations (Burger 2002). The actions of androgens are very complex and may also differ according to the level of androgen receptor (AR) or estrogen receptor (ER) expression, the bioactivity of 5α-reductase and aromatase, the co-activators and co-repressors present in each cell type, and the pattern of interacting in target cells.

Testosterone deficiency and/or increased levels are associated with several health complications including osteoporosis, cardiovascular disease, type 2 diabetes, and metabolic syndrome, among others. However, this is beyond the scope of this chapter.

The actions of androgens are thus important in understanding the normal physiology, pathophysiology, and development of female reproductive system.

The Action of Sex Steroid Hormones in the Pathophysiology of Bulimia Nervosa

Sex steroid hormones comprise testosterone, estrogen, and progesterone. Individuals with BN as well as anorexia are at increased risk of developing physiologic and endocrine disturbances, including menstrual irregularities (Poyastro Pinheiro et al. 2007). The underlying causes of menstrual irregularities are multifaceted and result from a complex interplay of many factors including psychological stressors, frequent purging, and hormonal imbalance (Vyver et al. 2008). Disturbances in the hypothalamic-pituitary-ovarian axis result in impairments of the gonadotropins, follicle-stimulating hormone (FSH), and luteinizing hormone (LH), which in turn leads to functional hypothalamic amenorrhea (FHA) (Genazzani 2005). FHA is classified as hypogonadotropic hypogonadism and is one of the most common causes of amenorrhea in fertile women (Gordon 2010). Furthermore, estrogens' actions and irregular menstrual function are also implicated in the pathophysiology of BN (Hudson et al. 2007), where reduced concentrations of estradiol (E2) and luteinizing hormone (LH) and pulsatile release of luteinizing hormone were observed (Devlin et al. 1989). Thus, in association with other sex steroid hormones and transmitter substances, estrogens have many complex functions.

It is well known that menstrual irregularities are present in women with BN, but the incidence is highly variable (Gendall et al. 2000). Even though amenorrhea occurs in healthy-weight women with BN at a rate of about 5–40%, oligomenorrhea is more common with a frequency of 40–60% (Austin et al. 2008). This variability may be because patients have adequate estrogen secretion and present with an anovulatory syndrome combined with irregular bleeding.

Weight loss, emotional stress, and overexercise mutually or separately can result in complex hormonal changes, i.e., mild hypercortisolemia, low serum insulin levels, low insulin-like growth factor 1 (IGF-1), and low total triiodothyronine, which are manifested by profound hypoestrogenism (Meczekalski et al. 2014). Moreover, high serum beta-hydroxybutyrate and low total triiodothyronine (T3) have been identified in both women with anorexia nervosa (AN) and BN, which can be explained by periods of malnourishment, purging, and/or excessive training (Altemus et al. 1996). Accordingly, normal-weight women with hypothalamic amenorrhea appear to have normal androgen and DHEAS levels (Miller et al. 2007). It is notable that normal-weight women with BN can also have abnormalities in the hypothalamic-pituitary-thyroidal axis, such as low levels of LH and FSH, along with low estradiol, characteristic of emaciated women with anorexia nervosa (Schweiger et al. 1992). Among other properties, the sex steroid hormones, estradiol, progesterone, and testosterone, seem to influence reward circuit alterations that contribute to eating disorders (Ullsperger and Nikolas 2017). Women who have hypothalamic amenorrhea exhibit susceptibility to restrictive disordered eating, depressive traits, and psychosomatic disorders (Meczekalski et al. 2014).

The sex steroid hormones estrogen, progesterone, and androgens are important modulators of food intake and energy balance in humans (Asarian and Geary 2013). They interact with neurotransmitters and gastrointestinal peptides to achieve central

control of appetite and energy expenditure (Asarian and Geary 2013). During the follicular phase of the menstrual cycle, when estrogen is at its peak, the appetite, meal size, and intake of sweets decrease (Asarian and Geary 2013). Just as healthy women may have eating behavior changes during their menstrual cycle, binge eating also varies throughout the menstrual cycle, with low frequencies in the late-luteal phase through the peri-ovulatory phases and high frequencies during the mid-luteal phase in women with BN (Culbert et al. 2016). Animal studies have shown that progesterone, an estrogen receptor antagonist, induces overeating (Roberts et al. 1972). Human studies have confirmed that estrogens reduce food intake during binge-like episodes (Klump et al. 2008; Yu et al. 2011). Whether this is a useful model of binge size or frequency of binging in women, on the other hand, is not known (Yu et al. 2011). Thus, estrogens appear to antagonize androgens' effect concerning eating behavior.

Binging and Purging: Hormonal Changes

Binge eating is a dysregulated form of eating that is rather prevalent in women (Hillbert et al. 2012). It refers to eating an abnormally large amount of food on a single occasion with a feeling of loss of control of eating and can precede even BN (Hillbert et al. 2012). Multiple episodes of binge eating followed by inappropriate weight compensatory behavior, (e.g., diuretic and laxative misuse, self-induced vomiting, fasting, and excessive exercise) are common in bulimics. One of the purging methods used by bulimics is vomiting. The emesis center in the medulla has been suggested to be the chemoreceptor trigger zone in the postrema area known to contain a high density of opioid and dopamine receptors. A rise in dopaminergic and opioid activity has been associated with menstrual dysfunction, hence why vomiting and menstrual irregularity may be linked to dopamine and opioid activity (Gendall et al. 2000).

In addition, craving and binging can result in intake of excess calories, which might promote weight gain and an increase in insulin levels. Elevated insulin levels in turn will stimulate ovarian androgen production, thereby contributing to a vicious circle of androgens and weight gain (Escobar-Morreale and Millán 2007). Further, vomiting itself may result in an increased insulin secretion (Kaye et al. 1989), which appears to mediate hyperandrogenism in young women with polycystic ovarian syndrome (PCOS) (Raphael et al. 1995). Interestingly, high levels of testosterone have also been reported in women with premenstrual syndrome (PMS), as they also have been in bulimic women (Eriksson 2000). Intensified craving for food during the luteal phase of the menstrual cycle means bulimics may experience aggravations of their symptoms (Ferrer-Garcia et al. 2017).

Emotional stress is the primary trigger factor during binge eating. It repeatedly activates the adrenal cortex for cortisol secretion. Activation of the hypothalamic-pituitary-adrenal axis in response to psychological stress results in continuous secretion of cortisol. This consistent stimulation could explain the increase in cortisol levels observed in women with PCOS (Vgontzas et al. 2001). Moreover,

testosterone can suppress activity of the hypothalamic-pituitary-adrenal (HPA) axis, thereby creating opposing interactions between the HPA and hypothalamic-pituitary-gonadal (HPG) axes (Viau 2002). For example, stress inhibits gonadotropins, which in turn precedes suppression of testosterone (Sapolsky 2004). Conversely, testosterone also can attenuate levels of glucocorticoids and other stress hormones (Viau and Meaney 1996). Excess stress can contribute to the major depressive disorder (Holzel et al. 2011). However, the precise mechanisms whereby testosterone inhibits the HPA axis remain unclear. Excess stress might have negative effects on the mental health, and can contribute to major depressive disorder (Holzel et al. 2011). However, the precise mechanisms whereby testosterone inhibits the HPA axis remain unclear.

Polycystic Ovarian Syndrome: A Hyperandrogenic Condition with Associations with Bulimia Nervosa

The pathophysiological actions of androgens in females are also of major importance, particularly as they relate to hyperandrogenic disorders in women. Polycystic ovarian syndrome (PCOS) has typical features of biochemical hyperandrogenism, irregular menstrual cycles, and polycystic ovarian morphology, as well as metabolic traits such as obesity hyperinsulinemia, and insulin resistance (McCartney and Marshall 2016) (Table 1).

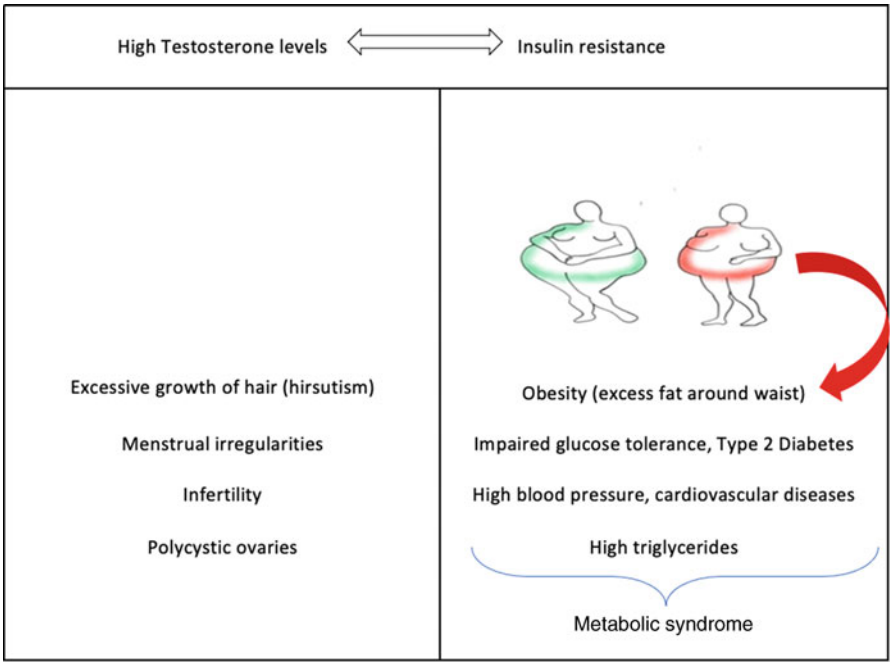
One of the primary pathological changes thought to lead to PCOS is increased ovarian androgen secretion (Lobo 1984), and an affected metabolism of estrogens and androgens (Baptiste et al. 2010). Excess adrenal androgen levels are prevalent in 40–65% of women with PCOS (Lobo 1984). The sources of androgens in women with PCOS are adrenal glands and the ovaries, with most androgens appearing to be formed in the ovaries (60%) and the remainder (40%) contributed by adrenal glands (Cedars et al. 1992).

In healthy women who were submitted to binge eating, hyperinsulinemia and abnormal ovarian morphology have been observed (Taylor et al. 1999). Hyperandrogenic manifestations like PCOS do appear in women with BN and can affect the pathophysiology of the disorder (Naessén et al. 2006; Steegers-Theunissen et al. 2020). Several studies support the hypothesis that androgens are of importance for bulimic behavior and can promote BN by influencing food craving, stimulating appetite, and reducing impulse control in susceptible individuals (Naessén et al. 2006; Baker et al. 2012).

As it has been pointed out, the increased frequency of PCOS in bulimic women may indicate increased androgen sensitivity in these women (Naessén et al. 2006). This susceptibility of androgens maybe reflected in the observed presence of mood and eating disorders in women with PCOS (Steegers-Theunissen et al. 2020).

Disturbances in the function of gonadotropin-releasing hormone (GnRH) in women with PCOS can cause an overproduction of LH, while FSH levels are low, and this in turn increases the androgen production by the theca cells due to a lack of negative feedback from progesterone (Walters et al. 2018).

Table 1 Signs and symptoms of polycystic ovarian syndrome (PCOS)



Binge eating is common among bulimic women and recurrent binge eating can increase insulin levels, by decreasing concentrations of sex hormone-binding globulin (SHBG). This in turn increases the free circulating testosterone levels, thereby negatively impacting follicular maturation and ovulation (Algars et al. 2014). Elevated insulin levels will then stimulate ovarian androgen production, contributing to a vicious circle of androgens and overweight status (Escobar-Morreale and Millán 2007). However, a recent study showed that increased levels of insulin in women with PCOS may lead in turn to BN (Vyver et al. 2008), although this finding could not be supported by a previous study (Raphael et al. 1995).

Antiandrogenic Treatment in Bulimia Nervosa

The fact that elevated testosterone levels and BN could be linked indicates the potential for drugs with antiandrogenic properties to alleviate the bulimic symptoms. There are a few drugs with proven effect on bulimic symptoms that can currently be prescribed.

Fluoxetine, a potent antidepressant, and a selective serotonin reuptake inhibitor (SSRI) (Broekkamp et al. 1980), was approved by the FDA for the treatment of major depressive disorder in 1987 and in 1994 for the treatment of BN. Reduced

symptoms in bulimic women have been obtained with flutamide, and the mechanism of action of the drugs is through the blocking of androgen receptors (Sundblad et al. 1994). Another drug, lisdexamfetamine, a central nervous system stimulant, is also approved by FDA for the treatment of BN (Bello and Yeomans 2018).

A known effect of combined oral contraceptives (COC) in healthy women of reproductive age is a decrease in testosterone, free testosterone, and DHEAS levels (Carlström et al. 2002). Therefore, in one study, a preparation consisting of ethinyl estradiol/drospirenone, widely used as an OC, and well tolerated (Foidart 2000), was administrated to women with BN. Bulimics who responded with a decrease in bulimic behavior had higher pretreatment levels of total and free testosterone and higher frequency of binge eating and of compensatory behavior (Naessén et al. 2007). Therefore, the antiandrogenic oral contraceptives appear to reduce meal-related appetite and bulimic behavior. As a result of that, one may speculate that, in some cases, BN may be a hormonal rather than primarily a psychiatric illness.

Drospirenone is a powerful progestogen with antiandrogen activity and mainly acts by blocking androgen receptors of target organs, in addition to reducing skin activity of 5α-reductase, the enzyme that converts T to 5α-DHT. This significant antiandrogenic effect has been seen even on hyperandrogenic symptoms such as hirsutism and acne (Batukan and Muderris 2006).

Androgen's Role in Relation to Psychiatric Disorders and Bulimia Nervosa

Another area where the role of androgens has been highlighted extensively is depression. Mood and eating disorders are among the most common psychiatric disorders observed in women with PCOS and are most likely the result of complex interactions between different factors. The core symptoms of mood and eating disorders, such as poor self-esteem, and body image dissatisfaction, are shown to be associated with stress (Murray et al. 2011).

The prevalence of depression and depression symptoms is significant in women with PCOS, ranging from 29% (Deeks et al. 2010) to 50% (Hollinrake et al. 2007), although elevated testosterone levels have been found even in premenopausal women without PCOS (Baischer et al. 1995).

Regarding the hypothalamic-pituitary-adrenal (HPA) axis, previous reports indicate a relative hypercortisolism (Bailer and Kaye 2003), and increased circulating concentrations of adrenocorticotropic hormone (ACTH) (Loucks et al. 1989) and of adrenal androgens (Monteleone et al. 2001) in women with BN. However, both normal (Naessén et al. 2006) and low levels of cortisol have been shown in women with BN (Levitan et al. 1997). One possible reason for these findings may be the partial glucocorticoid insensitivity of the HPA axis in women with BN, as described in many reports that show a poor response to dexamethasone in BN (Levy et al. 1989). Hypothetically, this may lead to a compensatory increase in ACTH secretion and thus to increased cortisol levels.

A growing body of research has focused on the notion that depression is the most common comorbid diagnosis in women with eating disorders (Mischoulon et al. 2011). Major depression is frequently noted in bulimics, although it is not clear if the mood disturbance is a function of bulimic disease or a separate phenomenon (Hay et al. 2008). Notably, there are gender differences, with females are more than twice as likely as males to be afflicted by mood disorders (Kessler et al. 2005).

Both androgen insufficiency and hyper-androgen states have been associated with mood disorders and depression (Herzog and Eddy 2007). Clinical evidence suggests that testosterone has anxiolytic and antidepressant benefits, with the potential to promote improved mood and mental health in both sexes. However, the neurobiological mechanisms underlying the protective effects of testosterone remain still poorly understood. Neurotransmitters, γ-aminobutyric acid (GABA), dopamine, and serotonin (5-HT) may underlie some of testosterones' protective benefits on psychological well-being (Dubrovsky 2005).

Testosterone administration has shown to improve the depressive symptoms (Miller et al. 2009) and even the onset of major depressive disorder when higher doses of testosterone were given in a previous study (Rohr 2002). In relation to depression, chronic exposure to T, or to its neuronal metabolites, E2 and DHT, selectively enhances metabolic activity in the mesolimbic system in an animal study (Alderson and Baum 1981).

Taken together, all these findings strengthen the link between androgens and depression.

Androgens have general anabolic effects upon several organ systems including fat distribution and behavior. The role of androgens in BN and its residual categories has not been fully investigated, but recent findings show that, among other functions, steroids play an essential role in eating behavior and are implicated in several major psychiatric disorders in women.

Some of the studies also consider Eating Disorder Not Otherwise Specified of Purging type (EDNOS-P) (APA 2000). The diagnosis EDNOS has often been regarded as a residual category of eating disorders, but it is the most common one in outpatient settings and is like BN in the nature, duration, and severity of psychopathology (Dingemans and van Furth 2015). Since the revision of the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM), there have been substantial changes regarding the classification of eating disorders. The residual diagnosis EDNOS seems to develop multiple subthreshold presentations over time, such that it may occur between the full criteria AN and BN (Fischer et al. 2015).

There are several well-designed studies according to DSM-IV that include the EDNOS diagnosis.

It has been shown that women with BN appear to exhibit greater eating and general psychopathology than those with EDNOS (Thomas et al. 2009). However, EDNOS itself represents a set of disorders associated with substantial psychological and physiological morbidity (Hudson et al. 2007). For example, it has been found that women with EDNOS-P exhibit the hyperandrogenic state to a greater extent and fulfill more criteria for PCOS than women with BN (Naessén et al. 2006, 2007).

Recent investigations have revealed profound differences in the origin of circulating T and the most potent androgen, DHT, in women with BN, EDNOS-P, and healthy control subjects, despite very similar anthrometric data and almost identical androgen and SHBG levels (Naessén et al. 2019). Concerning the origin of T, women with BN and control subjects had positive correlations to DHEAS but not to LH, which suggests peripheral conversion of DHEAS as the main source of T formation in these groups. Thus, not only T but also the major circulating steroid DHEAS serves as precursor to DHT via conversion to T and A-4 (Parker 1989).

However, the production of LH is not regulated by ovarian androgen through the feedback mechanism; hence, in women excess free testosterone or androstenedione (A4) will not reduce ovarian production of these androgens. In women with EDNOS-P, though, a direct ovarian gonadotropin-stimulated secretion was obtained as a main source of circulating testosterone. This knowledge of androgens' origin opens up further research regarding whether the action of androgens has a role in the pathogenesis, course, or treatment of BN.

Conclusions

The role of androgens in the etiology of BN has not been fully elucidated. The actions of androgens are very complex, differing according to the level of androgen receptor (AR) or estrogen receptor (ER) expression, the bioactivity of 5α-reductase and aromatase, the co-activators and co-repressors present in each cell type, and the pattern of interacting in target cells.

The actions of androgens are thus complex but important in understanding normal physiology, pathophysiology, and the involvements of the androgens in development of bulimic symptoms. The available, albeit incomplete, evidence makes it highly likely that the androgens in discourse with other sex steroid hormones seem to play an extensive role in BN. Future studies will hopefully further clarify the role of androgens.

Applications to Other Eating Disorders

- Binge eating
- Eating Disorder Not Otherwise Specified of Purging type (EDNOS-P)

Mini-Dictionary of Terms

- **Amenorrhea:** It is the absence of menstrual periods at least three months or more.
- **Androgens:** These are a group of sex hormones – testosterone (T), androstenedione (A4), dihydrotestosterone (DHT), dehydroepiandrosterone (DHEA), and DHEA sulfate (DHEA-S).

- **Appetite:** It is the desire to eat. Hunger is physiological, and it occurs because of biological changes throughout the body, which signal that you need to eat to maintain energy levels.
- **Binging, and purging:** Binging involves eating much larger portions of food quickly, in a short period of time and feeling a loss of control. Purging is *the act of getting rid of food from the body by* self-induced vomiting or misuse of diuretics, laxatives.
- **Bioavailability of a substance:** The ability of a drug or other substance to be absorbed and used by the body.
- **Gonadotropins:** They include luteinizing hormone (LH) and follicle-stimulating hormone (FSH), and they are made by a part of the brain called the hypothalamus.
- **Gonads:** These are the primary reproductive organs of men, testicles, and the ovaries in the women.
- **Hypothalamic amenorrhea:** It is the functional absence of menstruation. It results in estrogen deficiency in young women, often due to psychological stress, excessive exercise, disordered eating, or a combination of these factors.
- **Metabolic syndrome:** It is a group of disorders – increased blood pressure, high blood sugar, excess body fat around the waist (apple body shape), and abnormal fat levels – that occur together, increasing the risk of heart disease, stroke, and type 2 diabetes.
- **Pathophysiology:** It is the study of the disturbance of normal mechanical, physical, and biochemical functions, either caused by a disease or resulting from a disease.
- **Precursor:** A precursor is a chemical substance that participates in a chemical reaction that produces another compound. For example, cholesterol is the precursor for all steroid hormones.
- **Sex steroid hormones:** The male hormone testosterone and the female hormones progesterone and estradiol.

Key Facts

- The biologically active androgens, T and DHT, are formed by de novo synthesis in the ovaries and adrenal cortex and by peripheral conversion of the adrenal androgens A-4, DHEA, and DHEA-S in the liver, kidneys, muscles, fat, skin, and central nervous system.
- Steroid hormones DHEA and DHEAS can be converted in peripheral tissues to androstenedione (A-2), testosterone (T), and dihydrotestosterone (DHT), and both are aromatized to estrogens.
- Individuals with normal body weight and those with BN are at increased risk of developing physiologic and endocrine disturbances, including menstrual irregularities.
- Normal-weight women with hypothalamic amenorrhea appear to have normal androgen and DHEAS levels attributable to periods of malnourishment and purging.

- Intense ovarian androgen secretion and an affected metabolism of estrogens and androgens can promote PCOS.
- Profound differences in origin of androgens were found in women with BN and EDNOS, although almost identical androgen and SHBG levels were detected in both groups. Perhaps these results reflect the transitional state of the EDNOS to BN.
- The actions of androgens are very complex, and they may differ according to the level of androgen receptor (AR) or estrogen receptor (ER) expression, the bioactivity of 5α-reductase and aromatase, the co-activators and co-repressors present in each cell type, and the pattern of interacting in target cells.

Summary Points

- Androgens exert direct action on the CNS but in conjunction with estrogen and progesterone.
- Testosterone's effects may be explained by its metabolism into two additional bioactive hormones, E2 and DHT.
- Androgens can promote BN by influencing food craving, stimulating appetite, and reducing impulse control in susceptible individuals.
- During the follicular phase of the menstrual cycle, when estrogen is at its peak, the appetite, meal size, and intake of sweets decrease.
- Antiandrogenic oral contraceptives appear to reduce meal-related appetite and bulimic behavior.
- Increased frequency of hyperandrogenic manifestation like PCOS in bulimic women may indicate increased androgen sensitivity in these women.
- Women with EDNOS-P exhibit more clinical features of hyper-androgen state than those with BN.
- Similar levels of T, fT, DHT, DHEAS, and SHBG in BN and EDNOS-P but origin of T, DHT differed.
- T is formed in BN peripherally from DHEAS and by ovarian LH stimulation in EDNOS-P.
- These differences may influence diverging clinical manifestations of BN versus EDNOS-P.

risk groups and preventive strategies. Furthermore, the evaluation of extrinsic sources of acid seems to have been neglected in studies on dental implications and bulimia nervosa. Assessing risk groups is essential for the development and tailoring of effective strategies to prevent progress toward a full-blown eating disorder and its comorbidities. Raising awareness of dietary preferences, compensatory practices, and the possible association with dental implications among groups with bulimic symptomatology is both clinically and theoretically important. The chapter goes on to discuss dental implications, risk behaviors, and bulimia nervosa, emphasizing the need for considering the compounding effect of extrinsic sources of acids, such as food choices, among risk groups and/or patients already diagnosed with bulimia nervosa.

Introduction

Dental implications such as erosive tooth wear (ETW) and dental caries (DC) have been reported as oral manifestations associated with bulimia nervosa (BN), its risk behavior, and purging practices (Hermont et al. 2013; Johansson et al. 2012; Ximenes et al. 2010). The ability to diagnose early clinical signs of oral alterations, associated with a detailed anamnesis, enables the dentist to suspect cases of eating disorders (EDs) and refer patients for specialist care. Consequently, it allows people at risk for EDs to receive a timely, accurate diagnosis and treatment from appropriate professionals, thus preventing the development of severe comorbidities (Hermont et al. 2013). Research on risk behavior for EDs and bulimic symptomatology helps to broaden the understanding of these phenomena among nonclinical populations who have not yet developed a full-blown eating disorder (Fonseca-Pedrero et al. 2011; Hermont et al. 2014).

However, most studies have typically been conducted with patients already diagnosed with an ED and show a well-established link between oral implications and EDs in the presence of self-induced vomiting (Hermont et al. 2014). Conversely, there is less information regarding the occurrence of oral conditions in the absence of

purging practices; and important risk factors such as psychotropic-induced dry mouth, nutritional deficiencies, and/or acidic diet tend to be underestimated (Kisely et al. 2015). Studies tend to neither evaluate nor raise awareness related to extrinsic factors such as dietary habits. In fact, a recent pioneer study on this subject has reported that it was the food choices and not purging practices that differed among the participants with varying severity of bulimic symptomology. Likewise, the dietary habits among the sample were the factors mainly associated to higher prevalence of ETW (Hermont et al. 2021a).

Is this finding a surprise or does the surprise remain in the fact that eating habits of this risky population have been neglected in studies involving dental implications? To answer this question this chapter presents a review addressing dental implications and its association with bulimia nervosa risk behavior. This time, an effort has been made to broaden the knowledge related to the link between food choices and dentition among people with bulimic symptomatology.

Understanding the Dental Implications: An Outlook for Erosive Tooth Wear

Concepts and Epidemiology

According to the last Consensus Report of the European Federation of Conservative Dentistry, dental erosion, referred in a "collective term" as erosive tooth wear, is a chemical-mechanical process caused by an erosive acidic attack without bacterial involvement, resulting in progressive loss of hard tooth tissues (Carvalho et al. 2016; Ganss 2014; Lussi and Carvalho 2014; Schlueter et al. 2020). The sources of acid may be intrinsic factors, such as reflux and vomiting, and extrinsic factors, such as an acidic diet or medications, like acetylic salicylic acid (Hermont et al. 2014; Schlueter and Luka 2018). Diet has a key and complex role in ETW etiology, as its erosive potential relates to the pH, type of acid, buffering capacity of saliva, food consistency (retentiveness in the oral cavity), and frequency of consumption (Barbour and Lussi 2014).

ETW is the third most frequently observed oral condition, after dental caries and periodontal disease (Bartlett et al. 2019). An overview on the data related to the prevalence of ETW detected that heterogeneous methodologies applied within studies turn it difficult to estimate its actual global prevalence. There is an outsized variation in prevalence worldwide ranging between 0% and 100% (Schlueter and Luka 2018). This discrepancy seems to be primarily related to methodological issues such as different indexes used to detect ETW. Even though, Schlueter and Luka (2018) estimated a mean prevalence ranging from 30% to 50% in deciduous teeth, and from 20% to 45% in permanent teeth. In addition, there seems to be an increase in ETW prevalence with age and a gender difference, with a higher prevalence among males (Jaeggi and Lussi 2014).

Instead, differently from the inconsistency reported for global prevalence of ETW, a clear impact on ETW prevalence has been detected in patients with gastroesophageal reflux disease and EDs involving purging practices (Hermont et al. 2014; Schlueter

and Luka 2018). The evidence found in a meta-analysis indicates that patients suffering from anorexia and bulimia have a greater risk of presenting ETW in comparison to individuals without such exposure (Hermont et al. 2014). In addition, it was detected a significant association between bulimia with self-induced vomiting and ETW, but not for bulimia without vomiting practices. It reinforced the hypothesis that the purging practice is a crucial cofactor related to the occurrence of ETW, which results from a chronically acidic oral environment (Johansson et al. 2012).

However, despite the increasing scientific interest about ETW global epidemiology, its awareness is still not widespread. Studies conducted in academic fields worldwide have shown an alarming lack of knowledge of the condition and that it is still not routinely screened during standard dental examination (Al-Ashtal et al. 2015; Bartlett et al. 2019; Dugmore and Rock 2003; Hermont et al. 2011, 2021b; Ngoc and Donovan 2018; Verploegen and Schuller 2019). This may have a negative impact on health, and interventions to minimize the loss of tooth structure might have not been provided at early stages. Dentists usually monitor patients on a regular basis, sometimes throughout childhood up to adulthood. Therefore, they may be the first health professionals to suspect EDs, due to their oral implications. If those professionals are not capable of detecting dental implications such as ETW, patients with possible bulimic symptomatology might go undetected, jeopardizing their early referral to specific treatment (Rosen 2010; Shaughnessy et al. 2008).

Biological and Clinical Aspects

Enamel dissolution occurs both at the enamel/acid interface in the ETW process, as well as within a partly demineralized thin softened layer of enamel, in a process called near-surface demineralization, leading to loss of minerals, and consequently, loss of tooth substance (Shellis et al. 2013). The process starts by initial softening of the enamel surface followed by loss of volume, with a softened layer persisting at the surface of the remaining tissue (Ganss et al. 2014). The rate and severity of erosive wear are determined by the susceptibility of the dental tissues toward dissolution. Since enamel contains less soluble mineral than dentine, it tends to erode more slowly (Ganss et al. 2014).

Typical clinical signs of erosive lesions include a shiny, silky-glazed appearance, excessively smooth tooth surfaces, tooth cupping (small indentations caused by erosion), and a layer of intact enamel along the gingival margin (Ganss and Lussi 2014; Lussi et al. 2011; Shellis et al. 2013). It has been postulated that this preserved enamel band might be due to mechanical protection provided by dental plaque, which could act as a diffusion barrier for acids. In addition, this process could also be due to an acid neutralizing effect of the sulcular fluid (Lussi et al. 2006).

The distribution of ETW lesions among the worldwide population shows a predominance of lesions in occlusal surfaces (mainly on mandibular first molars) followed by facial surfaces (mainly on anterior maxillary teeth), but overall prevalence data are not homogeneous (Jaeggi and Lussi 2014). Clinical features of ETW are shown in Figs. 1 and 2).

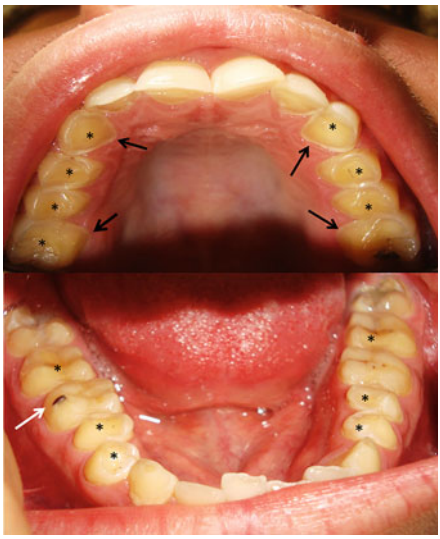

Fig. 1 Erosive tooth wear. Upper and lower dental arches of a 23-year-old male patient. Black arrows point to intact enamel along the gingival margin in permanent teeth secondary to intrinsic factors and daily consumption of acidic beverages (soda). White arrow points to an amalgam restoration rising above the level of the adjacent eroded tooth surface. Asterisks point to affected occlusal surfaces (the yellowish color corresponds to exposed dentin due to the erosive process)

Fig. 2 Erosive tooth wear. (**a**) Upper and lower dental arches of a 26-year-old female patient diagnosed with bulimia nervosa showing erosive tooth wear lesions in permanent teeth. White arrows point to intact enamel along the gingival margin. Black arrows point to affected occlusal surfaces (the yellowish color corresponds to exposed dentin). (**b**) The toothbrush used by the patient had a dual use: brush her teeth and help self-induced vomiting practices. The black circle shows deformed bristles due to excessive brushing force. The patient also presented an acidic diet (citric fruits and diet coke)

Etiology

Erosive tooth wear is a multifactorial condition, resulting from interplay between modifying macro-factors, nutritional, and patient-related factors (Buzalaf et al. 2018; Lussi and Carvalho 2014) (Fig. 3). Recurrent episodes of reflux and/or vomiting are the primary sources of intrinsic acids affecting risk groups, such as people suffering from gastroesophageal reflux disease and/or eating disorders, like bulimia nervosa, whereas diet represents the major etiological factor related to the prevalence and incidence of ETW in worldwide population (Chan et al. 2020; Rosten and Newton 2017; Schlueter and Tveit 2014).

However, it is noteworthy that while some people who consume acidic diets develop erosive lesions, others do not (O'Toole and Mullan 2018). Issues, such as salivary protecting effect (buffering capacity) and deleterious habits, like excessive mechanical force during oral hygiene habits, may account for individual variations (Figs. 2b and 3). Furthermore, other patient-related factors may modulate the erosive potential of foods, like its frequency of consumption. Higher rates of intake of carbonated and sports drinks and natural fruit juices have already been associated with higher prevalence of ETW (Buzalaf et al. 2018; Kitasako et al. 2017; Mafla et al. 2017).

Other important patient-related factors are the contact time of erosive foods/drinks with the teeth (Buzalaf et al. 2018) and the pattern of food consumption. These factors might enhance the erosive potential of dietary substances (e.g., swishing of soft drinks before swallowing, acidic food intake between meals). It has been stated that prolonged intermittent exposure of the teeth to orange juice increases the hazard of erosion progression, irrespective of salivary protective effects (Amaechi et al. 1999). Furthermore, the intake of acidic diets between main meals

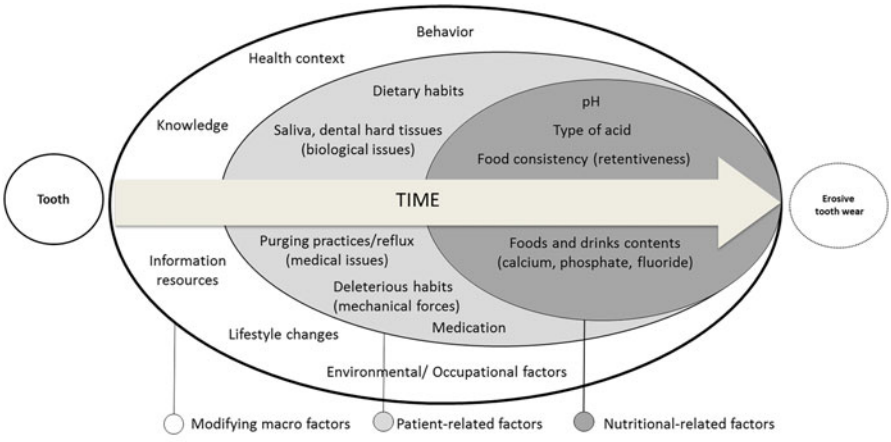

Fig. 3 Determinants related to the etiology of erosive tooth wear throughout life. It is divided in modifying macro-factors, patient-related factors, and nutritional-related factors

and before bedtime is also a risk factor. During these periods, there is a decrease in salivary flow rate that compromises saliva's protective effect against ETW, and the clearance of gastric acids in the esophagus (Buzalaf et al. 2018; Saads Carvalho and Lussi 2020).

Likewise, nutritional and dietary factors such as the type of acid (e.g., citric, acetic, or malic acid) or even the food or drink viscosity/consistency and content influence its erosive potential. While acidic food products, like fruit-based candies, are highly erosive due to an extended contact time with the tooth before oral clearance, high concentrations of minerals, such as calcium and phosphate, may reduce the erosive potential of low pH foods, like yoghurt (Saads Carvalho and Lussi 2020; O'Toole et al. 2017; Shrestha and Rajbhandari 2018). In addition, it is known that the temperature of an acidic drink might influence its erosive potential, which is less pronounced when the drink is consumed at lower temperatures (Amaechi et al. 1999).

Finally, it is important to mention the modifying macro-factors. ETW risk factors comprise not only patient and nutritional-related factors, but also broader social and environmental determinants such as occupational factors, health context, behavioral changes, and knowledge related to this dental implication. Individuals with occupations that predispose them to a regular and sustained acid contact (e.g., wine tasters) may be particularly prone to ETW (Barbour and Lussi 2014). It has also been reported that knowledge about ETW is not being shared with patients, especially concerning information related to preventive measures. Thus, it might corroborate to this dental implication occurrence and progression (Hermont et al. 2011, 2021a). The influence of all the factors described above determines whether the erosive process will proceed or not. The following infographic shows an easy-to-understand overview of this topic (Fig. 3).

Location of erosive lesions is strongly related to the source of acid. Among patients who vomit regularly, the distribution of erosive wear is typically on palatal surfaces of anterior maxillary anterior teeth (Rosten and Newton 2017) as shown in Figs. 1 and 2, whereas extrinsic sources of acid, such as acidic diets, usually affect the facial surfaces of teeth, especially the incisors. It is interesting to notice that while good oral hygiene has proven to be effective for dental caries prevention, deleterious brushing habits, like the application of excessive pressure during tooth brushing (Fig. 2b), may corroborate to ETW when it is carried out along with an ongoing acidic attack on teeth surfaces (Wang and Lussi 2012). This happens because the softened tooth surface resulting from the acidic challenge needs about an hour in the presence of saliva to remineralize, and mitigate the abrasion triggered by tooth brushing (Hemingway et al. 2006). Therefore, a possible correlation between tooth brushing shortly after eating and self-induced vomiting has to be considered, especially considering that it might occur during bulimic episodes (Hermont et al. 2013; Herpertz-Dahlmann et al. 2012; Riddlesberger Jr et al. 1991). In addition, it has been reported that the toothbrush may be used in two different ways. This tool can be employed to help vomit induction and subsequently to clean off vomiting breath and smell, through tooth brushing (Fig. 2b) (Faust and Schreiner 2001; Riddlesberger Jr et al. 1991).

Understanding the Dental Implications: An Outlook for Dental Caries

Concepts and Epidemiology

Dental caries is a multifactorial, diet-modulated disease, resulting in mineral loss of dental hard tissues (demineralization), which is reversible in its early stages. Unlike ETW, it is a biofilm-mediated disease and is the most prevalent non-communicable chronic disease, affecting up to 80% of the world's population from all age groups (Frencken 2018; Moynihan 2016; Selwitz et al. 2007). Unlike the direct association between ETW, purging practices, and acidic food choices (Hermont et al. 2014, 2021a; Rosten and Newton 2017), there is no consensus with respect to the link between bulimia nervosa and dental caries, even though an association has been reported by some researchers (Johansson et al. 2012; Romanos et al. 2012; Rosten and Newton 2017).

Biological and Clinical Aspects

The caries lesion is the cumulative result of an imbalance in the dynamic demineralization and remineralization process, caused by microbial metabolism on the tooth surface, which may result in a net loss of minerals (Fejerskov 1997; Young et al. 2015). Demineralization is the loss of tooth mineral due to acids, while remineralization is the net gain of mineral in previously demineralized tissue. However, the terminology "remineralization" might be misleading since it does not imply that the lesion has regained its original mineral content, and the tooth does not return to its original appearance (Machiulskiene et al. 2020).

Based on clinical parameters, caries lesions are categorized as non-cavitated or cavitated (Young et al. 2015). Non-cavitated lesions refer to the initial stages of the disease, being characterized by a change in color, with loss of glossiness resulting from demineralization, before macroscopic breakdown in tooth surface structure (Longbottom et al. 2009; Young et al. 2015) (Fig. 4a). Due to histological features, those lesions are more prone to be reversed (remineralized), but this process needs key elements such as dietary modification and good oral hygiene practices, including use of fluoride toothpaste (Machiulskiene et al. 2020).

Cavitated lesions are the result of loss of surface integrity, not necessarily restricted to enamel surface, since it can affect the dentin or even the tooth pulp (Longbottom et al. 2009). Commonly, cavitation refers to the total loss of enamel and, consequently, to the exposure of the underlying tooth structure, the dentin (Fig. 4b). The clinical sign of cavitation denotes the failure to biologically replace the loss of hard tissues (Young et al. 2015). The number and extent of carious lesions are related to the disease severity, which may affect both the crowns and roots of teeth, and develop in early childhood as aggressive tooth decay (Selwitz et al. 2007). Fissures and pits in occlusal surfaces of first molars and pits in facial surfaces of lower first molars are the most vulnerable sites for developing a carious lesion (Frencken 2018).

Fig. 4 Dental caries (cavitated and non-cavitated lesions). Dental arch of a 6-year-old female patient. (**a**) Black arrows point to non-cavitated white spots lesions (incipient dental enamel caries). (**b**) White arrows point to cavitated caries lesions (exposed dentin)

Etiology

The combination of behavioral, biological, psychosocial, and environmental determinants corroborates to the dental caries dynamic process (Fejerskov 1997; Pitts et al. 2017; Zero 1999). Consequently, this lifelong progressive and cumulative disease tracks to adulthood, even with exposure to fluoride through mouth-care products or water (Bernabé and Sheiham 2014). Dental caries forms through a complex interaction of multiple factors over time, such as the association between acid-producing bacteria and fermentable carbohydrate, lifestyle, and behavioral-related issues, such as oral hygiene, and host factors, like inadequate salivary flow rate (Selwitz et al. 2007).

However, as a diet-mediated disease, the intake of dietary sugars seems to be the most important risk factor for dental caries (Moynihan and Kelly 2014; WHO 2015), since the cariogenic bacteria produce organic acids as a by-product of their metabolism of fermentable carbohydrates (Selwitz et al. 2007). Therefore, the demineralization process is biofilm-mediated, while in ETW, the acidic attack is not related to bacterial involvement (Machiulskiene et al. 2020).

It is interesting to notice that dental caries seems to be less common than ETW among patients with EDs, since those patients are more prone to obsessional personality traits, and consequently, are more demanding in their oral hygiene (Kisely 2016). In addition, whereas ETW lesions tend to be found on plaque-free tooth surfaces, the presence of plaque is essential for the development of dental caries (Burgard et al. 2003; Huew et al. 2012). Despite having different etiologies, dental caries and ETW might coexist, since the determinants that corroborate to the erosive wear might change during life course, being replaced by risk factors related to dental caries and vice versa. In fact, at sites susceptible to plaque accumulation, dental caries may also occur among patients with ETW, and this is more commonly observed in the occlusal surfaces of molar teeth (Lussi et al. 2006). Figure 5 shows a tooth affected by both conditions. It must be stressed that the cupping lesions caused by erosive wear may represent risk factors for dental caries, since those sites are characterized by cavities that can favor plaque accumulation.

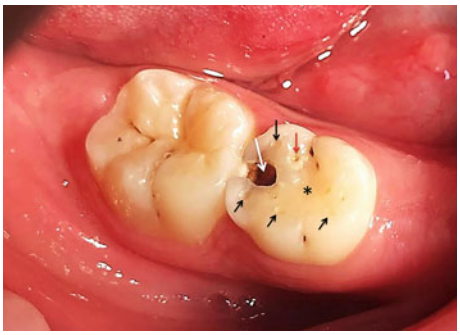

Fig. 5 Dental caries and erosive tooth wear. Lower hemiarch of a 7-year-old female patient. White arrow points to a cavitated caries lesion. Black arrows point to cup-shaped erosive tooth wear lesions (small indentations). Red arrow points to a cup-shaped erosive tooth wear lesion surrounded by a white spot lesion (non-cavitated tooth decay lesion). The asterisk shows an eroded molar occlusal surface with a polished and shiny appearance

Time to Link Bulimic Symptomatology with Oral Health and Food Choices

Food Choices and Erosive Tooth Wear vs. Bulimic Symptomatology

As previously reported, there is strong evidence supporting the association between ETW and bulimia nervosa, especially related to purging practices (Hermont et al. 2014; Schlueter and Luka 2018). However, less attention has been driven to evaluate the role of dietary habits as sources of acid contributing to ETW in patients with bulimia nervosa. It is not uncommon in the literature within the field of oral epidemiology and eating disorders, to see discussions in which authors interpret their data by quoting "known established facts," often derived from "significant associations," without the necessary reflection on the impact among the population addressed.

Few preceding researches have already detected that individuals with bulimic symptomatology presented regular consumption of acidic foods and that patients with EDs, who eat more acidic and sweetened foods, had higher prevalence and severity of ETW (Otsu et al. 2014; Rosten and Newton 2017). However, two questions need to be answered: is there scientific evidence supporting a high consumption of acidic foods among people with bulimic symptomatology? Which aspects contribute to this possible food choice?

Scientific Evidence

Regarding the first question, there is few data in the dentistry field pointing that individuals with bulimic symptomatology have a preference for an acidic diet. It has

been detected that dietary choices of patients with bulimia nervosa have an impact on their oral health, whether associated or not to vomiting practices (Rosten and Newton 2017). In a recent study, female adolescents with bulimic symptomatology, who were evaluated through the Bulimic Investigatory Test of Edinburg (BITE), differed with respect to the occurrence of dental implications and dietary habits (Hermont et al. 2021a). The prevalence of ETW increased along with the severity of BN symptomatology. Despite strong scientific evidence signalizing that the primary factor leading to ETW among patients with EDs is frequent self-induced vomiting (Hermont et al. 2014), and although this habit has been associated with ETW in the aforementioned study, no difference was detected between groups in relation to the self-reported frequency of purging practices (Hermont et al. 2021a). On the other hand, dietary habits differed significantly between groups. Female adolescents with severe bulimic symptomatology reported higher daily consumption of acidic foods and drinks. In fact, higher consumption of diet soda and citric fruits were the factors mainly associated with higher prevalence of ETW (Hermont et al. 2021a). Other researchers observed mild ETW lesions among EDs patients consuming significant amounts of water before self-inducing vomit, while those who routinely consumed sugar-sweetened food or carbonated beverages presented more severe lesions (Otsu et al. 2014).

Hypotheses

Concerning the second question, the intake of carbonated beverages has been identified to help decreasing hunger reflex stimulus in patients with EDs, probably by increasing dilation of the stomach (Gokul 2016; Klein et al. 2006; Lo Russo et al. 2008). Indeed, excessive diet soda intake is common in those patients, particularly the ones with lifetime diagnosis of BN. This dietary pattern could be explained by the combination between high appetitive drive and high weight concerns among patients with BN (Brown and Keel 2013). Not only carbonated drinks, but a preference for citric fruits, such as lemon juice or even slices of lemon, have been linked to people with EDs, since these contribute to eliminate or reduce the gustatory mechanism phase of hunger regulation (Lo Russo et al. 2008).

It is also important to consider foods that might be linked to vomiting/reflux effects. This hypothesis has not been addressed in the field of bulimic symptomology, but the question is worth discussing: does this risk group "learn" which foods might trigger reflux and consume them more frequently to assist purging behaviors? According to Mehta et al. (2020), some types of drinks are known to boost symptoms of gastroesophageal reflux, such as tea and fizzy beverages. Those drinks cause gaseous distension of the stomach and increase the pressure on the lower esophageal sphincter, corroborating to acid reflux (Mehta et al. 2020). Another overarching hypothesis for how these beverages might trigger reflux symptoms is through changes in the pH. An experimental study measured pH and esophageal impedance among healthy individuals when consuming several

beverages and detected that consumption of carbonated beverages decreased intra-esophageal pH (Jarosz and Taraszewska 2014).

Food Choices and Dental Caries vs. Bulimic Symptomatology

The occurrence of dental caries can be enhanced by bulimic episodes due to the uncontrolled events of overeating, which comprise the ingestion of high-carb fermentable foods (Kisely 2016; Rytomaa et al. 1998). In addition, it has been stated that nutritional deficiency might also corroborate to oral implications (Monda et al. 2021; Sheetal et al. 2013). However, there is still no consensus in the literature, since the association between caries, purging practices, and nutritional deficiency among patients with EDs is not clear (Hermont et al. 2013; Johansson et al. 2012; Lo Russo et al. 2008; Monda et al. 2021; Sheetal et al. 2013; Ximenes et al. 2010).

Hypotheses

A review about the impact of BN on oral health concluded that dental caries is a common oral implication in patients with bulimia (Rosten and Newton 2017). Differently from the majority of studies published in this field that mainly focuses on the effects of purging practices, the review detected that binge eating and other dietary habits, as well as antidepressant medication, can also have an effect on oral health among individuals with bulimic symptomatology (Rosten and Newton 2017). Indeed, as it was illustrated in Fig. 3, medication use and salivary issues are patient-related factors related to dental implications. This is applicable not only to ETW, but also for dental caries.

Individuals who use antidepressant drugs may suffer from dry mouth. Saliva acts to buffer organic acids produced by oral bacteria, corroborating to the maintenance of a remineralizing environment within the oral cavity, preserving the teeth from demineralization. Thus, a reduction in salivary flow rates might increase the risk of dental caries (Hopcraft and Tan 2010). Furthermore, patients with dry mouth might try to relieve their symptoms by chewing sugar-containing gums, sucking sweet confectionery, or consuming acidic and cariogenic drinks (Daly 2016). All these “palliative alternatives” are risk factors for dental caries. While some researchers indicate that the risk for dental caries is higher among those patients who also have a change in salivary flow (Moazzez and Bartlett 2014), there are authors pointing to an increased prevalence of this dental implication, due to the consumption of sugary foodstuff to “control” the constant feeling of hunger (Lo Russo et al. 2008). The fact is that both conditions contribute to dental caries; thus the risk may be enhanced in patients who present multiple risk factors.

The Role of Professionals Toward Oral Health Preventive Approach

As it was illustrated in Fig. 3, patient-related factors such as dietary habits (frequency and pattern of consumption) corroborate to the prevalence and incidence of ETW (Huang et al. 2015; O'Toole and Mullan 2018; Shahbaz et al. 2016). Therefore, nutritional-related factors must be considered in preventive measures planning, since some dietary contents such as acidic sweets, carbonated drinks, and acidic fruit juices might increase the prevalence of ETW, whereas calcium-enriched drinks and foods present a protective effect against this dental implication (Salas et al. 2015). With respect to food choices, it must be emphasized that despite their erosive potential, the consumption of healthy food, such as fruits, should be encouraged; instead the patient should be advised to reduce the intake of non-nutritious acidic foods and beverages. The World Health Organization recommends the daily consumption of at least 400 grams of fruits and vegetables to prevent the onset of chronic conditions. Therefore, dietary counseling toward oral health is in line with that of general health (Li et al. 2012).

Oral hygiene practices also have an important role in preventive measures, and good oral hygiene is of proven value in the prevention of DC. However, tooth brushing carried out in conjunction with an ongoing acidic attack may contribute to the loss of tooth surface. In addition, deleterious habits, such as excessive mechanical force during tooth brushing, enhance the occurrence of ETW and must be avoided (Hemingway et al. 2006). The following box (Fig. 6) presents a summary

Box 1- Strategies related to food choices, eating habits and oral hygiene practices that can be adopted to help preventing oral health implications

- Reduce the intake of non-nutritious acidic and sugary foods and beverages;
- Encourage the intake of safer food alternatives, such as milk products and calcium- enriched diets, particularly after an acidic intake;
- Discourage dietary acids and sugary food intake between meals and/or near/at bedtime;
- In case an acidic drink is consumed, it should preferably be chilled;
- Avoid deleterious habits that increase the contact time of the acid with oral cavity, such as swishing or holding acidic drinks in the mouth, before swallowing;
- Encourage the correct use of straws, properly positioned toward the back of the mouth, especially considering the intake of an acidic or sugary food/drink;
- Encourage oral hygiene practices to prevent dental caries;
- Teach patients how to properly conduct oral hygiene, avoiding deleterious habits, such as excessive mechanical force.

Fig. 6 Patient-related preventive measures toward oral health. A box with summary points about possible strategies related to food choices, eating habits, and oral hygiene practices that can be adopted to help preventing oral health implications

of possible patient-related preventive practices that might help preventing oral health implications. The box was based in all etiological factors previously mentioned in the chapter. The advices are applicable not only to risk groups with bulimic symptomology or other EDs, but also to the general population.

Applications to Other Eating Disorders

Scientific evidence points to an association between purging types of other eating disorders, such as anorexia nervosa, and the occurrence of erosive tooth wear, due to the practice of compensatory methods, such as self-induced vomiting and, consequently, to greater acidity in oral cavity (Hermont et al. 2014). Patients with avoidant/restrictive food intake disorder may also show a negative response associated with food intake, following or anticipating an aversive experience such as choking or vomiting. Furthermore, medical conditions such as gastrointestinal implications (gastroesophageal reflux) and persistent symptoms such as vomiting are associated with characteristic eating behaviors of this disorder (APA 2013; Eddy et al. 2015). Thus, it is possible to speculate that individuals with avoidant/restrictive food intake disorder may present greater risk of developing erosive tooth wear.

In addition to this direct association resulting from purgative habits, the occurrence of eating disorders, such as anorexia nervosa or unspecified feeding or eating disorder, can also compromise the function of the salivary glands and, consequently, the mechanisms of self-cleaning and neutralization of acids in oral cavity (Johansson et al. 2012; Kisely et al. 2015). As a result, individuals affected by these disorders could also be at increased risk of oral health implications, such as dental caries.

A literature review stated that the most common food choices among individuals with night eating syndrome include the intake of breads, sweets, and sandwiches (Vander Wal 2012). Considering the reduction in salivary flow at night, the ingestion of cariogenic and/or erosive foods could potentially expose these individuals to a greater risk of developing dental caries and/or erosive tooth wear (Vander Wal 2012).

Food preferences potentially harmful to oral health have also been identified in individuals with binge-eating disorder. The ones who preferred the sweet taste had monthly binge episodes six times higher compared to individuals with preferences for other flavors, as well as higher daily consumption of carbohydrates and calories (Goodman et al. 2018). Therefore, it is possible that, not only individuals with binge-eating disorder, but also people with the binge-eating type of anorexia nervosa, might also be at increased risk for dental implications. In addition, it has also been detected that individuals with avoidant/restrictive food intake disorder had an intake of added sugars and carbohydrates significantly higher than that of healthy individuals (Harshman et al. 2019), which could potentially imply a greater risk of dental caries.

Mini-Dictionary of Terms

- **Buffering capacity.** The measure of a buffer's ability to resist pH change. Refers to the amount of added acid or added base that can be neutralized by a buffer.
- **Cup-shaped lesions.** Small indentations in tooth surface caused by a chemical process of acid dissolution without bacterial involvement.
- **Tooth demineralization process.** The loss of minerals from dental hard tissues (e.g., enamel, dentine).
- **Dental caries.** A multifactorial dynamic disease, biofilm-mediated and sugar-driven. It happens when tooth is more susceptible to demineralization in comparison to remineralization, resulting in the destruction of dental hard tissues.
- **Erosive tooth wear.** The loss of dental hard tissues due to acids without bacterial involvement. It might happen simultaneous or subsequent to the exposure to mechanical forces.
- **Extrinsic acid.** Acids that come from sources other than human body.
- **Facial tooth surface.** A collective term referring to the teeth surfaces that face the cheeks or lips. The term "buccal surface" is used when referring to posterior teeth because it lies next to the buccinator (cheek muscle), and it is referred to as "labial surface" when referring to the anterior (front) teeth surfaces because it lies next to the lips.
- **Intrinsic acid.** Acids that come from gastric contents (produced by the human body).
- **Occlusal tooth surface.** The surface of the teeth that comes in contact with those of the opposite jaw during occlusion. It is the tooth surface used for chewing or grinding.
- **Palatal tooth surface.** It refers to the tooth surface that is directed toward the palate in maxillary teeth. The term "lingual surface" refers to tooth surface that is closest or next to the tongue in mandibular teeth.
- **Tooth remineralization process.** A biological repair mechanism that restores tooth minerals' gain. The remineralization process repairs the outer layer of tooth structure.
- **White spot lesion.** Incipient dental caries lesions characterized by a non-cavitated lesion, usually with a whitish coloration due to the demineralization of the tooth surface.

Key Facts of Bulimic Symptomatology, Food Choices, and Oral Health

- Erosive tooth wear is an irreversible loss of tooth structure, and the most common oral condition associated with bulimic symptomatology.
- Erosive lesions are characterized by a smooth, shiny, silky-glazed appearance, and usually affect the palatal surfaces of anterior teeth in patients with bulimia nervosa.

- Recurrent episodes of vomiting and/or reflux are the primary source of intrinsic acids among patients with bulimia nervosa.
- Acidic food choices may contribute to erosive tooth wear in patients with bulimia nervosa, in addition to purgative practices.
- Acids from dietary sources typically affect the facial surfaces of teeth, especially of the upper incisors.
- Bulimic episodes, with intake of foods rich in fermentable carbohydrates, may contribute to dental caries among people with bulimic symptomatology, but this association is not clear.

Summary Points

- Erosive tooth wear is the most prevalent dental implication related to bulimia nervosa, primarily due to frequent self-induced vomiting, but food choices might have an important role as well.
- The scientific evidence about the occurrence of dental caries among patients with bulimic symptomatology is not as clear as the one for erosive tooth wear.
- Studies on oral health have typically been conducted with patients already diagnosed with bulimia nervosa or other eating disorders, thereby limiting knowledge related to high-risk groups and preventive strategies.
- The evaluation of extrinsic sources of acid, such as dietary habits, has been neglected in studies on dental implications and bulimia nervosa.
- Awareness of dietary preferences, compensatory practices, and the possible association with dental implications among groups with bulimic symptomatology is both clinically and theoretically important.
- Dentists usually monitor patients on a regular basis. Therefore, they may be the first health professionals to suspect EDs, due to their oral implications.

Abstract

Individuals with bulimia nervosa and purging disorder often experience a range of difficulties effectively regulating their emotions, and eating disorder behaviors such as binge eating and purging often function as maladaptive emotion regulation strategies. A number of theoretical models are premised on or include the idea that eating disorder behaviors such as binge eating and purging function in large part to regulate negative emotions, and these models have been well supported by empirical research. Specific facets of emotion regulation that appear to be particularly challenging for many individuals with bulimia nervosa and purging disorder include accepting negative affective states, difficulties with impulse control during negative emotional states, and difficulty accessing and using emotion regulation strategies at such times. Research also shows a clear temporal and functional relationship between state negative affect and eating disorder behaviors. Several treatments including enhanced cognitive behavioral therapy for eating disorders, dialectical behavior therapy, and integrative cognitive-affective therapy for eating disorders include a focus on improving individuals' ability to more effectively regulate emotions.

Keywords

Bulimia nervosa · Purging disorder · Other specified feeding or eating disorder · Eating disorders · Emotion regulation · Emotion dysregulation · Distress tolerance · Mood intolerance · Negative affect · Impulsivity · Ecological momentary assessment · Dialectical behavior therapy · Cognitive behavioral therapy · Integrative cognitive-affective therapy

Abbreviations

AN-BP	Anorexia nervosa, binge eating/purging type
AN-R	Anorexia nervosa, restricting type

CBT	Cognitive behavioral therapy
CBT-E	Enhanced cognitive behavioral therapy for eating disorders
DBT	Dialectical behavior therapy
EMA	Ecological momentary assessment
ICAT-BN	Integrative cognitive-affective therapy for bulimia nervosa
OSFED	Other specified feeding or eating disorder

Introduction

Difficulties with emotion regulation are common in individuals with eating disorders. Eating disorder behaviors, such as binge eating and purging, often function as maladaptive emotion regulation strategies. Clinical experience and research show that negative emotions often directly precede binge eating and purging behaviors and that individuals commonly report relief from negative emotions afterward. This chapter focuses on issues related to emotion regulation difficulties in individuals with bulimia nervosa and other specified feeding and eating disorder (OSFED) – purging disorder (subsequently referred to in this chapter simply as purging disorder). Although separate diagnostic categories, there is considerable overlap in their presentation and psychopathology – and, as a result, much of the relevant research has grouped them together. However, purging disorder is a more recently defined disorder, and therefore, some of the research focuses only on bulimia nervosa. The chapter starts by considering conceptual and theoretical underpinnings of emotion regulation difficulties in individuals with bulimia nervosa and purging disorder, followed by a description of the ways these problems may manifest. Next, the chapter describes research demonstrating that binge eating and purging behaviors often function to regulate state negative affect, and finally, it reviews treatments and interventions that target these concerns.

Conceptual and Theoretical Underpinnings

Clinical Observation and Comorbidity

Clinicians who work with individuals with bulimia nervosa and/or purging disorder will be familiar with the fact that many such individuals appear to have difficulty tolerating distress and managing their emotions. Clinicians with experience working with clients with these disorders frequently hear individuals describe their emotions as intense and difficult to tolerate, and they often report using eating disorder behaviors – such as binge eating, self-induced vomiting, laxatives, exercise, and food restriction – to help them suppress, escape, numb, or otherwise feel in control of their emotions. In other words, they are using eating disorder behaviors as maladaptive emotion regulation strategies. *Emotion regulation* refers to a complex constellation of related concepts focused on awareness of emotions, acceptance of emotions, the ability to inhibit impulsivity and maintain goal-directed behavior during negative affective states, and the ability to engage in functional behaviors to modulate negative emotional states in a manner that is appropriate to the situation (Gratz and Roemer 2004). A significant body of literature

supports these clinical observations and has also informed the development of treatments targeting these concerns.

The types of mental health concerns that commonly co-occur with bulimia nervosa and purging disorder also suggest the presence of emotion regulation difficulties in this group. Mood and anxiety disorders are the most common comorbid mental health conditions (Ulfvebrand et al. 2015). Additionally, at least 20% of those with bulimia nervosa have symptoms of posttraumatic stress disorder (Ferrell et al. 2020), in which difficulty regulating emotions is highly characteristic. Substance use disorders as well as suicidal ideation and non-suicidal self-injury (e.g., cutting, burning) are common in those with bulimia nervosa and related eating disorders, and these problems may similarly function as ways to manage distress or reflect problems with impulsivity (a dimension of emotion dysregulation; Bahji et al. 2019; Cucchi et al. 2016; Goldstein and Gvion 2019). Finally, borderline personality disorder, which is a psychiatric condition characterized by extreme difficulties with emotion dysregulation, impulsivity, and interpersonal difficulties, is relatively common in individuals with bulimia nervosa and other specified eating disorder presentations (Farstad et al. 2016). The fact that bulimia nervosa and purging disorder are predominantly comorbid with other mental health concerns characterized by emotional difficulties supports the notion that problems with emotion regulation may be a central component of these eating disorders.

Theoretical Models of Bulimia Nervosa as a Disorder of Emotion Regulation

Affect Regulation Model

Although difficulties with emotion regulation are common to many types of mental health disorders, these problems may present or function in a particular way in individuals with eating disorders. According to the affect regulation model, binge eating commonly occurs in response to negative affective states, and is maintained through negative reinforcement, which occurs via an immediate decrease in negative affect following binge eating (Haedt-Matt and Keel 2011; Hawkins and Clement 1984; Polivy and Herman 1993). Since this model was first introduced, a wealth of empirical evidence has provided support for its tenets (Schaefer et al. 2020). For example, Smyth and colleagues (2007) showed a clear temporal relationship between negative emotions intensifying prior to and decreasing following binge/purge episodes. These processes will be further elaborated on later in this chapter, when ecological momentary assessment (EMA) research is reviewed.

Escape Theory

Heatherton and Baumeister's (1991) escape theory of bulimia nervosa shares similarities with the affect regulation model but extends further by suggesting a

functional relationship between negative affect related to perceived personal failures and binge eating. According to escape theory, individuals with bulimia nervosa engage in binge eating as a way to escape from self-awareness of perceived failures relative to their own self-imposed high standards. Awareness of perceived failures is aversive and highly distressing for individuals with bulimia nervosa, and during binge eating episodes, individuals focus their attention on eating and its sensations, which provides a cognitive escape from longer-term or bigger picture concerns (Heatherton and Baumeister 1991). According to escape theory, state negative affect escalates prior to binge eating and lessens after purging. Subsequent research has supported this model (Burton and Abbott 2017). For example, Blackburn and colleagues (2006) used structural equation modelling to provide support for escape theory, by demonstrating that perfectionism predicted aversive levels of self-awareness, which predicted negative affect. Negative affect predicted avoidant coping, and this coping style predicted binge eating (Blackburn et al. 2006). Both escape theory and the affect regulation model are important foundations for the now widely understood notion that emotion regulation concerns are a central problem for individuals with bulimia nervosa (and other eating disorders, including purging disorder).

Mood Intolerance and the Transdiagnostic Cognitive Behavioral Model of Eating Disorder Maintenance

More contemporaneous is Fairburn and colleagues' (2003) transdiagnostic cognitive behavioral model of eating disorder maintenance. The model is "transdiagnostic" in that it applies to the maintenance of all eating disorders, including bulimia nervosa, anorexia nervosa, binge eating disorder, and OSFED presentations. This model also forms the basis for enhanced cognitive behavioral therapy for eating disorders (CBT-E; Fairburn et al. 2008), the current leading evidence-based treatment approach for adults with eating disorders, including bulimia nervosa and related eating disorders such as purging disorder.

Although Fairburn and colleagues' cognitive behavioral model of eating disorder maintenance focuses on overvaluing eating, weight, and shape as the primary cognitive psychopathology driving behavioral eating disorder symptoms and therefore eating disorder maintenance, the role of *mood intolerance* is also highlighted as a key maintaining factor. Mood intolerance is defined as the inability to effectively cope with particular emotional states (typically aversive negative affective states, although for some individuals any intense emotions, including positive ones, may be difficult to regulate). These individuals may mentally disengage from the negative affective state by engaging in a maladaptive behavior, such as self-injury, substance abuse, or eating disorder behaviors like binge eating, vomiting, or driven exercise. Once the eating disorder is established, eating disorder behaviors, and in particular, binge eating, may become a regular or habitual way of managing negative affective states (Fairburn et al. 2003). Individuals with mood intolerance may experience more intense negative emotions compared to others, or they may be more sensitive to

these emotions, or both. Beliefs that one cannot effectively manage their emotions may further exacerbate the intensity of the emotions (Fairburn et al. 2003).

Manifestations of Emotion Regulation Difficulties in Bulimia Nervosa and Purging Disorder

All people use strategies to regulate emotions; however, some coping strategies are less adaptive than others. Those who rely on maladaptive emotion regulation behaviors (e.g., binge eating or purging, self-injury, substance abuse, or other avoidant coping behaviors), including many individuals with bulimia nervosa and purging disorder, are considered high on emotion *dys*regulation. Not only is emotion dysregulation an important correlate of psychopathology in general (Sloan et al. 2017), but emotion dysregulation also plays a critical role in the development and maintenance of eating disorders specifically (Lavender et al. 2015; Prefit et al. 2019; Puttevils et al. 2021). Importantly, it is likely not the experience of having negative emotions that influences eating disorder symptomatology as much as it is difficulty in effectively *regulating* one's negative emotions specifically that is most relevant (Mallorquí-Bagué et al. 2018).

It is well documented that individuals with bulimia nervosa tend to have significant difficulty with effectively regulating their behavior when experiencing distress (Lavender et al. 2014). In this group, severity of eating disorder psychopathology is associated with greater overall difficulties with emotion regulation, as well as problems specifically with nonacceptance of emotional states, difficulties with impulse control, and limited access to strategies to effectively modulate negative affect (Lavender et al. 2014, 2015). Furthermore, individuals with bulimia nervosa may also have problems with alexithymia (i.e., difficulties identifying and describing one's emotions; Lavender et al. 2015). Additionally, more frequent purging behaviors (and other compensatory behaviors such as driven exercise) are associated with greater difficulties staying focused on one's goals or the task at hand during negative affective states (Lavender et al. 2014). When examining the relationship between difficulties with emotion regulation and specific eating disorder symptoms, objective binge eating episodes are uniquely related to difficulties with impulse control, whereas purging behaviors may not be uniquely related to any particular facet of emotion dysregulation (Monell et al. 2018) and may therefore reflect more general problems with regulating emotions. Though the literature on purging disorder is more limited, there is preliminary evidence that individuals with purging disorder demonstrate fewer difficulties with emotion regulation compared to individuals with bulimia nervosa (Smith and Crowther 2013), suggesting that the presence of both binge eating and purging behaviors may reflect a pattern of greater difficulties with emotion dysregulation generally.

Individuals with eating disorders may also engage in other maladaptive emotion regulation behaviors (besides eating disorder symptoms like binge eating or purging). For example, cognitive rumination (i.e., hyper-focusing on negative emotions and thoughts) and suppression (i.e., attempting to push away negative thoughts

and/or emotional expressions) are maladaptive emotion regulation behaviors that are strongly associated with eating disorders including bulimia nervosa (Aldao et al. 2010). Rumination appears to play an especially important role in the maintenance of bulimia nervosa in particular, as binge eating and purging may serve to escape rumination (Prefit et al. 2019). Additionally, cognitive rumination predicts the onset of binge eating as well as increases in binge eating and purging frequency among adolescent girls (Nolen-Hoeksema et al. 2007).

In summary, it is clear that individuals with bulimia nervosa and purging disorder experience a broad constellation of difficulties with emotion regulation. Accordingly, one conceptualization is that it is difficulties with effectively *regulating* one's negative emotions generally (rather than simply the experience of having negative emotions) that may be the important antecedent to binge eating and purging behaviors (Mallorquí-Bagué et al. 2018). Therefore, learning and practicing adaptive emotion regulation skills is an important treatment target for any individual whose eating disorder is characterized by binge eating and/or purging. In fact, improvements in emotion regulation are directly related to positive treatment outcomes for individuals with eating disorders (Peterson et al. 2017), especially if improvements in access to emotion regulation skills occur rapidly during the initial weeks of treatment (MacDonald et al. 2017; MacDonald and Trottier 2019). Interventions targeting emotion regulation difficulties for individuals with eating disorders will be discussed in more detail later in this chapter.

Relationship Between State Negative Affect and Binge Eating/Purging Behaviors: Ecological Momentary Assessment Research

As discussed, bulimia nervosa and purging disorder are associated with emotion regulation difficulties. Although this suggests that eating disorders may function to regulate emotions, it does not demonstrate that eating disorder behaviors *specifically* serve this function or that there is an in-the-moment relationship between distressing emotions and eating disorder behaviors. In order to demonstrate an in-the-moment functional relationship between eating disorder behaviors and emotion regulation, research must reliably demonstrate a temporal association between intensifying negative emotions, engagement in an eating disorder behavior (e.g., binge eating or purging), and the subsequent attenuation of negative affect.

Ecological momentary assessment (EMA) is a methodology that has significantly advanced research on understanding the role of eating disorder behaviors as maladaptive emotion regulation strategies (Schaefer et al. 2020). EMA allows for nuanced examination of temporal relationships between state-level (i.e., in the moment) variables by using real-time assessments in an individual's natural environment multiple times per day for several days or weeks, typically using brief questionnaires completed on a smartphone or biometric data collected using activity trackers or heart rate monitors. In emotion research, EMA can be used to analyze state-level patterns of emotion and emotion intensity across time and examine the relationship between temporal patterns of emotion and behavior. This allows

researchers to draw conclusions about the temporal relationships between affect and behaviors such as binge eating and vomiting (Schaefer et al. 2020).

To date, EMA research has demonstrated a strong temporal relationship between state negative affect and eating disorder behaviors. In an early study in this area, Smyth et al. (2007) used EMA to show that individuals with bulimia nervosa experienced less positive affect, more negative affect generally, more anger and hostility specifically, and more stress on days when binge eating and purging occurred. Additionally, positive affect decreased, and both negative affect generally and anger/hostility increased in a reliable way, shortly prior to binge/purge episodes. Following binge/purge episodes, negative affect generally and anger/hostility both decreased, and positive affect increased (Smyth et al. 2007). Moreover, in an early meta-analysis of EMA research on binge eating, negative affect reliably increased prior to binge eating episodes, increased further after the binge, and then decreased after purging for those with bulimia nervosa (Haedt-Matt and Keel 2011). For individuals with purging disorder, negative affect increased prior to purging on purge days (compared to non-purge days) and was initially higher shortly after the purging episode but then followed a downward trajectory in the hours that followed (Haedt-Matt and Keel 2015). Additionally, among women with bulimia nervosa, guilt (a facet of negative affect) increased prior to, and decreased after, episodes of binge eating and purging as well as after episodes of purging only (Berg et al. 2013). Overall, the body of EMA research on this topic clearly demonstrates that eating disorder behaviors (such as binge eating and purging) often occur in the context of elevated state negative affect, and that negative affect often temporarily improves following these behaviors, and is consistent with the affect regulation model of eating disorders (Shaefer et al. 2020).

Interventions Targeting Emotion Regulation Difficulties for Bulimia Nervosa and Purging Disorder

Cognitive Behavioral Therapy (CBT) and CBT-Based Intensive Treatments

Given that binge eating and purging behaviors appear to function to regulate emotions in individuals with bulimia nervosa and purging disorder, it is important to consider how treatments for these disorders address emotion regulation difficulties. Enhanced cognitive behavioral therapy for eating disorders (CBT-E; Fairburn et al. 2008) is a transdiagnostic treatment based on the cognitive behavioral theory described earlier (Fairburn et al. 2003) and is the current leading evidence-based intervention for adults with eating disorders including bulimia nervosa and purging disorder (Fairburn et al. 2009, 2015). The main foci of CBT-E include behavioral changes (i.e., establishing regular eating, eliminating binge eating, purging, and

other weight control behaviors); reducing overvaluation of eating, weight and shape, and their control; and addressing event- and mood-related concerns, including mood intolerance, defined as the inability to effectively cope with intense mood states (Fairburn et al. 2003).

CBT-E targets event- and mood-related concerns using a cognitive-behavioral approach to help the client become more aware of how, and in what situations, triggering events, negative mood states, and intense emotions may lead to eating disorder behaviors and how to replace these with more functional mood modulation strategies. For example, individuals learn proactive problem-solving to address event-related disruptions in eating, and binge analysis helps them to analyze the antecedents of residual binge eating episodes to help them prevent these episodes. Furthermore, individuals learn to recognize the relationship between their cognitive appraisals of events, escalating negative emotions, and their use of maladaptive behaviors (e.g., binge eating) to modulate negative emotions. By learning to recognize this process early, clients can be taught to slow down, observe and analyze it unfolding, and intervene with more skillful behavior as early as possible (Fairburn et al. 2008). Interestingly, the initial version of CBT-E conceptualized mood intolerance as one of the several potential eating disorder maintenance mechanisms (along with perfectionism, core low self-esteem, and interpersonal difficulties), which could be addressed using a supplementary mood intolerance module. However, mood intolerance is now considered a core treatment target, and therefore this material is currently part of the core CBT-E protocol (Dahlenburg et al. 2019).

In addition to being effective for treating core eating disorder symptoms (Atwood and Friedman 2020), CBT-E is efficacious in reducing emotion regulation difficulties in individuals with bulimia nervosa (Wonderlich et al. 2014). Furthermore, improvements in emotion regulation during CBT-E are associated with improvements in overall eating disorder psychopathology at posttreatment and in binge eating and purging frequency four months posttreatment in a sample of individuals with bulimia nervosa (Peterson et al. 2017).

Many intensive treatment programs for moderate to severe presentations of bulimia nervosa, purging disorder, and other eating disorders also use cognitive behavioral approaches and include interventions aimed at improving clients' emotion regulation capacities (MacDonald et al. 2017; McFarlane et al. 2015; Olmsted et al. 2013). These typically include learning strategies to tolerate intense emotions and resist urges to engage in eating disorder behaviors in response to negative emotions. Research indicates that individuals' emotion regulation skills improve during intensive treatment. Importantly, increased access to emotion regulation strategies early in treatment (i.e., during the first four weeks) predicts abstinence from binge eating and purging and lower cognitive eating disorder psychopathology at posttreatment (MacDonald et al. 2017), as well as lower eating disorder psychopathology and lower impairment due to the eating disorder six months after treatment (MacDonald and Trottier 2019).

Dialectical Behavior Therapy

Dialectical behavior therapy (DBT) was originally designed for the treatment of individuals with borderline personality disorder and includes a primary focus on teaching skills to regulate intense emotions and tolerate distress (Linehan 1993). The fact that individuals with bulimia nervosa and other eating disorders often have difficulties with emotion regulation provided a strong rationale for applying DBT in this group (e.g., Safer et al. 2009). DBT approaches have been examined as a stand-alone treatment for bulimia nervosa (Safer et al. 2001; Brown et al. 2020), as well as an adjunct intervention to target emotion regulation difficulties within CBT-based treatment programs (Ben-Porath et al. 2014). DBT interventions have received preliminary research support, both for their impact on core eating disorder symptoms and emotion regulation (Linardon et al. 2017). Standard DBT typically includes four components: protocolized individual psychotherapy; group skills training (in which mindfulness, distress tolerance, interpersonal effectiveness, and emotion regulation modules are taught); therapist consultation teams; and 24-hour phone coaching (Linehan 1993). Stand-alone DBT for eating disorders may include all or several of these components (or iterations of them; e.g., the adapted DBT manual for bulimia nervosa by Safer and colleagues (2009) includes three of the four DBT skills training modules, with the interpersonal effectiveness module omitted). When DBT is included as a supplement to CBT-based eating disorder treatment, it is often implemented as a DBT skills group in which some or all of the core DBT skills are taught, whereas the other components of standard DBT (i.e., phone coaching, therapist consultation teams, and/or individual DBT sessions) might be omitted (Ben-Porath et al. 2014). There is also an adaptation of DBT for patients with multi-diagnostic presentations who have a primary eating disorder diagnosis as well as significant comorbid psychopathology, often including borderline personality disorder (Ben-Porath et al. 2020). This version of DBT combines components of CBT for eating disorders and DBT to concurrently manage both the eating disorder and other high-risk behaviors (e.g., suicidality, self-injury; Ben-Porath et al. 2020). Regardless of the format, the aim of using a DBT approach to treat eating disorders is to help individuals learn to understand, tolerate, and more adaptively regulate intense emotions, thereby eliminating the use of binge eating and purging behaviors as a maladaptive emotion regulation strategy (Brown et al. 2020; Safer et al. 2001).

Research on the effectiveness of DBT and DBT-informed treatments for individuals with bulimia nervosa has shown that integrating DBT into day treatment leads to significant improvements in patients' emotion regulation capacities (Brown et al. 2020). Similarly, the addition of a weekly DBT skills group to a CBT-based intensive eating disorder program was associated with small improvements in emotion regulation capacities in a mixed sample of individuals with anorexia nervosa and bulimia nervosa (Ben-Porath et al. 2014). Research has not specifically examined the impact of DBT interventions on emotion regulation difficulties in individuals diagnosed with purging disorder.

Integrative Cognitive-Affective Therapy for Bulimia Nervosa

Integrative cognitive-affective therapy for bulimia nervosa (ICAT-BN; Wonderlich et al. 2015) is a psychotherapy intervention with research support for its efficacy in treating individuals with bulimia nervosa (Wonderlich et al. 2014). It was designed with the aim of specifically targeting emotion dysregulation in this population and is based on the theory that momentary experiences of negative emotions play a primary role in the maintenance of bulimia nervosa (Wonderlich et al. 2015). Binge eating and purging symptoms are considered to play a significant role in regulating these emotion states and thus become positively reinforced. ICAT-BN shares some features with CBT-E (including self-monitoring of eating and learning how to plan and implement regular eating); however, the majority of the treatment focuses on modifying and tolerating momentary emotion-related experiences (Accurso et al. 2016; Peterson et al. 2017). Interventions aimed at addressing emotion dysregulation and eating disorder symptoms include improving awareness and tolerance of emotions, developing skills to reduce impulsive behaviors in response to negative emotions, and modifying sources of negative emotions and a lack of positive emotions in the individual's life (Wonderlich et al. 2015).

ICAT-BN led to similar improvements in eating disorder symptoms to CBT-E in a rigorous randomized controlled trial of individuals with bulimia nervosa (Wonderlich et al. 2014), and both interventions had comparable and positive impacts on emotion regulation capacities (Peterson et al. 2017). ICAT-BN may be particularly effective for individuals with bulimia nervosa who experience a high degree of emotion dysregulation before starting treatment. Accurso et al. (2016) found that individuals with higher affective lability (i.e., the tendency to frequently experience intense and unstable emotions) experienced greater improvements in symptom reduction and overall eating disorder psychopathology when treated with ICAT-BN versus CBT-E.

Conclusions

This chapter described the types of emotion regulation difficulties that are commonly experienced by individuals with bulimia nervosa and purging disorder. A number of theoretical models have been put forth to explain the role of negative affect in these disorders, and these models converge in their explanations of binge eating and purging behaviors as maladaptive efforts to regulate emotions. The nuanced temporal relationships that are elucidated by recent EMA research clearly demonstrate the functional relationship between eating disorder behaviors and negative emotions. Finally, the chapter reviewed several treatments for bulimia nervosa and purging disorder that include attention to difficulties with emotion regulation. Although CBT-E is currently the leading evidence-based treatment for eating disorders overall, DBT and ICAT both target emotion-related difficulties as core treatment targets and have accumulating evidence supporting them, making them important treatment options for this group.

Applications to Other Eating Disorders

Anorexia nervosa. Individuals with anorexia nervosa also experience difficulties with emotion regulation (Lavender et al. 2015). There are two subcategories of anorexia nervosa: restricting type (AN-R) and binge eating/purging type (AN-BP). In both types the individual maintains a low weight and restricts energy intake (i.e., via restrictive eating, fasting, and/or excessive exercise). Individuals with AN-R engage exclusively in restrictive behaviors, whereas individuals with AN-BP also engage in regular episodes of binge eating and/or purging behaviors. According to a recent review, individuals with AN-R, AN-BP, and bulimia nervosa do not differ in their use of maladaptive emotion regulation strategies, but individuals with anorexia nervosa are less likely to use adaptive (i.e., skillful) methods of emotion regulation, compared to those with bulimia nervosa (Puttevils et al. 2021). The authors explain that this may be due to the effects of underweight and greater alexithymia in individuals with anorexia nervosa (Puttevils et al. 2021). Other research has demonstrated that individuals with AN-BP tend to use fewer adaptive emotion regulation strategies relative to individuals with AN-R (Rowsell et al. 2016), providing support that emotion dysregulation and binge eating and purging behaviors are strongly related. In fact, one study showed that difficulties inhibiting impulsivity when distressed is the only facet of emotion regulation that was significantly related to binge eating/purging behaviors among individuals with anorexia nervosa (Racine and Wildes 2013).

Binge eating disorder. Binge eating disorder is characterized by recurrent episodes of binge eating without engaging in compensatory behaviors such as purging, fasting, or exercise. As reviewed earlier in the chapter, according to the affect regulation model of binge eating, binge eating is believed to often function as a way to regulate negative affective states. Therefore, it is not surprising that individuals with binge eating disorder report greater difficulty with emotion regulation relative to healthy controls (Brockmeyer et al. 2014). However, there is also evidence to suggest that individuals with binge eating disorder generally report less emotion regulation difficulties relative to individuals with anorexia nervosa and bulimia nervosa (Brockmeyer et al. 2014).

Mini-Dictionary of Terms

- **Affect regulation model:** A theoretical model that suggests binge eating functions to reduce negative affective states. According to this model, binge eating is maintained via negative reinforcement.
- **Cognitive behavioral model:** A transdiagnostic theoretical model of eating disorder maintenance. According to this model, overevaluation of eating, weight, and shape is considered the core cognitive psychopathology of eating disorder behaviors. This model also considers the role of mood intolerance as an important eating disorder maintaining mechanism.

- **Ecological momentary assessment:** A research methodology that uses repeated sampling of participants' real-time emotions, behaviors, and experiences in their natural environments, often using a device such as a smartphone.
- **Emotion dysregulation:** Difficulty with effectively modulating emotions using skillful or adaptive behaviors and/or the overreliance on maladaptive behaviors (e.g., eating disorder behaviors, self-harm, substance use) to manage emotions.
- **Emotion regulation:** A constellation of constructs related to one's ability to effectively modulate and manage emotions. Emotion regulation includes (but is not limited to) sub-constructs such as degree of emotion awareness, the abilities to inhibit impulsivity and maintain goal-directed behavior while experiencing negative emotions, and the ability to flexibly adapt behavior in emotional situations.
- **Escape theory:** A theoretical conceptualization of bulimia nervosa in which binge eating is viewed as a way to escape from states of self-awareness, which may be experienced as aversive and distressing.
- **Mood intolerance:** A central component of the transdiagnostic cognitive behavioral model of eating disorders, in which difficulty effectively tolerating emotions is considered an important eating disorder maintaining factor.

Key Facts of Emotion Regulation in Bulimia Nervosa and Purging Disorder

- Emotion regulation refers to the ability to effectively and adaptively modulate one's emotions
- Emotion regulation includes elements such as awareness of one's emotions, the ability to prevent impulsive behaviors and remain goal-directed during elevated affective states, and the ability to implement strategies aimed at modulating emotions
- Individuals with bulimia nervosa and related eating disorders such as purging disorder often experience difficulties with emotion regulation
- Eating disorder behaviors such as binge eating often function as maladaptive emotion regulation strategies
- During negative emotional states, eating disorder behaviors may help the individual bring down or escape from negative emotions
- This process also contributes to the persistence of eating disorder behaviors over time

Summary Points

- Difficulties with regulating emotions are characteristic of individuals with bulimia nervosa and purging disorder
- There are several theoretical models that include difficulty regulating emotions or tolerating distress as key to understanding the occurrence and maintenance of binge eating and/or purging behaviors

- Difficulties with emotion regulation may include nonacceptance of emotional states, difficulties with impulse control, limited access to emotion regulation strategies, and difficulties engaging in goal-directed behavior during negative affective states
- Ecological momentary assessment (EMA) research has clearly demonstrated a temporal relationship between state negative affect, the occurrence of binge eating and/or purging behaviors, and subsequent decreases in state negative affect
- There are several interventions for individuals with eating disorders that target difficulties with emotion regulation

Abstract

Although psychotherapy is effective for bulimia nervosa (BN), many individuals remain symptomatic after treatment. Therefore, pharmacotherapies have been studied as stand-alone treatments, and as adjuncts for psychotherapy, with the goal of improving outcomes for BN. Despite much research in this area, fluoxetine remains the only medication with regulatory approval. However, there are off-label options and several medications in development. The goal of this chapter is to review the literature related to the following pharmacotherapies for BN: a) antidepressants, b) antiepileptics, c) stimulants, and d) other medications. We will also review the literature related to combining pharmacotherapy and psychotherapy for those with BN and present the evidence for medication treatment in youth with this disorder.

Keywords

Bulimia nervosa · Eating disorders · Pharmacotherapy · Medications · Review · Antidepressant · Fluoxetine · Antiepileptic · Anticonvulsant · Topiramate · Stimulant · Lisdexamfetamine · Psychotherapy

Abbreviations

ADHD	Attention deficit hyperactivity disorder
AN	Anorexia nervosa
BED	Binge eating disorder
BMI	Body mass index
BN	Bulimia nervosa
CBT	Cognitive behavior therapy
DBT	Dialectical behavior therapy
ED	Eating disorder
EDNOS	Eating disorder not otherwise specified
IPT	Interpersonal therapy
IU	International units
LDX	Lisdexamfetamine dimesylate
MA	Methylamphetamine
MAOI	Monoamine oxidase inhibitors
MPH	Methylphenidate
Phen/Top ER	Phentermine/topiramate extended release
RCT	Randomized control trial
SSRI	Selective serotonin reuptake inhibitors
TCA	Tricyclic antidepressants

Introduction

Bulimia nervosa (BN) is a serious medical condition characterized by episodes of eating objectively large amounts of food in a discrete period of time and feeling a sense of loss of control during the episode. The shame and guilt associated with these binge episodes then triggers compensatory behaviors (e.g., self-induced vomiting) aimed at alleviating the negative feelings (American Psychiatric Association 2013). The lifetime prevalence of BN is approximately 2% and is associated with increased mortality rates from all causes, including elevated rates of suicide (Hudson et al. 2007; Crow et al. 2009). Although psychotherapy is effective for BN, approximately 40% of individuals remain symptomatic after treatment (Hilbert et al. 2019). As a result, pharmacotherapies have been extensively studied as stand-alone treatments, and as adjuncts for psychotherapy, with the goal of improving outcomes for BN. Despite many clinical trials aimed at developing medications for BN, fluoxetine remains the only option with regulatory approval. Even though fluoxetine is the only approved medication, there are some off-label options and medications in development. The goal of this chapter is to review the literature related to the following pharmacotherapies for BN: a) antidepressants, b) antiepileptics, c) stimulants, and d) other medications. We will also review the literature related to combining pharmacotherapy and psychotherapy in BN and present the evidence for medication treatment in youth with this disorder.

Applications to Other Eating Disorders – In this chapter, we review the evidence for treating BN with pharmacotherapy. Although the research described here relates specifically to BN, there is overlap with binge eating disorder (BED). BED is a distinct disorder, but there are symptom and neurobiological parallels between the two illnesses. As such, there are also similarities between the medications recommended for each disorder. For example, similar to BN, a meta-analysis showed that antidepressants are moderately effective for reducing binge episodes in BED (Stefano et al. 2008), though unlike in BN, fluoxetine does not have regulatory approval for BED. Similarly, as described in the BN literature, there are several randomized controlled trials supporting the use of topiramate in BED (Frank and Berner 2020). Another parallel between pharmacotherapy options for BN and BED is the use of stimulants. In North America, the stimulant prodrug lisdexamfetamine is approved for the treatment of moderate to severe BED in adults (McElroy et al. 2016). Although the same degree of evidence does not exist for using stimulants in BN, we will discuss the emerging evidence for this medication (in BN) later in the chapter. Finally, there is little overlap between pharmacotherapy options for BN and anorexia nervosa.

Antidepressants

Research and guidelines suggest antidepressants are the pharmacological treatment of choice for BN (American Psychological Association 2006; Hagan and Walsh 2021; Hilbert et al. 2017). Currently, fluoxetine (serotonin reuptake inhibitor; SSRI)

is the only approved medication for BN in North America. Several randomized controlled trials suggest that a dose of 60 mg of fluoxetine can reduce frequency of vomiting, binge eating, and purging, as well as improve eating attitudes and comorbid symptoms of depression relative to a dose of 20 mg and/or placebo (Fluoxetine BN Collaborative Study Group 1992; Goldstein et al. 1995; Romano et al. 2002). Notably, fluoxetine appears to result in reductions of BN symptoms in both adult and adolescent populations (Kotler et al. 2003), and in BN patients with or without comorbid depression (e.g., Goldstein et al. 1999). Fluoxetine appears to have low occurrences of adverse events (see Bello and Yeomans 2018 review of safety of fluoxetine for BN); however, it has been cautioned that higher doses of SSRIs like fluoxetine may trigger suicidal behaviors, which may be particularly noteworthy for adolescent populations (Frank 2020). Despite these promising findings, there is evidence of symptomatic regression over time in patients with BN treated with fluoxetine (Romano et al. 2002). As such, it has been suggested that fluoxetine alone may not be a sufficient treatment for BN.

In addition to fluoxetine, other antidepressants have been examined as potential treatments for BN. These include other SSRIs, tricyclic antidepressants (TCA), monoamine oxidase inhibitors (MAOI), and atypical antidepressants (e.g., trazodone; McElroy et al. 2019). While there are fewer randomized, placebo-controlled trials with antidepressants other than fluoxetine (McElroy et al. 2019), a recent meta-analysis found SSRIs, TCAs, and MAOIs have moderate efficacy for reducing binge eating and purging episodes (Svaldi et al. 2019). While these results are encouraging, there is substantial heterogeneity across RCTs with antidepressants (Svaldi et al. 2019). As such, additional research is required before concrete conclusions can be drawn about the effectiveness of classes of antidepressants on BN symptoms. In terms of safety, antidepressants are generally considered safe except for bupropion, which has been associated with seizures in those with BN (Horne et al. 1988).

Overall, the broader literature does not recommend antidepressants as the sole treatment for BN (National Institute for Health and Care Excellence 2017; Reas and Grilo 2021) unless the first line treatment of cognitive behavior therapy (CBT) is unavailable, there has been a poor response to psychotherapy, or patients prefer medication to psychotherapy (Hagan and Walsh 2021; Svaldi et al. 2019; Walsh et al. 2000; Table 1).

Antiepileptics

Of the antiepileptics, topiramate is the most studied as a treatment for BN. In 2003, Hoopes et al. conducted a 10-week RCT in which BN participants received either topiramate ($n = 35$) or placebo ($n = 34$). The study revealed that patients administered topiramate (median dose 100 mg/day) exhibited a 44.8% decrease in mean weekly binge and/or purge days, while those in the placebo group demonstrated a 10.7% reduction. In another RCT by Nickel et al. (2005), 60 participants received topiramate (titrated to 250 mg/day by 6 weeks), or placebo, over 10 weeks. 36.7% ($n = 11$) of the topiramate group experienced a greater than 50% reduction in the

Table 1 Selection of studies examining the use of SSRIs in bulimia nervosa

Authors	Study design duration	Sample size	Medication (daily dose)	Outcomes
Blouin et al. (1988)	Desipramine vs. fenfluramine in 15-week double-blind, placebo-controlled crossover design	22	Desipramine and fenfluramine	Both desipramine and fenfluramine associated with decreased binge eating and vomiting frequency
Fichter et al. (1991)	Fluoxetine vs. placebo in 4-week double-blind trial (patients simultaneously in psychotherapy)	40	Fluoxetine (60 mg/day)	Fluoxetine associated with significant weight loss. No significant improvement in eating attitudes or behavior beyond intensive inpatient psychotherapy
Agras et al. (1992)	Desipramine vs. CBT vs. combined for 16–24 weeks	71	Desipramine	At 16 weeks, CBT and combined > desipramine for binge eating and purging. At 32 weeks combined > desipramine
Fluoxetine Bulimia Nervosa Collaborative Study Group (1992)	Fluoxetine hydrochloride vs. placebo for 8 weeks in double-blind trial	387	Fluoxetine hydrochloride (20 and 60 mg/day)	Fluoxetine 60 mg/day > placebo in decreasing weekly binge eating and vomiting, carbohydrate craving, pathological eating attitudes and behaviors. Fluoxetine 20 mg/day effect between that of 60 mg/day and placebo
Goldstein et al. (1995)	Fluoxetine vs. placebo in 16-week double-blind trial	398	Fluoxetine (60 mg/day)	Fluoxetine > placebo for reduction in binge eating and vomiting
Kanerva et al. (1995)	Fluoxetine vs. placebo in 8-week double-blind trial	46	Fluoxetine (60 mg/day)	Fluoxetine > placebo for eating-related, depressive, and anxiety symptoms, as well as weight loss

Table 1 (continued)

Authors	Study design duration	Sample size	Medication (daily dose)	Outcomes
Goldbloom et al. (1997)	Fluoxetine vs. CBT vs. combined in 16-week trial	76	Fluoxetine (60 mg/day)	All three conditions associated with reduction in binge eating, vomiting, and dietary restraint. CBT and combined > fluoxetine. Combined offered no statistically significant advantaged to CBT alone
Beumont et al. (1997)	Fluoxetine vs. nutritional counselling vs. combined for 8 weeks	67	Fluoxetine (60 mg/day)	Fluoxetine > other conditions on Eating Disorder Examination subscales. Some recurrence of symptoms following cessation of fluoxetine
Walsh et al. (2000)	Fluoxetine vs. placebo in non-responders to, or those who had relapsed following, CBT or IPT	22	Fluoxetine (60 mg/day)	Fluoxetine > placebo in reducing binge eating and purge frequency
Mitchell et al. (2002)	Fluoxetine vs. interpersonal psychotherapy (IPT) in CBT non-responders for 15 weeks	62	Fluoxetine (60 mg/day)	Abstinence from eating disorder behaviors did not differ between fluoxetine and IPT conditions in CBT non-responders
Romano et al. (2002)	Fluoxetine vs. placebo in a 52-week single-blind trial of responders to fluoxetine	150	Fluoxetine (60 mg/day)	In those who initially responded to fluoxetine, fluoxetine > placebo for time to relapse. Fluoxetine > placebo for reduction of binge eating and vomiting
Jacobi et al. (2002)	Fluoxetine vs. CBT vs. combined in 16-week trial	53	Fluoxetine (60 mg/day)	All three conditions associated with reduction in binge eating and vomiting, body dissatisfaction, and restrained eating Conditions were not significantly different in effectiveness

(continued)

Table 1 (continued)

Authors	Study design duration	Sample size	Medication (daily dose)	Outcomes
Schmidt et al. (2004)	Fluvoxamine 8-week vs. fluvoxamine 52-week vs. placebo double-blind trial	267	Fluvoxamine (50–300 mg/day)	Fluvoxamine = placebo
Sundblad et al. (2005)	Flutamide vs. citalopram vs. flutamide +citalopram vs. placebo in 3-month double-blind trial	46	Flutamide (250–500 mg/day) Citalopram (20–40 mg/day)	Flutamide and flutamide + citalopram demonstrated a reduction in binge eating. Citalopram only and placebo groups did not demonstrate reduction in binge eating
Leombruni et al. (2006)	Fluoxetine vs. citalopram	37	Fluoxetine (20–60 mg/day) Citalopram (20–40 mg/day)	Both fluoxetine and citalopram were associated with improvements in eating psychopathology

CBT Cognitive behavioral therapy, *IPT* Interpersonal therapy

frequency of binge-purge compared to 3.3% (n = 1) of the control group. Topiramate also produced a significantly greater decrease in body weight relative to placebo, and significantly improved health-related quality of life. Topiramate is also effective in reducing binging and purging in BN patients with comorbid affective and anxiety disorders, and in those being concurrently treated with antipsychotics, antidepressants, and mood stabilizers (Barbee 2003; Bruno et al. 2009).

In a prospective flexible-dose study, 12 BN participants were treated with open-label zonisamide over a 12-week period (Guerdjikova et al. 2013). It was found that zonisamide use was associated with significant decreases in binge-purge episodes, binge-purge days, global illness severity, depressive symptoms, and obsessive-compulsive features of BN. Two participants achieved complete remission from BN prior to the last 4 weeks of the study. Finally, in several case studies, lamotrigine and valproate were associated with a reduction in ED symptoms and in-patients with comorbid affect or impulse dysregulation (McElroy et al. 2019; Table 2).

Stimulants

Similarities between BN and attention deficit hyperactivity disorder (ADHD), including executive dysfunction, have warranted growing interest in the use of stimulants for the management of BN (Keshen et al. 2022). To date, the only RCT

Table 2 Studies using antiepileptics to treat bulimia nervosa

Authors	Study design duration	Sample size	Medication (daily dose)	Outcomes
Barbee (2003)	Case reports of individuals with BN and comorbid mood and/or anxiety disorders	5	Topiramate (25–400 mg)	Topiramate associated with a marked reduction or complete cessation of binging and purging behaviors. This was often sustained for a period of many months, except in one individual who showed a temporary response
Hoopes et al. (2003)	Randomized, double-blind placebo-controlled trial measuring the efficacy and safety of topiramate in BN	69	Topiramate (25–400 mg)	Topiramate associated with a significant improvement in binging and purging symptoms
Nickel et al. (2005)	Randomized, double-blind placebo-controlled trial testing the influence of topiramate on behavior and body weight among patients with BN	60	Topiramate (25–250 mg)	Topiramate associated with a greater difference of change in decreasing binging/purging relative to the placebo Topiramate also resulted in a reduction in body weight that was significantly greater than the placebo
Bruno et al. (2009)	Case report of an individual with BPD, obsessive-compulsive symptoms, and BN treated with aripiprazole and topiramate	1	Topiramate (250 mg); aripiprazole (5 mg)	Co-administration of aripiprazole plus topiramate associated with a reduction in BPD symptoms, obsessive behavior, and frequency of binge episodes. Patient socio-relational functioning was also improved
Guerdjikova et al. (2013)	Open-label, pilot, prospective study investigating the potential effectiveness of zonisamide in BN	12	Zonisamide (100–600 mg)	Zonisamide associated with a significant reduction in binge-purge episodes, obsessive-compulsive behavior, global illness severity, and depressive symptoms

BN Bulimia nervosa, *BPD* Borderline personality disorder

using a stimulant for BN included four patients randomized to phentermine/topiramate extended release (Phen/Top ER; 3.75 mg/23 mg–15 mg/92 mg) or placebo over a 12-week period (Safer et al. 2020). Phen/Top ER was found to significantly reduce objective binge eating days, significantly increase abstinence rates, and reduce weight. There were no serious adverse events reported, and differences in heart rate and blood pressure between the Phen/Top ER and placebo groups were minimal. Considering the sample size of patients with BN was only four, the safety of Phen/Top ER for the treatment of BN still needs to be assessed.

Lisdexamfetamine dimesylate (LDX) has been approved for the treatment of ADHD in adults and children and for BED in adults. A Health Canada approved open-label feasibility study examining LDX (50–70 mg/day) as a treatment for adults with BN concluded that, over an 8-week period, there were reductions in objective binge episodes and compensatory behaviors (N = 23; Keshen et al. 2021). There was a clinically significant mean increase in heart rate observed and a decrease in BMI (which could be problematic if BN patients lose weight due to increased restriction from appetite suppression). These results indicate that an RCT using LDX for patients with BN is feasible, but that clinicians should not prescribe the drug until efficacy and safety are tested on a larger sample size over a longer study period.

Another study involved a one-time administration of either methylamphetamine (MA; 15 mg/75 kg body weight) or placebo intravenously, under double-blinded conditions (N = 8; Ong et al. 1983). Following administration of MA or placebo, patients were left alone with a large amount of food. The frequency of bulimic symptoms was significantly lower for those in the MA group compared to the placebo group.

Several case reports have described the successful use of stimulants in treating individuals with BN, including methylphenidate (Schweickert et al. 1997; Sokol et al. 1999; Guerdjikova and McElroy 2013), dextroamphetamine (Dukarm 2005), amphetamine/dextroamphetamine extended release or dextroamphetamine (Keshen and Ivanova 2013), and LDX or amphetamine/dextroamphetamine ER (Keshen and Helson 2017). Although there are no approved stimulants to reduce BN symptoms, these results support the need to explore further. Future controlled studies are required to better evaluate the efficacy and safety of stimulants for the treatment of BN (Keshen et al. 2022; Table 3).

Other Medications

Hormonal

Oxytocin and anti-androgens have been studied as potential hormonal treatments for BN. Two randomized, cross-over design experiments analyzed the effects of oxytocin on women with BN. In the first study, 34 BN patients, 35 AN patients, and 33 healthy controls received 40 international units (IU) of intranasal oxytocin or

Table 3 Studies using stimulants to treat bulimia nervosa

Authors	Study design duration	Sample size	Medication (daily dose)	Outcomes
Ong et al. (1983)	Administration of MA vs. placebo	8	MA (15 mg/75 kg body weight)	MA > placebo in immediate binge eating/ compensation
Schweickert et al. (1997)	Case report of an individual with comorbid BN and ADHD	1	MPH (15 mg)	MPH associated with cessation of binge eating episodes
Sokol et al. (1999)	Case reports of individuals with BN and cluster B traits	2	MPH (10–15 mg)	MPH associated with reduction in episodes of binge eating/ compensation
Dukarm (2005)	Case reports of patients with comorbid BN and ADHD	6	Dextroamphet (15 mg–30 mg)	Dextroamphet associated with cessation of binge eating/compensation
Guerdjikova and McElroy (2013)	Case report of an individual with comorbid BN, bipolar I disorder, and ADHD	1	MPH (72 mg)	MPH associated with complete remission of BN symptoms and improvement in ADHD symptoms
Keshen and Ivanova (2013)	Case reports of individuals with comorbid BN and ADHD	5	Amphet/ dextroamphet XR (20–40 mg) or Dextroamphet (20 mg)	Amphet/dextroamphet XR and Dextroamphet associated with decrease in episodes of binge eating and purging
Keshen and Helson (2017)	Case reports of individuals with BN (but not ADHD)	6	LDX (50–70 mg) or Amphet/ dextroamphet XR (40 mg)	LDX and Amphet/ Dextroamphet XR were associated with reduction in episodes of binge eating/compensation
Safer et al. (2020)	Placebo-controlled crossover trial of Phen/Top ER 12 weeks	4	Phen/Top ER (15 mg/92 mg)	Phen/Top > placebo for reducing objective binge eating days, binge abstinence rates, and weight
Keshen et al. (2021)	Open-label feasibility study 8 weeks	23	LDX (50–70 mg)	LDX was associated with reductions in objective binge eating episodes and compensatory behaviors. Safety and tolerability were generally acceptable. There was a mean increase in heart rate and decrease in BMI

LDX Lisdexamfetamine, *MPH* Methylphenidate, *Phen* Phentermine, *Top ER* Topiramate extended release, *Amphet/Dextroamphet XR* Amphetamine/dextroamphetamine extended release, *MA* Methamphetamine, *Dextroamphet* Dextroamphetamine

placebo, followed by an emotion recognition task (Kim et al. 2015). There was no significant change in appetite among healthy controls, while those with BN demonstrated a decrease in calorie consumption over 24 h. The second study compared 25 patients with BN or BED and 27 healthy controls who received 64 IU of intranasal oxytocin or placebo (Leslie et al. 2019). Oxytocin had no significant effect on eating behavior. A systematic review and meta-analysis of 12 controlled trials on the use of intranasal oxytocin to decrease food intake concluded that whether oxytocin is a viable treatment option for patients with eating disorders is yet to be determined (Chen et al. 2021).

Increased androgen levels in women may promote bulimic behaviors (Cotrufo et al. 2000; McCluskey et al. 1991; Naessén et al. 2007; Sundblad et al. 1994). Two RCTs have evaluated the use of anti-androgens in treating women with BN. In the first study, 46 BN patients received flutamide (an androgen antagonist), citalopram, flutamide plus citalopram, or placebo for 3 months (Sundblad et al. 2005). Final doses were 500 mg/day of flutamide and 40 mg/day of citalopram. Only the flutamide groups demonstrated a statistically significant reduction in binge eating from baseline. There was no significant decrease in vomiting in any group. In the second study, 93 BN patients received the androgen antagonist spironolactone or placebo (von Wietersheim et al. 2008). Spironolactone demonstrated no therapeutic effect. An ongoing RCT in Sweden is evaluating the use of the anti-androgenic oral contraceptive drospirenone/ethinyl estradiol in women with BN or EDNOS of bulimic type (EudraCT number 2011-006099-38).

Other Medications with Mixed/Negative Findings

Four small RCTs found mostly negative results for treating BN with opioid antagonists (e.g., naltrexone; McElroy et al. 2019); however, one open-label study determined that high dose naltrexone (200–300 mg/day) led to significant reductions in binge/purge symptoms relative to standard dose (50–100 mg/day; Jonas and Gold 1988). One RCT has examined the use of a prokinetic agent to treat BN. For 6 weeks, 39 women with BN and 22 healthy controls received erythromycin (up to 500 mg three times daily) or placebo (Devlin et al. 2012). Erythromycin did not significantly decrease binge eating or vomiting. The use of lithium to treat BN was studied in one 8-week RCT with 91 patients (Hsu et al. 1991). In comparison to placebo, lithium had no significant impact on decreasing binge eating. Conversely, case reports from open trials have demonstrated the successful reduction of binge/purge episodes in BN patients (Hsu 1984, 1987). Case reports on the use of second-generation antipsychotics, specifically clozapine and olanzapine, have noted their potential to induce binge eating or worsen bulimic behaviors (Brewerton and Shannon 1992; Gebhardt et al. 2007; Theisen et al. 2003); however, the use of aripiprazole to successfully treat BN has been reported in case series (Takaki and Okabe 2015; Trunko et al. 2011). Finally, in a case series examining baclofen 60 mg/day, two participants experienced a reduction in binge eating (N = 3) (Table 4).

Table 4 Studies using other medications to treat bulimia nervosa

Authors	Study design duration	Sample size	Medication (daily dose)	Outcomes
Hsu (1984)	Case reports of lithium following or concurrent with CBT Up to 16 months	14	Lithium (450–2350 mg)	Lithium associated with reduction in bulimia symptoms for 12 of 14 patients
Hsu et al. (1991)	Double-blind, randomized controlled trial of lithium vs. placebo 8 weeks	91	Lithium (600–1200 mg)	Lithium = placebo for reduction in bulimia symptoms
Brewerton and Shannon (1992)	Case report of 29-year-old female with BN and schizophrenia	1	Clozapine (up to 350 mg)	Patient was abstinent from binge eating/ purging for several months after beginning daily thiothixene (10 mg) and fluoxetine (80 mg). Six weeks after clozapine was added, binge-purge episodes returned
Jonas and Gold (1988)	Open-label trial of standard vs. high dose of opioid antagonist 6 weeks	16	Naltrexone: low dose (50–100 mg), high dose (200–300 mg)	High dose naltrexone associated with significant reduction in binge eating and purging
Sundblad et al. (2005)	Double-blind, randomized controlled trial of androgen antagonist vs. SSRI vs. androgen antagonist plus SSRI vs. placebo 3 months	44	Final doses: flutamide (500 mg), citalopram (40 mg)	Flutamide (with or without citalopram) associated with significant reduction in binge eating. Treatment groups = placebo for reduction in vomiting
Broft et al. (2007)	Open-label trial of a GABA-B agonist 10 weeks	3	Baclofen (60 mg)	Baclofen associated with reduction of binge eating frequency
von Wietersheim et al. (2008)	Double-blind, randomized controlled trial of androgen antagonist vs. placebo 8 weeks	93	Final dose: spironolactone (150 mg)	Spironolactone not associated with a reduction in binge eating or bulimic behavior
Trunko et al. (2011)	Case reports of aripiprazole	3	Aripiprazole (7.5–10 mg)	Aripiprazole associated with reduction of bulimia symptoms, anxiety, and depression
	Case reports of aripiprazole in	5	Aripiprazole (3–12 mg)	Aripiprazole associated with reduction of binge

(continued)

Table 4 (continued)

Authors	Study design duration	Sample size	Medication (daily dose)	Outcomes
Takaki and Okabe (2015)	patients resistant to antidepressants 8–26 months			eating and purging episodes, anxiety, and depression
Kim et al. (2015)	Double-blind, placebo-controlled, crossover trial of oxytocin 24 h	67	Intranasal oxytocin (40 IU single dose)	Oxytocin associated with a decrease in calorie consumption over 24 h in BN patients; healthy controls and BN patients showed a small increase in emotion recognition sensitivity
Leslie et al. (2019)	Double-blind, placebo-controlled, crossover trial of oxytocin 24 h	52	Intranasal (64 IU single dose)	Oxytocin not associated with a reduction in subjective hunger, immediate consumption of food, 24-h calorie consumption, or binge eating incidence
Chen et al. (2021)	Systematic review and meta-analysis of 12 controlled trials of oxytocin	423	Intranasal oxytocin (single dose)	Oxytocin not associated with a reduction in food intake in psychiatric patients. Oxytocin = placebo for reduction of food craving and hunger
Devlin et al. (2012)	Double-blind, randomized controlled trial of prokinetic agent vs. placebo 6 weeks	29	Erythromycin (up to 500 mg, TID)	Erythromycin not associated with reduction in binge eating or vomiting

Pharmacology Youth with BN

There is a paucity of literature examining the use of medications to treat EDs in youth, with most published studies investigating antipsychotics in adolescents with anorexia nervosa (Couturier et al. 2019; Gorrell and Le Grange 2019). The current evidence for medication use in children and adolescents with BN is insufficient to inform clinical treatment guidelines beyond the statement that medications should not be the only treatment offered (Gorrell and Le Grange 2019). There is a need for randomized controlled trials, yet the completion of these types of studies in youth remains challenging due to issues with recruitment and retention (Couturier et al. 2019).

Although there is a dearth of pharmacotherapy trials in youth with BN, recent studies indicate that use of psychotropic medications in pediatric ED clinical settings is common (Couturier et al. 2019; Garner et al. 2016). In a study of over 600 adolescents with EDs, 20% of participants were already using psychotropic medications at intake, and 1 year later this percentage had almost tripled (Monge et al. 2015). In a different study of youth attending eating disorder programs in school settings, Mizusaki et al. (2018) found almost 50% were taking psychotropic medications upon presentation, with increased likelihood associated with longer histories of ED symptoms and self-harm behaviors.

In addition to these observational studies (Monge et al. 2015; Mizusaki et al. 2018), there are several case series examining the use of medication in youth with BN. Kotler et al. (2003) conducted an 8-week trial of fluoxetine in 12–18-year-olds with BN (N = 10). A dose of up to 60 mg combined with supportive therapy showed improvement in seventy percent of patients with no adverse side effects. Encouragingly, average weekly binge episodes were reduced from 4.1 to 0 and purge episodes from 6.4 to 0.4. Limitations of the study include the small sample size, open-label design, and the lack of long-term follow-up (Kotler et al. 2003).

In a case study by Tor and Lee (2008), fluoxetine may have induced manic symptoms in a teenage girl with BN. Fluoxetine was discontinued, and valproate 200 mg was initiated to effectively treat both her mood instability and binge/purge symptoms. Dukarm (2005) proposed a possible role for stimulant medication in youth with comorbid BN and ADHD, after two adolescents reported rapid and complete cessation of binge/purge episodes with initiation of dextroamphetamine 5–10 mg three times daily.

Psychotherapy and Pharmacology Combination in BN

The two psychotherapies with demonstrated efficacy in the treatment of BN are CBT (Linardon et al. 2017) and interpersonal therapy (IPT; Fairburn et al. 2009). More recently, dialectical behavior therapy (DBT) has been investigated with some promising results (Hill et al. 2011). While psychotherapy is efficacious for some, only about 30–40% of treatment completers with BN achieve symptom abstinence (Linardon and Wade 2018).

In an attempt to improve outcomes, many clinicians prescribe medications in combination with psychotherapy for BN (Cooper and Kelland 2015). Despite the high numbers of people who are prescribed a combination of medication and psychotherapy, the evidence is lagging. Reas and Grilo (2021) conducted a comprehensive review of RCTs that investigated the use of combined treatment for EDs. For BN specifically, they found 12 RCTS that tested the combination of psychotherapy with 1) appetite suppressants, 2) tricyclic antidepressants, and 3) SSRI antidepressants. There was no benefit to adding an appetite suppressant (D-fenfluramine) to CBT treatment for 43 women with BN (Fahy et al. 1993). Similarly, three separate RCTs examined the combination of tricyclic antidepressants (imipramine or desipramine) with either CBT individual or CBT group therapy and found no additive

effects. For 171 patients with BN, all three active treatments were better than placebo; however, adding imipramine to group therapy offered no additional benefit (Mitchell et al. 1990). For 71 patients with BN, the combination of CBT (individual) and desipramine was only superior to desipramine alone (Agras et al. 1992). For 21 patients with BN, the combination of CBT and desipramine was not superior to CBT alone (Leitenberg et al. 1994).

Eight RCTs examined the combination of SSRI antidepressants with psychotherapy for BN. There was no benefit to adding fluoxetine to an in-patient behavioral psychotherapy program for 40 patients (Fichter et al. 1991). In an RCT with 76 patients, CBT and fluoxetine were superior to fluoxetine alone, but it did not differ from CBT alone (Goldbloom et al. 1997). For 67 patients with BN treated with either nutritional counselling and placebo, or nutrition and fluoxetine, no significant differences were found between the two groups (Beumont et al. 1997). Jacobi et al. (2002) examined the effectiveness of fluoxetine alone, CBT alone, and their combination. Adding fluoxetine did not produce supplementary benefit relative to CBT delivered alone. Walsh et al. (1997) compared two modalities of psychotherapy (psychodynamically oriented therapy and CBT), and added fluoxetine to both conditions if desipramine did not offer effects. Results showed that combining CBT (but not psychodynamically oriented therapy) with antidepressant medication was superior to medication alone.

Two of the RCTs examined the use of guided self-help in combination with medication. For 91 women with BN, researchers tested fluoxetine alone, self-help CBT and fluoxetine, and self-help CBT and placebo. Binge/purge abstinence rates did not significantly differ among the active treatment conditions; however, the self-help CBT and fluoxetine condition had greatest reductions in vomiting episodes (Mitchell et al. 2001). Walsh et al. (2004) tested the effects of guided self-help and fluoxetine in 91 women with BN. No significant differences were found across treatment conditions.

In the largest trial (293 patients with BN), Mitchell et al. (2011) compared standard CBT with a stepped-care condition (self-help first, followed by standard CBT in non-responders). Fluoxetine was added to both groups for non-responders (by session 6). The standard CBT and the stepped-care conditions did not differ at post-treatment, but the stepped-care condition was superior at 1-year follow-up. The stepped-care approach also improved outcomes at the end of treatment for those who had fluoxetine added to their treatment.

Conclusions

Many trials have examined pharmacotherapies for BN, but fluoxetine remains the only approved medication treatment. Although meta-analyses suggest that antidepressants other than fluoxetine have moderate efficacy for treating BN (Svaldi et al. 2019), many of these medications are no longer widely used in clinical practice (e.g., TCAs and MAOIs). Of the non-antidepressant medications studied for BN, topiramate could be considered the only practical alternative to fluoxetine as there

have been two small RCTs supporting its efficacy (Hoopes et al. 2003; Nickel et al. 2005). Topiramate can be prescribed as a second line option, or first line option, especially in patients with affective instability (e.g., borderline personality disorder and bipolar disorder). Of the medications in an experimental phase (see McElroy et al. 2019 for a description of medications in clinical trial phases), stimulants offer an interesting route for further exploration. In their review paper, Keshen et al. (2022) present a rationale for further stimulant-based research based on neurobiology, the relationship between ADHD and BN, and the preliminary evidence from a recent feasibility study (Keshen et al. 2021). The authors also summarize the potential risks of treating BN with stimulants, and based on those risks, do not *currently* recommend stimulants as a treatment for BN, but rather propose specific avenues for future research.

Another area that requires further research is pharmacotherapy in youth with BN. Initiation of effective and safe treatments earlier in the course of illness may prevent disease progression before the symptoms become more compulsive and difficult to treat. Finally, future research should explore how medications can augment psychotherapy, though evidence to date suggests that medications do not provide an additive effect.

Mini-Dictionary of Terms

Androgens. A class of steroid hormones, including testosterone, primarily involved in male reproductive development. While also produced in females, to a lesser extent, and needed for estrogen production, increased levels in females can cause a range of symptoms from excessive hair growth to virilism.

MAOIs. The first class of antidepressant developed. MAOIs prevent the enzyme monoamine oxidase from clearing the neurotransmitters serotonin, norepinephrine, and dopamine from the brain. Less frequently prescribed than SSRIs due to their potential side effects and interactions with other substances.

Open-label trial. An "unblinded" study in which researchers and participants are made aware of which treatment is being administered.

Oxytocin. A peptide hormone produced by the hypothalamus. Synthetic oxytocin is commonly used to induce labor by stimulating uterine contractions.

Prokinetic agent. A class of medications typically used to treat gastrointestinal symptoms, such as dyspepsia. Prokinetic agents work by increasing gastrointestinal motility and increasing the strength of the lower esophageal sphincter.

SSRIs. The most commonly prescribed type of antidepressant. SSRIs prevent serotonin (a neurotransmitter) from being reabsorbed into neurons, which increases serotonin levels in the brain and, in turn, stabilizes mood and increases a sense of well-being.

TCAs. A type of antidepressant that prevents the neurotransmitters serotonin and norepinephrine from being reabsorbed into neurons to increase their levels in the brain.

Key Facts of Pharmacology Options for Bulimia Nervosa

- Fluoxetine can reduce binge/purge frequency and cognitive symptoms of BN and remains the only approved medication to treat the disorder.
- Meta-analyses suggest that other antidepressants may also be effective for treating BN, but many of these medications are no longer being widely used (e.g., TCAs and MAOIs).
- Topiramate can decrease binge/purge frequency and may be most useful in those with comorbid mood symptoms.
- There are other medications (e.g., stimulants) that have preliminary support for BN, but these options are still in experimental phases.
- There is minimal support for using medications to treat BN in youth; however, there is some evidence for using fluoxetine.
- There is minimal evidence that adding medication to psychotherapy enhances the efficacy of talk therapy.

Summary Points

- Psychotherapy is effective for BN, but approximately 40% of individuals remain symptomatic after treatment.
- Therefore, pharmacotherapies have been studied as stand-alone treatments, and adjuncts for psychotherapy, with the goal of improving outcomes for BN.
- Despite many clinical trials aimed at developing medications for BN, fluoxetine remains the only option with regulatory approval.
- Several randomized controlled trials suggest that a dose of 60 mg of fluoxetine can reduce frequency of vomiting, binge eating, and purging, as well as improve eating attitudes and comorbid symptoms of depression relative to a dose of 20 mg and/or placebo.
- While there are fewer RCTs with antidepressants other than fluoxetine, a recent meta-analysis found SSRIs, TCAs, and MAOIs have moderate efficacy for reducing binge eating and purging episodes.
- Of the antiepileptics, topiramate is the most studied as a treatment for BN with two RCTs supporting its efficacy.
- There is emerging evidence supporting the use of stimulants and other experimental medications for BN, but the research is too preliminary to justify recommending these treatments.
- There are observational studies and several case series examining the use of fluoxetine in youth with BN (including an open-label clinical trial).
- Adding pharmacotherapy to psychotherapy does not appear to enhance the effects of psychotherapy alone.

Contents

Abstract

In this chapter, we provide an overview of the link between embodiment disturbances and bulimia nervosa. According to the cognitive behavioral perspective, the undue influence of body weight and shape concerns can lead to abnormal eating practices, such as binge eating, frequent body checks, and subsequent compensatory behaviors. In the phenomenological perspective, the classic symptoms of bulimia nervosa, including the overvaluation of body shapes and weight for self-esteem, are epiphenomena of a deeper core nucleus represented by a disorder of the embodiment, which consists in an alteration of the way that people experience their own body and shape their personal identity. According to the optical-cenesthetic hypothesis, the embodiment disorder derives from a disproportion between the optical and the cenesthetic perception of one's body, as a

consequence of the interoceptive deficits that characterize patients with bulimia nervosa. As an effect of the incapacity to experience one's body from within, patients with bulimia nervosa adopt a maladaptive coping mechanism focused on external means of self-definition, and the body becomes just an object that is looked at by others. The implications of embodiment disturbances regard not just eating behaviors but also many other domains of life in patients with bulimia nervosa, including the evaluation of time or space dimensions and sexuality. Beyond bulimia nervosa, embodiment disturbances were shown to influence body image concerns and sexuality in other clinical samples, as well as in the general population.

Cognitive behavioral · Phenomenology · Sexuality · Lived corporeality · Cenesthesia · Optical cenesthetic · Interoception · Exteroception · Attachment · Body image · Bulimia nervosa · Embodiment

Introduction

Bulimia nervosa is defined, according to DSM-5, as a recurrent pattern of binge-eating and subsequent compensatory behaviors. Bulimia nervosa is also described as a disorder with a specific and persistent influence of body weight and shape on the self-evaluation of the individual (American Psychiatric Association 2013). As for anorexia nervosa, in bulimia nervosa, the adoption of compensatory behaviors is secondary to binge-eating episodes, as a feeling of guilt and ruin pervades the individual that has a subjective feedback of inadequacy after interrupting the rigid dietary restrictions pursued. Furthermore, both disorders are characterized by a persistent and undue influence of body weight or shape on the self-evaluation of the individual, which multiple sources highlighted as both the initiating and maintaining factor across eating disorders irrespective of the specific diagnosis (Fairburn et al. 2008). Other similarities are shared between the two disorders, namely, the higher prevalence among females and a common onset during puberty (with rare to null novel presentations after reaching adulthood, American Psychiatric Association 2013). In support of a relevant overlap between these conditions, which may rather represent different phases of the same disorder, research has highlighted a high rate of diagnostic crossover in longitudinal studies (Castellini et al. 2011). In other words, DSM-5 diagnoses for anorexia and bulimia nervosa tend to be unstable and change across time (American Psychiatric Association 2013). Clinically, menstrual irregularities or amenorrhea is commonly found among individuals with a diagnosis of eating disorder, and the causal relationship between hormonal alterations and symptomatic severity is difficult identification (Castellini et al. 2019; Berner et al. 2019). In addition to binge-eating episodes, tentative dietary restrictions, and compensatory behaviors, an additional symptom commonly associated with bulimia nervosa is represented by emotional eating. Emotional eating is

described as the tendency to seek food in response to unpleasant feelings, as a modulation of anxiety, or as a reaction to placate feelings of emptiness and boredom (Stark and Lindeman 2001).

In both disorders, binge-eating episodes are subjectively interpreted not as neutral events in the life of the individual but rather as meaningful indicators of personal inadequacy and incompetence, as the main goal of most individuals suffering from an eating disorder is successfully adhering to dietary restrictions. Even in restrictive subtypes of anorexia nervosa, patients often report a subjective experience of loss of control secondary to food intake (Sassaroli et al. 2008). Dietary restriction itself, while the most recognized symptom of eating disorder, is not considered its core psychopathological feature. On the other hand, it is conceptually theorized to be an epiphenomenon of the underlying cognitive bias found across diagnostic labels, namely, the before-mentioned overreliance on body shape and weight for the appraisal of self-worth (Fairburn et al. 2008). In fact, empirical studies often fail to detect significant differences in the psychopathology of individuals with anorexia and bulimia nervosa, while current nutritional status and degree of adherence to dietary restrictions represent their main difference (Alvarenga et al. 2014). Indeed, nutritional status is a useful clinical observation, as medical and psychotherapy guidelines derive the urgency of their interventions based on both body mass index and overall clinical status of patients (Fairburn et al. 2008).

It should be noted that several theories attempted to elucidate the mechanisms of initiating coping mechanisms oriented to the control of body shape and weight. Primarily, they rely on findings of decreased visceral interoceptive capabilities across eating disorders (Klabunde et al. 2017), as well as reduced haptic response, negative feedbacks to social physical contact, and visual perception disturbances in patients (Engel and Keizer 2017; Engel et al. 2021). For these reasons, a specific disturbance in lived corporeality has been proposed in order to explain the over-evaluation of body weight and shape, as well as the decreased homeostatic response from hunger and physical fatigue.

The Lived Body, The Embodied Being

Embodiment has been broadly defined as the subjective preconscious experience of one's own body (Stanghellini et al. 2012). This definition has its philosophical roots in the work of Jean-Paul Sartre, who wrote about "lived corporeality," distinguishing the *lived* body (i.e., the way people experience their bodies in the first person, which is mainly based on cenesthesia, or common individual sensorium) from the *physical* body (i.e., what is objectively noticeable about one person's body, both aesthetically and anatomically, which is based on sight and measure). It has been hypothesized that people with bulimia nervosa, as well as other eating disorders, experience their own body first as an object looked by another person, rather than cenesthetically or from a first-person perspective. In particular, the main features of this disorder seem to be alienation from one person's own body and emotions, feelings of shame and aversion to it, and a disproportionate worry for the way one appears to the others

(Stanghellini et al. 2015). Phenomenological research has recently highlighted the importance of the gaze of the other in determining the symptoms of eating disorders. Indeed, while normally the constitution of one's own body (and consequently of one's own self and identity) depends on the dialectic integration between the *lived* body and the *physical* body, people with bulimia nervosa have difficulties in experiencing their own body from within or from the cenesthetic; for this reason, they tend to understand it from the perspective of another person (the so-called lived body for others, Mancini and Esposito 2021). When the dialectic is unbalanced toward the pole of the lived body for others, experienced from without, the symptom occurs (Mancini and Esposito 2021). Embodiment shows a complex interplay between the preconscious appraisal of one's own body and the conscious experience of it. In fact, embodiment is characterized as a significant factor in influencing cognition (Edelman 2005), perception (Nathan et al. 2021; Tversky and Hard 2009; Witt et al. 2009), memory (Dijkstra et al. 2007), and affective state (Damasio 1999).

As a primary alteration in embodiment is found in individuals with a diagnosis of bulimia nervosa, all behaviors and psychopathological correlates of the disorder can be better appreciated as compensatory strategies adopted to reduce the distress relative to insecurity and distrust toward one's body.

Bulimia Nervosa as a Disorder of Embodiment

According to a line of research embedded in phenomenology, the main features of bulimia nervosa (represented by shape and weight concern) are actually the result of a deeper alteration in the lived corporeality of these patients, a disturbance in embodiment (Castellini et al. 2014). In particular, embodiment alterations may be elicited by bodily modification experiences during puberty and adolescence, as the individual has a first subjective experience of significant physical changes (Striegel-Moore et al. 2001). This first occurrence may be lived with particular distress, as secondary sexual characteristics emphasize both body weight and body shape modifications (Corcos et al. 2000). Puberty can therefore be the first lived and cognitively conscious experience of a body that changes, in which the individual does not recognize its true self. In fact, embodiment has been observed to be significantly shaped and modified by puberty in women and girls (Piran 2016). The development of distress secondary to body changes can be conceptually assessed through two main factors: the biological components and the social environmental characteristics. For what concerns these components, most of the literature focused on body image disturbances rather than embodiment disturbances. Although both concepts apply to the body, the first is the conscious representation of one's own appearance, shape, and the weight, and embodiment is the actual lived experience of it (McBride 2018). For what concerns lived corporeality in bulimia nervosa, researchers mainly converged on the subsequent features:

Visceral Interoception

Abnormal bodily phenomena have been observed to represent a significant clinical feature of bulimia nervosa; this category pertaining to body image disturbances embraces various concepts relative to negative body image, such as body dissatisfaction, avoidance, or, on the contrary, compulsive control of one's body associated with pervasive worries about specific body parts, shapes or functions, and depersonalization (Cuzzolaro et al. 2006). These symptoms seem to be related to a psychopathological core (called *body image disturbance*) that often anticipates the onset of pathological eating behavior and persists even after its remission (Eshkevari et al. 2014), being associated with a worse prognosis and a higher risk of relapse (McLean and Paxton 2019). However, while scholars have traditionally focused on problems with body experience and visual alterations (such as seeing oneself fat while being significantly underweight), more recent research pointed out that those visual alterations involve something more complex than just a sensory deficit. Firstly, in support of the notion that sensory deficits underlie alterations in body image, the degree of body dissatisfaction was found to be directly proportional to deficits in proprioception and tactile perception (Eshkevari et al. 2012; Fontana et al. 2009). Secondly, these patients have been reported to often report poor interoceptive awareness (Jenkinson et al. 2018). In addition to sensory deficit, the conscious appraisal of visceral stimuli (such as the physical sensation of heartbeat, temperature, intestinal tension, hunger, and pain) could also be elicited by feelings and emotions. By now, several studies have documented that patients with bulimia nervosa often have difficulties in discriminating visceral perceptions related to hunger and satiety with sensations determined by emotional arousal (Khalsa et al. 2022). These results could represent a rational basis to explain why these patients exhibit more often than the general population signs of emotional noncompetence, such as emotion dysregulation, alexithymia, and impulsivity. According to the optical-cenesthetic hypothesis (Stanghellini et al. 2019), these deficits in the capacity to experience one's own body from within force patients to adopt maladaptive mechanisms to define the self, in particular for what concerns the perceptual (e.g., visual, haptic) and identity boundaries (e.g., core beliefs, core values) between the self and the other (Stanghellini et al. 2019). As a consequence of the impaired cenesthesia, the gaze of the others becomes a device for self-definition, and the body becomes just an object to be looked at by the others. Living one's own body, the *lived body*, or *body as subject*, as a function of the gaze of the other, and the *lived body for others*, or *body for others*, is then appreciated as a tentative resolution for embodiment disturbances at the basis of the preconscious feelings of anguish and alienation from one's own bodily experiences (Fuchs 2022).

Neural Correlates

Bulimia nervosa has been associated with modification of basal metabolism in specific regions of the brain, such as the striatum, which pertains to the reward

system (Broft et al. 2012). These findings support the hypothesis that reward sensitivity might underlie the symptomatology of bulimia nervosa. However, other brain structures have been shown to exhibit alterations in functional connectivity for bulimia nervosa, namely, the anterior dorsal cingulate cortex and the medial prefrontal cortex (Stopyra et al. 2019). These two structures pertain to the salience and default mode brain network, respectively, which are involved in salience attribution, self-referential processing, and cognitive control. Furthermore, investigations of neural correlates of body image dissatisfaction highlighted a relevant contribution by functional and structural alterations in the insular cortex (Mohr et al. 2011), which other sources described as relevant for the processing of interoceptive stimuli (Kuehn et al. 2016), reward (Monteleone et al. 2017b), and decision-making (Naqvi and Bechara 2010). Therefore, the insula seems central to an effective integration of visceral sensations, environmental factors, and emotional awareness (Simmons et al. 2013), which establishes the insular cortex as a relevant landmark for the embodiment of the self (Stanghellini et al. 2019), and with early evidence of functional and structural alterations in bulimia nervosa. Furthermore, embodiment disturbances in bulimia nervosa also entail internal perceptions of one's own body, the sensation coming from within one's own body. Neuroimaging evidence suggests that both body image and bodily self-consciousness are impaired in patients with bulimia nervosa, with findings of decreased integration between interoceptive and exteroceptive signals (Stanghellini et al. 2019). In particular, visual afferents appear to predominate over interoceptive stimuli, which favors the adoption of an objective stance toward one's own body as a mechanism to cope with the reduced feelings from within (Riva et al. 2015). A lived corporeality based on objective, external appraisal then can ensue, as a maladaptive mechanism in order to compensate visceral and interoceptive afferent deficits. These observations seem to confirm the optical-cenesthetic model previously described. In fact, deficits in integrating the perceptual experience from within (by the insular cortex) can also inhibit the functional coalescence of interoception, exteroception, and mental layers (as processed by the same brain region, Scalabrini, Wolman, and Northoff 2021; Simmons et al. 2013; Kuehn et al. 2016; Riva et al. 2015).

Attachment Style

Attachment styles seem to be of particular interest for what concerns embodiment. In fact, the relationship between attachment and embodiment can be understood in light of an alteration in preconscious subjective experiences of one's body as the most primitive form of self-awareness, acquired during the first interactions with the primary caregiver (Stanghellini et al. 2012; Needham and Libertus 2011). Moreover, the phenomena of attachment and emotional regulation are relevant for the development of a basic form of selfhood during early childhood. Higher levels of embodiment disturbances were observed in patients with anxious or avoidant attachment, and embodiment disturbances mediated the relationship between avoidant attachment and the eating disorder psychopathology (Monteleone et al. 2017a).

According to attachment theory, avoidance is defined as the tendency to distract oneself from emotional contents, which in time results in a reduced capacity to recognize and regulate internal feelings (Fuendeling 1998). This reduced capacity to recognize and moderate feelings appears not to be specific to the affective domain. In fact, patients with bulimia nervosa are observed to be less prone to correctly identify basic bodily signals such as hunger, satiety, and fatigue. Dysfunctional attachment styles are thus associated with a greater susceptibility to exteroceptive signals about the body, rather than interoceptive, and with a higher reliance on bottom-up attentional processes (Eshkevari et al. 2014). Furthermore, worse symptomatic presentations and clinical outcomes have been observed in those individuals with insecure attachment styles (Tasca and Balfour 2014). Significant bodily changes can also precipitate bodily distress secondary to physical or sexual traumatic experiences (Meneguzzo et al. 2021). The body can be the source of constant reminders of a traumatic past, and the persistent state of alertness in traumatized individuals facilitates the misinterpretation of even the most innocuous stimulus as a potential threat (van der Kolk 2015).

Tempo-spatial Dynamics

Patients with bulimia nervosa often report subjective feelings of fatness and heaviness. In addition to feelings directly associated with body shape and weight, patients describe a less defined sensation of "largeness" or distention. Their visual and spatial capacities are often characterized by a high degree of imprecision, and their ability to correctly estimate temporal or spatial dimensions seems to be impaired (Li et al. 2015). Lower abilities to shift between tasks and conditions have also been reported. This lower degree of cognitive flexibility can be conceptualized as the result of an altered perception of time. Some studies found that while time duration might be subjectively underestimated by individuals affected by anorexia nervosa, this is not the case for patients with bulimia nervosa. For this reason, restrictive subtypes of anorexia nervosa show an increased capacity to delay reward compared to individuals with bulimia nervosa or binge-eating disorder, as the first can discount a lower subjective time span (Vicario and Felmingham 2018). This disparity between subtypes is possibly related to differences in dopaminergic neurotransmission (Fung et al. 2021). Impairment in time perception, a critical component of decision-making, represents a crucial factor for the development and maintenance of binge-eating episodes through the enhancement of impulsivity (Mitchell et al. 2018).

For what concerns the spatial domain, early observations described how body schema can affect spatial perception and the perception of objects. Physical exercise, dance, or other tasks involving neuromuscular coordination have been found to shape the subjective appraisal of one's body, both during and after conditioning. Additionally, as an individual gains strength and endurance, a higher perceived self-efficacy can ensue. The lived body can thus be thought of as a dynamic system, undergoing constant change in all its components: from its preconscious awareness to its objective functioning and its subjective correlates. In bulimia nervosa,

mindfulness-oriented activities (e.g., yoga) have been found to facilitate a positive assessment of one's own body and to provide long-sought comfort in critical body areas (such as the lower abdomen, or thighs), as focusing on breathing or posture can reduce the level of distress experienced by these patients and establish a positive cycle of reinforcement learning toward one's own body (Perey and Cook-Cottone 2020). However, while approaches based on *positive embodiment* have been described (Cook-Cottone et al. 2020), *embodiment* rooted in negative affect consistently dominates the experiential landscape of individuals with bulimia nervosa. Spatial relationships with one's own body parts produce intense fear, a subjective feeling of vulnerability, and a high degree of disgust (Clancy 2022). A sense of alienation from one's body is often reported, which, in addition to visceral or interoceptive afferent alterations, can be conceptualized as a result of repeated insecurities experienced by or from one's body. This is the example of those patients where bulimia nervosa is deeply intertwined with histories of trauma, as the fear of exposure and unsafety can dominate the lived corporeality of individuals (Madowitz et al. 2015; Vanderlinden et al. 1993).

Embodiment and the Definition of the Self

Finally, it is well recognized that a significant proportion of patients with a diagnosis of eating disorder tends to develop chronic and ego-syntonic symptoms. Individuals with a diagnosis of eating disorder often have difficulties to define themselves through ordinary life domains, even before the onset of the disorder. These difficulties can be interpreted in light of the optical-cenesthetic model, according to which patients engage in external modes of defining themselves as a response to interoceptive deficits. In other words, this external definition of one's self, through compulsive body check, control over weight or food, starvation, or the gaze of the other, can be a response to an underlying embodiment disturbance (Stanghellini et al. 2012). Patients with embodiment disturbances can then engage in maladaptive habits in order to define one's self, since customary boundaries of one's own self are less detailed (*perceptual*, such as visual/haptic stimuli about one's own body, or *identity-based*, as answering fundamental questions on core beliefs or values) (Stanghellini et al. 2019). Moreover, patients with bulimia nervosa tend to value personality aspects such as perfectionism, rigidity, and control and frequently suffer from subjective or objective feedbacks of their deficit in these values (Silgado et al. 2010; Boone et al. 2012; Steele and Wade 2008). Episodes of restriction or binge eating may be interpreted cognitively in function of these values, as positive or negative feedbacks, respectively. These premises mean that patients with bulimia nervosa often value the thoughts and behaviors associated with their illness as aligned with their core selves. Especially when ill for extended periods of time, people can become stuck in a sick role, reinforcing a sense of self that is dominated by illness ("Who am I? I am my disorder"). In this picture, efforts made to achieve and maintain harsh diet rules and caloric restriction tend to enhance the marginalization of alternative domains of life. Hence, identification with the disorder acts as a

mechanism of avoidance to escape the doom of defining one's self through other life domains (Koskina and Schmidt 2019).

One of the core negative feelings experienced by patients with bulimia nervosa is shame. Shame is commonly experienced only as a function of social relations, as the resulting emotion subsequent to moral or social expulsion (Tracy and Robins 2007). However, patients with bulimia nervosa experience a more general and intimate feeling of shame, that of "wrongly" being, in general (Clancy 2022). Furthermore, patients with bulimia nervosa tend to exhibit particularly pronounced negative cognitive biases in their internal self-talk, such as overgeneralization, with the result that any perceived "failure" is interpreted as a confirmation of low self-worth (Fairburn et al. 1993). This tendency to negativity in the conversation with oneself worsens the core low self-esteem that most patients with bulimia nervosa have, with the result of an inhibition in the exploration of different domains of life. The relative scarcity of life experience in different domains, such as a wide range of interests, reinforces a cycle of negative self-appraisal, suffering the comparison with peers or significant others. For these reasons, fatness and failure acquire a specific moral value in bulimia nervosa, as the main domain in which the patient feels control and self-efficacy (Skårderud 2007).

Moreover, embodiment can refer to two distinct processes, simultaneous and synergic, that is, the phenomenon of being a living being, *being embodied*, and being a living being in a living society, *embodying the social aspect of human nature* (Tolman et al. 2014). While the first focuses on the experiential process of being both consciously aware and unconsciously influenced by one's own body, the second entails the social and historical implications of lived corporeality. This second aspect of corporeality, that is, being alive for others, with others, as a function of others, either as an active agent or as a passive medium, can either empower or isolate individuals, with a special interest by society on normalizing ways of being, ways of feeling, and ways of thinking (Foucault 1978). Thus, social components impose direct or indirect demands on individuals, potentially marginalizing those lived bodies that do not conform to societal standards. The high distress experienced by patients with bulimia nervosa to conform and seek social assessment can then be appreciated as a mechanism to pursue reintegration into a "standard" (Eli 2018). Cultural influences are also thought to influence the interaction between embodiment and personal identity, in line with a social constructionist perspective of lived corporeality (Musolino et al. 2020; Becker 2004). The socially derived concept of "femininity" seems to be relevant for the disturbances observed in bulimia nervosa (Musolino et al. 2020). In particular, "femininity" can be deflated to a simple concept of beauty and a reference to a standardized canon, with adolescent girls actuating mimic behaviors in order to obtain competitive advantages during a period of rapid social transitions (Becker 2004). To be noted, ritualized social practices and social influences seem to shape embodiment and its disturbances, as the collective imaginary and conceptual background aligns individual perceptions and behaviors to social normative types in a cognitively driven but preconscious manner (Durkheim and Cladis 2008; Bell 2009).

In light of the importance of restructuring one's identity around the control of one's shape and weight (Ip and Jarry 2008), the IDentity and EAting disorders (IDEA) questionnaire has been proposed (Stanghellini et al. 2012) to assess alterations in embodiment and personal identity. The IDEA questionnaire can identify significant psychopathological phenomena related to bulimia nervosa, such as the need to define oneself objectively through the gaze of the other or through objective measurements (e.g., weight scale, social media), feeling extraneous from one's own body, or feeling oneself predominantly through starvation. Importantly, IDEA was able to discriminate not only between patients and controls but also capable of identifying vulnerable individuals (Stanghellini et al. 2015).

Embodiment and Sexuality

Beyond psychiatric disorders, embodiment seems to be relevantly involved in sexuality and its functioning in the general population. In fact, the link between body image and sexual well-being is increasingly investigated in scientific and psychological research; recent studies hypothesized that disturbances in body image or embodiment may play a significant role in maintaining abnormal sexual functioning among women and men (Cash 2012). Although most of the research focused on the influence of intrusive thoughts and body image disturbances on sexuality (such as concerns about body weight and shape during a sex), recent approaches elucidated how, in turn, cognition itself can be shaped by sexuality. For instance, arousal has been observed to associate with higher rates of delay discounting, as well as higher propensity to risk-taking behaviors (Wilson and Daly 2004; Skakoon-Sparling et al. 2016). An embodied mind, integrating bodily stimuli with affective or cognitive content, thus seems to mediate sexuality, and an account of a lived corporeality seems to better describe human behaviors and thoughts in comparison to previous approaches (Tolman et al. 2014). In particular, social constructs have progressively interested scholars in the field, with ongoing debates on their role in shaping sexual desire, sexual identities, and sexual relationships (Angel 2010). Novel methods allowed promising findings on the topic, and the concept of "natural," "innate," or "true self" also emerged when describing the lived experience of sexuality (Plante 2006). This more contemporary approach is characterized by a complex definition of the *experienced* and *experiencing body*, defined as the outcome of multiple concurrent demands, in other words an embodied entity. In sexuality, both feelings of disembodiment and generalized shame can be observed in patients with bulimia nervosa. While the first has been more commonly reported in association with previous traumatic experiences, with dissociative or depersonalization episodes during sexual intercourses, impulsiveness can partially explain, and the pursuit of self-harming practices partially underlie, sexual promiscuity and risk-taking behaviors in bulimia nervosa (Swirsky and Mitchell 1996; Castellini et al. 2019). Recent research has also focused on the relationship between dietary restraint and reduced sexual desire and found that embodiment alterations significantly explained their association (Cassioli et al. 2020). These alterations in lived

corporeality, specifically impairments in interception, identity focus on dysfunctional eating behaviors, and the adoption of a third-person perspective in defying oneself, can integrate in predisposing to disturbing experiences during sexuality, with feelings of loss of control, objectification, lack of pleasure, shame during the encounter, and ultimately feelings of coercion or passivity (Castellini et al. 2016; Moradi et al. 2005; Spivak-Lavi and Gewirtz-Meydan 2022).

Embodiment, Clinical Perspectives

According to clinical guidelines, at the present time, only two types of therapies seem warranted in bulimia nervosa (NICE guideline [NG69] 2017), namely, family-focused interventions (Zipfel et al. 2014), and cognitive behavioral therapy – enhanced (CBT-E, Fairburn et al. 2008). Family-focused interventions focus on disrupting the family dynamics supporting and triggering eating symptoms (Zipfel et al. 2014). On the other hand, in CBT-E therapy, the aim is to disturb abnormal behaviors by challenging distorted beliefs about body shape and weight (Fairburn et al. 2008). CBT-E has shown evidence in superiority in comparison to the former type of interventions (Zipfel et al. 2014). However, there is high variability in individual responses, long-term remission rates are currently attested below 50%, and a high relapse rate has also been observed (Calugi et al. 2017). Therefore, targeting embodiment disturbances in bulimia nervosa, as well as in other kinds of eating disorders, can be expected to deliver promising results. Indeed, since a disturbance in lived corporeality can represent a core feature in these disorders, integrating ordinary clinical practice with specific embodiment-focused psychotherapeutic treatments could be crucial to improve prognosis in this category of patients (Rossi et al. 2021). In fact, empirical studies showed that in a multidisciplinary treatment of eating disorders, built on a CBT-E foundation, the variation of embodiment disturbances correlated to response to therapy (Rossi et al. 2021). To target these disturbances effectively, an approach that incorporates cognitive, psychodynamic, and phenomenological perspective seems warranted (Castellini et al. 2022). This integration could lead to a new psychotherapeutic model of intervention, directed not only toward the behavioral, cognitive, and ideational domains of eating psychopathology but also to the emotional, experiential, perceptual, and identity-related domains, which contribute to a large extent to the maintenance of illness (Castellini et al. 2022). In pursuit of this integration, a number of prescriptions for clinical practice derive from considering embodiment disturbances as the basis of bulimia nervosa. First and foremost, the initial assessment of patients should include an evaluation of the subjective lived experience, in order to overcome the limitations given by behavior-informed diagnoses (Stanghellini 2019). All dimensions of corporeality should be assessed: the *lived body*, or the *body as subject*; the *objective body* as appraised by sight or haptic feedback, or the *body as object*; and the body as lived by the *gaze of the other*, or the *body for others* (Fuchs 2022). Therapeutic approaches should be focused on all three of these dimensions of corporeality; in particular, clinicians should inform behavioral counseling based on the dynamic

changes in corporeality in correspondence to binge-eating episodes or compensatory practice (Castellini et al. 2022). In other words, changes in these dimensions of corporeality could efficaciously function as a functional access to otherwise unapproachable internal states of emotions, feelings, or beliefs (Nowakowski et al. 2013). Deficits in interoception should be specifically targeted. Indeed, the recovery of a healthy but critical appraisal of inner bodily signals could represent the first step in the complicated process of recovering a more functional contact with one's own body (Castellini et al. 2022). Furthermore, the impact of the gaze of the other and of defying one's own identity in adherence to an eating disorder should not be underestimated (Stanghellini et al. 2012). Recovering a healthy contact with one's own embodiment can facilitate the redefinition of one's own desires and values, allowing the patients to overcome the definition of one's own self strictly according to illness (Koskina and Schmidt 2019). In this field, new therapeutic interventions might be promising (Stanghellini 2019). Trauma-focused interventions should be implemented in selected patients, taking into account the decisive role of adverse childhood experiences and insecure attachment styles in the development of embodiment disturbances (Swirsky and Mitchell 1996; Madowitz et al. 2015). In conclusion, future developments could enhance recovery rates and reduce clinical relapses, overcoming the limitations of existing treatments, by taking the experience of patients into account in a single, multidimensional model of psychopathology and treatment.

Applications to Other Areas

In this chapter, we described the role of the embodiment disorder in the phenomenology of bulimia nervosa. However, the evidence about this psychopathological dimension shows that the alteration of lived corporeity is a transdiagnostic phenomenon in eating disorders, regardless of clinical subtype (Castellini et al. 2014). Because of that, it has been hypothesized that the different types of eating disorders are, in fact, epiphenomena of a common psychopathological core, represented by an optical-cenesthetic disproportion (Stanghellini et al. 2019). The inability to "feel oneself" seems to be a peculiar characteristic of these illnesses when compared to other psychiatric disorders. The different patterns of coping mechanisms implemented in response to this deficit shape their behavioral and clinical presentation (e.g., starvation as a way to feel oneself in restrictive subtypes of anorexia nervosa or binge eating in bulimia nervosa and binge-eating disorder). This model is also consistent with the high rates of diagnostic crossover and symptom fluctuation that occurs longitudinally in patients with eating disorders (Eddy et al. 2008). Furthermore, we must emphasize that the notion of embodiment is not limited to the field of eating disorders. For instance, embodiment disorders seem to be associated with emotional eating, a phenomenon often reported not just by patients with eating disorders but also by obese subjects, as well as patients with mood or anxiety disorders (Ricca et al. 2009). Moreover, embodiment disturbances can also be observed in other mental disorders, such as schizophrenia and depression. However,

previous research and clinical experience have demonstrated that, while the embodiment disturbance reveals itself in the context of eating disorders as an optical-cenesthetic disproportion, this is not the case for other disorders. For example, the essential characteristic of the alterations in lived corporeality for patients with schizophrenia has been called "disembodiment." Patients with schizophrenia experience their body as a de-animated object, losing the overarching sense of "personally belonging" to their embodied experience (Stanghellini 2009). In other words, patients with schizophrenia lose the ability to represent themselves from a first-person perspective (Doerr-Zegers et al. 2017). On the contrary, patients undergoing depressive episodes or suffering from a depressive disorder preserve the capacity to feel their body as their own from a first-person perspective, but they tend to represent it as an object from within (as their own objectified body). This feature, which has been called "objectification" or "corporealization," would be the causative phenomenon explaining the reduction of the body's feelings of being alive (Doerr-Zegers et al. 2017).

Therefore, the characterization of embodiment becomes of fundamental importance in the assessment of most mental disorders. The presentation of embodiment disturbances between disorders can vary and may sometimes overlap in their characteristics, determining the complex pathway of symptoms and clinical presentations in each different person. Although current practice suggests using the concept of comorbidity to explain the concurrent existence of these psychopathological features, an alternative explanation could be that the specificity and boundaries between the described disorders are not lacking; rather, they depend on the level of assessment. At last, adopting a phenomenological perspective to explore the core of lived experience in these patients reminds us that, while the behavioral level is certainly useful in informing clinical practice and research, estimating clinical severity in an objective and replicable manner, it may not adequately inform individual etiology, prognosis, or therapeutic outcomes, hence the need for integrated and multidimensional models, even beyond the boundaries of disordered eating.

Mini-Dictionary of Terms

- **Attachment style**: The systematic pattern of interpersonal expectations, emotions, and behaviors that result from the internalization of previous relational experiences, with the consequent reliance on a specific strategy to regulate emotions (Fraley and Shaver 2000; Shaver and Mikulincer 2002). For further information on the importance of the functional imprinting of early attachment experiences, as well as the role of adult attachment style in eating disorders, see the other chapters in the current book and the references offered in the present chapter.
- **Body image** is a complex construct that is often used in the clinical context to evaluate the patient's perception of its own corporeality. It is described as "the mental picture one forms of one's body as a whole, including its physical

characteristics and one's attitude toward them" (APA Dictionary of Clinical Psychology 2013). Body image encompasses thoughts, feelings, evaluations, and behaviors toward one's own body, which may range between positive and negative experiences, under the influence of both internal (e.g., personality) and external (e.g., social environment) factors (Tylka and Wood-Barcalow 2015; Tiggemann 2004). There are four fundamental aspects of body image: *perceptual*, the aspect that is about the way one person sees his own body; *affective*, the aspect that concerns the degree of satisfaction or dissatisfaction one person feels about his body shape, weight, or individual body parts; *cognitive*, the aspect that is about the way one person thinks about his own body and can lead to excessive preoccupation about body shape and weight; and *behavioral*, which embraces the behaviors that one person engages in as a result of his perceived body image (e.g., starvation as a way to cope with the persistent sensation of being fat). Body image misperceptions are the result of an alteration of one (or more) of the main elements described above; they represent the core component of body image disturbance and could be present in various types of psychiatric disorders, as well as, at a subclinical level, in healthy subjects (Fuentes et al. 2013).

Key Facts

- Bulimia nervosa is a severe psychiatric disorder, characterized by a disproportionate influence of body weight and shape on the self-evaluation of the individual.
- The undue influence of body weight and shape concerns leads to abnormal eating behaviors such as binge eating and vomiting.
- The onset and course of bulimia nervosa are determined by both biological and psychosocial factors.
- Embodiment disorder is a crucial primary alteration in individuals affected by bulimia nervosa.

Treating Adolescent Bulimia Nervosa

44

An Overview

Sasha Gorrell, Leigh Brosof, Lisa Hail, and Daniel Le Grange

Contents

Abstract

In this chapter, we provide a broad overview of the treatment of bulimia nervosa among adolescents. First, we describe the disorder prevalence and diagnostic criteria, along with commonly comorbid conditions. We then detail evidence regarding the most efficacious treatments for this disorder and some treatments that show promise and warrant further investigation. Finally, we provide discussion of challenges associated with the treatment of bulimia nervosa among youth and suggest future directions in clinical practice and research.

Introduction

Bulimia nervosa (BN) is a serious psychiatric disorder that typically has a chronic course of illness (Steinhausen and Weber 2009) and multifactorial etiology (American Psychiatric Association 2013). Accounts of binge eating and purging behavior reach all the way back to Greek and Roman antiquity, and also appear in recorded practices of saints in the Middle Ages (Gordon 2015). Current conceptualizations of the disorder in this century date from 1979, when Gerald Russell first published an account of BN, in which he described patients reporting a "morbid fear of becoming fat" who overate and purged afterward (Russell 1979). Individuals with BN typically do not present as underweight relative to population norms for age, height, and gender (American Psychiatric Association 2013). And yet, eating disorder (ED) pathology and medical complications for youth with BN can be severe

(Peebles and Sieke 2019) with striking levels of suicide (Crow et al. 2014) and psychological comorbidity (Thompson-Brenner and Westen 2005).

To date, less is known about treating BN in youth compared to adults, where findings across the literature support the efficacy of outpatient psychotherapy, and in particular, evidence-based treatments such as cognitive-behavioral therapy (CBT) (Lundgren et al. 2004). For youth and adolescents with BN, the current evidence base principally supports family-based treatment (FBT) (Le Grange et al. 2015; Lock and Le Grange 2019) and CBT enhanced for EDs (CBT-E) (Dalle Grave et al. 2013; Le Grange et al. 2020). Given the severity of this disorder, and the pressing need for early identification and intervention for this patient population, this chapter is focused on BN in youth and adolescence. First, we describe the clinical syndrome and its diagnostic criteria, with associated prevalence rates. This is followed by a description of current evidence-based treatment approaches, along with newer intervention efforts that are promising and warrant further investigation to determine their relative efficacy. Finally, we highlight future research directions that may help to determine where our resources should ideally be devoted to improve treatment outcomes for this high-priority clinical population.

BN Diagnostic Criteria

According to the latest edition of the *Diagnostic and Statistical Manual for Mental Disorders* (DSM-5; American Psychiatric Association 2013), BN is characterized by (1) episodes of eating an objectively large amount of food accompanied with a loss of control (i.e., objective binge eating), (2) inappropriate compensatory behaviors, as well as (3) overvaluation of weight and shape that unduly influences self-evaluation (American Psychiatric Association 2013). Compensatory behaviors may include purging (i.e., self-induced vomiting, laxative or diuretic misuse) or non-purging behaviors (i.e., excessive exercise, or significant restriction behaviors, such as fasting and skipping meals), which are symptoms that do not occur only within the context of anorexia nervosa (AN).

According to DSM-5 criteria, both binge eating and compensatory behaviors must occur at least *once per week* for a period of 3 months (American Psychiatric Association 2013). This frequency requirement was changed from DSM-IV-TR criteria, which required both binge eating and compensatory behaviors to occur at least *twice a week* for a period of 3 months (American Psychiatric Association 2000). Diagnosis is usually determined through clinical interview and self-reported symptoms by the patient, in conjunction with parental report of their observations. Due to the shame and secrecy associated with bulimic behaviors (Bottera et al. 2020), symptoms may be underreported and prevent treatment-seeking. In addition, adolescent patients may have more difficulty endorsing cognitions associated with BN (i.e., undue influence of weight and shape) compared with other EDs that are characterized by low weight such as AN (Le Grange et al. 2004; Le Grange and Loeb 2007), which may potentially further hinder determination of a diagnosis.

Prevalence, Onset, and Demographics

Prevalence estimates for BN vary widely based on whether studies have focused on those who meet full-threshold criteria versus those who fall below diagnostic threshold but have clinically significant presentations. In adolescents, estimates for full-threshold BN fall between 1% and 1.5% (Smink et al. 2012), whereas estimates that include subthreshold presentations fall between 14% and 22% (Swanson 2011). Prevalence of BN in adolescents is twice that of AN (Swanson 2011), and diagnostic crossover is relatively common (Eddy et al. 2008). It should be noted that many of these studies are based on DSM-IV-TR, rather than DSM-5 criteria, and thus these rates may underestimate the prevalence of BN. More recent studies applying DSM-5 criteria found that lifetime prevalence of BN falls between 2.4% and 2.6% (Stice et al. 2013; Bagaric et al. 2020; Silén et al. 2020), and in adolescents specifically, point prevalence is estimated at 4.6% (Mitchison et al. 2020).

According to DSM-IV-TR criteria, the median age of onset for BN is in preadolescence: 12.4 years (interquartile range 11.1–13.5 years) (Swanson 2011). A more recent meta-analysis of 8 epidemiological studies identified peak onset of BN at 15.5 years old (Solmi et al. 2021). In the United States, lifetime prevalence rates of BN are similar among different racial and ethnic groups, although Hispanic women may be at slightly higher risk for disorder development (Nicdao et al. 2007; Levinson and Brosof 2016). Prevalence estimates by gender show a lower rate for boys (1.21%) compared to girls (2.6%) (Bagaric et al. 2020). However, transgender individuals are at higher risk for developing BN (2.9–3.2%) compared to cisgender peers, and sexual minorities have also been shown to have higher lifetime prevalence rates than their heterosexual counterparts (Nagata et al. 2020; Kamody et al. 2020).

Transdiagnostic View of BN

BN has more similarities than differences with other ED presentations (e.g., Forbush et al. 2017). For instance, binge eating and purging are symptoms that may be characteristic of other ED diagnoses, including AN binge-purge subtype, atypical AN (i.e., meeting all criteria for AN except underweight BMI), and other specified feeding or eating disorder (OSFED) (American Psychiatric Association 2013). Further, diagnostic crossover between disorders is common, particularly between subthreshold and full-threshold BN in adolescents (Le Grange et al. 2004; Le Grange and Loeb 2007).

Subthreshold presentations may include not meeting the frequency criteria (i.e., one binge eating episode and compensatory behavior per week; American Psychiatric Association 2013). Individuals with subthreshold symptoms endorse similar levels of impairment to individuals with full-threshold symptoms (Le Grange et al. 2004) and thus should be treated similarly. Another common subthreshold presentation is the presence of subjective binge eating, where individuals endorse loss of control around eating but do not eat an objectively large amount of food (American Psychiatric Association 2013). Particularly among children and

adolescents, psychological impairment stems from the experience of loss of control, rather than amount of food consumed (Tanofsky-Kraff et al. 2011). Individuals with subjective binge eating endorse a similar frequency of binge eating and purging episodes as those with objective binge eating (Le Grange et al. 2004). Given that interventions for binge eating and purging behaviors generally appear the same regardless of diagnosis (Fairburn 2008), it may therefore be clinically useful to consider and treat symptoms transdiagnostically, rather than maintaining focus on a specific diagnosis.

Comorbidity

The vast majority of cases of BN present with a co-occurring psychiatric disorder, up to 88% (Hudson et al. 2007). The most common comorbid disorders are anxiety (66.2%) and mood (49.9%) disorders (see Fig. 1 for more information about BN comorbidity). In addition, 20% of adolescents with BN also endorse misuse of substances (Calero-Elvira et al. 2009) as well as attention-deficit and hyperactivity disorder (Seitz et al. 2013). It should be noted that these rates of comorbidity are based on DSM-IV-TR diagnostic criteria and thus may underestimate true rates of overlap. In a study of adults with DSM-5 EDs, lifetime estimates of BN and comorbid psychiatric disorders were 94.4%, with major depressive disorder (76.3%) and alcohol use disorder (61.0%) recorded most frequently (Udo and Grilo 2019). It is imperative that new prevalence studies using DSM-5 criteria continue to investigate rates of comorbidity in adolescents with BN, as the presence of a co-occurring disorder is associated with longer duration of illness, poorer outcomes, and increased psychosocial impairment (Fichter et al. 2008; Bodell et al. 2011; Quadflieg and Fichter 2019; Van Alsten and Duncan 2020).

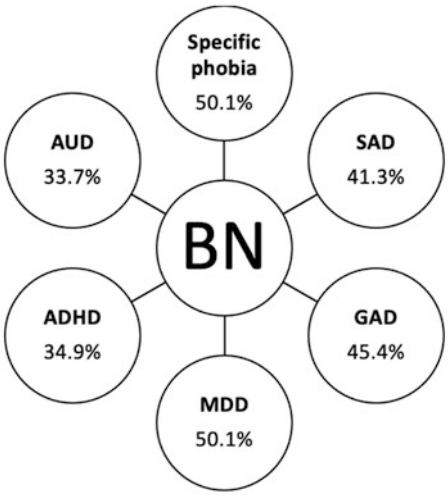

Fig. 1 Most frequently comorbid psychiatric disorders in BN: lifetime prevalence rates. BN, bulimia nervosa; AUD, alcohol use disorder; ADHD, attention deficit-hyperactivity disorder; MDD, major depressive disorder; GAD, generalized anxiety disorder; SAD, social anxiety disorder

Perhaps most concerning, adolescents with BN are at particular risk for suicide, endorsing higher rates than adults with BN or adolescents with another ED diagnosis, with over half reporting suicidal ideation (53%), and 25% reporting having a suicide plan (Swanson 2011; Crow et al. 2014). In addition, 34% report having made a suicide attempt, with 17.1% reporting multiple past attempts.

BN Treatment

Despite the severity of BN and its typical onset in adolescence, there continues to be a lack of systematic study of treatments for adolescent BN. The two main treatments are based in family-based and CBT approaches (see Table 1 for their comparison). At this time, there have only been four published randomized control trials (RCTs) for adolescent BN treatment, worldwide (Le Grange et al. 2007, 2015; Schmidt et al. 2007; Stefini et al. 2017). Most recently, an effectiveness study compared FBT and CBT-E in a transdiagnostic sample of adolescents presenting for treatment in an academic medical center (Le Grange et al. 2020).

Family-based approaches. FBT-BN (see Le Grange and Lock 2007 for treatment manual) uses the same core tenants as those for FBT for AN (see Table 2). In this behavioral treatment approach, parents are mobilized to intervene on the disordered behaviors with the adolescent enlisted to collaborate with parents in the process. In the first phase of treatment, parents are empowered to support their child in establishing a regular pattern of eating while also disrupting the pattern of binge eating and compensatory behaviors. A core intervention is externalization of the illness with the aim of promoting parental action while also reducing blame on the child. If the child is able to engage effectively in treatment, the clinician guides parents to be more collaborative with their child, more so than they might be in the context of FBT for AN. As abstinence from disordered eating and compensatory behaviors is achieved, the second phase of treatment centers on shifting developmentally appropriate control of eating back to the child. The final phase focuses on returning to normative adolescent development and addressing ways in which the ED may have disrupted typical development. An example FBT treatment formulation is presented in Fig. 2. The typical dose of treatment varies across studies, but usually concludes within 6 months from initiation of treatment with the expectation that caregivers remain empowered with their understanding of how to effectively intervene if their child exhibits symptoms of disordered eating again during their recovery journey.

Individual approaches. CBT is the most efficacious individual therapy and therefore a first-line treatment approach for adults with BN (Slade et al. 2018). Specifically, CBT-E is an individual therapy that focuses on interrupting disordered eating (e.g., restriction and binge eating) and compensatory behavior, and also targets distorted cognitions associated with body image concerns (see Fig. 3 for an example CBT-E treatment formulation). Similar to FBT, CBT-E is conceptualized with three stages. Treatment begins with engagement work between the clinician and patient, in an effort to build motivation while establishing rapport. This initial stage

Table 1 FBT-BN versus CBT-E. FBT-BN, family-based treatment for bulimia nervosa; CBT-E, cognitive behavior therapy enhanced for eating disorders; ED eating disorder

	FBT-BN	CBT-E
Structure of session	Brief individual check in with adolescent and therapist at start of session. During this time, weight is taken, and episodes of binge eating and purging are logged. Family joins and participates in remainder of the session	Agenda is set in collaboration with adolescent each session. Includes review of weight and ED symptoms, review of self-monitoring, and other relevant topics such as body image concerns. Sessions are individual with the adolescent who is encouraged to be active in making changes
Phases of treatment	Phase 1 (Sessions 1–10; meeting weekly): Parents take an active role ensuring that their child is eating regularly and not engaged in compensatory behavior. Phase 2 (Sessions 11–16; meeting every 2–3 weeks) Phase 3 (Sessions 17–20; meeting 3–4 weeks apart): Presuming that ED symptoms no longer occur, focus shifts to fostering healthy parent-adolescent relationship, general adolescent issues, relapse prevention	Phase 1 (~10 sessions): Focused on normalizing eating patterns using self-monitoring as a therapeutic tool. With adolescents, there is additional emphasis on bolstering motivation and establishing a collaborative relationship Stage 2 (7–8 sessions): Focus on targeting distorted cognitions Stage 3 (2–3 sessions): Brief stage focused on relapse prevention through anticipatory problem-solving
Role of the family	Parents take a very active role in each session to support their child in reestablishing regular eating without compensatory behavior. Siblings are invited to participate as well	Parents play an adjunctive role and may be asked to join a session for a specific reason. For example, they may support behavioral experiments
Relationship with therapist	Initially, the therapeutic alliance between parents is the priority over the relationship with the adolescent	Therapeutic alliance is between adolescent and therapist
Dose of treatment	Typically 20 sessions over 6–9 months	Typically 20 sessions over 6 months
Suitability for treatment	Parents' active role supports progress in treatment for adolescents who may be ambivalent about recovery. If there is a history of abuse between the parent and child, careful consideration should be taken to determine if it is appropriate for parent to be placed in this role	Adolescent must be able and willing to actively engage in the treatment; they are encouraged to take control of the problem. It is expected that the adolescent will be able to make progress with limited involvement by parents

Legend. FBT-BN, FBT for bulimia nervosa; CBT-E, cognitive behavior therapy enhanced for eating disorders; ED, eating disorder

includes self-monitoring homework (i.e., what is eaten and when, with associated behaviors, thoughts, and feelings) and is focused on normalizing patterns of eating while also interrupting compensatory behaviors. The second stage of treatment focuses on cognitive symptoms including specific integration of feared or avoided foods while using strategies to address triggers for binge eating and purging. In this

Table 2 Core principles and strategies of FBT-BN. FBT-BN, family-based treatment for bulimia nervosa; ED, eating disorder

Tenant	Description
Agnostic view of illness	No assumptions are made about the cause of the illness, and the focus is not on analyzing "why" the ED developed. Instead, the focus is on addressing potential maintaining factors or aspects which would leave someone vulnerable to relapse. This also serves to reduce blame
Caregiver empowerment	It is believed that parents are competent agents for reestablishing healthy eating patterns. Caregivers are charged with ensuring their child is eating appropriately to nourish their body and preventing compensatory behavior
Role of family	Members of the entire family system are important participants in the recovery process
Respect of adolescent development	The adolescent should be allowed to maintain control and autonomy in their life in areas that are unrelated to eating and weight
Externalization of the illness	The illness is viewed as an external force influencing the thoughts and actions of the teen. Caregivers and the therapist join forces to support the healthy part of the teen in fighting against the illness
Initial symptom focus	Treatment starts with a pragmatic focus on interrupting the pattern of restriction, binge eating, and compensatory behaviors including purging. The initial focus is on urgently restoring physical health with consistent nourishment
Non-authoritarian stance	Therapists take an active role guiding the family through the recovery process, without telling them exactly how to do it. The therapist partners with the caregivers to help them determine how to best support their child in breaking the cycle of the ED

Legend. FBT-BN, family-based treatment for bulimia nervosa; ED, eating disorderLegend. FBT-BN, family-based treatment for bulimia nervosa; ED, eating disorder

phase, the self-monitoring records include more intentional focus on cognitive symptoms. The third and final stage of CBT-E is focused on maintaining progress and relapse prevention. Throughout treatment, parents may be included in session for collateral information and to clarify ways in which they can support their child.

A modified CBT approach is in the guided self-care format which is the first-line intervention for adults with BN in the United Kingdom (National Collaborating Centre for Mental Health [UK] 2004). In this approach, a workbook or manual is provided with assigned homework. These modalities incorporate both psychoeducation and a practical focus on the key interventions. The therapist's role is to build motivation while also guiding patients through the workbook. Similar to clinician-guided CBT, core elements of the self-guided format include psychoeducation regarding the conceptual model of how ED symptoms are maintained with a personalized case formulation. Self-monitoring is used to track eating and cognitive symptoms. There is a focus on establishing regular eating and utilizing skills such as problem-solving, goal setting, and behavioral experiments.

RCTs. As mentioned above, there have been four randomized clinical trials evaluating treatment for adolescents with BN to date. All of these studies were

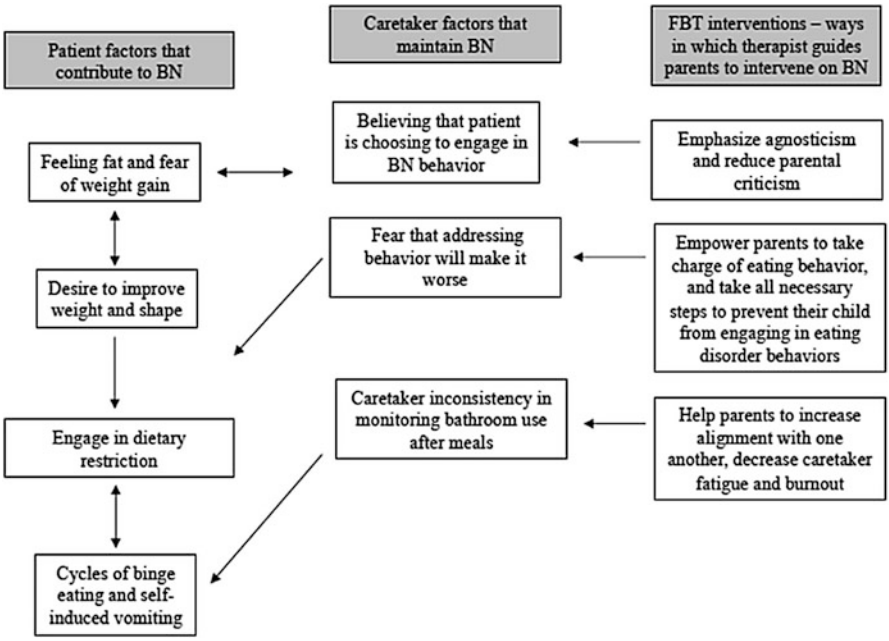

Fig. 2 Sample FBT formulation. BN, bulimia nervosa; FBT, family-based treatment

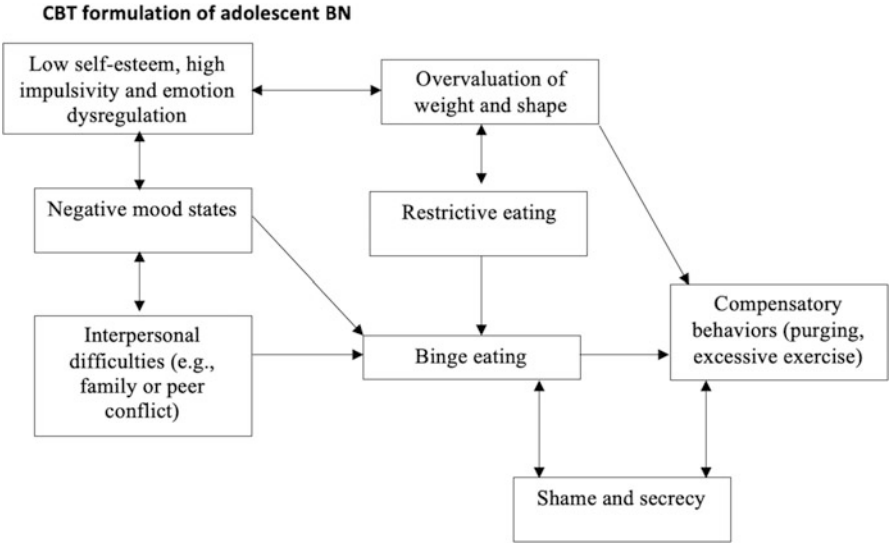

Fig. 3 CBT formulation of adolescent BN. BN, bulimia nervosa

based on DSM-IV-TR criteria for a diagnosis with additional, more flexible criteria that are generally consistent with revised DSM-5 criteria allowing those who endorsed behavioral symptoms less frequently to be included. Three of the four studies have evaluated the efficacy of a family-based approach with another treatment. In the United Kingdom, (Schmidt et al. 2007) compared family therapy with the leading treatment for adults with BN–CBT-guided self-care. This study provided up to 15 sessions of treatment for adolescents with DSM-IV-TR BN or ED not otherwise specified (EDNOS). EDNOS in this study was defined as binge eating and/or purging less than twice per week over 3 months or inappropriate compensatory behaviors without binge eating in patients who were not underweight. The primary outcome was measured by the abstinence from binge eating and self-induced vomiting at end-of-treatment (EOT; 6 months) and follow-up at 1 year, with results indicating no differences between the groups. However, when examining objective binge eating episodes in isolation at EOT, CBT-guided self-care was more effective than family therapy, though this difference was not upheld at follow-up.

In the United States, Le Grange et al. (2007) first compared 20 sessions of FBT to individual supportive therapy (SPT) in youths with BN as defined by DSM-IV-TR, also including those who endorsed binge eating or purge episodes at least once per week over 6 months. Results were defined by abstinence of binge eating and purging 1 month prior to EOT, reevaluated again 6 months later, 1 year from the start of the treatment. At EOT, FBT-BN had higher rates of abstinence, but the rates declined across both treatments at the follow-up time point. Following the comparison against SPT, another RCT compared FBT-BN to CBT for adolescents, offering 18 sessions over 6 months with the same inclusion criteria (Le Grange et al. 2015). As with the prior study, outcome was assessed by abstinence from binge eating and purging for the month prior to EOT, 1-year, and 18-month follow-up. In this study, FBT-BN achieved higher rates of abstinence at EOT. Unlike the prior study, both groups continued to improve with increased rates of abstinence across the 1-year follow-up period at both time points, with FBT-BN remaining more efficacious.

The final RCT by Stefini et al. (2017) did not examine family-based approaches, instead comparing CBT to psychodynamic therapy, the standard of care in Germany. To be in alignment with the longer duration of psychodynamic therapy, the dose of treatment was notably higher than the other studies, providing up to 60 sessions of either therapy over the course of a year. Similar to the prior studies, inclusion criteria comprised those meeting DSM-IV-TR BN criteria, extending to include those reporting binge eating and purging less than twice per week over the prior 3 months. Rather than determining abstinence as the outcome measure, Stefini et al. (2017) evaluated the proportion of participants who no longer met criteria for an ED diagnosis (based on DSM-IV-TR), finding no significant differences between groups.

Effectiveness trial. More recently, Le Grange and colleagues published the results of a non-randomized effectiveness trial which compared FBT to CBT-E on measures of weight and ED symptomatology (Le Grange et al. 2020). This study was transdiagnostic and included adolescents with a DSM-5 ED diagnosis (excluding avoidant-restrictive food intake disorder; ARFID), with 20% of participants meeting criteria for BN, binge eating disorder, or purging disorder. Within this

transdiagnostic sample, adolescents were classified into lower versus higher weight rather than specific ED diagnosis. Treatment effectiveness was measured based on improvement in ED psychopathology as measured by the Eating Disorder Examination interview (EDE) or questionnaire (EDE-Q) (Fairburn 2008) and weight gain, if relevant. Adolescents with BN would most likely be classified in the higher weight group as weight loss is not a core diagnostic feature of the illness. For this group, both FBT and CBT-E demonstrated improvements in the global scores on the EDE without significant differences between groups across time. These findings suggest that a larger higher-powered RCT is warranted.

Other Promising Avenues for Psychotherapy Treatments in Youth

As detailed just above, FBT and CBT are consistently recommended treatment approaches for adolescents with BN (Couturier et al. 2020). However, several "third wave" psychotherapy modalities (i.e., treatments that have evolved and extended from traditional CBT approaches [Hayes 2004]) have demonstrated reasonable efficacy among adults with BN (Hagan and Walsh 2021) and warrant further evaluation among youth. Specifically, research in the last two decades highlights the effective use of interpersonal therapy (IPT) (Agras et al. 2000), dialectical behavioral therapy (DBT) (e.g., Wisniewski and Kelly 2003), acceptance and commitment therapy (ACT) (e.g., Merwin et al. 2013), and integrative cognitive-affective therapy (ICAT-BN) (Wonderlich et al. 2014) for adults with BN.

To consider just a bit more detail on these approaches, IPT rests on the foundation that interpersonal functioning is a critical component of psychological well-being (Markowitz and Weissman 2004) and has been implemented as a focused treatment for EDs (Wilfley et al. 2002; Karam et al. 2019). Although CBT appears to work more efficiently than IPT among adults with BN at EOT, these two treatments demonstrated comparable efficacy when remission rates were compared at 1 year post treatment (Agras et al. 2000), and IPT may be particularly useful for those with marked interpersonal difficulties. DBT enhances skills in the domains of interpersonal effectiveness, distress tolerance, mindfulness, and emotion regulation, with the goal of reducing affective lability and engagement in ED behaviors (Eist 2015). DBT has demonstrated efficacy for treating BN among adults (Hill et al. 2011), and a recent uncontrolled case series of Radically Open DBT (RO-DBT) demonstrated preliminary efficacy in targeting overcontrol among adolescents with restrictive EDs (Baudinet et al. 2020). An ACT approach is intended to increase cognitive and behavioral flexibility, and to reduce experiential avoidance and illness accommodation (Hayes 2004). It has demonstrated efficacy for treating binge-spectrum EDs among adults (Juarascio et al. 2021), and in a recent trial that integrated ACT with a separated family approach (i.e., Acceptance-Based Separated Family Treatment) for adolescents with AN, results demonstrated preliminary feasibility, acceptability, and efficacy for improving weight gain and reducing ED pathology (Timko et al. 2015). Finally, ICAT-BN emphasizes coping and emotion regulation, intrapersonal factors (e.g., nutrition), and interpersonal relationships (Wonderlich et al. 2014). To date, it

has been tested in one RCT in a sample of adults with BN, demonstrating promising efficacy in reducing symptoms. Together, all four of these third wave treatments suggest promising avenues for future study in adolescent samples with BN.

Pharmacotherapy for BN

The use of pharmacology is one area of research that is greatly needed among adolescents with transdiagnostic EDs, particularly given how common medication use is among these youth (Gorrell et al. 2020). Due to the limited number of published studies, evidence-based pharmacological treatment for adolescents with BN is not yet possible, and current clinical guidelines for treating BN in adolescents do not include the use of psychopharmacology, other than to indicate that medication should not be offered as the only treatment option (Couturier et al. 2020). This is surprising, particularly given approval of fluoxetine by the United States Food and Drug Administration and the United Kingdom National Institute for Clinical Excellence for adults with BN (Crow 2019).

In adolescents with a DSM-IV-TR diagnosis of BN or EDNOS, one clinical trial has been published that investigated the feasibility, tolerability, and preliminary efficacy of fluoxetine in conjunction with psychotherapy (Kotler et al. 2003). In this trial, 10 female adolescents (aged 12–18 years) received an adult dose of fluoxetine (60 mg) over 8 weeks, with results indicating that the medication was well tolerated, no participants discontinued the trial, and on the whole, participants demonstrated a significant reduction in binge eating and purging episodes. Although these results suggest that antidepressants are similarly useful and well tolerated for the treatment of adolescent BN as with adults, in nearly two decades no systematic studies since this open trial have been conducted (Couturier et al. 2019). With either mechanistic or effectiveness trials, delineating the specific use of medications for either BN pathology, comorbid psychopathology (e.g., depression; anxiety), or their combination would greatly inform future prescribing practices.

Treatment Moderators

In order to improve treatment outcomes for BN, some research has investigated *how* these treatments work and for *whom* they may be more or less efficacious. Treatment mediators identify the mechanisms through which treatments affect change, or the key ingredients that make treatments effective (Kraemer et al. 2002). In contrast, treatment moderators are characteristics that predict who is more or less likely to benefit from a given treatment; moderators can be differentiated from nonspecific moderators, which are baseline traits that predict treatment outcomes (i.e., main effect on outcome), regardless of patient characteristics (i.e., no interaction effect) (Kraemer et al. 2002). For example, prior hospitalization related to medical complications of EDs is a non-specific predictor of treatment, in that it predicts worse outcomes across all individuals (Le Grange et al. 2012). Compared to AN, our

Table 3 Evidenced moderators of FBT outcomes in adolescents with BN. FBT, family-based treatment; RCT, randomized control trial; SPT, supportive psychotherapy; EDE, Eating Disorders Examination; CBT, cognitive-behavioral therapy

Study (year)	Treatment sample	Summary of moderation findings
Le Grange et al. (2008)	RCT with two treatment groups, FBT v. SPT	No moderators of remission (i.e., absence of binge eating and compensatory behaviors in the previous 4 weeks) or partial remission (i.e., no longer meeting diagnostic criteria) at end-of-treatment when comparing outcomes for treatment with FBT v. SPT At 6-m follow-up, baseline EDE global scores moderated the effects of treatment on partial remission such that individuals with *less* severe baseline global EDE scores had greater partial remission when treated with FBT relative to SPT
Ciao et al. (2015)	Secondary data analysis of data from Le Grange et al. (2008)	Using growth model analyses, participants with *greater* baseline purging had faster change in eating concerns when receiving FBT v. SPT, whereas when baseline purging was low, participants did comparably well in both treatments Age was also a significant moderator such that greater change in eating concerns was demonstrated for younger adolescents receiving FBT v. SPT, whereas those who were older showed an equal rate of change in both treatments; age did not moderate any other outcomes
Le Grange et al. (2015)	RCT with two treatment groups, FBT v. CBT, and one active control group, SPT	Family conflict emerged as a significant moderator such that participants with lower Family Environment Scale – *conflict subscale* scores responded better to FBT than CBT, but there was no differentiation between the treatments in families with higher conflict scores

Legend. FBT, family-based treatment; RCT, randomized control trial; SPT, supportive psychotherapy; EDE, Eating Disorders Examination; CBT, cognitive-behavioral therapy

understanding of treatment mediators and moderators for treatments for BN is limited, particularly in adolescents (see Table 3 for a summary of moderators of BN treatment). For instance, in a recent systematic review of mediators and moderators of ED treatment in adolescents, 16 papers were devoted to AN, whereas only 5 were devoted to BN (Hamadi and Holliday 2020). Further, out of 8 RCTs that have included analyses of moderators and mediators in ED treatments for adolescents, only two investigated BN (Le Grange et al. 2007, 2015). More recently, there has been one additional published treatment study investigating possible moderators in a transdiagnostic sample of EDs, including BN (Le Grange et al. 2020). There have

been no mediators of treatment identified in the current literature on BN in adolescents.

In one trial comparing FBT-BN to SPT that determined that FBT-BN was superior to SPT in reducing core bulimic symptoms (Le Grange et al. 2007), the authors also examined how ED pathology at baseline and throughout the treatment affected outcomes. In this study, remission was defined as abstinence of binge eating (both subjective and objective) and compensatory behavior during the one month prior to EOT. In terms of moderators, participants with less severe eating pathology (as measured by the EDE-Q global score) who were randomized to receive FBT were more likely to reach partial remission at 6-month follow-up compared to those randomized to receive individual supportive therapy (Le Grange et al. 2008). In addition, all EDE-Q subscales (*Restraint, Eating Concerns, Weight Concerns, Shape Concerns*) moderated treatment outcome. For those in the FBT group, lower eating psychopathology early in treatment was predictive of reaching partial remission at EOT. Mediators of treatment, including the mechanism through which FBT brings about change, were not investigated in this study.

A secondary data analysis of additional potential moderators of psychological outcomes in this original trial (Le Grange et al. 2007) included age, purging severity, and use of psychotropic medication (Ciao et al. 2015). The psychological outcomes investigated were cognitive ED symptoms, depression, and self-esteem. Only age and baseline purging severity were identified as moderators such that younger adolescents and those with greater baseline purging severity had larger changes in bulimic symptomatology in the FBT group compared to the SPT group. There were no other moderators of other psychological outcomes.

In the second trial comparing FBT-BN and CBT for adolescents (Le Grange et al. 2015), FBT for BN was found to be more effective in promoting abstinence from binge eating and purging behaviors compared to CBT for adolescents. Similar to a prior trial conducted by Le Grange et al. (2007), remission was defined as abstinence of binge eating (both subjective and objective) and compensatory behavior during the 1 month prior to EOT. In total, 29 moderators were investigated; however, only one moderator was identified such that participants with lower family conflict who received FBT-BN were more likely to reach partial remission by EOT compared to those who received CBT. These findings suggest that individuals with lower family conflict may be better suited that those with higher family conflict for FBT-BN. Interestingly, no other moderators were found, including ED symptom severity, depression, self-esteem, or obsessive-compulsive symptoms.

In the most recent study comparing the effectiveness of FBT versus CBT-E in a transdiagnostic sample (i.e., spanning across EDs) (Le Grange et al. 2020), several moderators were identified. At baseline, participants in the lower weight group (i.e., individuals $<$90% of their expected body weight), depressive symptoms, age, prior hospitalization for co-occurring psychiatric disorders, and family status (i.e., whether individuals lived with their family of origin or a reconstituted family) moderated weight gain at EOT. Specifically, adolescents with higher levels of depression gained comparable rates of weight to those with lower levels over the course of treatment in FBT, but adolescents with higher levels of depression gained

less weight than those with lower levels in CBT-E. Overall, adolescents in FBT gained weight faster than those in CBT-E. In addition, younger adolescents gained more weight than older adolescents in FBT, but older adolescents gained more weight than younger adolescents in CBT-E. Further, adolescents with a prior psychiatric hospitalization were more likely to gain weight in FBT, but lose weight in CBT-E. Overall, adolescents without a prior hospitalization were more likely to gain weight than those with in both treatments. Finally, adolescents living with their family of origin had poorer weight gain compared to those living in reconstituted families more so in CBT-E than FBT. Of note, these factors did not emerge as moderators in the higher weight group, which included individuals with BN. Overall, these findings suggest that younger adolescents, adolescents with higher levels of depression, a prior psychiatric hospitalization, or living in their family of origin may benefit more from FBT, particularly those who need to gain weight as part of their treatment. These moderators should continue to be investigated in adolescents with BN and in the context of binge eating and purging behaviors.

These preliminary studies provide initial evidence that may help guide clinical recommendations for treatment assignment, based on differential treatment response among adolescents for BN. Specifically, individuals with lower eating pathology at the start of treatment or those with less family conflict may respond particularly well to FBT compared to other treatments. However, more rigorous, larger studies will be needed to replicate these findings and to specifically test mediators and moderators of treatment with sufficient statistical power before reaching definitive conclusions (Hamadi and Holliday 2020). Identification of potential moderators and mediators has been quite limited thus far in BN and have to date been a secondary outcome to the main results comparing two treatments. In the future, it will be useful to conduct trials focusing on the mechanisms of action of treatments for BN and taking a stepwise approach to treatment to see who benefits the most.

Research and Clinical Future Directions

There are several domains of future research that are suggested by the current state of evidence reviewed within this chapter. In addition, there are features specific to the BN disorder that suggest shifts in the way that we screen and treat adolescents within our clinical practice. Here, we weave together both research suggestions and recommendations for practice – considering that a discussion of needed clinical research may help to determine where our resources should ideally be devoted to improve treatment outcomes for this high-priority clinical population.

Awareness of diagnostic crossover. As mentioned above, the criteria to meet a diagnosis of BN in DSM-5 is less stringent than the criteria required to meet a diagnosis for BN per DSM-IV-TR (prior to 2013). A majority of our current evidence base of clinical treatment trials for adolescents with BN is therefore based on participants who met DSM-IV-TR inclusion criteria. Arguably, it is "easier" to meet criteria for BN now than it was when these RCTs enrolled. However, much of these RCTS also included partial BN (i.e., subclinical) which naturally

would include youth who would now meet criteria for BN based on today's standards. Regardless of how we interpret the primary outcomes of these trials based on a now outdated definition of BN, it seems important to consider who should be considered for enrollment in future clinical trials to maximize the knowledge gained, based on a potentially shifting definition of this disorder.

"Diagnostic crossover" is a phrase that has been used to refer to the clinical phenomenon of a transition from one ED diagnosis or presentation to another (Eddy et al. 2008). For example, a young person who has been restricting their intake may meet criteria for AN for a certain period of time, but as their illness progresses, this individual may eventually develop binge eating and purging behavior. In a recent meta-analytic review specifically investigating this transition from restricting AN to a presentation that includes binge eating and purging behavior, over 40% of patients reported bulimic behavior at some point during follow-up (Serra et al. 2021). This specific type of diagnostic crossover appears to happen frequently, and it may also help to explain why there are higher rates of BN among adolescents compared to AN. Of note, in one 7-year study, women with BN were less likely to return to AN, supporting the distinction of BN as a separate diagnosis over time (Eddy et al. 2008). The conundrum remains however, that whether one begins with BN or "crosses over" from AN to BN, it is still not particularly clear as to how we might optimally prevent the disorder.

Building awareness among providers that diagnostic crossover from AN to BN is likely, and even more likely with a longer course of illness (Eddy et al. 2008; Serra et al. 2021), is important. In particular, building awareness may be helpful not only in encouraging providers to remain vigilant to screening for new behaviors over time, but also to help to inform patients and families of this compounded risk. Further, although testing interventions that are designed to treat BN are critical, we must also consider that subclinical presentations of this disorder – potentially just as they begin to represent diagnostic crossover – may be particularly important to address in a preventative fashion. In this way, future trials may benefit from including individuals across a diagnostic spectrum (i.e., AN with binge-purge behavior, subclinical BN, and BN).

Weight bias. Recent work describing prodromal symptoms that predict specific EDs found that overvaluation of shape and weight *and* simultaneously feeling fat and fear of weight gain – together were predictive of BN onset (Stice et al. 2021). This was in contrast to onset of AN, which was first predicted by overvaluation of shape and weight without report of a feeling of fatness or fear of weight gain. It is typical for youth with BN to present at a weight that may be lower than their historical weight, but still within the range of expected weight given their height, age, and gender.

Unfortunately, weight status is intricately linked with poor illness detection; specifically, we refer to the (errant) perception that normal weight status is synonymous with lower ED severity (Gaudiani 2018). As a consequence, highly symptomatic youth with BN are less often identified by medical professionals in standard screening, or less often suspected to be struggling with an ED by their caretakers or others who might facilitate treatment referral. A good amount of research has been

focused on low-weight disorders such as AN, and while low weight suggests greater medical acuity for some individuals, this weight-based bias in research has prevented expansion of research into the fuller spectrum of transdiagnostic EDs. Further, insurance companies may deny access to higher levels of care due to weight bias or perceiving that the patients' electrolytes are not "abnormal enough" (Gaudiani 2018). Assumptions based on weight collectively prevent many providers and parents from feeling that treatment for BN is urgently needed.

Adolescents with this disorder may certainly seek treatment on their own, the prospect of which is supported by the ego-dystonic nature of the disorder (e.g., distress caused by one's binge eating and purging) (Bottera et al. 2020). However, among young adults with BN, recent evidence indicates that sentiments reflecting self-criticism and fear of external judgment *decrease* help-seeking and self-referral for treatment (Ali et al. 2020), a problem that we can assume may be even more prevalent among adolescents. Further, prior weight status and stigma directly related to BN (e.g., that individuals with BN lack self-discipline, or are self-destructive) may also contribute to decreased help-seeking (Puhl and Suh 2015).

To offset these issues, we may again turn to the need for increased awareness among providers, but also among caretakers, educators, and individuals who interface with adolescents (e.g., athletic coaches), that EDs can occur in individuals of all sizes, and that screening for ED symptoms should be performed regardless of a presenting weight.

Testing treatments. So far, the evidence from RCTs testing FBT and CBT for BN in adolescents demonstrate relative robustness in their efficacy. However, even the best RCT outcomes leave a majority (nearly 60%) of youth as still partially symptomatic at the conclusion of treatment (Steiger 2017; Lock and Le Grange 2019). It is essential that we continue to study treatment for adolescents with bulimic symptoms in an effort to improve remission rates. We acknowledge that it is a departure to advocate for *not* studying BN as a singular diagnostic sample when calling for increased study of this disorder among adolescents. However, a diagnostically siloed approach to studying restrictive EDs has left us with little understanding of the complexity of these disorders, including mechanisms that drive cycles of binge eating and compensatory behaviors across weight status. Further, given the frequency of diagnostic drift (Eddy et al. 2008; Stice et al. 2009), it is untenable to maintain that a weight criterion or a given frequency of a behavior should determine the delineation of a study sample, diagnostic category, or indication of necessity to receive clinical resources. Therefore, although heterogeneity in a sample must be considered, we advocate for a less siloed approach in future study proposals, and appeal to reviewers in the grant and manuscript review process to recognize the importance of considering BN within a broader transdiagnostic context. Studying BN, atypical AN, and OSFED in tandem will undoubtedly facilitate improved identification of mechanisms that maintain BN behaviors across the weight spectrum and will ultimately translate to more inclusive and effective approaches in screening and treatment assignment.

We further advocate for studying youth with transdiagnostic binge eating and purging behavior with *both* an experimental therapeutics approach *and* with

effectiveness trials. Delineating the mechanisms by which behavior is either maintained or mitigated is critically important. It is equally important that we improve the effectiveness of BN treatment, in the context in which it is delivered. With either mechanistic or effectiveness trials, delineating the specific use of medications for either BN pathology, comorbid psychopathology (e.g., depression; anxiety), or their combination would greatly inform future prescribing practices.

In addition to medication trials and as mentioned earlier in this chapter, there are several third wave therapeutic treatments that show promise for BN in open trials among adolescents (e.g., ACT, Timko et al. 2015), but still require testing in larger-scale clinical trials. In conducting larger trials, more recent work has specified that policy and system changes must be made to improve the reach and ability to disseminate any type of ED treatment (Taylor et al. 2020). Given the burgeoning prevalence rates of ED behaviors in the past year (Phillipou et al. 2020), and the existing critical need for the dissemination of evidenced-based care for youth with EDs (Lock and Le Grange 2019), we do not have a luxury of time in closing a research-to-practice gap.

Summary/Conclusions

In summary, in this chapter, we provide an overview of the current evidence base for research and clinical practice among youth and adolescents with BN. We include prevalence rates and diagnostic criterion, common comorbidities, and the treatments that show the most robust evidence base to date. We also point to the perplexing finding that BN has nearly a twofold greater prevalence rate compared to AN, and yet clinical services do not represent this proportion. We discuss reasons for this phenomenon and provide ideas for moving forward. The symptoms of BN are present across ED diagnoses; therefore, in moving toward studying these phenomena mechanistically across diagnostic siloes, we will more efficiently be able to understand for whom and why these symptoms arise and are maintained. Increased study of BN symptoms (both in mechanistic and effectiveness trials) will help to determine where our resources should ideally be devoted to improve treatment outcomes for this high-priority clinical population.

Applications to Other Eating Disorders

As noted above, BN has significant overlap with the other EDs (e.g., Forbush et al. 2017). Given the shift toward dimensional approaches of psychopathology and the considerable diagnostic crossover that occurs, it follows that many of the considerations discussed above apply to other EDs (Le Grange et al. 2004; Le Grange and Loeb 2007). First and foremost, early detection is the most important indicator for full recovery (Treasure et al. 2015). Thus, screening among pre-adolescents and adolescents is imperative to identify early-onset EDs and refer individuals to appropriate treatment.

Further, treatment among the EDs in adolescents is relatively similar. FBT and CBT-E are the two gold-standard, first-line evidence-based treatments for adolescent EDs, regardless of diagnosis (Couturier et al. 2013; Lock 2015). Both treatments support regular eating and reduce of symptoms of restriction, binge eating, and purging and have been shown to be effective transdiagnostically (Le Grange et al. 2020).

Finally, similar challenges are common across EDs, such as weight bias and need for novel treatments, emphasizing the need for future research in these areas. Similar to BN, weight bias delays time to diagnosis for atypical AN and binge eating disorder (Puhl and Suh 2015). In addition, at least half of youth remain partially symptomatic after treatment (Steiger 2017). There is an urgent need to develop augmented or novel treatments to increase the number of individuals who achieve full recovery.

Thus, in conclusion, the ED field may be better served moving forward in treating these disorders as dimensional, composed of different symptoms, rather than as discrete, categorical disorders. Such an approach may streamline future research efforts to improve treatment outcomes for all EDs across the lifespan.

Mini-Dictionary of Terms

CBT	Cognitive-behavioral therapy is an evidence-based approach to psychotherapy focused on thoughts, behaviors, and emotions.
FBT	Family-based treatment is an empirically based approach where families are a key part of treatment for youth and adolescents with EDs.
Clinical trial	A clinical trial is a systematic study of a specific subject whereby response to an intervention is tested.
Bulimia nervosa	Bulimia nervosa is an eating disorder characterized by engagement in binge eating and compensatory behaviors (e.g., self-induced vomiting).
Self-efficacy	Self-efficacy in FBT refers to parental empowerment in being able to effectively engage with challenging the ED.
Agnosticism	Agnosticism is a term used to describe an attitude where there is no blame placed on any one individual, or any identified cause of a specific issue (e.g., the ED).
Externalization	Externalization refers to the stance where the ED is not identified as belonging to, or being the child.

Key Facts of Treatment for Bulimia Nervosa

- The core symptoms of BN (i.e., binge eating, compensatory behavior, and body image concerns) are present across ED diagnoses.

- BN has nearly a twofold greater prevalence rate compared to AN, and yet clinical services do not represent this proportion.
- FBT and CBT are currently the most efficacious treatments for youth with BN.
- FBT involves family members in treatment as important resources in interrupting the ED, and helping the child to recover.
- In FBT, parents initially take charge of eating and exercise and work to prevent ED behavior, and independence is gradually restored to the child over time.
- CBT is an individual approach to treatment where the child is responsible for making behavior change in the context of treatment. Even in CBT, parents can be a key part of supporting a child's recovery from BN.
- There is an urgent need to develop augmented or additional novel treatments to increase the number of individuals who achieve full recovery from bulimia nervosa and other eating disorders.

Summary Points

- In adolescents, point prevalence of BN is 4.6% though estimates vary based on the inclusion of individuals who fall below diagnostic threshold.
- There is a high rate of comorbidity for BN with anxiety and mood disorders along with substance misuse; suicidal ideation and attempts are also high.
- There is a lack of systematic study of treatment for BN in youth; family-based and cognitive-behavioral approaches have been the focus of the limited number of RCTs.
- There is reasonable efficacy of several "third wave" treatments extending from CBT in adults with BN which may also benefit adolescents.
- Although psychotropic medications are commonly prescribed for youth, current guidelines for treating BN in adolescents do not include the use of psychopharmacology with only one open trial of 10 female adolescents to date.
- There are several domains of future research in adolescent BN including awareness of diagnostic crossover, weight bias, and additional systematic testing of treatments.

Abstract

The dual pathway model (DPM) for bulimia nervosa (BN) symptoms proposes that increased body mass index (BMI) leads to pressures to be thin, and body dissatisfaction. Pressures to be thin are also thought to lead to thin-ideal

internalization and body dissatisfaction. According to the model, the effects of body dissatisfaction on BN symptoms are mediated via two pathways: dietary restraint and negative affect. Despite its theoretical appeal in being able to capture the multifaceted etiology of BN symptoms, only a few studies have been able to capture the DPM empirically. This chapter aimed to review all the cross-sectional and longitudinal studies to date that have assessed the DPM empirically in its entirety using path analyses or structural equation modeling (SEM). A total of ten studies were retrieved (five cross-sectional and five longitudinal). Overall, there was decent support for most of the paths included in the DPM both cross-sectionally and longitudinally. Understanding the processes that lead to BN symptoms has the potential to prevent and reduce the deleterious effects of BN symptoms.

Introduction

Bulimia nervosa (BN) is a debilitating eating disorder that is linked to poor health, psychosocial dysfunction, and comorbid mood disorders (APA 2013). Body mass index (BMI), sociocultural pressure to be thin, internalization of the thin ideal, body dissatisfaction, dietary restraint, and symptoms of negative mood (e.g., depression, anxiety, and negative affect, e.g., Puccio et al. 2016a) have all been identified as risk factors for the development and maintenance of BN symptoms (Stice et al. 2017). The dual pathway model (DPM) for BN (Stice et al. 1996) suggests that a series of recognized BN risk factors are causally connected, and hence generate and perpetuate the disease (see Fig. 1)

The DPM examines the mediating pathways that give rise to BN symptoms. Recurrent episodes of binge eating and compensatory behaviors which can be either purging (i.e., self-induced vomiting) or non-purging (i.e., excessive exercise; APA 2013) are symptoms of BN. Stice et al.'s (1996) DPM model hypothesizes that external pressures to be thin (e.g., the media, family, and peers) lead to the thin-ideal internalization (the extent to which an individual subscribes/aspires to the cultural standard of thinness). Furthermore, comparing one's body to this thin ideal can then

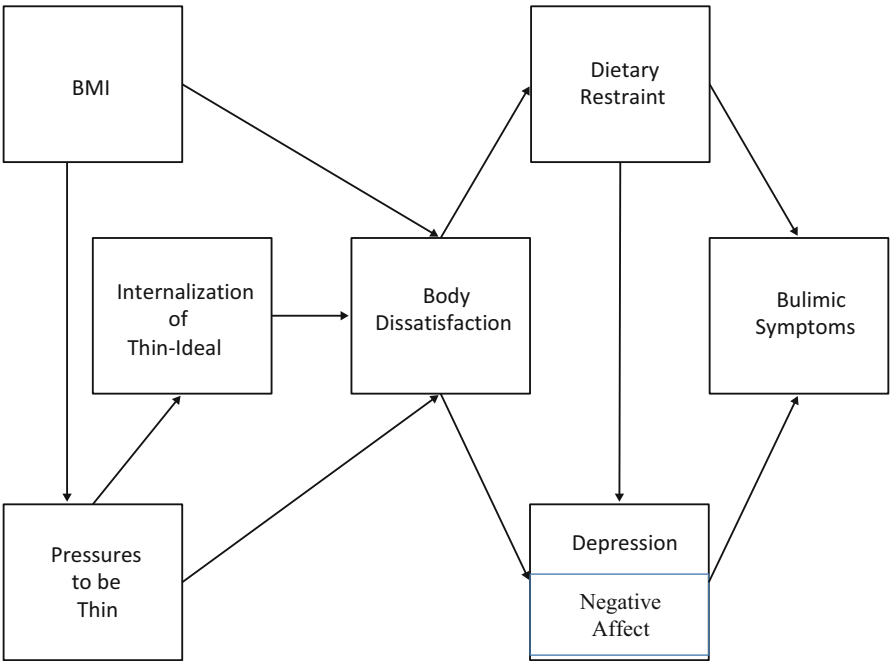

Fig. 1 The original conceptualisation of the DPM according to Stice et al. (1996). (*Notes*: BMI = body mass index. The original DPM model proposed by Stice et al. (1996) includes negative affect as the mood variable. However, other DPM studies have used depression and negative affect interchangeably. It should however be noted that these are different concepts. While depression is a mood disorder that is characterized by persistent feeling of sadness and loss of interest that affect everyday functioning, negative affect is an internal feeling that takes place when one has failed to achieve a goal or has avoided a threat)

lead to an increase in body dissatisfaction (dissatisfaction with one's weight, shape, and/or size) since this thin ideal offers an unachievable objective of thinness. Body dissatisfaction is at the heart of the DPM, and it is thought to cause BN symptoms via two paths. The first pathway is via dietary restraint: Binge eating, a core symptom of BN, is thought to be a compensatory mechanism for caloric deprivation associated with dietary restraint (Polivy et al. 2005). Dietary restraint is also proposed to lead to negative affect. The second pathway is therefore via negative affect: Increased body dissatisfaction, in turn, leads to feelings of disgust, depression, and anger, whereby bingeing and purging are believed to be coping mechanisms to distract attention from this negative mood state (Heatherton and Baumeister 1991). Since the DPM was first proposed, it has been examined in both cross-sectional (e.g., Stice et al. 1996) and longitudinal studies (e.g., Stice et al. 1998). However, to our knowledge, no study to date has systematically reviewed the studies that have assessed the DPM model empirically. Hence, the validity and predictive utility of the model remains unclear.

The aims of the current narrative review of the DPM were therefore to (a) outline the relevance of each of the key constructs included in the DPM and (b) provide

details on the studies that have attempted to validate the model empirically. Understanding if the proposed risk factors outlined in the DPM have meaningful causal relationships for BN symptoms and whether they have predictive power is crucial because they could influence early prevention efforts aimed at preventing individuals who are "at risk" from reaching a clinical BN diagnosis.

The Risk Factors Included in the DPM for BN

The DPM as originally proposed by Stice et al. (1996) outlines a multifaceted interchange among several putative risk factors (i.e., BMI, pressures to be thin, thin-ideal internalization, body dissatisfaction, negative mood/affect, and dietary restraint) that conclude in the experience of BN symptoms. Each of these risk variables will be introduced in the following section, as well as the background for its inclusion in the DPM.

Body Mass Index

BMI is a measurement of a person's weight and height. The BMI is calculated by dividing the body mass by the square of the body height and is given in kilograms per square meter. It is hence expressed in units of kg/m^2. According to the World Health Organization, the following BMI categories have been suggested: <18.5 = underweight, ≥ 18.5–24.9 = normal, ≥ 25–29.9 = overweight, and ≥ 30 = obese. A higher BMI is supposed to increase one's chance of developing disordered eating symptoms as it moves individuals further away from the slender ideal body image (e.g., Stice and Shaw 2002). BMI has been prospectively associated with the onset of BN symptoms (e.g., Abebe et al. 2012), sub-threshold binge eating disorder (Hilbert 2013), disordered eating symptoms (e.g., Ferreiro et al. 2012), and binge eating symptoms (e.g., Ferreiro et al. 2012) in male and female community samples. As a result, previous studies have revealed that having a higher BMI is a risk factor for developing eating disordered symptoms, including BN.

Sociocultural Pressures to Be Thin

Sociocultural pressures to be thin are defined as external media and interpersonal (parents and peers) influences which generate and diffuse unrealistic body-shape ideals that promote the desirability of the thin ideal (Rodgers et al. 2010). Parents, peers, and others who support media-portrayed body-shape ideals are thought to perpetuate these pressures. This is believed to occur through dieting-related encouragement or criticism, as well as modeling of behaviors and attitudes congruent with achieving the thin ideal, which ultimately might lead to a clinically significant eating disorder (Rodgers and Chabrol 2009). Peer pressure to be thin has been linked cross-sectionally to BN symptoms and negative affect (e.g., Hutchinson et al. 2010), body

dissatisfaction (e.g., Ruisoto et al. 2015), and disordered eating (e.g., Ruisoto et al. 2015). Pressures to be thin have also been connected to more severe dietary restriction and poorer teenage weight outcomes (i.e., being overweight; Blodgett Salafia and Gondoli 2011), hence emphasizing the negative impact of societal pressures to be thin on eating disorders.

Thin-Ideal Internalization

The thin ideal is a culturally sanctioned image purporting that a female's attractiveness is primarily based on having an "ultrathin" body (Pidgeon and Harker 2013). A figure with slender hips, buttocks, shoulders, arms, and thighs is regarded as a characteristic of this ultrathin shape and size (Furnham et al. 2002). Given that the thin ideal is a biological oddity, obtaining and/or maintaining this thin ideal is largely unattainable.

The degree to which an individual cognitively adopts the socially imposed beliefs and norms of attractiveness is termed thin-ideal internalization (Pidgeon and Harker 2013). In other words, thin-ideal internalization refers to a person's belief that the thin ideal is a desirable end state to strive for. This internalization process is assumed to take place over time because of frequent exposure to images and messages that purport the thin ideal (Rogers Wood and Petrie 2010).

A meta-analysis by Stice and Shaw (2002) found that the thin-ideal internalization was associated with body dissatisfaction, dieting, negative affect, the onset and maintenance of BN symptoms, and the onset of binge eating. Other research has linked the slim ideal internalization to body-focused anxiety and dissatisfaction (Peterson et al. 2006), dieting (Pidgeon and Harker 2013), and disordered eating (Pidgeon and Harker 2013). Internalization of the thin ideal has also been argued to maintain eating disorders (e.g., Paterna et al. 2021), presumably through social reinforcement mechanisms that signal to individuals that the ideal is desirable. Consequently, the thin-ideal internalization has been identified as a risk factor for the development of eating disorders.

Body Dissatisfaction

Body dissatisfaction has been coined as the subjective negative judgment of one's physique or bodily components (Stice and Shaw 2002). Body dissatisfaction is thought to comprise of two parts: evaluative body dissatisfaction, which is the difference between one's perceived body shape or size and one's ideal body shape or size, and affective body dissatisfaction, which are the negative affective states caused by dissatisfaction with one's shape or size (Bearman et al. 2006). Body dissatisfaction is also referred to as either general unhappiness with one's body or specific discontent with specific bodily parts (Allen et al. 2012). Body dissatisfaction has a high prevalence rate, with over 30% of boys and 60% of girls wanting to change their body shape and size (Lawler and Nixon 2011).

Restrained eating (Neumark-Sztainer et al. 2006), BN symptoms (Stice 2002), and depressive symptoms (Neumark-Sztainer et al. 2006) have all been associated with body dissatisfaction (Mond et al. 2011). Unsurprisingly, body dissatisfaction was found as a main risk factor for dieting, negative affect, and BN symptoms in Stice and Shaw's (2002) meta-analysis.

In terms of the trajectory of body dissatisfaction as a function of sex, Bucchianeri et al. (2013) examined 1902 participants in a sample that was designed to reflect culturally different ethnic/racial and socioeconomic origins. The study's findings revealed that between middle adolescence and early adulthood (10 year follow-up), both girls' and boys' body dissatisfaction grew significantly and that this rise was linked to an increase in BMI over time. When BMI was adjusted, increases in body dissatisfaction became nonsignificant, demonstrating that BMI has a major impact on body dissatisfaction.

Dietary Restraint

The DPM asserts that body dissatisfaction may lead to BN symptoms through two mechanisms: dietary restraint and negative affect (Stice et al. 1996). Dietary restraint refers to conscious efforts to lose weight by achieving a negative energy balance between calorie intake and expenditure (Allen et al. 2013). Dietary restraint is hypothesized to trigger binge eating episodes, which then precipitate BN symptoms (e.g., purging). Caloric restriction and dieting failures can then lead to disordered eating, particularly when people break their rigid and unrealistic dietary restrictions (Polivy and Herman 1985).

The meta-analysis by Stice and Shaw (2002) found that dietary restraint was a risk factor for negative affect and overall disordered eating. However, it should be noted that only a limited number of studies assessed this relationship (i.e., $N = 2$ for dietary restraint and $N = 9$ for negative affect). The idea that dietary restraint is a risk factor for BN symptoms has also been consistently explored in recent studies (Stice et al. 2017, 2021). Restraint eating has also been found to lead to uninhibited eating in a laboratory setting (Bottera et al. 2021). Finally, most BN patients claimed that their BN symptoms began after a period of dieting, and dieting has been identified as the most powerful risk factor for any type of eating disorder (Kabakuş Aykut and Bilici 2022; Stice et al. 2011).

Negative Affect

Negative affect is the second suggested pathway from body dissatisfaction to BN symptoms. Empirical research has suggested that negative affect plays a role in the development, occurrence, and maintenance of BN symptoms. Negative affect, for example, has been revealed to be a risk factor for eating disorders as well as a causal maintenance factor for binge eating (Stice and Shaw 2002). Furthermore, issues regulating negative emotional states have been observed to be more prevalent in

individuals with BN compared to controls and are linked to total symptom severity (Lavender et al. 2014).

Dietary Restraint and Negative Affect

Dieting and dietary restriction have also been linked to a low mood (da Luz et al. 2018). The DPM hypothesizes that dietary restraint has a direct impact on negative affect, which subsequently leads to BN symptoms. However, the literature on the longitudinal effects between depression and dietary restraint is inconclusive, and no study has assessed these relationships bidirectionally. Therefore, it remains unclear whether dietary restraint causes depression (e.g., Hilbert et al. 2013), whether depression causes dietary restraint (e.g., Allen et al. 2013), or whether the relationship between these variables is bidirectional. Therefore, further research is needed to determine the direction of effects between these dimensions.

Empirical Studies Assessing the Dual Pathway Model

While the DPM has received empirical support since its establishment, most of this literature has failed to replicate the model in its entirety, with many studies (e.g., Burton and Abbott 2019) only assessing individual paths by looking at bivariate relationships, and thus not examining the mediating processes by which these pressures ultimately lead to BN symptoms. Other studies have utilized path-analyses or structural equation modeling (SEM) to test alternative variations of the DPM (e.g., Dakanalis et al. 2014; Maraldo et al. 2016), and thus the specific results from these studies are somewhat difficult to compare to the original model proposed by Stice et al. (1996). The subsequent sections, therefore, outline all the cross-sectional and longitudinal studies that have assessed the DPM in its entirety. The inclusion criteria for this narrative review entailed those studies which (i) assessed the core proposition of the model, with flexibility only allowed for the BMI variable and one other missing variable (predominately, the thin-ideal internalization variable), and (ii) used path-modeling and/or SEM to assess the DPM model empirically.

We decided to only include studies that used either path analyses and/or SEM because these statistical techniques can analyze the structural relationship between the proposed constructs in the DPM. These methods are preferred since they assess numerous and interconnected dependencies in a single investigation. Path analyses differ from SEMs in that they employ observed variables, whereas SEMs may use a combination of observed and latent factors.

Cross-Sectional Studies

Cross-sectional research has provided support for the DPM from five studies that have utilized path-modeling or SEM (Anbari et al. 2020; Duemm et al. 2003;

Hutchinson et al. 2010; Maraldo et al. 2016; Stice et al. 1996). Table 1 presents an overview of these studies and the relevant findings.

As shown in Table 1, Stice et al. (1996) used a cross-sectional design to evaluate the DPM in a group of adolescent females. Using subscales from the Bulimia Test Revised (Thelen et al. 1991) and the Eating Attitudes Test-26, they were able to operationalize BN symptoms as a latent variable (Garner et al. 1982. The model was shown to be a good match to the observed data, accounting for 71% of the variance in BN pathology using SEM. All paths were significant, as predicted, demonstrating the model's validity. Although it was not hypothesized, Stice et al. (1996) also discovered that pressures to be thin had a direct effect on BN symptoms. This finding underlined the importance of social pressures, as such effects appear to lead to BN symptoms even when an individual does not internalize the thin ideal.

Duemm et al. (2003) conducted the second cross-sectional study that examined the DPM in its entirety. Duemm et al. (2003) tested whether the model could predict the commencement of BN behaviors using the Bulimia Test Revised (Thelen et al. 1991). Duemm et al. (2003) also looked at sociotropy as a personality trait to see if it had predictive value for the DPM, specifically for thin-ideal internalization and negative affect. Sociotropy is defined as a desire to rely on and/or be approved by others (Duemm et al. 2003). An individual with a high level of sociotropy is supposed to avoid social rejection by displaying signs of striving to please others and is focused on maintaining personal relationships.

Apart from the pressures to be thin → body dissatisfaction, and body dissatisfaction → negative affect pathways, Duemm et al.'s (2003) model was an excellent fit for the data, and most of the hypothesized pathways were supported. The variance accounted for in BN symptoms was 56%. Contrary to the model's primary claim, Duemm et al. (2003) discovered that body dissatisfaction had a direct influence on BN symptoms and was not fully mediated through the negative affect and dieting restraint pathways. According to Duemm et al. (2003), this direct effect may have been caused in part by weight loss that can occur because of purging behaviors. As such, the authors proposed that body dissatisfaction may have resulted in a direct effect on BN symptoms because purging behaviors may have acted as a mechanism for weight loss to alleviate body dissatisfaction.

Duemm et al.'s (2003) findings also revealed that sociotropy – the additional variable – had a direct effect on BN symptoms and was also associated with the thin-ideal internalization and negative affect. The authors concluded that individuals with higher levels of sociotropy may experience greater pressure from their environment to conform to cultural expectations of thinness. While Duemm et al. (2003) provide preliminary evidence for the inclusion of sociotropy in the DPM, more studies are needed to assess whether sociotropy interacts with other BN risk variables in the DPM.

Hutchinson et al. (2010) conducted a third study with 1094 Australian female adolescents to evaluate the model's core paths, without thin-ideal internalization. They also included additional paths of peer perception of weight-related attitudes and behaviors, teasing, and peer-related eating behaviors. According to Hutchinson et al. (2010), peer influence had a significant relationship with body dissatisfaction

Note: DPM = dual pathway model; BMI = body mass index; DR = dietary restraint; NA = negative affect; BD = body dissatisfaction; BN = bulimia symptoms

and dietary constraint. As hypothesized, negative affect mediated the pathway from body dissatisfaction to BN symptoms. However, contrary to predictions, dietary restraint did not predict BN symptoms, and hence body dissatisfaction was not linked to BN symptoms via the restrained eating pathway. Furthermore, Hutchinson et al. (2010) found no evidence of a connection between dietary restraint and negative affect. This null result, according to Hutchinson et al. (2010), may reflect the possibility that restrained eating may cause negative emotional states in some people, but that if restrained eating is maintained and weight loss is achieved, others may experience a heightened sense of self-control and positive affect. A noteworthy limitation of Hutchinson et al.'s (2010) study was that the observed variance in the BN outcome variable was not reported.

The last two studies by Maraldo et al. (2016); Anbari et al. (2020) undertook considerable additions to the original DPM. The study by Maraldo et al. (2016) replicated and extended the DPM by considering additional constructs that may predict and/or precipitate thin-ideal internalization, namely, fear of negative evaluation, suggestibility, rumination, and self-compassion. Fear of negative evaluation and suggestibility were examined as precursors to thin-ideal internalization, given the substantiated role of fear of negative evaluation in the prediction of disordered eating symptoms (DeBoer et al. 2013), and the role of suggestibility in increasing ones' tendency to be influenced by sociocultural messages purporting the thin ideal (Davison et al. 2000). Furthermore, given that individuals with a ruminative response style may use maladaptive behaviors such as disordered eating to avoid self-directed rumination (Etu and Gray 2010), rumination was examined as a predictor of body dissatisfaction and negative affect, and as a mediator of their associations. Lastly, self-compassion, which has been shown to negatively predict body image and disordered eating concerns (Ferreira et al. 2013), was investigated as a predictor of BD and dietary restraint and as a mediator of their associations.

The study was conducted among 609 women recruited from the community and a university sample. The findings demonstrated that fear of negative evaluation and suggestibility predicted thin-ideal internalization, while rumination and self-compassion (inversely) predicted BD. Fear of negative evaluation, rumination, and self-compassion (inversely) predicted negative affect. Overall, this highlights the need to consider these constructs as individual vulnerability factors that increase the influence of ones' susceptibility to the thin-ideal internalization. One limitation of this study, like Hutchinson et al. (2010), was that the observed variances for each of the outcome variables were unclear.

The final study by Anbari et al. (2020) aimed to determine the DPM of binge eating based on Stice et al.'s (1996) original framework with two proposed additions: self-esteem and fear of negative evaluation. Low self-esteem and fear of negative self-evaluation have been suggested to motivate individuals to seek achievements in a valued domain such as weight and shape, which in turn may lead to unhealthy weight control behaviors (Trompeter et al. 2018). Binge eating occurs when cognitive control of overeating is disrupted.

This extended DPM was tested on 252 female university students with a BMI higher than 25. It was found that neither binge eating nor self-esteem predicted

restrained eating. Fear of negative evaluation predicted binge eating through body dissatisfaction. Binge eating was inversely predicted by self-esteem. The authors concluded that fear of negative evaluation is a vulnerability factor that enhances body image concerns, decreases self-esteem, and leads to binge eating. Once again, the variance accounted for in the binge eating outcome variable was not assessed.

In summary, the five cross-sectional studies have found evidence for the DPM, accounted for between 56% (Duemm et al. 2003) and 71% (Stice et al. 1996) of the variance in the BN outcome measures. However, only two out of the five studies provided data on the variance accounted for by the model in the BN or binge eating outcome variable. While these studies provide preliminary support for the DPM, there are some inconsistencies among them, most notably, regarding the influence of dietary constraint, as noted above. The next section of this review will look at longitudinal research that has investigated the DPM.

Longitudinal Studies

To our knowledge, only five studies (Allen et al. 2012; Puccio et al. 2016b; Puccio et al. 2019; Blodgett Salafia and Gondoli 2011; Stice et al. 1998) to date have employed a longitudinal design using either SEM or path-analysis to assess the validity of the DPM. Table 2 provides an overview of these longitudinal studies.

The model was initially examined longitudinally by Stice et al. (1998). A sample of 218 adolescent females was examined at Time 1 and then again 9 months later at Time 2 to assess BN symptoms. The results showed that the model explained 33% of the variation in BN symptoms, and all paths were significant except for BMI and pressures to be thin. While this study found that dietary restraint and negative affect predicted BN symptoms at follow-up, all the other pathways investigated in the model were cross-sectional. As such, Stice et al.'s (1998) study can only give limited evidence for the original DPM's predictive value.

In a later study, Blodgett Salafia and Gondoli (2011) prospectively investigated the DPM in a sample of grade 5 females over a 4 year period including four assessment points, including baseline. The authors evaluated all factors in Stice et al.'s (1996) original DPM, except for internalization of the thin ideal. Blodgett Salafia and Gondoli (2011) also investigated the impact of mothers, dads, and peers on the emergence of BN symptoms. The DPM was supported in this study, except for the path from T3 dietary restraint to T3 depression, which was not significant. Furthermore, different forms of sociocultural influences (e.g., peers, mothers, and fathers) were associated with a greater risk of developing BN symptoms, with peers having the greatest influence in the model. Because the average age of this sample at baseline was around 10 years, analyses from this study also revealed that these putative risk variables had predictive value during childhood. A limitation of this study was that the study did not provide any data with regard to how much variance was accounted for by each of the outcome variables.

The third longitudinal study of the DPM was conducted by Allen et al. (2012), which evaluated 236 children (48% male, ages 8–13) at baseline (T1), 1 year after

baseline (T2), and then 2 years after baseline (T3). Allen et al. (2012) assessed all factors in the original DPM (Stice et al. 1996), apart from thin-ideal internalization, as did Blodgett Salafia and Gondoli (2011). While Allen et al. (2012) found their model to have an acceptable fit for the data, the following paths were found to be nonsignificant: BMI T1 → pressures to be thin T1 and body dissatisfaction T2 → depressed symptoms T3. It is worth mentioning that Allen et al. (2012) did not examine the effect of T3 dietary restraint on T3 depression. Their model explained 54% of the variance in binge eating symptoms at T3; however, they did not consider compensatory behaviors in their analyses. Therefore, their findings could not be generalized as an etiological model for BN symptoms.

The fourth study by Puccio et al. (2016) aimed to assess the validity of the original DPM (Stice et al. 1996) longitudinally. A total of 247 young females participated in the baseline (T1) and at 1-month follow-up (T2) assessments. A shorter 1-month follow-up timeframe than the previous studies was used in Puccio et al.'s (2016) study to further understand the mediating processes that may contribute to BN symptoms. This decision was made because previous research (Dormann and Griffin 2015) has identified that the optimal time-lags might in fact be shorter (e.g., within the vicinity of months) rather than longer [e.g., within the vicinity of a year(s)]. The aims of Puccio et al.'s (2016) study were twofold: (1) to evaluate the DPM prospectively, considering all components as described by Stice et al. (1996), by looking at the model at baseline (time 1; T1) and dietary constraint, depressive symptoms, and BN symptoms 1 month later (time 2; T2). (2) to test a revised DPM with two additional variables Facebook social comparison and sociotrophy, had an impact on the BN risk factors reported in the model.

Social comparisons made on Facebook were included since previous DPM research was constrained by not measuring modern pressures that women are exposed to, including social media. Given Facebook's apparent global ubiquity, Puccio et al. (2016) contended that it was vital to investigate whether this factor is etiological to BN symptomology by including it in the DPM. In this redesigned DPM, Puccio et al. (2016) examined whether social comparisons on Facebook were associated with body dissatisfaction and thin-ideal internalization. The researchers also aimed to explore whether sociotropy was linked to pressures to be thin, thin-ideal internalization, and Facebook social comparisons. This study was the second study to include the cognitive bias of sociotropy in the DPM, and the authors' rationale for this inclusion was guided by the findings obtained by Duemm et al. (2003) which found sociotropy to be an important variable influencing the DPM.

The findings of Puccio et al.'s (2016) path-analyses revealed that the original and revised DPMs had excellent fit to the data once the respective models were modified. T1 pressures to be thin and T1 thin-ideal internalization were both linked to T1 body dissatisfaction in both DPMs. T1 body dissatisfaction, but not T2 dietary restraint, predicted T2 depressed symptoms and T2 BN symptoms prospectively. Furthermore, T2 dietary restraint was related to T2 BN symptoms, but not T2 depressed symptoms. T2 dietary restraint was also linked to T2 depressive symptoms. For the revised DPM, T1 social comparisons on Facebook were linked to T1 body dissatisfaction, T1 pressured to be thin, and T2 BN symptoms. T1 social comparisons on

Facebook were also related to T1 sociotropy, and T1 social comparisons on Facebook were related to T1 sociotropy. Like Stice et al.'s (1998) study, this study was limited by only assessing certain variables (dietary restraint, depression, and BN symptoms) at T2.

The second study by Puccio et al. (2019) assessed the DPM using the same sample as in their 2016 study but employing a different type of analysis. The first aim of this study was to assess the original DPM (Stice et al. 1996) cross-sectionally and to include a longitudinal extension of the model that examined the bidirectional effects among T1 and T2 symptoms of BN, depression, and dietary restraint. To assess these bidirectional effects, cross-lagged modeling was used to determine if two or more constructs were unidirectionally or bidirectionally connected over time. Cross-lagged modeling is a type of SEM that allows researchers to evaluate non-recursive models (i.e., a postulated relationship between two or more variables assessed at two or more time points and assumed to be reciprocally causal) (Martens and Haase 2006), to look at the stability of constructs over time, simultaneously (cross-sectional) and cross-lagged (longitudinal) direction of effects. This type of analysis is crucial when determining whether the relationship between depression and eating disorders is bidirectional. Figure 2 depicts the cross-lagged DPM model used in Puccio et al.'s (2019) study.

The second goal of Puccio et al.'s (2019) study was to examine whether negative urgency improved the DPM's predictive value over and above the initial bidirectional model described in Fig. 2. A previous meta-analysis by Fischer et al. (2008) found that negative urgency had the strongest association with impulsivity. Furthermore, numerous studies have shown that behaving rashly when experiencing psychological distress/poor affect (i.e., negative urgency) increases the risk of binge eating and purging behavior (Hagan et al. 2021; Magel and von Ranson 2021).

Except for T1 BMI and body dissatisfaction, Puccio et al.'s (2019) model had an excellent fit to the data, indicating that all paths of the DPM described by Stice et al. (1996) were positive and significant. The following paths were also found to be positive and significant in improving the model fit: T1 pressures to be thin → T1 dietary restraint, T1 pressures to be thin → T2 depression, T1 body dissatisfaction → T2 depression, T1 body dissatisfaction →T2 depression, T1 body dissatisfaction →T2 BN symptoms. As a result, the outcomes of this research provided reasonable evidence for the validity of the DPM. There were no bidirectional effects between BN, depression, and dietary restraint in this first model that was evaluated; nevertheless, T1 dietary restraint predicted T2 BN symptoms, and T1 depression predicted T2 dietary restraint. The results for the second goal showed that T1 negative urgency was strongly related to T1 pressures to be thin, T1 body dissatisfaction, and T2 depression, indicating a good model fit for the second model that was examined.

Overall, Puccio et al.'s (2019) model explained 59% and 44% of the variance in T1 and T2 BN symptoms, respectively. These findings suggest that T1 BN symptoms were significantly more explanatory than T2 BN symptoms when considered longitudinally. Regardless, the findings of this study imply that the DPM is a relevant paradigm for BN symptom onset and persistence. The model was also found to

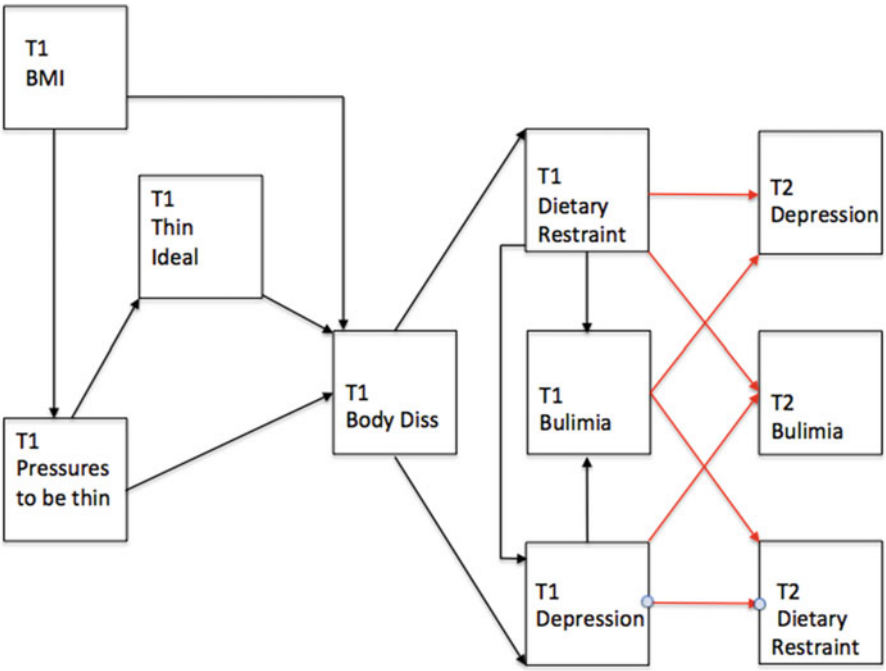

Fig. 2 Cross-lagged model of the DPM assessed in Puccio et al.'s (2019) study. *(Note.* BMI = body mass index; thin ideal = thin-ideal internalization; body diss = body dissatisfaction; bulimia = bulimic symptoms; depression = depressive symptoms; T1 = time 1; T2 = time 2. Black lines represent the original DPM as proposed by Stice et al. (1996). Red lines represent the extended conceptualization of the DPM that includes longitudinal bidirectional effects between symptoms of depression, bulimia, and dietary restraint at T1 and T2)

explain 44% and 63% of the variance in T2 symptoms of depression and dietary constraint, respectively.

Overall, the findings of this study show that early social pressures to be thin, thin-ideal internalization, and higher BMI and body dissatisfaction lead to symptoms of depression, constrained eating, and BN both cross-sectionally and longitudinally. The findings of this study also imply that depression and dietary restraint symptoms occur simultaneously, and that these symptoms lead to BN symptoms, which predict later BN and dietary restraint symptoms.

In conclusion, only a small number of studies ($n = 5$) have used path-models or SEM to examine the DPM over time. Despite differences in conceptualization and assessment of the DPM among individual studies, these studies provide reasonable support for the DPM's central proposition: that the effects of body dissatisfaction on eating pathology are mediated by depression/negative affect and dietary restraint. The overall variance accounted for in BN/binge eating symptoms in these studies ranged from 33% (Stice et al. 1998) for BN symptoms to 54% (Allen et al. 2012) for binge eating symptoms. However, as only three longitudinal studies (Puccio et al.

2016, 2019; Stice et al. 1998) evaluated the full DPM model, further research is needed to see if the model can predict outcomes in a longitudinal design.

A Note on the Predictive Utility of the DPM for BN

As previously stated, preliminary evidence supports the DPM's (Stice et al. 1996) predictive value. The five longitudinal studies that have examined the model using SEMs or path-models (Allen et al. 2012; Puccio et al. 2016b, 2019; Salafia and Gondoli 2010; Stice et al. 1998) have explained between 33% (Stice et al. 1998) and 54% (Allen et al. 2012) of the variation in their individual measures of eating disorder symptoms. This conclusion shows that there are other key risk variables for eating disorders that have yet to be included in the DPM. According to the DPM, BN symptoms are caused by a cascade of cognitive and psychological processes triggered by sociocultural expectations to be thin. While the DPM has shown some predictive utility in limited research, there is a theoretical gap in the model that needs to be addressed: The DPM is unable to explain why only some people who are exposed to sociocultural pressures to be thin develop BN pathology, while most people who are exposed to similar pressures do not.

It is arguable that most, if not all, people in Western civilization are subjected to sociocultural pressure to follow the thin ideal. Despite this, only a small percentage of people will develop eating disorders. The DPM's central hypothesis is that negative affect and dietary restraint mediate the relationship between body dissatisfaction and BN symptoms; however, the model makes no predictions about the factors that predispose a person to transition from body dissatisfaction to restrained eating and/or negative affect. Understanding why only some people with body dissatisfaction develop restrained eating behaviors and negative affect will not only help to improve the model's validity and predictive utility but provide insight into the etiology of BN and therefore, assist in the development of treatment interventions designed to alleviate these eating pathology symptoms.

Limitations of Previous Studies and Future Directions

While the research detailed above has shown support for the predictive utility of the DPM for BN symptoms, these studies are not without limitations.

First, as highlighted above, only five cross-sectional studies (e.g., Duemm et al. 2003; Stice et al. 1996) and five longitudinal studies (e.g., Puccio et al. 2016b, 2019; Stice et al. 1998) have assessed the DPM in its entirety. Given these low numbers, further research is required to assess the entire DPM to determine evidence for its validity and predictive utility.

Second, despite the use of well-validated self-report measures, social desirability bias and mood at the time of assessment may have hindered the validity of the results reported in the different studies. Multiple report methods and/or clinical interviews should be used in future studies to strengthen the current findings.

Third, to date, only a paucity of studies (e.g., Allen et al. 2012; Blodgett Salafia and Gondoli 2011; Stice et al. 1996) have examined the influence of BMI on specific paths within the DPM.Therefore, it is difficult to draw firm conclusions regarding the influence of BMI within the DPM. As such, future studies are required to assess the influence of BMI on the DPM.

Fourth, most studies have relied on female studies, limiting generalizability. As BN symptoms are also prevalent among males (van Eeden et al. 2021), future research should determine whether the revised DPM is also applicable in this sample. Moreover, while the DPM has been associated with a desire to obtain the thin ideal, past research (Yelland and Tiggemann 2003) has identified that many males might also engage in eating pathology behaviors to achieve a muscular physique. Therefore, future research utilizing males as well as females would be beneficial. Such research into the links between the risk factors outlined in the DPM for males might also benefit from utilizing measures that assess eating pathology cognitions and behaviors that focus on the pursuit of muscularity (e.g., the drive for muscularity scale; Yelland and Tiggemann 2003).

Fifth, most studies that examined the DPM assessed either children, adolescents, or very young adults. Thus, to date no study has examined whether the model applies to an older age range of individuals. As research (e.g., Jaite et al. 2013) has found that the age range of onset for meeting criteria for BN is between 20 and 24 years of age, the current literature is limited in that is has yet to examine the validity of the DPM in a sample of older individuals (e.g., aged 40 years and above).

Sixth, while the DPM was originally proposed to be a model that accounts for the development and maintenance of BN symptoms, some studieshave only assessed binge eating (e.g., Allen et al. 2012) and not complete BN symptoms. While these studies have contributed important findings regarding the factors that influence the etiology of eating pathology as assessed via the DPM, further research is required to test the original proposition that the DPM is a model that accounts for the etiology of BN symptoms. Hence, further studies that utilize BN symptoms as the outcome measure for the DPM are required.

Seventh, all cross-sectional and longitudinal studies to date that have assessed the DPM have been nonclinical in nature. It is therefore essential to replicate the DPM model in clinical populations. However, since SEM and path-models require relatively large sample sizes, it can be difficult to obtain these sample sizes through recruitment of tertiary treatment facilities.

Eighth, only one of the longitudinal studies (Puccio et al. 2019) examined the bidirectional relationship between BN symptoms and depression. Given that each of these constructs might be a risk factor for the other (Puccio et al. 2016a), future research should test such bidirectional effects. Future research might also attempt to map more specific affective states onto specific BN behaviors. For instance, depression may be particularly related to binge eating, whereas anxiety is more associated with purging.

Ninth, although some predictive pathways were found in the revised longitudinal DPMs (e.g., Puccio et al. 2016b), many of the conclusions drawn regarding the new constructs were based on cross-sectional data, which precluded causal

understanding. A prospective design with multiple time points might assist in confirming the hypothesized direction of the pathways in these revised DPMs.

Finally, only one study (Puccio et al. 2019) assessed negative urgency as a potential moderating variable. More research should begin to examine factors that might moderate the proposed pathways. Future research should also attempt to provide more integrative analyses of the probably mediational and interactive relations among the putative risk factors for BN.

Clinical and Prevention Implications

The findings of the reviewed studies suggest important implications for future BN preventive efforts. Specifically, since most of the factors in the original and revised DPM have been found to direct or indirect effects on BN risk factors or symptoms, an integrative prevention approach may be required. Indeed, randomized control trials that have focused on the prevention of various BN risk factors (i.e., healthy weight control behaviors, coping skills to challenge pressures, media literacy, and body satisfaction) have shown to reduce BN symptoms in females at 12-month follow-ups (e.g., McVey et al. 2003; Stice et al. 2012). Based on the results from the revised DPMs (e.g., Anbari et al. 2020; Maraldo et al. 2016; Puccio et al. 2016b), future iterations of such preventative efforts could educate women on the deleterious effects of these additional risk factors (e.g., social comparisons on Facebook, fear of negative evaluation, rumination, etc.) may have on body dissatisfaction, dieting, negative affect, and BN symptoms.

In addition, the current findings also highlight the need for preventative efforts to identify individuals scoring high on certain personality traits (e.g., sociotropy and negative urgency) to assess which individuals might be more susceptible for these BN risk factors and tailor prevention efforts accordingly. For instance, people scoring high on sociotropy could learn to become less dependent on others for approval and challenge peer-related pressures to be thin (Puccio et al. 2016b). In terms of negative urgency, interventions could help individuals to regulate negative emotions efficiently to prevent them to act rashly during times of distress and therefore reduce bingeing/purging symptomatology (Puccio et al. 2019). Overall, lowering all these different facets of the DPM could be instrumental in helping reduce the risk of future BN symptoms in women.

Conclusions

The present chapter provides a review of the DPM for BN symptoms by first outlining the key risk factors included in the DPM and then presenting a narrative review of the studies that have empirically assessed the DPM using either path-analyses or SEMs. A total of ten studies were retrieved that have assessed the DPM in its entirety, five of which were cross-sectional and five longitudinal. Overall, the findings from the identified studies provide support for most of the pathways

outlined in the DPM; however, the predictive capacity of the assessed models suggests that the DPM is not able to explain the full occurrence of BN symptoms. It is hoped that upcoming research can assist in informing future preventive efforts for BN risk factors, with the hope that the DPM might become broader. Some promising extensions of the DPM have already been suggested and tested. It would be important for future studies to agree on the additional key factors so that standardized research on these new facets in addition to the original DPM can be conducted. Finally, for our understanding of the development of BN symptomology to progress, further research is needed to clarify the direction of effects between the risk factors outlined in the original and revised versions of DPM.

Applications to Other Eating Disorders

In the current chapter, we reviewed studies that replicated and/or extended the original DPM of BN (Stice et al. 1996). Empirical evidence has shown that variables within the DPM (i.e., sociocultural pressure to thin, thin-ideal internalization, body dissatisfaction, negative affect, and dietary restraint) are risk factors not only for BN but also for other eating disorders such as anorexia nervosa (Ahern et al. 2008; Urvelyte and Perminas 2015), binge eating disorders (Allen et al. 2012), and other specified feeding and eating disorders [which have many features in common and high rates of diagnostic crossover (Fairburn and Harrison 2003)]. These variables are also known risk factors for subclinical forms of eating disorders among community/nonclinical samples (Quick and Byrd-Bredbenner 2013). Specifically, both thin-ideal internalization and initial pressure to be thin predicted subsequent increase in body dissatisfaction, initial body dissatisfaction is a precursor for dieting and negative affect, and initial dieting and negative affect predicted growth in anorexia nervosa, BN, and binge eating disorder symptoms. Hence, it is tempting to speculate that Stice et al.'s (1996) original DPM may also be applicable to a broader range of clinical eating disorders and disordered eating symptoms beyond BN. This has implications for enhancing understandings of the etiology of all type of eating disorders and disordered eating symptoms, as well as the factors underpinning their diagnostic crossover,therefore informing potential prevention and early intervention strategies that prevent against the likelihood of ominous consequences associated with eating pathology.

Mini-Dictionary of Terms

Body dissatisfaction – dissatisfaction with one's weight, shape, and/or size.

Body mass index – is calculated by dividing the body mass by the square of the body height and is given in kilograms per square meter.

Bulimia nervosa – is an eating disorder characterized by binge eating and purging behaviors.

Depression – is a mood disorder characterized by persistent feeling of sadness and loss of interest that affect everyday functioning.

Dietary restraint – the conscious efforts to lose weight by achieving a negative energy balance between calorie intake and expenditure.

Negative affect – an internal feeling that takes place when one has failed to achieve a goal or has avoided a threat.

Path-analyses – is a statistical analysis used to assess the interrelationship among observed variables.

Structural equation modeling – is a statistical analysis used to assess the interrelationship among observed and latent variables.

Sociocultural pressures – external media and interpersonal (parents and peers) influences which generate and diffuse unrealistic body-shape ideals.

Thin-ideal internalization – the extent to which an individual subscribes/aspires to the cultural standard of thinness.

Key Facts

- A higher BMI is supposed to increase one's chance of developing disordered eating symptoms.
- Pressures to be thin from peers, parents, and the media have been linked to all variables included in the DPM.
- Thin-ideal internalization, body dissatisfaction, and dietary restraint are the most prominent risk factors for eating disorders.
- Disordered eating symptoms lead to negative affect/mood and negative affect/mood to disorder eating symptoms.
- The dual pathway model is an etiological model for BN.

Summary Points

- The DPM is a prominent model to explain the multifaceted etiological relationship of various BN risk factors.
- The current review found a total of ten studies that assessed the DPM in its entirety, five of which were cross-sectional and five longitudinal.
- The findings from the identified studies provide support for most of the pathways outlined in the DPM for the cross-sectional and longitudinal studies.
- The predictive capacity of the assessed models suggests that the DPM is not able to explain the full occurrence of BN symptoms.
- Some promising extensions of the DPM have already been suggested and successfully tested.

Contents

Abstract

Bulimia nervosa (BN) is characterized by cycles of recurrent episodes of binge eating and compensatory behavior, i.e., vomiting, in order to prevent weight gain. In women, the peak incidence of BN is between 15 and 29 years of age, signifying

the importance to understand the impact of the disease on reproductive function, pregnancy, and postpartum period *and* how children to mothers with eating disorders are affected. Bulimia nervosa is associated with menstrual disturbances, which commonly are attributed to either functional hypothalamic amenorrhea or polycystic ovary syndrome, and hence impaired fertility.

On long term, women with BN seem to have similar reproductive outcomes as healthy women. Importantly, pregnancy constitutes a vulnerable time period and could affect the disease course among women with ongoing disease and possess a relapse risk for women with previous disease. Consequently, it is important to identify these women in maternal healthcare in order to provide adequate support and management to prevent adverse outcomes. Maternal bulimia nervosa is associated with several adverse pregnancy-related outcomes, including anemia, hyperemesis gravidarum, gestational diabetes, and premature delivery. Children to mothers with eating disorders seem to suffer from an increased risk of developing specific conditions throughout childhood. This chapter reviews available evidence on the impact of bulimia nervosa on fertility, pregnancy, and postpartum period and childhood health.

GnRH	Gonadotropin-releasing hormone
HG	Hyperemesis gravidarum
LH	Luteinizing hormone
PCOS	Polycystic ovary syndrome
SGA	Small for gestational age
SHBG	Sex hormone-binding globulin

Introduction

Despite that women with bulimia nervosa (BN) commonly are of normal weight, the prevalence of menstrual dysfunction in BN is high. Periods of starvation can induce functional hypothalamic amenorrhea (FHA) by a similar mechanism as seen in women with anorexia nervosa (AN). BN is additionally linked to polycystic ovary syndrome (PCOS), characterized by hyperandrogenism and oligo- or anovulation.

Pregnant women with ongoing or previous BN suffer from an increased risk of multiple pregnancy complications and are likewise at increased risk of impaired exacerbation of eating disorder symptoms and depression in the postpartum period. Therefore, early identification of women with BN in fertility and antenatal maternal healthcare is essential in order to provide adequate advice, treatment, and intensified support throughout the pregnancy and postpartum period.

Bulimia Nervosa and Fertility

The prevalence of secondary amenorrhea among women with bulimia nervosa (BN) is higher (between 7% and 40%) (Kimmel et al. 2016) compared with the general population, and many bulimic women suffer from oligomenorrhea (irregular menstruations with long intervals). Whereas the amenorrhea among women with anorexia nervosa (AN) is mainly explained by functional hypothalamic amenorrhea (FHA), amenorrhea in BN may have various etiologies. FHA is characterized by a hypothalamic inhibition of the reproductive system induced by energy deficit and is described in detail in chapter "Anorexia Nervosa and Reproductive Health". The temporary starvation periods between binge-eating episodes, which are characteristic of BN, may result in FHA and consequently amenorrhea and infertility. In fact, endocrine disturbances, including low levels of estradiol, gonadotropins, and thyroid hormones, have been observed in women with BN. In addition to FHA, BN has been associated with polycystic ovary syndrome (PCOS), a hormonal aberration characterized by oligo- or amenorrhea.

Polycystic Ovary Syndrome

PCOS is a common endocrinopathy in reproductive-aged women, with a reported prevalence of between 6 and 16% in population-based studies (Li et al. 2013; Lizneva et al. 2016). PCOS is characterized by oligo- or anovulation, hyperandrogenism, and numerous small ovarian cysts (Goodarzi et al. 2011). The Rotterdam consensus diagnostic criteria are used for diagnosis and include (i) oligo- or anovulation, (ii) clinical or biochemical hyperandrogenism, and (iii) polycystic ovarian morphology (Table 1). Fulfilment of two out of three diagnostic criteria is

Table 1 Diagnostic criteria of PCOS according to Rotterdam consensus

Two of three criteria necessary for PCOS diagnosis
I. Oligo- or anovulation.
II. Clinical and/or biochemical hyperandrogenism. *Clinical signs = hirsutism, acne* *Biochemical = elevated FAI (S-testosterone > SHBG)*
III. Polycystic ovarian morphology (PCOM) on ultrasound.

PCOS, polycystic ovary syndrome; FAI, free androgen index; PCOM, polycystic ovary morphology; SHBG, sex hormone-binding globulin

needed for diagnosis (Rotterdam 2004). Given the heterogenous presentation of PCOS, further stratification into distinct phenotypes based on prevalent Rotterdam criteria is recommended (The not fully known etiology of PCOS is presumably multifactorial and involving both environmental and genetic factors. A reported aggregation of PCOS within families and first-degree relatives implies a genetic predisposition (Yildiz et al. 2003). The syndrome is frequently associated with the metabolic syndrome, including insulin resistance, abdominal obesity, and dyslipidemia (McCartney and Marshall 2016).

PCOS is characterized by hypothalamic dysfunction, but it is not known whether the dysfunction is primary or rather secondary as a consequence of abnormal steroid feedback. Regardless of etiology, the altered GnRH pulsatility in PCOS leads to increased levels of luteinizing hormone (LH) in relation to follicle-stimulating hormone (FSH). The altered LH:FSH ratio results in an increased production of androgens within the ovaries and a decreased ovarian conversion of androgens into estradiol (Goodarzi et al. 2011). High intraovarian levels of androgens lead to follicular atresia and anovulation. Circulating high levels of androgens leads to dyslipidemia (increased levels of low-density lipoprotein [LDL], triglycerides, and total cholesterol and decreased levels of high-density lipoprotein [HDL]), acne, and hirsutism. In the periphery, circulating androgens are converted into estrogens, in particular in adipose tissue, and conversion is therefore amplified in obese patients. Hyperinsulinemia further stimulates the androgen production and suppresses the production of sex hormone-binding globulin (SHBG) in the liver, resulting in even higher androgen levels. The constant conversion of androgens into estrogens leads to unfluctuating high estrogen levels and a constant, nonfluctuating feedback to the hypothalamus and pituitary gland, which further disrupts the secretion of gonadotropins. Constant increased levels of estrogens promote endometrium hyperplasia resulting in an increased risk of endometrial abnormalities, including malignancies (Goodarzi et al. 2011; McCartney and Marshall 2016) (Fig. 1).

Polycystic Ovary Syndrome in Bulimia Nervosa

Bulimia nervosa is associated with PCOS, but the direction of the association is unclear. PCOS could be a consequence of the abnormal eating behavior in BN; alternatively, hyperandrogenism may predispose of the key symptoms of BN. In fact, appetite regulation is frequently disturbed among women with PCOS, and the prevalence of eating disorders in PCOS is increased (Hirschberg et al. 2004; Thannickal et al. 2020). Vice versa, there is an increased prevalence of PCOS features, including polycystic ovaries, acne hirsutism, and biochemical hyperandrogenism, in women with BN (McCluskey et al. 1992; Naessen et al. 2006).

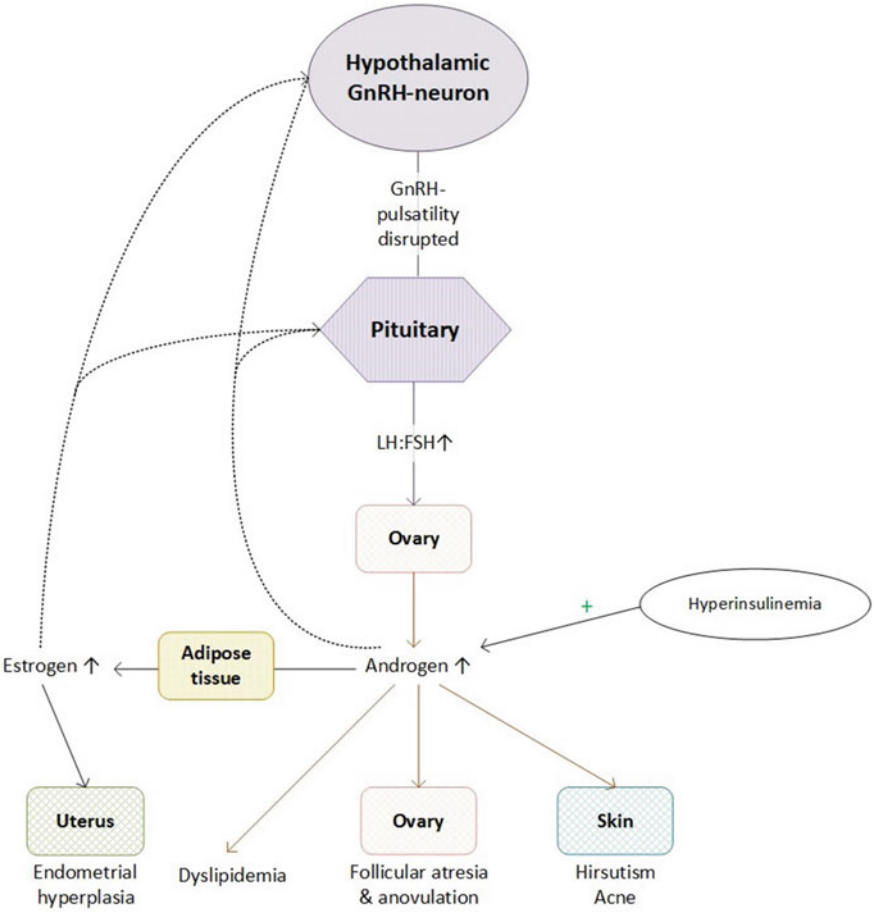

Fig. 1 Overview of pathophysiology in PCOS

Management and Treatment of Amenorrhea in Bulimia Nervosa

Oligo- or amenorrhea occurs frequently in women with BN, and as previously discussed, the most common underlying conditions are FHA and PCOS. In order to distinguish between the two and to rule out alternative or concomitant conditions, medical assessment including endocrine evaluation is necessary. FHA, which is described in detail in chapter on "Anorexia Nervosa and Reproductive Health," is characterized by low levels of gonadotropins, estradiol, and thyroid hormones, whereas PCOS is characterized by an increased LH:FSH ratio, high testosterone level, and low levels of SHBG (Phylactou et al. 2021). The endocrine differences between FHA and PCOS are summarized in Table 2.

Women with BN and FHA should be managed as women with AN and FHA (chapter "Anorexia Nervosa and Reproductive Health"), i.e., focusing on

Table 2 Clinical and biochemical differences between functional hypothalamic amenorrhea and polycystic ovary syndrome

	Polycystic ovary syndrome	Functional hypothalamic amenorrhea
Primary symptom	Oligo- or amenorrhea	Amenorrhea more common than oligomenorrhea
BMI	↑→	↓
Ovary morphology	Polycystic	N/A
Endometrial thickness	↑	↓

management of disordered eating and restoring energy balance. In women with BN and PCOS, treatment depends on the woman's goal in combination with endocrine aberrations and BN disease severity. Focusing on recovery from BN should be prioritized. Antiandrogenic combined oral contraceptives regulate menstruation, improve hirsutism and acne, and may additionally improve bulimic symptoms. Antiandrogenic oral contraceptives have been reported to improve eating behavior in women with BN (Naessen et al. 2007). In anovulatory infertility, ovulation could be stimulated using letrozole or clomiphene citrate (Legro et al. 2013). Metformin may improve ovulatory function and is recommended for women with PCOS and type 2 diabetes or insulin resistance (Conway et al. 2014).

Long-Term Effect on Fertility

In FHA, the menstrual function commonly normalizes with nutritional restoration and fertility naturally restores. PCOS expression seems to decline with increasing age and leading to normalized menstruation (Welt and Carmina 2013). It has been reported that women with PCOS have similar birth rates as women with normal ovulation (Forslund et al. 2019), but one study reported a lower rate of ≥2 deliveries in women with a PCOS history compared to PCOS-free controls (West et al. 2014). The specific long-term effect of FHA or PCOS in combination with BN has not been investigated. Compared to women with AN, women with BN seem to experience a more moderate reduction and delay in reproduction, and one study has reported that women with BN have similar reproductive outcomes as their discordant sisters (Tabler et al. 2018).

The Prevalence of Bulimia Nervosa in Pregnancy

Few studies have investigated the incidence of BN. Depending on the study setting and case definition, the reported incidence varies between 20 and 180 BN cases per 100,000 person-years in the general population, and the peak age of incidence is between 15 and 29 years (van Eeden et al. 2021). In contrast to AN, which seems to be increasing over time, the incidence of BN has reported to be declining in all age groups, except among girls between 10 and 14 years of age where an increasing trend has been observed (Reas and Ro 2018).

The lifetime prevalence of BN is between 0.3% and 4.6% (Galmiche et al. 2019).

The prevalence of BN in pregnancy has not been addressed specifically, but based on studies on eating disorders and pregnancy outcomes, the estimated prevalence of BN (past or current) in pregnancy is between 0.1% and 0.9% in studies using registered diagnosis as case definition (Ante et al. 2020; Eik-Nes et al. 2018; Mantel et al. 2020; Perrin et al. 2015). In studies identifying BN using diagnostic interviews or questionnaires, the self-reported prevalence is, slightly higher, between 0.7% and 1.3% (Easter et al. 2014; Micali et al. 2016; Popovic et al. 2018).

Disease Course in Pregnancy and Pregnancy and Perinatal Outcomes in BN

In similarity with AN, the recovery from BN is gradual, and one third of bulimic women have persistent eating disorder (Treasure et al. 2020). A high frequency of BN relapse in pregnancy among women with disease remission prior to pregnancy has been reported (Koubaa et al. 2005; Makino et al. 2020). In contrast, other studies have reported a continuation of eating disorder symptoms during pregnancy, but an improvement of symptom severity, in pregnancy among women with ongoing eating disorder (Blais et al. 2000; Micali et al. 2007b). Pregnant women with eating disorders, including BN, have a high prevalence of coexisting psychiatric disorders, including depression and anxiety (Bye et al. 2020; Mantel et al. 2020).

Maternal eating disorder is associated with several adverse pregnancy outcomes. Multiple studies have assessed the impact of AN or composite eating disorder exposure on pregnancy and perinatal outcomes, making it difficult to extrapolate these results to BN. In general, the increased risks of adverse pregnancy and perinatal outcomes seem to be more moderate in maternal BN compared with maternal AN, but still the risks of several outcomes are significantly increased. Women with BN are at increased risk of miscarriage (Micali et al. 2007a; Morgan et al. 2006).

Anemia during pregnancy is a more common finding in women with current or past BN compared to healthy pregnant women (Mantel et al. 2020), as is gestational diabetes (Morgan et al. 2006; Watson et al. 2017). Some studies have found an association between maternal BN and risk of preeclampsia (Eik-Nes et al. 2018), while others have not (Mantel et al. 2020).

Women with BN are at increased risk of developing hyperemesis gravidarum (HG) (Koubaa et al. 2005; Mantel et al. 2020; Morgan et al. 2006), a severe form of

Table 3 Overview of adverse pregnancy and perinatal outcomes in women with bulimia nervosa and anorexia nervosa

↑ indicates increased risk of outcome in women with bulimia nervosa (or their neonate), and → indicates no difference in outcome in women with bulimia nervosa compared to women without eating disorder

nausea and vomiting in pregnancy, which is described in detail in the chapter on "Anorexia Nervosa and Reproductive Health".

In contrast to AN, which has been associated with antepartum hemorrhage, placenta abruptio, and acute liver failure (Ante et al. 2020; Mantel et al. 2020), BN has not. In similarity with AN, mode of delivery does not seem to differ between women with BN and women without eating disorders, and likewise, women with BN are not at increased risk of postpartum hemorrhage.

Pregnant women with BN are at moderately increased risk of delivering prematurely (before 37 gestational weeks) (Mantel et al. 2020; Morgan et al. 2006). BN does not seem to be associated with fetal growth restriction in general, but is associated with an increased risk of delivering neonates with a small head circumference (Eik-Nes et al. 2018; Koubaa et al. 2005; Mantel et al. 2020; Micali et al. 2016).

Neonates to mothers with BN have similar Apgar scores as neonates to healthy mothers (Mantel et al. 2020) (Table 3).

The Postpartum Period

The postpartum period has been reported to constitute a high-risk time for relapsing or experience deterioration of eating disorder symptoms (Micali et al. 2007b), and eating disorder history independently predicts the risk of developing postpartum depression (Johansen et al. 2020).

Several studies with conflicting results have investigated breastfeeding pattern in women with eating disorder. Most studies have not observed a major difference in initiation or cessation of breastfeeding in mothers with BN (Micali et al. 2007b; Torgersen et al. 2010) compared with healthy mothers. However, feeding difficulties seem to be more common in infants to bulimic mothers (Micali et al. 2009), and maternal BN has been associated with infant overweight (Micali et al. 2009).

Children to Mothers with Eating Disorders

Understanding the risk of adverse outcomes in children to mothers with eating disorders and identifying factors mediating these risks are of importance to provide sufficient resources and to identify potential key preventive interventions. There are indications of an increased risk of various adverse health outcomes among children to mother with BN. A recent systematic review has compiled existing studies on maternal eating disorder and childhood development. Children to mothers with BN seem to have a higher degree of early developmental difficulties, including poorer motor, language, and social development, compared with children to mothers without eating disorder. Additionally, hyperactivity and peer difficulties are more common in children to bulimic mothers, as are anxiety and obsessive-compulsive symptoms (Martini et al. 2020). In a large population-based study, maternal BN was associated with an increased risk of autism spectrum disorder and attention-deficit/hyperactivity disorder (Mantel et al. 2022). Factors driving the association between maternal eating disorders and increased risk of offspring developmental impairment are presumably a complex interplay between genetic and environmental factors.

One study has investigated the impact of maternal BN on childhood respiratory morbidity and found that maternal BN is associated with an increased risk of early childhood wheezing. Additional studies on long-term consequences on childhood health are lacking, but warranted.

Management of Pregnant Women with Bulimia Nervosa

In similarity with AN, BN is associated with an increased risk of menstrual disturbances and multiple adverse pregnancy and perinatal outcomes. Therefore, the recommendations on management of pregnant women with BN are virtually analogous to the management of women with AN.

Among women with infertility planning to conceive with prevalent eating disorder, focusing on treatment of the eating disorder is essential due to the associated risks in pregnancy. Advice and education on the importance of an adequate weight and nutritional intake and well-being prior to attempting to conceive is recommended to increase the likelihood of conception and promote a healthy pregnancy (NICE 2020).

In many countries, a routine enquiry of ongoing and previous mental illness, including eating disorder, is recommended for all women enrolling in antenatal

maternity healthcare. It is important to acknowledge that women with eating disorder may be reluctant to share their ongoing or previous eating disorder to health professionals. The stigma surrounding eating disorders and feelings of shame are patient-related factors known to impede health seeking for eating disorders in general (Ali et al. 2017). Additionally, among health professionals in maternal healthcare, lacking of confidence, due to insufficient professional training, has been reported to hamper the identification of pregnant women with eating disorders (Bye et al. 2018). Keeping the many barriers for acknowledging pregnant women with eating disorders in mind, focus on a nonjudgmental and delicate enquiry when screening for eating disorders is important (Bye et al. 2018).

Women, who disclose an ongoing or previous eating disorder, should be regarded as a risk population during pregnancy and postpartum period and be offered intensified support throughout the pregnancy. An early pregnancy appointment with an obstetrician for assessment of the patient's physical and mental health is recommended. Depending on whether the eating disorder is ongoing or past, the co-occurrence of other psychiatric diseases, the severity of the disease, and the patient's individual need and wish, a tailored follow-up scheme should be developed. A low threshold for referral to specialized eating disorder unit (or perinatal specialist mental health service if not available) is preferable during the pregnancy and postnatal period. Referral to a curator or psychologist, specialized in management of eating disorders, is another alternative. In order to provide information on the importance of adequate nutrition and nutritional support and pregnancy-adjusted exercise during pregnancy, referral to nutritionist and physiotherapist should also be considered. Intensified frequency of antenatal visits to midwife with a focus on continuity of care in order to facilitate identification of altered patient well-being throughout pregnancy is preferable. In agreement with the patient, frequent weight measurements are recommended in conjunction with the antenatal visits. Underweight patients (BMI <18.5) and patients with insufficient weight gain or patients with weight and shape change preoccupation are alarming signs of relapsing or uncontrolled disease and hence reasons for concern. BN is not associated with fetal growth restriction, and extra fetal growth scan is indicated in pregnant women with BN as well, in particular among women with poor gestational weight gain. Clearly, women with severe eating disorder presentation during pregnancy should be managed by a multidisciplinary team involving specialized obstetric, internal medicine and psychiatric care.

In light of the increased risk of deteriorated eating disorder symptoms, disease relapse, depression, and anxiety and attachment difficulties postnatally, the intensified support should continue for up to 1 year postpartum (NICE 2020) (Fig. 2).

Applications to Other Eating Disorders

In this chapter we have reviewed the impact of bulimia nervosa (BN) on fertility, pregnancy, postpartum period, as well as neonatal and child health. There is a separate chapter reviewing the impact of anorexia nervosa (AN) on fertility,

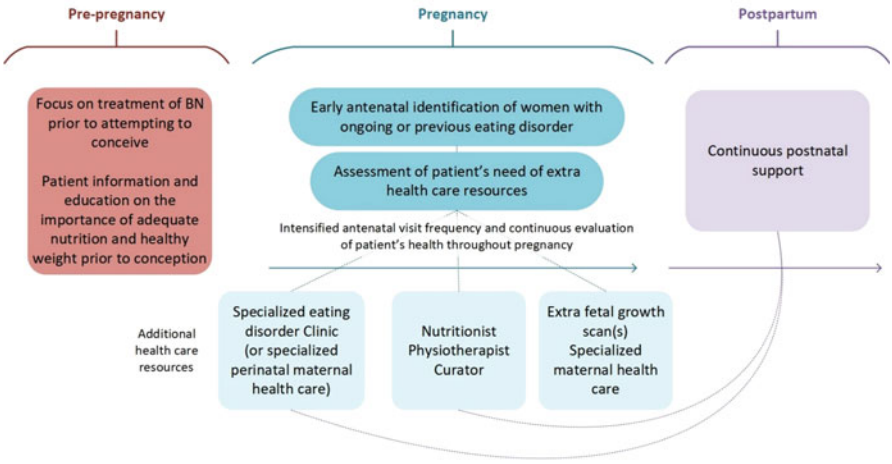

Fig. 2 Overview of clinical management of women with bulimia nervosa prior to pregnancy and during the pregnancy and postpartum period

pregnancy, postpartum, and child health. In brief, the prevalence of amenorrhea among women with BN is higher compared with the general population but lower compared to women with AN. Periods of starvation in BN could induce functional hypothalamic amenorrhea by similar mechanism as among women with AN, but BN is additionally associated with polycystic ovary syndrome (PCOS), which is characterized by oligo- or amenorrhea. Women with BN are at increased risk of several adverse pregnancy and perinatal outcomes, but not to the same extent as women with AN. Moreover, there is evidence of separate distinct neurocognitive phenotypes in AN versus BN, which is likely to partly explain some of the differences in childhood developmental outcomes. Hence, the information within this chapter can only partly be transferable to women with AN. Moreover, a majority of studies have focused on women with specific eating disorders such AN or BN, wherefore it is difficult to extrapolate results to women with unspecified eating disorders. There are however indications of similar rates of adverse pregnancy and perinatal outcomes among women with unspecified eating disorder as women with AN.

Key Facts

Key Facts of Amenorrhea in Bulimia Nervosa

Menstrual disturbances are common symptoms in women with bulimia nervosa and are usually caused by functional hypothalamic amenorrhea (FHA) or polycystic ovary syndrome (PCOS).

In FHA, stress and energy deficit induce an aberration in the hormonal regulation of the menstrual cycle, by interfering with the release of regulating hormones from the hypothalamus and pituitary, leading to amenorrhea and consequently infertility.

First-line treatment of FHA consists of treating underlying eating disorder and restoring the energy balance, which normalized the menstruation and restores fertility.

PCOS is characterized by hyperandrogenism, oligo- or anovulation, and polycystic ovarian morphology.

Key Facts of Pregnancy and Perinatal Outcomes in Women with Bulimia Nervosa

Women with bulimia nervosa might experience improved or deteriorated eating disorder symptoms throughout pregnancy.

Anemia and gestational diabetes are more common in pregnant women with bulimia nervosa compared with healthy pregnant women.

Pregnant women with bulimia nervosa are at moderately increased risk of preterm delivery, and their children more commonly have a small head circumference as compared to healthy women.

Key Facts of Management of Pregnant Women with Bulimia Nervosa

Among pregnant women, ongoing, recent, or previous bulimia nervosa should be identified and acknowledged in antenatal screening.

Given the association between bulimia nervosa and increased risk of adverse pregnancy, neonatal, postpartum, and child outcomes, pregnant women with bulimia nervosa should be considered a high-risk population.

Pregnant women with ongoing or previous bulimia nervosa should be offered additional support throughout pregnancy, including psychologist or psychiatrist contact, nutritional support and intensified follow-up, extra growth ultrasound in third trimester, and earlier postpartum follow-up.

Summary Points

- Menstrual disturbances are common symptoms in women with bulimia nervosa (BN) and commonly attributed to either functional hypothalamic amenorrhea (FHA) or polycystic ovary syndrome (PCOS).
- FHA and PCOS are diagnosed, and differentiated between, by careful examination, including endocrine evaluation.
- First-line treatment of FHA consists of restoring energy balance, leading to normalized menstruation and fertility.

- Some women with bulimia nervosa experience improvement of eating disorder symptoms during pregnancy, whereas others experience deterioration of eating disorder symptoms throughout the pregnancy.
- Pregnant women with bulimia nervosa are at increased risk of several pregnancy complications, including anemia, hyperemesis gravidarum, and gestational diabetes.
- Maternal bulimia nervosa is associated with adverse perinatal outcomes, including preterm delivery and low head circumference in their neonates.
- Depressive and anxiety symptoms are more common among women with bulimia nervosa in the postpartum period.
- Feeding difficulties are more common in children to mothers with bulimia nervosa.
- Children to mothers with bulimia nervosa are at increased risk of impaired neuropsychiatric and cognitive development and more likely to seek healthcare for childhood wheezing.
- Pregnant women with recent or previous bulimia nervosa should be recognized as a high-risk population in antenatal screening and offered additional appropriate healthcare resources.

Binge Eating Disorder

Long-Term Outcome of Inpatients and Outpatients with Bulimia Nervosa

47

Norbert Quadflieg

Contents

Abstract

The long-term outcome of bulimia nervosa is highlighted from several perspectives. The percentage of patients not meeting criteria for bulimia nervosa at follow-up varied widely over studies with no recognizable temporal pattern. Relapse after remission was frequent. About 10 years after treatment, remission seems to get increasingly rare in bulimia nervosa. Poor outcome at follow-up was found in the long run in one third to one half of the patients treated for BN. Compared to the general population, all-cause mortality was elevated in bulimia nervosa increasing the risk of death for bulimia nervosa patients by 50%.

https://doi.org/10.1007/978-3-031-16691-4_51

Compared to anorexia nervosa, bulimia nervosa is associated with less mortality but is nevertheless a severe eating disorder. Judging from the rare studies on males with bulimia nervosa, there seems to be no larger differences in the outcome of bulimia nervosa between males and females.

Introduction

Bulimia nervosa (BN) is an eating disorder which was introduced as a separate entity only some 40 years ago (Russell 1979). This limits the number of outcome studies, and some clarifications are in order to define the meaning of key terms for this chapter. Long-term outcome is meant to describe the status of a patient beyond the end of treatment. This may involve a time period as short as several months or as long as several decades. To reflect a real long-term outcome – and based on the studies available – this chapter includes studies with at least 5 years of follow-up.

Although findings are very limited for some areas, outcome in this chapter includes the status of the eating disorder at follow-up as well as some aspects of social functioning and, as the worst possible outcome, mortality. The spectrum of symptoms in BN includes both behavioral (binge eating and compensatory behavior) and psychological symptoms (e.g., focus on avoiding weight gain, body weight and shape as a central aspect of self-evaluation). As behavioral symptoms remit earlier than psychological symptoms (Clausen 2004), it is important to include both aspects in the definition of eating disorder outcome (Bardone-Cone et al. 2010; Richmond

et al. 2020). The best approach to reflect both aspects in the same outcome measure seems to be eating disorder diagnosis, and this is what is used in this review.

One outcome category not included in this review is partial remission. While improving on the severity of the eating disorder is important for the patient, their caregivers, and the therapists, this category is often not clearly defined in the literature. For example, some studies define the change from BN to eating disorder not otherwise specified (ED-NOS) as partial remission, while other studies with well-founded rationale (see Crow et al. 2009) include ED-NOS as a diagnosis of eating disorder.

Additionally, studies on inpatient and outpatient treatment are included without differentiating between these treatments in reporting outcome. The decision of treating BN patients as outpatients or inpatients depends heavily on the healthcare system of a specific country and does not necessarily reflect symptom severity.

The Studies

A total of 21 studies were included in this review. Table 1 gives an overview of the study characteristics. For several studies, more than one key publication is available, and this is shown in the table. Some studies reported outcome for more than one follow-up. Most studies focused on females, and some studies included females and mostly a rather small and unspecified number of males. Only one study reported on a larger number of males with BN.

One study used clinical charts to establish eating disorder diagnoses, while the other studies followed the criteria published in the *Diagnostic and Statistical Manual of Mental Disorders*, third (*DSM-III*; American Psychiatric Association 1980), third revised (*DSM-III-R*; American Psychiatric Association 1987), fourth (*DSM-IV*; American Psychiatric Association 1994), or fifth (*DSM-5*; American Psychiatric Association 2013) edition.

Remission from Bulimia Nervosa

A necessary requirement for recovery is achieving absence of illness symptoms. For eating disorders this is a requirement rarely achieved completely, as eating includes a broad spectrum of behaviors and attitudes towards food and eating. The intake of food is a behavior that cannot be ceased completely, so there is always the possibility for intervening disturbance. Consequently, remission from BN often includes some residual symptoms, an implication also applying to the outcome measure of eating disorder diagnosis. One major issue concerns the length of symptom-free interval to declare a patient recovered. While the authors of the large study from Boston (initiated by David Herzog; long-term outcome published by Eddy et al. 2017) recommended 6 months of absence of symptoms for the definition of recovery (De Young et al. 2020), shorter intervals are common, and many studies do not define the symptom-free interval at all.

Table 1 Studies on the long-term outcome of bulimia nervosa. This table lists all long-term outcome studies of bulimia nervosa included in this review. In these studies outcome was assessed after a minimum of 5 years after treatment. Several studies reported more than one follow-up with different time points. The diagnostic system refers to the *Diagnostic and Statistical Manual of Mental Disorders*, third (*DSM-III*), third revised (*DSM-III-R*), fourth (*DSM-IV*), and fifth (*DSM-5*) edition, published by the American Psychiatric Association in 1980, 1987, 1994, and 2013, respectively

Remission rates (absence of an eating disorder diagnosis at follow-up) varied widely from 20% to 77% (Table 2). One obvious assumption would be to find increasing remission rates with increasing length of follow-up. As Fig. 1 illustrates, however, this is not the case. The highest remission rates (above 70%) were reported for follow-up intervals of 5 (Ben-Tovim et al. 2001), 9 (Reas et al. 2000), and 10–15 (Abraham 1998) years, while the lowest remission rates (below 30%) were found 5 (Van Son et al. 2010) years, 7 (Hergenroeder et al. 2015), and 17 (Eielsen et al. 2021) years after treatment. Interestingly, one study found the identical remission rate of 68% at the 9- and 22-year follow-up in the same sample of treatment-seeking females (Eddy et al. 2017). Similarly, the remission rate was nearly identical at 6-year (67%) and 12-year (66%) follow-up in the same inpatient sample (Fichter and Quadflieg 2004). Actually, no temporal pattern of remission is identifiable at this time, but we may cautiously conclude that with increasing length of observation, improvement and remission are found more often in these patients (Herzog et al. 1999). However, concluding from a few studies, after about ten years, additional remission seems to get increasingly rare in BN.

Two studies covered very long follow-up intervals of more than two decades. In a subgroup from a large sample of inpatients, Quadflieg and Fichter (2019) found 42% recovered after 21 years, and Eddy et al. (2017) reported 68% recovered in their treatment-seeking sample after 22 years. Clearly, more very long-term studies are needed to explain this discrepancy.

A different approach to follow-up is observing remission not at the time of follow-up, but at any time point of the follow-up period. The Boston study reported recovery in 73% of treatment-seeking females at some time point of the 7.5-year follow-up interval. Over this time 35% relapsed into BN again after recovery (Herzog et al. 1999).

Persistence of Bulimia Nervosa at Follow-Up

A certain proportion of patients treated for BN retained this diagnosis at follow-up. While it is generally unclear if this diagnosis was present throughout the entire follow-up period, or was present again at follow-up after periods without the diagnosis, both variants reflect a chronic state of BN. As with remission, rates of chronic BN varied widely between studies (Table 3). With one exception (Tseng et al. 2004), all studies reported less than a quarter of the patients having BN at follow-up. Again, as illustrated in Fig. 2, there is no evident temporal pattern of chronicity of BN. In the

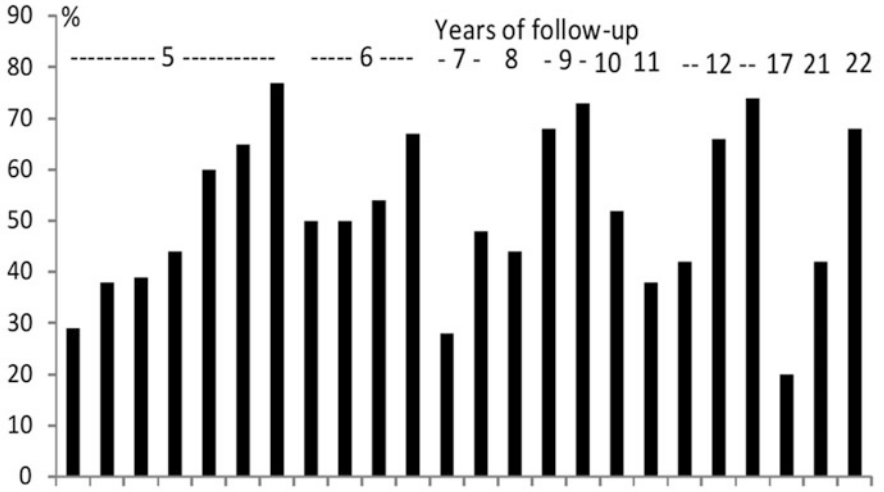

Fig. 1 Remission from eating disorder at follow-up. The percentage of patients remitted from bulimia nervosa and who had not switched to another eating disorder at follow-up is shown by the height of the bars. Bars are organized according to length of follow-up and within this category by the value of percentage. Each bar represents one study

study of Quadflieg and Fichter (2019), percentages of persistent BN were similar in the large total sample after 11 years (14%) and the smaller subsample after 21 years (12%).

Cross-Over to Other Eating Disorders at Follow-Up

While the broader category of eating disorders is fairly stable, there is a well-known instability of single-eating-disorder diagnoses with a frequent change between diagnoses (Milos et al. 2005). Only a small number of patients crossed from BN at treatment to anorexia nervosa (AN) at follow-up. Cross-over to AN was rare and observed in 0 to 4% of the follow-up samples (Table 4). The only exception was the outpatient sample of Castellini et al. (2011) with a somewhat higher rate of 9%. This study also reported a relatively high rate of cross-over to binge eating disorder (BED; 11%), and these numbers may reflect a special design feature of the study. Only a few other studies reported cross-over to BED with a maximum frequency of 2% in the female sample of Fichter and Quadflieg (2004) and the male sample of Strobel et al. (2019). Much more frequent was the cross-over to ED-NOS (Fig. 3) with rates as high as 38% in the very long-term subgroup of Quadflieg and Fichter (2019). However, these findings are not easy to interpret. Considering that all patients had a full BN at intake into the studies, cross-over to ED-NOS may well be attributed to an improvement of the eating disorder. On the other hand, ED-NOS includes several subtypes (American Psychiatric Association 1994) and is also a severe eating disorder (Crow et al. 2009), and this cross-over may simply reflect a change of symptoms.

Table 3 Persistence of bulimia nervosa at follow-up. This table lists all long-term outcome studies of bulimia nervosa included in this review which reported the number of patients who still had bulimia nervosa at follow-up

./. not reported separately and included in the eating disorder not otherwise specified category

Chronicity of Eating Disorders

Above we have taken a look at persisting BN and cross-over to other eating disorders. Considering the high interchangeability of eating disorder diagnoses, a more global look at diagnostic outcome is justifiable. Combining all eating disorder diagnoses in one category, chronicity of eating disorders is considerable. Percentages range from 22% (Ben-Tovim et al. 2001) to 56% (Strobel et al. 2019) with half of the studies below 32%. The other half of the studies reported about half of the samples

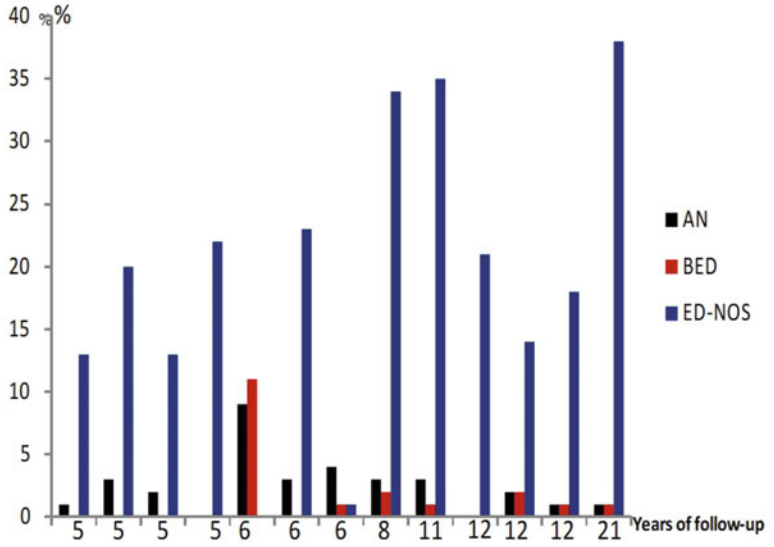

Fig. 3 Cross-over from bulimia nervosa at treatment to other eating disorders at follow-up. The percentage of patients who switched from bulimia nervosa at treatment to anorexia nervosa (black bars), binge eating disorder (red bars), or eating disorder not otherwise specified (blue bars) at follow-up is shown by the height of the bars. Each cluster of bars represents one study. The cluster of bars is organized according to length of follow-up. Missing bars in a cluster indicate either no such eating disorder was found at follow-up or not reported

with chronic eating disorder. So we may conclude that one third to one half of patients treated for BN will have a poor outcome of their eating disorder in the long run. Clearly there is a need for still more improved therapies of BN.

Aspects of Social Functioning at Follow-Up

Only very few studies reported on a limited number of indicators of social functioning at follow-up (Table 5). In the long run, more than half of the patients reported to have been married or cohabiting over the follow-up period or at follow-up. However, a considerable percentage also reported a divorce or separation over the follow-up period. Two studies reported the percentage of patients with children (58% and 39%), and two studies reported on employment of the patients at follow-up (49% and 100%). Using a questionnaire on social adjustment, patients reported improvement of social adjustment but still showed continuing impairment 10 years after treatment (Keel et al. 2000).

Table 5 Aspects of social functioning at follow-up. This table lists all long-term outcome studies of bulimia nervosa included in this review which reported on some characteristics of social functioning at follow-up

Study	Length of follow-up (years)	Married or cohabiting over follow-up period or at follow-up %	Separated or divorced over follow-up period or at follow-up %	Had children at follow-up %	Employed at follow-up %

Mortality

Several studies mentioned the number of deaths at follow-up, allowing the calculation of the percentage of deceased patients in a sample. However, this crude mortality rate depends on sample size and will be inflated in small samples. A more precise assessment of mortality is the standardized mortality ratio (SMR) which compares the number of deaths in a sample with the expected number of deaths in the reference population of the same age and sex. Two long-term studies reported SMRs. In a mixed sample of mostly female and a small number of male inpatients, the SMR of 1.49 (95% confidence interval 1.10–1.97) was significantly elevated ($p < 0.05$), indicating a risk of death about one and a half times higher in BN than in the general population (Fichter and Quadflieg 2016). For a larger sample of 81 male inpatients, the SMR was 1.88 (95% confidence interval 0.86–3.58) and not significantly elevated (Quadflieg et al. 2019). These numbers include mortality from all causes. Causes of death directly attributable to BN are hard to define and not reported in the studies.

Outcome of Bulimia Nervosa in Males

There is only one study reporting long-term outcome in a larger sample of males (Strobel et al. 2019). Results regarding remission (Table 2), persistence (Table 3), and cross-over to other eating disorders (Table 4) are fairly within the range of studies of female patients, and we may conclude little difference between sexes from this scarce evidence. In an additional analysis of the inpatients from the mortality studies mentioned above, Fichter et al. (2021) compared the SMRs directly between males and females and found no significant difference in mortality between sexes.

Application to Other Eating Disorders

Long-term outcome studies similar to those described for BN exist for AN. Summarizing the results, AN is a still more severe eating disorder than BN, with lower remission rates and greatly higher mortality (SMR 5.35 ($p < 0.05$) in the study of Fichter and Quadflieg 2016; for males 5.91 ($p < 0.05$) in the study of Quadflieg et al. 2019). A number of patients with AN cross-over to BN at follow-up. Considering that a binge eating/purging type of AN is defined, a change between AN and BN may simply be a question of low versus normal weight. Additionally, ED-NOS of an anorectic type is defined as meeting criteria of AN with a body weight above the usual threshold of AN, but no maximum weight is given. This may contribute to higher cross-over rates from AN to ED-NOS.

For BED, comparable long-term outcome studies are less frequent. There are important differences to AN and BN. Compared to AN and BN, a much larger number of males seems to be affected by BED, and because of the exclusion of inappropriate compensatory behaviors after binge episodes, a better outcome could be hypothesized. Actually this is not the case, BED showing a similar outcome to BN. One exception is mortality which seems to be lower than in BN with a nonsignificant SMR for BED.

Mini-Dictionary of Terms

- **Chronicity:** Long enduring state of an illness with decreasing perspective of recovery or with an increase of necessary efforts to achieve improvement
- **Cross-over of diagnosis:** Transformation from one diagnosis to another, generally from the same spectrum of illness
- **Crude mortality rate:** Percentage of deceased individuals in a given sample or population
- **Follow-up:** Reassessment of a patient after treatment has ended for a certain time period
- **Inpatient treatment:** Treatment with the patient residing in a hospital for intensive treatment
- **Outcome:** The state of an illness or a functional characteristic at follow-up

- **Outpatient treatment:** Ambulatory treatment in the rooms of a therapist with the patient leaving after treatment session to return home
- **Relapse:** The reappearance of symptoms after recovery was achieved
- **Remission/recovery:** Being free from symptoms after an illness
- **Standardized mortality ratio:** The ratio of the number of observed deaths in a sample compared to the expected number of deaths in the reference population

Key Facts of Bulimia Nervosa

- Bulimia nervosa is a mental disorder with frequent binge eating episodes when more food than usually is consumed in a short time
- To avoid weight gain, measures are taken to remove the food before digestion (e.g., self-induced vomiting or use of laxatives)
- A low body weight and slim body shape are central to the self-evaluation of one's person
- Binge eating disorder is essentially bulimia nervosa without compensatory behavior
- The proportion of males is lower in bulimia nervosa than in binge eating disorder

Key Facts of Follow-Up

- In most studies follow-up is a cross-sectional assessment of the current state of the patient
- Retrospective assessment beyond the current state at follow-up depends heavily on the precision of the patient's memory and the careful exploration of the assessor
- Cross-sectional follow-ups reveal a picture at the time of assessment but not of the complete time period between end of treatment and follow-up
- Often patients received additional treatment during the follow-up period which is rarely reported in studies
- Only the follow-up status of patients who participated in follow-up can be reported
- It is not known if patients who did not participate in follow-up have a good or poor outcome
- There are a few long-term studies on bulimia nervosa in population samples, but it is not clear if these studies cover clinical cases requiring treatment

Key Facts of Mortality

- Mortality is more difficult to assess than one would expect
- Central registries of mortality allow a higher ascertainment rate of deceased patients

- Causes of death are rarely attributable directly to bulimia nervosa
- Computing the standardized mortality ratio requires a centralized death statistics of the population
- Death statistics yields the number of deaths from all causes, and only special causes of death are differentiated in these statistics
- The expected number of deaths in the general population includes also the patients with the illness of interest (here bulimia nervosa)

Summary Points

- In the long run, one third to one half of the patients treated for BN will have a poor eating disorder outcome
- Relapse after remission is frequent
- About 10 years after treatment, remission seems to get increasingly rare in bulimia nervosa
- The risk of death is elevated by 50% for bulimia nervosa patients, compared to the general population
- Bulimia nervosa is associated with less mortality than anorexia nervosa but is nevertheless a severe eating disorder
- Based on the current limited knowledge, no significant difference in the outcome of bulimia nervosa exists between males and females

Parental Care and Binge-Eating Disorder

48

Federico Amianto and Benedetto Vitiello

Contents

Abstract

Binge-eating disorder (BED) has the highest prevalence among the EDs. Early attachment experiences are considered relevant cofactors for the development of BED and obesity later in life. A deficit attachment impairs the development of emotional control producing inability to cope with negative emotions in a framework of negative experiences. The inadequate coping mechanisms are strongly

associated with BED and obesity. The risk for obesity is significantly increased by non-authoritative parenting styles in childhood. Physical and psychological abuses in childhood are strictly related to the development of obesity in adulthood. Parenting experience recalled by BED and non-BED obese participants is significantly different from that of healthy controls. The relationship between the obesity, distorted parenting in infancy, and psychopathology and personality traits of obese subjects can be considered as well established. The chapter goes on discussing specific researches linking parenting style to BED and obesity development. Clinical and prevention issues are discussed.

Keywords

DALYs	Disability adjusted life years
DBT	Dialectical behavior therapy
DLPC	Dorsolateral prefrontal cortex
DSM 5	Diagnostic and Statistical Manual 5th edition
ED	Eating disorders
LNO	Light neglect obesity
Non-BED	Not affected with BED
PBI	Parental Bonding Instrument
SNO	Severe neglect obesity

Introduction

Binge-Eating Disorder (BED) is relatively common, with an estimated lifetime prevalence of about 1.53% in the general population, which is the highest rate among the EDs (Quian et al. 2021). Its prevalence is likely to increase along with the worldwide rising incidence of obesity and also in consideration of the greater attention that this disorder is receiving since the introduction of the diagnostic criteria into the DSM-5 (Amianto et al. 2015; Hudson et al. 2010; Trace et al. 2012).

BED has particular interest for primary care because of its link with obesity and with other medical and psychiatric comorbidities. In fact, BED is characterized by an excessive food intake without energy consumption compensation. This produces a rapid weight increase, and, in the subjects with a medium-long-term time of disease, it also produces the almost constant comorbidity with overweight or obesity. About

40–70% of people with BED who are overweight reach severe obesity conditions which make people with BED susceptible to the medical complications of being overweight (Kessler et al. 2013).

Psychopathological Aspects

Despite the fact that obese subjects with and without BED do not differ from each other in degree of overweight, binge eaters show considerable more concern about body weight and shape and also lower levels of self-reported physical appearance and global self-worth. In fact, BED is also associated with higher rates of psychopathology: among obese individuals, those with BED report greater eating psychopathology, psychiatric and medical disorders, social and occupational impairment, and low quality of life than those without BED (Herbozo et al. 2015). The relationship of BED with psychiatric symptoms like depression, anxiety, and substance abuse and the excessive concerns about food, body shape, and weight, along with increased body dissatisfaction and decreased self-esteem which affect people affected with BED, severely impair their well-being with consequences for their overall functioning (Grilo et al. 2013). This leads to reduced quality of life, increased health service utilization, and negative socioeconomic implications (Amianto et al. 2011a; Wang et al. 2011).

Other problematic features characterize BED patients. They often show relevant alexithymia and deficit in emotional identification and regulation (Carano et al. 2012; Compare et al. 2012). As a consequence (or not) of the difficulties in emotional management, they often carry high interpersonal problems (Blomquist et al. 2012; Sawaoka et al. 2012). Moreover, they often display rigid and poorly adaptive personality traits, so that the diagnosis of personality disorders is frequently present among the clinically referred population (Kessler et al. 2013; Schag et al. 2013). As it happens with other EDs, the comorbid diagnosis of a personality disorder is generally related to more severe psychopathology and worse prognosis (Amianto et al. 2011b; Carrard et al. 2012; Peterson et al. 2005), so that it has been proposed as a marker of major severity, rather than just an associated condition (Amianto et al. 2011b; Carrard et al. 2012; Peterson et al. 2005).

Epidemiology

The incidence of BED is the highest among EDs to such an extent that BED has been considered for a long time a disorder of adulthood. Instead, recent research suggests that the age of onset is lower than previously assumed (Kessler et al. 2013). In fact, it already occurs in childhood and adolescence with a slope in the curve of the age of onset between 15.5 and 27 years. Instead, the mean persistence of 4.3 years is lower with respect to that of BN (Kessler et al. 2013). As it concerns the long-term evolution, data show that BED tends to be a stable syndrome and that also the

binge-eating patterns display a relative stability (Peterson et al. 2012). Moreover, as a difference between AN and BN, the crossover rates with other EDs are significantly lower (Castellini et al. 2011).

Attachment Liability in the Pathogenesis of BED

Among the pathogenic factors which can contribute to the pathogenesis of eating disorders, attachment experiences have been claimed as a relevant component (Abbate-Daga et al. 2010; Kiesewetter et al. 2010; Tasca and Balfour 2014). Women affected with anorexia nervosa and bulimia nervosa often report high levels of separation anxiety in childhood and an insecure style of attachment in adulthood (Amianto et al. 2012; Fassino et al. 2009, 2010; Milan and Acker 2014). These experiences have been found to be related to the body dissatisfaction in ED subjects (Abbate-Daga et al. 2010).

A consistent body of research suggests a strong influence of family functioning on the development of obesity (Bahrami et al. 2013; Hernandez-Hons and Woolley 2012; Pinard et al. 2012). Many studies on family liability in the development of obesity support the addiction-model hypothesis of the pathogenesis of the binge eating. According to this model, the binge-eating behavior would reenact the pattern of unstable relationships, alternating merging and rejection, perceived in infancy by binge eaters (Cleveland et al. 2010). More specifically, early attachment experiences are considered relevant cofactors for the development of BED and obesity later in life (Abbate-Daga et al. 2010; Anderson and Keim 2016; Bahrami et al. 2013; Tasca and Balfour 2014). The attachment insecurity seems to predict the development of the key features of these disorders. Child and adult excessive food intake and obesity have been related to parental attachment insecurity (Anderson et al. 2012; Faber and Dubè 2015). A deficit attachment impairs the development of emotional control producing an individual's inability to cope with stress and negative emotions in a framework of internalized negative experiences. In fact, excessive food intake is conceptualized by many authors as an alternative coping mechanism to manage relational stress and related negative emotions (Faber et al. 2018; Kittel et al. 2015; Leehr et al. 2015). These inadequate coping mechanisms are strongly associated with the disordered eating behaviors which lead to obesity (Kittel et al. 2015; Leehr et al. 2015). Finally, some research underlined that attachment insecurity also represents a relevant prognostic factor for treatment of ED subjects, including the BED participants (Illing et al. 2010; Maxwell et al. 2014). In fact, treatments that address attachment insecurity are effective for decreasing binge eating in BED participants (Maxwell et al. 2014) (Tables 1 and 2).

Table 1 Parenting characteristics of BED and non-BED obese subjects[a]

	BED (a) $n = 357$ mean ± sd	Non-BED (b) $n = 453$ mn ± sd	HS (c) $n = 463$ mean ± sd	F	p	Post hoc	Effect size

Parenting Style as a Measure of Early Attachment in Psychiatric Disorders

In the context of the research on attachment liabilities on eating disorder outburst, many studies related the development of obesity to parenting styles. These researches evidenced that the risk of obesity was significantly increased by non-authoritative parenting styles in childhood. Instead more authoritative parenting styles seem to be protective against the development of obesity (Gartstein et al. 2018; Halliday et al. 2014; Kakinami et al. 2015; Sokol et al. 2017). On the other hand, it was also evidenced that physical and psychological abuses in childhood are strictly related to the development of obesity in adulthood, also from a neuropsychobiological point of view. In fact, familiar childhood traumas are effective in producing mental and emotional troubles related to maladaptive coping responses and, as an indirect consequence, to favor stress-induced metabolic disturbances which can be related to obesity development (Amianto et al. 2018; Ehlert 2013).

Some recent studies on parenting styles in ED subjects have been conducted using a traditional but still unsurpassed instrument, the Parental Bonding Instrument (PBI). The PBI represents a worldwide known validated instrument assessing parenting style during childhood and adolescence (until 16 years) through the child recollection of maternal and paternal relational attitudes. Parental attitudes are then classified into two dimensions: care and overprotection. The scores in these dimensions are considered in the high vs. low range based on a cutoff derived from the general population (Parker et al. 1979).

Many studies on parenting style conducted with PBI have demonstrated that low levels of parental care and high overprotection recalled in childhood are associated with acute and severe psychiatric symptoms in adulthood such as to depressive symptoms (Mannarini et al. 2018) and suicidal ideation (Goschin et al. 2013). Moreover, the same researches underline that the parenting style produced by the combination of low care and high overprotection from both parents was associated with schizotypy and anxiety (Giakoumaki et al. 2013), internalizing and externalizing symptoms (Mannarini et al. 2018), and high neuroticism (Takahashi et al. 2017).

Other studies on parenting influence on psychiatric disorders, including eating disorders, explored possible differential effects of maternal and paternal parenting styles on psychopathology development and expression. It is so that maternal overprotection has been associated with the expression of mood symptoms in adulthood, while, instead, paternal overprotection seems to be less correlated (Heider et al. 2006). Recent research on adolescents supports this previous evidence on adults. In fact, it is evident that a high maternal control is related to a higher risk for developing depressive, eating, anxiety, and behavioral disorders (Eun et al. 2018). On the other hand, it also suggests that high paternal care represents a strong resilience factor against the risk for social phobia, agoraphobia, and alcohol abuse/dependence (Eun et al. 2018) (Table 3).

Parenting Correlates in Eating Disorders, BED, and Obesity

The evidence from the research of Eun et al. (2018) that eating disorders are significantly associated with the perception of a low parental care and high overprotection in childhood is corroborated by a literature review including 24 studies applying the PBI to adult women (Tetley et al. 2014). Instead, specific research on parenting influences on the development of EDs produced less evidence concerning a well-differentiated role of maternal and paternal parenting attitudes in favoring eating psychopathology. A study in a large population of adult ED participants found that low maternal care seems to exert a direct effect on the development of body dissatisfaction (Grenon et al. 2016). Also the low paternal care seems to be influential on this psychopathological trait, but the influence is mainly mediated by attachment anxiety and media internalization (Grenon et al. 2016).

As it concerns obesity, previous studies have found that the personality abnormalities and the higher levels of psychopathology in subjects with obesity may be related to worse parenting recalled in adulthood (Amianto et al. 2012, 2016a, 2018, 2021). The research by Takahashi et al. (2017) evidenced that BED and non-BED recall lower maternal and paternal care and higher overprotection with respect to healthy participants, supporting a relevant role of attachment in the pathogenesis of their condition (Abbate-Daga et al. 2010; Anderson and Keim 2016; Bahrami et al. 2013; Tasca and Balfour 2014). Another study by Amianto et al. 2016a explored the characteristics of parenting style in a large sample of BED and non-BED obese participants who were searching for treatment at an eating disorder center and compared them with those of healthy controls (Masheb et al. 2011; Moroshko

Table 3 Odds ratio (OR) of different PBI maternal and paternal clusters

PBI subscales	BED/HS OR [95%CI]	Non-BED/HS OR [95%CI]	BED/Non-BED OR [95%CI]	BED + Non-BED/HS OR [95%CI]

Table extracted from Amianto et al., 2021

et al. 2011; Ruini and Fava 2012). According to previous literature, the parenting experience recalled by BED and non-BED obese participants was significantly different from that of healthy controls (Anderson et al. 2012; Faber and Dubè 2015). In particular, careless and overcontrolling parenting was described by obese participants as recurrent conditions, thus confirming that these parenting attitudes may represent possible risk factors for obesity development (Bahrami et al. 2013; Hernandez-Hons and Woolley 2012). Moreover, BED reported lower maternal and parental care than non-BED obese participants (Amianto et al. 2016a). This finding suggests that it is possible that particularly low levels of care may be specifically associated with BED, and it may explain the positive effects of attachment-based therapies in BED patients (Maxwell et al. 2014).

Nevertheless, the same study also performed a cluster analysis of the PBI characteristics which sharply distinguished the obese participants into two clusters (Amianto et al. 2016a). The larger one was characterized by fewer parenting patterns' distortions (i.e., intermediate care and overprotection) and was then defined the "light neglect obesity" cluster (LNO). The other one, including about one third of the whole sample, was characterized by severe neglectful and overcontrolling patterns (low care and high parental overcontrol) by both parents and was then defined as a "severe neglect obesity" cluster (SNO). The first cluster is poorly related to psychopathology and dysfunctional personality measures, while the second one shows more severe eating and general psychopathology and a personality profile characterized by more dysfunctional traits. The authors suggest that this cluster distribution implies that even the slight parenting distortions evidenced in the LNO can be related to the development of adult obesity and thus recommend a higher vigilance on parental attitudes (Anderson et al. 2012). In fact, also relatively mild parenting distortions may be related to the growing epidemic of obesity, which scientific literature does not justify with a growth of traumatic experiences within the family (Stevens et al. 2012). Moreover, they suggest that the more severe parenting distortions in the SNO are directly related to worse eating psychopathology in obese subjects with the only exception of the body dissatisfaction which is similar in both clusters.

The direct relationship between parenting and the development of obesity is supported also by the correlation pattern of parenting dimensions with personality traits, eating, and general psychopathology. In fact in the non-BED obese group, it is very extensive and interests all parenting dimensions (Amianto et al. 2016a). This definitely supports that also for both BED and non-BED obese participants, worse childhood parenting represents a relevant risk factor for eating and general psychopathology and also more dysfunctional personality traits.

The direct relationship between parenting and the development of obesity is supported also by the correlation pattern of parenting dimensions with personality traits, eating, and general psychopathology. In fact, in the non-BED obese group, it is very extensive and interests all parenting dimensions (Amianto et al. 2016a). This definitely supports that also for both BED and non-BED obese participants, worse childhood parenting represents a relevant risk factor for eating and general psychopathology and also more dysfunctional personality traits.

The relationship between the obesity and the distorted parenting in infancy and also between psychopathology and personality traits of obese subjects and their parenting features can be considered as well established (Amianto et al. 2012; Castellini et al. 2012; Müller et al. 2014; Schulz and Laessle 2010). Moreover, some literature also related the degree of attachment problems to the severity of psychopathology in BED (Caroleo et al. 2018; Otani et al. 2016). Nevertheless, it is less clear what is the role of parenting for the development of the binge-eating behavior and BED. In fact, despite the differences between BED and non-BED obese participants in personality and psychopathology features, no significant association between a specific parenting pattern and the development of BED has been established. Moreover, in the study by Amianto and coworkers (2016a) in BED subgroup, the relationship with participants' psychopathology is almost completely centered on the deficiency of maternal care, while a direct relationship between parenting and personality traits is not evident. It is thus suggested that obese participants with and without BED express different dynamics relating childhood parenting to the eating and general psychopathology and that these dynamics are direct for non-BED obese and indirect for BED participants (Kittel et al. 2015; Leehr et al. 2015). This supports that even if inadequate parenting is a relevant risk for obesity development (Anderson et al. 2012), it is not directly related to the development of overeating attitudes (Faber and Dubè 2015). This evidence is in accordance with the fact that while the diagnosis of BED was included into the DSM psychiatric disorders, obesity is not recognized as a psychiatric condition in itself (Amianto et al. 2015). This implies that BED is characterized by a complex pathogenesis in which concur numerous risk factors which mediate the influence of parenting features on psychopathology, as it happens in other eating disorders (Fassino et al. 2010). Obesity alone, instead, may represent a direct overcompensation of inadequate parenting patterns and of their deficits in emotional regulation as proposed by many authors (Faber et al. 2018; Kittel et al. 2015; Leehr et al. 2015).

Parenting Influence on Personality Traits of Obese Participants With and Without BED

The relationship between attachment and personality traits in obese participants is complex. According to literature, BED and non-BED obese participants display high harm avoidance, low reward dependence, persistence and self-directedness, and worse eating and general psychopathology than controls (Amianto et al. 2016a). BED participants also displayed higher harm avoidance, lower reward dependence, and self-directedness with respect to non-BED and healthy participants. These personality traits were coupled with a worse psychopathology profile of BED participants with respect to non-BED obese. Hence, BED shares with eating and other mental disorders a "core" personality profile (high harm avoidance and low self-directedness), and this is linked to both less caring parenting and greater psychopathology features (Fassino et al. 2013). Literature demonstrated that parenting attitudes are influent on the development of both traits (Oshino et al. 2007).

Moreover, a lower reward dependence has been related to maternal neglect in participants with obesity in a study by Amianto et al. (2016a). The relevance of these traits for psychological functioning is also supported by studies on healthy subjects which evidence that these personality traits mediate the influence of parental bonding on the perception of well-being (Murakoshi et al. 2020). It is thus possible, and should be explored in perspective studies to avoid the "effort after meaning" effect and to establish a causal connection, that personality traits mediate between attachment troubles and BED psychopathology.

According to the research available on the psychobiological model of personality (Cloninger et al. 1993), the severity of neglect and other parenting distortions directly influence the development of novelty seeking, harm avoidance, and self-directedness (Hintsa et al. 2007; Hwang et al. 2006; Keltikangas-Jarvinen and Salo 2009; Oshino et al. 2007).

The research conducted by Amianto and colleagues (2016a) shows the same correlation also in the obese population. It also evidences that the LNO group of obese adults is characterized by a low persistence. This result is in accordance with previous findings (Hwang et al. 2006; Sullivan et al. 2007) in the pediatric population, corroborating the hypothesis of an epigenetic influence of early parenting on the expression of this temperament trait. Instead, the SNO group, which is related to the most severe neglect, is characterized by low cooperativeness. Moreover, the study of Amianto et al. (2018) underlines that this trait displays lower levels in BED than non-BED participants. The low cooperativeness in obese participants, particularly in BED ones, is a common finding in the previous literature (Fassino et al. 2002; Sullivan et al. 2007), and it represents a severe risk factor for the therapeutic compliance, because it correlates with the expression of severe cluster B disorders (Cloninger et al. 1993). These evidences suggest a path in which severe neglect or abuses mediated cooperativeness may indirectly influence the outcomes of treatments for obesity. Future research is needed to confirm it.

One of the most surprising pieces of research by Amianto and colleagues (2016a) is that it displays an extensive correlation of parenting traits with personality and psychopathology in the LNO and control groups and a weaker and more limited one in the SNO cluster. In fact, in the less neglected participants belonging to the LNO group, maternal and paternal care are directly related with personality (Svrakic et al. 2002) and psychopathology features (Fassino et al. 2010). This pattern is different from that of control subjects in which both maternal care and overprotection are correlated with personality and psychopathology, suggesting that different parenting dynamics produce different effects in obese and non-obese subjects. Moreover, a novel finding from the study was that parenting features are poorly related to the personality or psychopathology traits in the SNO cluster. Instead, only in the SNO group, the BMI was related to paternal overprotection. This evidence suggests that the two obese clusters based on parenting are affected by dynamics connecting attachment to personality that are nonlinearly related to the severity of attachment troubles. A very high degree of neglect may be permissive for a stronger influence of the external environment on child development than it would be in a caring family (Cleveland et al. 2010). Hence, subjects growing in a severely neglectful family may

be heavily influenced by environmental factors (e.g., family distortions, traumas, sexual or physical abuses) that may distort personality development and foster psychopathology in a way that is relatively independent of parenting attitudes in itself. On the other hand, malfunctioning personality and psychopathology traits may also have produced more recollection biases in the SNO cluster as a consequence of an "effort after meaning" effect (Amianto et al. 2012). Definitively, the mechanisms linking early parenting experiences to the development of current personality and psychopathology are radically different between the LNO and SNO obese participants and may guide future research and help the personalization of therapeutic approaches (Ruini and Fava 2012).

What about the prevalence of the diagnosis of BED in the SNO and LNO parenting clusters? It was expected to have a higher prevalence of BED in the SNO cluster, since the subjects with BED display a greater level of psychopathology (Amianto et al. 2012; Castellini et al. 2012; Schulz and Laessle 2010). Instead, BED subjects are almost equally distributed among the two clusters. This unrelatedness of the BED diagnosis suggests that early parenting experiences measured with the PBI are not a specific risk factor for the development of BED. The paper thus suggests that other researches are needed to explore other risk factors, more specific for the BED pathogenesis, which possibly interact with the inadequate parenting to produce the complex and nonlinear pathogenesis which probably characterize the BED subgroup of obese subjects (Kiesewetter et al. 2010; Pinard et al. 2012; Schulz and Laessle 2010). The need for further research is also supported by the limitations of the study itself, which is cross-sectional and thus does not permit causal effects in the relationship between parenting style, personality, and psychopathology. Moreover, the sample was represented by treatment-seeking obese subjects; thus, its findings could not be generalized to all obese population but probably to those obese subjects with most severe psychopathology and worse personality trait functioning, possibly with a lesser differentiation with BED population. Moreover, also BED subjects may not be completely represented since some of them may be normal weight or may display lower levels of eating and general psychopathology.

Evidences About Combined Maternal and Paternal Parenting Styles

In the recent study by Amianto and coworkers (2021), the analysis of the parenting style combined between maternal and paternal influences was conducted in a large obese sample to better define the specific parenting mechanisms which may be influent on the development of obesity and BED. According to the expectations, the research outlined that the parenting style defined "affectionless control" (Parker 1989) is a relevant and specific risk factor for the development of obesity alone. The relevance of this finding descends by the evidence that neither parental neglect nor parental overcontrol alone was effective in increasing the risk for obesity (Amianto et al. 2016a). In fact, affectionless control is the combination of parenting attitudes of parents unresponsive to their child's needs for care and at the same time unable to

foster appropriate independence, hence producing an anxious attachment. Affectionless control has been suggested as a common pathogenic factor for different eating problems (e.g., anorexia or bulimia nervosa) which apparently do not share a common pathogenesis (Monteleone et al. 2019). Its relevance for the pathogenesis of obesity is also suggested by its correlations with higher neuroticism, with depressive symptoms, and with an altered expression of glucocorticoid receptor factors which may be considered specific for the weight increase (Avila et al. 2015; Preiss et al. 2013; Takahashi et al., 2017). Finally, affectionless control, even when expressed by only one parent, is so strongly associated with obesity, regardless of the presence of BED, that it may exert a very specific role in the pathogenesis of obesity, regardless of the presence of eating psychopathology (Amianto et al. 2016a, b; Faber et al. 2018).

Anxious attachment promoted by affectionless control impairs the development of positive working models and self-identity, both relevant to the pathogenesis of EDs (Tasca and Balfour 2014). Thus, obesity may derive from a failure, or at least a deficit, in the development of a coherent self, as suggested for the anorexia nervosa and other eating disorders (Amianto et al. 2016b). As suggested by Scalabrini and coworkers (Scalabrini et al. 2018), altered attachment patterns may impair the maturation of specific brain areas (mainly DLPC) pertaining to the midline structures which are implied in the perception of the sense of the self. In particular, among the functions of the self, self-awareness and self-regulation could be particularly relevant, for the dysregulated eating and problems in keeping a healthy body image. In fact, overeating may represent an attempt to fill a void due to the lack of self-boundaries, the food avoidance is an attempt to remark on them. The hypothesis of a common deficit represented by the fragility of self-boundaries which may be managed using different coping mechanisms in the two disorders with opposite weight effects may explain why obesity often precedes or follows anorexia nervosa (Murray et al. 2017).

There would be different pathogenic pathways from affectionless control to the disorders through the deficits of the self (Amianto et al. 2016b; Hymowitz et al. 2017). According to the double psychopathological pathway for eating disorders proposed by Arcelus et al. (2013), the first, connected to the sense of self-worth, would represent the basis for an extreme weight alteration, and it would be expressed in the anorexia nervosa or obesity. The second, connected with the sense of relational connectedness, would produce binge eating, thus leading to binge-purging anorexia nervosa, bulimia nervosa, and BED (Amianto et al. 2012).

No Specific Parental Style for BED Expression

The research on parenting styles by Amianto and coworkers (2021) did not find any specific association between a particular parenting and the expression of BED. The finding was unexpected since BED is the psychopathological condition most frequently associated with obesity; it is characterized by worse levels of attachment and involves a worse personality functioning and higher levels of psychological

suffering than obesity alone (Amianto et al. 2016a, 2018; Kessler et al. 2016). The fact that the affectionless control even being a relevant risk factor for obesity is not related to BED implies that it may only be influential on the unhealthy eating attitudes of subjects with obesity, without being related to specific BED psychopathology. Hence, since BED participants reported a particularly low care from both parents, their attachment problems may only be directly related to the development of their obesity and only indirectly involved in the pathogenesis of their BED.

Only the analysis of the combined parenting styles of the parental couple permitted some more specific association between parenting styles and BED (Amianto et al. 2021). In fact, the specific association of maternal neglectful parenting with paternal optimal parenting represented the highest relative risk for BED, while maternal affectionate constraint alone seems to display a protective effect. This evidence referred to the interactions of parenting styles within the parental couple is the more specific link between parenting style and BED pathogenesis. According to previous findings, it supports that BED, as it happens for other eating disorders, displays a complex pathogenesis more linked to the family dynamics than to the alteration of the parenting style of a parent alone (Fassino et al., 2009). On the other hand, when it is coupled with the evidence of the lower levels of maternal and paternal care in BED participants, it suggests that, consistent with previous literature, these complex dynamics are amplified and empowered by neglect to foster the pathogenesis of BED, similarly to what happens for other psychiatric conditions (Amianto et al., 2016a; Mannarini et al. 2018; Sokol et al. 2017).

Clinical Implications

The exploration of attachment, and in particular of parenting styles, among treatment-seeking obese participants permitted to identify specific distinctive features among BED and non-BED obese populations which can borrow relevant clinical implications.

As it concerns the relevance of the attachment dynamics for BED and non-BED population, the research findings may guide psychotherapeutic approaches in these disorders. In particular, they suggest the need for a particular attention paid by the therapists to the transfer and countertransfer reactions and to attachment relationship (Fassino et al. 2008). In fact, both the phase of engagement and that of dismissing from the therapeutic relationship may be particularly affected by attachment troubles of these subjects strictly related to early parenting experiences (Tereno et al. 2008).

The findings on parenting clusters identified two distinct groups of obese participants, which are independent from the diagnosis of BED. Mild neglectful parenting characterizes obese participants that, regardless of the BED diagnosis, are affected with moderate character immaturity, laziness, and low persistence. This suggests that this specific clinical group may need therapeutic projects with few drug treatments and limited psychiatric support due to their lower rates of psychopathology. Instead,

they could benefit from specific psychoeducation and psychological support, along with nutritional counseling, to balance their personality weaknesses. When psychotherapy could be indicated, CBT treatments may be recommended. In contrast, more severe neglect levels identify those subjects who need more medicalization due to their high psychopathology. These may include both antidepressants, useful to treat their mood disorders and to control binge eating, and also psychiatric drugs addressed to improve the treatment for personality disorders (e.g., atypical antipsychotics). Instead of a mere psychological support coupled with nutritional support, these subjects may deserve structured psychotherapy. Moreover, the psychotherapeutic approach in this subgroup should be personalized. Due to the higher personality disturbances, CBT treatments could be poorly applicable, while dialectical behavior therapy (DBT) or psychodynamic approaches addressed to personality disorders could be more effective (Amianto et al. 2012).

The differentiation of the clinical and psychological approaches between BED and non-BED obese subjects based on the findings on attachment features is less easy, since BED may not be related to a specific parenting style. Nevertheless, this absence of evidence based on attachment dynamics suggests building specific therapeutic protocols for each target symptom based on the diagnosis of obesity alone of the association with BED (Saltzman and Liechty 2016). In fact, obesity alone could be approached by psychological care protocols directly addressed to the psychodynamic consequences of the early troubled parenting and more specifically of affectionless control (e.g., the lack of self-care and self-compassion). Instead, those addressing the obese subjects affected with BED should prior take into account the personality troubles which may be considered mediators of the inadequate attachment on psychopathology (Amianto et al. 2015). Moreover, the treatment of obese subjects with BED should also consider their higher levels of psychopathology needing specific drug treatments. At this regard, some attempts have been made to address more specifically obese subjects affected with BED. The protocol described by Compare et al. (2013) as more effective on this disorder consists in a psychotherapy focused on the cognitive and interpersonal experiential perspectives of emotions, associated with dietetic assistance, drugs, psychoeducational interventions, and self-help activities.

In general terms, the research on attachment and parenting styles of BED and non-BED subjects permitted to conduct the pathogenesis of these disorders to a complex theoretical framework connecting the obesity symptoms to early attachment dynamics and their consequences for the development of the sense of the self, as for anorexia nervosa (Amianto et al. 2016b). This new theoretical framework may help clinicians and psychotherapists to modulate their interventions with a higher attention paid to attachment-related dynamics and the fragility of self-boundaries in these subjects. This may overcome the current difficulties (e.g., high dropout rate) and the low efficacy with respect to their medium- to long-term evolution of the psychological treatment for the obesity and BED as it was evidenced for anorexia nervosa (Amianto et al. 2019; Fassino et al. 2013).

Preventions Issues

Research underlines that dietary factors contribute worldwide to a large number of deaths and to a relevant loss of disability adjusted life years (DALYs) and also that the prevention of obesity and BED in particular is often conceived as a mere nutritional psychoeducation offered to children and less often to their families to prevent feeding distortions (The Lancet Public Health 2019). The present review suggests that more interventions targeted to improving parenting styles in childhood, in particular those focused on parenting neglect and on affectionless control, may be necessary to effectively prevent obesity and BED. According to a recent review, the improvement of the healthcare system in the USA accounts for a very low rate of improvement in population life expectancy; instead, the larger influences on population health derive from changes in habits and culture (Kaplan and Milstein 2019). Since parenting attitudes are a cultural factor more than a consequence of healthcare system functioning, moreover they are influenced by acculturation and thus may be modified by psychoeducation; the interventions directed toward their modulation display a high potential for improving the health of the population. It is for this reason that the prevention of the epidemics of obesity and BED should involve interventions which promote healthy parenting styles in addition to nutritional styles in the families at risk for development of obesity in their children (Chu et al. 2018). Primary prevention of obesity and BED through the changes of parenting styles in the general population should involve mass media and social communication. Also the healthcare systems (e.g., pediatricians or general practitioners) should be involved because it may represent a concrete support for the parents to be addressed to more empathic and less intrusive parenting attitudes toward their children since childhood (Atzil et al. 2011). Also the strategies for secondary and tertiary prevention of childhood and adult obesity and BED need to couple nutritional assistance to patients with psychoeducational and psychotherapeutic approaches addressed to affected subjects but also to their families when necessary (Arenaza et al. 2020).

In addition, according to the research of Amianto and coworkers (2021), the psychoeducational interventions may give a good chance for improvement even if they involve only one parent and if the parenting style of parents is not the optimal one. In fact, it has been evidenced that affectionless control represents a greater risk for obesity if both parents display it, while it is significantly lower if only one parent displays it. This means that the effects of affectionless control of one parent can be attenuated if the other has a different parenting style, although nonoptimal.

Conclusion

Notwithstanding their limitations, the reviewed studies provide the evidence for a strong association between a specific parenting style in childhood, i.e., the affectionless control, and the development of obesity in adulthood. Instead, even if BED displayed lower levels of care by both parents and higher overprotection with respect to non-BED obese participants, which are coupled with worse personality profile and

psychopathology features, no parenting style results as a specific risk factor for the development of this disorder. This seems to be a consequence of a more complex pathogenesis characterizing BED with respect to obesity alone, which probably involves traumas and life events which are not linearly related to parenting styles. Thus, as evidenced for other mental disorders, research suggests that parental neglect may represent the most relevant risk factor related to parenting for developing BED. In fact, parental neglect may help the development of inadequate personality traits and psychopathology under the pressure of environmental stressors, both within and outside the family.

Efforts to prevent child and adult obesity should take into account the existence of dysfunctional parental styles in childhood and their consequences for child and adult functioning, and the strategies which should be implemented to correct them. To take care of the parenting styles in infancy may elicit consistent cultural changes to adapt the parenting attitudes in the general population toward a greater attitude to respond to the needs of children. This may be particularly useful in view of the rapid evolution and greater complexity of current society. Future research should be addressed to explore the efficacy of these psychoeducational efforts (Morhosko et al., 2011).

Implications for Other Eating Disorders

Present research supports the importance of attachment dynamics for pathogenesis of eating and nutrition disorders and obesity, which at the present moment is not included in the DSM-5 ED chapter. Nevertheless, it suggests some specification in this regard. First, it supports that while the role of childhood attachment dynamics in favoring the outburst of obesity is direct and linear also in adulthood, the consequences of these dynamics are more difficult to be found in other eating disorders, as evidenced for BED (Amianto et al. 2021). In fact, even though some authors sustained the relevance of attachment dynamics for the outburst of eating disorders, they also suggested that this relationship is not linear, disorder-specific, and easy to be recognized with the studies of attachment in the adult population (Tasca and Balfour 2014). Recent theories concerning the outburst of anorexia nervosa, and eating disorders in general, suggested that the mediator for this relationship could be the deficitary development of the self in those subjects who received insufficient parental care (Amianto et al. 2016b). Future research concerning the role of parenting in the pathogenesis of EDs could benefit from a more objective assessment of the concept of the self which may be useful to underline the pathway by which defective attachment produces each eating disorder. Also the research connecting attachment dynamics with other concausal risk factors may help a better definition of the pathogenesis of each ED.

Second, the present research also suggests that childhood obesity may represent the early expression of attachment distortions, and the early recognition of overweight or obesity may help to recognize early risk factors of the development of a fragile self in adolescence. The assessment of any ED for future research should

consider and valorize the preexistence of childhood obesity and consider it as a specific indicator of dysfunctional attachment dynamics in this population. Future research may differentiate the risk factors implicated in the pathogenic pathways in those ED subjects with and without previous childhood obesity.

Mini-Dictionary of Terms

Parenting style = The ensemble of the attitudes that parents express managing the needs of their children.
PBI = Parental Bonding Instrument (PBI) is a worldwide known validated instrument assessing parenting style during childhood and adolescence.
Affectionless control = A parenting style characterized by low caring attitudes coupled with high overcontrol toward children activities, a major risk factor for obesity.
LNO obesity = Obese subjects that display low levels of childhood parenting neglect and lower psychopathology in adulthood.
SNO obesity = Obese subjects that display high levels of childhood parenting neglect and higher psychopathology in adulthood.

Key Facts of Parental Care and Binge-Eating Disorder

- Parental care alterations in childhood are strictly related to the development of obesity in adolescence and adulthood.
- Obese individuals with or without BED display parenting neglect with respect to controls.
- The severity of neglect is strictly related to more severe personality distortions and psychopathology expression.
- Recent research evidenced that childhood affectionless control is a specific risk factor for the development of obesity in adulthood.
- No specific parenting style is a predictor of BED.

Summary Points

- Binge-eating disorder (BED) has the highest prevalence among the EDs, and it is likely to increase.
- BED has particular interest for primary care because of its link with medical and psychiatric comorbidities.
- BED is associated with eating psychopathology, psychiatric and medical disorders, social and occupational impairment, and low quality of life.
- Early attachment experiences are relevant components of BED pathogenesis and of the other disordered eating behaviors which lead to obesity.

- Deficit attachment impairs the development of emotional control producing inability to cope with negative emotions in a framework of negative experiences.
- Non-authoritative parenting styles in childhood and physical and psychological abuses in childhood are strictly related to the development of obesity in adulthood.
- Personality abnormalities and the higher levels of psychopathology in subjects with obesity may be related to worse parenting.
- Parenting experience recalled by BED and non-BED obese participants is significantly different from healthy controls.
- The parenting style defined "affectionless control" is a relevant and specific risk factor for the development of obesity.
- The anxious attachment promoted by affectionless control impairs the development of positive working models and of self-identity.
- Obesity may derive from a failure in the development of a coherent self, as suggested for the anorexia nervosa.
- Obese participants express different relationships relating childhood parenting to psychopathology: direct for non-BED obese and indirect for BED.
- BED displays a complex pathogenesis possibly more linked to the family dynamics than to the alteration of the parenting style.

DeltaFosB and Preclinical Binge Eating

49

Implications for Clinical Contextual Applications

Richard Quansah Amissah and Igor Timofeev

Contents

Abstract

Binge eating (BE), an addictive behavior, can develop as a coping mechanism to mitigate the effects of a stressful event. It results in the expression of deltaFosB (ΔFosB), a protein involved in the initiation and maintenance of addictive behaviors, in the reward system. In humans, BE is characteristic of anorexia nervosa binge-purge subtype (AN-BP), bulimia nervosa (BN), binge eating disorder (BED), and other specified feeding or eating disorder (OSFED). Patients who binge display feelings of guilt, shame, and disgust following the binge. It was hypothesized that patients binge to reactivate a hypofunctioning reward system. However, following the binge, this system returns to its previous hypofunctioning state, suggesting that BE is associated with decreased reward system activity as demonstrated by several human and animal studies. Several treatment

methods have been developed for BE; however, most are ineffective partly due to our poor understanding of the mechanisms underlying BE. As ΔFosB expression decreases neuronal excitability, it may underlie the decreased reward system activity observed in BE patients. These findings suggest that BE treatments that increase reward system activity may be an optimal treatment strategy. Moreover, most pharmacological treatments decrease dopamine release or dopamine receptor activity, which seems contradictory to the reward deficiency theory, which proposes that addictive behaviors are promoted by decreased dopamine release and receptor density, suggesting that treatments should rather stimulate dopamine release or increase dopamine signaling. Based on ΔFosB expression experimental results in bingeing animals, we suggest that treatments that block ΔFosB expression may be a promising new way to treat BED.

VTA	Ventral tegmental area
ΔFosB	DeltaFosB

Introduction

In our day-to-day activities, humans are exposed to stimuli which could either result in positive or negative affect. Positive affect is associated with motivation and enthusiasm, while negative affect is associated with depression, anxiety, and fear (Watson et al. 1988). While positive affect is welcome, negative affect is not and usually forces individuals to develop coping mechanisms for them. These mechanisms may involve engagement in activities that help to mitigate the negative affect and could lead to maladaptive behaviors like drug and food addiction to mitigate the negative affect.

Drug addiction involves compulsively seeking and using drugs, accompanied by a feeling of loss of control. This is similar to what happens in patients who engage in binge eating (BE). DeltaFosB (ΔFosB) is a protein expressed in the brain, with highest degree of expression in the nucleus accumbens (Acb) and dorsal striatum, brain regions important for addiction (Nestler et al. 2001). It is responsible for the initiation and maintenance of addictive behaviors, and since BE is a form of addiction, the same protein may be implicated in its initiation and maintenance.

Due to the complexity of BE, several human and preclinical studies have been conducted to understand their underlying mechanisms. Knowing these mechanisms will help to develop effective treatments that target the etiology of the disorder and not just the symptoms. The main purpose of this chapter is to elucidate the involvement of ΔFosB in BE and to discuss possible treatments for BE, based on our knowledge of the role of ΔFosB in BE. Below, we will describe the main features of ΔFosB, how it is expressed, and its implication in eating behavior. We will also focus on eating disorders (EDs) that involve BE and are likely to be mediated by ΔFosB. We will compare results of imaging studies involving human patients with EDs with those in animal studies on EDs. We will further establish a relationship between these EDs and ΔFosB and subsequently discuss what the findings mean in the context of treatments for BE.

ΔFosB and BE

As animals interact with their environment, they are exposed to several stimuli. These stimuli are translated into signals within the brain through gene expression. Each time an animal is exposed to a stimulus, immediate early genes (IEGs) such as c-Fos, zinc finger protein, early growth response 1, and activity-regulated cytoskeleton-associated protein are expressed in the brain (Minatohara et al. 2016). These IEGs encode transcription factors that regulate gene expression. Unlike IEGs, which are transiently expressed and degrade immediately, ΔFosB is expressed following chronic stimulation, as shown in Fig. 1. It is a truncated *fosB* gene with a 37 kD isoform that is quite stable and was detected 1 month after last exposure to a stimulus (Nestler et al. 2001).

ΔFosB: What, When, and How?

ΔFosB is expressed following chronic stimulation with stress (Vialou et al. 2010), drugs (Perrotti et al. 2008), and palatable food (Wallace et al. 2008; Quansah

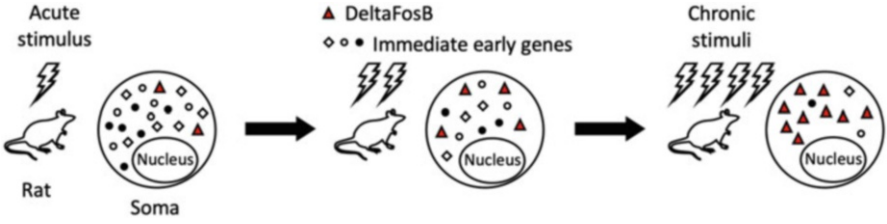

Fig. 1 ΔFosB expression in neurons following chronic stimuli. An acute stimulus results in the expression of immediate early genes and only a small amount of ΔFosB in neurons within the brain; however, as the stimulus progresses to chronic stimuli, immediate early genes degrade and ΔFosB expression increases

Amissah et al. 2020). Environmental enrichment (Lobo et al. 2013) and sexual activity (Sanna et al. 2019) also lead to ΔFosB expression. Other activities and stimuli which result in ΔFosB expression are listed in Table 1. Basically, chronic engagement in activities that are considered rewarding leads to ΔFosB expression. Even though most studies focus on ΔFosB expression in the Acb, it can also be expressed in the hippocampus, parabrachial nucleus, cingulate cortex, dorsal raphe nucleus, nucleus of the solitary tract, paraventricular nucleus of the hypothalamus, ventral bed nucleus of the stria terminalis, locus coeruleus, and ventral pallidum (Eagle et al. 2018; Cunningham et al. 2008). More importantly, it is expressed in reward processing regions, specifically the Acb, prefrontal cortex (PFC), and ventral tegmental area (VTA), in binge-like eating rats (Muñoz-Escobar et al. 2019; Quansah Amissah et al. 2020).

The stimulation of dopamine and glutamate receptors on Acb medium spiny neurons (MSNs) results in increased intracellular protein kinase activity which causes the activation of cAMP-response element binding protein (CREB) (Bito et al. 1996). The activated CREB is then phosphorylated, resulting in the expression of *fosB* and *c-fos* genes and a small amount of ΔFosB (Nestler et al. 2001). Persistent stimulation of receptors on MSNs leads to the downregulation of *c-fos* and *fosB* and the upregulation of ΔFosB (Renthal and Nestler 2009). As a transcription factor, ΔFosB regulates the transcription of other genes including nuclear factor kappa B (NK-κB), cyclin-dependent kinase 5 (Cdk5), α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) glutamate subunit 2 (GluR2), Ca^{2+}/calmodulin-dependent protein kinase II (CAMKII), N-methyl-D-aspartate (NMDA) Z1, and glutamate decarboxylase (McClung and Nestler 2003).

What Is the Effect of ΔFosB Expression on Behavior?

Several studies have been conducted to elucidate the effects of ΔFosB expression on animal behavior, and these studies generally involved ΔFosB overexpression in the Acb of transgenic animal models. While this technique is not ideal, in that the protein is generally expressed at moderate levels within the brain, it has contributed significantly to our understanding of how ΔFosB mediates behavior. In drug abuse studies, ΔFosB overexpression in the rat Acb protects against the cocaine addiction phenotype by decreasing reinstatement of cocaine self-administration, promoting the extinction of cocaine seeking, and reducing cocaine self-administration (Zhang et al. 2014). ΔFosB overexpression also increases the sensitivity of transgenic rats to the rewarding effects of cocaine (Kelz et al. 1999). ΔFosB blockade in the Acb either promotes vulnerability or decreases resilience to social defeat in male mice (Vialou et al. 2010), while its overexpression in the rat Acb produces an antidepressant-like effect evaluated as decreased immobility time during the forced swim test. Regarding natural rewards, while the overexpression of ΔFosB in Acb dynorphin-producing MSNs increases wheel running, its overexpression in Acb enkephalin-producing MSNs has the opposite effect on wheel running (Werme et al. 2002). Rats overexpressing ΔFosB in the Acb shell increase their number of bar presses to obtain sucrose pellets (Zhang et al. 2014). Moreover, overexpressing ΔFosB in the Acb increases the number of nose pokes and lever presses of mice and rats, respectively, for a food reward (Olausson et al. 2006). These studies suggest that ΔFosB expression mediates motivational processes involved in the seeking and consumption of both drug and natural rewards, behaviors that are impaired during addiction.

What Is the Effect of ΔFosB on Neuronal Activity?

In the Acb, ΔFosB can regulate MSN synaptic properties by regulating the expression of the AMPA GluR2 receptor subunit gene (McClung and Nestler 2003). High ΔFosB expression causes an increase in the number of GluR2-containing AMPA receptors at the synapse. GluR2 regulates most of the biophysical properties of AMPA receptors (Isaac et al. 2007). AMPA receptors are tetramers, meaning they comprise of four subunits: GluR1, GluR2, GluR3, and GluR4, in different

combinations (Borges and Dingledine 1998). While the GluR1, GluR3, and GluR4 receptor subunits contain glutamine in the M2 membrane-associated hydrophobic domain at position 607, the GluR2 subunit contains arginine instead. The presence of arginine in the GluR2 receptor subunit introduces an additional positive charge at the receptor pore, which prevents the entry of Ca^{2+} (Isaac et al. 2007). By so doing, MSN neurons with GluR2-containing AMPA receptors show decreased firing rate and permeability to divalent cations like Ca^{2+} (Vialou et al. 2010). In hippocampal CA1 pyramidal neurons, ΔFosB overexpression causes a decrease in intrinsic membrane excitability, due to a reduction in hyperpolarization-activated depolarizing current, without an effect on the resting membrane potential or spike frequency adaptation (Eagle et al. 2018). The hyperpolarization-activated depolarizing current also reduces excitatory synaptic potentials at distal dendritic sites (Magee 1998). ΔFosB expression is therefore associated with decreased neuronal excitability. This is consistent with the assumption that ΔFosB expression likely signifies tolerance to chronic stimulation resulting in a decrease in neuron responsiveness to subsequent stimulation and the proposition that ΔFosB expression following chronic palatable food consumption in binge-like eating rats led to decreased activity in reward processing regions (PFC, Acb, and VTA) (Quansah Amissah et al. 2020; Nestler et al. 1999).

BE: What, When, and How?

BE is characterized by the consumption of large amounts of food in a discrete amount of time and loss of control during bingeing. BE involves the consumption of palatable foods (Allison and Timmerman 2007), and it is characteristic of multiple EDs such as anorexia nervosa binge-purge subtype (AN-BP), bulimia nervosa (BN), binge eating disorder (BED), and other specified feeding or eating disorder (OSFED) (American Psychiatric Association 2013).

The lifetime prevalence for AN is 0.6% (men, 0.3%; women, 0.9%), BN 1% (men 0.5%; women, 1.5%); and BED 3% (men, 2%; women, 3.5%) (Hudson et al. 2007). This shows that BN and BED are the most prevalent EDs and are more prevalent in females than males (Kessler et al. 2013). In the United States of America (USA), the economic cost of EDs for the 2018–2019 fiscal year was $64.7 billion (Streatfeild et al. 2021). The high prevalence of EDs and the associated cost suggest the need for studies to investigate the mechanisms that underlie EDs. Below, we will focus mainly on BN and BED which are the most prevalent EDs that involve BE.

Comorbidities associated with BE include depression and anxiety. Individuals who binge report feeling ashamed, anxious, guilty, and disgust following a binge (American Psychiatric Association 2013). Seventy-five percent of adults and 85% of adolescents who binge experience other comorbidities such as mood and substance use disorders, and even though majority of individuals who binge are obese, some have normal weights (Hudson et al. 2007). Individuals who binge also exhibit deficits in inhibitory control and mental inflexibility (Mobbs et al. 2011).

BE occurs in people of all ages, even though it typically occurs during adolescence (Hudson et al. 2007). BE is more commonly triggered by negative affect (Womble et al. 2001), including stress, and people who binge usually do so to decrease the negative effects of a stressful event (Hawkins and Clement 1984). BE is often associated with a sense of relief following the binge (Heatherton and Baumeister 1991); however, the experienced relief is short lasting, and individuals continue to binge (Deaver et al. 2003). The desire to avoid the aversive consequences because of abstinence from palatable foods has also been linked to relapse among BE individuals in recovery (Heatherton and Baumeister 1991).

What Do We Know from Human Studies?

In humans, the neurobiology of BE has been studied using imaging techniques. fMRI studies involving *monetary rewards* revealed decreased activity in the striatum, insula, and PFC of BED patients (Balodis et al. 2014; Balodis et al. 2013), while those that involved *food rewards* reported diminished insula, thalamus, and frontostriatal region activity during anticipation and consumption in BN patients (Bohon and Stice 2011; Skunde et al. 2016) and decreased activity in the insula and hippocampus in BED patients (Lyu and Jackson 2016). MRI studies have also revealed decreased gray matter volumes in the caudate nucleus and Acb in BN patients (Coutinho et al. 2015). Overall, these studies suggest that BE is associated with decreased activity in brain regions involved in reward processing and inhibitory control such as the PFC, striatum, and insula, supporting a hypothesis that individuals binge to reactivate a hypofunctioning reward system (Wang et al. 2001). A number of studies have also reported opposing results in similar regions in BE patients using neuroimaging techniques (Lee et al. 2017); however, the disparity in results could be due to differences in patient sexes and groups.

What Do We Know from Animal Studies?

Human neuroimaging studies provide information on major brain structures involved in BE, pointing to possible underlying mechanisms, but they do not tell us which types of neurons are implicated and how their manipulation will affect BE. These questions were investigated in animal models of BE using different approaches (see below).

Animal Models of BE

Even though several animal models of BE exist, none replicates all aspects of BE as defined in the DSM V; however, these models still provide useful information on BED. The main characteristic of BE is the consumption of larger than normal amounts of palatable food within a short period of time. To replicate this characteristic, rodents are given intermittent access to palatable food, like sucrose, chocolate, cookies, etc. (Calvez and Timofeeva 2016). Additional techniques include food restriction and some form of stress (Boggiano et al. 2007; Corwin et al. 1998). However, only intermittent access to palatable food was sufficient to induce binge-like eating in rats (Corwin et al. 1998). This technique may not be ideal because by definition BE is the consumption of food when not feeling physically hungry

(American Psychiatric Association 2013). Another approach that is employed to develop binge-like eating models is the use of stress since BE is usually triggered by some stressful event and BE patients usually binge to mitigate the effects of the stress (Boggiano et al. 2007; Calvez and Timofeeva 2016). Finally, people who binge report the feeling of a sense of loss of control during the binge. This loss of control is associated with compulsivity or loss of inhibitory control. In rodent models, this can be evaluated by assessing how much discomfort rodents are willing to endure to obtain a reward (palatable food). Indeed, the foot-shock maze test (Oswald et al. 2011) and the modified light/dark box test, tests that assess compulsivity, validate the similarity of this model with BED in humans (Quansah Amissah et al. 2020; Calvez and Timofeeva 2016).

Overview of the Reward System

The reward system mainly comprises of structures that make up the meso-corticolimbic dopamine system such as the VTA, PFC, and Acb (Kelley and Berridge 2002) (Fig. 2). The major types of neurons in the VTA, PFC, and Acb are dopaminergic, glutamatergic, and GABAergic (MSNs), respectively. The dopaminergic VTA projects to the Acb and PFC (Beier et al. 2015). In turn, PFC glutamatergic neurons target the VTA and Acb (Vertes 2004). The Acb GABAergic neurons target the VTA but not the PFC (Heimer et al. 1991) (Fig. 2). In the normal brain, reward consumption activates VTA dopaminergic neurons, which subsequently release dopamine in the PFC (Phillips et al. 2004) and Acb (van Zessen et al. 2012). PFC activity excites the Acb and VTA, leading to more dopamine release in the Acb (Murase et al. 1993). MSNs in the Acb target mainly GABAergic VTA neurons (Xia et al. 2011), resulting in the disinhibition of VTA dopaminergic neurons to further increase the dopamine release in the Acb. The optogenetic stimulation of VTA GABAergic neurons interrupts reward consumption (van Zessen et al. 2012), while VTA dopamine neuron stimulation leads to positive reinforcement

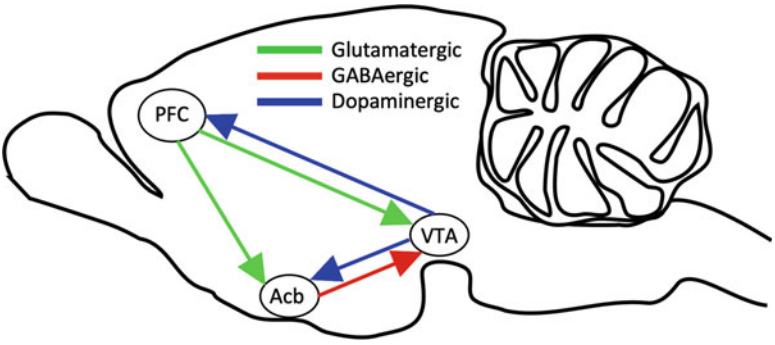

Fig. 2 Main projections from the key regions that form the mesocorticolimbic dopamine system. Neurons within the PFC, Acb, and VTA project to other regions within the reward system. PFC, prefrontal cortex; Acb, nucleus accumbens; VTA, ventral tegmental area. Red arrow, GABAergic neuron projection; green arrow, glutamatergic neuron project; blue arrow, dopaminergic neuron projection

(Kim et al. 2012). PFC activity increases following reward consumption (Horst and Laubach 2013), and inactivating the prelimbic part of the PFC results in a decrease in reward seeking (Sangha et al. 2014). During reward consumption, the activity of Acb MSNs decreases, while their stimulation attenuates consumption (Krause et al. 2010).

The neurons within the VTA, PFC, and Acb can be subclassified based on the types of receptors they express. Within these regions, neurons express receptors for a variety of neurotransmitters/modulators. Of particular importance, neurons that express D1 and D2 dopamine receptors can be found in the PFC and Acb (Simon et al. 2013). An increase in D2 dopamine receptor expression in the Acb increases motivation (Trifilieff et al. 2013). Compulsively eating obese rats have decreased D2 dopamine receptor expression in the striatum, while the knockdown of striatal D2 receptors resulted in the development of addiction-like reward deficits and the initiation of compulsive food seeking (Johnson and Kenny 2010).

Similarities Between Human and Animal Studies

BE involves the chronic stimulation of neurons through repeated palatable food consumption, which results in neuron desensitization (Moore et al. 2018), which may explain the decreased activity observed in the reward system of both patients and binge-like eating animals. Both human and preclinical studies seem to support the reward deficiency theory which suggests that addictive behaviors, including BE, are associated with hypofunctioning of the dopaminergic system reflected by decreased dopamine release and reduction in D2 dopamine receptor density (Blum et al. 2000). Obese individuals have lower D2 dopamine receptor densities in the striatum (Wang et al. 2001). Therefore, individuals who binge do so because of their hyposensitivity to dopamine, and they consume more food in order to experience its rewarding value. This supports the theory that people binge to reactivate a hypofunctioning reward system (Wang et al. 2001). In regions involved in inhibitory control like the PFC, decreased dopamine D2 receptor density was also associated with decreased activity, which may mediate the compulsive behavior associated with BE (Blum et al. 2014).

We propose that the desensitization or decreased activity of neurons that occurs during BE may be due to ΔFosB expression in the reward system (Fig. 3). We recently demonstrated that the number of ΔFosB-expressing neurons in the reward system of BE-prone (BEP) rats was significantly larger than that in BE-resistant (BER) rats (Fig. 4a, b, d, e, g, and h). The increase in the number of ΔFosB-expressing neurons in BEP rats was found in the mPFC, Acb, and VTA (Fig. 5a–c) (for details, see Quansah Amissah et al. (2020)). In a follow-up study, using an in vivo electrophysiological approach, we investigated reward system activity in a similar binge-like eating rat model. Local field potential, in particularly evoked potentials per lick, was lower in BEP rats as opposed to BER rats (Fig. 4c, f, i). These differences were significant in all investigated structures (Fig. 5d–f) and were mirror images of results obtained with ΔFosB expression. Unit recordings demonstrated that (a) the firing rate of neurons in the reward system in BEP rats was lower than that in BER rats, (b) sucrose consumption resulted in increased firing rate

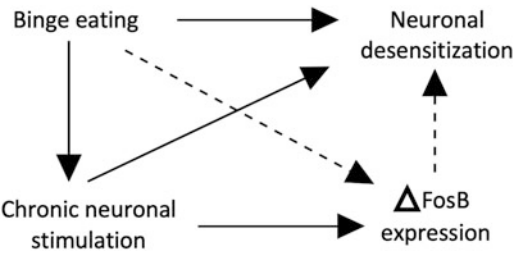

Fig. 3 Summary of possible relationship between BE, chronic stimulation, ΔFosB expression, and neuronal desensitization. BE causes chronic stimulation of reward system neurons, reward system desensitization, and ΔFosB expression suggesting that the desensitization observed in patients with BE may be due to ΔFosB expression in the reward system. Dashed arrow, possible mechanisms; solid arrow, known mechanisms

(2020). **c, f,** and **i** from Quansah Amissah et al. (2021)

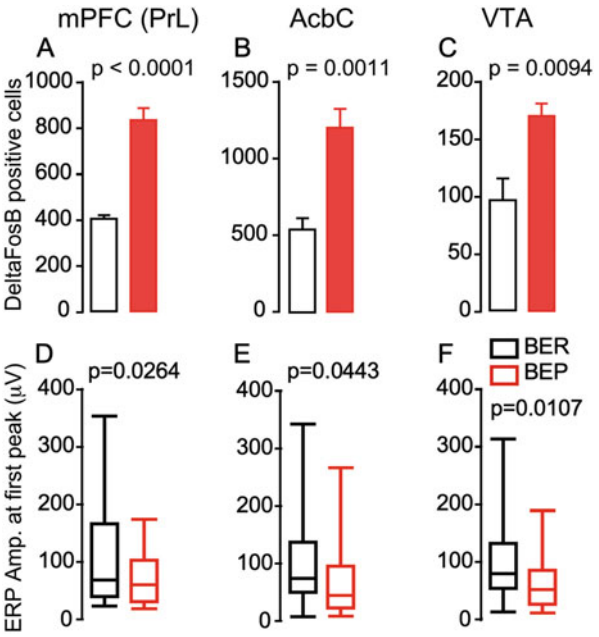

Fig. 5 Quantification of ΔFosB-expressing cells and the amplitude of the event-related potential in the reward systems of BEP and BER rats. (**a**–**c**) The number of ΔFosB-positive cells in the prelimbic cortex of the medial prefrontal cortex (prelimbic), the nucleus accumbens core, and the ventral tegmental area. (**d**–**f**) The event-related potential amplitude at the first peak just after each lick in BEP and BER rats for the medial prefrontal cortex, nucleus accumbens, and ventral tegmental area. (**a**–**c**) from Quansah Amissah et al. (2020), (**d**–**f**) from Quansah Amissah et al. (2021)

in both groups of rats, and (c) firing within 1 s before the beginning of palatable food consumption was significantly increased in BEP rats (Quansah Amissah et al. 2021). These studies are consistent with human fMRI studies that reported decreased reward system activity in BE patients. Thus, all available data point to the fact that patients binge to reactivate a hypofunctioning reward system.

Implications for Clinical Contextual Applications

Above, we described the neurobiology of BE. Based on known mechanisms, we propose below optimal treatments for BE.

For the prevention or treatment of BE, one needs to consider comorbid conditions such as stress, depression, or anxiety. Most common current treatments of BE include cognitive behavioral therapy (CBT), neuromodulation, pharmacotherapy, and, more recently, virtual reality. CBT is the best validated and frequently used treatment for BE, even though BE symptoms still remain in more than 60% of patients who undergo CBT (Slade et al. 2018; National Institute for Health and Care Excellence 2017). The use of virtual reality, which involves user interaction with and immersion in a simulated environment, often provides better results compared to CBT (Riva et al. 2021).

Pharmacological treatments for BE are used when patients do not respond to psychotherapy, patients are unwilling to undergo psychological or behavioral interventions, psychotherapy is unavailable, or there are other psychiatric comorbidities (McElroy 2017). Most pharmacological treatments aim to modulate the

dopaminergic system (Towell et al. 1988). Additionally, several animal studies have shown deficits in dopamine release and positive effects of dopamine receptor agonists on binge-like eating (Davis et al. 2009; Rada et al. 2010).

Lisdexamfetamine (LDX) is the only Food and Drug Administration-approved drug in the USA for treating moderate to severe BED (Heo and Duggan 2017). In humans, LDX reduces BE severity, BE days, and the associated compulsivity (McElroy et al. 2016). It works by blocking the reuptake of dopamine and noradrenaline (Heal et al. 2016). Unfortunately, LDX does not affect comorbidities of BE such as depression and anxiety, implying that it targets the main pathology of BE. Bromocriptine, a D2 dopamine receptor agonist, is another drug used for treating BE. In obese patients, it decreases body fat, body weight, and hyperglycemia (Meier et al. 1992). Another drug, KB220Z, an agent that stimulates dopamine release, has shown some success as a treatment for drug addiction. It is a homeostatic agent used to improve neurological deficits and the resistance of the nervous system to trauma, anxiety, stress, fatigue, and chemical imbalances (Chen et al. 2011). In heroin addicts, treatment with KB220Z significantly activated the caudate-accumbens dopaminergic pathway, alleviated withdrawal from antidepressant medication, and was considered a safer therapy for mild depression (Blum et al. 2012). This drug could have positive effects in the treatment of BE, a form of addiction.

A new pharmaceutical treatment for BE may be aiming to block the expression of ΔFosB in the brains of BE individuals to attenuate this addictive behavior. In animals, ΔFosB overexpression increases palatable food consumption (Wallace et al. 2008), suggesting that its downregulation or blockage might have the opposite effect in bingeing rats. In one study, ΔFosB expression in the orbitofrontal cortex was blocked through virally mediated expression of deltaJunD, a dominant negative antagonist of ΔFosB (Winstanley et al. 2007). ΔFosB expression can therefore be blocked; however, further studies on BE in animal models are needed before preclinical studies and further treatments in humans.

Neuromodulation is performed to modify the activity of specific neural circuits through the application of electric current with predetermined parameters in order to restore a functional state without damaging the brain tissue (Luan et al. 2014). Using this approach, action potentials can either be stimulated or blocked through invasive and noninvasive techniques (Luan et al. 2014). Invasive techniques for brain stimulation include intracranial and deep brain stimulation (DBS), while noninvasive techniques include transcranial magnetic stimulation (TMS), transcranial direct current stimulation (tDCS), transcranial alternate current stimulation (tACS), and more recently focused ultrasound stimulation (FUS).

Our results suggest that the PFC, Acb, and VTA are implicated in the generation of BED (Quansah Amissah et al. 2021; Quansah Amissah et al. 2020). Besides reward, the PFC is involved in several cognitive processes including cognitive control, attention, impulsive behavior, addiction, long-term declarative memory storage, etc. Therefore, the PFC is often targeted during neuromodulation in BE patients. Because comorbid conditions are different in different patients and the parameters of stimulation are different, the results of neuromodulation for ED are often contradictory. tDCS of the right or left DLPFC resulted in improvements in BE

symptoms among patients (Sreeraj et al. 2018). It has been known for a long period of time that intracortical anodal stimulation depolarizes neurons and increases firing (Purpura and McMurtry 1965). To achieve similar effects with tDCS, the needed current intensity has to be much higher than the established safety parameters. However, new stimulation parameters (intermittent stimulation) may result in better control of neuronal firing (Vöröslakos et al. 2018). Stimulation using such parameters have not been tested yet in BED.

In BED and BN patients, rTMS of the left dorsolateral prefrontal cortex (DLPFC) resulted in significant improvements in BE symptoms such as inhibitory control of impulsive behavior (Guillaume et al. 2018). Other studies reported no differences in symptoms following rTMS of the same region (Gay et al. 2016).

So far, DBS in BED patients has been rarely used. DBS of the bilateral lateral hypothalamus (Whiting et al. 2013) and Acb (Tronnier et al. 2018) improved bingeing and weight loss. In patients with cluster headaches, VTA DBS was attempted with some success, even though it resulted in side effects such as elevated blood pressure, tachycardia, and diplopia (Akram et al. 2016). In pigs, VTA DBS results in changes in blood-oxygen-level-dependent (BOLD) activity in the bilateral dorsolateral prefrontal cortex and ipsilateral posterior cingulate (Settell et al. 2017). VTA stimulation could therefore be applied in BE treatment; however, considering the associated adverse effects and the subsequent effects on other brain regions, it may be necessary to use this approach when other approaches fail.

Focused ultrasound stimulation is a new technique which can be used to noninvasively stimulate deep brain structures to control BED. So far, it has been used successfully in mice for peripheral stimulation in obesity-induced metabolic dysfunctions (Huerta et al. 2021). The use of this technique can be very promising for the stimulation of the Acb or VTA to increase neuronal firing which should reactivate the hypofunctioning reward system in affected patients.

To conclude, the control of BED can be achieved via either reduction of expression of ΔFosB, which, as secondary effect, will increase neuronal excitability in the PFC, Acb, and VTA, or by direct stimulation of these brain regions. Because the PFC, Acb, and VTA also control other brain functions, stimulation of these structures with current, magnetic field, or ultrasound can cause secondary effect. For the moment, secondary effects of activation due to reduction in ΔFosB expression cannot be excluded but are not known. Therefore, control of ΔFosB expression seems to be one of the most promising mechanisms in the control of BED.

Application to Other EDs

Similar to BN and BED, the etiology of AN, one of the three main EDs characterized by food restriction, severe emaciation, and distorted body image (Kaye et al. 2013), is poorly understood. Thus, the treatment is symptomatic (Rantala et al. 2019). There is no approved medication for AN (Bodell and Keel 2010), suggesting the need for

further research. Like BN and BED, the dopaminergic and serotonergic neurotransmitter systems are implicated in AN. In AN patients, increased 5-HT_{1A} serotonin receptor density and decreased 5-HT_{2A} serotonin receptor density have been reported in the PFC, leading to decreased activity (Carli et al. 2006; Bailer and Kaye 2010). PET studies in AN patients also revealed decreased extracellular levels of dopamine and increased D2/D3 receptor densities in the striatal regions (Frank et al. 2005). This suggests the need for new treatment methods, including pharmacotherapy and neuromodulation, which can increase activity in these regions by increasing serotonin and dopamine release or signaling, similar to treatments proposed for BED.

rTMS of the left DLPFC has been used in a number of studies involving AN patients resulting in significant improvements in AN symptoms (Choudhary and Roy 2017), but no improvement was found in similar treatments (Jaššová et al. 2018). An open-label, single-arm study also reported significant improvement in AN symptoms in seven patients following tDCS of the left DLPFC (Khedr et al. 2014). In terms of DBS, significant improvements in AN symptoms such as weight gain and obsession have been reported. In these studies, the regions targeted include the bilateral Acb (Wu et al. 2013) and the ventral striatum (McLaughlin et al. 2013).

Several pharmacological treatments that block dopamine and serotonin release and those that block serotonin reuptake have been attempted for AN with little to no improvements in symptoms (Ruggiero et al. 2001; Halmi et al. 1986), suggesting a need for alternative treatments. Mechanistic understanding of AN may reveal important insights into treatment strategies especially since AN is prevalent and associated with a high mortality rate (Harris and Barraclough 1998).

Mini-Dictionary of Terms

Comorbidity: Disorders or diseases that are present simultaneously as another disease or disorder of interest.

Compulsivity: Behaviors characterized by repetitive and persistent actions not related to a specific goal, even in the presence of adverse consequences.

Impulsivity: It involves rash decision-making without prior thought of the consequences of one's action to maximize pleasure.

Inhibitory control: The ability to inhibit a specific behavior in response to a stimulus to achieve a specific goal.

Medium spiny neurons: Neuron type that makes up the majority (about 90%) of neurons in the striatum.

Reward: A stimulus that is pleasurable, induces motivation to obtain it, and promotes learning of cues and behaviors to obtain it.

Key Facts of ΔFosB

- The ΔFosB protein is 101 amino acids shorter than the FosB protein.
- Upon initial expression, ΔFosB has a molecular weight of 33 kD; however, persistent stimulation results in the modification of the protein into its stable 37 kD isoform.
- All drugs of abuse lead to ΔFosB expression.
- ΔFosB modulates the growth of neurites and the function of neurons by regulating the expression and activity of the cyclin-dependent kinase 5 protein.
- ΔFosB is a molecular switch that sustains addiction.
- Chronic wheel running and alcohol consumption also leads to ΔFosB expression.

Summary Points

- BE is characteristic of EDs such as AN-BP subtype, BN, BED, and OSFED.
- BE involves the consumption of large amounts of palatable food which results in the chronic stimulation of neurons within the reward system.
- The chronic stimulation of reward system neurons results in the desensitization of the reward system which is observed as decreased activity in human patients who binge and in binge-like eating animal models, consistent with the hypothesis that people binge to reactivate a hypofunctioning reward system.
- The desensitization observed in the reward system of patients who binge may be due to the expression of ΔFosB in neurons in brain regions within the reward system.
- According to the reward deficiency theory, addictive behaviors, including BE, are characterized by decreased dopamine release and signaling in the reward system, and therefore techniques that promote dopamine release and signaling may be effective as treatments for BE.
- Due to the role played by ΔFosB in initiating and maintaining addictive behaviors, treatments that block its expression may be effective in BE patients.

Abstract

Binge eating refers to eating an unusual large amount of food coupled with experiencing a loss of control over eating. Although various methodologies have been used to assess binge eating and its momentary antecedents, ecological momentary assessment (EMA) has been most influential recently, as it examines these states in daily life and thus provides the most naturalistic data. EMA results showed that not only negative affect/stress, dieting, food craving/hunger but also

cognitive states (e.g., executive functioning), physical appearance/body dissatisfaction, and external context precede binge eating in daily life. Reported consequences of binge eating are negative affect and compensatory behaviors. Apart from reviewing the existing literature on antecedents and consequences of binge eating in different populations, we discuss future directions for research and clinical implications.

Introduction

Binge Eating in Eating Disorders

Binge eating is defined as eating an unusual large amount of food in a certain time period while experiencing a loss of control over eating, that is, not being able to control what to eat and when to stop (American Psychiatric Association 2015). Such binge eating episodes are a diagnostic criteria of bulimia nervosa (BN), binge eating disorder (BED), and the binge-purge subtype of anorexia nervosa (AN). Reliably assessing binge eating seems crucial and identifying antecedents and consequences of such episodes seems important to tailor helpful interventions curbing binge eating.

Measuring Binge Eating: State of the Art and Its Limitations

Binge eating can be assessed with different methodologies. *Self-report questionnaires* represent the most economic method, for example, by asking about the frequency of binge eating episodes and its associated states and traits. Most questionnaires assess the two main features of objective binge eating separately: whether the amount of consumed food was larger than what another comparable individual would have eaten under the same circumstances and whether control over eating was lost. Yet, it might not be easy to estimate the amount of food so that also subjective binges during which an individual experiences a loss of control without having eaten an objectively large amount of food may be counted as objective binge eating

episodes. Thus, the frequency of objective binge eating may be overestimated. Moreover, in these one-time measurement questionnaires, time-varying as well as momentary and short-lived antecedents and consequences of binge eating are hard to capture and reliance on memory is high. To exemplify, the Eating Disorder Examination Questionnaire (EDE-Q) or the Eating Disorder Diagnostic Scale assesses eating disorder symptoms such as the frequency of binge eating episodes (see Peyser et al. 2020 for an overview). Individuals need to recall binge eating episodes over the last 28 days, which might be easier with only a few episodes occurring, however, more difficult with several episodes per week. Interestingly, a study showed that whereas the diagnostic interview revealed two groups of individuals with and without BED, the frequency of binge eating episodes in the following naturalistic assessment was similar between both groups (Le Grange et al. 2001). Thus, relying on the diagnostic interview only might have overlooked binge eating episodes and potentially resulted in inadequate diagnosis. Moreover, self-reports make retrospective attribution more likely (e.g., "I had a binge eating episode so I must have been sad before"). Similarly, there is an ongoing discussion, whether emotional eating can validly be assessed with self-reports or if they rather reflect mere attribution effects (so-called emotional about eating hypothesis; Bongers and Jansen 2016; Adriaanse et al. 2011).

Another possibility to assess binge eating more objectively is through *laboratory test meals* which allow greater degree of standardization and minimize recall biases. Binge eating episodes can reliably be assessed in the laboratory (Peyser et al. 2020) and experimental manipulation of antecedents is possible (e.g., eliciting negative affect for emotions through a sad movie). To illustrate, participants were randomized into one group viewing a sad movie and another group viewing a neutral movie for 45 min (Van Strien et al. 2012). Both groups were offered crisps and M&Ms while watching the movie. Participants were invited to eat whatever they liked and were instructed to eat at least one piece of snack without knowing that the amount of food they have eaten was being measured. Results showed that self-reported high emotional eaters ate more during the sad compared to the neutral movie, whereas low emotional eaters ate less. However, the approach of experimentally assessing antecedents of binge eating also suffers from several limitations: Because of the artificial setting in the laboratory, binge eating episodes lack ecological validity. Eating in the laboratory is restricted to certain food types the experimenter presents (i.e., mostly one or two types of foods), while natural binge eating may be highly person-specific (e.g., one person preferring cookies as binge foods, another one crisps). Further, individuals may feel discomfort during the experiment as binge eating is often accompanied by shame or guilt. As a result, individuals might present socially desirable behavior, avoid binge eating in the laboratory, and postpone it to later when being at home. Finally, there are several challenges with regard to conducting laboratory binge eating studies (e.g., costs and time for setting up the laboratory, test meals, etc.).

To overcome these limitations, assessing binge eating and its predictors in daily life presents a promising avenue. Ecological Momentary Assessment (EMA), or more broadly speaking Ambulatory Assessment, enables researchers to measure

behavior, emotions, or cognitions several times throughout the day as they unfold in their natural environment (Shiffman et al. 2008). Individuals are prompted on their smartphone several times a day to answer questions about their mood, context, location, among others ("signaled measures"), while at the same time reporting binge eating episodes whenever they occur (self-initiated, "event-based" measurement). Hence, EMA allows to naturally assess binge eating alongside its potential antecedents and consequences at a relatively high temporal resolution (order of a few hours). In the following paragraph, we will exemplify an EMA study assessing binge eating and its antecedents before summarizing the most influential predictors (i.e., affect, dieting, hunger/food craving, physical appearance-related aspects, cognitive constructs, and external context) as previously reported in EMA studies.

Example of Studying Binge Eating through EMA

In a recent study, we examined patients with an interview-diagnosed eating disorder with regard to binge eating and other eating disorder symptoms in their daily life. Participants installed a customized smartphone app and answered questions about their affect, stress, and eating behaviors six times a day at specific time points (i.e., signal-contingent sampling) for eight consecutive days (see Fig. 1). Binge eating was further assessed "event-contingent" so that whenever a binge eating episode occurred, participants self-initiated the smartphone app (exemplified by the red figure between the last two prompts) and answered questions about potential binge episodes (e.g., whether overeating, loss of control, and compensatory behavior occurred, as well as affect after the binge). Please note that sometimes participants forget to report the binge eating episode separately on an event, which might be due to the affective turmoil during and after the binge. Thus, an additional, retrospective measurement on the subsequent signal (e.g., at 9.30 pm in this example) was taken.

In this study, one patient diagnosed with BED reported a binge eating episode in the late afternoon. As you can see in Fig. 2, the participant reported negative affect and nearly no hunger on a scale from 0 (=not at all) to 100 (=very much) at the last prompt before the binge eating episode. At 3:37 pm, the participant completed an EMA *event* for the binge episode, reporting to be alone, having eaten ~700 calories in that binge and again being in a negative affective state directly after the binge.

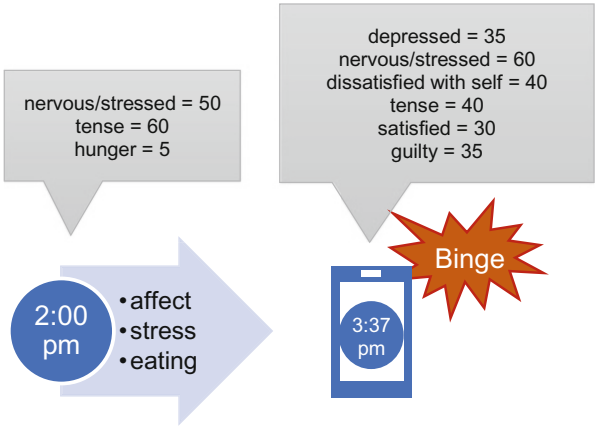

Fig. 2 Exemplified binge episode during Ecological Momentary Assessment. EMA sampling of a binge eating episode with information of the previous prompt (=antecedent) on the left and aspects after the binge (=consequences) on the right

Affect

Nibbling candy while studying for an exam, eating chocolate after a breakup – such additional food intake in response to negative affect (e.g., sadness, worry) is termed *emotional eating*. Emotional eating is relatively prevalent in the general population and thus not inherently pathological, but can gain clinical relevance when the additional food intake evolves into binge eating (i.e., eating large amounts, experiencing loss of control). Indeed, patients with eating disorders regularly attribute their binge eating episodes to negative affect (Alpers and Tuschen-Caffier 2001), and correspondingly, negative affect resembles the most widely reported antecedent of binge eating (Wolfe et al. 2009). According to the affect regulation model (Booth 1994), negative affect triggers binge eating which in turn alleviates negative affect by distraction or the use of comfort foods. Through principles of instrumental conditioning with negative reinforcement, binge eating will thus become more likely in the future.

General and Specific Negative and Positive Affect in Daily Life

A meta-analysis by Haedt-Matt and Keel (2011b) reviewed 36 previous naturalistic studies with a total of 968 patients with an eating disorder and demonstrated that greater negative affect preceded binge eating episodes in daily life. Since then, study activity has been increasing and also those newer studies have supported this positive relationship between negative emotions and binge eating across the eating disorder spectrum (Svaldi et al. 2019; Goldschmidt et al. 2012, 2014b; Ambwani et al. 2015; Engel et al. 2013; Lavender et al. 2016; Munsch et al. 2012; Smith et al. 2018; Stevenson et al. 2018; Keating et al. 2019; Schaefer et al. 2020; Berg et al. 2017; Chami et al. 2021; Wonderlich et al. 2022). Another study specified negative affect to emotions high on negative valence, arousal, and avoidance relation (e.g., nervous, distressed) preceding binge eating episodes (Becker et al. 2018).

Apart from general negative affect, certain emotions may play a particular role in emotional binge eating: Previous research highlighted the role of anger (Engel et al. 2007), fear, hostility, sadness, but especially guilt (Berg et al. 2015) in preceding binge eating episodes. Similarly, other research emphasized the role of stronger feelings of guilt (Schaefer et al. 2020) and shame (Goldschmidt et al. 2018) as important affective states prior to binge eating in daily life.

In contrast to greater negative affect, also lower *positive* affect has been found prior to binge eating episodes (e.g., Becker et al. 2018; Schaefer et al. 2020; Le Grange et al. 2001). However, evidence is more inconsistent with also nonsignificant associations being reported in individuals with obesity (Smith et al. 2018) and a reverse direction of association in associations in men, that is, higher positive affect prior to binge eating episodes (Mason et al. 2021a).

Stress

Strongly intertwined with negative affect, also higher stress predicted subsequent binge eating (Smith et al. 2021b). Another study showed that stress was higher before binge eating episodes and normal eating episodes in individuals with BED compared to a non-BED sample (Le Grange et al. 2001). However, stress might not be independently related to binge eating but through increases in negative affect: interpersonal stressors, daily hassles, and stress appraisal impacted subsequent binge eating through an increase in negative affect (Goldschmidt et al. 2014b). In the same vein, other research suggests that momentary stress might predict increases in binge eating through increase in negative affect (Srivastava et al. 2021a).

Affective Lability, Emotion Dysregulation, and Dissociation

Although affect "peaks" (e.g., high negative affect) seem pivotal in binge eating prediction, also affective *lability*, that is, fluctuations in emotional experiences may be interesting. Affective lability predicted binge eating episodes (Anestis et al. 2010; Kukk and Akkermann 2017). Such momentary fluctuations seem to be stronger predictors of binge eating episodes compared to retrospective self-reported affective lability (Anestis et al. 2010). Other studies found that emotion dysregulation seems important in daily binge eating (Keating et al. 2019; Kukk and Akkermann 2017). The dysfunctional emotion regulation strategy rumination, that is, repetitive thinking, predicted subsequent binge eating in individuals with BED, although no role of emotion regulation as moderator of the negative affect–binge eating relationship was found (i.e., stronger affect-bingeing relationship in those with dysfunctional emotion regulation) (Svaldi et al. 2019). This partially contrasts with findings showing that rumination actually mediated the association of negative affect with subsequent binge eating, that is, negative affect increased binge eating through its effect on rumination (Smith et al. 2021a). Relatedly, dissociation (i.e., a state in which a person disconnects from one's own feelings or thoughts) was elevated prior to binge eating episodes, independent of negative affect (Engelberg et al. 2007) and higher momentary dissociation even led to sharper increases of negative affect (Mason et al. 2017).

Dietary Restraint and Weight Loss Dieting

Besides affect, another group of theories explain binge eating through dieting and dietary restraint. According to the "dietary restraint theory," weight loss dieting or restrictive eating puts people at risk for binge eating (Polivy and Herman 1985). Dieting and withstanding omnipresent eating pleasures consume cognitive control resources; however, whenever dietary rules are broken, such dietary slips are interpreted as evidence for a lack of self-control. As a result, individuals may temporarily abandon their efforts to restrict eating behavior, binge eating resulting in binge eating. In the end, individuals end up in a vicious circle in which strict dietary restraint is repeatedly punctuated with episodes of binge eating (see Fig. 3). Hence, the importance of dietary restraint for binge eating is emphasized in several influential theoretical models of eating disorders (e.g., see Fairburn et al. 2003; Burton and Abbott 2017, 2019). In contrast to that, other research has emphasized that well-planned dietary restriction alongside consistent self-monitoring and realistic weight and eating goals can have positive health outcomes and does not necessarily increase the risk to binge eating (Schaumberg et al. 2016). The discussion on the advantages and disadvantages of dietary restraint is ongoing and EMA research is giving important insights.

In an EMA study in individuals with BN, higher caloric restriction on a given day increased the probability of binge eating on the same day as well as the next day (Zunker et al. 2011). Similarly, restraint has been noted as antecedent for binge eating in individuals with BED (Le Grange et al. 2001) or unselected individuals (Kukk and Akkermann 2017). Interestingly, individuals with AN experienced a higher risk of binge eating after fasting for 8 h; however, meal skipping was associated with a lower risk of same-day binge eating (De Young et al. 2014). However, other studies could not find a significant relationship between restrictive eating behavior and subsequent binge eating episodes in individuals with AN (Fitzsimmons-Craft et al. 2015) or BN (Engelberg et al. 2005) or same-day binge eating episodes in individuals with BN or BED (Chami et al. 2021). Other studies even found the reverse relationship in that a higher level of restraint was associated with lower risk of binge eating in individuals with obesity or binge eating pathology (Legenbauer et al. 2018; Pearson et al. 2018). However, please note that both of these studies assessed the *desire to* restrict or *thought about* restricting food intake

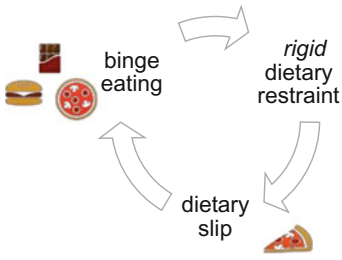

Fig. 3 Relationship between restraint and binge eating. Vicious circle of dietary restraint causing binge eating and vice versa

instead of actual restriction, potentially accounting for the reverse direction. Interestingly, the study of Engelberg et al. (2005) showed that higher restraint preceded stronger binge craving, suggesting that restraint might influence binge eating via higher urge to binge, with additional factors determining whether such cravings translate into actual binges.

Food Craving/Hunger and Urge to Binge

Within this pernicious cycle mentioned above, hunger and food craving may be important interfaces between dietary restraint and binge eating (Booth et al. 1990). While actual caloric restriction can trigger hunger and hunger can drive (homeostatic) overeating, problematic eating behaviors are probably more related to food craving. Food craving has been linked with snacking and with palatable, high-caloric food consumption in the context of self-reward or "comfort eating" (Hill 2007).

Indeed, in BED samples, craving sweets preceded binge eating (Greeno et al. 2000), and binge eating was more likely on days with higher food craving than on days with lower food craving (Chami et al. 2021). Regarding mechanisms, another study showed that higher food craving preceded binge eating but only in individuals whose appetitive network was activated in a laboratory food cue reactivity task (Wonderlich et al. 2017). There might also be an interplay between different factors: Food cravings that led to a binge eating episode were associated with higher tension, lower mood, and lower hunger than those food cravings that did not lead to a binge eating episode (Waters et al. 2001). As a related construct, desire to binge (i.e., binge craving) was higher before binge eating episodes but also normal eating episodes in daily life in individuals with BED compared to healthy individuals (Le Grange et al. 2001).

Interestingly, hunger alone does not seem to constitute an important precursor of binge eating: A meta-analysis showed that hunger was higher before regular eating episodes compared to binge eating episodes (Haedt-Matt and Keel 2011a). Similarly, also Goldschmidt et al. (2018) reported lower hunger prior to binge eating episodes relative to non-binge episodes.

Physical Appearance and Body Dissatisfaction

According to the spiral model of eating disorders, comparing one's actual self to an ideal-self results in a discrepancy that can triggering eating disordered behavior (Heatherton and Polivy 1992). Similarly, the transdiagnostic model of eating disorders (Fairburn et al. 2003) points to the core psychopathology of an overevaluation of shape and weight and their control. Thus, appearance, and especially body-related aspects, might also be of relevance when considering antecedents of binge eating.

Indeed, upward comparisons against subjectively more attractive individuals did increase the likelihood of binge eating in daily life (Drutschinin et al. 2018). Experience of a higher self-ideal discrepancy interacted with higher negative affect in predicting binge eating (Mason et al. 2021c). Other research found that

momentary body dissatisfaction predicted subsequent binge eating episodes (Srivastava et al. 2021b) or urges to binge eat (Fitzsimmons-Craft 2017). The impact of body dissatisfaction on binge eating in daily life may best be explained by a dual-pathway model in which body dissatisfaction influences negative affect on the one hand and dietary restraint on the other, which in turn lead to binge eating in daily life (Holmes et al. 2015). Moreover, in women with AN, stress associated with food, shape, or weight-related media exposure was associated with greater risk of subsequent binge eating (White et al. 2016). Similarly, state weight and shape concerns were related to concurrent and subsequent binge eating in daily life (Panza et al. 2021). Greater momentary appearance-related stress preceded binge eating in individuals with AN which might be mediated by momentary anxiety (Mason et al. 2018).

Cognitive States: Expectancy and Executive Functioning

Emotions, cognitions, and behavior are interconnected so that cognitive aspects might also play a role for binge eating (i.e., a behavior) to occur. Previous research showed that individuals with BED tend to selectively allocate their attention towards palatable food (i.e., attentional bias; e.g., Sperling et al. 2017) which might facilitate binge eating. When experiencing a strong urge to binge, inhibitory control could aid in withstanding that impulse. However, research demonstrated that individuals with binge eating as in BED have poorer executive functioning and thus less inhibitory control (e.g., Iceta et al. 2021; Prunell-Castañé et al. 2021).

Smith et al. (2020a) showed that apart from negative affect itself, a positive eating expectancy (i.e., believing that eating would actually improve one's mood) was associated with binge eating. Schaefer et al. (2021) replicated this finding and showed that such eating expectancies correlated with reductions in negative affect after binge eating (negative reinforcement). Additionally, executive functioning might interact with negative affect in their impact on daily binge eating: The relationship between negative affect and binge eating was stronger on days marked by reduced inhibitory control, at least in individuals with AN-BP or BN (Smith et al. 2020b). Additionally, Smith et al. (2020a) used ambulatory tasks to measure attentional biases towards food via the dot-probe task. The authors found that a higher momentary attentional bias towards palatable foods was related to an increased risk of subsequent binge eating.

External Context

Binge eating might need a specific external context in order to occur. As stated above, binge eating may be accompanied by feelings of shame or guilt or feeling disgusted with oneself so that being with others would be experienced as discomforting. In some individuals (especially with AN-BP or BN), binge eating may also be followed by subsequent compensatory behavior like vomiting so that a bathroom nearby may be important. Finally, binge eating requires an unusually large

amount of food available which might pose specific requirements to the environment (e.g., storage space).

Consistent with this context dependency, binge eating was found to be more likely when being alone and at home (Munsch et al. 2012; Greeno et al. 2000; Svaldi et al. 2019; Stein et al. 2007; Goldschmidt et al. 2018) than in other settings. In addition, binge eating was more likely in the early afternoon or evening hours (Stein et al. 2007; Smyth et al. 2009; Schreiber-Gregory et al. 2013), but additionally around 1 pm (Smyth et al. 2009), on weekdays compared to weekend days, and its average duration in daily life was reported to be 42 min (Schreiber-Gregory et al. 2013).

The Aftermath: Consequences of Binge Eating

According to theories of operant learning, binge eating would need to be followed by positive consequences in order to be self-reinforcing. However, a meta-analysis concluded that negative affect actually increased following a binge eating episode in daily life and decreased only after purging behavior in individuals with BN (Haedt-Matt and Keel 2011b). Yet, this research is inconsistent with other findings of a significant decrease in negative affect after binge eating in BED (Schaefer et al. 2020; Wonderlich et al. 2022), AN or BN (De Young et al. 2013; Lavender et al. 2016; Wonderlich et al. 2022), as well as with findings of decreased stress following a binge episode in BN (Fischer et al. 2017). Research also points to individual differences so that decreases in guilt following a binge eating episode are moderated by diagnosis (i.e., stronger decrease in BN compared to AN) and compensatory purging (i.e., more decreases in those who did not typically engage in self-induced vomiting than those who are)(De Young et al. 2013). Such affective responses to binge eating episodes may be a marker of treatment response, at least in BED (Mason et al. 2021b): Patients with greater net increases in positive affect after bingeing at baseline exhibited better treatment responses at the end of the treatment and follow-up.

With regard to compensatory behavior after a binge eating episode, research is mixed. Binge eating did neither predict subsequent fasting nor meal skipping in individuals with AN (De Young et al. 2014). Similarly, binge eating was associated with subsequent purging behavior in individuals with AN either in a negative direction, that is, binge eating reducing the likelihood of purging (Lavender et al. 2016), or a positive direction, that is, binge eating increasing the likelihood of purging (Goldschmidt et al. 2015).

Future Directions in EMA Research on Binge Eating Prediction

Methodological Considerations in the Affect–Binge Eating Relationship

Our review suggests that the most consistent precursor of binge eating is negative affect; however, the range of affective states is very broad. The affective

consequences of binge eating episodes are heterogeneous and thus the maintaining mechanism seems less clear. In this regard, several methodological aspects when assessing and analyzing the mutual relationship between affect and binge eating in daily life seem worth mentioning:

First, choosing an appropriate sampling frequency seems necessary to capture the highly dynamic process of an affect–binge eating relationship. Kockler et al. (2018) illustrated how emotional processes during binge eating change every 15 min across a 1.5 h time window; a dynamic which lower sampling frequency would have overlooked. Similarly, inconsistent results with regard to the post-binge affect ratings might be explained by sampling frequency (Berg et al. 2017): Average pre-binge ratings were assessed 2.5 h before the binge eating episode whereas post-binge ratings are on average closer in time to the binge eating episode (~20 min). The pre- and post-assessments are not equidistant and research suggests that negative affect might even further increase during the 2.5 h before the binge. As a result, previous findings might not ultimately be contradictory and negative affect might be reduced after a binge episode, but future research with a more fine-grained sampling frequency is needed. Second, the majority of studies assumed a linear relationship between negative affect and the probability to binge eating (i.e., the higher the negative affect, the more likely a binge). However, other research supports a threshold model in which the impact of affect on binge eating is nonlinear and dependent on whether a threshold value of negative affect is breached (Fuller-Tyszkiewicz et al. 2014). Hence, testing different modeling approaches when analyzing the affect–binge eating relationship might be worthwhile.

Moderators in the Relationship Between Antecedents and Binge Eating

Our review mostly covered the main effect of antecedents (states) on binge eating (see Fig. 4). However, there might also be several person-level (traits) characteristics like self-report data (e.g., emotional, restrained or external eating style, trait food craving, trait stress eating, impulsivity), sex, patient status (e.g., AN-BP, BN or BED), or body mass index that moderate the momentary relationships between an antecedent and binge eating (see Fig. 4). Research also points to the advantage of combining daily binge eating data with preceding laboratory assessments of impulsivity (Smith et al. 2019a) or assessments of altered responses to food cues in response to stress (Fischer et al. 2017; Wonderlich et al. 2018) as they might impact the affect–binge eating relationship in daily life. Hence, accounting for such aspects might further aid in disentangling the complex and partially inconsistent relationships between antecedents and binge eating in daily life.

Including Objective Assessment Measures

Most EMA studies reduce retrospective biases but still rely on self-report data. However, certain aspects might be complemented by objective measures by the use of mobile technology (Smith and Juarascio 2019; Smith et al. 2019b). To illustrate, negative affect or stress might be objectively assessed via physiological responses (e.g., heart rate or cortisol) or voice recordings (Grabowski et al. 2019). Similarly, objective measures of context might be measured through smartphone

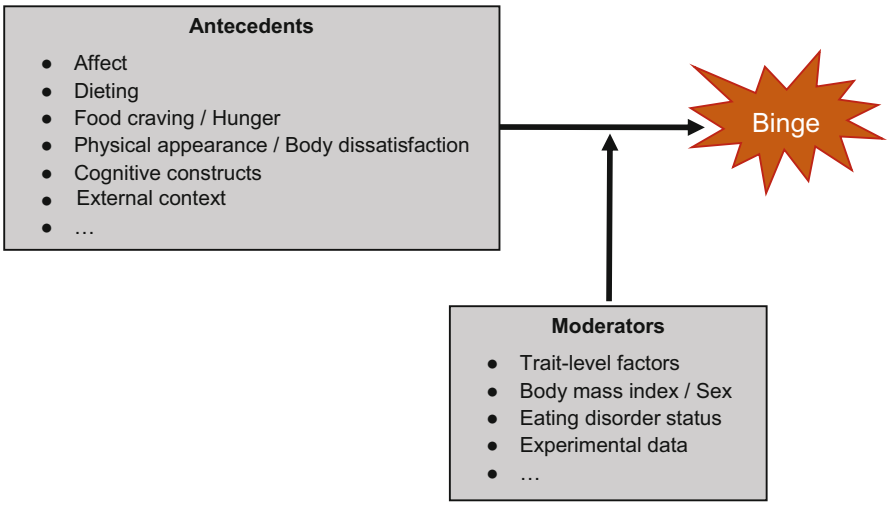

Fig. 4 Main effects and moderators on binge eating. Main effect of antecedents on binge eating in daily life and their moderation by several between-person moderators

sensors assessing GPS location or acoustic features of the environment (e.g., see Trull and Ebner-Priemer 2013 for an overview). Acquiring such information from sensors instead of asking individuals would be less burdensome on the one hand and would avoid interfering with one's natural routine while providing a high temporal resolution of context changes. Future EMA studies might profit from including such objective assessments and examining distinct and shared associations with subjective reports as antecedents of binge eating.

Individualized Approaches ("N of One Studies")

The EMA research reviewed above has linked a relatively broad range of factors with binge eating. Thus, binge eating predictions for a given individual are difficult to make based on the current, group-based research approach. Although indispensable for theory building and generalization, such nomothetic models (models derived from group data) perform poorly in predicting binge eating for a given individual (Adolf et al. 2014; Fisher et al. 2018). Negative emotions might accurately predict binge eating in some individuals, but fail to do so in others, for whom other antecedents (e.g., extensive fasting or dissociative states) are predictive. Thus, idiographic analyses and intervention approaches in the domain of binge eating research and treatment are on the rise (Smith and Juarascio 2019). The longitudinal time series data that come with EMA studies afford statistical modeling of individual relationships, for example, through multilevel modeling (e.g., Schwartz and Stone 1998). Further approaches like Network Models, Latent Class/Profile Analyses, and Latent Class Vector-Autoregression can be used to identify person-specific variable sets associated with binge eating within a single participant or identify clusters of

individuals with similar person-specific variables sets (Goldschmidt et al. 2014a; Müller et al. 2014; Pannicke et al. 2022).

Interventions/Clinical Implications

Knowledge on antecedents of binge eating is crucial for developing effective interventions to reduce binge eating. However, intervention approaches specifically aiming at reducing the relationship between an antecedent and binge eating by interventions being delivered in daily life are still rather scarce (e.g., Smith and Juarascio 2019). Yet, modern technology allows the use of ecological momentary interventions (EMIs), defined as interventions which are delivered in real time, for example, via smartphone app. Indeed, previous research has reported that EMIs might be effective in reducing binge eating (e.g., see Smith and Juarascio 2019; Anastasiadou et al. 2018; Ahmadiankalati et al. 2020 for overviews and further information). Based on the ideographic models mentioned above (person-specific networks), new kinds of individualized interventions in daily life can be applied. Taking these idiographic binge eating models to predict person specific high-risk times for binge eating episodes and send interventions via smartphone application right before these times is termed "Just-in-Time Adaptive Intervention" (JITAI; Juarascio et al. 2018). An intervention might be sent to the user when being in a specific state (e.g., negative affect, stress) and environmental context (e.g., alone at home) and at certain times (e.g., in the evening) to tackle binge eating.

Application to Other Eating Disorders

In this chapter, we reviewed studies that assessed antecedents (e.g., negative affect, dieting, food craving) of binge eating in daily life using ecological momentary assessment. Several eating disorders like bulimia nervosa, binge eating disorder, and the binge-purge subtype of anorexia nervosa are characterized by frequent binge eating episodes. However, binge eating episodes with lower frequency can also occur in individuals diagnosed with the restrictive subtype anorexia nervosa or in individuals with overweight and obesity. Antecedents and consequences should mainly be similar but potentially with a slightly different focus (e.g., dieting may be a more important predictor of binge eating in daily life in the restrictive subtype anorexia nervosa). Moreover, the momentary antecedents assessed in daily life have also been shown in laboratory and psychometric studies. In this regard, two meta-analyses examined the relationship between laboratory-elicited affect and eating behavior, however, with contradictory conclusions: Cardi et al. (2015) reported that negative affect was related to higher food intake, whereas Evers et al. (2018) could not find a significant relationship between negative affect and food intake. Note that both meta-analyses did not explicitly review binge eating behavior but food intake in general. Similarly, caloric deprivation (Agras and Telch 1998) or body-related aspects (Svaldi et al. 2009) have been shown in laboratory studies as

antecedents of binge eating or desire to binge, but again, results are mixed with other research finding no associations between these antecedents and binge eating assessed in a laboratory setting (e.g., Sysko et al. 2017; Hetherington et al. 2000). More consistently, previous research using self-reports underpin the antecedents mentioned in the chapter, especially affect, dieting, food craving, and body dissatisfaction (Vanderlinden et al. 2004; Wolfe et al. 2009).

Mini Dictionary of Terms

- **Binge eating**. Eating an unusual large amount of food without being able to control yourself.
- **Urge to binge**. A strong negative desire to binge eat that might evolve into an actual binge eating episode.
- **Ecological Momentary Assessment**. A method to study the natural behavior and environment of a person, mostly by the use of a smartphone app.
- **Emotional eating**. Experiencing food craving or eating in response to negative emotions.
- **Food craving**. Experiencing a strong desire to consume a specific food, especially high-caloric, high in fat or sugar.

Key Facts of Emotional Eating

- Nearly half of the individuals eat more in response to stress, half eat less.
- Individuals may change their eating behavior in response to negative but also positive emotions.
- Positive emotional eating may be a functional eating style associated with a lower body mass index.
- Healthy individuals and patients with an eating disorder differ on negative and positive emotional eating.
- Other consummatory behaviors like smoking or alcohol drinking could also be used as emotion regulation strategy.

Key Facts of Ecological Momentary Assessment

- The term Ecological Momentary Assessment (EMA) was coined in 1994 by Stone and Shiffman.
- EMA can be applied to a wide range of behaviors, experiences, and conditions.
- EMA sampling includes signal-, event-, and interval-contingent sampling.
- Reactivity (i.e., changing behavior in response to the assessment) and compliance should be considered.
- EMA may pose a burden to participants as they frequently have to answer questions during their daily routine.

Summary Points

- Binge eating can be examined using self-reports, experimental or naturalistic studies.
- Higher negative affect and stress are robust predictors for binge eating in daily life.
- Research on the importance of dietary restriction on binge eating in daily life is mixed.
- Whereas food craving and desire to binge seem important for subsequent binge eating, hunger seems not.
- Exposure to physical-appearance-related content and body dissatisfaction constitute antecedents of binge eating.
- Higher eating expectancy and lower executive functioning facilitates binge eating.
- Binge eating in daily life occurs mostly in the afternoon and evening when being alone at home.
- Future research on naturalistic binge eating should consider the sampling frequency of EMA data, between-person characteristics, and include objective assessment methods.
- Individualized approaches may aid in disentangling divergent findings and inform treatment approaches in the form of Just-in-Time-Adaptive-Interventions.

Contents

Abstract

Cancer and binge eating each place significant burden on individuals' mental and physical health, which ultimately impacts the healthcare and public health sectors. While there has been a high volume of research on cancer and binge eating separately, the possibility of a relationship between cancer and binge eating is an important, yet understudied, topic for scientific research and discussion. In the current chapter, similarities between cancer and binge eating are highlighted, including the overlap of major known risk factors and psychological correlates of cancer and binge eating. Many risk factors for cancer development, such as obesity, low physical activity, poor nutrition, and substance use, are also associated with binge eating and related disorders. Additionally, many of the psychological correlates of binge eating are commonly experienced by individuals with cancer – e.g., negative affect, emotion dysregulation, and impulsivity. From the cancer and binge-eating literatures, it is possible that there might be an association

between cancer and binge eating, but the nature of the association is unclear. Future empirical research is needed to study the relationship between cancer and binge eating.

Introduction

Cancer currently stands as the second leading cause of death in the United States, and common comorbidities of the disease (e.g., obesity, poor nutrition, smoking, and alcohol use) often decrease survival rates even further (Rivera and Brawley 2019). Although the rate of cancer incidence has remained fairly stable since the 1990s, the peak of diagnoses has not yet fallen from the drastic increase in prevalence from 1974 to 1992 (Incidence 2021; National Cancer Institute 2021). High mortality rates related to cancer, as well as its noncommunicable nature, have made it a serious topic of discussion throughout the public health sector, especially because the risk of cancer development is multifaceted, spanning beyond just physical health (American Cancer Society 2021). In addition to its impact in the United States, cancer has been found to disproportionately impact low- and middle-income countries, which is associated with a deficit in the healthcare systems necessary for supporting the burden of the disease (American Cancer Society 2018). Consequently, low- and middle-income areas have less access to prevention at the primary level due to lack of educational tools and increased exposure to risk factors, at the secondary level through lack of diagnostic materials, and at the tertiary level through lack of access to treatment and rehabilitation (List and O'Connor 2020). Figure 1 displays some of the leading behavioral, environmental, and biomedical risk factors for cancer development.

Additionally, cancer is one of the most prevalent diseases that has continued to spread in developed countries despite advances in research and technology. Specifically, the most common cancers, such as lung, breast, and colon cancer, have been associated with workplace carcinogens that are common in developed regions (Viegas et al. 2017). Previous research has shown associations between cancer incidence and access to public healthcare, treatment quality, and both structural and social inequality (Rivera and Brawley 2019). With these factors in mind, cancer is something that adversely impacts public health through high mortality rates, expensive treatments, and increasing prevalence, whereas major risk factors for cancer heavily rely on public health interventions and preventions to rectify (Rivera and Brawley 2019; Viegas et al. 2017).

Cancer has a myriad of negative physical and mental health impacts. A few of the many common physical side effects of cancer include anemia, bleeding and bruising, osteoporosis, heart problems, and hypothyroidism (Knight Cancer Institute). In

Fig. 1 Leading behavioral, environmental, and biomedical risk factors for cancer

addition to these symptoms, research has also found that cancer is negatively correlated with health-related quality of life as a result of decreased physical functioning, increased pain over the course of the disease, and lower overall health status of patients (Boini et al. 2004). Cancer patients are also more likely to be diagnosed with future comorbidities such as cardiovascular disease, hypertension, high blood pressure, and musculoskeletal problems (Ng et al. 2018). Additionally, individuals with cancer have higher rates of endocrine, nutritional, and metabolic diseases (Ng et al. 2018). These factors shed light on the decline in physical health status that is commonly associated with cancer.

Mental health of cancer patients is also an increasing topic of discussion, as previous studies have shown increased mental health disorders among cancer groups. Mood disorders are specifically prevalent among populations with cancer, and patients are prescribed antidepressants more often than non-cancer groups (Ng et al. 2018). The psychological impacts of cancer are thought to arise from stressors present in diagnosis, treatment, remission, and recurrence of the disease (Iwamitsu et al. 2005; Lloyd et al. 2019; Reece et al. 2013). Therefore, mental health is an issue that influences all stages of the disease development and treatment. Support for the various stressors that can arise throughout the course of cancer

often goes unaddressed and contributes to disproportionate negative mental health outcomes for individuals with cancer (Ferrell et al. 2003). In addition, stress-related psychological factors such as maladaptive coping mechanisms and negative emotional response have also been associated with higher cancer incidence (Mason and Smith 2021).

While cancer is clearly one of the most pressing public health issues currently, associations between cancer and binge eating and associated disorders, such as bulimia nervosa and binge-eating disorder, have rarely been studied (Mason and Smith 2021). Given lack of data on binge eating and cancer, the current chapter will highlight behavioral risk factors for cancer and how these overlap with binge eating as well as mental and emotional health in binge eating and cancer. Then, conclusions and future directions will be provided.

Behavioral Risk Factors for Cancer

Obesity. Obesity is an established risk factor for cancer development (De Pergola and Silvestris 2013), and obesity and weight problems are said to account for as high as 20% of cancer cases (Wolin et al. 2010). The extent of risk that is associated with obesity-related cancer has been shown to vary by race/ethnicity. Research has found that Black adults with obesity are more susceptible to cancer development than other racial groups (Renehan et al. 2008). Additionally, obesity has been attributed to approximately 20% of cancer deaths in women and 14% in men, suggesting some gender disparities related to obesity and cancer risk (Renehan et al. 2008). Specifically, women with obesity and breast cancer have poorer outcomes than counterparts without obesity, and inflammation caused by obesity is linked to shorter survival rates in breast cancer patients (Goodwin and Boyd 1990). However, equally increased risk of colon cancer has been related to greater adiposity among patients with obesity, suggesting gender disparities in obesity-related cancer may be dependent on cancer type (Willett 2000). Studies have also found various incidences of cancer patients with obesity receiving inadequate chemotherapy dosages based on their weight, decreasing positive treatment outcomes in populations with obesity (Griggs et al. 2005). Obesity can also weaken the immune system, which further relates obesity to negative cancer outcomes and increased rates of diagnosis among individuals with obesity (Moulin et al. 2008).

Nutrition and diet. Nutrition and diet quality have been linked to both the risk and prevention of cancer. Research has found that diet may account for up to 35% of cancer deaths alone (Doll and Peto 1981). Statistics from Doll and Peto (1981) do not account for the influence of diet and nutrition on cancer development, suggesting diet and nutrition may play an even more significant role in cancer development, incidence, and mortality combined. Certain dietary suggestions have been made by the American Cancer Society and World Cancer Research Fund, such as decreasing consumption of high calorie foods and beverages, to lower cancer risk (American Cancer Society 2018). Research has shown that following these guidelines can

decrease risk of developing cancer by between 10% and 61% (American Cancer Society 2018).

Specifically, high fruit and vegetable, fiber, and dairy product consumption are correlated with decreased cancer risk, and consumption of red meat, processed meat, and salt are positively correlated with greater cancer risk (Block et al. 1992; Latino-Martel et al. 2016; Steinmetz and Potter 1991). Additionally, a systematic review by Makarem et al. (2018) found elevated sugar intake was associated with anywhere from 23% to 200% higher cancer risk. Overall sugar intake as well as intake from added sugars, free sugars, sucrose, desserts, and sugary drinks was each related to higher cancer risk (Debras et al. 2020; Faruque et al. 2019). Consequently, sugar and saturated fat intake have been correlated with increased weight gain and obesity, which may provide an indirect mechanism through which saturated fat intake, sugar intake, and cancer are related (Beulen et al. 2018; Stanhope 2016).

Diet and nutrition have also been associated with increased risk and mortality of certain cancers. For example, fiber intake was inversely correlated to colorectal and colon cancer incidence, and doubling fiber intake led to a 40% reduction in colorectal cancer diagnosis (Bingham and Riboli 2004). Increased caloric intake has been found to increase risk of breast, colon, rectum, prostate, endometrium, kidney, cervix, ovary, thyroid, and gallbladder cancers (Albanes 1987). Further, colon cancer rates are correlated with increased consumption of animal fat and meat (Giovannucci et al. 1994), and higher saturated fat consumption is associated with higher risk for developing breast cancer by over twofold (Bingham and Riboli 2004).

In addition to nutrient consumption, malnutrition is also related to lack of cancer control, particularly in regions where food insecurity is abundant. In low-income areas, malnutrition is often associated with decreased access to cancer treatment and increased risk of cancer-related morbidity and mortality (Sala et al. 2004). Overall, data shows that diet is an important risk factor for cancer and that increased risk can develop from both overconsumption of specific foods and through malnutrition caused by underconsumption (Albanes 1987; Sala et al. 2004).

Physical activity. Physical activity is a significant protective factor against cancer development, and increased levels of physical activity are related to longer survival times for cancer patients (Wolin et al. 2010). Low levels of physical activity are often associated with obesity and weight gain, which can lead to increased cancer risk through obesity mechanisms (Wolin et al. 2010). Yet, physical activity has also been shown to reduce cancer risk irrespective of obesity status (Hardman 2001). For example, research found that physically active men with higher body mass index were less likely to develop cancer than their nonactive counterparts (Hardman 2001), suggesting physical activity on its own is correlated with lower risk.

Various cancers have been studied individually with regard to physical activity and its possible protective effects. Research has found particularly robust evidence for the protective effect of physical activity in colon cancer compared to other cancers (Hardman A. 2001; Thune and Furberg 2001). Further, physical activity reduced incidence of prostate cancer from 10% to 30% on average (Hardman A. 2001), and physical activity directly after breast cancer diagnosis was associated with reduced disease-related mortality (Holmes et al. 2005).

Multiple mechanisms have been suggested through which physical activity may lower cancer risk. The first is through reduced likelihood of obesity and weight gain, which have been discussed as major risk factors for cancer development (Wolin et al. 2010; Thune and Furberg 2001). Physical activity also improves the immune system, and research suggests that exercise increases natural killer cells, macrophages, and cytokines (Hardman 2001). Additionally, increased physical activity is associated with increased oxygen free radicals, which stimulate the secretion of enzymes that have been studied to help prevent cancer development on a cellular level (Hardman 2001).

Substance use. Substance use behavior can also influence one's risk of cancer development. In the United States, four percent of cancer deaths are attributed to alcohol consumption (Sauer et al. 2019), and, in Europe, approximately 10% of all cancer incidence is related to alcohol consumption (Roswall and Weiderpass 2015). Additionally, Khan et al. (2010) found that alcohol increased risk of breast cancer by 2% for each additional drink consumed per week. Gender may also affect these associations with research showing that men are at higher risk for alcohol-related cancer diagnoses (Roswall and Weiderpass 2015). This may partly be due to environmental factors that lead to increased rates of binge drinking and higher overall alcohol consumption rates in men (Peralta et al. 2010).

An arguably more serious risk factor for cancer development is cigarette smoking and use of tobacco. Studies found that cigarette smoking causes up to 90% of lung cancers in the United States, and cigar, cigarette, and secondhand smoke are all directly correlated with some of the deadliest cancers, such as lung and respiratory (Khan et al. 2010; Sauer et al. 2019). This is becoming increasingly more relevant in the United States where cigarette smoking accounts for 29% of all cancer deaths (Sauer et al. 2019). Additionally, advertisements by the tobacco industry are targeting younger generations (Josefson 1998), which is problematic, as research suggests those who quit smoking earlier in life see larger decreases in mortality from lung cancer (Khan et al. 2010). Although quitting early in life leads to lower mortality rates, smokers who quit at any life stage have been shown to live 10 years longer on average after cancer diagnosis (Sauer et al. 2019).

Cancer screening behaviors. Important protective factors for cancer have also been identified, and arguably one of the most significant is the use of cancer screening and overall screening behaviors. The National Cancer Institute 2021 discusses the importance of screening behavior in early cancer diagnosis and prevention, typically before symptom onset. Cancers that are identified in early stages, before symptoms appear, are much easier to treat and often lead to better patient outcomes. Screening behaviors can include physical examinations, lab tests, imaging, and genetic tests, which may identify cancer biomarkers and other signs of cancer.

Research regarding the effects of screening behaviors on cancer mortality and incidence has had mixed results. Studies showed that up to 50% of decrease in prevalence and mortality rates of colorectal cancer (which has one of the highest mortality rates) are attributed to increased screening (A.G. Zauber 2015). Mammography screening has been widely accepted as a successful preventive factor for breast

cancer and involves a simple, noninvasive physical examination (Miller et al. 2010). However, some evidence suggests that both low- and high-risk groups for cancer development have similar rates of screening, which may suggest that the method is less efficacious than previously believed (Song and Giovannucci 2016). But, it is possible that high-risk groups develop more serious types of cancer, and other modifiable risk factors may play a role in these statistics. Regardless, screening has begun to play a significant role in primary and secondary cancer prevention over the last 30 years. Rates of screening are largely dependent on knowledge of risk, screening attitudes, social norms, and fear of cancer development (Wardle et al. 2015).

Associations with Binge Eating and Related Disorders

Binge eating occurs across the lifespan in diverse groups of individuals and can range in frequency and severity. Binge-eating disorder (BED) is a specific type of eating disorder that is characterized by recurrent binge-eating episodes and represents a high frequency and severity form of binge eating (Hilbert 2019). It differs from other more commonly known eating disorders because no compensatory methods (such as purging, laxative use, or restriction of intake) are used after binge eating. BED has just recently been included as a recognized eating disorder in psychiatric classification systems (Hilbert 2019). Although there is almost no research directly examining associations between binge eating and BED with cancer risk and mortality, many behavioral risk factors and comorbidities of binge eating are also risk factors for cancer development and mortality (see Fig. 2).

For example, patients with BED have significantly increased rates of obesity (Dingemans et al. 2002; McCuen-Wurst et al. 2018; Smith et al. 1998). Specifically, McCuen-Wurst et al. (2018) reported that those with BED were at three to six times greater likelihood of obesity compared to those without BED. Childhood obesity and early onset of being overweight are also more significantly reported in patients with BED (Fairburn et al. 1998). It is suggested that BED may have a causal effect on obesity development, likely due to increased energy intake from recurrent binge-eating episodes (Dingemans et al. 2002). In addition, the prevalence of BED among individuals with obesity was found to increase proportional to degree of obesity (Dingemans et al. 2002). Higher prevalence of obesity in patients with BED suggests the possibility of increased cancer risk in these populations, as obesity is a significant risk factor for cancer.

In addition to obesity, BED is also related to poorer nutrition and dietary intake. Studies have found that individuals with BED are more likely to skip meals, engage in night eating, and consume high-fat diets, snack foods, and desserts (Dingemans et al. 2002; Kiziltan et al. 2005). Relatedly, a recent study showed that intake of sweet and fast foods was associated with elevated ratings of binge-eating symptoms in middle-aged men (Mason et al. 2021), and, in a separate study, pregnant women with BED had higher consumption rates of fat, monounsaturated fat, saturated fat, and total energy (Siega-Riz et al. 2008). This suggests that both men and women

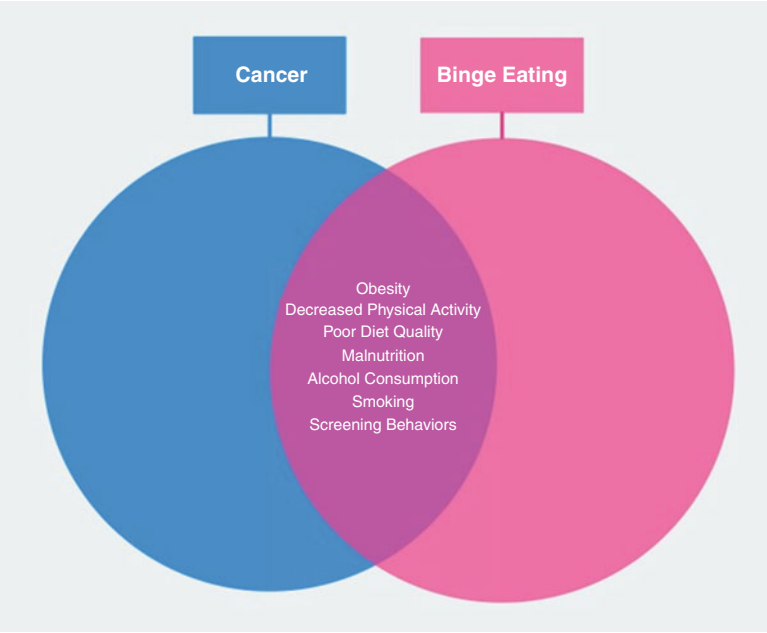

Fig. 2 Shared behavioral risk factors between cancer and binge eating

with binge eating are at an increased risk for poor diet, which could increase risk for cancer development.

Although little research has been done on the correlational or causational effects of BED and physical activity, trends have shown lower physical activity levels in those with BED (Galasso et al. 2020). In addition to lower physical activity, patients with BED are less physically fit than counterparts with obesity but without BED and are more likely to report musculoskeletal pain, which could be related to lack of consistent exercise (Vancampfort et al. 2014). Consequently, these individuals may be less likely to experience the protective effects of exercise on cancer outcomes. Research has also begun to consider physical activity as a possible mitigating factor for binge-eating episodes. For example, research showed adults reporting higher levels of physical activity had lower binge-eating symptoms compared to those with lower activity (Mason et al. 2021; Smith et al. 2020). Thus, lack of physical activity is a comorbidity of both BED and cancer, and increased physical activity may improve binge-eating symptoms and cancer outcomes.

Smoking and alcohol use are associated with binge eating, and similar mechanisms may operate in predicting the onset and maintenance of binge eating and substance use. For example, both alcohol consumption and binge eating are often used as maladaptive coping mechanisms and are strongly correlated with measures of maladaptive coping (Fitzsimmons and Bardone-Cone 2010; Metzger et al. 2017). A study by Munn-Chernoff et al. (2013) also found that addictive personality traits were common in both individuals who engage in binge eating and those with alcohol

problems. In addition, disordered eating behaviors among men are positively correlated with higher alcohol consumption (Berro et al. 2021), and substance use comorbidities are common in those with binge eating and associated eating disorders (Hudson et al. 2007; Munn-Chernoff et al. 2013). Further, a study on college students by Saules et al. (2009) found smokers to disproportionately engage in binge eating compared to those who had never smoked. Also, a separate study by Udo et al. (2016) noted increased metabolic abnormalities in individuals with binge eating who smoked, which suggests smoking in combination with binge eating may be correlated with poorer metabolic health than either alone. In relation to smoking cessation efficacy, smokers who engaged in binge eating had lower success rates with smoking cessation and more weight gain while trying to quit compared to smokers without binge eating (Marney et al. 2010; Udo et al. 2016). Therefore, higher rates of smoking among those with binge eating may increase cancer risk due to increased adverse health effects of smoking and poorer cessation rates.

Lastly, individuals with binge eating may be less likely to complete routine cancer screening and other preventive behaviors. A study on the utilization of healthcare among those with BED found lower rates of healthcare utilization after diagnosis (Watson et al. 2018). This may be due to a lack of awareness and knowledge of BED throughout the medical field and stigma that is associated with BED and obesity (Watson et al. 2018). While research has yet to examine associations between binge eating and cancer screening behaviors, Lawrence et al. (2015) found lower cancer screening rates in those with comorbid mental illnesses. Similarly, those with preexisting mental disorders were less likely to seek out healthcare and had lower rates of cancer treatment than those without preexisting mental disorders (Baillargeon et al. 2011). These studies highlight the importance of increasing access to healthcare and screening behaviors among those with binge eating to reduce cancer risk.

Mental and Emotional Health, Binge Eating, and Cancer

The mental and emotional consequences of cancer also may contribute to a relationship between cancer and binge eating, given the high overlap between binge eating and mental and emotional health (Hudson et al. 2007). Previous research has focused on all phases of cancer and their known impacts on mental and emotional health. For example, after cancer diagnosis, individuals have major increases in risk of anxiety, stress reaction/adjustment disorder, depression, and substance use (Lu et al. 2016). Cancer type and patient demographics also relate to the severity and type of mental health consequences experienced (Linden et al. 2012; Iwamitsu 2005). For example, female and youth cancer patients had the highest levels of anxiety and depression, while women with hematological cancer had the most severe emotional distress, cancer severity (such as advanced stages, poor prognosis, and invasive treatments), and increased risk of emotional distress. (Linden et al. 2012). Additionally, Iwamitsu et al. (2005) found strong relationships between adjustment to cancer and anxiety both before and after diagnosis. Breast cancer patients who suppressed negative

emotions and anxiety symptoms ended up with more emotional distress, and chronic anxiety significantly contributed to rates of psychological distress in these women. Additionally, emotional and mental health consequences have been studied in cancer treatment populations. For instance, of women undergoing chemotherapy for stage I–III breast cancer, one-third experienced moderate depression and over 15% experienced moderate to severe anxiety (Reece et al. 2013). Both radiation and chemotherapy treatments were also associated with decreased overall quality of life in children and adults (Bell et al. 2018).

The mental and emotional health of cancer patients both before and after diagnosis and treatment is strongly related to recovery rates and overall outcomes for these individuals (Ji et al. 2020; Lloyd et al. 2019; Cunningham et al. 2015; Baillargeon et al. 2011). For example, a cohort study by Cunningham et al. (2015) found cancer patients who had received recent psychiatric services had poorer survival rates of breast and colorectal cancer. The same study also noted a more general correlation with history of mental illness and lower cancer survival rates. The timeline of cancer survival also may play a role in the mental health status of those in remission, as long-term cancer survivors did not show any significant differences in terms of self-reported mental health status (Keating et al. 2005). Furthermore, the severity of cancer influences the mental health of patients, specifically those with colorectal cancer. Previous research has found increased risk for depressive, cognitive, anxiety, and overall mental health disorders in colorectal cancer survivors, with lower survival rates in those diagnosed with any mental illness (Lloyd et al. 2019). Additionally, cancer survivors used significantly more mental health services than the general population which suggests poorer mental health status among this group (Hewitt and Rowland 2002).

Poor mental and emotional health status (that is oftentimes associated with cancer diagnosis, treatment, and remission) is also a common risk factor for binge-eating development, course, and treatment (Dingemans et al. 2020; Goldschmidt et al. 2014; Mason and Smith 2021). Given this, cancer diagnosis may be associated with the development of binge eating; Fig. 3 outlines possible pathways by which cancer may lead to binge eating. Specifically, the pathways between cancer diagnosis and binge eating may be through poor mental and emotional health and maladaptive

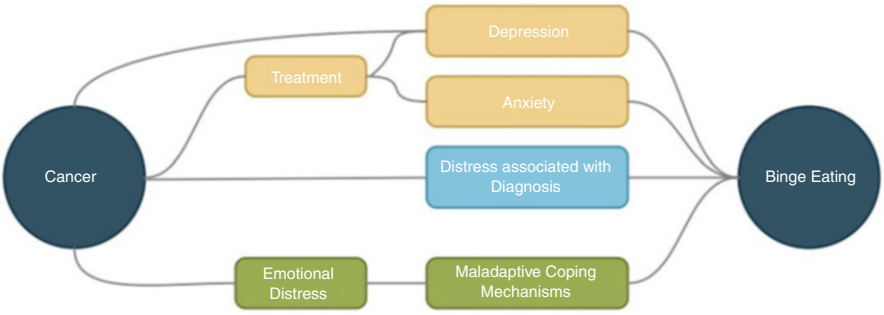

Fig. 3 Possible pathways from cancer diagnosis to binge eating

coping responses. Broadly, depression and anxiety rates are much higher in individuals with BED, and mood disorders are more common in individuals with BED and obesity compared to those with only obesity (Rosenbaum and White 2015; Sheehan and Herman 2015). Further, specific psychological characteristics associated with poor mental health, including low self-esteem, negative affect, emotional dysregulation, and maladaptive coping, are positively correlated with BED and binge eating risk (Sulkowski et al. 2011; Agüera et al. 2021). These characteristics also parallel many mental health problems that may emerge in cancer patients after diagnosis. Additionally, cancer diagnosis and treatment are often considered traumatic life events (depending on the severity, progression of disease, and cancer type), and previous research has reported trauma to be relevant for predicting onset of binge eating (Brewerton 2008; Timothy 2007).

Conclusions and Future Directions

Although little to no research exists on the direct relationship between cancer and binge eating or BED, studies on risk factors for cancer and binge eating individually suggest that there may be a relationship between cancer and binge eating. However, the nature of the relationship is unclear (e.g., whether this is a correlational, causational, bidirectional, or unidirectional relationship). As displayed in Fig. 4, there are likely bidirectional and complex relationships between cancer and binge eating. Nevertheless, obesity, poor nutrition, decreased physical activity, increased smoking and alcohol consumption, and lower utilization of screening behaviors share commonality for both cancer prevalence and mortality and binge eating. Additionally, similar mental and emotional health risks have been associated with both binge eating and cancer, suggesting that a combination of physical, environmental, mental, and emotional health factors contribute to this multifaceted relationship.

In conclusion, the lack of direct research on binge eating and cancer prevents any definite conclusions from being made about the nature of the relationship between

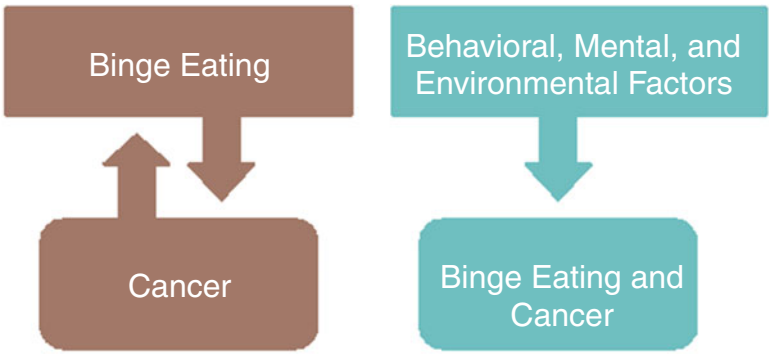

Fig. 4 Possible directional relationships between cancer and binge eating

the two. Shared risk factors may act as a pathway through which binge eating and cancer are related. This topic is becoming increasingly more relevant in the twenty-first century as cancer stands at the second largest cause of death in the United States, and binge eating and related disorders increasingly impact public health (National Cancer Institute 2021; Hudson et al. 2007). Cancer poses a serious risk to individual mortality, physical, and mental health in addition to its burden on global healthcare systems (Cunningham et al. 2015; Ferrell et al. 2003; Knight Cancer Institute 2020; Ng et al. 2018; Rivera and Brawley 2019; Viegas et al. 2017). Consequently, the recent inclusion of BED in psychiatric classification systems suggests that both prevalence and significance of the disorder are increasing, due to increased recognition and new diagnostic procedures (Kornstein 2017). As binge eating and BED continue to be researched, important future directions should include the study of the nature of the relationship between binge eating and cancer.

Application to other Areas

Food addiction, obesity, health and well-being, cancer mortality, public health, psychological outcomes for cancer patients, preventative interventions for cancer, and binge eating.

Mini-dictionary of Terms

- **Binge Eating Disorder (BED):** An eating disorder that is characterized by recurring binge eating episodes without compensatory behaviors and associated distress
- **Cancer:** A disease resulting from the uncontrolled division of abnormal cells that can lead to tumor growth and metastasis
- **Binge eating:** Consuming abnormally large quantities of food accompanied by a feeling of loss of control
- **Behavioral risk factors:** Behaviors that increase risk for disease or disorder and can be changed or prevented
- **Correlational effects:** Variables that are thought to be statistically related, such that changing of one variable will result in changes to another
- **Causational effects:** Change in a specific variable is directly responsible for the production of some change in another variable
- **Maladaptive coping mechanisms:** Unhealthy or ineffective methods used by an individual to reduce negative affect, such as stress or anxiety
- **Metabolic abnormalities:** Abnormal chemical reactions in the body that are responsible for disrupting metabolism
- **Modifiable risk factors:** Factors that may increase the risk of developing a disease or disorder that can be changed
- **Obesity:** A medical condition in which a person has excess body fat accumulation often defined as a body mass index greater than 30

- **Protective factors:** Factors that are associated with reduced risk for a negative outcome
- **Screening behaviors:** Use of preventative methods that help to screen an individual for risk or presence of specific diseases and disorders
- **Secondhand smoke:** Smoke that is inhaled involuntarily from being in close proximity to smokers
- **Substance use behavior:** Use of either drugs or alcohol that can lead to addiction or problematic use
- **Workplace carcinogens:** Substances found in the workplace that are known to be capable of causing cancer

Key Facts

- The relationship between cancer and binge eating is of increasing importance due to the significant prevalence of both in the twenty-first century.
- Clear overlap exists between behavioral risk factors and mental and emotional health correlates for both binge eating and cancer.
- More research is needed on the nature of the relationship between binge eating and cancer.

Summary of Points

- Binge eating and cancer are both increasing in prevalence in the twenty-first century, and both significantly impact individual and public health.
- Cancer and binge eating share similar behavioral risk factors such as obesity, nutrition status, physical activity, smoking and alcohol use, and utilization of healthcare.
- Cancer and binge eating also have similar mental and emotional health correlates such as anxiety, depression, emotion dysregulation, and maladaptive coping.
- Little research exists on the relationship between binge eating and cancer although evidence suggests a plausible association between the two.

Fat Mass and Obesity-Related Gene (FTO) and Binge Eating Disorder in Adults and Adolescents

52

Luzia Jaeger Hintze, Éric Doucet, and Gary S. Goldfield

Contents

Abstract

The fat mass and obesity-related gene (FTO) is expressed in all body tissues regulating energy homeostasis, eating behavior, and appetite. More recently, studies have shown that FTO is associated with several eating disorders such as binge eating disorder (BED), bulimia nervosa, and anorexia nervosa, as well as several subclinical manifestations of disordered eating. Indeed, adults and adolescents with FTO alleles (e.g., rs993909, rs1558902, rs1421085) exhibited higher scores in BED scales and number of binge episodes and higher scores in

emotional eating scales as well as the number of emotional eating episodes. Children and adolescents with FTO alleles reported higher scores in food enjoyment and food responsiveness compared to control groups. The results are supported by the neurological studies that showed higher activation in brain areas responsible for rewarding and motivation to eat in carriers of the FTO alleles. Taken together, the studies indicated a significant association between FTO variants and BED and eating behaviors/pathologies, which suggest that these genotypes likely contribute to the onset and/or maintenance of eating disorders.

Keywords

Binge eating disorder · Emotional eating · Bulimia nervosa · Anorexia nervosa · Eating behavior · Obesity-related gene · Energy intake · Food rewarding · Food enjoyment · Food responsiveness · Motivation to eat

Abbreviations

AN	Anorexia nervosa
BED	Binge eating disorder
BMI	Body mass index
BN	Bulimia nervosa
DSM-5	*Diagnostic and Statistical Manual of Mental Disorders, 5th edition*
FTO	Fat mass and obesity-related gene
TFEQ	Three-Factor Eating Questionnaire

Introduction

Eating disorders are psychiatric illnesses, characterized by abnormal or disturbed eating habits, with a higher incidence in adult women and female adolescents (Bhattacharya et al. 2020; Herpertz-Dahlmann 2015). One type of eating disorder, binge eating disorder (BED), is characterized by a large amount of food consumption in a short period of time, and it is not followed by compensatory behaviors (e.g., use of laxatives, prolonged periods of fasting, excessive exercise). It is commonly associated with rapid eating, eating to uncomfortable fullness, eating large amounts of calories even in absence of hunger, and feeling guilty or embarrassed after overeating. According to the *Diagnostic and Statistical Manual of Mental Disorders*, *5th edition* (DSM-5), these binge episodes should occur at least once a week for at least 3 months to be classified as BED. Previous evidence showed that about 8% of individuals with obesity present with BED, and this prevalence is even higher (20–30%) in individuals enrolled in weight loss treatments and in those waiting for bariatric surgery (48%) (Ágh et al. 2015; Bhattacharya et al. 2020; de Zwaan 2001; Vinai et al. 2015).

Another related eating disorder, bulimia nervosa, is defined by recurrent episodes of binge eating followed by some type of compensatory behavior. Those episodes

should occur at least once a week for a period of 3 months to be considered an eating disorder according to DSM-5. On the other hand, anorexia nervosa refers to the restriction of energy intake relative to the body requirements, resulting in a significantly low body weight in the context of age, sex, and development. Individuals with anorexia nervosa present intense fear of weight gain or becoming fat or engage in persistent behaviors that interfere with weight gain despite low body weight. Both, bulimia nervosa and anorexia nervosa, are accompanied by a fear of weight gain and/or becoming overweight and by an overvaluation of weight and shape.

In addition, eating disorders are associated with several pathologies and health consequences; among others, cardiac complications, decreased bone density, and gastrointestinal and endocrine disorders are the most common (Bhattacharya et al. 2020; Bulik et al. 2019). BED is associated with diabetes and metabolic syndrome, mainly due to its link with overweight/obesity, as well with addiction disorders (Grilo et al. 2013; Keski-Rahkonen and Mustelin 2016; Yip et al. 2011). However, anorexia nervosa carries the highest mortality rate among individuals with eating disorders, mainly due to medical complications from starvation or suicide (Smink et al. 2012; Winkler 2017). A recent study stated that 60% of the deaths in individuals with anorexia nervosa are accounted by sudden cardiac arrest and suicide (Westmoreland et al. 2016). The high prevalence and associated morbidity and mortality highlight the need for more research on the etiology of eating disorders to prevent its onset and/or the development.

Even though the etiology of eating disorders involves a complex combination of environmental, psychological, and biological factors, genetics has been considered one of the strongest components in the development of these conditions (Bulik et al. 2019; Davis 2015). For instance, one of the candidate genes is mapped in the obesity-related gene (FTO), which encodes for a 2-oxoglutarate-dependent nucleic acid demethylase (Gerken et al. 2007). Most of the studies on FTO genotypes have been carried out on rs9939609 variant (Castellini et al. 2017; Mehrdad et al. 2021; Melhorn et al. 2018; Müller et al. 2012; Palmeira et al. 2019; Rivas et al. 2018); however, studies including multiple variants can also be noted in the literature (Cameron et al. 2019; González et al. 2021; Jonassaint et al. 2011).

It is known that the FTO gene is expressed in all body tissues and also widely expressed in the hypothalamus, a brain region that regulates energy homeostasis, eating behavior, and appetite (Doaei et al. 2019; Gerken et al. 2007; Gholamalizadeh et al. 2018). Indeed, individuals with the FTO rs9939609 variant presented decreased fullness and hunger suppression (Mehrdad et al. 2021; Melhorn et al. 2018; Carvalho et al. 2018; Dougkas et al. 2013; Karra et al. 2013) as well as higher food craving frequency for high-energy food items and higher food reinforcement (Dang et al. 2018; Rivas et al. 2018). As such, the consumption of highly palatable food items among children and adults with the rs9939609 allele was found to be higher compared to control groups (Chuang et al. 2015; Tanofsky-Kraff et al. 2009). In addition, the FTO in multiple variants (rs9939609, rs1558902, rs861869) was associated with lower scores in cognitive restraint measured by the Three-Factor Eating Questionnaire (TFEQ) (Mehrdad et al. 2021; Kirac et al. 2016; Cornelis et al. 2014).

Some FTO variants, particularly the rs9939609 variant, foster greater appetite and food hedonics, drive to eat, and less control over food which may ultimately predispose to the development of eating disorders and/or subclinical eating pathologies. Accordingly, the present chapter synthesizes available literature on the association between the FTO variants and eating disorders, focusing mainly, but not only, on BED in the pediatric and adult population. This review also contributes evidence of the association between the FTO variants and emotional eating and other eating behaviors and pathologies that contribute to the onset and maintenance of eating disorders. Finally, neural studies in reward and inhibitory control circuits in individuals with FTO polymorphisms will be presented and discussed in order to provide neurobiological support to the eating behavior findings of the studies included in this chapter.

FTO and Eating Disorders in Adults

In the following section, we included the studies that investigated the association between FTO multiple variants and eating disorders. Also included in this section are results of studies that measured emotional eating in individuals associated with FTO and multiple different variants. Even though emotional eating is not classified as eating disorder, it is considered a pathological behavior defined as the tendency to eat in response to different emotions, and it is highly associated with the development of eating disorders and obesity (Fioravanti et al. 2014; Ricca et al. 2009).

Table 1 displays the studies including BED, bulimia nervosa, and anorexia nervosa and FTO polymorphisms in adults. Most of the studies that investigated the relationship between different FTO variants and eating disorders found significant associations between them. More specifically, adults with the rs9939609 (Castellini et al. 2017; Mehrdad et al. 2021) and rs1558902 (Cornelis 2014) alleles presented higher scores in BED scales and greater number of binge eating episodes (González et al. 2021; Cameron et al. 2019; Castellini et al. 2017; Cornelis et al. 2014). In fact, a multivariate analysis reported that individuals carrying the FTO rs9939609 allele present 2.72 higher score on a scale to estimate risk of eating disorders compared to individuals who did not present this genotype, indicating higher risk of developing eating disorders in these individuals (Mehrdad et al. 2021). Similarly, González et al. (2021) observed that individuals with FTO rs9302652/rs2388405/rs17818902 variants were almost two times (IC = 1.12–3.21) more likely to present with BED compared to the control group.

It should be noted, however, that some studies did not find associations between FTO variants and BED. Specifically in women living with obesity and BED, no significant differences in the frequencies of polymorphisms of the FTO gene were observed when compared to a control group without the eating disorder (Cameron et al. 2019; Palmeira et al. 2019). Even though both studies presented methodological strengths, the authors discussed that the low sample size that yielded limited statistical power could have contributed to the null associations. On the other hand, the number of binge eating episodes was found to be higher in the group with FTO

Table 1 FTO alleles and eating disorder studies in adults

Study	Sample size	Type of study	Variables	Main results
Abdella et al. (2019)	475 adults	Cross-sectional	FTO rs9939609 variant TFEQ, food craving	↑ Cognitive restraint associated with ↓ food craving in individuals <25 years FTO allele significantly affects the relationships between age, BMI, eating behaviors, and food cravings ↓ Emotional eating with age in the FTO allele + genotype group
Cameron et al. (2019)	178 women BED with obesity ($n = 73$) BED without obesity ($n = 55$) Normal weight without BED ($n = 50$)	Cross-sectional/ case control	FTO rs9939609, rs8050136, rs3751812, rs1421085, and rs1121980 variants BED score Body composition Attachment Styles Questionnaire (ASQ)	No differences in FTO alleles or body composition between groups FTO alleles ↑ binge frequency in the subgroup of individual with high ASQ relationships as secondary
Carvalho et al. (2018)	70 women living with obesity	Cohort	FTO rs9939609 variant Appetite, food preferences, body composition, hormones and inflammatory markers, BED score	↑ Insulin preprandial ↓ Ghrelin and IL6 ↑ Leptin in the postprandial period in the FTO allele + genotype FTO allele + genotype presented moderate BED ↑ Cholesterol consumption No differences in caloric intake between genotypes
Castellini et al. (2017)	369 participants Eating disorders ($n = 250$) Control group ($n = 119$)	Cross-sectional/ case control	FTO rs9939609 variants Emotional Eating and Identity Scale and eating disorders questionnaire, body composition	FTO allele more frequent among patients with eating disorders FTO allele was associated with BED behavior, ↑ emotional eating, ↑ eating disorder scores including AN and BN

	controls ($n = 3951$)			
Palmeira et al. (2019)	93 women BED ($n = 31$) Control group ($n = 62$)	Cross-sectional/ case control	FTO rs9939609 variant and BED	No significant associations were found between FTO alleles and BED

FTO, fat mass and obesity-associated gene; *BMI*, body mass index; *BED*, binge eating disorder; *BN*, bulimia nervosa; *AN*, anorexia nervosa; *TFEQ*, Three-Factor Eating Questionnaire

rs1421085 allele and BED who also presented high attachment avoidance as measured by the Attachment Styles Questionnaire Relationship (Cameron et al. 2019). In this particular study, FTO polymorphisms seemed to interact with attachment style to increase binge eating in women with obesity.

Along the same lines, FTO variants were also associated with higher scores in questionnaires assessing eating disorders such as bulimia nervosa and anorexia nervosa (González et al. 2021; Castellini et al. 2017; Müller et al. 2012). Indeed, those individuals were 12% and 18% more likely to present bulimia and anorexia nervosa, respectively, compared to a control group without the FTO rs9939609 allele (Müller et al. 2012). The association became more robust after adjustment for BMI and age in the participants with anorexia nervosa (OR = 1.67). Anorexia nervosa and other FTO variants (rs10521303, rs9924877, rs7203181, and rs12599672) were also linked to other personality dimensions and psychopathological traits such as anxiety, depression, phobic anxiety, interoceptive awareness, and maturity fears (González et al. 2021).

As was the case with BED, not all studies found significant associations in adults. Two studies included only women or adults that found no association between FTO alleles and bulimia nervosa (Jonassaint et al. 2011; Palmeira et al. 2019), anorexia nervosa, or any other psychological/psychopathological traits such as impulsivity, anxiety, harm avoidance, obsessionality, or compulsivity (Jonassaint et al. 2011). The authors stated that those results can be due to the small sample size (Jonassaint et al. 2011; Palmeira et al. 2019) and the number of comparisons conducted (Jonassaint et al. 2011), which compromised the power of the analyses.

Several studies have investigated FTO and subclinical forms of disordered eating in adults. Specifically, the FTO rs9939609 and rs1558902 variants have been shown to be associated with emotional eating scores, emotional eating episodes (Abdella et al. 2019; Castellini et al. 2017; Cornelis et al. 2014; Mehrdad et al. 2021), as well as increased severity of emotional eating (Castellini et al. 2017). A recent study indicated that individuals with FTO rs9939609 alleles presented 50% higher risk of presenting emotional eating episodes compared to participants who did not present

this genotype (Mehrdad et al. 2021). Noteworthy, emotional eating scores in individuals with this allele were found to decrease with age (Abdella et al. 2019).

Collectively, the studies included in Table 1 present strong evidence of the association between FTO variants and eating disorders and/or eating pathologies. We observed that four out of six studies indicated association between BED and FTO alleles, four out of four studies indicated association between FTO variants and emotional eating, and three out of four studies indicated association between anorexia nervosa and FTO genotype in the adult population. The FTO rs9939609 was the most common allele included in the studies. More precisely, BED and emotional eating were found to be highly associated with the FTO genotype in adults.

FTO and Binge Eating Disorder in Children and Adolescents

Table 2 lists the studies that included eating behavior and FTO polymorphisms in children and adolescents. The association between FTO rs1558902 and BED was only examined and observed in one study with children and adolescents (Micali et al. 2015). The other studies conducted in the younger population reported associations between the FTO rs9939609 and loss of control overeating, which is one of the main characteristics of binge eating (Tanofsky-Kraff et al. 2009; Emond et al. 2017; Velders et al. 2012), and scales of food responsiveness and food enjoyment (Emond et al. 2017; Tanofsky-Kraff et al. 2009; Velders et al. 2012), which might also predispose to binge eating episodes.

In the lone study that examined an association between BED and FTO rs1558902 in adolescents, Micali et al. (2015) observed that girls aged 14–16 years were slightly more likely to present an association between this genotype and BED compared to boys. Furthermore, at age 16 years, adolescents with the FTO rs1558902 allele were 28% more likely to have increased binge eating frequency.

Association between FTO rs9939609 variant and loss of control overeating, increased food responsiveness, and emotional eating frequency were also observed in other studies (Emond et al. 2017; Tanofsky-Kraff et al. 2009; Velders et al. 2012). Children and adolescents with one or two FTO alleles were nearly two times more likely to have a loss of control eating episodes and selected foods higher in fat at a buffet meal compared to those who did not present any FTO allele (Tanofsky-Kraff et al. 2009). Children with the FTO rs9939609 were more likely to present high scores of food enjoyment and in food responsiveness (Velders et al. 2012), similar to the results observed in preadolescents (Emond et al. 2017; Rivas et al. 2018). Those observations were found in children as young as 4 years of age (Velders et al. 2012), demonstrating the early effects of genetic factors in eating behaviors and the need for interventions and nutrition education at early ages in order to potentially prevent the onset of disordered eating and BED.

In summary, consistent association between FTO variants and eating behaviors/pathologies was reported in studies with children and adolescents. These results thus suggest that carriers may be genetically predisposed to the development of

Table 2 FTO alleles and eating disorders in children and adolescents

Study	Sample size	Type of study	Variables	Main results
Emond et al. (2017)	178 preadolescents 9–10 years	Cross-sectional	FTO rs9939609 variant, BMI, enjoyment of food, and food responsiveness	Association between FTO alleles and ↑ food enjoyment ↑ Food responsiveness
Mendoza et al. (2020)	99 adolescents with eating disorders AN ($n = 22$) BN ($n = 56$) BED ($n = 21$)	Cross-sectional/ case control	FTO rs9939609 variant, BED, AN, BN, circulating leptin	Circulating leptin levels higher in individuals with BED Association between FTO alleles and ↑ weight/leptin index and ↑ leptin levels in the BN group
Micali et al. (2015)	9912 participants Adolescents at age 14 years ($n = 5958$) and 16 years ($n = 4948$)	Cohort	FTO rs1558902 variant, BED, BMI, age, gender	Association between BED and FTO allele FTO allele ↑ risk of BED among girls compared to boys

disordered eating. All studies that measured food enjoyment (three studies) and food responsiveness (three studies) observed associations with FTO alleles. These data also indicate possible mechanisms through which FTO variants operate to increase the likelihood of excess body weight in children and adolescents (Mendoza et al. 2020; Rivas et al. 2018; Tanofsky-Kraff et al. 2009).

Neural Studies in Homeostatic and Reward Circuits and FTO

An extensive number of studies have been carried out in an attempt to map the neural circuits of eating behavior in hopes of identifying potential brain regions associated with eating pathologies and unhealthy eating habits. Figure 1 displays the neural

systems involved in reward, cognitive, and executive functions that also are involved in the ingestive behavior.

In a nutshell, ingestive behavior consists of preparatory, consummatory, and post-consummatory phases (Berthoud 2002), and reward processing is carried out during the entire process (Berthoud et al. 2011; Berthoud and Zheng 2012; Epstein et al. 2011). In the preparatory phase, "executive control," "decision-making," and "reward expectancy" play an important role in the food choice and selection. Higher activation in the orbitofrontal, insular, and cingulate cortices represents a higher reward expectancy for a meal containing rewarding food items (Appelhans et al. 2011). During the consummatory phase, direct pleasure is derived mainly from gustatory and olfactory sensations, and the nucleus accumbens and the ventral tegmental area are activated according to the pleasantness of consuming those food items (Felsted et al. 2010; Rolls 2005). Higher activation in these regions portrays higher pleasantness during eating (Mccrickerd and Forde 2016). Finally, the post-consummatory phase is a general feeling of satisfaction of eating. Meals that demonstrated higher pleasantness enhance higher reinforcement power, and those items are more likely to be consumed in future meals (Epstein et al. 2003, 2011).

The "memory and learning" regions of the brain (e.g., amygdala, insula, striatum, and thalamus) mediate the entire process of food consumption, connecting with the rewarding evaluation during the consummatory and post-consummatory phase as well as with reward expectancy in the pre-consummatory phase (Mccrickerd and Forde 2016). Consumed items that presented in higher rewarding evaluation (during consummatory and post-consummatory phases) are more likely to activate the learning and memory regions and are more likely to be selected in future meals (Epstein et al. 2003, 2011; Mccrickerd and Forde 2016).

In the following section, we will present the results of studies on the FTO genotype and brain regions involved in "executive control," "decision-making," "reward expectancy," "learning and memory," and "reward calculation." Those results provide biological and neurological evidence of altered brain functions in individuals with the FTO variants that contributes to binge eating episodes and binge eating disorders in these individuals.

Table 3 displays the studies that assessed brain activity in areas associated with executive control, reward expectancy, learning and memory, and reward calculation in individuals with the FTO alleles. fMRI studies showed greater responsivity in brain areas responsible for reward expectancy such as the insula (Ndiaye et al. 2020; Olivo et al. 2016), as well in areas involved in the learning and memory circuits such as the amygdala (Melhorn et al. 2018), striata (Lancaster et al. 2018), nucleus accumbens (Dang et al. 2018; Lancaster et al. 2018; Melhorn et al. 2018; Olivo et al. 2016), and putamen (Karra et al. 2013) in individuals with FTO alleles when exposed to a palatable food image. Most part of the studies were carried out in the rs9939609 allele, and a single study included the rs1558902 allele (Ndiaye et al. 2020). The higher striatal activation was observed with food and monetary stimulus in young adults (Lancaster et al. 2018), indicating that the neurobiological response associated with FTO genotypes may not be food-specific and may confer an increased risk for multiple rewarding stimuli (i.e., smoking, alcohol, drugs of

Table 3 FTO alleles and neural studies

Study	Sample size	Type of study	Variables	Main results
Chuang et al. (2015)	697 participants	Cohort	FTO rs1421085 variant and impulsivity, food choices, aging	FTO allele + genotype: presented a dose-dependent increments in BMI during aging ↓ Medial prefrontal cortical function ↓ Brain function in regions intrinsic to impulse control and taste responsiveness ↑ Impulsivity ↑ Intake of fatty foods
Dang et al. (2018)	78 participants	Cross-sectional	FTO rs9939609 variant and food cravings, dopamine function	↓ Food craving with age except in individuals with FTO allele + genotype ↑ Lack of control overeating No difference in activity in the putamen and ventral striatum No association between FTO allele and dopamine receptor density in the striatum
Heni et al. (2016)	5166 participants	Cross-sectional	FTO rs8050136 variant and dopamine receptor density, insulin sensitivity	FTO allele + genotype ↑ Body fat and waist circumference ↓ Reduced peripheral insulin sensitivity ↓ Central insulin sensitivity in the caudate nucleus in individuals with the FTO allele + genotype ↓ D2 receptors
Karra et al. (2013)	359 participants	Cross-sectional	FTO rs9939609 variant and body composition, brain activity, ghrelin, PYY, leptin levels, visual analogue scale	FTO allele + genotype: ↑ BMI, body fat mass, and visceral fat area No differences in fasting appetite ↓ Suppression of hunger High-calorie food images ↑ appealing in the postprandial ↑ Activity of the hypothalamus, ventral tegmental area/substantia nigra, left globus pallidus, and left thalamus

(continued)

Table 3 (continued)

Study	Sample size	Type of study	Variables	Main results
Lancaster et al. (2018)	1055 participants	Cross-sectional	FTO alleles (not specified) and activation of the striatum during reward, BMI	FTO allele + genotype ↑ Response in reward-dependent striatal activation during monetary stimuli ↑ Appetitive stimuli (calorically high food images)
Melhorn et al. (2018)	114 participants	Cross-sectional	FTO rs9939609 variant and appetite measures, food cues, brain activity related to reward, insulin, ghrelin, GLP-1	FTO allele + genotype ↓ Fullness ↑ Energy intake Pre-meal ↑ Activation by "fattening" food images (compared with objects) in the medial orbital frontal cortex Post-meal ↑ Activation by fattening (compared with nonfattening) food cues in the ventral tegmental area/substantia nigra, amygdala, and ventral striatum
Ndiaye et al. (2020)	4236 participants	Cross-sectional	FTO rs1558902 variant and brain areas related to reward (insula and substantia nigra)	FTO allele + genotype ↑ Eating addiction and reward behaviors ↑ Expression in substantia nigra and insula
Olivo et al. (2016)	30 men	Cross-sectional	FTO rs9939609 variant and brain activity in areas related to reward	FTO allele + genotype ↑ Anxiety and punishment sensitivity ↑ Dopaminergic cortico-striatal circuit and areas involved in inhibitory control, decision-making, and salience attribution (the insular cortex, middle orbital gyrus, and inferior frontal gyrus) ↑ Anxiety scores and hypersensitivity to the hunger state

FTO, fat mass and obesity-associated gene; *BMI*, body mass index; *CHO*, carbohydrates; *PFC*, prospective food consumption

abuse, gambling, etc.). Only one study found no difference in the activation in the putamen and ventral striatum in seniors with FTO rs9939609 allele (Dang et al. 2018); however, the study included only 78 participants, which offers limited statistical power to detect associations. Alternatively, it is possible to argue as well that the seniors were able to develop non-food-related coping strategies over a lifetime to maintain healthier eating behavior, but future research is needed to verify why associations may differ based on age and maturity.

Studies observed that high-calorie food images compared to non-food-related images were more appealing for individuals with the FTO rs9939609 variant compared to individuals who did not present this genotype (Karra et al. 2013; Lancaster et al. 2018; Melhorn et al. 2018), whereas no genotype differences in appeal ratings for nonfattening food were observed in a different study (Melhorn et al. 2018). After a standard meal, individuals with this genotype exhibited higher activation in brain regions responsible for rewarding calculation (ventral tegmental area/substantia nigra) and brain regions involved in memory and learning process (amygdala and ventral striatum) when exposed to high energy density food items. Those results suggest that the energy density of the meals was more rewarding among individuals with the FTO rs9939609 (Karra et al. 2013; Melhorn et al. 2018) and rs1558902 (Ndiaye et al. 2020) variants.

Furthermore, other studies investigated the activity of brain areas involved in inhibitory control and decision-making and FTO variants (Chuang et al. 2015; Karra et al. 2013; Olivo et al. 2016). Indeed, previous evidence suggested the association between lower inhibitory control and higher impulsivity in individuals with BED and bulimia nervosa (Manwaring et al. 2011; Schag et al. 2013; Stojek and MacKillop 2017). For instance, Chuang et al. (2015) observed the FTO rs1421085 variant is associated with hyporesponsivity in the activity of medial prefrontal cortical function with aging, enhancing lower impulse control and impulse control toward food in these individuals. Similarly, other studies observed lower sensitivity in the medial orbital frontal cortex (Melhorn et al. 2018) and in the left putamen, a region implicated in regulating goal-directed behavior (Karra et al. 2013), and in the middle orbital gyrus and inferior frontal gyrus (Olivo et al. 2016) in individuals with the FTO rs9939609 variant. Indeed, those results were associated with lower scores in cognitive restraint measured by the TFEQ in these individuals (Olivo et al. 2016; Mehrdad et al. 2021), which also contributed to energy overconsumption in this population. Taken together, these results show that the FTO rs9939609 and rs1421085 variants play an important role in neural responsivity to food and reward cues in brain regions controlling energy homeostasis and reward and inhibitory control in adults.

Limitations and Strengths

It is important to acknowledge the limitations of this review. Firstly, we did not conduct a meta-analysis to quantify the association between FTO and eating disorders due to significant heterogeneity across studies, so the magnitude of

observed associations should be verified in future research. For the most part, the studies included in the chapter are cross-sectional; only two were cohort longitudinal studies. As such, causal links between FTO variants and eating disorders and/or eating pathologies cannot be determined, and more longitudinal studies with multiple follow-up evaluations are needed to better determine directionality. In addition, some of the studies presented small sizes that likely limited the statistical power to detect significant associations. Additionally, the criteria used to assess eating disorders were often different among the studies, which also might have contributed to the heterogeneity of the observed results. Additionally, very few studies have investigated whether carriers of these FTO variants display a different response to psychological or pharmacological treatment of eating disorders, an important area of future inquiry in this era of personalized medicine. Finally, more studies in children and adolescents are also necessary to better determine whether early nutritional education or psychoeducation can help attenuate the effects of FTO genotypes on the development of eating disorders.

Summary and Conclusions

Most of the results of the studies included in this review indicated associations between BED, emotional eating, and FTO alleles in adults. In the younger population, the association of FTO alleles and eating behaviors and/or pathologies that favors the development of BED was more common rather than an association with BED per se, but it is noteworthy that we observed only one study that investigated the association between FTO alleles and BED in children and adolescents. The studies that measured brain activity in individuals with this genotype collectively reported that the FTO variants are associated with neural circuits that normally modulate motivational changes to food reward, food cues, decision-making, and inhibitory control. As such, this provides some neurobiological evidence for a potential mechanism in which FTO genotypes may confer risk of disordered eating and diagnosable eating disorders, but future research using prospective longitudinal designs with multiple follow-up evaluations are needed to provide a clearer understanding of the potential neurobiological mechanisms.

Taken together, the results of studies reviewed in this chapter indicate that FTO variants are consistently associated with an increased risk of eating disorders such as BED, bulimia nervosa, and other eating pathologies, with supporting neurobiological evidence from neuroimaging studies in both adult and pediatric populations. This highlights that carriers of the FTO variants may be genetically predisposed to the development of eating disorders, information that is important for targeted prevention and treatment programs in the era of personalized medicine.

Mini-dictionary of Terms

- **Anorexia Nervosa**: eating disorder characterized by constant small amount of energy intake causing excessive weight loss. It is accompanied by the fear of gaining weight and body image disturbances.
- **Binge Eating**: eating disorder characterized by the consumption of large quantities of food in a short period of time and a sense of lack of control overeating.
- **Bulimia Nervosa**: eating disorder characterized by binge episodes followed by compensatory mechanisms (e.g., excessive exercise, purging, use of laxatives, etc.).
- **Emotional Eating**: tendency to eating in response to different emotions.
- **Food Craving**: is defined as a strong, irresistible, desire to consume specific type of food.
- **Food Enjoyment**: refers to the extent to which an individual finds pleasure in eating and desire to eat.
- **Food Responsiveness**: refers to the extent to which an individual indicates interest in and desires to spend time eating food.
- **Food Reward**: momentary value of a food item at the time of ingestion; usually high-calorie food items tend to be more rewarding.
- **Relative Reinforcing Value**: how hard the individual is prepared to work to gain access to food rather than a nonfood alternative.

Key Facts of Binge Eating

- It was considered an eating disorder only in 2013 in the "*Fifth Edition of the Diagnostic and Statistical Manual of Mental Disorders*."
- The global prevalence of BED was 0.9% in 2018, whereas women had a prevalence of 1.4% and men 0.4%.
- It is the most common eating disorder in the USA and in individuals with obesity.
- It impairs health-related quality of life, and it is associated with increased healthcare utilization and healthcare costs.
- The healthcare costs per patient with BED might range between $2372 and $3731 per year in the USA.

Summary Points

- FTO alleles are associated with BED scores and binge episodes mainly in adults.
- FTO alleles are associated with higher scores in emotional eating scales and the number of emotional eating episodes in adults and children.
- FTO alleles are associated with higher scores in food enjoyment and food responsiveness in children and adolescents.

- FTO alleles are associated with higher activation in brain areas responsible for rewarding and motivation to eat.
- FTO alleles are associated with lower inhibitory control.

Neuroimaging in Binge Eating Disorder

53

Serkan Turan

Contents

Abstract

Binge eating disorder (BED) is defined as recurrent and distressing episodes of excessive food intake despite psychological and physical consequences without the inappropriate compensatory weight loss behaviors characteristic of bulimia or anorexia nervosa. Neurobiological underpinnings associated with BED have been investigated; however, few structural and functional neuroimaging studies to date have described on the etiology, clinical features, and course of BED. The purpose of this chapter is to synthesize the recent literature on neuroimaging studies on the etiology, clinical features, and course of BED, which has been excluded from the category of "eating disorders not otherwise specified" in *DSM-V* and has specific diagnostic criteria. Neuroimaging studies provide evidence including altered function of prefrontal, insular, and orbitofrontal cortices and the striatum with altered reward sensitivity and food-related attentional biases. These unique neurobiological changes might be crucial in defining the overlapping neural features and directing targeted therapies of BED. To disrupt this vicious cycle, novel research-based studies examining the endogenous DA, NE, 5-HT, opiate, and

other systems (e.g., glutamatergic) in the striatum and cortex of individuals with BED are necessary.

Keywords

Binge eating disorder · Neuroimaging · Eating disorders · Obesity · Magnetic resonance imaging

Introduction

Binge eating disorder (BED) is an eating disorder (ED) characterized by uncontrolled episodes of overeating in a short period of time. In May 2013, the American Psychiatric Association (APA) recognized BED as a distinct eating disorder in the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (*DSM-V*) (APA 2013). One of the main features of BED is the distinguishing feature of bulimia nervosa (BN); the patient does not resort to compensatory behaviors and interventions such as forcing himself to vomit, using drugs that cause diarrhea, or using diuretic drugs.

In prevalence studies conducted in recent years, the lifetime and 1 year prevalence of BED according to *DSM-V* is estimated to be 0.85% and 0.44%, respectively. Eating behavior is a complex paradigm with or without conscious awareness, directed by internal or external stimuli. From a holistic perspective, it is recommended to consider environmental and individual factors and their interactions to understand the complexity of BED. Based on data from clinical functional imaging and cognitive studies, there is a growing consensus that several interconnected behavioral intermediate phenotypes are impaired in BED, including mindful bias toward food cues, impulsivity and cognitive inflexibility, persistent or compulsive behaviors, motivation, and reward processing.

Neuroimaging studies have contributed to understanding the etiopathogenesis of EDs; but there are some limitations of the studies in the literature: (1) difficulty in distinguishing whether the differences observed in the brains of individuals with EDs are the cause of the disease or whether they occur afterward with the effect of weight loss; (2) a high comorbidity frequency; (3) generalized sample (AN, BN, BED), not specified; (4) the wide age range of the sample groups, including adolescents and adults.

There is limited information in the literature about the neuroimaging findings that may play a role in the etiology of BED. The current literature focuses on functional changes when reviewed, so little is known about the putative changes as the structural data have not been extensively investigated. Studies on the biological processes that lead to the formation of BED suggest that dopamine, opioids, ghrelin, and serotonin have a role in the etiology. Changes in the reward-related regions of the brain, dopamine, acetylcholine, or opioid systems are said to increase binge eating episodes.

In this section, we aimed to review neuroimaging studies on the etiology, clinical features, and course of BED, which has been excluded from the category of "eating disorders not otherwise specified" in *DSM-V* and has specific diagnostic criteria.

Structural MRI Studies

Magnetic resonance imaging (MRI) is a medical imaging technique which used three dimensional pictures of anatomic structure. Recent developments in brain imaging techniques have also been reflected in the field of eating disorders. Although the number of studies is less than for other eating disorders (AN and BN), the results provide important steps to be taken in the detection of possible brain regions for a better understanding of the etiopathogenesis of BED. Computerized tomography (CT) and MRI studies, which provide information about structural abnormalities, report that BED patients have changes in brain regions particularly associated with reward and impulsivity. Structural MRI studies in binge eating disorder are summarized in Table 1. Schäfer and colleagues (2010) described gray matter volume (GMV) abnormalities in the anterior cingulate cortex (ACC) and medial orbital frontal cortex (OFC) which were implicated in decision-making in BED. In a recent study, Turan et al. (2021) acquired structural MRI which examined regional brain volumes in obese with or without BED. Greater GMVs were found in the right medial OFC and the left medial OFC compared to the non-BED obese. These findings might point to a behavioral mechanism in people with BED that is even more gratifying than regular hunger satiation.

In a study evaluating voxel-based morphology of brain volume, (1) the use and repetition of habit-based learning was observed more frequently in obese individuals with BED compared to obese individuals without BED, and (2) significant reductions in the left lateral OFC volumes were detected in individuals with BED (Voon et al. 2015). These findings are consistent with rodent and human imaging researches that have linked these areas to model-based goal-directed behavior. In a recent study, subcortical brain volumes and cortical thickness were measured in BED individuals by using MR brain scan imagings. Another aim of the researchers was to evaluate the relationship between these measures and the scores on dietary restraint, disinhibition, and hunger from the Three-Factor Eating Questionnaire (Abdo et al. 2020). According to the study's findings, higher scores in uncontrolled eating were associated with increases in GMV in the nucleus accumbens. The larger nucleus accumbens volume suggests that it may be associated with greater motivation for food and uninhibited binge eating behavior observed in the BED.

Functional MRI Studies

fMRI is an imaging method that allows to show the changes in cerebral blood supply dependent on blood oxygen level at rest or during function. These changes are called BOLD (blood oxygen level dependent), which provides a reliable measure of a local

Table 1 Summary of structural MRI studies in binge eating disorder

Study	Region	Study group	Study design	Demographics	Diagnostic criteria	Aims & findings	Conclusions
Schäfer et al. 2010	Germany	BED: $n = 17$ BN: $n = 14$ HC: $n = 19$	Cross-sectional, outpatient clinical sample	BED: 22.3 y (SD: 2.6) F: 100% BN: 26.4 y (SD: 6.4) F: 100% HC: 23.1 y (SD: 3.8) F: 100%	*DSM-IV-TR*	To investigate the GMVs of BN and BED. All patient groups were characterized by increased GMVs of the medial OFC compared to HCs	Greater volume of the medial OFC in BED was associated with decision-making, reward, and self-regulation processes
Voon et al. 2015	USA and UK	BED: $n = 20$ Obese: $n = 20$ HC: $n = 93$	Cross-sectional, community sample	BED: 43.95 y (SD: 9.47) F: 60% Obese: 44.70 y (SD: 10.12) F: 45% HC: 23.22 y (SD: 2.75) F: 42.4%	*DSM-IV-TR* The Research Diagnostic Criteria	To examine the premature responding in obese patients with and without BED. Significant reductions in left lateral OFC volumes were detected in individuals with BED	The role of these areas was associated with model-based goal-directed behavior

Abdo et al. 2020	USA	BE: $n = 54$ Non-BE: $n = 412$	Cross-sectional, community sample	BE: 48.7 y (SD: 18.6) F: 64.82% Non-BE: 47.0 y (SD: 19.4) F: 65.78%	Semi-structured diagnostic psychiatric interviews (EDE-Q and the TFEQ)	To evaluate the subcortical brain volumes and cortical thickness of BE and its associated eating behaviors by analyzing structural brain scans. Higher scores in uncontrolled eating were associated with increases in GMV in the nucleus accumbens	The larger nucleus accumbens volume suggests that it may be associated with greater motivation for food and uninhibited binge eating behavior observed in binge eaters.
Turan et al. 2021	Turkey	BED: $n = 26$ Obese: $n = 25$ HC: $n = 27$	Cross-sectional, outpatient sample	BED: 15.04 y (SD: 1.79) F: 68% Obese: 14.64 y (SD: 1.73) F: 68% HC: 14.59 y (SD: 1.39) F: 70.37%	*DSM-V*	To investigate the regional GMV abnormalities and appetite-regulating hormone levels (NPY and leptin) in obese patients either with or without BED compared to HCs. Left medial OFC volumes were greater in patients with a diagnosis of BED compared with other groups	Alterations of GMVs might point to a behavioral mechanism in people with BED that is even more gratifying than regular hunger satiation

increase in neural activity. Due to the heterogeneity throughout the design of the fMRI studies included, investigations differ according to the type of stimuli used during the test (decision-making and learning paradigms; food-related stimuli; body image-related stimuli). A number of functional connectivity alterations in patients with BED have been found in imaging studies that examined task-dependent brain activity. Functional MRI studies in BED are summarized in Table 2. Balodis and colleagues (2013a) examined brain activation in BED using a monetary incentive delay task and found diminished activity in several prefrontal and insular regions. The same researchers also examined the neurobiological underpinnings of reward processing by using a monetary incentive delay task during fMRI. After the treatment, the results of the study found that ventral striatal activity during a reward expectation was inversely related to binge eating deprivation (Balodis et al. 2014). However, another study in patients with BED, BN, and HC showed a significant difference in neural response to food cues but not monetary reward (Simon et al. 2016). In a neuroimaging study which investigated neural reward processing and binge eating in adolescent girls, the relationship between task-guided brain regions and attack intensities was evaluated from the Pittsburgh Girls Study – Emotions Substudy. Shared underpinnings between reward processing and EDs have also been described; greater vmPFC and caudate responses during reward receipt were concurrently associated with severity of binge eating episodes (Bodell et al. 2018).

A recent study conducted by Stopyra et al. (2019) demonstrated functional connectivity changes in dorsal ACC-somatosensory cortex coupling in BED. This network is essential for the self-referential and personally salient stimuli processing. Lee and friends (2017) used functional MRI while performing a Stroop Match-to-Sample task acquisition to investigate the differences in prefrontal cognitive control over disease-salient stimuli. Participants with BED showed increased ventral striatal activity in response to food images compared to healthy controls. The ventral striatum has a prominent role for processing salience of stimuli and reward-related cues. The researchers found that patients with BED had greater reward sensitivity but lack inhibitory control, indicating a loss of eating control.

Based on evidence that it may be associated with changes in reward processing, in a study published in 2021, clinicians evaluated that individuals with BED would exhibit lower ventral and dorsal frontostriatal rsFC involved in self-regulatory control and perform poorer performance on tasks assessing the tendency toward impulsivity and compulsivity in reward-seeking behaviors (Haynos et al. 2021). Researchers examined the correlations of resting state functional connectivity with frequency of binge eating days as indicative of symptom severity, and they also examined the relation between rsFC patterns and performance on neurocognitive paradigms that measure the tendency toward impulsive or compulsive drive for reward. Individuals with BED demonstrated a lower rsFC between the nucleus accumbens, a ventral striatum region involved in goal-oriented behavior; the left superior frontal gyrus (SFG), a frontal region involved with executive control; and the left posterior cingulate. They showed a lower rsFC between the ventral caudate and two clusters in the left SF. This ventral frontostriatal hypoconnectivity was significantly associated with a poorer performance on a reversal learning task as well

Table 2 Summary of functional MRI studies in binge eating disorder

Study	Region	Study group	Study design	Demographics	Diagnostic criteria	Aims & findings	Conclusions
Schienle et al. 2009	Germany	BED: $n = 17$ BN: $n = 14$ HC-NW: $n = 19$ HC-OW: $n = 17$	Cross-sectional, outpatient clinical sample	BED: 26.4 y (SD: 6.4) F: 100% BN: 23.1 y (SD: 3.8) F: 100% HC-NW: 22.3 y (SD: 2.6) F: 100% HC-OW: 25.0 y (SD: 4.7) F: 100%	*DSM-IV-TR*	To investigate the neural correlates of visually induced food reward and loathing in BED. The BED patients reported enhanced reward sensitivity characterized by increased OFC responses while viewing food pictures compared to HCs	Strong OFC recruitment together with the self-reported elevated reward responsiveness might be associated with increased reinforcement sensitivity in BED patients
Weygandt et al. 2012	Germany	BED: $n = 17$ BN: $n = 14$ HC-NW: $n = 19$ HC-OW: $n = 17$	Cross-sectional, outpatient clinical sample	BED: 26.4 y (SD: 6.4) F: 100% BN: 23.1 y (SD: 3.8) F: 100% HC-NW: 22.3 y (SD: 2.6) F: 100% HC-OW: 25.0 y (SD: 4.7) F: 100%	*DSM-IV-TR*	To evaluate the role of different visual food cues encoded in the brain and how this encoding differs between patients suffering from BED, BN, HC-NW, and HC-OW. BED patients decoding above chance in the ventral striatum show that it is central for the processing of the incentive value of reward-related cues	The best differential diagnostic separation between BED and BN patients was obtained in the left ventral striatum

Table 2 (continued)

Study	Region	Study group	Study design	Demographics	Diagnostic criteria	Aims & findings	Conclusions
		$n = 30$ HC-OW: $n = 28$		6.59) HC-OW: 39.40 y (SD: 10.48)		ACC-somatosensory cortex coupling in BED	
Fleck et al. 2019	USA	BED: $n = 18$ HC: $n = 15$	Cross-sectional, clinical sample	BED: 37.2 y (SD: 9.9) F: 100% HC: 40.0 y (SD: 8.2) F: 100%	*DSM-V*	To investigate the effects of lisdexamfetamine treatment on ventral prefrontal cortex (vPFC) and striatal brain activation in BED. After 12 weeks of treatment, vmPFC subcortical activation levels were found to be predictive of response to treatment	Activation of the vmPFC and thalamus is correlated with a decrease in binge eating attacks and obsessive-compulsive symptoms
Martins et al. 2020	UK	BED: $n = 5$ BN: $n = 20$ HC: $n = 23$	Cross-sectional, clinical sample	BED/BN: 23.6 y (SD: 3.79) F: 100% HC: 25.58 y (SD: 6.31) F: 100%	*DSM-V*	To investigate the abnormalities in resting brain physiology in women with BN/BED. Findings showed significantly increased rCBF in the medial PFC, OFC, right insula, and ACC in women with BN/BED likely reflecting basal regional hypermetabolism and increased resting neural activity	The increased rCBF may be associated with continuous feelings of monitoring of binge-activating stimuli in the environment and body shape/weight self-judgment

Haynos et al. 2021	USA	BED: $n = 27$ HC: $n = 21$	Cross-sectional sample	BED: 23.6 y (SD: 2.6) F: 100% HC: 23.3 y (SD: 2.2) F: 100%	*DSM-V*	To investigate the functional organization of brain networks that mediate reward in BED. Individuals with BED would exhibit lower ventral and dorsal fronto-striatal rsFC involved in self-regulatory control and perform poorer performance on tasks assessing the tendency toward impulsivity and compulsivity in reward-seeking behaviors	Hypoconnectivity of striatal networks that modulate self-regulation and reward processing may promote the clinical phenomenology of BED

Note: *ACC* anterior cingulate cortex, *BED* binge eating disorder, *BN* bulimia nervosa, *DSM Diagnostic and Statistical Manual of Mental Disorders*, *F* female, *GMV* gray matter volume, *HC* healthy controls, *HC-NW* healthy controls normal weight, *HC-OW* healthy controls overweight, *LC* loss of control, *OFC* orbitofrontal cortex, *PFC* prefrontal cortex, *rCBF* regional cerebral blood flow, *SD* standard deviation, *UK* United Kingdom, *USA* United States of America, *y* years

as with frequency of binge eating. This dysconnectivity may be the drive of compulsive pattern of reward seeking among individuals with a higher weight and the reflection of compromised ability to shift away from a reward; individuals with BED showed a lower rsFC between the dorsal caudate and clusters distributed across the frontal regions (left SFG and left inferior frontal gyrus) and the temporal regions (left middle temporal gyrus and right superior temporal gyrus). This hypoconnectivity between the striatum and posterior and temporal regions suggests deficits in decision-making function. More widespread hypoconnectivity was present in the dorsal striatum which is especially implicated in habitual reward learning. This chapter suggests that the brain regions subserving cognitive and behavioral inhibition are less synchronized at rest in BED compared with individuals of a similar body weight without an eating disorder.

Ensemble coding findings were reported by Weygandt and colleagues, who investigated how different visual food cues are encoded in the brain and how this encoding differs between patients suffering from BED and BN, overweight controls, and normal weight controls (NWC). Subregions of the amygdala, the ventral striatum, and the ACC separated between food and non-food stimuli only in patients with eating disorders. This suggests that eating disordered patients exhibit a deviant motivational and attentional processing of visual food cues, which could trigger binge eating attacks. BED patients decoding above chance in the ventral striatum show that it is central for the processing of the incentive value of reward-related cues. Interestingly, striatal patterns and patterns in the ACC, characterized by stronger responses to food cues as compared to neutral stimuli, in BN patients and obese controls suggest that relative to BED patients, food cues are more attractive and attention grabbing for BN patients and obese subjects and exert a stronger impact to seek and consume food (Weygandt et al. 2012).

In another fMRI study, obese patients with BED have decreased activities in brain regions associated with inhibition control (right lateral and anterior medial orbital cortex, ventromedial prefrontal cortex, and inferior frontal gyrus) when compared to obese and normal subjects without BED (Balodis et al. 2013b). As a result, BED patients' reduced capacity to engage impulse-control-related brain areas appears to be linked to food constraint. The observed variations in brain correlates of inhibitory processing in BED compared to obese and lean comparison groups show that binge eating, an eating strategy used by obese people, has specific neurobiological contributions. In parallel with the results of this study, a food-cue stimuli presentation during fMRI by Schienle and colleagues (2009) describes changes in neural activity in the ACC and medial OFC against increased sensitivity to food reward in the BED group. These findings point to the ACC's possible role in binge eating behaviors, which might include negative emotionality. Strong OFC recruitment together with the self-reported elevated reward responsiveness might be associated with increased reinforcement sensitivity in BED patients.

A very elegant task by Fleck and colleagues (2019) show that the effect of lisdexamfetamine on emotional network can regulate BED's increased brain reaction to food imagery and reduce binge eating, indicating that the dopamine and noradrenaline systems are involved in binge eating pathophysiology. After 12 weeks of

treatment, vmPFC subcortical activation levels were found to be predictive of response to treatment. The findings suggest that activation of the vmPFC and thalamus is correlated with a decrease in binge eating attacks and obsessive-compulsive symptoms.

A fMRI study was conducted with one group of obese people with binge eating episodes given a placebo ($n = 21$) and the other group given an opioid receptor antagonist (GSK1521498) ($n = 21$). In the study, the participants' power to comprehend high-/low-calorie food images and their motivation to see these images were measured. The group receiving opioid receptor antagonists had, compared to placebo, (1) a decreased motivation to see images of high-calorie food but liked the images and (2) decreased activity of the right pallidum/putamen in response to images of high-calorie food (Cambridge et al. 2013). Although motivation and liking were associated prior to drug administration and in the placebo group, this relationship was lost following mu-opioid antagonism.

Although it is known that BED patients suffer from behavioral control deficits during recurrent binge eating episodes, identification and intervention methods for behavioral control skills continue to be investigated. On the behavioral level, Reiter and colleagues (2017) investigated neural correlates of model-free prediction errors (PEs) and flexible behavioral adaptation via PEs incorporating inference about unchosen options and expected these signals to be associated with BOLD activation in the vmPFC. The authors found impaired behavioral adaptation in a dynamic environment in BED as compared with healthy controls. The study found that the decision-making in BED was characterized by enhanced switching between choices, indicating a bias toward exploratory decisions during behavioral adaptation in a dynamic environment. In addition to this, BED was characterized by less aI/vlPFC activation during exploratory decisions. This finding supported that patients learn similar to controls but perform suboptimally owing to enhanced switching. They found reduced BOLD activation in the vmPFC of BED patients, which is one possible substrate for impaired goal-directed decision-making. vmPFC PE signatures incorporating inference on alternative options were positively associated with successful choices and negatively associated with switching behavior. Patients suffering from BED in this study did not exploit a relatively better option as consistently as controls but showed pronounced switching behavior which can be regarded as an impaired balance between exploratory and exploitative choice behavior. This disbalance was accompanied by fewer correct choices.

Another study addressed two questions (Martins et al. 2020): Do women with BN/BED, compared with HC, present alterations in resting brain perfusion? Can intranasal oxytocin restore or attenuate these resting alterations? A significant increase in regional cerebral blood flow (rCBF) was shown in the medial PFC, OFC, right insula, and ACC in women with BN/BED likely reflecting basal regional hypermetabolism and increased resting neural activity. This increased rCBF may be associated with continuous feelings of monitoring of binge-activating stimuli in the environment and body shape/weight self-judgment since the medial PFC and ACC are two key areas involved in self-monitoring and control regulation. Additionally the medial PFC, ACC, and right insula correlated positively with global scores on

the EDE-Q. Researchers also found decreased GMV in the right temporal lobe in BN/BED patients. This negative correlation is explained with two mechanisms: the first was that increased rCBF was the result of local functional plasticity in response to GMV loss in this region, and the second was that GMV loss occurred due to excitotoxicity as a result of increased rCBF caused by neural hyperactivity. The absence of functional and structural abnormalities in the ventral or dorsal striatum in this study explained by alterations may become evident by anticipation or valuation of hedonic stimuli (e.g., food).

Diffusion Tensor Imaging and Magnetoencephalography Studies

Diffusion tensor imaging (DTI) is a developed magnetic resonance imaging (MRI) technique that can be used to evaluate the structural integration of white matter (WM) tracts in the brain and to identify pathological changes at the microstructural level, such as axonal or myelin damage. In recent years, there have been studies using advanced imaging techniques such as DTI to determine that there are some disorders in the connection pathways such as association and commissural fibers that connect different lobes and hemispheres in the brains of patients diagnosed with eating disorders. Diffusion tensor imaging and magnetoencephalography studies in BED were summarized in Table 3. Estella et al. (2020) used DTI to investigate WM microstructure in women with BED and obesity, compared to normal weight control (NWC) and to women with obesity only (OBC). The hypothesis was that those with BED would show WM alterations in pathways involved in reward and inhibitory control circuitry (i.e., self-regulation), compared to other groups. The BED group compared to NWC showed greater axial diffusion (AD) in the forceps minor, superior and inferior longitudinal fasciculus, inferior fronto-occipital fasciculus, anterior thalamic radiation, and forceps major. Fractional anisotropy (FA) increases in the forceps minor in BED may also reflect self-regulation difficulties. BED group showed differences in pathways connecting fronto-limbic and parietal regions. To be specific, greater FA in the forceps minor which is involved in flexible cognitive responses and greater AD in the superior longitudinal fasciculus, cingulate gyrus, and corpus callosum compared to the OBC group were observed. This difference between OBC and BED groups may reflect a distinction independent of BMI. The increase in FA in the BED group appears to be consistent with the findings in the previous studies of BN, that is, increases in FA being associated with greater symptomatology (binge eating episodes) and less intact executive functions beyond the effects of BMI. The microstructural differences present in fronto-limbic regions suggested that BED may be associated with changes in reward-related structural organization. Briefly they all indicated altered microstructure organization in pathways involved in decision-making and reward appraisal in BED patients. Since they corrected for BMI, they suggested that WM changes specific to the BED group may be part of BED pathology. Based on the data, they propose that in BED, WM alterations in AD and FA in pathways connecting the fronto-limbic and

Table 3 Summary of diffusion tensor imaging, PET-SPECT, and magnetoencephalography studies in binge eating disorder

Reference	Region	Study objective	Population	Clinical assessment	Main assessment	Main results	Risk
Karhunen et al. 2000	Finland	BED: $n = 8$ Obese: $n = 11$ HC: $n = 12$	Cross-sectional, clinical sample	BED: 36.1 y (SD: 9.3) F: 100% Obese: 45.0 y (SD: 10.0) F: 100% HC: 39.8 y (SD: 9.7) F: 100%	*DSM-IV*	To investigate the cerebral responses of binge eating subjects elicited in response to exposure to food. rCBF increases in the left frontal and prefrontal cortices of patients with BED in response to food/body shape-related stimulus	The left hemisphere and its frontal and prefrontal regions could thus play a role in binge eating behavior
Kuikka et al. 2001	Finland	BED: $n = 11$ Obese: $n = 7$	Cross-sectional, clinical sample	BED: 39 y (SD: 9) F: 100% Obese: 41 y (SD: 9) F: 100%	*DSM-IV*	To investigate the serotonin transporter binding in obese binge eating women. BED patients have reduced serotonin transporter binding in the midbrain region compared to those without BED	Impaired 5-HT transporter binding in their midbrain may contribute to concurrent or sequential periods of binge eating and depression
Hege et al. 2015	Germany	BED: $n = 17$ Obese: $n = 17$	Cross-sectional, outpatient sample	BED: 41.88y (SD: 8.46) F: 100% Obese: 41.35 y (SD: 12.33) F: 100%	*DSM-IV*	To assess the neuronal correlates of increased impulsivity in BED during behavioral response inhibition. Results show a hypoactivity in the prefrontal control network and increased errors during inhibitory control	BED is associated with an attentional impulsiveness-related attenuation in response inhibition performance

(continued)

Table 3 (continued)

Joutsa et al. 2018	Finland	BED: $n = 7$ Obese: $n = 19$ HC: $n = 14$	Cross-sectional, clinical sample	BED: 49.4 y (SD: 5.1) F: 100% Obese: 41.8 y (SD: 10.3) F: 100% HC: 44.9 y (SD: 12.9) F: 100%	*DSM-V*	To compare MOR availability between morbidly obese and BED subjects. BED patients had widespread reduction in [11C] carfentanil binding compared to control subjects	MOR system dysfunction may be a shared pathophysiological feature in BED
Estella et al. 2020	Brazil	BED: $n = 17$ Obese: $n = 13$ HC: $n = 17$	Cross-sectional, clinical sample	BED: 33.82 y (SD: 7.2) F: 100% Obese: 38.03 y (SD: 9.7) F: 100% HC: 23.7 y (SD: 11.0) F: 100%	*DSM-V*	To assess the white matter microstructure in BED. The BED group (vs. HC) had greater axial diffusion in the forceps minor, anterior thalamic radiation, superior and inferior longitudinal fasciculus	The microstructural differences present in fronto-limbic regions suggested that BED may be associated with changes in reward-related structural organization

Note: *BED* binge eating disorder, *DSM Diagnostic and Statistical Manual of Mental Disorders*, *F* female, *HC* healthy controls, *MOR* mu-opioid receptor, *rCBF* regional cerebral blood flow, *SD* standard deviation, *y* years

temporal-parietal regions may be associated with repetitive difficulties during processes of eating-related decision.

Furthermore, findings from a magnetoencephalography study support that patients with BED show a hypoactivity in the prefrontal control network and increased errors during inhibitory control (Hege et al. 2015).

PET-SPECT Studies

Obtaining molecular and functional information about metabolism, tissue perfusion, structure of vessels, and cellular contents is very important in the diagnosis and treatment of psychiatric diseases such as eating disorders. In this context, single photon emission computed tomography (SPECT) and positron-emission tomography (PET) are used to investigate functional states such as explaining the molecular and biological interactions in the onset of the disease, monitoring treatment response, drug development, biodistribution, receptor interactions, and evaluation of target binding kinetics. SPECT and PET studies in BED are summarized in Table 3. In a SPECT study using [99m Tc] ethyl-cysteine-dimer, neural responses to neutral versus food cues were examined. rCBF increases in the left frontal and prefrontal cortices of patients with BED in response to food-/body shape-related stimulus (Karhunen et al. 2000). In this direction, in another study by Kuikka et al. (2001), 11 obese women with BED and 11 obese women without BED were examined for serotonin transporter binding by radioligand labeling method. It has been shown that obese women with BED have reduced serotonin transporter binding in the midbrain region compared to those without BED.

Morbid obesity and eating disorders are both associated with widespread alterations in brain mu-opioid receptor availability with regional differences. A recent study was conducted with radioligand [11C] carfentanil using PET on the availability of mu receptors in the brain and the relationship of these receptors with various behavioral phenotypes, especially in patients with BED and morbid obesity (Joutsa et al. 2018). They found that obesity with and without binge eating was associated with decreased mu-opioid receptor availability throughout the brain, and it may be a general neurobiological mechanism associated with disorders involving excessive food intake. Considering the PET and SPECT studies, there is a need for prospective studies examining the endogenous DA, NE, 5-HT, opiate, and other systems (e.g., glutamatergic) in the striatum and cortex of individuals with BED.

Future Directions

Given the prevalence of the disease and treatment outcomes for many individuals with BED, evidence-based treatments are only possible with a better understanding of the underlying mechanisms of the disease. Although the cost of designing neuroimaging research is high compared to other research, larger sample sizes and longitudinal study designs will add much more information to this field, thereby

increasing the generalizability and applicability of the results of these studies. There is an increasing need for therapeutic neuroimaging studies that evaluate mindfulness-based interventions, which have been increasing in recent years. Additionally, especially with the lack of data reproducibility in neuroimaging research, future studies will be well positioned to design and record preclinical experiments and to plan how neuroimaging data is carefully planned.

Mini-Dictionary of Terms

- **Neuroimaging:** The method is the use of various techniques to view the structure, function, or pharmacology of the nervous system, either directly or indirectly
- **Binge eating:** Eating much more food than normal in a short time in attacks and losing control in the meantime
- **Reward processing:** The hedonic pleasure derived from reward consumption and the motivational salience of a reward
- **Gray matter**: It is the region where neuron cell bodies are present and without myelin sheath
- **Inhibitory processing:** The capacity to exert control over one's mental processes and behaviors, to disregard an internal or external stimulus, and to take a different course of action

Key Facts

- Binge eating disorder (BED) is an eating disorder characterized by binge eating episodes not accompanied by compulsive behaviors
- Neuroimaging studies in BED mostly focus on the evaluation of functional structures
- Neuroimaging techniques suggest a causal relationship between altered reward sensitivity and food-related attentional biases in BED individuals
- The latest causal relationships have been established between regional gray matter volumes and eating disorder psychopathology
- Beyond health consequences, the effects of clinical presentations of BED have significant social and economic losses to individuals and society at large

Summary Points

- BED can be defined as impulsive/compulsive eating disorders with altered reward sensitivity and food-related attentional biases
- Structural MRI studies report that BED patients have changes in brain regions particularly associated with reward and impulsivity

- Functional connectivity alterations in patients with BED have been found in imaging studies that examined task-dependent brain activity
- In BED cases, increased regional cerebral blood flow response was detected in the left temporal and prefrontal region in response to stimuli
- The precise neurobiology of BED remains unclear, and ongoing, large-sample, and longitudinal researches are required

The Role of Bariatric Surgery

Fabiana Salatino Fangueiro and Patrícia Colombo-Souza

Contents

Abstract

Obesity is a complex multifactorial disorder that combines biological, psychological, and social aspects and requires a multidisciplinary approach for proper understanding, diagnosis, and treatment. Bariatric surgery, for some patients, is the most effective tool for obesity treatment and control; however, some patients do not achieve the desired weight or regain part of the lost weight. Even though it is an effective treatment for obesity and associated comorbidities, emotional and behavioral changes can damage lifestyle's recovery and adjustments to maintain the expected results with the surgical procedure. Among eating disorders (EDs), binge eating disorder (BED) and binge eating (BE) are those with the highest incidence among obese candidates for bariatric and metabolic surgery (BMS). Considering that changes in eating behavior can negatively influence weight loss, recognizing this condition becomes essential for early reintervention in order to guarantee the expected success to the patient after undergoing bariatric surgery.

Introduction

It is known that weight loss is a recurrent difficulty in the life of obese patients. Obtaining good results using the conventional treatments offered, such as the use of drugs, adoption of healthy eating habits, and the practice of physical activity, transforms the lives of these patients into a daily struggle. Thus, the demand for bariatric surgery has increased considerably and has demonstrated some success.

Bariatric surgery is becoming widely recognized and has become the most effective treatment for controlling severe obesity. Added to this, its results can bring about a decrease or remission in diabetes, a reduction in cardiovascular risk, improvement in sleep apnea and joint pain, and, consequently, an improvement in quality of life and a considerable reduction in the risk of mortality (World Health Organization (WHO) 2000; Al-Najim et al. 2018; Opozda et al. 2018). In view of this, bariatric surgery came to be called bariatric and metabolic surgery (BMS).

One of the important factors determining the success of the surgical procedure is the percentage of weight loss. Weight loss occurs drastically in the immediate postoperative period. This is due to the decrease in gastric capacity and the consequent reduction in nutrient absorption. Together, these factors provide quick satiety to the patient (Nikiforova et al. 2019). However, this rapid weight loss stabilizes on

average between 12 and 18 months after the surgery, which is the period known as the "honeymoon" in which the patient manages to lose as much weight as possible (Associação Brasileira Para o estudo da obesidade e da síndrome metabólica (ABESO) 2016; Fangueiro et al. 2021).

However, a proportion of patients may not achieve the expected weight loss or may experience significant weight regain over the next decade (Nasirzadeh et al. 2018). A Swedish study, carried out with obese individuals, showed that 10 years after surgery, 9% of patients lost less than 5% or maintained their baseline weight (Sjöström et al. 2015).

After this period, several determinants act in the maintenance and weight loss of the patient. These determinants are changes in eating habits, physical activity, hormonal or metabolic alterations, postoperative anatomical factors, and emotional and behavioral changes (Freire et al. 2020; Ribeiro et al. 2018). These factors can influence the recovery and the readjustment of the patient's lifestyle needed to maintain the results expected from the surgical procedure (Meany et al. 2014; Pinto-bastos et al. 2019). The effectiveness of surgical interventions considering weight loss alone can vary significantly between individuals; 20% to 30% of patients have insufficient weight loss or weight regain in the medium and long term after the surgical procedure (Bianciardi et al. 2021).

Thus, as the number of surgeries performed increases, the time elapsed since performing the procedure also increases, making postoperative clinical and psychological evaluations increasingly necessary. Parallel to this is the importance of verifying, from a psychosocial perspective, possible changes in symptoms as a result of weight loss.

Concern about the preoperative psychosocial status is one of the reasons why clinical practice requires that individuals seeking bariatric surgery undergo multidisciplinary assessments before surgery. This assessment is designed to identify potential psychiatric and behavioral contraindications to surgery (psychosis, untreated major depression, active substance abuse, or significant behavioral noncompliance). In addition, in the preoperative period, it is the role of the health professional to provide patients with information about the dietary and behavioral challenges they will face after surgery. During this multidisciplinary follow-up, patients will then be educated on the basic elements of the postoperative diet and the behaviors needed to achieve optimal postoperative results. This includes meals with small portions; chewing food thoroughly and slowly; avoiding foods high in carbohydrate, fat, sugar, and other poorly tolerated foods; increasing water intake; avoiding alcoholic beverages; and identifying and treating binge eating (BE) and/or snacking (Behary and Miras 2015).

The majority of patients undergoing bariatric surgery maintain adequate weight loss in the long-term follow-up. However, a subset of patients undergoing bariatric surgery experience less than expected weight loss, weight gain, or psychosocial distress after surgery. Some of these negative results are due to the manifestation of what is known as an eating disorder (ED).

BE episodes are included in the classification of EDs from the Diagnostic and Statistical Manual of Mental Disorders (DSM-V), organized by the American

Psychiatric Association (American Psychiatric Association 2013). These episodes are defined by eating more food in a short period of time than most people would consume under similar circumstances (Moshe et al. 2017). The episodes are marked by the feeling of lack of control and the feeling of guilt or shame, usually described by those whose eating behavior is defined as compulsive (Moraes and Almeida PE de M 2018).

These dietary pathologies can be predictors for weight regain, demonstrating the importance of their identification, through appropriate postoperative monitoring, so that it is possible to provide a timely referral for reassessment and counseling to mitigate weight regain (Sarwer et al. 2012). Therefore, better understanding of dietary psychopathology in the years following bariatric surgery, the times when they reappear, and their impact on weight regain can provide insights into the timing of postsurgical interventions (Nasirzadeh et al. 2018).

This disorder has significant impacts on the individual's organism and social life, as it acts directly on the quantity and quality of food consumed and on the absorption of nutrients. The literature recognizes as EDs the rumination disorder, pica, restrictive food intake disorder, anorexia nervosa, bulimia nervosa, and binge eating disorder (BED) (American Psychiatric Association 2013; Sena 2014; Chao et al. 2016).

Here, we are going to talk specifically about BED, which is one of the EDs that can directly influence the long-term weight loss success expected by the surgical procedure. The occurrence of a high prevalence of EDs in patients who are candidates for bariatric surgery is common. It is observed that this relationship occurs because BED is prevalent among obese individuals (Ivezaj et al. 2017a; Opolski et al. 2015; Sarwer et al. 2019; van Hout et al. 2005).

After bariatric surgery, the consumption of large amounts of food, which characterizes BE and which is necessary for a diagnosis as established by the Diagnostic and Statistical Manual of Mental Disorders, fifth edition (DSM-V), is often physically difficult or impossible. This is due to the anatomical and physiological alterations that are imposed by the surgery. Studies show that, eventually, some postbariatric patients can ingest an objectively large amount of food (Meany et al. 2014; Brode and Mitchell 2019). Even faced with the difficulty of eating large amounts of food, patients can develop new problematic eating behaviors related to BE. These new behaviors are manifested by the loss of control while eating (LOCE), the habit of snacking, subjective BE, or the consumption of small amounts of nutrient-rich foods, which circumvent the action mechanism of the surgery. It is noteworthy that the patients at a higher risk of developing new eating behaviors, especially LOCE, are usually the patients who met the criteria for BED before surgery (Freire et al. 2020; de Zwaan et al. 2010; Ivezaj et al. 2017b). Studies suggest that LOCE – characterized as the feeling of an inability to stop eating or control the amount of food consumed, regardless of the amount ingested – should be considered the main characteristic of BE (Andrea and Ana 2020; Goldschmidt 2017). Furthermore, the behavior of eating at night may also be present in some of the patients undergoing bariatric surgery. These eating pathologies can be enough for the patient to progress to postoperative weight recovery (Nasirzadeh et al. 2018).

The occurrence of BE as well as the other EDs mentioned above is not considered a contraindication for the performance of bariatric surgery. This is because in the first years after surgery, the period when the greatest weight loss occurs, the frequency of these eating behaviors is significantly reduced (Freire et al. 2020; Bianciardi et al. 2021). The literature to date indicates that bariatric surgery generally produces good results and a decline in dietary psychopathology in the first year after surgery; however, recurrence can occur at any time beyond this initial year, emphasizing the need for these conditions to be monitored, controlled, and handled by the multidisciplinary team (Nasirzadeh et al. 2018).

Definitions and Indications of BMS

BMS has evolved considerably since its origins in 1952. The first surgical technique applied was small bowel resection with subsequent anastomosis. Initially, the bariatric surgical procedure was performed without many controls, triggering high rates of surgical failure, morbidity, and mortality. Over the years, several surgical techniques have been tested. Some have proven to be beneficial, while others have been abandoned due to low weight loss, postsurgical complications, or the development of new safer and more effective procedures. With the advances in surgical techniques, as well as better monitoring of patients before and after surgery, improvements in long-term weight loss and a reduction in morbidity and mortality were observed. In 1967, the technique called Roux-en-Y gastric bypass (RYGB) was performed for the first time. The surgery was developed with the objective of exclusively treating obesity; however, throughout history, it has also gained great prominence for the control, improvement, or even remission of associated comorbidities. As it provides these benefits, it has since been denominated BMS (World Health Organization (WHO) 2000; Phillips and Shikora 2018; Buchwald 2014; Eldar et al. 2011).

Between 2011 and 2018, the number of bariatric surgeries performed by Brazilians grew by 84.73%, according to data from the Brazilian Society of Bariatric and Metabolic Surgery (SBBMS). This exponential increase placed Brazil in second position as the country that most performs this surgery in the world, just behind the United States. Despite these expressive data, however, there are many prerequisites to be met for the patient to become suitable for surgery.

The surgical procedure is indicated for adults up to 65 years of age with resistance to clinical treatment for at least 2 years and with a BMI > 40 Kg/m^2 regardless of the presence of comorbidities or BMI > 35 Kg/m^2 associated with comorbidities (Associação Brasileira Para o estudo da obesidade e da síndrome metabólica (ABESO) 2016). Adolescents aged 16 to 18 years can be operated on as long as there is pediatric follow-up by the multidisciplinary team and that they respect the consolidation of the epiphyses cartilage of the wrist. In Brazil, the most recent Resolution of the Federal Council of Medicine (2172/2017) expanded the indication of bariatric surgery for patients with diabetes mellitus type 2 between 30 and 70 years of age and BMI from 30 to 34.9 Kg/m^2, as long as the disease has not

been controlled with clinical treatment. Furthermore, it is necessary that the diagnosis has been defined for at least 10 years. Contraindications for bariatric surgery are Cushing's syndrome; dependence on alcohol or illicit drugs during surgery; severe uncontrolled psychiatric illness; moderate to severe dementia; a recent history of myocardial infarction, stroke, and cardiac stent; current cardiac ischemia or severe valve dysfunction; and the difficulty of understanding risks, benefits, expected results, treatment alternatives, and lifestyle changes required after the procedure (Associação Brasileira Para o estudo da obesidade e da síndrome metabólica (ABESO) 2016).

According to the American Society for Metabolic and Bariatric Surgery (ASMBS), a patient who is unable to achieve weight loss and maintain it for a period of time and who has a BMI $\geq$ 40 kg/m^2 or is more than 100 pounds overweight is eligible for bariatric surgery. Patients with a BMI $\geq$ 35 kg/m^2 and at least one or more obesity-related comorbidities, such as type 2 diabetes (DM2), hypertension, sleep apnea and other respiratory disorders, nonalcoholic fatty liver disease, osteoarthritis, lipid abnormalities, gastrointestinal disorders, or heart disease, are also eligible for BMS. In adolescents, the recommendation to perform BMS is for those with a BMI $\geq$ 35 kg/m^2 and who present the following comorbidities: DM2, moderate or severe sleep apnea, pseudotumor cerebri, or severe fatty liver disease. Those with a BMI $\geq$ 40 kg/m^2 and those with less severe comorbidities such as high blood pressure, high cholesterol, and mild or moderate sleep apnea are also qualified.

The surgeries are differentiated by the working mechanism. There are three basic procedures in BMS, which can be didactically divided and classified as restrictive procedures, malabsorptive procedures, or mixed procedures.

Restrictive procedures are those that reduce gastric capacity, leading the patient to consume less food and inducing a quick feeling of satiety. Among these procedures, there are those that are purely restrictive, those that do not stop the patient's hunger, and those that are restrictive and metabolic, such as *sleeve* gastrectomy, which, in addition to inducing early satiety, also reduce the degree of hunger (de Oliveira et al. 2019).

Malabsorptive procedures, currently in disuse, slightly alter the gastric capacity and drastically alter the absorption of nutrients. These are surgical techniques that cause a large intestinal diversion, reducing the time the food is in the intestinal transit and, consequently, also reducing its absorption capacity, which will lead to weight loss (Associação Brasileira Para o estudo da obesidade e da síndrome metabólica (ABESO) 2016).

Mixed procedures, considered the gold standard, are those that cause restriction in gastric capacity and a mild reduction in nutrient absorption capacity, such as the RYGB technique.

Currently, the laparoscopic approach is the most widely used method for performing BMS, with only a small percentage of all procedures performed in open access. The most commonly performed BMSs are the laparoscopic sleeve gastrectomy, also known as the *sleeve*, and the laparoscopic RYGB (Wolfe et al. 2016; Sociedade Brasileira de Cirurgia Bariátrica e Metabólica (SBBMS) 2017).

RYGB is characterized by the creation of a gastric reservoir (with a capacity of 40 to 50 ml) close to the small gastric curvature. The remainder of the stomach is excluded, including the entire fundus and the gastric antrum, the duodenum, and the initial portion of the jejunum. The reconstruction of the transit is carried out by forming a Roux-en-Y loop, with a length that varies from 75 to 150 cm. In addition, a silicone band can be placed a few centimeters above the gastrojejunal anastomosis to calibrate the passage of food. Thus, nutrients are shifted from the upper to the middle of the small intestine. As a consequence, there is a feeling of satiety more quickly and less absorption of nutrients due to the formation of the Y-shaped transit. This technique promotes weight loss equivalent to approximately 70% of the patient's total weight, which is greater than that found in techniques that are only restrictive, such as the *sleeve*, for example, as well as having a low mortality rate (0.5%). However, supplementation with vitamins and minerals, such as vitamin B12, is necessary, in addition to frequent monitoring of serum levels of vitamin D, calcium, and iron (Associação Brasileira Para o estudo da obesidade e da síndrome metabólica (ABESO) 2016).

Sleeve gastrectomy is an anatomically simple but irreversible operation in which 80% of the greater curvature of the stomach is excluded, leaving the anatomy of the small intestine unchanged. A probe is passed into the pylorus against the small curvature of the stomach, and a laparoscopic stapler positions a line of staples that follows the length of the probe to the angle of His. Although the process does not involve anastomosis, the length of the staple line puts the patient at risk for bleeding or fistula, particularly as it is a high-pressure chamber, which differs from RYGB. This surgical technique causes the stomach to reduce its storage capacity to 60–100 ml. Due to the removal of the bottom of the stomach, ghrelin levels decrease, consequently decreasing the feeling of hunger, thus characterizing the restrictive metabolic technique (Wolfe et al. 2016; Stein and Silverberg 2015).

The degree of weight loss that patients experience varies according to individual, the surgical technique applied, and the time elapsed since the surgical procedure. The SBBMS considers obesity recurrence when, in the long term, there is a recovery of 50% of the weight loss or 20% of the weight regained associated with the reappearance of comorbidities. The controlled relapse of obesity, on the other hand, is when the patient recovers, in the long term, between 20% and 50% of the weight loss (Buchwald et al. 2004; Berti et al. 2015; Bryant et al. 2020).

Throughout its history, BMS has undergone major advances related to patient safety and the development of more reliable and effective surgical techniques. However, $<1\%$ of patients eligible for bariatric surgery according to established criteria actually undergo the surgery. Some likely reasons for this include lack of health plan coverage and fear of long-term adverse events. Whatever the reason, these trends highlight the continuing need to not only care for a global population of patients who experience an increasing degree of mortality from a variety of causes but also to find a more efficient way to treat a greater percentage of patients and at the same time educate them about their fears around the stigma of BMS.

The challenge for metabolic and bariatric surgeons is to continue to foster a culture of safety, and for this to occur, high standards of effectiveness in carrying out

BMS must be maintained. Fortunately, given the need to evolve and advance surgical techniques targeting metabolic diseases and weight loss, BMS has a promising and exciting future. New procedures, technologies, devices, and interventions are under development while maintaining high standards of safety and effectiveness. These advances include the emergence of numerous technologies and devices that are currently undergoing extensive research. All of these devices offer the promise of significant weight loss with greater safety and simplicity compared to more conventional operating procedures. The future of BMS promises improved techniques and continued attention to patient safety, with new mechanisms of action that will result in less change in the gastrointestinal anatomy, which, in turn, will likely lead to better patient acceptance for surgery (Phillips and Shikora 2018).

BED

The BED is of particular interest due to its relationship with obesity and its medical and psychiatric comorbidities. BED has a high socioeconomic impact due to a higher risk of morbidity and mortality, as well as a reduction in quality of life, greater problems of social coexistence, and increased use of health services compared to people with the same BMI and who do not have the disorder (Dawes et al. 2016).

Although BED was first described in the 1950s by Stunkard, its elevation to diagnostic category only occurred in 1994, when it was included in Appendix B of the Diagnostic and Statistical Manual of Mental Disorders, fourth edition (DSM-IV) in the form of a disorder that needs further studies for better characterization. Thus, since then, there has been greater interest in research in this area, due to the need to discriminate obese individuals with BE from those without BE and bulimics. BED is thus included in the DSM-V as a new ED category.

BED is evidenced through its main characteristic: regular episodes of BE. Each episode of BE is characterized by the objective consumption of large amounts of food over a period of up to 2 h and accompanied by the subjective feeling of loss of control over the type of food ingested, as well as its quantity. If these episodes are recurrent, that is, they occur on average at least once a week for 3 months, the syndrome denominated BED is confirmed (American Psychiatric Association 2013; Sarwer et al. 2011).

In addition, the identification of BE is reinforced whenever the manifestation of suffering marked by compulsive attitudes toward eating is observed in the individual. Among these attitudes, it is necessary that at least three of the following characteristics are present: (World Health Organization (WHO) 2000) consuming the food excessively quickly, unusually when compared to people who do not have BED; (Al-Najim et al. 2018) ingesting an excessive amount of food to the point of causing gastric discomfort; (Opozda et al. 2018) ignoring the physical feeling of hunger and consuming large amounts of food; (Nikiforova et al. 2019) isolating oneself during food intake due to shame about how much one eats; and (Associação Brasileira Para o estudo da obesidade e da síndrome metabólica (ABESO) 2016) and feeling guilty, depressed, and disgusted with oneself. It is also observed that, unlike

other EDs, which also involve BE, BED differs, for example, from bulimia nervosa, by the absence of inappropriate compensatory behaviors for weight loss that routinely occur, such as induction of vomiting, strenuous physical exercise, or misuse of laxatives and/or diuretics (Sena 2014).

It is increasingly recognized that a small subset of patients are diagnosed with EDs after bariatric surgery (Brode and Mitchell 2019).

BE is usually evidenced in individuals who tend to have greater problems in their social life, who suffer a lack of affection, and who have low self-esteem, negative feelings related to body weight, and very restrictive diets, among many other causes that can be observed at the clinical follow-up.

Allied to this, we need to consider that binge episodes should be followed by a feeling of lack of control over the type of food eaten as well as its quantity. One of the signs of loss of control is the individual's inability to avoid eating or to know how to stop eating. Here, the individual's need to eat an excessive amount of food is observed, not considering the quality, appearance, or flavor of the food.

BED has an impulsive characteristic. Impulsivity refers to the lack of ability to inhibit automatic behavior (also known as response inhibition) and the tendency not to measure future consequences in favor of more immediate outcomes (known as delay discounting). These choices between preferences for immediate rewards in relation to future rewards will become evident when the professional indicates to the patient the choice of smaller immediate rewards. Furthermore, executive function, defined as an individual's ability to regulate attention and maintain goal-directed behavior, is believed to play a central role in impulsiveness. Lack of impulse control can reduce the ability to inhibit automatic behavior (e.g., excessive consumption of highly palatable snacks) and can increase preference for immediate rewards over long-term rewards (e.g., choosing highly palatable snacks over a healthier option). Thus, impulsivity can contribute to the excessive weight gain seen in extreme obesity and can impact the results of bariatric surgery (Sarwer et al. 2019).

It should be noted that we must consider the way in which this occurs, and thus it is necessary to analyze the moment when BE episodes occur. Do these episodes occur during special occasions, such as holiday festivities and social events with friends, or do they occur daily at everyday meals? These situations must be taken into account during clinical care as they will help the professional to delimit the existence of BE.

BE is of particular concern in bariatric populations due to the possible attenuation of weight loss. Studies suggest that postoperative disorders, and particularly postoperative BED and LOCE, may contribute to worse weight loss outcomes (Ivezaj et al. 2017b). Although BE episodes in bariatric surgery are alleviated by the anatomical and physiological alterations imposed by the surgery, restricting the amount of food consumed, over time many individuals are able to endorse or develop this behavior (Brode and Mitchell 2019; Smith et al. 2019). Thus, suboptimal weight loss and regain may result not only from an uninhibited diet but also because, over time, patients are able to consume greater amounts of food (Brode and Mitchell 2019).

In addition, patients can develop new problematic eating behaviors, such as loss of control while eating (LOCE), snacking, subjective BE, or consumption of small

amounts of nutrient-rich foods, which make up the mechanism of action of the surgery. The behavior of eating at night may also be present in some patients undergoing bariatric surgery. These dietary pathologies may be sufficient for postoperative weight recovery (Nasirzadeh et al. 2018). Successful weight loss has been associated with self-monitoring of weight-related behavior, which could be indicative of self-regulatory capacity. Since LOCE and BE are largely characterized by difficulties in self-regulation, the lack of self-monitoring may be related to postoperative LOCE.

BE and excessive food intake are two prevalent obesity-related characteristics that contribute to excessive calorie intake and weight gain. BE is characterized by the subjective experience of loss of control (LOCE) during eating, regardless of the actual amount of food consumed. Overeating is characterized by eating a large amount of food, regardless of LOCE. Therefore, LOCE and the ability to eat large amounts of food are two independent but interrelated constructs (Eldar et al. 2011).

Although the diagnosis of BED, specifically the criteria for an episode of BE, requires the consumption of an objectively large amount of food, evidence suggests that it is the characteristic of loss of control while eating that may be the most important characteristic (Lavendera et al. 2014).

Both BE and BED are more common among individuals with obesity compared to individuals with normal weight (Schag et al. 2016). In addition, previous research has documented that 43.4% of candidates for bariatric surgery report LOCE (Smith et al. 2019).

Although binge-eating episodes are often alleviated because surgery restricts the amount of food patients can eat, over time some may be able to consume larger amounts (Smith et al. 2019). Therefore, the importance of identifying eating behaviors through appropriate postoperative monitoring is clear, in order to mitigate weight regain.

Prevalence of BED in Bariatric Patients

Surgery is recognized as an effective treatment for severe obesity and associated comorbidities; however, there is enormous variability in weight loss outcomes after surgery. The weight change trajectories of bariatric patients start to diverge between 6 and 12 months after surgery, and different trajectories have an impact on the prevalence of comorbidities and the corresponding health costs (Cassin et al. 2020).

Studies estimate that 50% of patients who undergo the RGBY technique and 59% of those who undergo sleeve gastrectomy experience some degree of weight gain and approximately half of the patients who undergo RGBY regain more than 20% of the maximum initial weight loss (Ivezaj et al. 2017b).

BED is a relatively common disorder, with an estimated lifetime prevalence in the general population of around 1.4%. However, this estimate increases substantially among obese individuals, without marked differences between sexes.

Establishing a psychiatric diagnosis before bariatric surgery is a challenge. Although preoperative guidelines recommend that patients undergo a clinical

psychological evaluation prior to surgery, it is possible that some patients become more engaged during assessments, minimizing psychopathology symptoms. Thus, these patients present themselves in the most favorable way possible in order to obtain a positive recommendation for surgery from the professional (Dawes et al. 2016).

In obese individuals who are candidates for bariatric surgery, the prevalence of BED was estimated at 4.6% to 27.1% (Chao et al. 2016; Sarwer et al. 2019). Added to this is the presence of a diagnosis of depression (19%) at the time of surgery (Dawes et al. 2016). It is likely that the prevalence will increase, especially considering the increasing incidence of both obesity and EDs around the world and not because of the expansion of diagnostic criteria introduced in the DSM-V (Ivezaj et al. 2017b).

Although LOCE and BED initially decrease soon after surgery, a substantial proportion of patients report postoperative LOCE and BED, with studies showing wide variation in postoperative rates, from 0% to 46% (Fangueiro et al. 2021; Meany et al. 2014; Cella et al. 2019; Latner et al. 2004; Kalarchian et al. 2002). A recent study that carefully evaluated the presence of BED before surgery found no statistically significant difference in weight loss at the end of the first postoperative year between those who received the diagnosis before surgery and those who did not. However, by the 24th month after the surgical procedure, participants diagnosed without BED had lost 23.9% of their initial weight, compared with 18.6% for those with BED (Chao et al. 2016).

Possible contributions to this wide variation in the prevalence of LOCE and BED include the different types of surgery used, the type of instrument used for diagnosing EDs, and the length of postsurgical follow-up. Another possibility that justifies this wide variation in the prevalence of LOCE and BED is that individuals minimize problems related to eating before surgery, or even that, over time, individuals find it more difficult to adhere to the necessary postoperative dietary guidelines to maintain the expected results of the surgery and, as a result, experience a sense of loss of control over eating (Meany et al. 2014; van Hout et al. 2005; Eldar et al. 2011; Maggard et al. 2005; Branson et al. 2005).

Furthermore, in obesity, BE episodes are known to be difficult to assess because they are not as distinct as episodes of bulimia nervosa, which often end with some type of compensatory behavior, such as vomiting (Meany et al. 2014).

These data suggest how beneficial it would be to perform routine monitoring assessments of eating behavior well beyond the first year after surgery, as many individuals continue to report a feeling of long-term loss of control over their eating (Smith et al. 2019). This self-reported inability to control these impulses in the postoperative period is associated with less weight loss and greater emotional distress in the first postoperative years.

Data on the incidence of postoperative BED are scarce due to the lack of follow-up, screening, and standardization in the assessment of these comorbidities. Given this and the rapid increase in demand for bariatric surgery in the last decade, the need for better understanding of the outcomes in the postoperative period is evidenced.

Instruments Used to Diagnose BED

The guidelines recommend a multidisciplinary assessment of candidates for bariatric surgery to identify potential psychological factors that could compromise surgery outcomes. After performing the procedure, it is recommended that multidisciplinary follow-up takes place beyond the first year.

During the assessment and follow-up of the patient by the multidisciplinary team, BED assessment instruments can be used. The instruments are divided into three categories: (World Health Organization (WHO) 2000) clinical interviews, (Al-Najim et al. 2018) self-monitoring, and (Opozda et al. 2018) self-administered questionnaires. The set of these instruments helps the professional in tracking, monitoring, and diagnosing BED (American Psychiatric Association 2013).

A clinical interview is considered the gold standard for the diagnosis of BED. The lines of treatment include different types of therapy, such as cognitive behavioral (CBT), dialectical, and interpersonal behavior, in addition to the possibility of associating the use of drugs when necessary. The clinical interview is the essential element of the doctor-patient meeting and aims to identify/treat the disorder, get to know the individual, and establish a relationship of trust, respect, complicity, and bond with them and their family. However, this follow-up requires time, privacy, and, above all, patient compliance. If this does not occur, the success of the treatment will be compromised.

The self-monitoring instrument consists of diaries or food records completed by the patient and aims to describe in detail what was consumed; the time and place of meals; the feelings associated with these moments, such as guilt or anger; and compensatory behaviors associated with food. The advantage of food diaries is the fact that records are made at the time of consumption, so do not depend on the patient's memory. This instrument also identifies the types of foods and preparations consumed, measures current consumption, and provides less error when there is detailed guidance for completing the diary. As disadvantages, it is observed that the patient may not perform the recording correctly because they know they are being evaluated or because they are not motivated and committed to the treatment. In addition, it may be difficult to estimate quantities and servings as this requires time and knowledge of household food measurements (Fisberg et al. 2009).

Self-administered questionnaires used in clinical practice serve only as a screening tool for the diagnosis of BED. We can cite the self-administered EDE-Q questionnaire (self-administered version of the EDE interview), the Binge Eating Scale (BES), the Questionnaire on Eating and Weight Patterns-5 (QEWP-5), and the self-administered questionnaire in the bariatric surgery version (EDE – BSV).

The EDE-Q is a tool used to help diagnose EDs in general. It addresses several dietary and self-image issues, such as objective BE, subjective BE, and LOCE, and is applied through questionnaires and self-report criteria. This tool is composed of a global score of psychopathology of EDs, totaling 41 items, and its result is presented through four subscales: food restriction and concern with food, weight, and body shape (Taba et al. 2021).

The BES aims to assess behavioral, emotional, and cognitive parameters of individuals with obesity and is also validated for application in bariatric patients (Nasirzadeh et al. 2018). It consists of 16 items, each of which has three to four statements, totaling 62 statements. Each statement is worth from zero to three points, from the absence ("0") to the maximum severity ("3") of BE symptoms. The final score is the result of the sum of the points for each item. The result is divided into severe BE (score $\geq$ 27), moderate BE (score between 18 and 26), and no BE (score $\leq$ 17) (Freitas et al. 2001; Ribeiro et al. 2016; Järvholm et al. 2020).

The QEWP-5 is composed of 28 questions related to BE episodes, indicators of loss of dietary control, compensatory weight management methods, weight and diet history, degree of concern about weight and body, and basic demographics. The QEWP-5 was specifically developed to provide a diagnosis of BED according to the criteria of the DSM-IV, having been subsequently revised to fully meet the proposals established in the manual and named the QEWP-R. The questionnaire can be administered in an interview format, where it is read to the patient. It is indicated for screening BED in the general population and for distinguishing purgative BN from non-purgative BN. It can also be applied to patient samples; however, the diagnosis of BED as stated above must be confirmed by a clinical interview (De Moraes et al. 2020, 2021).

The EDE-BSV, in turn, was adapted and modified for bariatric surgery. It is a semi-structured clinical interview that has been adapted for bariatric patients and designed to assess the extent and severity of ED psychopathology, including LOCE, during the past 28 days. LOCE eating episodes are defined as the number of episodes with a feeling of loss of control that occurred during the previous month. The EDE-BSV captures four categories (or "subscales") of the EDE-Q, including dietary restriction, dissatisfaction with shape and body weight, and overvaluation of shape and body weight. These categories, however, were adapted in some ways in order to meet the specifications of the bariatric population. First, the items that made up the original restriction category, which is related to pathological behavior, were also extended to a new and revised restriction category in order to avoid the physical discomfort that can occur in patients undergoing BMS. Second, items relating to compensatory behaviors (such as vomiting, use of laxatives, and diuretics), which were labeled "purging," were also included as a category. Additionally, these items were classified into purging to prevent weight gain and purging to avoid physical discomfort. These items and categories were added because the motivation to avoid or alleviate physical discomfort after bariatric surgery could elucidate the endorsement of restrictive and compensatory behaviors (Globus et al. 2021; Lawson et al. 2020).

The relevance of using these questionnaires in preoperative patients requires in-depth observation, since in the postoperative stage the amount of food ingested is subjective. The limited gastric capacity imposed by the surgery masks the behavioral parameter and can compromise the answers to the questionnaires. Therefore, the assessment should be focused on loss of control, that is, on the sentimental and cognitive side of the compulsion, which will enable better identification of patients with BE in the postoperative period (Colquitt et al. 2014).

We cannot fail to consider that self-administered questionnaires, despite working as a screening method, also have some limitations. The data are self-reported which may, perhaps, alter/compromise the results obtained. It is also suggested that bariatric patients receive nutritional guidance before the time of surgery. Most patients go through a dietary re-education process aiming to achieve a more adequate diet, already expecting good results after the bariatric surgery. It is therefore necessary to raise the hypothesis that these patients may have been influenced beforehand when they received guidance on healthy eating habits, inducing them to opt for the "best answer" without actually leading to an internal change.

Psychological Aspects: Behavioral and Dietary Reorganization

The presentation of "traditional" BED with objectively large amounts of food is uncommon in the postoperative period due to the physical changes after bariatric surgery. However, loss of control while eating, regardless of size, occurs and is associated with psychological impairment, including greater psychopathology of the ED in the postoperative period. Preliminary findings suggest that adults with LOCE who present for treatment after bariatric surgery and who meet all criteria for BED except the ingesting an excessive amount of food criterion have a presentation similar to adults with "traditional" BED (with the size requirement) (Goldschmidt 2017; Gradaschi et al. 2019).

Secretive eating, which is characterized by the hidden consumption of food, occurs among adults with BED. This behavior is considered one of the indicators for LOCE, which in turn determines BE or BED. However, the frequency and clinical characteristics of this secretive eating among post-bariatric patients who experience LOCE ingestion remain unknown (Lydecker et al. 2019).

The treatment for BED, as well as for EDs in general, is influenced by its etiological history, consisting of a complex interaction between hereditary, psychological, and environmental factors, and should be taken into account in treatment planning (Brambilla et al. 2009).

Treatment options must be multidisciplinary and appropriate to deal with symptoms and comorbidities. One should also consider the high rates of treatment dropout and the low maintenance of the results achieved, which are typical of this disease (Ivezaj et al. 2017b).

The main objective of treatment with BED is to achieve abstinence from BE episodes. Weight loss will be a consequence and not the focus of the treatment. The increase and maintenance of motivation, education for a healthier diet and lifestyle, modification of dysfunctional thoughts and habits, the increase in insights and skills to deal with conflicts and negative emotions, the treatment of physical and psychiatric comorbidities, good relationship with food and the body, and relapse prevention should be considered as the main points.

It is essential to identify patients at risk of postoperative LOCE and to monitor their eating behaviors and the progress of weight loss. Patients identified with LOCE and psychological comorbidities can then benefit from a targeted intervention to

address both situations. However, these patients may need additional support to remain involved in treatment because there is evidence that patients with BED and LOCE may be less compliant with postoperative dietary recommendations and are less likely to attend postoperative appointments (Brode and Mitchell 2019; Andrea and Ana 2020).

Clinical interventions that make simultaneous use of CBT and medications for emotional and psychiatric problems were also linked to a lower probability of LOCE, helping to reduce the negative effects of EDs (Smith et al. 2019).

Monitoring food intake may be particularly relevant for self-regulation in this population and may help to prevent LOCE, as eating smaller portions more often is recommended after bariatric surgery. Eating more frequent meals and snacks can be a good indicator of better adherence to postsurgical guidelines and perhaps another marker of self-regulatory capacity.

It should also be considered that during meals some patients may have certain feelings, such as guilt or fear. In these cases, the act of eating should be practiced without judgment. Attention should be focused only on what food does to the body. When we judge what we are eating and the amount of it, more food will be needed to satisfy our cravings, which can result in overconsumption. Therefore, it is essential to work on the importance of eating for pleasure and with full attention, demystifying the beliefs that there are permitted or prohibited foods, healthy or unhealthy (Warren et al. 2017).

The practice of mindful eating reduces episodes of BE as it acts on impulsivity. Impulsiveness leads to greater food consumption and loss of control over feelings of hunger and satiety (Schag et al. 2016). Thus, it is important to ensure that the patient eats at regular times and avoids prolonged fasting. There are practices that reduce impulsiveness and that should be used to facilitate patient adherence to treatment, such as eating in quiet places; preparing the table for meals; avoiding stimuli such as TV, cell phones, and other media devices; breathing deeply before starting any meal; paying attention to the taste, odor, and appearance of the food; enjoying every moment of the meal; and using the cutlery every time you take the food to your mouth.

As postoperative eating behaviors are associated with weight loss and/or recovery, attention should be focused on the follow-up period. Considering the prospective value of eating in BE, BED, and LOCE, preventive or early detection attitudes seem to be sensitive strategies to help prevent worse outcomes.

Thus, given the stigma of bariatric surgery, along with the strict dietary guidelines recommended in the postoperative period, examining the secretive eating of individuals seeking treatment for EDs after bariatric surgery represents an opportunity to better understand the psychopathology of the ED.

The field of metabolic and bariatric surgery continues to evolve, and it is increasingly important to continuously develop research and studies aimed at understanding which characteristics and behaviors associated with outcomes are similar, both unsuccessful and successful, with a view to the high diversity and complexity of behaviors and the triggers that each patient presents.

Future studies on these issues may shed additional light on important procedures in preoperative assessments, such as the value of psychological assessment and

weight control. These studies also have great potential to improve patient selection, refine preoperative education and intervention algorithms, and develop action strategies to help patients who do not have an optimal outcome after the initial procedure.

Mini-Dictionary of Terms

- Bariatric surgery is becoming widely recognized and has become the most effective treatment for controlling severe obesity.
- However, a proportion of patients may not achieve the expected weight loss or may experience significant weight regain over the next decade.
- BED negatively influences long-term weight loss.
- How patients can develop new problematic eating behaviors related to binge eating (BE), even faced with the difficulty of eating large amounts of food.
- The occurrence of binge eating is not considered a contraindication for the performance of bariatric surgery.
- There are three basic procedures in BMS, which can be didactically divided and classified as restrictive procedures, malabsorptive procedures, or mixed procedures.
- BE is characterized by the objective consumption of large amounts of food over a period of up to 2 h and accompanied by the subjective feeling of loss of control over the type of food ingested, as well as its quantity.
- A substantial proportion of patients report postoperative LOCE and BED, despite the fact that both initially decrease soon after surgery.
- A clinical interview is considered the gold standard for the diagnosis of BED.
- Treatment options must be multidisciplinary and appropriate to deal with symptoms and comorbidities.
- Monitoring food intake may be particularly relevant for self-regulation in this population and may help to prevent LOCE, as eating smaller portions more often is recommended after bariatric surgery.
- The field of metabolic and bariatric surgery continues to evolve, and it is increasingly important to continuously develop research and studies aimed at understanding which characteristics and behaviors associated with outcomes are similar, both unsuccessful and successful, with a view to the high diversity and complexity of behaviors and the triggers that each patient presents.

Key Facts

- The benefits of bariatric surgery are significant for patients with severe obesity.
- It is widely accepted that bariatric surgery patients require lifetime follow-up to assess for weight loss, comorbidity changes, and nutritional deficiencies.
- The best established and most successful method for durable weight loss.
- Bariatric surgery has significant impact on many of the complications associated with obesity.
- Lifelong follow-up of patients is helpful to prevent weight regain and ensure they are meeting their goals.

Summary Points

- Bariatric surgery is becoming widely recognized and has become the most effective treatment for controlling severe obesity.
- BED negatively influences long-term weight loss.
- Even faced with the difficulty of eating large amounts of food, patients can develop new problematic eating behaviors related to binge eating.
- The identification of binge eating is reinforced whenever the manifestation of suffering marked by compulsive attitudes toward eating is observed in the individual.
- BED has an impulsive characteristic.
- Successful weight loss has been associated with self-monitoring of weight-related behavior, which could be indicative of self-regulatory capacity.
- Binge eating and excessive food intake are two prevalent obesity-related characteristics that contribute to excessive calorie intake and weight gain.
- Treatment options must be multidisciplinary and appropriate to deal with symptoms and comorbidities.

Abstract

Acute and chronic sleep deprivation have detrimental effect on physical and mental health and may affect eating behavior. Empirical findings demonstrated that sleep deprivation increases food intake and alters eating behavior through different potential pathways. These underlying mechanisms may be biological, cognitive, neural, emotional, and behavioral. Furthermore, cross-sectional evidence documented an association between sleep deprivation and disordered eating and binge eating. Similarly, some studies linked poor sleep due other comorbidities with binge eating. Additional novel experimental studies also

support the link between sleep deprivation and binge eating. Despite these summarized findings, still little evidence is available to establish firm conclusions about the directionality of this link, and the need to further research is predominant.

Keywords

Poor sleep · Sleep deprivation · Eating behavior · Binge eating · Disordered eating · Sleep · Underlying mechanism · Eating disorder · Binge eating disorder · Chronic sleep deprivation · Acute sleep deprivation · Food intake

Abbreviations

BED	Binge eating disorder
BMI	Body mass index
ED	Eating disorder
IFG	Right inferior frontal gyrus
NES	Night eating syndrome
OSAs	Obstructive sleep apnea syndrome
vMPFC	Ventral medial prefrontal cortex

Introduction

In the last years, the interest in the link between sleep and eating behavior has grown exponentially, thus leading researchers to increase the production of studies and evidence supporting this association. A quick search on the main scientific databases (e.g., PubMed), inserting the keywords eating disorders OR eating behavior AND sleep, found 96 results between 2000 and 2010. From 2010 to 2020, the number of studies has tripled to 339. This number increases more when we insert the keyword "obesity" (i.e., 8431 results from 2000 to 2020). Indeed, the relationship between sleep and obesity has been largely investigated since an increase in obesity and a parallel decrease of sleep duration have been registered worldwide (World Health Organization 2021; Ford et al. 2015).

Despite the increased interest in these topics, few studies directly examined the link between poor sleep quantity or quality and eating disorders, especially binge eating disorder (BED). In part, evidence may be extrapolated from the cross-sectional and longitudinal studies linking poor sleep quantity or quality with eating disorders (e.g., Allison et al. 2016; Harvey et al. 2011) or obesity (e.g., Bacaro et al. 2020). Other evidence can be derived from the experimental studies testing the effect of sleep deprivation on eating behavior and food intake (e.g., Al Khatib et al. 2017). Similarly, other empirical evidence comes from studies examining the effect of poor sleep quantity or quality on emotion regulation and executive functions (e.g., Vriend et al. 2013; Ballesio et al. 2018, 2019; Cerolini et al. 2020), which are involved in

self-regulation of eating behavior (e.g., Ruscitti et al. 2016; Dohle et al. 2018). Consistently, different potential pathways underlying the relationship between poor sleep and changes in eating behavior have been hypothesized (e.g., biological, cognitive, emotional, and behavioral; Lundahl and Nelson 2015).

Considering this framework, the chapter aims to review the literature presenting possible indirect and direct evidence supporting the link between chronic and acute sleep deprivation and disordered eating behavior, especially binge eating. The potential pathways underlying this link will be analyzed and discussed.

The Detrimental Effects of Sleep Deprivation

Sleep deprivation can be defined as the condition of not having enough sleep, and it can be either chronic or acute. Chronic sleep deprivation may consist of persistent poor sleep quantity and/or quality. Inversely, acute sleep deprivation may be defined as not having adequate duration and/or quality of sleep for a short period of time, usually 1 or 2 days. The overall detrimental long-term effect of chronic sleep deprivation is clear enough: shortened sleep duration has been associated with increased risk of all-cause mortality (Liu et al. 2017). Similarly, poor sleep quantity and quality (i.e., chronic insomnia) have been associated with mortality risk (Parthasarathy et al. 2015). Negative long-term effects of chronic sleep deprivation resulted in an increased risk of many physical (i.e., cardiovascular diseases, Sofi et al. 2014) and mental diseases (i.e., depression, Baglioni et al. 2011). Meta-analytic evaluations of longitudinal data agreed in demonstrating the role of short sleep duration in increasing the risk of obesity among adults (Bacaro et al. 2020) and children (Fatima et al. 2015).

In parallel, the short-term effects of experimentally induced sleep deprivation (i.e., acute sleep deprivation) have been demonstrated by many studies, causing an increase in food intake (Al Khatib et al. 2017; Capers et al. 2015) and impairments in cognitive (e.g., de De Bruin et al. 2017; Lim and Dinges 2010) and emotional functioning (Killgore et al. 2008, 2017). Biological and neural changes implicated in increased dietary intake or altered eating behavior have also been reported in results of acute sleep deprivation (e.g., Van Cauter et al. 2008; Demos et al. 2017).

Association Between Sleep Deprivation and Increased Food Intake and Impaired Dietary Behavior: Underlying Mechanisms

The link between chronic and acute sleep deprivation and food intake seems quite complex. Hence, several underlying mechanisms may regulate this relationship. Different authors (e.g., Lundahl and Nelson 2015; Knutson et al. 2007) suggested that biological, cognitive, emotional, and behavioral factors may function as mediators or moderators of this relationship.

Biological Pathway

The potential underlying biological mechanism can be illustrated through the studies evaluating the association between sleep, circadian rhythmicity, hormones, and metabolism. Particularly, the levels of several hormones fluctuate according to the light and dark cycle, and their regulation is influenced by interactions between the effects of sleep and the circadian rhythms (Kim et al. 2015). Studies examining the impact of sleep disturbance and circadian disruption on hormonal and metabolic function are useful to understand if hormonal or metabolic imbalances may occur when the sleep cycle and intrinsic timing system are unsynchronized (Kim et al. 2015). The first evidence supporting the biological mechanism is the seminal studies of Spiegel et al. (2004) examining the effect of acute sleep deprivation on appetitive hormone disruption. They found a reduction in leptin level (i.e., the hormone that sends satiating signals to the appetite control centers in the hypothalamic region of the brain; Ahima et al. 2000) and an increase in ghrelin level (i.e., the hormone that sends signals from the stomach to the brain that triggers an increase in appetite; Van Der Lely et al. 2004). Later evidence supported this first finding in children (Hart et al. 2013) and adults (Chaput et al. 2007; Taheri et al. 2004). In 2007, in the article entitled "The metabolic consequences of sleep deprivation," Kristen Knutson argued that the relationship between sleep deprivation, weight gain, and increased risk of diabetes involves alterations in glucose metabolism, upregulation of appetite, and decreased energy expenditure. Overall, acute sleep deprivation has been demonstrated to have detrimental effects on appetite regulation, carbohydrate metabolism, and endocrine function (Van Cauter et al. 2008), as synthetized in Fig. 1.

Cognitive and Neural Pathways

Secondly, cognitive and neural mechanisms can underlie the association between sleep deprivation and eating behavior (as showed in Fig. 2). Executive functions can

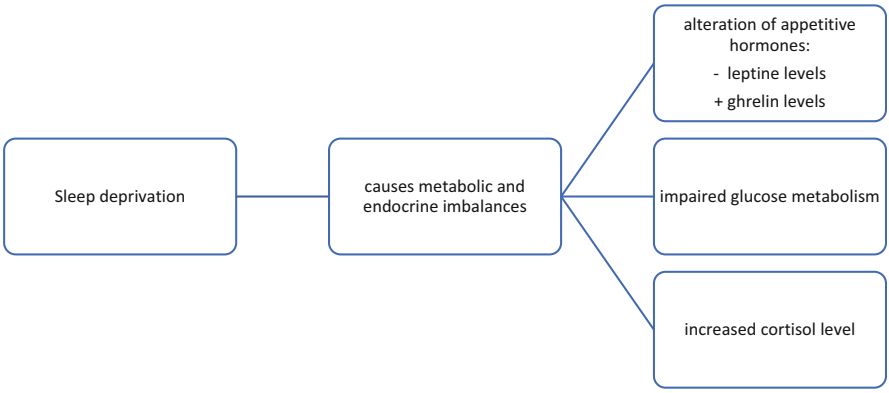

Fig. 1 Potential biological mechanisms implicated in the relationship between sleep deprivation and altered eating behavior

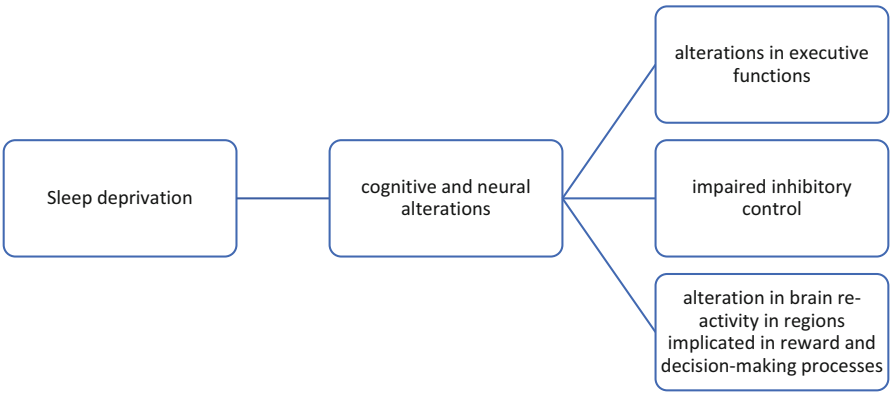

Fig. 2 Potential cognitive and neural mechanism underlying the relationship between sleep deprivation and altered eating behavior

be defined as cognitive processes involved in the control of basic psychological processes such as attention, memory, and emotion (Miyake et al. 2000) and include inhibitory capacities and switching attention processes (Diamond 2013). Impairments in executive functions, such as depletion of inhibitory abilities, have been measured after sleep deprivation (Couyoumdjian et al. 2010; Gorgoni et al. 2014). Poor executive control has been associated with higher caloric consumption and greater consumption of snacks and high-fat food (Rollins et al. 2010; Hall 2012). However, the directionality of the link between executive functions and eating self-regulation is still unclear (Egbert et al. 2019). Cedernaes et al. (2014) found that total sleep deprivation impaired cognitive control in response to food stimuli in healthy young men, increasing the impulsivity in response to food cues. Consistently, other authors found that sleep deprivation and sleepiness may impair executive and cognitive functioning, such as inhibitory control over food intake, motivation, and mood (Burke et al. 2015; Killgore et al. 2013). Also, neuroimaging evidence (Demos et al. 2017) indicates that sleep deprivation increases the reactivity to food stimuli in regions of reward processing (i.e., nucleus accumbens/putamen) and sensory/motor signaling (i.e., right paracentral lobule). These authors found that the whole brain showed greater food cue-responsivity after sleep deprivation in an inhibitory control region as the right inferior frontal gyrus (IFG) and the ventral medial prefrontal cortex (vMPFC), which has been implicated in reward coding and decision-making.

Similarly, Katsunuma et al. (2017) argued that unrecognized sleep loss (i.e., sleep debt accumulated in daily life) could promote brain hyper-reactivity to food cues compared to optimal sleep conditions. Consistently with these results, Benedict et al. (2012) found that acute sleep deprivation enhances the brain's response to hedonic food stimuli in normal-weight men (i.e., increased activation of the right anterior cingulate cortex in response to food images). Contrarily, some studies reported the opposite pattern of results, demonstrating that youths' poor sleep was associated with decreased brain reactivity to reward (Hasler et al. 2012; Holm et al. 2009). Lundahl and Nelson (2015) claimed that this effect of disrupted sleep pattern on

reward processing (increasing or decreasing reward sensitivity) might negatively affect eating behavior, resulting in greater reward-seeking behaviors given the high reinforcing value of the reward, or alternatively, leading to a compensatory increase in reward-seeking behavior. In fact, the positive association between reward sensitivity and food craving, overeating, and BMI has been previously reported (Davis et al. 2004, 2007; Franken and Muris 2005; Stice and Yokum 2016). Furthermore, a study including a sample of children by Nederkoorn et al. (2006) found that sensitivity to reward was greatest in children who engaged in binge eating compared to healthy controls.

Emotional and Behavioral Pathways

Lastly, emotional and behavioral mechanisms can underlie the relationship between sleep deprivation and eating behavior. The negative effects of acute and chronic sleep deprivation on emotional functioning are well documented, leading to increased negative emotions, emotional reactivity, and poorer emotion regulation skills (Killgore et al. 2008, 2017; Baglioni et al. 2010). A complex interplay has been suggested between sleep and emotion regulation, namely, sleep influencing emotion regulation and vice versa, through a bidirectional link (Cerolini et al. 2015; Fairholme and Manber 2015; Kahn et al. 2013). Daily emotions may affect sleep and sleep may affect emotions during the following day in a vicious cycle (Cerolini et al. 2016; Simor et al. 2015; Takano et al. 2014). This impairment in emotional functioning or sleep quantity or quality may, in turn, lead to an alteration of dietary behavior. Hence, the lack of emotion regulation is a key element of disordered eating behavior such as emotional eating and binge eating (Kukk and Akkermann 2017; Ruscitti et al. 2016; Cerolini et al. 2018). The use of dysfunctional strategies for regulating emotions is associated with increased food intake, especially comfort foods (Evers et al. 2010). More, the experimental induction of negative affect has been shown to cause greater food intake in laboratory settings, particularly among individuals with high levels of self-reported emotional eating (Wallis and Hetherington 2004). Likewise, negative affect has been identified as one of the main triggers precipitating binge eating (Leehr et al. 2015).

In parallel, chronic sleep deprivation and sleep disturbances have been associated with binge eating (Trace et al. 2012). Experimentally induced negative affect has been associated with increased food intake among women with high levels of emotional eating and reporting sleep deprivation (Dweck et al. 2014).

Taken together, all these findings indirectly support the hypothesis that sleep deprivation may increase food intake and trigger overeating through an emotional pathway.

Behavioral factors are also relevant in the association between sleep deprivation and increased eating behavior or binge eating. For example, a systematic review of the literature by Felső et al. (2017) found that sedentarism and unhealthy dietary patterns could be considered a mediator of the relationship between short sleep and childhood obesity. More, a reduction in energy expenditure after sleep deprivation

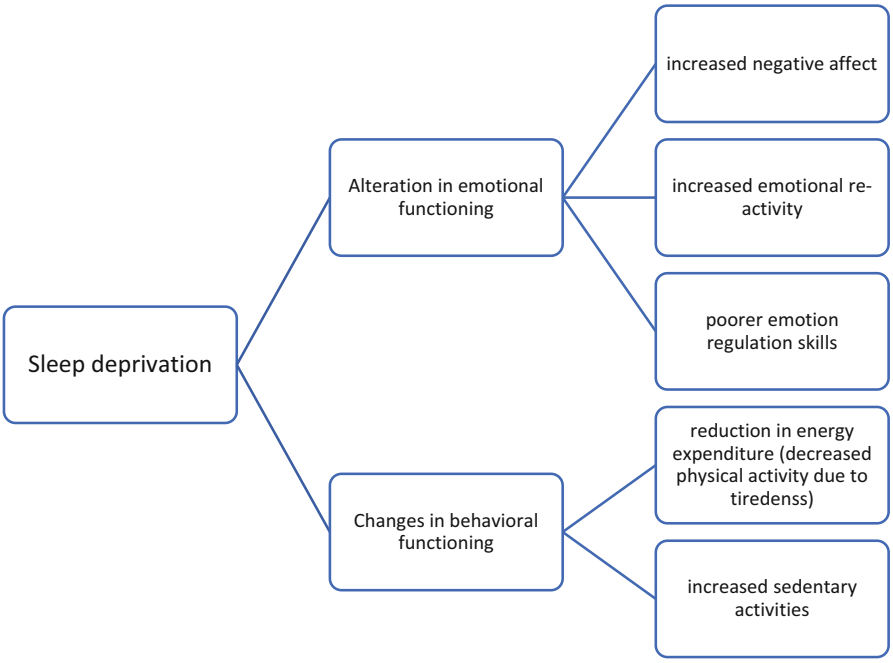

Fig. 3 Potential emotional and behavioral mechanisms underlying the relationship between sleep deprivation and altered eating behavior

could result from decreased physical activity due to tiredness (Dinges et al. 1997; Patel et al. 2006). This may lead to frequently engaging in modern sedentary activities (e.g., television viewing, video game playing, cognitive working, music listening), which promote overconsumption of food in our current obesogenic environment (Chaput et al. 2011) and binge eating (Burmeister and Carels 2014). Also, a recent study by Zhu et al. (2020), using a daily diary approach for seven consecutive days, found that between-person fatigue and poor sleep quality were predictors of uncontrolled eating, emotional eating, and snacking. Figure 3 synthetically shows the above explained mechanisms.

In conclusion, disordered eating behavior and binge eating can be associated with a previous condition of chronic sleep deprivation. Still, it can also be triggered by acute sleep deprivation through different mechanisms, such as biological, cognitive, neural, emotional, and behavioral (please see Fig. 4).

Sleep Deprivation and Binge Eating: Still Little Evidence

Despite the growing interest in the relationship between sleep deprivation and eating behavior, few studies still directly examined the link between sleep deprivation and binge eating. The larger body of studies in support of this link is that one including

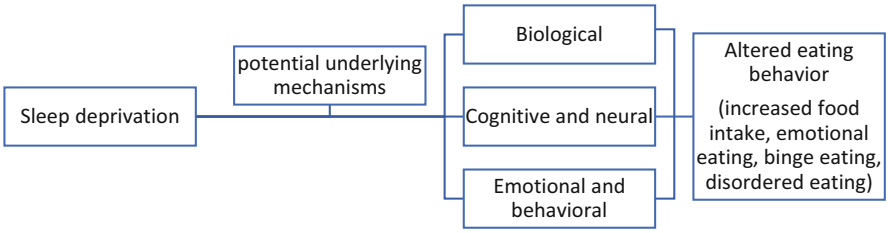

Fig. 4 Potential mechanisms underlying the relationship between sleep deprivation and altered eating behavior

the cross-sectional association between chronic sleep deprivation (e.g., insomnia) and eating disorders, including BED, bulimia nervosa, or subthreshold binge eating symptomatology (which will be briefly discussed in this section, but it will be deeply documented in ▶ Chap. 9, "Insomnia in Eating Disorders"). Other evidence derives from the studies linking binge eating and night eating syndrome, which may result in disrupted sleep patterns and poor sleep quantity and quality (similarly, also, in this case, some points will be mentioned, but the topic is deepened by the two chapters dedicated to night (nocturnal) eating syndrome). In addition, very few novel experimental studies directly investigated the impact of acute sleep deprivation on eating-related behavior in participants with binge eating symptomatology.

Chronic Sleep Deprivation and Binge Eating

Poor sleep quality and poor sleep quantity are highly prevalent among patients diagnosed with an eating disorder (ED, e.g., 50.3% reported by Kim et al. 2010), and chronic sleep deprivation may exacerbate the severity of ED symptoms (Kim et al. 2010; Lombardo et al. 2015). The relationship between poor sleep and ED symptomatology can be mediated by depression (Lombardo et al. 2015), which is known to be comorbid with both (e.g., Baglioni et al. 2011; Slane et al. 2010). A prospective study by Lombardo et al. (2015) including 271 ED patients found that:

1. Poor sleep at admission predicted worse ED symptomatology through the mediation of depression
2. Six-month chronic sleep deprivation predicted the severity of ED symptoms both directly and through the mediation of depression
3. Chronic sleep deprivation predicted worse clinical conditions after 6 months of treatment

Overall, the literature linking poor sleep (i.e., insomnia) and ED pathology is still understudied. Innovative research is necessary to understand this potential bidirectional association deeply and to identify the risks posed by dysregulated sleep on ED treatment outcomes and relapse rates (Christensen and Short 2021).

Focusing on binge eating symptomatology, some studies reported the presence of poor sleep quantity and quality (i.e., difficulties in the sleep onset latency; Vardar et al. 2004) in obese BED patients seeking treatment. Relatedly, a study by Trace et al. (2012), including 3790 women aged 20–47 years, documented the presence of current poor sleep quantity and quality and lifetime binge eating in 6.4% of the total sample, after controlling for obesity. The authors found that binge eating symptomatology was associated with self-reported poor sleep and sleep problems such as difficulties falling asleep, sleepiness during the daytime, and disturbed sleep. Additionally, a study by Quick and co-workers (2016) reported a cross-sectional association between poor sleep quantity and binge eating among 1252 US college students. These authors found that individuals sleeping less than 8 h per night had significantly more negative eating attitudes, poorer internal eating behavior regulation, and greater binge eating, compared to those sleeping for a longer duration, even after controlling for potential confounding variables. Additional evidence, including obese and normal-weight children with and without binge eating and objectively measured sleep, found that obese children with binge eating slept significantly worse than the other two groups (Tzischinsky et al. 2000). Furthermore, sleep disturbances such as obstructive sleep apnea syndrome (OSAs), which is known to be accompanied by chronic sleep deprivation (Cho et al. 2018) and obesity (Kuvat et al. 2020), has been found to be associated with binge eating and BED in a sample of 1099 obese patients candidate for bariatric surgery (Sockalingam et al. 2017).

These findings indirectly support the association between chronic sleep deprivation and binge eating. However, cross-sectional findings do not establish the directionality of this link, which remains an open debate.

Poor Sleep Quantity and Quality in Night Eating Syndrome Are Associated with Binge Eating

Overall, empirical evidence supported the association between poor sleep quantity and quality and night eating syndrome (NES, Lombardo and Cerolini 2022). In parallel, NES has been found to be often associated with eating disorders, especially BED. A study by McCuen-Wurst and co-workers (2018) documented that around 15–20% of patients with NES presented comorbid BED. Also, another study (Tu et al. 2019) found that NES was present in different subgroups of patients diagnosed with EDs. Specifically, NES was identified in 10.3% of patients with anorexia nervosa, 34.9% of patients with bulimia nervosa, and 51.7% of patients with BED. These authors reported that some clinical features might overlap among groups (i.e., depression, sleep quality, sleep medications use, and daytime dysfunction). However, other specific clinical features may clearly distinguish between diagnostic categories discussed elsewhere (i.e., see Lombardo and Cerolini 2022).

Considering the studies linking sleep deprivation and binge eating and the studies linking NES and binge eating is not clear yet if chronic sleep deprivation triggers binge eating behavior, or inversely, urge to binge eating and binge eating behavior impairs sleep, thus leading to chronic sleep deprivation.

Novel Empirical Evidence Exploring Both Sleep Deprivation and Binge Eating

Overall, very few studies have considered sleep deprivation and binge eating-related behaviors. As mentioned before, the link is mostly supported by studies investigating the cross-sectional association between chronic sleep deprivation and binge eating. Nevertheless, few experimental evidence analyzing the effect of acute sleep deprivation on binge eating behavior, or including sleep-deprived individuals with binge eating, are available. Preliminary results of studies addressing these points will be described below.

Particularly, a first quasi-experimental study by our research group at Sapienza University of Rome (Cerolini et al. 2018) evaluated the effect of acute sleep deprivation on food intake in participants reporting binge eating symptoms and depressive emotional eating. The procedure consisted of two lab sessions: one after a night of partial sleep deprivation (5 h of sleep allowed) and one after a habitual night of sleep. Two groups of participants took part in the study: one group of individuals reporting binge eating and one control group of participants denying any eating symptomatology. All participants slept at their homes and went the subsequent morning to the lab. A large breakfast buffet was served during both lab meetings, and researchers unobtrusively measured food intake. This novel preliminary study yielded inconsistent results: a single night of partial sleep deprivation increased the number of snacks and decreased the amount of fiber consumed during the day independently from binge eating symptomatology. The authors found an increase in daily food intake in people who habitually do not binge and do not eat in response to negative emotions, while individuals reporting this symptomatology seemed to be not affected by partial sleep deprivation in increasing food intake. Moreover, participants with depressive emotional eating consumed overall fewer Kcal and carbohydrates during breakfast and from snacks during the day, compared to individuals with low emotional eating. These findings may be explained in different ways: (a) since the binge eating group reported poorer sleep (i.e., more severe insomnia symptoms), the partial sleep deprivation induction (5 h) may have been insufficient to produce the expected results; (b) this group may skip breakfast more often than controls; (c) the procedure may have triggered restrictive and dieting goals, and social desirability may have intervened, especially in participants with eating symptomatology.

Additional findings are derived from a study using the same procedure but including participants with chronic sleep deprivation (i.e., chronic insomnia) and good sleepers (Lombardo et al. 2020), thus providing first evidence on the effect of chronic and acute sleep deprivation on eating behavior. Results revealed that only good sleepers increased food intake at breakfast at an increasing body mass index (BMI) level after sleep deprivation. At the same time, no effect was found on the amount of food consumed during the day. Moreover, participants with chronic insomnia consumed less food after both nights than good sleepers. Also, in this case, the potential explanations may be different. One of them may concern eating habits: this group may skip breakfast more often than good sleepers; therefore, daily

habits should be considered. Likewise, in the long run, people with insomnia may be less vulnerable to the effects of acute sleep deprivation on food intake. This suggests the need for studies especially addressing the long-term effects of sleep deprivation both with longitudinal and experimental designs. This study has the merit of being the first employing partial sleep deprivation in an ecologically translatable setting, as the free-living condition, and a food intake assessment in a laboratory setting, taking also into account chronic sleep deprivation.

Lastly, a similar procedure has been used in another study (Cerolini et al. 2020) evaluating the effect of partial sleep deprivation on executive functions, which, as explained before in this chapter, are involved in the self-regulation of eating behavior (e.g., Dohle et al. 2018). This study is the first to explore the impact of sleep deprivation on executive functions in participants reporting binge eating and healthy controls. The only exception is the study by Cedernaes et al. (2014), in which authors tested the effect of total sleep deprivation in healthy young men, registering an impairment in inhibitory control in response to food stimuli. In our study, instead, we found that partial sleep deprivation decreased inhibitory control in the binge eating group, thus preliminary supporting one of the potential cognitive mechanisms underlying the relationship between sleep deprivation and binge eating behavior. At the same time, we also measured more overall inhibitory control in the binge eating group compared to the healthy controls after the habitual night. This may suggest that usually, people reporting binge eating symptomatology show higher inhibitory control. Still, when sleep-deprived or triggered by emotional stimuli, they may decrease this cognitive control, thus leading to disinhibition and binge eating. Moreover, we did not find any effect of the sleep deprivation or the impact of the group on attentional switching, a measure of cognitive flexibility, though this result is in line with previous studies (Kittel et al. 2017; Manasse et al. 2015; Wardle-Pinkston et al. 2019). This preliminary study demonstrates that sleep deprivation may affect inhibitory control in participants reporting binge eating, highlighting their potential mediating role in influencing eating behavior.

In summary, the heterogeneity of these preliminary results does not allow to establish a firm conclusion about the effect of sleep deprivation on eating behavior. Future studies replicating and extending the procedure and taking into account different variables are needed to clarify these effects. Moreover, to better understand the directionality of this relationship, studies exploring the impact of sleep deprivation on eating behavior, specifically focusing on binge eating behavior, and, at the same time, investigating the role of eating behavior (i.e., binge eating) in affecting sleep, are warranted. Different population groups should be evaluated within this aim, including patients with other ED diagnoses or individuals with different BMI or eating habits.

Conclusions

This chapter aimed to review the literature's heterogeneity considering sleep deprivation and eating behavior, especially binge eating. Few studies directly examined this link, except for some cross-sectional studies, which do not allow to determine a

causal and, therefore, temporal relationship. The broader body of evidence is derived from experimental studies evaluating the effect of sleep deprivation on eating-related behaviors. However, studies assessing the impact of sleep deprivation on eating behavior in the clinical population with ED are still lacking. This is a big gap in the research literature since the role of poor sleep and disrupted sleep patterns in exacerbating ED symptomatology, predicting worse treatment response, and increased relapse rates and hindering recovery has been pointed out (Christensen and Short 2021; Lombardo et al. 2015). Moreover, to the best of my knowledge, until now, no studies have yet explored the potential bidirectionality of the link between sleep deprivation and eating behavior, especially binge eating, which would be a topic of great interest for both sleep and ED researchers and clinicians. If demonstrated, this bidirectionality should be taken into account both at the time of evaluation, diagnosis, and during the treatment process, since sleep and eating behavior may continuously interact. Clinicians should know and take into account the effect of chronic and acute sleep deprivation on eating behavior, and vice versa the effect of disordered eating, especially binge eating, on sleep patterns. Ideally, this may lead to an integration of the assessment, diagnostic, and treatment process in which sleep and eating behaviors are equally considered. This may include cognitive behavioral therapy programs for insomnia, the promotion of good sleep hygiene, and psycho-educational interventions in patients with EDs about the effects of sleep deprivation on dietary behavior, and also, about how changes in eating behavior may affect sleep.

Applications to Other Eating Disorders

In this chapter, studies examining the association between sleep deprivation and eating behavior have been reviewed. Particularly, the main focus has been the link between chronic and acute sleep deprivation and disordered eating, especially binge eating. Potential underlying mechanisms of this relationship have been hypothesized, presenting the literature in support of each pathway. Despite the lack of experimental and longitudinal studies directly supporting this association, the broader body of literature analyzed in this chapter provides indirect aid to this link. This includes studies linking chronic or acute sleep deprivation in patients with different eating disorders, not only presenting binge eating. Hence, understanding the association between poor sleep and eating behavior/disordered eating may be of strong interest for clinicians and researchers involved in the field of eating disorders. In fact, sleep and eating behavior are two fundamental processes which may bidirectionally interact. This can mean that they can influence each other both negatively and positively, and therefore they should be taken into account both at the time of evaluation, at diagnosis, and during the treatment process. Clinicians should know and take into account the effect of chronic and acute sleep deprivation on eating behavior, and vice versa the effect of disordered eating, especially binge eating, on sleep patterns. Ideally, this may lead to an integration of the assessment, diagnostic, and treatment process in which sleep and eating behaviors are equally

present. This may include cognitive behavioral therapy programs for insomnia, the promotion of good sleep hygiene, and psycho-educational interventions in patients with eating disorders about the effects of sleep deprivation on dietary behavior, and vice versa, how changes in eating behavior may affect sleep.

Mini-Dictionary of Terms

- **Acute sleep deprivation**. The condition of not having adequate duration and/or quality of sleep for a short period of time, usually 1 or 2 days.
- **Chronic sleep deprivation**. The condition of having persistent poor sleep quantity and/or quality.
- **Circadian rhythm**. The natural 24-h cycle that regulates physiological, behavioral, and molecular changes, according to the light and dark cycle.
- **Insomnia**. Clinical condition associated with habitual sleep deprivation and sleep fragmentation. It is the most prevalent sleep disorder involving difficulties in falling asleep or maintaining sleep accompanied by impaired daytime functioning, negative mood, and fatigue.
- **Sleep deprivation**. The condition of not having enough duration and/or quality of sleep.

Key Facts of Sleep Deprivation and Binge Eating

- Sleep deprivation is the condition of not having enough sleep, and it can be either chronic or acute.
- In the long-term, chronic sleep deprivation detrimentally impacts physical and mental health, increasing risk of obesity in adults and children.
- Experimentally induced sleep deprivation increases food intake and alters dietary behavior.
- Biological, cognitive, neural, emotional, and behavioral mechanisms may underline the relationship between sleep deprivation and eating behavior, especially binge eating.
- Cross-sectional and preliminary experimental studies examining the link between sleep deprivation and eating behavior and binge eating are available.

Summary Points

- Sleep deprivation affects eating-related behaviors. Chronic sleep deprivation has been proved to be associated with increased incidence of obesity, while acute sleep deprivation increases food intake and alters dietary behavior.
- Several potential underlying mechanisms might be involved: biological changes in hormones and metabolism, cognitive and emotional impairment, neural changes in brain reactivity, and behavioral factors as sedentary activities.

- Cross-sectional findings support the link between sleep deprivation and disordered eating, especially binge eating. However, a lack of experimental and longitudinal evidence examining this association is available.
- Novel preliminary findings including experimental procedures and participants reporting binge eating symptomatology yielded mixed results, thus preventing to establish causal relationships.
- Future studies analyzing the potential bidirectional link between sleep deprivation and eating behavior, such as binge eating, are highly desirable.

Contents

Abstract

The Criterion B binge-eating symptoms are five symptoms that co-occur with binge-eating episodes. Three out of five Criterion B symptoms must be endorsed for an individual to be diagnosed with binge-eating disorder (BED) under the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders*. The first aim of the current chapter is to describe the development of the Criterion B binge-eating symptoms. The second aim of the current chapter is to review evidence supporting the validity and clinical utility of the Criterion B binge-eating symptoms. Specifically, some studies have been interested in determining if three is the

appropriate number of these symptoms that should be required to fulfill this diagnostic criterion. Other studies provide information about the commonality of each Criterion B symptom, the validity of each Criterion B symptom, and each symptom's clinical utility. The third aim of this chapter is to describe how the Criterion B symptoms may be relevant for assessing BED in special populations (e.g., youth, men, different ethnic and/or racial identities, persons seeking bariatric surgery) and treating BED in general. Finally, we also discuss how the Criterion B symptoms may be relevant to understanding other eating-disorder diagnoses because binge-eating episodes occur across various eating disorders.

Introduction

Binge-eating disorder (BED) is an eating disorder associated with a significant detrimental impact on affected individuals' mental health, psychosocial functioning, and physical health. This impact leads to greater need for healthcare services and increased healthcare costs (Ágh et al. 2015). For example, in a nationally representative sample of US adults, individuals who met criteria for BED had greater functional impairment relative to individuals without BED in a variety of life domains, including professional, home, and social activities (Pawaskar et al. 2017). Other nationally representative research in US adults found that BED was significantly associated with numerous medical concerns (Udo and Grilo 2019). After controlling for other psychiatric diagnoses (any lifetime mood, anxiety, substance use, personality, conduct, or post-traumatic stress disorder), significant associations remained between BED and greater likelihood of high blood pressure and

diabetes (Udo and Grilo 2019). Given the impact of BED on individuals' physical and mental health, it is critical to accurately identify, assess, and effectively treat individuals with BED.

The accurate identification and assessment of psychiatric disorders is facilitated by valid diagnostic criteria. A diagnosis of BED requires binge-eating episodes that are distressing and occur at least once weekly on average. When using the fifth edition of the *Diagnostic and Statistical Manual of Mental* Disorders (DSM-5; American Psychiatric Association 2013) as a diagnostic guide, binge-eating episodes must also be associated with at least three additional specific symptoms. These specific binge-eating symptoms are the Criterion B symptoms, which we review in this chapter. First, we briefly detail the development of the Criterion B binge-eating symptoms from proposed research criteria into diagnostic criteria. Second, we review evidence supporting the validity and clinical utility of the Criterion B symptoms. Finally, we discuss these symptoms' relevance to special populations, BED treatment, and other eating-disorder diagnoses.

The BED Diagnostic Criteria

Diagnostic criteria for BED (see Table 1) are formally outlined in the DSM-5 (American Psychiatric Association 2013). BED is also included in the 11th published edition of the International Classification of Diseases and Related Health Problems (ICD-11; World Health Organization 2019). To receive a BED diagnosis in the DSM-5, an individual must repeatedly engage in objective binge-eating episodes. Objective binge-eating episodes in the DSM-5 have two main components: 1) feeling a loss of control (LOC; i.e., feeling like one must keep eating) and 2) eating an objectively greater amount than most people would in a similar setting and within a similar discrete timeframe (American Psychiatric Association 2013). Binge-eating episodes in the ICD-11 require only the presence of LOC (Berner et al. 2020). In other words, the amount of food consumed is irrelevant for defining binge-eating episodes according to the ICD-11. According to both the DSM-5 and ICD-11, individuals diagnosed with BED should experience binge-eating episodes at least once weekly for an extended period of time (see Table 1). Under both diagnostic systems, individuals diagnosed with BED should also report distress pertaining to their binge-eating episodes. Both diagnostic systems also require that other eating-disorder diagnoses be ruled out (see Fig. 1) because binge eating occurs in several different eating-disorder diagnoses. In the context of BED, binge-eating episodes are not accompanied by compensatory behaviors (e.g., restricting, excessive exercise, purging) as they are in bulimia nervosa (BN). Episodes are also not accompanied by significantly low body weight as they are in anorexia nervosa binge/purge subtype (AN-BP).

In addition to the difference in binge-size requirements between the DSM-5 and ICD-11 definitions of BED, there is one additional difference: in the DSM-5, binge-eating episodes in BED must be also associated with three or more specific binge-eating features. These features (the Criterion B symptoms) are 1) eating more rapidly

Table 1 DSM-5 (American Psychiatric Association 2013**) versus ICD-11** (World Health Organization 2019) Criteria for Diagnosing Binge-Eating Disorder. This table provides a paraphrased summary comparison of the BED criteria as outlined in the DSM-5 (American Psychiatric Association 2013) and the ICD-11 (World Health Organization 2019)

DSM-5	ICD-11
Criterion A: Binge-eating episodes are present. During these episodes, a person experiences a loss of control while eating an objectively large amount of food in a given timeframe	Binge-eating episodes are present. During these episodes, a person experiences a loss of control while eating in a given timeframe
Criterion B: At least three of the subsequently listed features accompany the binge-eating episodes: Eating more rapidly during binge eating, eating to the point of having physical discomfort, eating large quantities in the absence of physical hunger, eating alone due to embarrassment about binge size, and feeling depressed, disgusted, or guilty following binge eating	A person eats a greater quantity *or* in a different manner while binge eating. Episodes may commonly be associated with emotions generally perceived as uncomfortable and/or negative (e.g., disgust, guilt)
Criterion C: Binge eating is associated with significant distress	Binge eating is either associated with substantial distress or causes substantial impairment in a person's functioning
Criterion D: Binge-eating episodes are at least as frequent as once per week for a 3-month period	Binge eating is recurrent (i.e., at least once a week) over the course of "several" months
Criterion E: The person does not engage in compensatory behaviors. If such behaviors were present, a diagnosis of bulimia nervosa would be more appropriate. The person also does not have medically low bodyweight. If low bodyweight was present, a diagnosis of anorexia nervosa would be more appropriate	Compensatory behaviors are not paired with binge-eating episodes like in bulimia nervosa

during binge eating, 2) eating to the point of having physical discomfort, 3) eating large quantities in the absence of physical hunger, 4) eating alone due to embarrassment about binge size, and 5) feeling depressed, disgusted, or guilty following binge eating (American Psychiatric Association 2013). These five "features" constitute the Criterion B binge-eating symptoms. The ICD-11 BED definition does not specifically require the presence of Criterion B symptoms. However, the ICD-11 does reference additional possible characteristics of binge eating such as negative emotions (e.g., disgust, guilt) and eating "differently than usual" (World Health Organization 2019). Overall, reference to these additional binge-eating features in both diagnostic systems suggests that Criterion B symptoms may provide important additive information when assessing BED.

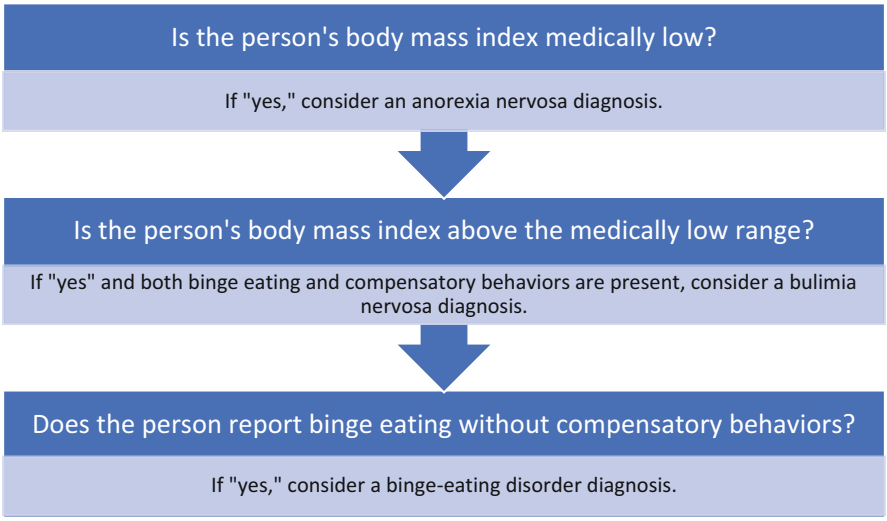

Fig. 1 Hallmark symptom consideration for eating-disorder diagnoses. This figure displays the core symptoms that distinguish the three specific eating-disorder diagnoses in the DSM-5 and ICD-11 from one another. If full criteria (e.g., any necessary frequency criteria and/or other core features, such as the Criterion B symptoms, beyond the hallmark symptom for each diagnosis) for the otherwise most appropriate diagnosis are not met, an "other specified" or "unspecified" diagnosis should be considered. Although Criterion B binge-eating symptoms may be present across diagnoses that include binge eating, they are only considered diagnostically when assigning a diagnosis of binge-eating disorder

The Development of Criterion B in BED

When BED was first studied for consideration as a potential eating-disorder diagnosis, the Criterion B symptoms were included as part of the provisional BED diagnostic criteria for research purposes. The Criterion B symptoms were originally referred to as "associated features" that co-occurred with the LOC that individuals experience during a binge-eating episode (Spitzer et al. 1992). As a result of preliminary research and input from experts, BED was provisionally designated an Eating Disorder Not Otherwise Specified (EDNOS) in the DSM-IV (American Psychiatric Association 1994; Mond 2013). BED was formally added to the eating-disorder diagnostic category in the DSM-5, eliminating its previous status as a "provisional diagnosis needing additional research" (Mond 2013). To reduce the use of non-specific eating-disorder diagnostic codes in the International Classification of Diseases and Related Health (ICD), BED was also included in the 11th version of the ICD (ICD-11; World Health Organization 2019) in 2019 (Claudino et al. 2019).

According to both the DSM-IV and the DSM-5, a person must endorse a minimum of three of the five Criterion B symptoms for a diagnosis of BED to be

appropriately made. There may be instances when someone endorses fewer than three of the Criterion B symptoms, yet has binge eating that is not associated with compensatory behaviors or low weight. In such instances, a clinician may instead diagnose the person with an "Other Specified Feeding or Eating Disorder" (OSFED, the DSM-5 equivalent of EDNOS). Thus, the three-symptom Criterion B threshold can make an important diagnostic difference. As a result, some studies have focused on determining whether the three-symptom "threshold" is the appropriate threshold to accurately identify individuals with fully diagnosable BED.

The Validity and Clinical Utility of the Criterion B Three-Symptom "Threshold"

Since the publication of the DSM-5, research has examined the validity and clinical utility of the three-symptom threshold for diagnosing BED (e.g., White and Grilo 2011; Klein et al. 2016; Vannucci et al. 2013). White and Grilo (2011) used a community sample of individuals diagnosed with BED, BN, or no eating disorder. They tested whether the number of Criterion B symptoms (i.e., endorsing anywhere from one through five symptoms) affected the ability to distinguish individuals with binge eating from those without. Results suggested that three symptoms were the appropriate number of symptoms for "correctly" diagnosing clinically significant binge eating characteristic of either BED or BN. Klein et al. (2016) studied a sample of university students in which nearly 75% of the sample met full criteria for DSM-5 BED. Klein et al. (2016) found that endorsing three Criterion B symptoms best distinguished university students who endorsed an item measuring distress about their binge eating from those who did not. Mustelin et al. (2017) employed a population registry-based study in Finland to examine factors associated with Criterion B symptoms in general community members. The number of Criterion B symptoms a person endorsed was significantly positively associated with both distress and body mass index (BMI). In contrast, Vannucci et al. (2013) found that college-aged women who met the three-symptom Criterion B threshold did not differ on eating disorder-related impairment from those who endorsed only one or two symptoms. In summary, the majority of evidence suggests that the three-symptom threshold does an adequate job in distinguishing individuals with binge eating-related distress from those without such distress.

Research Supporting the Validity of Individual Criterion B Symptoms

Research on the characteristics associated with binge-eating episodes provides information about the individual validity of each Criterion B symptom. For example, laboratory-based studies and ecological momentary assessment studies provide information about experiences prior to, during, and/or after binge eating. Some research tested the prevalence of each symptom to determine whether a given

symptom is uncommon or, alternatively, very common. Inferences about each symptom's relationship to eating-disorder severity may also be made from some research. Research pertaining to the validity and clinical utility of each individual Criterion B symptom is reviewed in the following sections.

Eating more Rapidly during Binge Eating

Research studies suggest that during binge-eating episodes, individuals with BED consume around 2000 calories within approximately 42 min (Forbush and Hunt 2014; Mourilhe et al. 2021). However, based on the available empirical evidence, it is unclear whether eating more rapidly during binge-eating episodes is a reliable characteristic of binge-eating behavior (White and Grilo 2011). Early research on the BED criteria found that eating more rapidly than usual showed the lowest reliability of the five Criterion B symptoms (Brody et al. 1994). Authors suggested that the low reliability may be because individuals with BED *typically* eat rapidly. Therefore, eating rapidly during a binge-eating episode may not be an experience unique to binge eating (Brody et al. 1994). More generally, increased eating rate is associated with having a BMI in the obese range, suggesting that this criterion may simply reflect weight status (Guss et al. 1994; Ohkuma et al. 2015).

One objective method for measuring rate of intake during binge-eating episodes includes laboratory feeding paradigms. During laboratory feeding studies, individuals are instructed to simulate both binge eating and normal eating in a "buffet style" setting where a range of foods are provided. Food intake is measured by weighing food before and after the meal. In some studies, food is placed on a scale that is concealed underneath a fake panel in the table. This facilitates covert weighing of food throughout the meal. Average eating rate is calculated by dividing total energy intake by meal duration. Change in the rate of intake (acceleration or deceleration) is calculated by measuring intake every few seconds during the meal. Some laboratory feeding studies showed that individuals with BN displayed a faster average eating rate when instructed to binge eat compared to when instructed to eat normally (Hadigan et al. 1989; LaChaussee et al. 1992). Additionally, the difference in average eating rate between binge-eating episodes and normal meals was greater among individuals with BN compared to controls (Hadigan et al. 1989; LaChaussee et al. 1992). However, these findings are not consistently found for binge-eating episodes among individuals with BED (Goldfein et al. 1993; Guss et al. 1994). Two studies found that, when instructed to binge eat, individuals with BED ate at a *slower* average rate and over a longer duration compared to non-BED controls (Guss et al. 1994; Goldfein et al. 1993).

In summary, research lacks strong support for the idea that individuals with BED eat relatively more rapidly during binge-eating episodes. However, there is some evidence that eating more rapidly does occur in the binge-eating episodes of individuals with BN. Therefore, eating more rapidly during binge eating may not be a consistently valid symptom of binge-eating episodes in BED but may have relevance for assessing binge eating in other eating disorders.

Eating to the Point of Having Physical Discomfort

During binge eating, people with BED may consume food to a point of fullness that is associated with physical discomfort. This uncomfortable fullness has been positively associated with binge-eating episode frequency (Richson et al. 2020). One survey of university students (the majority of which had BED) suggested that uncomfortable fullness associated with binge eating is commonly reported (Klein et al. 2016). Studies measuring gastric capacity among individuals with BED may also provide validity evidence. Studies have reported that individuals with BED have greater gastric capacity, which may impact the experience of satiety and fullness after a fixed-sized meal (Geliebter et al. 2004). One study measured gastric capacity using ratings of abdominal discomfort with increasing stomach pressure. Specifically, participants swallowed a gastric balloon which was subsequently filled with water. As the balloon was filled, participants rated their discomfort level until reaching maximum tolerance. Findings indicated that individuals with BED tolerated more discomfort than did a group of non-BED controls who had a BMI within the overweight category (Geliebter et al. 2004). Another study used a two-step water-load test to examine differences in gastric signals between individuals with BN or BED and BMI-matched healthy controls. Results showed that individuals with BN or BED drank more water to reach satiation, which was closer to their self-rated maximum fullness level than BMI-matched healthy controls (van Dyck et al. 2021).

Together, results suggest that individuals with BED may have greater gastric capacity that may delay the development of satiety during a meal and increase the likelihood of eating large amounts of food. Without normal satiation, individuals with BED may have trouble terminating intake until reaching a point of physical discomfort. Eating until one is uncomfortably full may, therefore, be a symptom of a larger deficit in satiety and fullness among individuals with BED. However, it remains unclear whether larger gastric capacity precedes or is a consequence of BED. Overall, eating until one experiences physical discomfort (i.e., uncomfortable fullness) appears to be a valid characteristic of binge-eating episodes (and possibly also eating style more generally) in individuals with BED.

Eating Large Quantities in the Absence of Physical Hunger

Certain models of binge eating suggest that binge eating may serve as a maladaptive form of affect regulation, whereby individuals engage in binge eating to cope with, weaken, or distract from negative emotionality (Haedt-Matt and Keel 2011a). From this perspective, binge-eating episodes may be triggered by negative affect rather than physiological cues (e.g., hunger) that otherwise normally regulate eating. Indeed, research suggests that affect may be more likely to trigger binge eating than hunger cues (Haedt-Matt and Keel 2011b). Eating when one is not physically hungry may also contribute to the sense of LOC experienced during binge-eating episodes because of the absence of an obvious physiological reason for eating.

Another factor that may contribute to the symptom of eating large quantities despite a lack of physical hunger is hedonic hunger, which is defined as a motivation to eat tasty or palatable foods in the absence of physiological hunger (Lowe and Butryn 2007). Individuals with high levels of hedonic hunger may consume palatable food for enjoyment rather than for satiation/energy needs. Pleasure-driven consumption may, in turn, increase risk for overeating and excess weight gain. Initial studies showed that hedonic hunger was associated with the development or worsening of LOC over eating, which represents a defining feature of binge eating (Witt and Lowe 2014; Lowe et al. 2016). Increased motivation to consume rewarding foods and hedonic processes may lead to increased craving for food, which may contribute to initiation of binge eating (Fedoroff et al. 2003). Recent research also suggests that the symptom of eating large quantities in the absence of physical hunger is positively associated with binge-eating episode frequency (Richson et al. 2020). In sum, binge eating in BED may be triggered by both affective and hedonic processes, both of which may motivate eating behavior outside of physical hunger. Overall, the Criterion B characteristic of eating large quantities of food regardless of physically "feeling" hunger appears to be an important, valid characteristic of binge-eating behavior.

Eating Alone Due to Embarrassment about Binge Size

Individuals often have binge-eating episodes when they are alone (Latner and Clyne 2008; Svaldi et al. 2019). Eating alone during binge-eating episodes is more common among individuals with objectively large binge-eating episodes relative to individuals with smaller LOC eating episodes (Palavras et al. 2013). Therefore, eating alone may be a particularly valid characteristic of binge-eating episodes in DSM-5-defined BED. Research that has measured binge-eating episodes and the emotions associated with binge eating in real time (i.e., ecological momentary assessment research) has found that shame prior to binge-eating episodes is associated with binge eating alone (Goldschmidt et al. 2018). This finding suggests that shame subsequently leads to eating alone. However, the wording of this symptom assumes that individuals eat alone *because* they are specifically embarrassed about the quantity of food they are eating, rather than because they are experiencing shame or embarrassment, in general.

Research has shown that eating in secret is indicative of greater eating-disorder psychopathology among individuals with BED (Lydecker and Grilo 2019). Similarly, the.

"eating alone" Criterion B symptom was associated with greater impairment among individuals with any eating disorder that included binge-eating episodes (i.e., binge-spectrum eating disorders; Richson et al. 2020). Finally, eating alone due to embarrassment was the least frequently endorsed Criterion B symptom in several studies of individuals with binge-spectrum eating disorders (White and Grilo 2011; Klein et al. 2016; Richson et al. 2020). These studies also suggested that the "eating alone" symptom was indicative of greater binge-eating severity

(Richson et al. 2020) and distress about binge eating (Klein et al. 2016). Taken together, eating alone due to embarrassment about binge size may be a less common Criterion B symptom, but one that is still important to assess because it may be indicative of greater severity. Therefore, binge eating alone that is facilitated by embarrassment may be a clinically useful symptom for both assessing BED and for BED treatment planning.

Feeling Depressed, Disgusted, or Guilty Following Binge Eating

Research on negative emotions after binge-eating episodes is mixed (Berg et al. 2015). More specifically, some research suggests that binge eating is effective at subsequently reducing negative affect (Berg et al. 2015); this research is consistent with the affect regulation model of binge eating. In contrast, other research suggests that negative affect persists or even increases after binge eating (Haedt-Matt and Keel 2011a). The latter research is consistent with the Criterion B symptom of "feeling depressed, disgusted, or guilty following binge eating."

Several studies on the Criterion B symptoms specifically found that the symptom of depressed mood, disgust, or guilt following binge eating is commonly endorsed (White and Grilo 2011; Klein et al. 2016; Richson et al. 2020). Because of its high prevalence, the endorsement of negative affect following binge eating may not be a particularly useful indicator of impairment levels or level of binge-eating psychopathology (Richson et al. 2020). The commonality of post-binge negative affect may also be inconsistent with the affect regulation model of binge eating. In other words, the commonality of feeling depressed, disgusted, or guilty following binge eating suggests that binge eating is *not* effective at reducing negative emotional experiences like the affect regulation model suggests. However, the common presence of negative affect following binge eating does support the overall validity of the "feeling depressed, disgusted, or guilty following binge eating" symptom.

The separate requirement within the BED diagnosis that binge eating be experienced as distressing may explain the high prevalence of this Criterion B symptom, as depressed mood or guilt may be experienced as distress (see Table 1). Indeed, one study found that this Criterion B symptom had the strongest association with distress about binge eating (Klein et al. 2016). This symptom may be a useful binge-eating screening item due to its absence being an accurate identifier of non-binge-eating controls in one study (White and Grilo 2011). Overall, results suggest that "feeling disgusted/depressed/guilty afterward" is a valid, common characteristic of binge eating. However, as a result, it may be difficult to make inferences about BED severity or associated impairment solely from the endorsement of feeling depressed, disgusted, or guilty following binge eating.

Relevance of Criterion B Symptoms to Special Populations

In addition to adults, BED can occur in children and adolescents. Due to developmental differences between children/adolescents and adults, some researchers have posited that the BED diagnostic criteria (including the Criterion B symptoms) may need to be adjusted for children and young adolescents (Tanofsky-Kraff et al. 2008; Marcus and Kalarchian 2003). For example, it may be difficult for children to eat alone because caregivers may monitor eating or due to school-settings in which children are required to eat with peers. Additionally, LOC during eating may be more important for diagnosing BED in children/adolescents than the amount of food eaten during the LOC eating episodes (Morgan et al. 2002; Tanofsky-Kraff et al. 2004; Tanofsky-Kraff et al. 2005; Goldschmidt et al. 2008). Thus, eating to the point of uncomfortable fullness may be a symptom that is less applicable in younger populations; however, this possibility has not been explicitly tested in research to our knowledge. Overall, relative to adults, little is known about how the Criterion B symptoms may apply to the experiences of children/adolescents with binge eating.

Though much of what is known about the Criterion B symptoms comes from adult samples, there are also special adult populations in which less is known about these symptoms (e.g., individuals who identify as men, individuals with minoritized racial and/or ethnic identities). One study that compared women and men found that the majority of binge-eating symptoms examined (including variations of the Criterion B symptoms) were more common among women than men (Mustelin et al. 2017). Men and women also may exhibit differences in terms of which Criterion B symptoms are most commonly endorsed (White and Grilo 2011). Certain symptoms may also be more or less relevant to the experience of binge eating among persons from different ethnic and/or racial backgrounds. For example, one study noted that the experience of embarrassment associated with overeating may be particularly helpful for assessing binge eating in girls and young women from Native American backgrounds (Striegel-Moore et al. 2011). Another study found that various binge-eating symptoms were relatively less common among participants who identified as African American (Franko et al. 2007). More research is needed to clarify the validity of the Criterion B symptoms across a fuller, more inclusive spectrum of adult populations. Addressing existing gaps in knowledge about the Criterion B symptoms in minoritized populations is particularly important given that binge eating may occur at elevated rates in certain minoritized populations (e.g., Perez et al. 2016).

Another population in which it is important to assess BED (and the Criterion B symptoms) is individuals who have undergone bariatric surgery. Bariatric surgery refers to a range of surgical procedures (e.g., gastric bypass) that are intended to facilitate weight loss and prevent serious weight-related medical complications in individuals with obesity (Wolfe et al. 2016). Research suggests that BED is one of the most common mental health disorders among individuals seeking and undergoing bariatric surgery (Dawes et al. 2016; Kalarchian et al. 2007). Although a substantial number of bariatric surgery candidates may endorse binge eating or are diagnosed with BED prior to bariatric surgery, evidence largely suggests that BED

diagnosis prior to bariatric surgery does not reliably predict long-term weight-loss outcomes (Kops et al. 2021). However, the development or re-emergence of BED or binge-eating symptoms following surgery may interfere with weight loss and increase post-operative complications such as uncomfortable gastrointestinal symptoms (Conceição et al. 2017; Sarwer et al. 2008; Smith et al. 2019). Thus, it may be important to understand the extent to which the Criterion B binge-eating symptoms represent the eating experiences of individuals following bariatric surgery. Additionally, binge-eating behavior may present differently among individuals who have undergone bariatric surgery. Specifically, because of restricted gastric capacity resulting from bariatric surgery, the consumption of large amounts of food may not be feasible. However, individuals may experience distress related to LOC over eating and Criterion B symptoms following surgery, which may increase risk for weight regain or poor weight loss outcomes following surgery (Meany et al. 2014). For example, rapid eating may be associated with eating that is emotionally driven in bariatric populations (Canterini et al. 2018). Emotionally driven eating could, in turn, lead to poorer surgical outcomes (e.g., weight regain). Among individuals who have had bariatric surgery, the presence of several Criterion B symptoms in addition to LOC eating may also be associated with greater distress and poorer weight loss outcomes relative to individuals who only endorse LOC eating (Ivezaj et al. 2018). In summary, assessing and treating Criterion B symptoms in bariatric populations may hold clinical utility for ensuring positive surgical outcomes.

The Criterion B Symptoms in Non-pharmacological BED Treatment

BED is commonly treated using Enhanced Cognitive Behavior Therapy, an adaptation of traditional cognitive-behavioral therapy for eating disorders (CBT-E; Fairburn 2008). Individuals participating in CBT-E log their food intake (including recording binge-eating episodes) as well as any thoughts or notable circumstances surrounding food intake. As a result, it may become clear that certain Criterion B symptoms are commonly associated with a client's binge-eating episodes. For example, food logging may reveal that an individual only experiences binge-eating episodes when they are alone. Therapy may then focus on identifying ways the client could remove themselves from an environment where being alone leads to binge eating (e.g., by going on a walk or for a drive) or identifying alternative activities to do when alone. CBT-E's focus on increasing regular eating may reduce the occurrence of other Criterion B symptoms such as eating rapidly and eating to physical discomfort because regular eating increases structure in a person's pattern of eating and gradually facilitates the return of accurate hunger/fullness cues (Fairburn 2008). Behavioral weight loss interventions also emphasize structured eating (Grilo 2017), thus potentially leading to a similar effect on binge-eating symptoms.

Rapid eating and physical discomfort resulting from binge eating may also be similarly targeted in the emphasis on meal planning within Integrative Cognitive-Affective Therapy (ICAT; Wonderlich et al. 2010). Even more directly than CBT-E,

Integrative Cognitive-Affective Therapy (ICAT) emphasizes identifying specific situations and emotions that are associated with binge eating. Thus, awareness of both binge-eating triggers (especially emotional triggers) and emotional consequences is increased through ICAT. As a result, ICAT could be particularly effective at reducing the presence of negative affect-related Criterion B symptoms. However, to our knowledge, this possibility has not been directly examined through research.

BED treatments that focus on mindfulness, including Dialectical Behavior Therapy (DBT) for binge eating (Telch et al. 2001) and Mindfulness-Based Eating Awareness Training (MB-EAT; Kristeller and Wolever 2010), may also reduce certain Criterion B symptoms. A core focus of both DBT and MB-EAT is mindfulness skills, which may be useful for individuals with BED who experience binge-eating episodes despite not feeling hungry or have trouble stopping a binge-eating episode despite nearing a point of uncomfortable fullness. Mindfulness skills could raise a person's awareness to these bodily cues before or during binge eating. Similarly, another DBT focus is emotion regulation. These skills encourage noticing thoughts, emotions, and behaviors that may be unhelpful or distorted so one can then behaviorally respond in a healthier way. Such emotion regulation skills may target Criterion B symptoms that are associated with negative emotional experiences, such as feeling depressed, disgusted, or guilty following binge eating.

Summary

The Criterion B symptoms originated from research on potential characteristics associated with binge-eating episodes. Although the Criterion B symptoms may be experienced by anyone who presents with binge eating, the Criterion B symptoms are only part of the diagnostic criteria in DSM-5 BED (although the ICD-11 BED diagnosis alludes to similar binge-eating symptoms). The Criterion B symptoms vary in terms of their validity and clinical utility. More research is needed on the validity of the Criterion B symptoms in special populations across ages, persons of different weight status, and persons of different identities. Finally, the Criterion B symptoms have relevance across BED treatment modalities.

Applications to Other Eating Disorders

Binge eating is a transdiagnostic symptom that is present across several DSM-5 eating disorders, including AN-BP, BN, and certain presentations of OSFED. Criterion B symptoms are included only in the DSM-5 diagnosis of BED. However, it is possible that persons with other eating disorders also experience Criterion B symptoms during binge-eating episodes. The extent to which Criterion B symptoms could predict eating-disorder severity or impairment has not been explored extensively in different eating-disorder diagnostic groups. In clinical settings, understanding what behaviors, cognitions, and emotions are present during binge eating, regardless of diagnosis, could be important in informing case conceptualizations and treatment

plans. For example, knowing that a client has binge-eating episodes despite a lack of physical hunger may point to the importance of identifying and addressing non-physiological binge-eating triggers. Similarly, knowing that a client tends to binge eat alone may lead to treatment goals of trying to eat meals with others. Therefore, the Criterion B binge-eating symptoms may have the potential to inform severity, impairment, case conceptualization, and treatment plans in AN-BP, BN, and certain forms of OSFED. Future research could explore the extent to which the Criterion B binge-eating symptoms apply to subjective binge-eating episodes, in which an individual feels out of control when eating a small or normal amount of food. Subjective binge eating is present in DSM-5 OSFED diagnoses such as purging disorder. Individuals who experience subjective binge eating often report similar levels of distress pertaining to this behavior as individuals who experience objective binge eating (Li et al. 2019). Therefore, Criterion B symptoms may also apply to the experience of subjective binge eating across diagnostic boundaries.

Mini-Dictionary of Terms

- **Binge-eating disorder.** An eating disorder in which individuals have a normal or greater body mass index and have one main eating-disorder behavioral symptom: binge-eating episodes during which one feels out of control over their eating.
- **Bulimia nervosa.** An eating disorder characterized by normal or greater body mass index, as well as both binge-eating episodes and compensatory behaviors (e.g., restricting/fasting, laxative use, diuretic use, self-induced vomiting, exercising very hard).
- **Criterion B binge-eating symptoms.** The Criterion B symptoms are five symptoms that may be associated with binge-eating episodes and are part of the DSM-5 diagnostic criteria for binge-eating disorder.
- **DSM-5.** The DSM-5 is a manual of psychiatric diagnoses (such as eating disorders, anxiety disorders, etc.) used in the United States that specifies the different symptoms/characteristics a person should have in order to be given a certain diagnosis.
- **ICD-11.** The ICD-11 is an internationally used diagnostic system (i.e., for medical diagnoses, psychiatric diagnoses, etc.) that describes the criteria for various diagnoses.
- **Other Specified Feeding or Eating Disorder.** This DSM-5 eating-disorder diagnosis may be given to characterize a set of clinically significant eating-disorder symptoms that do not fit with a specific diagnosis of binge-eating disorder, bulimia nervosa, or anorexia nervosa.
- **Validity.** Validity is a psychometric term broadly referring to how well a construct (e.g., binge-eating psychopathology) is measured or represented by something (e.g., a symptom set, a questionnaire) intended to assess/represent that construct.

Key Facts of the Criterion B Binge-Eating Symptoms

- The Criterion B symptoms are five symptoms or characteristics that may be associated with binge-eating episodes.
- Endorsement of at least three out of the five Criterion B symptoms is required to meet the DSM-5 criteria for a diagnosis of BED, but not the ICD-11 criteria for BED.
- The five Criterion B symptoms vary in terms of how common they are and in terms of how much they are associated with other factors relevant to BED assessment (e.g., distress, severity).
- The Criterion B symptoms are often relevant to BED treatment targets.
- Because binge eating occurs in additional eating-disorder diagnoses beyond BED, the Criterion B symptoms also likely apply to the experiences of people with other eating disorders.

Summary Points

- In the DSM-5, BED is characterized by binge-eating episodes, distress about binge eating, and various other symptoms that are associated with the binge-eating episodes known as the Criterion B symptoms.
- The Criterion B symptoms are not formally a part of the ICD-11 BED diagnostic criteria but are referenced as possible characteristics of binge-eating episodes.
- BED is a relatively new eating-disorder diagnosis; as a result, its diagnostic criteria (including the Criterion B binge-eating symptoms) continue to be studied.
- Research supports the three-symptom Criterion B threshold in the DSM-5.
- Certain Criterion B symptoms appear to be more common than others, whereas other symptoms may be less common but more strongly associated with clinical characteristics like greater severity and impairment.
- The Criterion B symptoms may need to be adjusted to meet the unique needs of children/adolescents.
- The Criterion B symptoms should be assessed regardless of BED status in bariatric populations.
- The Criterion B symptoms are often relevant to various treatments that aim to reduce the frequency of binge-eating episodes and normalize eating patterns.
- Future research may wish to study the Criterion B symptoms across other eating-disorder diagnoses that include subjective binge-eating episodes.

Abstract

Purging disorder is an eating disorder subtype characterized by purging behaviors to control weight (i.e., self-induced vomiting or misuse of laxatives, diuretics, and/or other medications). It was recognized for the first time in the DSM-5 (2013) within the other specified feeding or eating disorder category. The lifetime prevalence of purging disorder is comparable to both anorexia nervosa and bulimia nervosa, placing it as a significant eating disorder phenotype. Purging disorder is symptomatologically similar to bulimia nervosa, except for the absence of binge eating episodes. However, despite the common features with other eating disorders, purging disorder appears as a clinically significant and potentially distinctive disorder. Therefore, the present chapter reviews and discusses the clinical and distinctiveness features of this disorder, as well as the treatments of first choice (i.e., cognitive-behavioral therapy). This chapter also highlights that studies on PD treatment outcomes are currently limited, available results are inconsistent, and evidence-based treatments are lacking.

Keywords

Cognitive-behavioral therapy · Eating disorders · Medical complications · Other specified feeding or eating disorder · Purging disorder

Abbreviations

AN	Anorexia nervosa
BED	Binge eating disorder
BMI	Body mass index
BN	Bulimia nervosa
CBT	Cognitive-behavioral therapy
CBT-E	Enhanced cognitive-behavioral therapy
CCK	Cholecystokinin
DSM-5	*Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*
ED	Eating disorder
GLP-1	Glucagon-like peptide type 1
OSFED	Other specified feeding or eating disorder
PD	Purging disorder
PYY	Peptide YY
RCT	Randomized controlled trial

Introduction

Defining Purging Disorder

Purging disorder (PD) is an eating disorder (ED) subtype included for the first time within the other specified feeding or eating disorder (OSFED) category in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) (American Psychiatric Association 2013). However, before the formal recognition of PD as a diagnostic subtype, some previous studies already attempted to describe the characteristics of clinical conditions consistent with PD (Keel et al. 2005), often as a category of subthreshold bulimia nervosa (BN). According to the DSM-5, PD is symptomatically characterized by recurrent purging behaviors to control weight or shape similar to BN (i.e., self-induced vomiting or misuse of laxatives, diuretics, or other medications), but in the absence of binge eating episodes. In addition, PD requires a body mass index (BMI) greater than 18.5 kg/m^2, which differentiates it from anorexia nervosa (AN) purging subtype (American Psychiatric Association 2013). In fact, PD appears to lie in the middle of the weight spectrum, with AN at the lower and binge eating disorder (BED) at the higher end of this continuum.

PD is considered the ED diagnostic subtype most similar to BN, given the shared psychopathology and personality traits (Krug et al. 2021) and the overlap in purging behaviors as core symptoms (American Psychiatric Association 2013; Riesco et al. 2018). However, while individuals with PD may or may not report a subjective loss of control overeating, it differs from BN in the endocrine and psychological factors linked to binge eating episodes (e.g., hunger, intense feelings of satiation after meals, and ability to control food intake) (Murray and Anderson 2015; Dossat et al. 2015). This growing evidence that PD is a clinical diagnostic entity per se has also been supported by a recent study that has identified different clusters within the PD category with differential symptomatological and severity characteristics (Krug et al. 2020).

Literature has yielded lifetime prevalence rates of PD ranging from 1.1% to 5.3% for women in community samples (Tasca et al. 2012; Murray and Anderson 2015; Hammerle et al. 2016). Specifically, in clinical settings, prevalence of PD reaches rates of 3–18% in inpatient units (Dalle Grave and Calugi 2007) and up to 24% in outpatient settings (Binford and le Grange 2005). However, since these prevalence rates were published before the DSM-5, it is not clear whether they have captured the real prevalence of PD based on the DSM-5 criteria (Stice et al. 2013). To our knowledge, no studies of prevalence for men with PD are reported so far. However, a study on high school samples shows a significantly higher prevalence of PD in females compared to males (Haedt and Keel 2010).

Etiopathogenesis and Risk Factors

PD sometimes remains unrecognized, but its clinical significance needs to be highlighted (Lydecker et al. 2018). In comparison with other EDs, PD usually presents with a later age of onset (Stice et al. 2009; Smith et al. 2017; Riesco et al.

2018). In fact, PD most typically first onsets in early adulthood, at approximately 20 years of age (Murray and Anderson 2015), and it is uncommon before the age of 18 years (Stice et al. 2009).

As with other EDs, the heterogeneous etiopathogenesis of PD includes multiple interacting factors, such as biological, developmental, psychological, and sociocultural aspects.

Biological factors: (a) Genetic factors and familiar influence (Munn-Chernoff et al. 2015; Hübel et al. 2018); (b) endocrine factors related to appetite regulation (e.g., peptide YY (PYY), cholecystokinin (CCK), glucagon-like peptide type 1 (GLP-1), leptin, amylin, insulin, ghrelin) (Steiger and Bruce 2007; Jimerson et al. 2010; Dossat et al. 2015; Keel et al. 2018; Keel 2019; Maske et al. 2020); and (c) other endocrine systems (e.g., serotonin dysregulation, neurotrophins, dopamine, the hypothalamic-pituitary-adrenal axis, opioids, estrogen, etc.) (Steiger and Bruce 2007).

Psychological factors: Certain psychological factors have been frequently associated with the development and maintenance of PD, as in the case of other EDs, such as specific personality traits (i.e., low self-directedness and high sensation seeking, harm avoidance, and perfectionism), high levels of somatization, emotional distress and negative affect, body dissatisfaction, and eating and weight concerns (Haedt-Matt and Keel 2015; Smith et al. 2017).

Developmental and sociocultural factors: Higher premorbid BMI, parent-perceived childhood overweight, family modeling of dieting or weight concerns, perceived family pressure to lose weight or be thin, and the influence of the ideal of beauty based on thinness, mass media influence, peer pressure regarding body-related criticisms, body dissatisfaction, and frequent dieting are associated with the onset of PD (Stice 2001; Haines et al. 2008; Neumark-Sztainer et al. 2010; Allen et al. 2015; Keel 2019). Family environmental variables, such as childhood trauma or abuse, have also been identified as risk factors for purging behaviors (Steiger and Bruce 2007).

The risk factors above described are common with other EDs. Furthermore, in PD, both behavioral (e.g., purging behaviors) and cognitive symptoms (e.g., fear of gaining weight or becoming fat) tend to emerge simultaneously (Stice et al. 2021). Thus, it is very important to identify the duration and onset of these symptoms to know whether the PD symptoms are primary/secondary to another diagnosis, such as BN, and the crossover ED diagnosis (Fig. 1).

Clinical and Personality Features

Common with other EDs, PD is associated with significant functional impairment, severity, chronicity, medical complications, suicidality, and mortality (Stice et al. 2013; Koch et al. 2014; Forney et al. 2016, 2021; Smith et al. 2017). As noted above, purging behaviors to control weight, fear of weight gain, and overvaluation of body shape are the core symptoms (behavioral and cognitive) of this disorder. Similar to BN, PD exhibits significantly greater drive for thinness, dietary restraint, and body

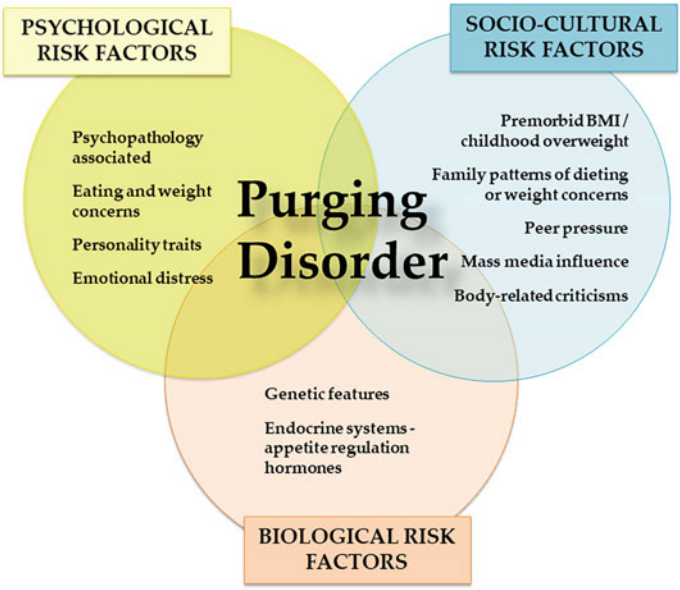

Fig. 1 Risk factors of purging disorder. The etiopathogenesis of purging disorder includes interacting biological, psychological, and sociocultural aspects

dissatisfaction (Keel et al. 2011). It is also well documented that approximately 30% of individuals with PD feel a loss of control eating, even when they intake small amounts of food (i.e., "subjective binge eating") (Goldschmidt et al. 2016; Smith et al. 2017), leading to an increased desire to purge (Keel 2019). Despite common features with BN, PD has been associated with significantly lower eating disinhibition and different subjective and physiological responses to food than BN (Keel et al. 2005, 2007).

Premorbid overweight conditions have also been associated with the development of PD (Keel 2019), while the current BMI of patients with PD could be linked to ED severity, in terms of using more extreme weight control methods (Krug et al. 2020). Diagnostic crossover between BN, BED, and PD appears rare in adult groups (Fairburn et al. 2000; Keel et al. 2005), but it is more frequent for BED and PD than for BN in the adolescence (Stice et al. 2013).

Individuals with PD report an impaired quality of life in the physical, psychological, and social domains (Forney et al. 2021). They also exhibit high levels of general psychopathology and emotional distress (Keel et al. 2008; Krug et al. 2021), similar to BN and AN (Tasca et al. 2012). Notably, PD shows elevated mortality and suicide rates (Koch et al. 2013, 2014), as well as frequent comorbidity with psychiatric disorders such as anxiety disorders, depression, compulsive behaviors (such as skin-picking, non-suicidal self-injury, hair-pulling, and compulsive exercise), impulsive behaviors (such as aggression, alcohol use, and drug use), and some personality disorders (i.e., obsessive-compulsive, borderline, and avoidant personality disorder)

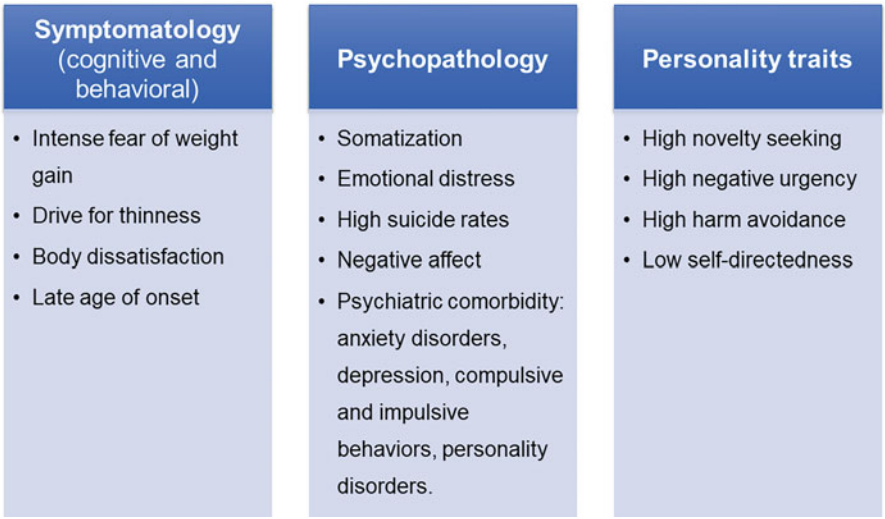

Fig. 2 Clinical profile of purging disorder. This figure shows the main eating-related, psychopathological, and personality features of purging disorder

(Keel 2007; Keel et al. 2008; Smith et al. 2017; Balasundaram and Santhanam 2022). In comparison with BN, PD has been associated with lower levels of lifetime mood disorders, but higher rates of current anxiety disorders (Keel et al. 2008). However, in both EDs, purging behavior would act similarly as a regulator of negative affect (Haedt-Matt and Keel 2015; Smith et al. 2017).

Regarding personality traits, individuals with PD usually present dysfunctional personality traits, characterized by both high novelty seeking/negative urgency and harm avoidance, and low self-directedness (Davis et al. 2020). However, compared to BN or BED, PD reports lower prevalence of impulse control disorders and lower levels of impulsivity, as well as higher levels of self-esteem (Keel et al. 2011; Smith et al. 2017; Davis et al. 2020). Furthermore, although BN and PD share clinical features, some mechanisms underlying these characteristics might be different. For example, while purging behaviors in PD are associated with anxiety-related traits, in BN, however, they are linked to more impulsive traits (Brown et al. 2011) (Fig. 2).

Medical Complications for Purging Behaviors

Purging behaviors present in PD contribute to aggravating and/or triggering medical complications at different levels, but the individual premorbid somatic conditions in each case must be considered (Forney et al. 2016). Many of these medical disturbances are shared by different ED (e.g., AN, BN), especially those derived from vomiting or misuse of laxatives/diuretics. In this line, medical problems across body systems include metabolic and electrolyte disturbances (e.g., dehydration, hypokalemia), gastrointestinal affection (e.g., inflammation, functional dysregulation, bleeding, intestinal obstruction),

musculoskeletal and bone consequences (e.g., skeletal muscle weakness, rhabdomyolysis, osteomalacia, bone fracture), and cardiovascular damage (e.g., heart muscle affection, tachycardia, hypotension), among others (Smith et al. 2017; Keel 2019; Balasundaram and Santhanam 2022). Specifically, vomiting is associated with oral and dental damage (e.g., erosions, ulcers, bleeding), gland problems (e.g., parotid sialadenosis), blood affection (e.g., facial purpura, subconjunctival hemorrhages), and gastrointestinal mucosal irritation and reflux. Typically, Russell's sign (characterized by lesions on the hands in the context of skin scraping against teeth) has been described among patients with self-induced vomiting. On the other hand, the abuse of purging products (i.e., laxatives) is linked to interference with insulin secretion and acute hepatic failure, altered bowel habit, seizures, and renal disturbances (e.g., inflammation, calcium deposits). Interestingly, some of the described complications are closely associated with the electrolyte imbalance (i.e., hypokalemia) derived from purging behaviors, such as prolonged QT intervals in patients with self-induced vomiting or a characteristic arrhythmia called "torsade de pointes" in the cases of laxative abuse. Regarding the presence of the different purging behaviors among patients with PD, the study by Krug et al. (2020) differentiated three clinical clusters: Cluster 1 (only self-induced vomiting), Cluster 2 (self-induced vomiting and laxative use), and Cluster 3 (all the methods). In this vein, the latest cluster was associated with a more severe clinical profile, and this may lead to greater medical complications (Fig. 3).

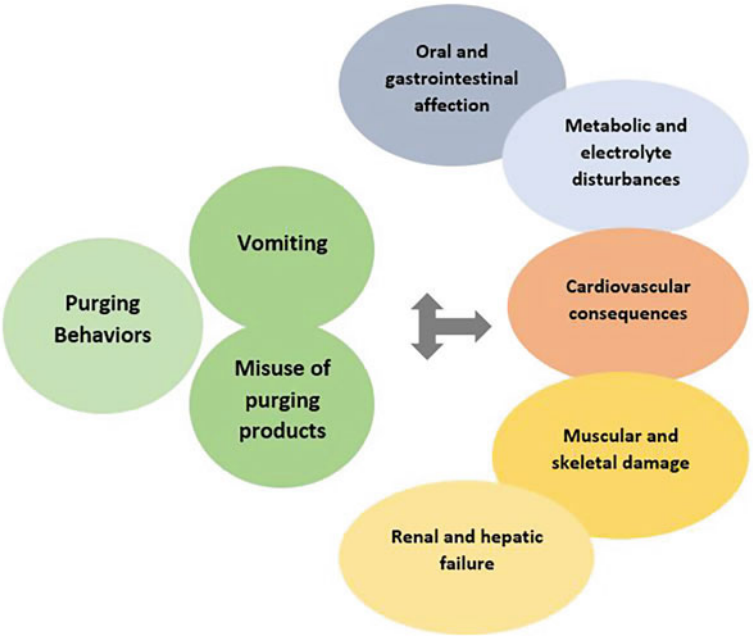

Fig. 3 Medical complications. Medical complications in purging disorder affect different body systems and are mostly related to purging behaviors

Treatment Approaches

The management of PD is similar to that for BN. The treatment strategies should address cognitive and behavioral symptoms, comorbid psychopathology, and psychosocial aspects, as well as the acute and chronic medical complications arising from purging behaviors (Forney et al. 2016; Balasundaram and Santhanam 2022). However, a major limitation in the literature is that no controlled trials (RCTs) have examined specific treatment protocols for PD so far, and usually those ED subtypes have been excluded from RCTs (Murray and Anderson 2015).

Medical and Pharmacological Approach

Considering the medical complications cited above, the medical examination of individuals with PD should include a complete metabolic panel, a blood count, and a comprehensive body examination including the teeth to prevent serious complications (Forney et al. 2016).

Medications like antidepressants, antipsychotics, or mood stabilizers may help treat coexisting psychiatric illnesses such as anxiety or depression. Fluoxetine is the only FDA-approved drug used for the treatment of BN and BED although its use has not been approved for PD.

Cognitive-Behavioral Therapy

Cognitive-behavioral therapy (CBT) and the enhanced version of CBT (CBT-E) are the first-line treatments for adults with ED. CBT is the most empirically supported treatment for ED, including PD. The CBT-E, according to Fairburn's manual (Fairburn 2008), is an evidence-based treatment that emphasizes the core of ED-related psychopathology, such as overvaluation of body weight and shape, body image distortion, or unhealthy weight control measures. It also includes modules to address other factors that may be maintaining the ED, such as interpersonal functioning, low core self-esteem, or clinical perfectionism. Patients with PD may benefit from the CBT-E mood intolerance module. This module provides strategies for accepting the sensation of fullness and related anxiety. Exposure and response prevention techniques may also be helpful in avoiding purging after eating. These approaches can help individuals with PD learn to reinterpret bodily sensations and satiety cues as a natural part of the digestive process. In the last sessions, relapse prevention is addressed. In addition, growing evidence suggests the convenience of focusing on targets aimed at learning emotional regulation skills from the first sessions of CBT (MacDonald et al. 2017b; MacDonald and Trottier 2019). Additionally, psychoeducational and motivational aspects may need to be considered in the management of PD, in order to facilitate both early detection and intervention to diminish the duration of the disorder (Fernández-Aranda et al. 2021) (Table 1).

Table 1 Evidence-based treatment targets for purging disorder

Evidence-based treatment targets for purging disorder	
Cognitive-behavioral therapy (CBT) *(as first-line treatment approach)*	Eating disorder-related psychopathology
	Interpersonal functioning
	Low self-esteem and clinical perfectionism
	Emotional regulation skills
	Teaching strategies for accepting the sensation of satiety and related anxiety
	Exposure and response prevention techniques for avoiding purging after eating
Additional therapy goals	Enhancing motivation
	Psychoeducation
Medical management	Blood test and complete metabolic examination
	Dental examination
	Complete body examination
Pharmacological treatment	Antidepressants[a], antipsychotics, or mood stabilizers for comorbid psychiatric illnesses

[a]Fluoxetine has been approved for bulimia nervosa, but not yet for purging disorder

CBT Outcome for Purging Disorder

Little is known about the treatment outcome of PD. The literature in this topic is still scarce and controversial. Moreover, recent research reports inconsistent remission rates in this clinical population, ranging from 45% (Ekeroth et al. 2013; Riesco et al. 2018) to 95% (Stice et al. 2013). Reported recurrence rates range from 5% to 6% (Stice et al. 2009, 2013). This relapse rate is lower for PD than for other EDs, suggesting that the maintenance processes of purging behaviors may be weaker in this disorder (Stice et al. 2013). Long-term follow-up studies show that at 10 years of follow-up, 30% meet criteria for full recovery (Forney et al. 2021).

Likewise, the few studies comparing treatment outcomes with other EDs also reveal conflicting results, due to heterogeneous samples. While some studies find similar remission rates with other OSFED types or with full ED syndromes (Keel et al. 2005; Tasca et al. 2012; Ekeroth et al. 2013; Riesco et al. 2018), others find a better prognosis of PD compared to AN (Smith et al. 2017). In this vein, specific personality traits such as higher harm avoidance, persistence, and self-directedness have been associated with greater remission rates after a CBT treatment (Riesco et al. 2018). Likewise, it has been shown that training in emotion regulation strategies from the first CBT sessions can be beneficial for patients, with even better outcomes at 6-month follow-up after treatment (MacDonald et al. 2017b; MacDonald and Trottier 2019). In addition, CBT intervention with emotional regulation techniques appears to be associated with a more rapid response to treatment compared to motivational interviewing (MacDonald et al. 2017a).

Regarding treatment adherence, PD shows high dropout rates, even higher than those of other EDs. It has been suggested that PDs are less motivated and have less

illness perception than full syndromes. Specifically, in these patients, the risk of dropping out therapy has been associated with a personality profile characterized by lower scores on harm avoidance, reward dependence, and self-directedness (Riesco et al. 2018).

Applications to Other Eating Disorders

In this chapter, we have reviewed purging disorder (PD) and its treatment outcome following cognitive-behavioral therapy (CBT). First, the need to study PD as a diagnostic entity and not just as a phenotype within other specified feeding or eating disorder (OSFED) has been highlighted. This review has revealed that PD presents distinctive and no less severe features than other DSM-5 full syndromes such as anorexia nervosa (AN), bulimia nervosa (BN), or binge eating disorder (BED). In this vein, these findings could be extrapolated to reinforce the interest in further examining other subtypes of OSFED such as atypical AN, subthreshold BN, subthreshold BED, or night eating syndrome, mainly the latter. Identifying the intrinsic characteristics, the clinical significance, and the distinctiveness of the diagnostic phenotypes, beyond considering them as subthreshold subtypes, justifies the intervention. In addition, it is important to identify significant differences in severity between different EDs, full or partial syndromes, to warrant appropriate treatments. Controlled trials examining specific treatment protocols are also needed, not only for PD but also for other less studied specified and non-specified ED diagnostic subtypes. In conclusion, understanding the functional nature of purging behaviors in PD and other clinical features of other less studied ED may improve their characterization in future diagnostic systems, as well as their prevention and intervention modalities.

Mini-Dictionary of Terms

- ***Other specified feeding or eating disorders (OSFED)***. A diagnostic category that encompasses those individuals who do not meet the full diagnostic criteria for anorexia nervosa, bulimia nervosa, or binge eating disorder but who have a significant eating disorder
- ***Purging behaviors.*** Compensatory behaviors to control weight and shape including self-induced vomiting or misuse of laxatives, diuretics, and/or other medications.
- ***Purging disorder.*** An eating disorder subtype characterized by purging behaviors, included in the OSFED diagnostic category
- ***Cognitive-behavioral therapy***. A treatment approach designed to recognize and address dysfunctional thoughts, emotions, and behavioral patterns
- ***Adherence.*** The degree of agreement in complying with the medical/therapeutic recommendations given by the healthcare professional

- ***Remission.*** The absence of symptoms for a sustained period (full remission). Partial remission means a substantial symptomatic improvement but with residual symptoms
- ***Dropout.*** Treatment discontinuation before the completion of a predetermined treatment program

Key Facts of Purging Disorder

Purging disorder is an eating disorder more prevalent among females with lifetime prevalence rates between 1% and 5% and up to 24% in clinical population.

Although purging disorder shares clinical features with other eating disorders, such as bulimia nervosa, its clinical significance and distinctiveness have been proven.

Medical complications in purging disorder affect different body systems, mostly shared with other eating disorders and associated with purging behaviors.

Cognitive-behavioral therapy (CBT) has been described as the first-line treatment in eating disorders, including purging disorder.

Results related to treatment outcomes to CBT in purging disorder are scarce and inconsistent. However, emotion regulation and exposure and response prevention strategies might be key therapeutic target in the treatment of this disorder.

Higher dropout rates have been described in purging disorder compared to other eating disorders, which has been associated with specific personality traits.

Summary Points

- Purging disorder is a clinically significant and distinctive disorder
- Purging disorder lifetime prevalence rates range from 1.1% to 5.3% among general population and up to 24% in clinical settings
- Medical disturbances in purging disorder are mostly shared by different eating disorders, especially those derived from self-induced vomiting or the abuse of purging products
- Like bulimia nervosa, cognitive-behavioral therapy is the first-choice treatment for adults with purging disorder
- Although results related to treatment outcome of purging disorder are scarce and inconsistent, cognitive-behavioral therapy intervention with emotional regulation and exposure and response prevention techniques seems to be associated with positive treatment outcomes
- High dropout rates among patients with purging disorder may be associated with some personality traits (i.e., low scores on harm avoidance, reward dependence, and self-directedness) and with limited motivational aspects

of dietary restraint, whereby individuals limit the overall amount of food they eat, purposely go long periods of time without eating, and/or exclude foods from their diet as a means of influencing shape or weight. This chapter reviews the serious nutritional consequences associated with dietary restraint, self-induced vomiting, laxative misuse, and diuretic misuse and outlines the important role that dietitians may play in the treatment of purging disorder.

Introduction

Definition of Purging Disorder

Purging disorder is an eating disorder characterized by recurrent purging behaviors in the *absence* of objectively large binge-eating episodes in individuals who are not underweight. These purging behaviors are used to forcefully evacuate matter from the body as a means of influencing shape or weight and include self-induced vomiting and laxative, enema, diuretic, and medication misuse. Within the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders*, purging disorder is a specified condition included under the other specified feeding or eating disorder (OSFED) category (American Psychiatric Association 2013).

Purging disorder may be confused with other eating disorders such as anorexia nervosa and bulimia nervosa. Though there are some overlapping features between purging disorder and each of these disorders, respectively, it is a distinct condition (see Fig. 1). Purging disorder differs from bulimia nervosa in three ways. First, objectively large binge-eating episodes are a central feature of bulimia nervosa and do not occur in purging disorder. Second, although purging may occur in bulimia nervosa, it is not required. Individuals with bulimia nervosa may compensate for binge eating through fasting or excessive exercise. Neither of these constitute purging behaviors. Third, individuals with purging disorder may experience a loss of control over their eating, but this is not required for a diagnosis of the disorder, whereas loss of control is a required aspect of binge eating in bulimia nervosa. Purging disorder differs from anorexia nervosa in several ways. First, medically low

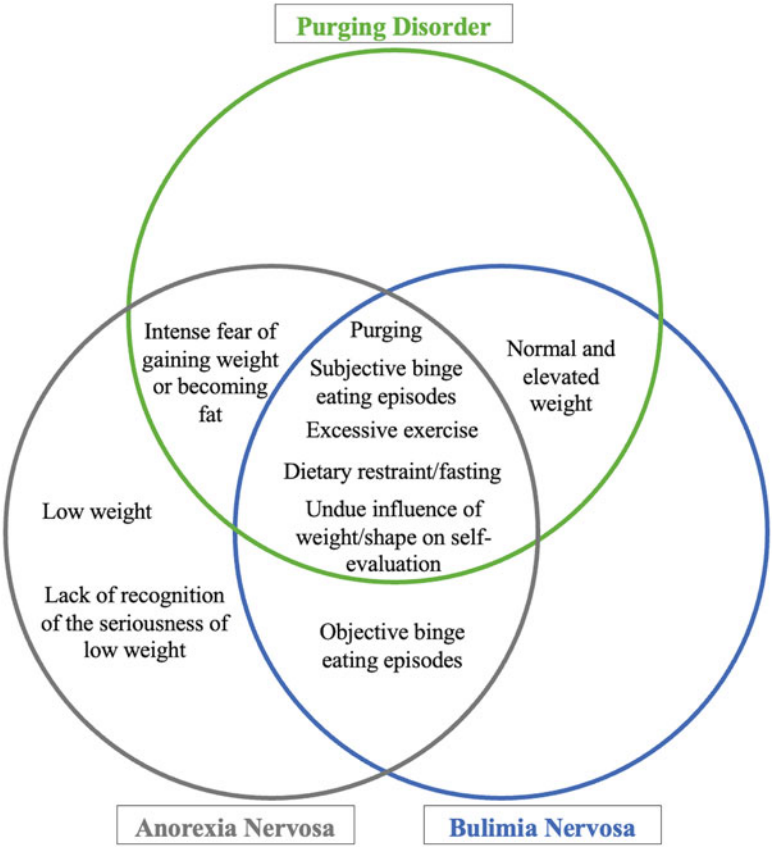

Fig. 1 Features of purging disorder, bulimia nervosa, and anorexia nervosa. This figure shows the overlapping and distinct features of bulimia nervosa, anorexia nervosa, and purging disorder

weight is a central feature of anorexia nervosa and is absent in those with purging disorder. In addition, although individuals with anorexia nervosa may engage in purging, this is not required for a diagnosis. Further, individuals with anorexia nervosa may engage in objectively large binge-eating episodes, and these do not occur in those with purging disorder for whom purging occurs after normal or small amounts of food.

Prevalence and Age of Onset

Studies examining the lifetime prevalence of purging disorder have reported estimates ranging from 1.1% in adult women (Favaro et al. 2003) to 6.2% in adolescent girls (Glazer et al. 2019). These differences may reflect secular changes that have been found for bulimia nervosa (Hudson et al. 2007; Kendler et al. 1991) and may

suggest that the disorder is becoming increasingly common in more recent birth cohorts. Alternatively, differences in assessment method or retrospective recall of conditions may account for this range (Moffitt et al. 2010). The prevalence of purging disorder does appear to be greater in adolescent girls and women than in adolescent boys and men (Mitchison et al. 2020; Keel 2020); however, it is important to note that purging disorder does occur in males. Finally, compared to bulimia nervosa and anorexia nervosa, purging disorder appears to have a later age of onset (Smith et al. 2017), with one study indicating peak age of onset between 18 and 20 years (Stice et al. 2009).

Biological Correlates

Despite purging and dietary restraint, individuals with purging disorder are not underweight. Recent findings suggest that this may reflect elevated premorbid body mass index (BMI). Specifically, Yilmaz et al. (2019) found that children who went on to develop purging disorder later in their lives had significantly higher BMIs by age 6 for boys and age 5 for girls, compared to children who did not go on to develop an eating disorder. Notably, this difference in BMIs between groups continued over time.

Although purging and dietary restraint do not produce a medically low weight in purging disorder, they may produce weight loss and maintenance of a weight below premorbid body weight (i.e., weight may be *suppressed*). Weight suppression is defined as the difference between one's highest prior adult weight and their current weight (Lowe 1993), and it has been shown to predict future onset of purging disorder (Stice et al. 2020). Weight suppression has also been identified as a predictor of illness maintenance in bulimic syndromes, including purging disorder (Keel and Heatherton 2010; Bodell et al. 2017). This association is mediated by heightened drive for thinness (Bodell et al. 2017).

Research has revealed several differences in biological responses to food among groups of women with purging disorder, women with bulimia nervosa, and women without eating pathology (Keel et al. 2007, 2018; Jimerson et al. 2010; Dossat et al. 2015). Compared to women without eating disorders, both the purging disorder and bulimia nervosa group have demonstrated elevated levels of ghrelin (Keel et al. 2018), a hormone which triggers hunger, and lower levels of leptin (Jimerson et al. 2010), a hormone that modulates energy balance in the body. These findings may reflect consequences of elevated dietary restraint and evidence of weight suppression in both groups and contribute to an increased drive to eat and feeling that eating is out of control.

In response to a standardized meal, women with bulimia nervosa have demonstrated significantly lower cholecystokinin (CCK) and glucagon-like peptide 1 (GLP-1) responses, hormones that signal the brain to stop eating a meal (Keel et al. 2018), compared to healthy women and women with purging disorder. This finding may contribute to excessive food intake in bulimia nervosa compared to

purging disorder and healthy eating. Finally, in response to a standardized meal, women with purging disorder demonstrated significantly greater increases in a hormone called peptide tyrosine tyrosine (PYY) compared to the other groups. This hormone signals the brain to delay onset of a subsequent meal, and the differences in this hormone predicted the differences in gastrointestinal distress across groups (Keel et al. 2018). Intact CCK and GLP-1 satiation signals combined with *excessive* PYY responses could help to explain why individuals with purging disorder do not consume an excessive quantity of food but feel as if they have eaten too much (Keel et al. 2018).

Summary

Purging disorder is an eating disorder that shares features with both bulimia nervosa and anorexia nervosa but represents a distinct constellation of symptoms. Similar to other disorders of eating, purging disorder is most commonly observed in women and girls, but it can affect men and boys. Unique biological correlates may account for purging in the absence of objectively large binge episodes among individuals who maintain a minimally healthy body weight. The remainder of this chapter will discuss the serious negative impact purging disorder can have on diet and nutritional status, specifically outlining how levels of nutrients (i.e., carbohydrates, fat, protein, water, vitamins, and minerals) may be altered by this disorder. Additionally, the important role that dietitians may play in the treatment of purging disorder will be outlined.

Effects of Dietary Restraint

What Is Dietary Restraint?

Dietary restraint includes behaviors such as limiting the overall amount of food one eats, purposely going long periods of time without eating (i.e., fasting), and excluding certain foods from one's diet as a means of influencing shape or weight. Individuals with purging disorder report dietary restraint at a level equal to or exceeding the levels of dietary restraint observed in other eating disorders. A review of purging disorder through meta-analysis revealed that individuals with purging disorder endorsed significantly greater dietary restraint compared to individuals with anorexia nervosa and binge-eating disorder and did not differ significantly from those with bulimia nervosa (Smith et al. 2017). Given differences in body mass index observed across eating disorders, self-reported differences between purging disorder and anorexia nervosa may not represent differences in actual food intake, particularly if those with anorexia nervosa underreport their symptoms. Despite this, it is clear that purging disorder involves elevated dietary restraint, which has negative consequences for nutritional status.

Micronutrient Deficiencies Associated with Dietary Restraint

Studies of micronutrient deficiencies in eating disorders characterized by food restriction elucidate potential nutritional consequences in purging disorder (see Table 1 for a summary of the vitamin deficiencies potentially associated with dietary restraint and purging). Specific micronutrient deficiencies linked to dietary restraint in eating disorders include calcium, iron, folic acid, vitamin A, vitamin B12, vitamin C, thiamine, vitamin D (Díaz-Marsá et al. 2017), vitamin B6 (Rock and Vasantharajan 1995), vitamin E, copper, and zinc (Humphries et al. 1989; Ross 2007; see Table 2 for a summary of the mineral deficiencies potentially associated with dietary restraint and purging). Each of these micronutrient deficiencies can have

Table 1 Potential vitamin deficiencies associated with purging disorder

	Dietary restraint	Self-induced vomiting	Laxative misuse	Diuretic misuse
A	X		X	
B1 (thiamine)	X	X		X
B6	X			X
B9 (folic acid)	X		X	X
B12	X			
C	X			X
D	X	X	X	
E	X		X	X
K		X	X	

This table summarizes vitamin deficiencies associated with dietary restraint, vomiting, laxative use, and diuretic use generally and thus represents possible vitamin deficiencies associated with purging disorder

Table 2 Potential mineral deficiencies associated with purging disorder

	Dietary restraint	Self-induced vomiting	Laxative misuse	Diuretic misuse

Copper	X			
Iron	X		X	
Magnesium		X		X
Manganese		X		
Phosphorus			X	
Potassium		X	X	X
Sodium		X	X	X
Zinc	X	X		X

This table summarizes mineral deficiencies associated with dietary restraint, vomiting, laxative use, and diuretic use generally and thus represents possible mineral deficiencies associated with purging disorder

different adverse effects. For example, a short-term B12 deficiency may cause fatigue, and a thiamine deficiency may exacerbate psychiatric symptoms, including depression and anxiety (Setnick 2010; Hart 2016). Individuals with purging disorder endorse elevated depression and anxiety (Keel et al. 2008), and micronutrient deficiencies should be considered as a potential underlying factor. As such, it is important for medical professionals to monitor potential micronutrient deficiencies in patients with purging disorder and consider nutritional supplements to address them.

Macronutrient Deficiencies Associated with Dietary Restraint

In addition to micronutrient deficiencies, individuals with eating disorders characterized by dietary restraint may also experience deficiencies in macronutrients (Reiter and Graves 2010) which include carbohydrates, fat, protein, and water. Carbohydrates are an important source of energy (Herrin and Larkin 2013), and insufficient carbohydrate consumption can have negative consequences such as muscle breakdown (Hart 2016). Insufficient fat consumption can lead to problems such as impaired growth and problems with reproduction (Jones and Rideout 2014; Hart 2016). Finally, protein deficiency can impair growth and contribute to problems with immune function (Wu 2009; Hart 2016). As with micronutrient deficiencies, it is important for medical professionals caring for individuals with purging disorder to monitor and treat potential macronutrient deficiencies.

Effects of Purging

Purging behaviors include self-induced vomiting, laxative/enema misuse, diuretic misuse, and medication misuse for the purposes of weight control. While each method of purging may be associated with a unique set of nutritional consequences, all methods can produce dehydration. Importantly, some individuals who engage in purging use multiple methods (Haedt et al. 2006), which may compound adverse effects on nutritional status. The following section will focus on the nutritional effects of self-induced vomiting, laxative misuse, and diuretic misuse.

Nutritional Consequences of Self-Induced Vomiting

Self-induced vomiting is the most commonly used method to evacuate matter from the body in purging disorder (Keel 2020; Forney et al. 2014). Self-induced vomiting is performed by stimulating the back of the throat to induce gagging, which causes the abdominal walls to contract and expel stomach contents such as food, fluids, and stomach acid. Over time, some individuals may gain the ability to vomit without physically stimulating the back of the throat (Mehler 2011). When an individual consumes food and then engages in self-induced vomiting, some of the food is

expelled from the stomach and thus never reaches the small intestine where the majority of nutrients are absorbed. Therefore, frequent self-induced vomiting contributes to nutrient deficiencies.

Both low potassium and low sodium have been directly linked to self-induced vomiting in individuals with eating disorders (Forney et al. 2016; Rock and Curran-Celentano 1996). Repeatedly engaging in self-induced vomiting causes the kidneys to eliminate potassium from the blood, which can result in hypokalemia (low potassium; Keel 2020). Self-induced vomiting also produces dehydration, which causes the kidneys to eliminate sodium, potentially resulting in hyponatremia (low sodium; Keel 2020). A retrospective chart analysis found that individuals with bulimia nervosa had significantly lower magnesium, manganese, zinc, calcium, potassium, ferritin, and vitamin D compared to individuals without eating disorders (Barron et al. 2017). Although these deficiencies cannot be solely attributed to self-induced vomiting (i.e., they could be a result of dietary restraint and/or other methods of purging), they do indicate *potential* nutritional consequences of self-induced vomiting which may be relevant to purging disorder.

Research on the effects of frequent vomiting in other conditions may generalize to effects of frequent self-induced vomiting. For example, frequent vomiting in the context of hyperemesis gravidarum (a disorder characterized by severe, persistent vomiting during pregnancy) has been linked with thiamine and vitamin K deficiencies (London et al. 2017). Severe, frequent vomiting in hyperemesis gravidarum and cyclic vomiting syndrome is associated with electrolyte imbalances, particularly hypokalemia (Lacy et al. 2018).

Nutritional Consequences of Laxative Misuse

Laxatives are used to eliminate stool from the body. There are several types of laxatives: bulk-forming, osmotic, lubricant, stool softeners, and stimulant. Bulk-forming laxatives (e.g., psyllium, methylcellulose) are fiber-based and work by absorbing additional liquid into the intestines in order to form a softer and bulkier stool. Osmotic laxatives (e.g., milk of magnesia, magnesium citrate) also increase fluid in the intestine to soften the stool. Lubricant laxatives (e.g., mineral oil) lubricate the stool allowing it to pass more easily through the intestines. Stool softeners (e.g., Colace) increase the amount of water in the stool. Finally, stimulant laxatives (e.g., senna, bisacodyl, castor oil) stimulate muscle contractions to move stool through the intestines more quickly. Bulk-forming laxatives and stool softeners work over the course of 1–3 days, while osmotic laxatives, lubricant laxatives, and stimulant laxatives typically produce a bowel movement within hours.

Stimulant laxatives are the most frequently misused among individuals with eating disorders (Roerig et al. 2010). Misusing stimulant and osmotic laxatives can result in the malabsorption of nutrients (Bo-Linn et al. 1983), by speeding passage of nutrients through the intestine too quickly for proper absorption. Fat-soluble vitamin deficiencies are a common result of laxative misuse (Anderson et al. 1997; Baker and Sandle 1996). Laxative misuse has also been linked with dehydration and low levels

Table 3 Potential nutrient deficiencies linked to laxative type

Laxative type	Potential deficiency
Bisacodyl (stimulant laxative)	Potassium
Magnesium hydroxide (osmotic laxative)	Iron Phosphate Folic acid
Mineral oil (lubricant laxative)	Beta-carotene Calcium Phosphorus Potassium Vitamin A Vitamin K Vitamin D Vitamin E

This table provides examples of specific nutrient deficiencies that have been linked to different types of laxatives

of potassium and sodium given that a significant amount of fluid and minerals are lost through diarrhea. Laxatives generally have been linked with specific nutrient deficiencies depending on the type used (see Table 3 for examples of potential nutrient deficiencies associated with specific laxative types; Moss 2007). These include deficiencies in iron, phosphate, folic acid, beta-carotene, calcium, phosphorus, vitamin A, vitamin K, vitamin D, and vitamin E (Moss 2007).

Nutritional Consequences of Diuretic Misuse

Diuretics increase urination to reduce water weight. Individuals with purging disorder may abuse prescription diuretic medications meant to treat high blood pressure (e.g., thiazides, furosemide), or they may use other agents that have diuretic effects (e.g., dandelion, caffeine). As with self-induced vomiting and laxative misuse, frequent diuretic misuse may lead to dehydration and electrolyte imbalances, particularly with regard to sodium, potassium, and calcium (Keel 2020). Diuretic misuse also often leads to deficiencies in magnesium, zinc, vitamin B1, vitamin B6, vitamin C, vitamin E, and folic acid (Moss 2007).

Role of the Dietitian

Dietitians can play an important role in treating purging disorder, similar to their role in the treatment of other eating disorders (Reiter and Graves 2010; Jeffrey and Heruc 2020; Heruc et al. 2020a; see Table 4 for a summary of their role). The scope of a dietitian's practice includes but is not limited to providing education on the importance of nutrition for overall well-being, correcting false beliefs about nutrition and weight, aiding in meal planning and the development of treatment goals, and treating nutritional deficiencies through use of nutritional supplements (Reiter and Graves

Table 4 Summary of the role of the dietitian

Key role of the dietitian
Recognize possible signs and symptoms of eating pathology
Recommend referrals to other clinicians and specialists (e.g., primary care physicians, psychologists, psychiatrists)
Debunk weight loss myths and fad diets
Recommend dietary supplements
Aid in meal planning
Aid in the development of treatment goals
Provide general nutrition education

This table summarizes the important role dietitians can play in the treatment of purging disorder

2010; Ozier and Henry 2011; Herrin and Larkin 2013). It is recommended that dietitians participate as a part of a larger, multidisciplinary team (Ozier and Henry 2011; Thomas 2000), rather than attempting to treat eating disorders alone. Their support may be most beneficial for patients with nutritional complications, for those at high risk of refeeding syndrome, and for those with comorbid conditions that may impact nutritional recommendations (e.g., diabetes, food allergies, inflammatory bowel disease; Heruc et al. 2020b).

Peebles et al. (2017) developed and tested an inpatient nutrition rehabilitation protocol that may be of interest to dietitians treating children or adolescents with eating disorders as part of a multidisciplinary team in an inpatient setting. This protocol provides details on how to determine developmentally appropriate clinical goal weights as well as calorie intake goals to promote weight restoration. Of note, clinical goal weights are based on the examination of the patient's premorbid historical growth curves (where the aim is to return to their premorbid growth trajectory), and it takes into consideration the patient's current pubertal stage, their cognitions, and their growth potential (Peebles et al. 2017).

In their book *Nutrition Counseling in the Treatment of Eating Disorders*, Herrin and Larkin (2013) emphasize the importance of nutrition counselors educating patients about "biologically appropriate weight," meaning a genetically predetermined bodyweight that is comfortably and easily maintained when not engaging in disordered eating behaviors (Herrin and Larkin 2013). According to Herrin and Larkin, a biologically appropriate weight is also consistent with premorbid weight. Herrin and Larkin recommend explaining to patients what biologically appropriate weight is and potential signs that a biologically appropriate weight has been achieved. These signs include no longer experiencing disordered eating behaviors, regular menses for biological females and normal testosterone levels for biological males, sufficient energy, and adequately consuming food in response to feelings of hunger and feelings of fullness (Herrin and Larkin 2013). The authors also provide more specific potential indicators of biologically appropriate weight that can be discussed with patients. These include a weight that is at least 10 to 20 pounds heavier than one's weight at high school graduation, a BMI between 20 kg/m^2 and 30 kg/m^2 for female adults, a BMI between 25 kg/m^2 and 35 kg/m^2 for male adults, and for children/adolescents, a weight between the 25th and 85th

percentile that is also consistent with their growth curve (Herrin and Larkin 2013). Although potentially challenging, helping individuals come to accept that there is a wide range of weights that can be considered biologically appropriate and that their own biologically appropriate weight may be higher than their current weight (or a weight that is promoted by one's family or culture) can be an important part of eating disorder treatment.

Dietitians may be the first healthcare professional consulted by an individual with purging disorder, making it important that they recognize possible signs and symptoms of eating disorders (Reiter and Graves 2010; Herrin and Larkin 2013). Because purging disorder can occur in any individual regardless of sex, gender, age, race, or ethnicity, universal screening for eating disorders is recommended. Dietitians should routinely assess for eating disorders in patients who have recently gained or lost a significant amount of weight, have significant concerns about body shape or weight, are adhering to restrictive diets (whether self-imposed or due to medical conditions like celiac disease or irritable bowel syndrome), report gastrointestinal symptoms, or participate in activities that are sensitive to weight or require meeting a specific weight criterion (e.g., dancers, figure skaters, wrestlers; Heruc et al. 2020a). In cases where a dietitian suspects an untreated eating disorder, they may begin by recommending referral to a primary care physician for bloodwork, including a work-up of electrolytes, manganese, phosphate, ferritin, vitamin B12, vitamin D, cholesterol, complete blood count, red cell folate, magnesium, and zinc (Barron et al. 2017). Dietitians may use lab results to inform recommendations for low-risk supplements to offset abnormalities caused or exacerbated by dietary restraint or purging, such as phosphate and B12 supplements (Barron et al. 2017).

When dietitians are the first healthcare contact, they should also refer patients for psychotherapy for their purging disorder. While providing therapy is outside the scope of a dietitian's practice, it is important for them to have a working knowledge of principles of evidence-based eating disorder treatment such as the importance of regular eating and psychoeducation surrounding the (lack of) efficacy of purging for weight control. This may require continuing education, as care of patients with eating disorders may not be adequately addressed in standard dietetic training (Heruc et al. 2020a). Dietitians should secure mutual release of information permission to coordinate the care they provide with others on a patient's treatment team, including but not limited to the primary care physician, psychotherapist, and, as relevant, psychiatrist, through regular team-based communication. Frequent communication among members of the treatment team is critical to a successful outcome.

Even after nutrient deficiencies are corrected, continued nutrition counseling may be required to address changing nutritional needs (Setnick 2010). The Australia & New Zealand Academy for Eating Disorders published extensive practice and training standards for dietitians providing eating disorder treatment to help clarify their role (Heruc et al. 2020a). These practice and treatment standards include detailed information for dietitians on how to properly screen for eating disorders; their professional responsibilities (e.g., engaging in clinical supervision); how to assess, diagnose, and treat nutritional issues; as well as how to monitor and evaluate progress made throughout intervention (Heruc et al. 2020a).

Conclusion

Purging disorder is an eating disorder characterized by recurrent purging behaviors to influence shape or weight in the *absence* of objectively large binge-eating episodes in individuals who are not underweight. Although purging is the central feature of the disorder, it is also characterized by high levels of dietary restraint. Both purging and dietary restraint have severe consequences for nutritional status that a dietitian should address as part of a multidisciplinary treatment team. When a dietitian suspects that a patient may have an undiagnosed eating disorder, an important first step may be recommending referral to a primary care physician for bloodwork, following guidelines for the medical management of eating disorders (Academy for Eating Disorders 2021). In addition to recommending low-risk supplements to offset deficiencies, dieticians have an important role to play in refuting myths about weight management, discouraging use of fad diets, and meal planning. Recently practice and training standards have been developed to clarify these important responsibilities in the care of patients with eating disorders.

Applications to Other Eating Disorders

In this chapter, the impact of purging disorder on diet and nutritional status and the role of the dietitian in treating purging disorder were reviewed. Information presented on the nutritional consequences of dietary restraint (i.e., micronutrient deficiencies, macronutrient deficiencies, and their associated effects) are applicable to eating disorders characterized by dietary restraint. Other eating disorders that involve dietary restraint include anorexia nervosa, bulimia nervosa, and other types of OSFED (e.g., atypical anorexia nervosa, bulimia nervosa of low frequency and/or limited duration). Information presented on the nutritional consequences of purging (e.g., micronutrient deficiencies, macronutrient deficiencies, electrolyte imbalances, dehydration, etc.) through self-induced vomiting, laxative misuse, and diuretic misuse is applicable to other eating disorders characterized by purging behaviors. Other eating disorders characterized by purging behaviors include bulimia nervosa, anorexia nervosa binge/purge subtype, and other types of OSFED (e.g., bulimia nervosa of low frequency and/or limited duration).

Information presented on dietitians' roles in treating purging disorder is applicable to all eating disorders. Indeed, helping to correct nutritional deficiencies, educating patients on the importance of nutrition for overall health and well-being, identifying and correcting false beliefs about nutrition, and meal planning are key aspects of the treatment of any eating disorder within the context of nutrition counselling.

Mini-Dictionary of Terms

- ***Macronutrients***. *Fat, protein, carbohydrates, and water.*
- ***Micronutrients***. *Vitamins and minerals.*
- ***Nutrients***. *Substances found in food and water that are essential for proper human development and functioning.*
- ***Other specified feeding or eating disorder***. *A specified condition in the fifth edition of the Diagnostic and Statistical Manual of Mental Disorders that encompasses clinically significant eating pathology that does not meet criteria for full-threshold anorexia nervosa, bulimia nervosa, or binge-eating disorder.*
- ***Purging***. *A behavior used to influence shape and/or weight that forcefully evacuates matter from the body.*

Key Facts of Purging Disorder

- Purging disorder was first officially recognized and defined as an other specified feeding or eating disorder in the 5th edition of the *Diagnostic and Statistical Manual of Mental Disorders* in 2013.
- Although individuals with purging disorder do not have binge-eating episodes, they may experience a loss of control while eating small or normal amounts of food. This is called a *subjective* binge-eating episode.
- While purging disorder appears to disproportionately affect women and girls, it also affects men and boys.
- Elevated pre-illness body mass index and weight suppression predict future onset of purging disorder.
- Individuals with purging disorder report elevated levels of depression and anxiety, which may be exacerbated by nutritional deficits (e.g., thiamine deficiency).

Summary Points

- Purging disorder is characterized by recurrent purging behaviors in the absence of binge-eating episodes in individuals who are not underweight.
- Purging behaviors include self-induced vomiting and laxative, enema, diuretic, and medication misuse.
- Individuals with purging disorder often engage in dietary restraint, whereby they limit the overall amount of food they eat, purposely go long periods of time without eating, and/or exclude foods from their diet as a means of influencing shape or weight.
- Dietary restraint and purging are associated with nutritional abnormalities, including macronutrient and micronutrient deficiencies.
- Dietitians can help to treat nutritional abnormalities associated with purging disorder as part of a multidisciplinary team.

Abstract

Purging disorder (PD) is a potentially debilitating eating disorder that is characterized by recurrent purging behaviors including self-induced vomiting or misuse of laxatives, diuretics, or other medications to influence shape or weight in the absence of objective binge eating. Evidence is mixed as to whether PD is more, less, or equally severe relative to other eating disorders that involve purging. Some researchers have questioned whether PD should be considered a unique diagnosis at all given the mixed evidence on the specificity of PD compared to other eating disorders. Yet, PD is common with lifetime prevalence rates ranging from 4 to 6%, and up to 7% of patients who present for treatment for an eating disorder having a diagnosis of PD. PD is also associated with a number of medical and psychiatric issues. Both psychological (emotion regulation, body dissatisfaction, trait anxiety, and cognitive restraint) and biological (satiety) factors have been identified as potential mechanisms in the development and maintenance of PD. In comparison to bulimia nervosa (BN) in which purging is used specifically to compensate for food eaten during an objective binge episode, in PD, purging may represent a persistent weight control strategy. Little has been written about whether or how treatment should differ for PD based on this functional distinction. Specific treatments for PD have not been developed and compared to existing evidence-based treatments making it difficult to know if treatment outcomes could be optimized by prioritizing the specific mechanisms (e.g., cognitive restraint, trait anxiety, satiety) that drive purging in PD.

PD	Purging disorder

Introduction

Purging disorder (PD) is a potentially debilitating eating disorder that is characterized by recurrent purging behaviors to influence shape or weight in the absence of objective binge eating (*American Psychiatric Association* [*APA*] 2013). Purging behaviors include self-induced vomiting, or misuse of laxatives, diuretics, or other medications (e.g., herbal supplements, thyroid medications, appetite suppressants, etc.). Up to 7% of patients who present for treatment for an eating disorder have a diagnosis of PD (Tasca et al. 2012; Vo et al. 2017). Differential diagnosis between PD and other eating disorders that involve purging behaviors, including anorexia nervosa (AN), binge eating/purging subtype (AN-BP), and bulimia nervosa (BN), can be challenging due to overlap in symptoms. Mixed evidence as to the specificity of PD on topographical (purging type and frequency), developmental (age of onset, course of illness), and treatment (prognosis, treatment outcomes) indicators has led some researchers to question whether it should be considered a separate diagnosis from BN at all. Little is known about whether or how treatment should differ for PD based on the core mechanisms implicated in its development and maintenance. Like other eating disorders, both emotion regulation and drive for thinness have been implicated as core mechanisms. However, differences from other eating disorders have been found in psychological (impulsivity, trait anxiety, cognitive restraint) and biological (hunger and satiety) mechanisms. This chapter will review key diagnostic differences between PD and the other eating disorders. Given the topographical similarities, special consideration will be given to differential diagnosis between PD and the other eating disorders that may involve purging behaviors, namely, AN-BP and BN. Next, the chapter will review potential mechanisms that are thought to contribute to its development and maintenance. Finally, considerations for treating PD will be highlighted. Before addressing these clinical questions, the chapter will begin by briefly defining PD and then describing the scope of PD's impact including prevalence, medical comorbidities, and psychosocial impairment.

Purging Disorder Defined

Traditionally, research on eating disorders focused on the diagnoses of AN and BN. However, over the last two decades there has been increasing recognition that a broader range of eating disorders exists. PD was added to the *Diagnostic and Statistical Manual fifth Edition* (APA 2013) as a subclass of the Other Specified Feeding and Eating Disorder (OSFED) diagnostic classification. The OSFED category captures symptom presentations that are characteristic of an eating disorder but do not meet the full criteria for a full-threshold eating disorder. For instance, symptoms that are limited in duration (e.g., symptoms occurring for less than 3 months), low frequency (e.g., binge eating or purging occurring less than once a week), or atypical in presentation (e.g., significant weight loss with a body mass index within the normal range) are generally subsumed under the OSFED designation.

PD is typically defined as recurrent purging behaviors in the form of self-induced vomiting, or misuse of laxatives, diuretics, or other medications for the purpose of influencing shape or weight, and in the absence of binge eating (APA 2013). PD shares many common features with other eating disorders. Thus, differential diagnosis between PD and other eating disorders that involve purging can be particularly challenging. Since the construct of PD was first introduced, the definition has evolved to better differentiate it from other eating disorders. Early on, some advocated for the inclusion of non-purging weight control behaviors such as fasting and compulsive exercise (Favaro et al. 2003; Keel et al. 2005; Machado et al. 2007). However, the current consensus favors the narrower inclusion criteria of recurrent purging in the form of self-induced vomiting or misuse of laxatives, diuretics, or other medications occurring at least once a week in order to prevent an overly heterogeneous diagnostic category (Glazer et al. 2019; Haedt and Keel 2010; Keel 2019).

Currently, a diagnosis of PD requires that the individual not be "underweight" (differentiating it from AN), not engage in binge episodes (differentiating it from BN), and engage in body image disturbance (APA 2013; Keel and Striegel-Moore 2009; Keel 2019). However, the *DSM-5* criteria provide little guidance as to how to define "underweight" or whether the binge must be "objectively large." Unlike BN, in which purging primarily functions to compensate for objective binge eating, in PD, purging is noncompensatory, meaning it occurs after eating small or normal-sized quantities of food. Individuals with PD often experience subjective binge episodes, in which they experience a loss of control during eating episodes that are not objectively large in quantity. This has led some researchers to argue for the inclusion of loss of control as a clinically significant feature of PD that should be included in its definition (Forney et al. 2014). Differences from other eating disorders may also exist with regard to the typical method of purging used. Some evidence suggests that compared to individuals with BN, individuals with PD are more likely to use laxatives rather than vomiting as their primary method of purging (Wade 2007), although not all studies have found a difference in methods (Binford and le Grange 2005).

Prevalence of Purging Disorder

In comparison to other eating disorders, PD is relatively common. Lifetime prevalence rates of PD in population-based surveys range from 3.8% to 6.2%, which is between two to three times higher than AN (1.3%) or BN (0.75%; Glazer et al. 2019; Keel 2019; Munn-Chernoff et al. 2015). Whereas the prevalence of PD is similar in treatment seeking and population-based samples (4.5–6.7%; Tasca et al. 2012; Vo et al. 2017), AN or BN have been shown to outnumber PD by as much as 17 to 1 in inpatient treatment settings, and 6 to 1 in outpatient treatment settings (Nakai et al. 2018). As will be discussed later in this chapter, these discrepancies in prevalence rates may be due to differences in severity, such that PD may be less likely to require intervention than AN or BN. At the same time, PD can be associated with dangerous physical and psychological consequences and can be chronic and difficult to treat. This raises the question of whether PD is less likely to be detected due to the absence of objectively impairing characteristics (e.g., low weight, binge eating) that may be more likely to draw clinical attention. In contrast, because purging behaviors are typically done in secret and may be easier to conceal, they may go unnoticed unless they occur frequently enough to cause significant functional impairment or medical instability, making them all the more dangerous.

In terms of demographic characteristics, similar to AN and BN, PD is more prevalent among women and girls than boys and men (Haedt and Keel 2010; Mitchison et al. 2020), and is particularly common among adolescents and young adults. However, the peak prevalence of PD extends across a wider age range (ages 16–27 years) than AN (ages 16–18) or BN (ages 19–22; Glazer et al. 2019). PD also has a later peak age of onset (18–20 years), and shorter illness duration than either AN or BN (Smith et al. 2017). PD is associated with higher premorbid BMI as early as age five (Yilmaz et al. 2019), and PD is associated with a higher BMI than AN but a lower BMI than BN (Krug et al. 2021). Together, these demographic characteristics paint a picture of PD as more common but potentially less enduring than AN or BN.

Impact of Purging Disorder

Research widely supports conceptualizing PD as a clinically significant disorder marked by impairments in eating and a number of other life domains (see Keel and Striegel-Moore 2009 for a review). Specifically, individuals with PD may experience serious medical complications and greater social, physical, psychological, familial, and educational impairment compared to those without an eating disorder (Forney et al. 2021; Haedt and Keel 2010; Krug et al. 2020). They are more likely to have been diagnosed with a comorbid psychiatric disorder (e.g., depression, anxiety, personality, substance use, or impulse control disorder) and report greater emotional distress and suicidality than those without an eating disorder (Allen et al. 2013; Smith et al. 2017). Because of these complications, PD is associated with increased risk of mortality, particularly in those with severe illness that requires inpatient treatment (Koch et al. 2013).

In terms of medical risk, the serious and life-threatening medical complications of purging behaviors are well-documented (see Forney et al. 2016 for a review). Self-induced vomiting is associated with a host of medical problems including dental complications (gum recession and tooth erosion, pain, and lesions), gastric reflux, heartburn, and irritable bowel syndrome all caused by excess stomach acid. Dehydration from self-induced vomiting and laxative or diuretic misuse also causes imbalances in key electrolytes like sodium, chloride, and potassium, which can result in kidney failure, arrhythmias, and, ultimately, cardiac arrest. Leaching of key nutrients can also cause muscular-skeletal complications like softening of the bones, muscle weakness, and muscle tenderness. Additionally, laxative misuse can result in impaired colon motility, bowel dysfunction, chronic diarrhea, constipation, and pelvic floor dysfunction. Due to these and other severe medical risks, it is critical that patients should be educated on the warning signs of such medical complications and instructed to follow up with a medical professional immediately. Because medical issues can progress quickly, close and regular medical monitoring is critical for patients with PD.

Differences between PD and Other Eating Disorders

While the available evidence widely supports the utility of classifying PD as a clinically significant eating disorder syndrome, the data are decidedly less clear on where it falls on the spectrum of severity in comparison to other eating disorders characterized by purging behaviors. Studies that have examined comparisons between PD, AN-BP, and BN on a range of eating and non-eating related outcomes have varied widely, with some studies finding PD to be less severe on a range of indicators (purging frequency, ED psychopathology, illness course, treatment outcomes) than either AN-BP or BN and others finding it to be equivalent or more severe than one or both (see Smith et al. 2017 for a review). This variability may be due to differences in sample (adolescent vs. adult), setting (treatment-seeking vs. community), and definitions of PD that are used. Indeed, clinical characteristics of PD (e.g., treatment response, BMI, ED psychopathology) have been shown to vary based on a number of severity indicators with more frequent purging and purging via self-induced vomiting (vs. other methods) showing worse outcomes (Krug et al. 2021). In an effort to make sense of these conflicting findings, Smith et al. (2017) conducted a meta-analysis comparing PD with other eating disorders. Results suggested that despite having similar duration of illness, PD may have a later age of onset, less pervasive course, and better treatment outcomes compared to AN-BP. At the same time, those with PD had more frequent purging behaviors and higher dietary restraint compared to AN-BP. Compared to BN, individuals with PD had higher remission rates over the natural course of the illness, along with lower eating disorder psychopathology, less frequent purging, and lower body dissatisfaction (Smith et al. 2017). Several studies have also found PD to be associated with lower rates of mood disorders and suicidality than either AN-BP (Koch et al. 2013) or BN (Keel et al. 2008; Roberto et al. 2010). In contrast, other studies suggest that

comorbid mood and anxiety disorders, substance use, suicidality, and psychosocial impairment are equivalent to or greater than that seen in either AN-BP (Tasca et al. 2012) or BN (Krug et al. 2021; Wade 2007). Meta-analytically, individuals with PD appear to have higher rates of substance use and equivalent levels of depression, anxiety, and suicidality compared to individuals with AN, but lower levels of depression, and equivalent levels of suicidality, anxiety, and substance use as individuals with BN (Smith et al. 2017).

Together this evidence suggests that PD is less severe than AN-BP on most severity indicators except purging frequency and dietary restraint. This is likely attributable to the negative impact of low weight associated with AN-BP, but the greater prominence of purging as a persistent weight control strategy in PD. Likewise, PD appears to be topographically similar and less or equally severe as BN on most, if not all, indicators, which has led a number of researchers to question whether PD should be conceptualized as a distinct disorder from BN (e.g., Ekeroth et al. 2013). Data on diagnostic crossover further support this argument, with diagnostic crossover rates up to 51% for BN to PD and 24% for AN-BP to PD (Eddy et al. 2010; Glazer et al. 2019). In contrast, low crossover in the opposite direction may point to the persistence of PD (Ekeroth et al. 2013; Koch et al. 2013). Indeed, PD has been shown to have diagnostic stability over a mean follow-up period of 10.2 years, with similar long-term prognoses as AN and BN (Forney et al. 2021). These findings have led researchers to highlight that at least some transitions into PD represent partial remission from another eating disorder rather than a "true" diagnostic crossover (Eddy et al. 2010; Ekeroth et al. 2013; Koch et al. 2013).

Clearly the research on where PD stands within the spectrum of eating disorders is mixed at best and in need of further empirical attention. There are several reasons why this might be the case. First, variability in how PD has been defined across studies has likely muddied the comparisons that can be made, and inconsistencies across studies should be contextualized in light of these different definitions. Second, severity is a broad construct that has been operationalized by a variety of indicators including frequency of ED behaviors, other ED psychopathology (e.g., dietary restraint, restriction, body dissatisfaction, etc.), age of onset, length of illness, and treatment outcomes (e.g., remission, drop out, loss of diagnostic status). The multitude of indicators makes clear comparisons across eating disorders challenging, particularly given that within each disorder individuals can vary greatly on these metrics. Third, and related to this point, one consistent theme that appears to emerge from the extant literature so far is that, despite efforts to reduce diagnostic heterogeneity, PD remains a broad diagnostic category that captures a wide range of severity. In this way, community samples may paint a much less severe picture of PD than samples in which patients are purging at a frequency that warrants inpatient treatment. As an example, some data suggest that in an inpatient setting, PD has a significantly higher mortality rate than BN (but not AN; Koch et al. 2013; Koch et al. 2014). However, because few existing studies have examined mortality rates, it is not clear if this finding is limited to PD in its most severe form, or extends to all presentations of the disorder. As such, overarching statements about the relative

severity of PD compared to other eating disorders characterized by purging may be less meaningful than an assessment of severity within the disorder itself.

Potential Mechanisms

A number of researchers have advocated for retaining PD as an independent diagnosis based on the fact that PD shows unique associations with certain clinical characteristics thought to drive engagement in ED behaviors. Specifically, purging in the context of AN-BP or BN is typically a method of compensating for binge eating, and is often driven by emotion regulation, negative affect, and impulsivity. In contrast, while PD does show associations with emotion regulation, as will be reviewed below, evidence suggests that purging in PD is more likely than AN-BP or BN to be used as a pervasive weight control strategy that is also motivated by anxiety and a drive for thinness. We review the evidence for each of these potential mechanisms in relation to PD below.

Overvaluation of Body Shape and Weight

Body dissatisfaction is a known transdiagnostic risk factor of eating disorders. A core tenet of the transdiagnostic cognitive behavioral theory of eating disorders (Cooper and Fairburn 2011; Fairburn et al. 2003) is that overvaluation of body shape and/or weight drives the use of eating disorder behaviors, specifically restriction, in order to control body shape and weight. For individuals who engage in bingeing and purging, bingeing is a consequence of restriction, and purging follows to compensate for the excessive food intake, which, in turn, further fuels overvaluation of shape and weight. In this way, the presence of binge eating maintains the eating disorder cycle in AN-BP and BN by promoting overvaluation of shape and weight and dietary restriction and restraint (Fairburn et al. 2003; Tabri et al. 2015). In support of this point, research has shown that presentations of PD which include subjective binge eating episodes are associated with significantly greater body dissatisfaction and negative affect as compared to when subjective binge eating is not present (Smith et al. 2017). Consequently, binge eating may be a particularly distressing symptom for individuals with AN-BP and BN given its close association with weight gain. In the absence of binge episodes, purging may be experienced as less naturally reinforcing, which shortens the course of the illness (Smith et al. 2017).

As noted, individuals with PD tend to have histories of higher childhood weight and may use purging to control eating due to longstanding dissatisfaction with their bodies. In support of this, a prospective examination of unique risk factors for different eating disorders found that PD was predicted by both body dissatisfaction and more frequent dieting compared to AN (which was predicted by negative affect and low BMI), and compared to BN (which was predicted by body dissatisfaction and overeating) (Stice et al. 2017). Thus, although body dissatisfaction increases risk

for most eating disorders, overeating was a specific risk factor for BN, whereas dieting uniquely predicted PD.

Hunger and Satiety

Biological evidence supports the notion that PD may represent a pervasive weight control strategy that differs from the impulsively driven compensatory purging that occurs in BN. Specifically, PD has been associated with similar degrees of cognitive restraint but lower degrees of hunger, food preoccupation, and fear of losing control over eating compared to BN (Keel et al. 2005; Wade 2007). This suggests that both disorders are marked by strict dietary rules, but that in PD, the use of purging is less motivated by the hunger and preoccupation with food that appear to motivate binge eating. These findings have been replicated in experimental studies that have shown that in individuals with PD, satiety-related hormones are significantly higher compared to individuals with BN, and on par with healthy controls (Dossat et al. 2015; Keel et al. 2018). In these studies, women with BN ate significantly more in an ad libitum meal test to reach the same level of fullness as women with PD, and both groups reported significant increases in gastrointestinal distress (nausea, stomach ache, and desire to vomit). Moreover, only individuals with PD showed elevations in the postprandial gut satiety peptide, PYY, which signals to the brain to delay the start of the next meal after eating has ended. Together, these findings support the idea that individuals with BN, but not PD, experience increased hunger and decreased satiety, which might contribute to the loss of control seen in binge eating, followed by purging to compensate (Keel et al. 2018). In contrast, in PD the combination of intact satiation (i.e., fullness) and excessive satiety (i.e., desire to delay eating after last meal) may promote the urge to vomit after consumption of normal amounts of food.

Emotion Dysregulation

There is a large body of literature indicating that eating disorder behaviors in general (Stice 2002), and purging behaviors in particular, function as behavioral strategies to cope with negative emotions (Keel et al. 2005; Keel et al. 2008; Wade 2007). In such cases, purging behaviors typically represent one of multiple forms of maladaptive coping that are used to manage or modulate negative emotions, along with other eating disorder behaviors, self-injury (e.g., cutting, burning, scratching, hair pulling), substance use, and/or risky sexual behaviors. Indeed, substantial research links purging symptoms to difficulties with emotion regulation. A more comprehensive review of this work in relation to BN and PD is covered in another chapter in this volume (▶ Chap. 41, "Emotion Regulation in Bulimia Nervosa and Purging Disorder"). Briefly, certain components of emotion regulation (e.g., negative emotionality, poor emotional awareness, and nonconstructive coping with negative emotions) may interact with body dissatisfaction to explain purging in the absence of binge eating. Extensive research demonstrates that negative affect may be a

particularly salient risk factor for binge eating and purging behaviors, with ecological momentary assessment data showing that in individuals with BN, negative affect is most elevated immediately before purging, decreases after purging, and then subsequently increases again (Haedt-Matt and Keel 2011). This pattern has also been found after purging in the absence of objective binge (Smyth et al. 2007) or subjective loss of control eating (Engel et al. 2013), as well as in individuals with PD (Haedt-Matt and Keel 2015). Such findings highlight the affect regulatory function of purging. Adding to this picture, a lack of positive affect has been shown to predict purging and to decrease more slowly when purging occurs compared to when it does not (Haedt-Matt and Keel 2015). Together, these findings demonstrate the negatively reinforcing function of purging in the context of PD through the combined effects of reducing negative affect and preventing decreases in positive affect.

Impulsivity

Impulsivity is a broad construct that has been examined widely with regard to different eating disorders. BN has been shown to be more highly associated with impulsivity compared to PD, which is thought to contribute to the compensatory nature of purging in BN (Fink et al. 2009). Specifically, lower scores on facets of impulsivity such as disinhibition (Roberto et al. 2010) and negative urgency (i.e., the tendency to act rashly when distressed; Davis et al. 2020) have been shown to differentiate BN from PD. Subjective binge eating in the context of PD also appears to be associated with higher levels of impulsivity and anxiety compared to individuals with PD who do not engage in subjective binge eating (Brown et al. 2011). Facets of impulsivity may also interact with overvaluation of shape and weight to predict noncompensatory purging, explaining some of the inconsistencies in the literature on the role of body dissatisfaction and related constructs in PD.

Some evidence suggests that behavioral inhibition – a facet of impulsivity marked by the tendency to withdraw from harmful situations (broadly, the opposite of negative urgency) – moderates the relationship between overvaluation of shape and weight and noncompensatory purging. Specifically, in one study, overvaluation of weight and shape had a stronger positive association with noncompensatory purging at higher (compared to lower) levels of behavioral inhibition. In contrast, when overvaluation of weight and shape was lower, behavioral inhibition appeared to protect against engagement in noncompensatory purging (Liebman et al. 2019). In combination with the weaker association with negative urgency, this finding suggests that noncompensatory purging in the context of PD may be associated with a temperamental disposition to avoid, rather than react to harmful or anxiety-provoking stimuli. In the context of high overvaluation of shape and weight, individuals with PD may evaluate purging behaviors as less harmful than the risk of gaining weight, leading to reliance on this behavior as a weight control strategy. In contrast, when shape and weight is not a primary concern, behavioral inhibition may actually dissuade individuals from engaging in this harmful weight control strategy. This is in line with research showing that PD is particularly associated with trait

anxiety (Brown et al. 2011). Other research has documented that harm avoidance is negatively associated with treatment drop out and positively associated with full or partial remission from PD (Riesco et al. 2018). These findings suggest that that recognition of the dangers of purging may be an important motivational factor for treatment of PD, particularly when overvaluation of shape and weight is high.

Treatment Considerations

Few treatment studies have examined treatment outcomes for PD specifically, and to date, no randomized controlled trials of PD treatment have been conducted (Keel 2019). In one case series of 57 patients with PD, dropout was high (37%) and full remission by the end of treatment was low (21%; Riesco et al. 2018). This data is preliminary and needs to be replicated in randomized controlled trials before conclusive statements about treatment outcomes for PD can be made. However, while not a treatment study, at least one longitudinal study of 563 non-treatment-seeking adolescents with PD showed a similarly persistent course of PD (31%) after one or more years of follow-up (Glazer et al. 2019). Clearly, for some individuals PD can be persistent and, as reviewed above, associated with a range of psychosocial complications that can cause serious long-term impairment. Current evidence-based eating disorder treatments such as CBT-E (Fairburn et al. 2008) are effective options for eating disorders, but have not been examined for PD specifically. Thus, it is not yet known if certain adaptations may be necessary to optimize treatment gains for this disorder. Below we highlight a few key clinical recommendations that clinicians should consider when working with someone with PD.

As noted earlier, in the absence of binge episodes, patients may be less motivated to change their purging behaviors due to the greater perceived benefits of being able to control their weight. Indeed, individuals with PD tend to report lower motivation to change their symptoms, and have a greater likelihood of treatment drop out than those with full spectrum eating disorders (Riesco et al. 2018). One potential explanation for this is that they may experience less severe physical consequences of their eating disorder, and therefore may be less motivated to stop the behaviors and continue in treatment. Indeed, an early study found that PD was associated with less distress related to the eating disorder, but equivalent impairment compared to BN, suggesting that despite the impairment it causes, individuals may not experience PD as problematic (Keel et al. 2008). This may be particularly the case for less severe presentations of the disorder where physical symptoms and impairment are not motivating enough to outweigh the perceived benefits of the behavior. Moreover, even for more severe presentations, individuals may view purging as an acceptable and controllable strategy to manage weight, akin to exercise, fasting, or other dieting behaviors. Thus, recognition of the dangers of purging may be an important motivational factor for treatment of PD, particularly when overvaluation of shape and weight is high. Clinicians should educate patients on the multitude of physical and psychological risks associated with purging, as well as the fallacy that purging is an

effective and controllable dieting strategy to help them re-evaluate their cost-benefit analysis of this behavior.

Second, the research summarized in this chapter highlights an important point regarding the function of purging behaviors in the context of PD. Namely, while purging in both BN and PD serves an emotion regulatory function, in BN, purging is more commonly used as an impulsive strategy to make up for excess food intake, whereas at least for some individuals, the function of purging in PD is a persistent and controlled strategy to maintain weight. In both cases individuals may use purging to cope with distress associated with emotion regulation difficulties. However, the disorders may differ in how purging is used to manage this distress (impulsively in BN vs. planfully and persistently in PD). Although CBT-E (Fairburn et al. 2008) is designed to be transdiagnostic, it is possible, (and to date untested) whether certain modifications may be necessary to address the unique cycle of ED thoughts and behaviors that characterizes PD. For instance, while restriction may still be a primary target, treatment may also need to prioritize targeting subjective binges through education about the difference between a binge and a normal-sized eating episode. Further, treatment of PD with CBT-E may require addressing dietary restraint early in treatment to identify food rules that trigger purging episodes and identifying food and body related beliefs that fuel overvaluation of shape and weight. Finally, in recognition of the fact that the precipitants for purging are multi-determined, patients with PD may benefit from a "purging analysis" earlier in treatment to help them identify the multitude of triggers (e.g., physiological symptoms, perceived loss of control, breaking a dietary rule, emotion dysregulation) for purging.

Third, treatment should also acknowledge the unique physiological processes that underlie PD and predispose individuals to experience nausea, stomach ache, and a desire to vomit after eating normal amounts of food (Keel 2019). Components of existing evidence-based treatments like CBT-E target these symptoms through psychoeducation on fullness as a barrier to regular eating and a trigger for non-compensatory purging (Fairburn et al. 2008). However, for some patients for whom behavioral inhibition and overvaluation of shape and weight is high, psychoeducation may not be enough. In such cases, the most effective treatment may incorporate exposure exercises to build patients' tolerance for these gastrointestinal symptoms after meals, in order to ultimately reduce them. However, such clinical techniques have yet to be examined in treatment studies.

Conclusion

Purging disorder is a debilitating eating disorder that affects a sizable minority of the population and carries with it significant physical and psychological consequences. Research on PD has grown considerably over the last two decades with the extant literature largely supporting that PD is a clinically significant disorder. However,

more research is needed to better understand how PD differs from other eating disorders including if it should be considered as categorically distinct, or is better represented as a subtype of eating disorders marked by purging. Currently, the extant literature on PD is mixed at best, which may be in part because it has relied on inconsistent and shifting definitions of the PD construct. Therefore, more research is also needed to clarify and standardize the diagnostic criteria for PD in order to ensure comparability across studies. Finally, treatment studies are needed to understand how PD responds to existing interventions for eating disorders and whether modifications are needed. Existing research points to the hypothesis that treatment outcomes could be optimized if motivation, dieting mindset, and physiological symptoms associated with eating are prioritized, although this also has yet to be tested directly. Addressing these questions could significantly enhance treatment effectiveness for this disorder.

Applications to Other Eating Disorders

Purging disorder (PD) shares many clinical features with other eating disorders. Anorexia nervosa (binge eating/purging subtype; AN-BP) and bulimia nervosa (BN) share the same features of purging with PD but are separate, standalone diagnoses in the *DSM-5* (APA 2013). PD is currently classified under the Other Specified Feeding and Eating Disorder (OSFED) diagnostic category along with other eating disorders that include purging behaviors, such as BN of low frequency and/or limited duration. Even within the OSFED category, the frequency and exact type of purging required for a diagnosis of PD compared to other eating disorders characterized by purging are not clearly described in the *DSM-5*, making accurate diagnosis challenging. On top of this, diagnostic crossover is common from full-threshold eating disorders to PD, suggesting that eating disorders may be better understood as a continuum of severity rather than discrete categories. Continued research using a standard definition is needed to help differentiate between PD and other eating disorders.

PD appears to respond to leading evidence-based treatments for eating disorders; however, there may still be opportunities for adaptation to optimize treatment response. First, high diagnostic crossover between eating disorders, and particularly from full-threshold eating disorders to PD, means that ongoing assessment of symptoms is critical to ensure that treatment prioritizes the most current symptom profile. Given the similarities of PD with other eating disorders, existing evidence and knowledge can be leveraged as a starting point in understanding and treating PD. For example, adaptations to enhanced Cognitive Behavioral Therapy for eating disorders (CBT-E; Fairburn 2008) may include addressing subjective binges by reframing the perception of an eating episode as a binge, rather than conducting a "binge analysis" or identifying and managing the precipitants for binges as would be the goal for BN or AN-BP.

Mini-Dictionary of Terms

Anorexia nervosa (AN): An eating disorder characterized in the *DSM-5* (APA 2013) by restriction of food intake resulting in significantly low weight (based on age, sex, etc.), intense fears of weight gain or behaviors that interfere with weight gain, and undue influence of weight and shape on self-evaluation or disturbance in how one perceives one's weight or shape.

AN includes two subtypes: 1) **Restricting type (AN-R)**, which refers to AN without recurring binge eating or purging in the last 3 months, and 2) **Binge eating/purging type (AN-BP)**, which refers to AN with recurring binge eating *or* purging in the last 3 months (i.e., self-induced vomiting or misuse of laxatives, diuretics, or enemas).

Binge eating disorder (BED): An eating disorder characterized in the *DSM-5* (APA 2013) by objectively large binge eating episodes occurring at least once per week for 3 months. Other potential features of a binge include eating faster than usual, eating until uncomfortably full, eating when not hungry, eating alone due to embarrassment, and feeling guilty afterwards. No recurring inappropriate compensatory behaviors (e.g., purging) are present for BED.

Bulimia nervosa: An eating disorder characterized in the *DSM-5* (APA 2013) by objectively large binge eating episodes *and* recurring compensatory behaviors to prevent weight gain (e.g., self-induced vomiting; misuse of laxatives, diuretics, or other medications; fasting; or excessive exercise). *Both* binge eating and compensatory behaviors must occur at least once a week in the last 3 months. There must also be undue influence of weight and shape on self-evaluation.

Some authors (e.g., Koch et al. 2013) further specify a **BN purging subtype (BN-P)**, which is not described in the *DSM-5*. This refers to BN in which the compensatory behaviors refer to purging behaviors and *not* fasting or excessive exercise.

Objective binge eating: A discrete eating episode (e.g., within 2 hours) in which the amount of food eaten is much larger than what most people would eat in similar circumstances, and importantly there is a loss of control (e.g., feeling like one cannot stop eating).

Other Specified Feeding and Eating Disorder (OSFED): An eating disorder characterized in the *DSM-5* (APA 2013) by clinically significant or distressing eating disorder symptoms that do *not* meet full criteria for another eating disorder. Examples include purging disorder (see below), atypical anorexia nervosa, and bulimia nervosa of low frequency or duration.

Purging disorder (PD): A type of eating disorder classified under OSFED in the *DSM-5* (APA 2013) in which recurring purging behaviors (e.g., self-induced vomiting or misuse of laxatives, diuretics, or other medications) are used to influence weight or shape. Binge eating is absent.

Outside of the official *DSM-5* description, researchers have more narrowly described PD as purging in the form of self-induced vomiting or misuse of medications (as described above), at the *exclusion* of fasting and excessive exercise, with

these behaviors occurring at least once a week (e.g., Glazer et al. 2019; Haedt and Keel 2010).

Subjective binge eating: Similar to an objective binge eating episode, there is a loss of control in eating, but the amount of food is not larger or is only minimally larger than what most people would eat in similar circumstances (e.g., a regularly sized meal or snack).

Key Facts of Purging Disorder

1. PD is a subclass of Other Specified Feeding or Eating Disorder (OSFED) in the *DSM-5*.
2. PD involves purging behaviors (e.g., self-induced vomiting or misuse of laxatives, diuretics, or other medications) in the absence of binge eating.
3. Unlike BN, in which purging primarily functions to compensate for objective binge eating, purging in the context of PD is non-compensatory, meaning it occurs after eating small or normal-sized quantities of food.
4. Individuals with PD often experience subjective binge episodes, in which they experience a loss of control during eating episodes that are not objectively large in quantity.
5. Exact definitions of PD, including severity, have evolved over time which may partly explain inconsistent findings in the literature.
6. Lifetime prevalence rates of PD in population-based studies range from 4% to 6% (Glazer et al. 2019; Keel 2019; Munn-Chernoff et al. 2015).
7. Current rates of PD range from 5% to 7% in treatment seeking samples (Tasca et al. 2012; Vo et al. 2017).
8. The peak age of onset of PD is later, and duration of illness is shorter (Smith et al. 2017) than AN or BN.
9. PD is associated with a number of medical (e.g., dental complications, electrolyte imbalances, and potentially fatal organ issues; Forney et al. 2016) and psychiatric issues such as depression and anxiety (Allen et al. 2013; Smith et al. 2017).
10. PD appears to be less severe than AN-BP on most severity indicators (e.g., comorbid mood disorders and suicidality; Koch et al. 2013), except purging frequency and dietary restraint (Smith et al. 2017).
11. PD appears to be less or equally severe as BN on most severity indicators (e.g., comorbid mood and anxiety disorders, suicidality, substance use; Keel et al. 2008; Krug et al. 2021; Roberto et al. 2010; Smith et al. 2017; Wade 2007).
12. Diagnostic crossover from BN to PD (up to 51%) and from AN-BP to PD (up to 24%) is high (Eddy et al. 2010; Glazer et al. 2019), whereas the reverse is not (3–5%; Ekeroth et al. 2013; Keel et al. 2005; Koch et al. 2013).
13. Purging in PD appears to represent more of a pervasive weight control strategy that is motivated by anxiety and a drive for thinness, whereas purging in the context of AN-BP or BN is more typically a method of compensating for binge eating, and is often driven by negative affect and impulsivity.

Summary Points

1. PD is a common and debilitating form of eating disorder, and research is mixed in terms of whether or not it is more, less, or similar in severity compared to other eating disorders with purging behaviors, such as AN and BN.
2. Mechanisms of action relevant to PD include emotion regulation, body dissatisfaction, trait anxiety, and cognitive restraint and satiety.
3. More research is needed that uses consistent definitions of PD to better differentiate it from other eating disorders.
4. More research examining treatment outcomes specifically for PD is needed to inform the development and tailoring of optimal treatments for PD.
5. Potential treatment adaptations for PD include addressing motivation for eliminating purging, providing psychoeducation on the psychological and physical consequences of purging, and addressing physical symptoms that may precipitate purging.

Body Weights and Mass and Links with Nighttime Eating

Contents

Abstract

Night eating syndrome is an eating disorder with the core features of evening hyperphagia and nocturnal eating. It is considered as a dysfunction of circadian rhythm which results in a dissociation between daily sleep and food intake rhythms. Out-of-phase eating can have adverse effects on the metabolism, such as increased risk of obesity and metabolic syndrome. Many studies have had outcomes supporting this view, presenting associations of nighttime eating with higher BMI, whereas other studies failed to find any association. This chapter provides an overview of the circadian rhythm of food intake and changes in

nighttime eating and details the effects of nighttime eating on body weight and disease management in individuals with diabetes. Studies on the genetic basis of nighttime eating and the proposed mechanisms underlying this disorder are also discussed.

Keywords

Nighttime eating · Night eating syndrome · Out-of-phase eating · Food intake · Body mass index · Obesity · Circadian rhythm · Sleep · Single nucleotide polymorphism · Hypocretin receptors · HCRTR1

Abbreviations

AN	Anorexia nervosa
BED	Binge eating disorder
BMI	Body mass index
ED	Eating disorder
HCRTR1	Hypocretin receptor 1
NE	Nighttime eating
NEQ	Night Eating Questionnaire
NES	Night eating syndrome
NPY	Neuropeptide Y
SCN	Suprachiasmatic nuclei
SNP	Single nucleotide polymorphism
T1D	Type 1 diabetes
T2D	Type 2 diabetes

Introduction

Food intake and energy expenditure are the two main determinants of body weight and adiposity, the latter often measured as body mass index (BMI) (Piaggi 2019). Eating disorders (EDs) may lead to changes in body weight and BMI since they dramatically affect food intake. In fact, BMI is an important criterion for differential diagnosis of ED types. For example, bulimia nervosa may be ruled out if the patient's BMI is below a specified threshold, and instead anorexia nervosa (AN) with binge/purge subtype might be considered as the appropriate diagnosis (Treasure et al. 2020). Similarly, binge eating disorder (BED) is characterized by obesity due to the recurrent episodes of excessive food intake (Monteleone and Maj 2008). Another ED that has been gaining increased attention due to its contribution to BMI is night eating syndrome (NES).

NES was first described in 1955 by Albert Stunkard as an eating pattern seen in people with obesity. The disorder manifested with nocturnal hyperphagia, insomnia, and morning anorexia. Nocturnal hyperphagia, the main feature of NES, was defined as consuming at least 25% of total daily calories during the evening and night hours (Stunkard et al. 1955). Since this original description of NES, the criteria for

nocturnal hyperphagia, insomnia, and morning anorexia have been modified in various literature (Striegel-Moore et al. 2006), the major change being the inclusion of nocturnal periods of waking from the sleep to eat into the definition of nocturnal hyperphagia by Birketvedt et al. (1999). In 2008, an international research meeting was held to establish consensus criteria for NES (Allison et al. 2010). The newly proposed criteria retained nocturnal hyperphagia as the core feature of NES and redefined it as >25% of daily caloric intake occurring after the evening meal, which might be accompanied or replaced by regular nocturnal awakenings (≥2 per week) for food intake. Sleep disturbances and morning anorexia are listed as possible features along with the other symptoms like depressed mood and a strong urge to eat before sleep onset (Allison et al. 2010). The proposed diagnostic checklist also included criteria for differential diagnosis: awareness of nocturnal eating episodes to distinguish NES from sleep-related eating disorder, not having another medical or psychiatric disorder as a primary diagnosis, and maintenance of nocturnal eating for over 3 months.

The prevalence of NES is estimated to be 1.5% in the general population (Vander Wal 2012) but is reported to be much higher in different study cohorts for obesity. In a study of bariatric surgery candidates by Allison et al. (2006), and a study of patients with obesity by Gluck et al. (2001), 9% and 14%, respectively, of the participants met the criteria for NES. However, most studies do not characterize individuals for NES, but instead only consider the core feature of NES, namely, the nighttime eating (NE) habit. Studies on NE showed an even higher prevalence (14%–36%) for this eating pattern among people with obesity (Adami et al. 2002; Cerú-Björk et al. 2001; Gluck et al. 2008), suggesting that NE might be causative for obesity. In support of a causative role for obesity, NE behavior as part of NES or as an isolated phenotype has been shown to predict weight gain (Gluck et al. 2008). This correlation is not surprising given the previous findings from out-of-phase eating and sleep restriction experiments. Out-of-phase food intake resulted in obesity in mice (Arble et al. 2009), while sleep restriction has been shown to increase food intake (Spaeth et al. 2013). It is important that the daily rhythms of food intake and sleep should be in harmony to maintain healthy weight.

Circadian Rhythm of Food Intake and Changes in Nighttime Eating

Food intake is regulated by homeostatic processes and circadian rhythm in the body. Homeostatic regulation of food intake is under control of two opposing pathways: orexigenic and anorexigenic pathways. These pathways involve the actions of anorexigenic and orexigenic agents such as leptin, ghrelin, insulin, neuropeptide Y (NPY), and α-MSH, as well as anorexigenic and orexigenic neuronal populations residing in the hypothalamus (Huvenne and Dubern 2014). Anorexigenic pathways act after meals by increasing satiety. The adipocyte-derived hormone leptin binds to the leptin receptors in the hypothalamus and activates POMC-expressing neurons while inhibiting NPY expressing neurons. POMC is cleaved into α-MSH peptides,

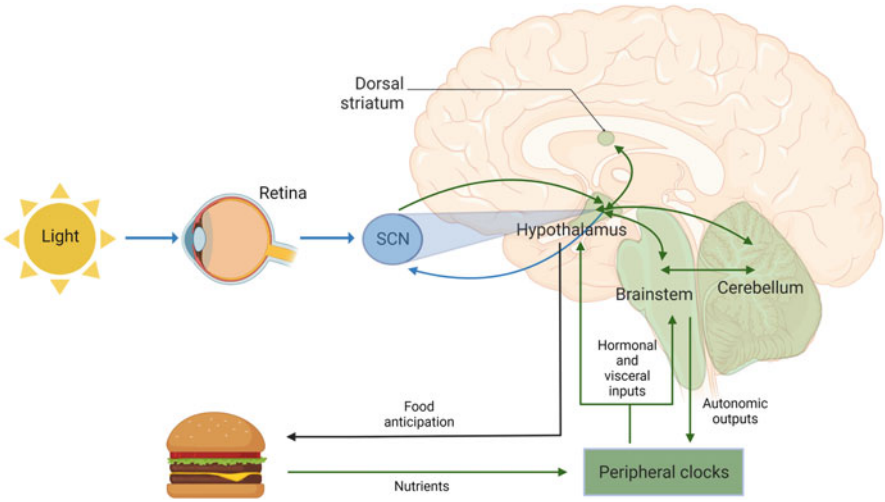

Fig. 1 Circadian control of feeding by the master and the secondary clocks. Circadian clock systems and their interaction with each other and the environmental cues. The master clock and its entrainment pathway are shown in blue. The secondary clocks and their entrainment pathways are shown in green. Circadian rhythmicity enabled by the master and food clocks enables the organism to predict food availability and engage in food anticipatory behavior. SCN = suprachiasmatic nuclei. Created with BioRender.com

which can bind to MC4R and MC3R. This interaction results in a suppression of food intake (Zegers et al. 2012). Orexigenic pathways are predominant in the fasted state, during which ghrelin is released from the gastric cells and activates the NPY and Agouti-related peptide expressing neurons in the hypothalamus (Nakazato et al. 2001).

In addition to hormonal regulation, circadian rhythm is one of the main systems in the regulation of food intake. Circadian rhythm is the internal process of organisms that predict the day-night cycle to regulate physiological functions accordingly. Circadian rhythmicity is enabled by endogenous clocks including a master clock located in the suprachiasmatic nuclei (SCN) of the hypothalamus and several secondary clocks in the brain and peripheral organs (Challet 2019) (Fig. 1). The master clock is synchronized by light; however, when light is absent, the master clock sustains itself and generates ~24 h cycles (Froy 2011). The secondary clock system in the brain and periphery can be reset by other environmental and physiological clues (Fig. 1). The secondary circadian system involved in food intake is referred as the food clock, and it can be readjusted by the timing of food intake via a feedback mechanism. The food clock together with the master clock sets daily windows for food intake that mostly occur during the daily active phase of an animal. Within these feeding windows, animals present behavioral anticipation for the food (Challet 2019). Secretion of many hormones involved in metabolism oscillate in sync with feeding windows, showing peak levels during anticipated feeding or fasting phases (Challet 2015).

Delayed Timing in NE and Its Consequences

The sleep-wake cycles of people with NES are typically undisturbed despite regular nocturnal awakenings (O'Reardon et al. 2004). However, their circadian rhythm of food intake is delayed. These observations suggested a dissociation of the circadian clocks of sleep and food intake (O'Reardon et al. 2004). Delayed timing of eating seen in NES and NE may reset the secondary circadian clocks, since these can be entrained by meal timing. However, the master clock in the SCN cannot be reset by habitual late eating because it is synchronized only by light (Challet 2019). Therefore, out-of-phase eating results in desynchronization of circadian clocks. For example, meal anticipation triggers an increase in plasma cortisol levels, yet a major cortisol peak always occurs early in the morning regardless of eating or skipping breakfast (Bogdan et al. 2001). Out-of-phase eating, such as Muslims practice during Ramadan, results in a totally different pattern of cortisol oscillation rather than a simple delay (Bogdan et al. 2001).

As a result of the complex interactions between circadian clocks and metabolic hormones, out-of-phase eating can have adverse effects on metabolism (Challet 2019), such as increased adiposity or metabolic syndrome (Allison et al. 2014). It has been shown that night shift workers have a higher prevalence of obesity, type 2 diabetes, and cardiovascular disease (Akerstedt and Wright Jr 2009). Circadian disruptions in shift work give rise to decreased insulin sensitivity and increased blood pressure (Scheer et al. 2009). Similarly, NE behavior results in a change in neuroendocrine profiles leading to weight gain (Birketvedt et al. 1999; Gluck et al. 2008).

Hormone Profiles in NE

Many hormones involved in metabolism exhibit circadian oscillation, and their rhythms and plasma levels change in NES. In a study of neuroendocrine profiling in NES, daily phases of ghrelin were similar between NES cases and controls, but the nocturnal levels were significantly lower in NES cases (Allison et al. 2005). The same study reported that leptin, melatonin, and cortisol did not show a significant difference between NES and control groups; however, an earlier study reported lower nocturnal plasma levels for leptin and melatonin and higher plasma levels for cortisol throughout the day (Birketvedt et al. 1999). Based on their findings, Allison et al. (2005) concluded that the differences in plasma hormone levels between NES and control groups were likely to be the result of the altered timing of food intake rather than the cause. A 2009 study (Goel et al. 2009) focused more on the pattern of circadian rhythms of the hormones rather than plasma concentrations. They found that people with NES have 1–3 h phase delays for circadian rhythms of leptin and insulin and about 5 h phase advance for ghrelin. These studies showed that the general pattern of daily peaks and lows was similar for both NES and control groups with a variation on the timing and the amplitude of the plasma level peaks, suggesting that the circadian disruption is not as prominent as more drastic changes

in eating patterns such as fasting during Ramadan. Although neuroendocrine characteristics have been reported only for people with NES, as opposed to people with NE habit with or without the additional phenotypes of NES, similar circadian changes may be predicted for NE phenotypes in general based on our current knowledge on the relation of meal timing and circadian rhythms.

Assessment of NE

As mentioned above, NE is characterized by the consumption of at least 25% of daily caloric intake after dinner and/or at least two episodes of nocturnal eating per week. However, in the absence of nocturnal eating episodes, it can be difficult to be certain of the NE phenotype because different cultures/societies eat dinner at different times in the evening. Allison et al. have proposed that dinner be defined as the first meal occurring between 5 pm and 8 pm (Allison et al. 2010), and subsequent food ingestions are regarded as calories consumed after dinner. However, in many parts of the Mediterranean, Asia, and South America, the standard dinner time is well after 8 pm, the most well-known examples being Spain and India. Therefore, nocturnal eating seems to be more reliable factor in characterization of NE. The time frame for nocturnal ingestion is usually taken as the 6–8 h period starting after 10 pm or 11 pm ((Gluck et al. 2008; O'Reardon et al. 2006).

The Night Eating Questionnaire (NEQ) is a widely used tool to assess the presence and the severity of NE. The original 9-item NEQ was later expanded to include 14 questions about daily food intake and sleeping pattern (Allison et al. 2008; Gluck et al. 2001; Marshall et al. 2004), and modified versions of NEQ have been developed to be used in children (Lundgren et al. 2012) or to include additional phenotypical assessments related to NES (Innamorati et al. 2018). In outpatient study settings, diary data logged by the participants frequently accompanies NEQ for NE assessment. Participants keep daily logs about their food intake as well as sleep and mood (Birketvedt et al. 1999; Lundgren et al. 2008; O'Reardon et al. 2004). In addition to diaries, some studies include the use of motion sensors to keep track of an individual's nightly awakenings (Birketvedt et al. 1999; O'Reardon et al. 2004).

After the first description of NES (Stunkard et al. 1955), NE and NES have rarely been assessed in inpatient settings, where phenotyping can be done with more accuracy (Allison et al. 2005; Birketvedt et al. 1999; Gluck et al. 2008). One exception is a study by Gluck et al. (2008), which utilized computerized vending machines (Venti et al. 2009) in an inpatient setting to allow for ad libitum access to food 24 h per day. The vending machine recorded both the time of use and the quantity of food selected such that nocturnal ingestions could be precisely recorded, enabling a robust phenotyping within the study group.

Effects of NE on Weight Management and Diabetes Management

NE and BMI

Numerous studies have examined whether there is a relationship between NE and BMI. Many studies have reported a positive correlation (de Zwaan et al. 2014; Gluck et al. 2008; Kucukgoncu et al. 2014; Morse et al. 2006); however, other studies have found no association between NE and BMI (Cerú-Björk et al. 2001; Friedman et al. 2006; Melo et al. 2018; Runfola et al. 2014). The main limitation for most of these studies is that the phenotyping depends on questionnaires for NE and self-reported height and weight values for BMI; therefore, there could be differences due to accuracy of the data. In addition, most of these studies are cross-sectional and compare the BMI of NE and non-NE groups at the time of recruitment; therefore, these cross-sectional data cannot be used to predict weight gain over time. The study by Gluck et al. (2008) was one of the few studies that did include follow-up data on weight measurements, and this study concluded that NE is related to weight gain. Nevertheless, this study was listed in a review (Gallant et al. 2012) among those with negative findings for BMI and NE relation because the baseline BMI values did not differ between NE and non-NE groups.

Several theories have been proposed to explain the discrepancy in findings of a relationship between NE and BMI. For example, Gallant et al. proposed that the genetic background of a person and/or population could affect the relationship between NE and BMI (Gallant et al. 2012). Another theory has been that weight gain is gradual and cannot be easily observed in cross-sectional studies of young adults (Bruzas and Allison 2019). Supporting this view, Meule et al. (2014a) showed that NE was positively associated with BMI specifically in a sample of middle age to older adults (ages 31–60). Given that the mean ages of individuals differ greatly among studies examining NE and BMI, age could be an important moderator on this relationship. Yet another explanation for the lack of association between NE and BMI in some studies could be differences in compensatory behaviors. For example, some people with NE could participate in excessive exercising and/or calorie restriction during the day (Bruzas and Allison 2019; Lundgren et al. 2008; Runfola et al. 2014). Runfola et al. (2014) found that university students with NES were significantly more likely to have histories of being underweight due to past AN. Therefore, the relationship between NE and BMI may be complex, and although the few studies with BMI follow-up data report gradual weight gain in individuals with NE (Andersen et al. 2004; Gluck et al. 2008), more studies with follow-up data are needed to fully understand the long-term effects of NE.

NE and Diabetes

EDs have been suggested to affect individuals with either type 1 diabetes (T1D) or type 2 diabetes (T2D). Among people with T2D, the more prevalent form of diabetes, around 40% of people have an ED. NES and BED are the two most

common forms of EDs seen in T2D populations (García-Mayor and García-Soidán 2017). A study of NE in relation to T2D found that 7% of participants with T2D met the diagnostic criteria for NES, a prevalence higher than the general population (Hood et al. 2014). Similar to what has been reported among individuals with T2D, NE was observed in about 8.5% of people with T1D (Morse et al. 2006).

NE behavior has also been proposed to increase difficulty in diabetes management (Hood et al. 2014; Vander Wal 2012). Poor dietary habits among individuals with NE, such as breakfast skipping, may be one cause of poor glycemic control (Hood et al. 2014). Since NE is a prevalent comorbidity in diabetes and has adverse effects on the disease management, it must be assessed in patients with T1D and T2D along with the other types of EDs.

Etiology of Nighttime Eating and Links to BMI

Psychological Factors

The original study that describes NES suggested that this disordered pattern of eating was a response to stress (Stunkard et al. 1955). In fact, the NES cases presented in that study suffered from traumatic life events and periods of high stress and anxiety, which coincide with the reoccurrences of NES symptoms. Later studies showed that emotional triggers are associated with NE. Emotional regulation was suggested to be a moderator of the NE and BMI relationship (Meule et al. 2014b). Data from questionnaires indicate that high levels of emotional eating are associated with NE severity and BMI (Meule et al. 2014b). NE has also been found to associate with stress, anxiety, and depression (Borges et al. 2017). Techniques that reduce stress and anxiety were found to be helpful in managing NE, indicating that these psychological factors have a role in NE (Pawlow et al. 2003). Depressed mood and major depressive disorder are highly comorbid with NE (Vander Wal 2012). Although it is not clear that depression, anxiety, and stress have a causative role in NE, the presence of any of these mental conditions is more common among individuals with NE (Bruzas and Allison 2019).

Genetic Components

Familial aggregation has been shown for NES indicating that genetic factors contribute to this ED (Lundgren et al. 2006). However, to date, very few genetic studies have been conducted for NE. Since NE can be conceptualized as a disorder of circadian rhythm of food intake, the circadian clock genes (Rijo-Ferreira and Takahashi 2019) have been the most studied candidate genes for NE. Liu et al. (2014) studied the *PER1* gene which is a member of the period gene family and one of the main clock genes. *PER1* is expressed in the SCN, and in studies of mice, a mutation in this gene caused a change in peak time of food intake.

Although findings from animal models can help to establish a set of candidate genes to search for variations underlying the heritability of NE, genetic studies of NE in humans are very limited. One study in humans analyzed the *VGF* gene as a candidate based on a database search (Sabbagh et al. 2016). However, conducting a genome-wide association study for NE, which is the standard method for identifying genetic variants that contribute to a polygenic trait, is challenging because no large cohorts of individuals clinically characterized for NE currently exist. In contrast to NE, common types of EDs, such as AN, do not have these sample size limitations, and genome-wide association studies have been performed on thousands of individuals characterized for AN (Wang et al. 2011).

A small study by Köroğlu et al. (2020) is the only genetic study, to our knowledge, that utilized data from humans who were clinically characterized for NE. Rather than conduct a genome-wide association study which lacked power in their small sample of cases and controls, this study assumed a correlation between NE and BMI and therefore only considered a preselected set of variants that have been shown to significantly associate with BMI in large cohorts from the Genetic Investigation of Anthropometric Traits (GIANT) and UK Biobank databases (Yengo et al. 2018). Among these BMI-associated variants, Koroglu et al. determined that variation in *HCRTR1* also associated with NE in their sample of inpatients characterized for NE. *HCRTR1* encodes hypocretin (also known as orexin), whose physiology (detailed below) gives credibility to the association results. However, future genome-wide studies with large, well-powered sample sizes could uncover the role of additional genes that contribute to NE and NES.

Hypocretin Receptors and NE

The hypocretin (also known as orexin) system can be regarded as the junction of the sleep and feeding regulation mechanisms. It has been considered as one of the secondary circadian clocks regulating food intake. Hypocretin 1 and 2 peptides are encoded by *HCRT* in the hypothalamus. *HCRT* is a clock-controlled gene, and its expression varies during the day (Challet 2019). Hypocretin neuropeptides are endogenous ligands for two G-protein-coupled receptors, hypocretin receptor 1 encoded by *HCRTR1* gene and hypocretin receptor 2 encoded by *HCRTR2* gene (Sakurai 2007). Hypocretin-producing neurons originating from the hypothalamus innervate the entire brain and regulate sleep and stimulate feeding.

The different types of hypocretins and their distinct receptors are thought to have unique physiological roles (Marcus et al. 2001). Mutations in *HCRT* and *HCRTR2* cause narcolepsy (Hungs and Mignot 2001; Lin et al. 1999; Peyron et al. 2000), whereas no mutation in *HCRTR1* was found in human narcolepsy cases, and Hcrtr1 knockout mice, unlike Hcrtr2 knockout mice, did not present disturbed wakefulness and rapid-eye movement sleep patterns (Sakurai 2007). The involvement of *HCRTR1* in feeding is better supported than its role in sleep. Intraperitoneal injection of hypocretin receptor 1 antagonist reduced feeding in rats, revealing the important role of Hcrtr1 in mediating food intake (Haynes et al. 2000). It has also been found

that Hcrtr1, but not Hcrtr2, is upregulated in response to fasting (Lopez et al. 2000). These studies reveal the important functions of hypocretins and their receptors in feeding and sleep regulation and indicate the divergence in functions between the receptors, which makes them intriguing candidates for increased risk of NE.

Applications to Other Eating Disorders

In this chapter we have reviewed neuroendocrine changes due to NE and the adverse effects of this habit on weight management and diabetes and discussed the genetic and environmental factors that might contribute to the development of NE. We also described the characteristics of NES, an ED with NE as the main feature, which is included in the *Diagnostic and Statistical Manual of Mental Disorders*.

Although NES was previously considered as a disorder similar to BED (Napolitano et al. 2001), according to the current view, diagnosis of any other ED excludes NES (Cleator et al. 2012). Therefore, NES cannot be comorbid with another ED. On the other hand, NE is reported to be common in individuals with a diagnosis of other EDs (Lundgren et al. 2011). This indicates an overlap in causes, including genetic factors. Therefore, a genetic susceptibility locus identified for NES could be a candidate locus for another ED and vice versa.

Identification of genes and/or genetic variants that contribute to ED could help in understanding the underlying physiology and lead to improved therapies and or drug targets. A major challenge for these genetic studies is the lack of large datasets of robustly phenotyped individuals for the less common EDs. Until large samples are collected for the uncommon EDs to allow for adequately powered genome-wide association studies, hypothesis-based studies must be conducted. For example, if a particular eating phenotype is consistently associated with a higher or lower BMI or another anthropometric trait, genetic data from current large biobanks could be used in conjunction with the genotyping results from the limited sample of that ED. This strategy, employed by Köroğlu et al. (2020) who restricted their analysis of genetic determinants for NE to only variants known to affect BMI, uncovered a compelling candidate for NE. Knowledge of risk variants that are unique to a specific ED could aid in the diagnosis. In addition, merging information on metabolic pathways affected by genetic risk factors with knowledge of environmental influences may ultimately lead to better treatment of EDs.

Mini-Dictionary of Terms

- ***Anorexia***. *Markedly reduced appetite or complete aversion to food*
- ***Bariatric surgery***. *Variety of procedures performed on the stomach or intestines to induce weight loss in people with obesity*
- ***Body mass index***. *A measurement derived from the weight of a person in kilograms divided by the square of their height in meters. It is expressed in units of* kg/m^2*, and it is the most used value to determine adiposity*

- ***Circadian rhythm***. *The internal process of the organisms that predicts the day-night cycle and regulates the physiological functions*
- ***Genome-wide association study***. *In this method, the genomes in a sample set including phenotypically different individuals are scanned using genetic markers, and the differences in the allele frequencies of those genetic markers are used in statistical tests to identify associations of genotypes and phenotypes*
- ***Hyperphagia***. *Abnormally increased appetite and excessive hunger*
- ***Narcolepsy***. *A neurological disorder characterized by a disorganization of sleep and wakefulness. Patients with narcolepsy have disturbed sleep during the night and chronically sleepy during the day. They tend to prematurely enter rapid-eye-movement sleep phase*

Key Facts of Night Eating Syndrome

The main diagnostic criterion is the presence of nighttime eating, which is defined as intake of >25% of daily calories after the evening meal and/or the occurrence of regular nocturnal awakenings (≥2 per week) for food intake.

The patients are aware of and recall their nocturnal eating episodes.

To be diagnosed with night eating syndrome, at least three of the following five symptoms must be present: morning anorexia, strong urge to eat after dinner and before sleep, having sleep onset or sleep maintenance problems at least four nights per week, believing that one must eat to initiate or return to sleep, and depressed mood that worsens in the evening.

At least 3 months of nighttime eating must have been maintained to consider night eating syndrome diagnosis.

Night eating syndrome diagnosis is considered only if the disordered pattern of eating is not secondary to substance abuse or another psychiatric disorder.

The prevalence of night eating syndrome is about 1.5% in the general population.

Treatment options include medications such as selective serotonin reuptake inhibitors and nonmedical interventions, mainly cognitive behavioral therapy.

Summary Points

- *Food intake is regulated by homeostatic processes and circadian rhythm in the body*
- *Nighttime eating is a disruption in circadian rhythm with a dissociation between eating and sleeping rhythms*
- *Out-of-phase eating seen in nighttime eating results in a change in neuroendocrine profiles*
- *Many studies showed that nighttime eating is associated with a higher BMI, and studies with follow-up weight measurements reported gradual weight gain in people with nighttime eating*

- *Nighttime eating is also associated with poor glycemic control and poor dietary habits in patients with type 2 diabetes*
- *Assessment of nighttime eating commonly includes questionnaires and food diaries*
- *Familial aggregation indicates genetic factors for nighttime eating, and the genetic background could be one of the major contributors to the NE and BMI relationship*
- *Circadian clock genes and others involved in sleep and feeding regulation such as hypocretin peptides and their receptors have been highlighted as candidate genes for nighttime eating*
- *A genetic susceptibility locus identified for night eating syndrome can be a candidate locus for another eating disorder because of the overlap of symptoms*

Abstract

Night eating syndrome (NES) is an eating disorder (ED) characterized by a disrupted circadian rhythm that results in aberrant sleep, mood, and eating behaviors. The core features of NES include evening hyperphagia (i.e., consumption of $\geq$25% of total daily calories after the evening meal) and/or nocturnal ingestions of food after awakening from sleep. The conceptualization of NES has been informed by the medical model paradigm of disease, which assumes the presence of a distinct, underlying mechanism that causes symptoms. Utilizing this paradigm presents challenges for research and practice related to NES, as the causal mechanisms of NES are relatively unknown and conceptualization of NES has varied considerably over the past few decades. In response to the limitations of the medical model paradigm, recent work on EDs has focused on reconceptualizing ED psychopathology using the network approach to psychopathology. This approach focuses on identifying (a) functional, causal interactions among symptoms and (b) symptoms most important to specific disorders. This chapter provides an exploration on the conceptualization of NES when examined through this network approach. First, this chapter examines the history of NES conceptualization through a medical model lens. Next, it offers an overview of network analysis, emphasizing the methodology used to model the network approach to psychopathology. Findings from recent work on NES using network analysis are also presented. Finally, research and clinical implications from this study will be provided, as well as future directions for network analysis of NES.

Introduction

Night eating syndrome (NES) is an eating disorder (ED) characterized by a disrupted circadian rhythm that results in aberrant sleep, mood, and eating behaviors (Muscatello et al. 2021). Indeed, individuals with NES experience a delay in their circadian pattern of food intake, which manifests as the two core features of NES: (a) evening hyperphagia (i.e., consumption of $\geq$25% of total daily calories after the evening meal) and/or (b) nocturnal ingestions of food after awakening from sleep (Allison et al. 2010). These individuals must also demonstrate awareness of their eating (i.e., they must be awake while eating), experience possible morning anorexia and/or concomitant mood or sleep disturbances, and exhibit distress or impairment for at least 3 months (Allison et al. 2010).

Historically, conceptualization of NES has been guided by the medical model paradigm of disease, which assumes the presence of a distinct, underlying mechanism that causes symptom presentation. Therefore, researchers have focused on identifying the exact causal mechanism from which NES symptoms manifest. However, despite advances in understanding the etiology of NES since it was first described in the literature, the underlying causal mechanism is still relatively unknown. In addition, NES criteria have varied considerably over the past few decades, which has contributed to significant challenges in research and clinical examinations of this disorder (Vander Wal 2012).

As an alternative to the medical model approach, recent work on other EDs has focused on reconceptualizing ED psychopathology using the network approach to psychopathology (Levinson et al. 2018b). Whereas the medical model paradigm emphasizes casual mechanisms from underlying factors, the network approach to psychopathology focuses on identifying (a) functional, causal interactions *among* symptoms and (b) symptoms most important to specific disorders (Borsboom and Cramer 2013). The network approach to psychopathology gained popularity in the past decade, with growing number of studies focusing on ED psychopathology and treatment (Monteleone and Cascino 2021).

This chapter aims to deliver insight on the conceptualization and unique features of NES when examined through this network approach. First, this chapter examines the history of NES conceptualization through a medical model lens. Next, it offers an overview of network analysis, emphasizing the methodology used to model the network approach to psychopathology. Findings from recent work on NES using network analysis are also presented. Finally, research and clinical implications from this study will be provided, as well as future directions for network analysis of NES.

Night Eating Syndrome

History of Night Eating Syndrome

NES was first identified in 1955 as a cluster of nonnormative eating behaviors that would arise during periods of stress (Stunkard et al. 1955). Such behaviors included morning anorexia (i.e., lack of morning hunger or eating behavior in the morning),

evening hyperphagia, and sleep-onset insomnia (i.e., difficulty getting to sleep more than 50% of the time; Stunkard et al. 1955). Since then, the conceptualization and diagnostic criteria of NES have evolved considerably (Striegel-Moore et al. 2006a). Although iterations of NES criteria retained some form of the three original symptoms, amendments to these symptoms – particularly with regard to evening hyperphagia – have led to definitional inconsistencies across studies.

Following the proposal of the original NES symptoms in 1955, the first revision to NES criteria occurred in 1996 to better operationalize the symptoms. Subsequently, NES was defined as absence of appetite for breakfast, consumption of 50% or more of total daily calories after 7:00 p.m., and difficulty with sleep onset or maintenance (Stunkard et al. 1996). However, as interest and recognition of NES emerged, researchers often amended or operationalized these symptoms differently. For example, studies have specifically operationalized morning anorexia in terms of food quantity or consumption cutoff times (i.e., "skipping breakfast" or "delay of eating for several hours after awakening"; Geliebter 2002; Gluck et al. 2001; Rand et al. 1997). The definition of evening hyperphagia was interpreted by Rand et al. (1997) simply as "excessive evening eating," with a proposal to exclude the specified percentage of daily caloric intake (50%) after the evening meal due to claims that persons with obesity were inaccurate at reporting caloric intake. Studies that have retained a percentage-based specification of evening caloric intake have ranged considerably (e.g., >25%, >50%), along with the operationalization of "evening" (e.g., after evening meal, after evening meal but before bed, after 6:00 pm–after 8:00 pm; Striegel-Moore et al. 2006a). Lastly, several studies failed to define sleep disturbance beyond "insomnia," and there exist wide ranges of frequencies for number of sleep disturbances (i.e., three times/week, four times/week, more than half the time, or nightly; Striegel-Moore et al. 2006a).

Additional NES symptoms were also proposed as research in NES continued to grow. Rand et al. (1997) suggested that symptoms should include delay of eating after awakening for several hours and "evening tension and/or feeling upset" (an early allusion toward negative mood, which would be added later). Spaggiari et al. (1994) examined NES through the lens of a sleep disorder, proposing criteria that were more focused on symptoms that occurred during sleep, including (a) a drive to eat upon awakening in the night, (b) the inability to return to sleep without eating, (c) becoming fully awake during nocturnal eating episodes and full recall of such episodes in the morning, (d) and a quick return to sleep after eating. Nocturnal ingestions of food after awakening from sleep were again referenced in 1999, as was worsening of mood in the evening (Greeno et al. 1995; Birketvedt et al. 1999; Vinai et al. 2008).

The variation in operationalized diagnostic criteria for NES has presented a significant challenge in research and clinical examinations of this disorder (Vander Wal 2012). For example, studies reviewing prevalence and epidemiology of NES will often cite the inconsistent diagnostic criteria as possible reasons for high variability in prevalence rates across different populations (Muscatello et al. 2021). In addition, the *Diagnostic and Statistical Manual of Mental Disorders*, including its most recent edition (DSM-5; American Psychiatric Association [APA] 2013), has

not recognized NES as a separate diagnosis, likely due in part to these varying definitions (Striegel-Moore et al. 2006a). Currently, NES is subsumed under the "eating disorder not otherwise specified" (EDNOS) or "other specified feeding and eating disorder" (OSFED) categories, with little specification. Criteria for NES in the OSFED category do not include any mention of morning anorexia and conceptualize evening hyperphagia and nocturnal ingestion as "[r]ecurrent episodes of night eating, as manifested by eating after awakening from sleep, or by excessive food consumption after the evening meal. There is awareness and recall of the eating" (APA 2013, p. 354). With such little specification, accurate identification and diagnosis of NES and its distinction from other EDs under OSFED remains a challenge for clinicians.

Development of the Research Diagnostic Criteria

To provide a standardized definition for NES, the First Night Eating Symposium was held in Minneapolis in 2008, and from this, Allison and colleagues proposed a set of specific research diagnostic criteria, presented in Table 1 (Allison et al. 2010). Within these criteria, evening hyperphagia, defined as consumption of at least 25% of daily caloric intake after the evening meal; nocturnal ingestion of food, defined as evening awakenings with ingestions at least twice a week; or both must be present for a diagnosis of NES (Criterion A), along with awareness of these eating episodes (Criterion B), at least three of five additional symptoms (Criterion C), and associated distress or impairment in functioning (Criterion D) lasting for at least 3 months (Criterion E).

Table 1 Research diagnostic criteria for night eating syndrome (NES)

Criterion	Definition
A	The daily pattern of eating demonstrates a significantly increased intake in the evening and/or nighttime, as manifested by one or both of the following: 1. At least 25% of food intake is consumed after the evening meal 2. At least two episodes of nocturnal eating per week
B	Awareness and recall of evening and nocturnal eating episodes are present
C	The clinical picture is characterized by at least three of the following features: 1. Lack of desire to eat in the morning and/or breakfast is omitted on four or more mornings per week 2. Presence of a strong urge to eat between dinner and sleep onset and/or during the night 3. Sleep onset and/or sleep maintenance insomnia are present four or more nights per week 4. Presence of a belief that one must eat in order to initiate or return to sleep 5. Mood is frequently depressed and/or mood worsens in the evening
D	The disorder is associated with significant distress and/or impairment in functioning
E	The disordered pattern of eating has been maintained for at least 3 months
F	The disorder is not secondary to substance abuse or dependence, medical disorder, medication, or another psychiatric disorder

Prevalence and Comorbidities

Estimates of prevalence rates for NES are quite varied due to inconsistent criteria and exclusion from DSM. Nonetheless, current estimates include ranges between 0.5% and 1.5% in the general population (Rand et al. 1997; Striegel-Moore et al. 2005), 5.7% in university students (Nolan and Geliebter 2012), 12.3–22.4% in psychiatric outpatient populations (Saraçlı et al. 2015), 6–16% among those patients visiting obesity clinics (Cerú-Björk et al. 2001; Gluck et al. 2001; McCuen-Wurst et al. 2018), and up to 55% in patients undergoing bariatric surgery for obesity (de Zwaan et al. 2015). There are little differences in rates of NES between gender, age, and ethnicity (Aronoff et al. 2001; Striegel-Moore et al. 2006b; Colles et al. 2007). Individuals with NES also show high comorbidity with major depressive disorder (Küçükgöncü and Beştepe 2014), substance use disorder (Lundgren et al. 2006; Küçükgöncü and Beştepe 2014), sleep-wake disorders (Lundgren et al. 2011; Hood et al. 2014), and other EDs (Colles et al. 2007; Allison et al. 2007; Vander Wal 2012; Tu et al. 2019).

NES has shared close ties with overweight/obesity since its inception, as the syndrome was first identified through the clinical observation of individuals with obesity and was thought to be a behavioral expression of this weight status (Stunkard et al. 1955; Gluck et al. 2017). Prevalence rates for NES are higher in populations with obesity (6–16%; Küçükgöncü et al. 2015), and individuals with obesity in psychiatric outpatient settings are five times more likely to meet criteria for NES compared to individuals without obesity (Lundgren et al. 2006). Despite this relationship between obesity and NES, however, extant research has suggested that not all individuals with NES are persons with overweight/obesity (Birketvedt et al. 1999; Striegel-Moore et al. 2006b; de Zwaan et al. 2006; Lundgren et al. 2008). In addition, Vander Wal (2012) noted that obesity may be associated with NES, but the directionality of this relationship is not known, and symptoms of NES may balance out the likelihood of potential weight gain (i.e., morning anorexia compensating for evening hyperphagia and nocturnal ingestion of food).

Etiology and Medical Model Conceptualization

As is the case with many disorders, the evolution of NES conceptualization and etiology have been heavily influenced by the medical model paradigm of disease. This paradigm (Lilienfeld and Treadway 2016) posits that mental health disorders are causal entities that result in myriad dysfunctional symptoms (Borsboom and Cramer 2013). In other words, the medical model proposes that psychiatric disorders have underlying causes that (1) lead to the expression of certain symptoms and (2) explain the co-occurrence of certain symptoms in related clusters. For NES, the proposed core mechanism is a circadian rhythm shift, and several causes have been suggested, including genetic (Root et al. 2010), biobehavioral (Stunkard et al. 2006; Lundgren et al. 2013; Pollack and Lundgren 2014), neuroendocrine (Birketvedt et al. 1999, 2014), and psychosocial (Allison et al. 2007; Takeda et al. 2004; Vander Wal

2012; Sevincer et al. 2016; He et al. 2018) factors. Despite these proposals, the cause of NES is still relatively unknown (Lundgren et al. 2012b), but current conceptualizations suggest that NES has an underlying common cause, and research to date has been focused on identifying causal mechanisms of NES.

Network Theory of Psychopathology

Weaknesses of the Medical Model

One of the major weaknesses of the medical model paradigm when applied to conceptualizing psychiatric disorders is the reliance on a latent variable theory. This theory proposes that unseen factors give rise to observable phenomenon. This concept is applied to psychiatry insomuch that mental health disorders are thought to precipitate dysfunctional mental health symptoms. For example, major depression is posited as the manifestation of specific observable symptoms (e.g., depressed mood, loss of interest, fatigue, difficulty concentrating, etc.) that are caused by an underlying unobserved factor, much like how an infection would give rise to a fever, headache, and respiratory symptoms (Borsboom and Cramer 2013). While these symptoms are distinct (i.e., seen as separate symptoms), they are causally homogeneous, and the removal of the underlying factor (i.e., depression, the infection) will result in symptom alleviation. Furthermore, in the medical model, symptoms are distinct from the underlying condition (i.e., medical conditions can occur asymptomatically).

When applying the medical model to psychopathology, it seems reasonable to suggest that a psychiatric disorder like depression should (a) have an underlying cause that is independent from the symptoms, and (b) this underlying cause should give rise to all related depressive symptoms (Borsboom and Cramer 2013). Therefore, such a theory asserts that an individual could have depression without any symptoms. It is highly unlikely that this scenario exists, and it remains unlikely that any future measurement techniques will be developed to detect disorders independent of their symptoms. Indeed, the medical model of disease as the cause of symptoms does not appear to hold true with psychiatric disorders, and the relationship between symptoms and disorders needs to be conceptualized differently (Borsboom and Cramer 2013).

Network Theory

Network theory presents an alternative approach to this conceptualization. It suggests that symptoms are not the result of an underlying latent cause, but that psychiatric disorders result from a functional, causal interaction among symptoms (i.e., symptoms cause each other; Borsboom and Cramer 2013; Borsboom 2017). This interaction is conceptualized as connections between, and dynamic relationships among, a network of symptoms. This has been referred to as the "network

approach to psychopathology" (Borsboom 2017). Indeed, interest in the network approach to psychopathology has grown considerably since Borsboom and Cramers' (2013) seminal article (Contreras et al. 2019; Robinaugh et al. 2020), with Robinaugh et al. (2020) identifying 363 articles on this topic across myriad psychiatric disorders.

Figure 1 illustrates this approach through a visual representation of a proposed network structure. The external field represents circumstances from outside the network that have direct influences on symptoms (i.e., adverse life events). These circumstances can "activate" symptoms within the network, which may activate neighboring symptoms, leading to the presentation of psychiatric disorders (Borsboom and Cramer 2013). Some symptoms may be more strongly connected to others, or clustered closely with others, and these symptoms are likely to impact each other to a greater degree. Indeed, such connections can lead to symptoms becoming self-sustaining and the disorder persisting even with the removal of the original influence (see Fig. 2; Borsboom 2017).

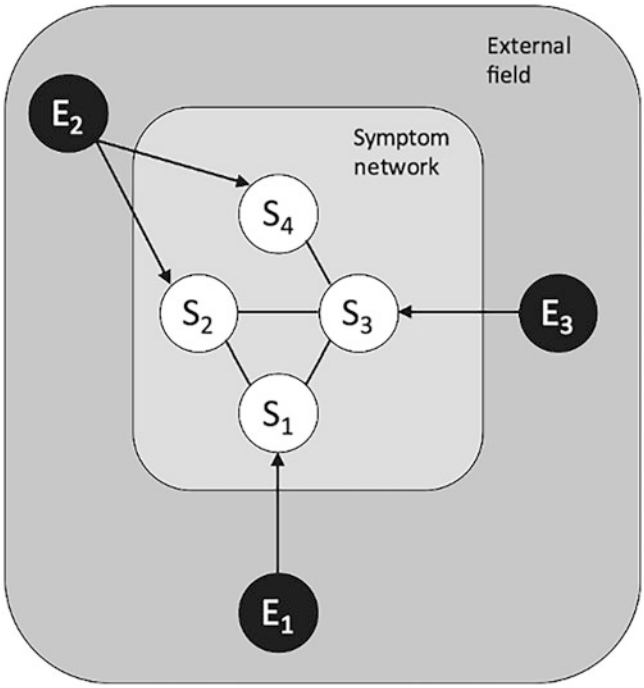

Fig. 1 A symptom network of four symptoms. Symptoms that have a tendency to activate each other are connected by a line (e.g., S_1–S_2). Symptoms can also indirectly activate each other (e.g., S_1–S_4) through a shared symptom (e.g., S_3). External factors (e.g., adverse life events) exist in the external field and can directly affect one or more symptoms. *S* symptom, *E* external factor. (From Borsboom (2017) with permission)

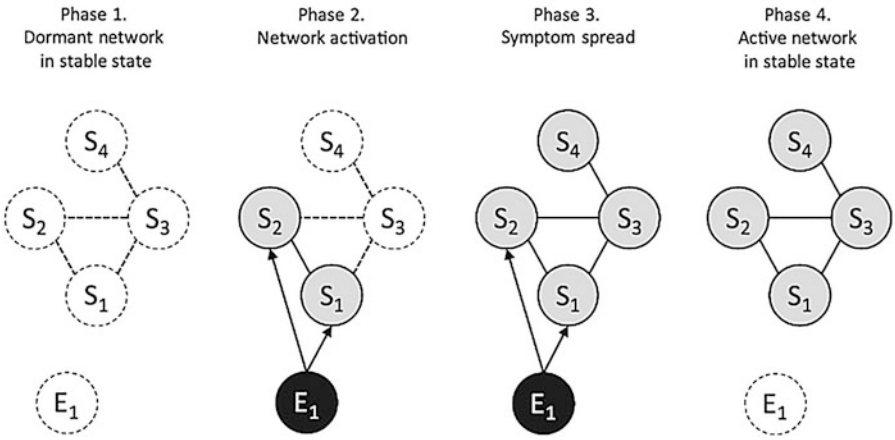

Fig. 2 The development of psychiatric disorders according to network theory. Phase 1 represents a dormant network. An external event occurs that triggers the activation of select symptoms (phase 2), which spreads to connected symptoms (phase 3). If the network is strongly connected, the network may become self-sustaining after the external event is removed (phase 4). *S* symptom, *E* external factor. (From Borsboom (2017) with permission)

Advantages of Network Theory

Network theory presents several advantages over latent variable theory. Chief among these advantages is that network theory more closely models how clinicians instinctively conceptualize, diagnose, and treat psychopathology (Borsboom 2017). For example, in contemporary cognitive-behavioral models of psychopathology, there is an emphasis on how patterns of thoughts, behaviors, and emotions might be self-reinforcing within a triangular system. Thus, cognitive-behavioral therapists employ techniques to elucidate how these patterns are functionally linked together and how they may perpetuate a disorder (DuBois et al. 2017). Interventions are then chosen based on this interaction of symptoms, rather than identifying and addressing an underlying cause (Borsboom 2017). Therefore, an examination of a disorder through network theory appears to best match this approach, whereby a clinician conceptualizes a network that identifies which symptoms are present and which interactions are sustaining each other. As a result, a clinician would ideally identify the most important or most influential symptoms – based on how that symptom maintains or activates other symptoms – as a target for treatment.

Modeling the Network Approach to Psychopathology: Network Analysis

Networks can be both graphically and quantitatively modeled using network analysis (Borsboom and Cramer 2013; Epskamp et al. 2018a). This method is a

data-driven approach used to determine the network structure of a particular disorder. Techniques for network analysis have been derived from methodology used on social networks (Otte and Rousseau 2002) and neural networks (de Haan et al. 2009). A brief primer on the basic concepts of network analysis as applied to the network approach to psychopathology is presented below.

Network Structure

Within a given network, symptoms are represented as *nodes*, and the connection between symptoms is referred to as an *edge.* These edges can either represent the presence of a correlation (unweighted) or can be used to indicate both the presence and the magnitude of the correlation (weighted). In a weighted network, the size of an edge denotes the strength of the correlation (thicker lines indicate stronger correlations and vice versa), and the color reflects the sign of the correlation. In addition, edges can also be used to determine the directionality of relationships between symptoms, with directed models using arrows on the edges to represent the direction of the association (i.e., symptom A predicting symptom B in the order toward the arrow's end, suggesting possible causation) and undirected models using lines with no arrows (i.e., indicating a relationship but not modeling directionality or possible bidirectionality).

Approaches to Modeling Network Structure

There exist various approaches to modeling network structure using cross-sectional data that assess relationships between symptoms at one point in time, often using self-report questionnaires or structured clinical interviews (McNally 2021). These approaches include *association*, *concentration*, *relative importance*, and *Bayesian networks* and differ on their use of undirected versus directed models and whether their edges represent zero-order correlations or partial correlations (Borsboom and Cramer 2013). As concentration networks are more commonly used in psychopathology research, this approach will be explored in depth, and readers are encouraged to review McNally (2016, 2021) for more information on the other approaches.

Concentration networks utilize a matrix of partial correlations as a means to determine direct or indirect relationships (Borsboom and Cramer 2013). These networks are also known as Gaussian graphical models (Lauritzen 1996) and are part of a more general class of models called pairwise Markov random fields (Epskamp and Fried 2018). As partial correlations are correlations between nodes that remain after all other nodes are controlled for, this approach may assist in determining the causal structure of a network. Data used to model these networks are typically continuous, but there exist options to model binary (Ising model; van Borkulo et al. 2014) and mixed continuous and categorical (mixed graphical model; Haslbeck and Waldorp 2020) data. These networks, however, are vulnerable to sampling error, which may result in artificially inflated or spurious edge estimates (Epskamp and Fried 2018).

One strategy to solve the issue of many small and potentially spurious correlations is the use of regularization, which sets a penalty on network estimation based on model complexity (Epskamp and Fried 2018). The graphical least absolute shrinkage and selection operator technique (GLASSO; Friedman et al. 2008) is one such regularization method. This reduces the overall number of edges by fixing a penalty on small values, shrinking them to zero, and dropping them from the model. This leads to the estimation of a sparse model with relatively few (i.e., presumably true) edges. Such parsimonious models are considered more interpretable (Epskamp et al. 2018a). Recent studies, however, have called into question the use of GLASSO, as this technique was originally developed for networks where the number of nodes exceeded the number of cases, which is unusual in psychopathology networks (Williams et al. 2019; Williams and Rast 2020). These studies suggest through simulations that GLASSO could eliminate true edges in the effort to estimate a sparse model. They suggest instead using confidence intervals to determine nonzero edges (Williams and Rast 2020).

Network Properties

Centrality

Network analysis can also be used to identify the core symptoms that are most important to maintaining the structure of the network (Borsboom and Cramer 2013). By adapting methodology from social network analysis (McNally 2021), these core symptoms are identified by assessing centrality indices, which work by determining the relative influence of specific nodes within the network. While centrality indices identify nodes that are of the greatest importance to the overall network structure (i.e., they can be considered the driving or maintaining force in the network provided certain conditions are met), these nodes *do not* have to represent hallmark symptoms of a disorder (i.e., depressed mood in major depressive disorder; McNally 2016; Borsboom 2017).

Indeed, there are several indices used to determine centrality, all of which differ slightly in their approach, but they all represent how interconnected a specific symptom is to other symptoms within the network. Such indices include *degree*, *betweenness*, *closeness*, *strength*, and *expected influence*. As *strength* and *expected influence* are the most widely used indices in psychopathology networks (as well as the most stable indices; Epskamp et al. 2012), readers are encouraged to see McNally (2021) for more information on the other three.

Strength centrality is measured by the sum of the absolute value of the edge weights between a particular node and all other nodes directly connected to it and represents how strong the direct connections are between that node and all other in the network. This is a useful index because it is likely that activation of symptoms with high strength centrality will trigger the activation of other symptoms (McNally 2016). This represents an accurate measure of relative importance if all edges in a network are positive; however, the accuracy of this index can become distorted by the increasing presence of negative edges (McNally 2021). *Expected influence*

centrality arose as a response to this limitation and takes the sign of the edge weights into account, thus providing a more accurate measure of centrality as the number of negative edges in a network increases, or one identical to strength if the network only contains positive edges (Robinaugh et al. 2016).

In order to state accurately that a node is more central than other nodes in a network, a high centrality value on a specific node should be statistically significantly different from centrality values on most, if not all, other nodes in the network (Fried 2016, 2018). This is assessed via bootstrapped difference tests (Epskamp et al. 2018a). To date, there are no established rules for how many significant differences between nodes are sufficient to consider a node highly central, and some studies have stated that a highly central node is meaningfully interpretable if its centrality indices are significantly different from at least half of the other nodes (Forrest et al. 2019; Beauchamp et al. 2021).

Accuracy and Stability

After estimating the network structure based on one of the above approaches and analyzing the network structure with regard to its parameters (i.e., presenting a graphical representation to reveal relationship density between nodes, assessing node centrality, determining clustering of nodes into communities), the next step is to evaluate the accuracy and stability of these network parameters before a thorough interpretation of the network can be made. As networks are based on sample data and given the relatively small sample sizes used in some psychopathology research (Hevey 2018), network analysis can be susceptible to sampling variation as network complexity increases (Epskamp et al. 2018a). Thus, researchers using network analysis are encouraged to follow three steps to assess for accuracy (i.e., how prone the network is to sample variation) and stability (i.e., how similar the network interpretation remains with fewer observations): (1) use bootstrapped confidence intervals to assess the accuracy of the estimated edge weights, (2) assess the stability of centrality indices that are estimated on subsets of the data, and (3) explore significant differences between edge weights and centrality indices using bootstrapped difference tests (Epskamp et al. 2018a). These steps, in addition to methods that determine if differences in network parameters between samples are genuine (Jones et al. 2021), have been used to address concerns regarding the replicability of findings in network analysis (McNally 2021). Readers are suggested to review Epskamp et al. (2018a) for a tutorial on these procedures.

Network Approach to Psychopathology in Eating Disorders

Outline of Emerging Research

The application of network analysis in psychopathology research has extended to EDs within recent years. Indeed, network analysis has been used in over two dozen studies to estimate network models among individuals with anorexia nervosa,

bulimia nervosa, binge eating disorder, and OSFED (Monteleone and Cascino 2021). Although researchers have continued to advocate for efforts to reconceptualize EDs from the network approach to psychopathology (Smith et al. 2018; Levinson et al. 2018b), recent work has also been done to derive other clinical applications from this approach, namely, the prediction of treatment outcomes in EDs (Smith et al. 2019; Vanzhula et al. 2019; Hilbert et al. 2020; Elliott et al. 2020; Brown et al. 2020; Monteleone et al. 2021). Despite this growing literature, however, only one study has been done that has specifically examined this approach with relation to NES (Beauchamp et al. 2021).

Network Approach to Psychopathology in NES

Beauchamp et al. (2021) examined the psychopathology network of NES in a community sample of individuals diagnosed with NES recruited over 5 years. One hundred and forty-four participants were included in the study, participants were between 20 and 85 years of age ($M_{age} = 43.97$, $SD = 12.14$), and the majority were female (67.6%), were White (60.1%), and had a body mass index (BMI) score that put them in the obese range (56.1%). NES diagnoses, based on the research diagnostic criteria (Allison et al. 2010), were confirmed using the Night Eating Syndrome History and Inventory (Lundgren et al. 2012a), and participants also completed the Night Eating Questionnaire (Allison et al. 2008) and the Eating Disorder Examination (Fairburn et al. 2008). To further capture behavioral symptoms associated with NES (i.e., morning anorexia, nocturnal awakenings, nocturnal ingestions of food, and evening hyperphagia), participants completed 10-day, 24-h food and sleep diaries. In addition, participants were asked about non-NES-specific symptoms (i.e., symptoms that have been associated with NES but are not part of the diagnostic criteria) to broaden the potential plausible causal network of symptoms. Based on the proposed etiology and maintenance of NES in the literature thus far, this included depressed mood, circadian rhythm patterns, sleep quality and daytime sleepiness, and perceived stress. Symptoms were assessed via the Beck Depression Inventory-II (Beck et al. 1996), Morningness-Eveningness Questionnaire (Horne and Östberg 1976), Pittsburgh Sleep Quality Index (Buysse et al. 1989), Epworth Sleepiness Scale (Johns 1991), and Perceived Stress Scale-10 (Cohen and Williamson 1988), respectively. After the removal of one symptom that was found to be capturing a similar construct of another (i.e., number of awakenings removed, as this was captured by the number of nocturnal ingestions which inherently suggests nocturnal awakenings), there were 17 symptoms included in network estimation.

Results from this study found that the psychopathology network of NES was sparsely connected (i.e., relatively few connections between symptoms; see Fig. 3), though the estimates of symptom centrality were stable. Surprisingly, neither evening hyperphagia nor nocturnal ingestions of food were found to be central symptoms in the network, which are necessary symptoms for a diagnosis of NES to be made as per the research diagnostic criteria. Instead, depressed mood, poor sleep quality, and a strong urge to eat during the night (all represented by Criterion C in the

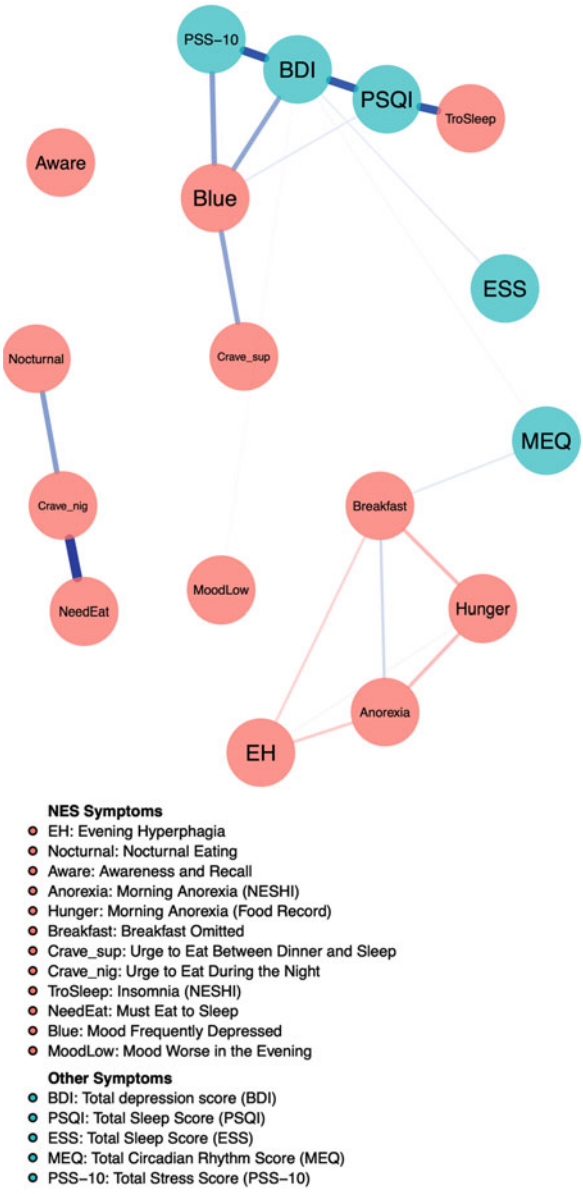

Fig. 3 The psychopathology network of NES. Blue and red lines indicate positive and negative associations, respectively, and line thickness indicates strength (e.g., thicker line equals stronger association). (From Beauchamp et al. (2021) with permission)

research diagnostic criteria) were found to be the most central symptoms (i.e., symptoms with the greatest importance to the network; see Fig. 4) and statistically more central than most other symptoms in the network (see Fig. 5).

The authors stated in their conclusions that these results call into question the conceptualization of NES as presented by the research diagnostic criteria,

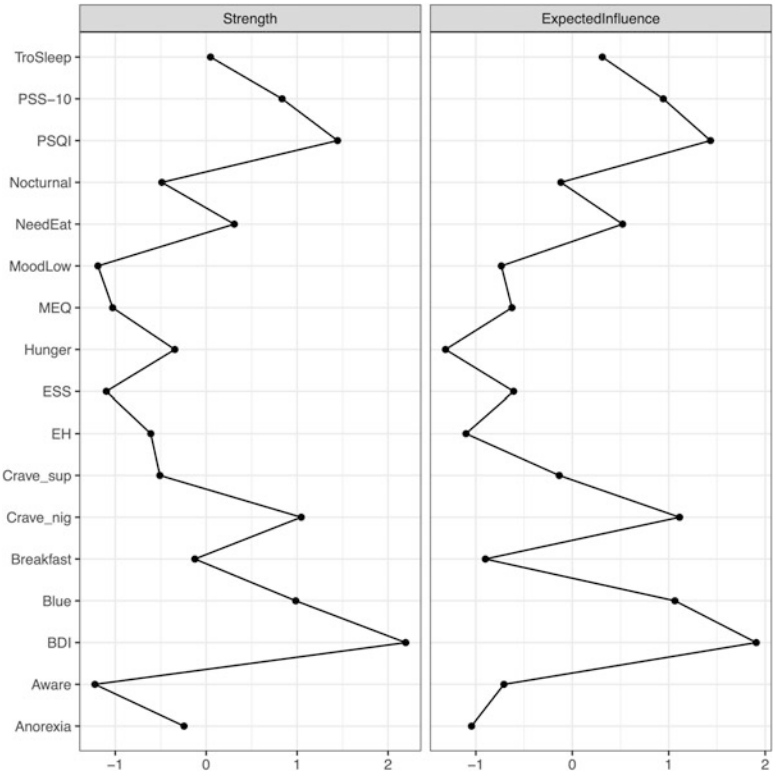

Fig. 4 Centrality plot for the psychopathology network of NES. Plot is standardized on z-scores ($M = 0$, $SD = 1$) and higher numbers mean greater centrality. (From Beauchamp et al. (2021) with permission)

particularly that both evening hyperphagia and nocturnal ingestion of food – both symptoms in Criterion A and considered defining features of NES – were not the most central symptoms. Other researchers of network theory, however, have emphasized that central symptoms do not have to be hallmark symptoms of a disorder and are instead conceptualized as having greater importance (i.e., driving or maintaining forces in a network; Borsboom 2017; McNally 2021). Beauchamp et al. (2021) claimed that perhaps evening hyperphagia and nocturnal ingestion of food are not the most important symptoms, but are instead resulting behaviors in a symptom chain that begin with depressed mood and urge to eat during the night, respectively.

In examining the connections between symptoms in the NES network model to determine this potential symptom chain, Beauchamp et al. (2021) found that depressed mood was directly associated with disturbances in sleep, stress, circadian rhythm patterns, and the urge to eat between dinner and sleep, with no other direct connections to remaining NES symptoms. Of course, this would mean that if depressed mood was indeed the most central symptom, it appeared that increases in depressed mood would correlate with poorer sleep quality (which was also the

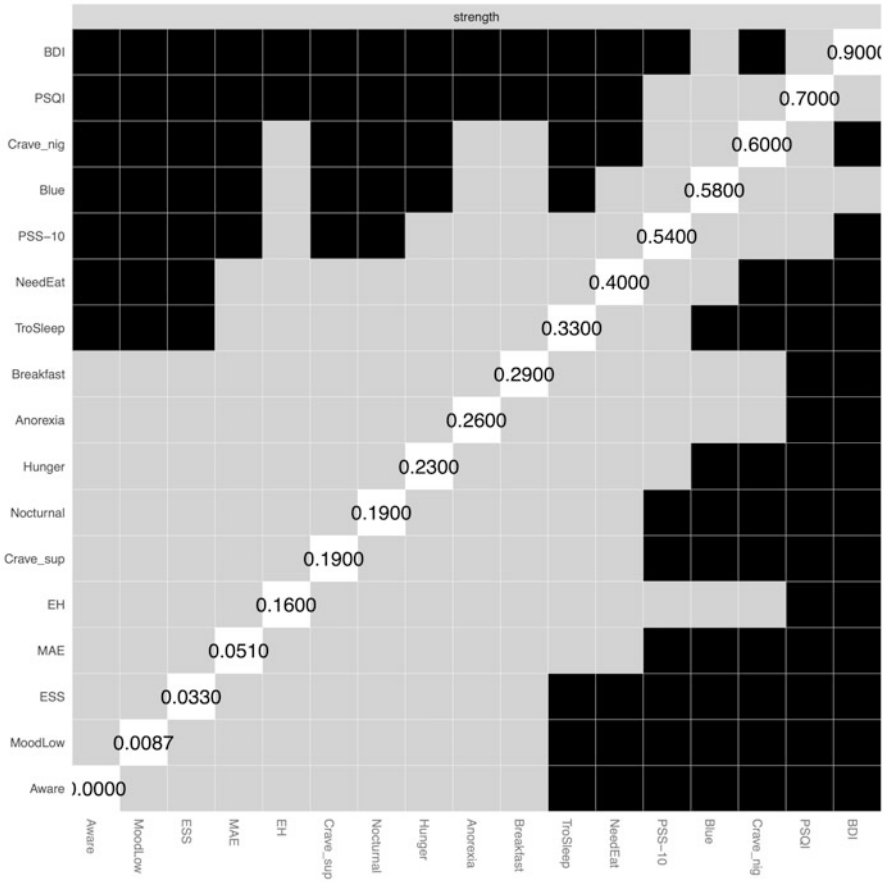

Fig. 5 Bootstrapped strength difference results. Values on the diagonal indicate unstandardized strength centrality values for the corresponding symptom. Black boxes represent significant differences in strength between symptoms, and gray boxes represent nonsignificant differences. (From Beauchamp et al. (2021) with permission)

second most central symptom), increased stress, a preferred evening circadian pattern, and increased urges to eat between dinner and sleep. Indeed, this connection eventually leads to evening hyperphagia. In addition, urge to eat during the night (the third most central symptom) was directly associated with the need to eat in order to sleep and nocturnal eating (i.e., nocturnal ingestion of food). Therefore, it is likely that two symptom chains exist, whether alone or concurrently, and are ordered such that (a) an individual may feel that they have an urge to eat during the night which makes returning to sleep virtually impossible, and so they engage in nocturnal ingestions of food, and/or (b) a combination of depressed mood and poor sleep, along with an urge to eat between dinner and sleep, cascades through additional symptoms and eventually results in evening hyperphagia. The authors caution that

the directionality and temporal ordering of these associations are unclear due to the cross-sectional nature of the data and that these results need to be confirmed with longitudinal studies.

Clinical Implications

The conceptualization of NES through the lens of network theory presents several advantages from a clinical standpoint. Beauchamp et al. (2021) indicated that the three central symptoms (i.e., depressed mood, poor sleep quality, and urge to eat during the night) can be considered primary intervention targets, as treating these symptoms may lead to disruptions in the symptom chain that maintain NES. Indeed, researchers exploring EDs with network analysis postulate that interventions that target highly central symptoms may also greatly impact other symptoms in the network (Levinson et al. 2018b). In addition, changes to the most central symptoms seen in psychopathology networks have been strongly associated with changes in overall symptom severity compared to changes in less central symptoms (Robinaugh et al. 2016). Researchers have cautioned, however, that it is also possible that central symptoms may arise as the consequence of other symptoms, or a bidirectional relationship may occur and central symptoms may be both a cause and consequence (Levinson et al. 2018b; McNally 2021). In addition, it is questionable if current psychological treatments could target a specific symptom without simultaneously impacting adjacent symptoms in the network (McNally 2021). Nevertheless, extant literature supports targeting highly central symptoms as a means to provide treatment (Levinson et al. 2018b) or predict treatment outcomes (Hilbert et al. 2020; Elliott et al. 2020; Brown et al. 2020).

An additional domain of conceptual and clinical utility explored by Beauchamp et al. (2021) was NES symptom heterogeneity as determined by network structure and density. The authors stated that, under current research diagnostic criteria, only three of five symptoms in Criterion C are necessary for a diagnosis of NES. This is consistent with several other DSM-5 diagnoses (e.g., major depressive disorder requiring five or more symptoms from a list of nine), and such heterogeneity is considered another limitation of the medical model paradigm (van Borkulo et al. 2015). As network structure is concerned with the clustering and/or ordering of symptoms (i.e., "where" the symptoms are in the network) and network density is connections between symptoms (i.e., "how" symptoms are connected, how sparse or densely connected is the overall network, and how strong is each individual connection), how might the activation of one symptom (and its connection with core and distal symptoms) lead to differences in presentation and levels of clinical impairment/distress in an individual with NES? In addition, are certain clusters of symptoms more likely than others to sustain NES or might influence prognosis or recovery? Beauchamp et al. (2021) recommended comparisons of different network models between samples (i.e., the network comparison test; van Borkulo et al. 2022). Indeed, such a technique has been used to suggest that (a) network density, as well as certain clusters of symptoms, can predict response to treatment (van Borkulo et al.

2015; Smith et al. 2019) and (b) network density, but not network structure, is different (i.e., stronger) when comparing clinical versus nonclinical samples (Vanzhula et al. 2019). Therefore, clinical assessments and treatments may wish to target select clusters of symptoms, as well as focus on ways to weaken symptom connections as whole. In addition, network comparisons may be especially useful when evaluating samples of individuals that meet clinical versus subclinical thresholds of NES, particularly with symptoms that require specific occurrence rates (i.e., episodes of nocturnal ingestions of food per week).

Future Directions in Network Analysis of NES

This chapter provided a brief overview of NES, an ED presently characterized by a disrupted circadian rhythm resulting in a shifted pattern of food intake in individuals with concomitant alterations in sleep, mood, and eating behaviors. Research to date has conceptualized NES through a medical model paradigm of disease, which suggests that symptoms of NES are the result of an underlying common cause, though this causal mechanism remains poorly understood, and the functional relationships between symptoms are relatively unknown. In addition, the numerous variations in diagnostic criteria for NES have presented a significant challenge in accurately conceptualizing this disorder from a research and clinical perspective. Beauchamp et al. (2021) presented an alternative approach to conceptualization of NES by examining the core symptoms using the network approach to psychopathology. Results from this study suggested that depressed mood, poor sleep quality, and a strong urge to eat during the night after the initiation of sleep were found to be the core symptoms of NES, rather than evening hyperphagia and nocturnal ingestion of food, the key symptoms presented by Allison et al. (2010). Lastly, research and clinical implications of these results were presented. Of course, results from this one study have propagated numerous research questions, and the emergence of network analysis as a technique in the field of psychopathology over the past decade has resulted in several novel methods to allow such further exploration into the psychopathology network of NES. Thus, this chapter closes with a discussion on future directions for network analysis of NES.

Network Comparisons

First, among one of the next steps in further exploring the conceptualization of NES using the network approach to psychopathology is to include a larger, more diverse sample. However, it might also be of great benefit to examine group differences with a somewhat different network analysis technique. Recently, Costantini et al. (2019) outlined a new method for estimating and analyzing psychopathology networks, particularly when estimating networks between different groups (e.g., clinical versus nonclinical samples, males versus females, etc.), called the *fused graphical lasso* (FGL) method. These researchers state that estimating a single network that includes

all groups will fail to illustrate inter-group differences, but also that estimating a separate network for each group would fail to capture inter-group similarities. In addition, they report that differences observed are likely to arise as much from sampling fluctuations as from true differences. This FGL method more accurately estimates different networks for each group by including group similarities as they occur among the different groups. This technique has also been used in other ED network analysis literature to compare diagnosis and age differences between networks (Schlegl et al. 2021).

In addition to making comparisons between demographic variables, it would be important to explore differences in weight status among individuals with NES. As stated above, NES can occur in individuals with and without overweight/obesity. While some studies have found no differences in symptomatology between these two groups, others have found (a) higher incidences of nocturnal awakenings and food consumption, (b) that populations with NES who were persons without overweight/obesity were younger, and (c) that NES symptoms preceded obesity. Indeed, it is unknown if network structure and/or density differs between individuals with and without overweight/obesity. Also, it is possible that BMI does not represent the appropriate cutoff that differentiates such network differences between those with and without overweight/obesity. These classifications are based on a BMI cutoff of 25 kg/m^2. Future studies can explore this by identifying where networks differ on a BMI continuum through the use of model-based recursive partitioning. This technique uses decision trees to detect optimal splits on selected variables by assessing parameter instability and is seen as similar to a moderation analysis (e.g., examining how parameters differ based on subgroups; Jones et al. 2020). This technique could more accurately explore exactly where network differences are on a continuum of BMI, rather than by cutoff.

Temporal Network Analysis Models

Second, future studies should also include longitudinal analyses of individuals with NES via temporal time-series networks. Network analysis models developed from cross-sectional data are limited in their ability to model within-subject variance or to account for changes across time. Newer methods that can assess for intraindividual differences have been developed to capture this within-subject variation and more accurately how symptoms maintain disorders at both group and individual levels (Fisher et al. 2017; Epskamp et al. 2018b). These temporal group-level models (i.e., multilevel vector autoregression models) can assess for intraindividual differences across time, between-subjects similarity, and differences between the within- and between-subjects networks. This would require large amounts of frequent longitudinal datapoints, and such methods have been used in prior ED network analysis research by adopting ecological momentary assessment (Levinson et al. 2018a) or perceived causal relations (Klintwall et al. 2021) techniques. Notably, Levinson and colleagues (Levinson et al. 2018a) claim that better understanding how symptoms maintain themselves at both group and individual levels will lead to

(1) the development of novel, personalized treatments and (2) explaining the large amounts of heterogeneity among EDs.

Refine Intervention Targets

Lastly, newer literature on network theory has called into question the usefulness of identifying central symptoms as effective treatment targets, particularly among models using cross-sectional data (Henry et al. 2021; Lunansky et al. 2021). These researchers have argued that symptom centrality is based on structure/density of the network, but do not account for network *dynamics* (i.e., how symptoms influence one another; Lunansky et al. 2021). While they do not rule out the usefulness of temporal time-series networks, these authors suggest using concepts from *control theory* (a discipline from the field of mathematics that deals with controlling dynamic systems; Henry et al. 2021) to facilitate the selection of intervention targets. Indeed, such an approach can not only identify the best symptom (or set of symptoms) to target for intervention, but can estimate how effective the intervention might be on affecting other symptoms in the network (Henry et al. 2021). Conversely, this technique can also estimate which symptom would have the most profound effect on activating other symptoms (i.e., which symptom, after being influenced by an external event, would set off the cascade of symptoms leading to the presentation of a disorder; Lunansky et al. 2021). In light of these potential findings, the utilization of such an approach in a sample of individuals with NES should be prioritized.

Applications to Other Eating Disorders

This chapter reviewed the application of the network approach to psychopathology on NES to explore the core features and symptom relationships in an NES network. This approach has already been used to estimate network models among other EDs, particularly to explore the reconceptualization of ED psychopathology, to predict treatment outcomes, and to develop novel, personalized treatments. However, the NES network is unique among other ED networks in that it included symptoms that are related to, but not specific to, ED behavior (e.g., mood, circadian rhythm, sleep, and stress). Indeed, few other ED networks include such nonspecific symptoms (Monteleone and Cascino 2021), and including a broader range of these symptoms in network estimation may help refine ED conceptualization, explore symptom connections between EDs and comorbid disorders, and capture central symptoms more accurately. In addition, given the high rates of heterogeneity in ED symptom presentation and response to treatment, researchers have suggested including more general psychopathology symptoms, as well as external field factors, to help explain interindividual differences in treatment response (Levinson et al. 2018a; Monteleone and Cascino 2021). While these clinical applications have yet to be explored with an NES network, efforts to conceptualize NES with the network approach to

psychopathology have found that NES-specific symptoms (i.e., evening hyperphagia and nocturnal ingestion of food) were not of great importance to the network. Rather, non-NES-specific symptoms (e.g., depressed mood, poor sleep quality) were found among the most central symptoms in the network.

Mini-Dictionary of Terms

- **Centrality.** A relative measure of a node's overall importance (i.e., influence) within a network.
- **Concentration networks.** Networks that are estimated using partial correlations. Edges between nodes can be interpreted as relationships that exist when the effects of all other nodes are accounted for.
- **Network approach to psychopathology.** An approach to conceptualizing psychiatric disorders that focuses on how a network of causal interactions among symptoms influences the development and maintenance of the disorder.
- **Night eating syndrome (NES).** An eating disorder currently characterized by a delayed circadian pattern of eating that results in increased consumption of food after the evening meal and/or eating during the night after awakening from sleep. Individuals with NES may also experience reduced eating behavior during the morning, as well as changes in sleep and mood.
- **Strength and expected influence.** Two widely used centrality indices that determine how strongly a node is directly connected with all other nodes in a network. Expected influence accounts for the valence of a connection and is more accurate than strength when networks have negative edges.

Key Facts of Night Eating Syndrome and Network Analysis of Features

Key Facts of Night Eating Syndrome

Night eating syndrome (NES) was first identified in 1955 by Stunkard and colleagues as a cluster of nonnormative eating behaviors that came during periods of stress in individuals with obesity.

Prevalence rates for NES are about 1.5% for the general population and are higher in populations with obesity (6–16%; up to 55% in patients undergoing bariatric surgery for obesity), but not all individuals with NES are persons with overweight/obesity.

NES has not been recognized as a separate diagnosis in the *Diagnostic and Statistical Manual of Mental Disorders* and is subsumed under the "other specified feeding and eating disorder" category.

Specified diagnostic criteria were proposed in 2010 by Allison and colleagues to provide as standardized definition of NES for clinical and research purposes.

Core features of NES include the consumption of ≥25% of total daily calories after the evening meal (i.e., evening hyperphagia) and/or nocturnal ingestions of food after awakening from sleep.

When conceptualized with the network approach to psychopathology, these core features are not the most important symptoms in the NES network model.

Depressed mood, poor sleep quality, and a strong urge to eat during the night after the initiation of sleep were considered the most important symptoms.

According to the network approach to psychopathology, these symptoms may cause evening hyperphagia and nocturnal ingestions of food and should be considered primary intervention targets.

Summary Points

- Night eating syndrome (NES) is an eating disorder characterized by the consumption of ≥25% of total daily calories after the evening meal (i.e., evening hyperphagia) and/or nocturnal ingestions of food after awakening from sleep.
- Conceptualizations of NES have been based on the medical model paradigm of disease, which assumes an underlying mechanism that causes symptoms.
- Other eating disorders have been reconceptualized using the network approach to psychopathology, which assumes a functional, causal network of symptoms.
- Network analysis can be used to model the network approach to psychopathology and can assess for symptoms that are most important or influential to the network.
- Evening hyperphagia and nocturnal ingestions are not the most important symptoms in an NES model; rather depressed mood, poor sleep quality, and a strong urge to eat during the night are considered most important.
- These three important symptoms may be the cause of evening hyperphagia and nocturnal ingestions and should be considered primary intervention targets.
- Beyond more accurately conceptualizing NES, network analysis can also be used to examine group differences (i.e., gender, weight status), understand how symptoms maintain themselves, and facilitate the selection of intervention targets.

Avoidant/Restrictive Food Intake Disorder in Children

62

Yaara Shimshoni and Eli R. Lebowitz

Contents

Abstract

Avoidant/restrictive food intake disorder (ARFID) is characterized by dietary restrictions that are not based on weight or shape concerns but that result in marked interference in feeding, growth, or psychosocial functioning (American Psychiatric Association, Diagnostic and statistical manual of mental disorders, 5th edn. American Psychiatric Publishing, Arlington, 2013; Eddy et al., Int J Eat Disord 52(4):361–366. https://doi.org/10.1002/eat.23042, 2019). ARFID was introduced as a diagnostic category in the 5th edition of the DSM in 2013, and research into ARFID remains limited and provides only partial understanding of the different aspects of the problem such as its prevalence, characteristics and driving factors, assessment, and treatment. The aim of this chapter is to summarize and discuss this knowledge with a focus on childhood ARFID.

Introduction

Avoidant/restrictive food intake disorder (ARFID) was introduced in the 5th edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) in 2013 as an expansion of the DSM-4 diagnosis of feeding and eating disorder of infancy and early childhood (American Psychiatric Association 2013). This change allowed for individuals – children and adults – with significant food selectivity who previously did not meet diagnostic criteria for feeding and eating disorder of infancy and early childhood to receive recognition in the DSM. The main changes were the removal of restrictions on the age of onset (which was previously before age 6 years) and on weight (which previously had to be low). A similar diagnosis of ARFID has been recently included in the newest version of the International Classification of Diseases (ICD-11), which is the World Health Organization's comprehensive classification system for all diseases and health problems (Claudino et al. 2019). The inclusion of ARFID in the ICD-11 indicates that this eating problem is gaining universal recognition.

Individuals with ARFID limit the variety or quantity of foods they eat to the extent that these limitations are associated with marked interference in feeding, growth, or psychosocial functioning (American Psychiatric Association 2013). While many young children, especially between the ages of 2 and 5, exhibit picky eating which is usually not severe and tends to resolve over time (Taylor et al. 2015), ARFID is different. To meet a diagnosis of ARFID, the restricted eating must persist and lead to meaningful interference in at least one of the following ways: (a) weight loss or failure to gain weight; (b) nutritional deficiency; (c) dependence on nutritional supplements or enteral feeding (e.g., tube feeding); or (d) psychosocial impairment such as difficulty with friends, at school, in the family domain or experiencing personal feelings of distress (DSM-5, criteria A1–A4). There are also several exclusion criteria. First, the restricted eating cannot be driven by fear of gaining weight or by distorted body image. If this is the case, a different eating disorder such as anorexia nervosa or bulimia nervosa might be considered. Additionally, the restricted eating cannot be due to lack of available foods or cultural norms. It is possible for ARFID to co-occur with other psychiatric or medical conditions, although to qualify for an ARFID diagnosis in addition to other conditions, the eating problem must meet criterion A and be severe enough to require specific clinical attention, beyond what would be expected for the co-occurring problem (DSM-5 criteria B–D).

Although seemingly clear, the operationalization of these diagnostic criteria has ambiguities, potentially contributing to inconsistent findings on various aspects of ARFID, including assessment, prevalence, correlates, course, and treatment, all of

which impede our understanding of this problem. For example, one recently published study sought to examine the degree to which different operationalizations of the diagnostic criterion A for ARFID contributed to differences in the frequency of individuals who were eligible for an ARFID diagnosis (Harshman et al. 2021). These researchers identified 19 different potential operational definitions and determined how many individuals in a sample of 80 individuals enrolled in an avoidant/restrictive eating study (children, adolescents, and young adults) would meet for ARFID using each of the definitions. They found considerable differences in ARFID diagnosis eligibility depending on the operational definition utilized. Using the strictest definition, 50.0% ($n = 40$) of participants met criteria for ARFID, while the application of the most lenient definition led to nearly double that number, resulting in 97.5% ($n = 78$) meeting criteria for ARFID. For an in-depth account of the challenges relating to the diagnosis and operationalization of the ARFID diagnostic criteria, see a summary by the Radcliffe ARFID Workgroup, a cohort of international experts in the field of feeding and eating disorders (Eddy et al. 2019), and a systematic review of diagnostic validity in ARFID (Strand et al. 2019).

Although there are many aspects of ARFID that are not well understood, since its official introduction in 2013, research into this eating disorder has been rapidly expanding. This chapter aims to provide a summary of current evidence-based understanding of ARFID – its characteristics, impact, etiology, assessment, and available treatments. Of note, although ARFID can be diagnosed throughout the lifespan, the vast majority of publications to date focus on ARFID in children and adolescents (Strand et al. 2019). For this reason, this chapter will focus on findings relating to ARFID in this population.

ARFID in Children

Characteristics

Current research into the clinical characteristics of ARFID highlights its heterogeneity. For example, some children with ARFID are underweight, while others maintain average and even above-average weight, often due to supplements intake, tube feeding, or consuming mostly energy-dense processed foods. Some have a long-lasting history of difficulty with food intake, often dating back to infancy, while others may have started only recently to restrict their intake, perhaps following a choking incident or severe stomach bug. Some have additional medical or mental problems that impact their eating, such as gastrointestinal problems, oral-sensory motor problems, autism spectrum disorder (ASD), or anxiety, while others do not. For some, the ARFID manifests in significant nutritional deficiency (e.g., low levels of minerals like iron, zinc, and magnesium and vitamins A, C, and D), while for others most ARFID-related impairment occurs in the psychosocial domain (e.g., interfering with the ability to function well with friends and family members and at school).

The DSM provides examples of factors that may be driving the restriction in eating: (a) apparent limited interest in eating or poor appetite; (b) selectivity of foods based on their sensory properties such as smell, texture, color, and temperature; and (c) fear of aversive consequences from eating such as choking, vomiting, or gastrointestinal pain (American Psychiatric Association 2013). The validity of these three distinct presentations has been examined and is gaining support (Norris et al. 2018; Zickgraf et al. 2019a). Based on these phenomenological distinctions, Thomas et al. (2017c) proposed a three-dimensional model of the neurobiology of ARFID, rooting these phenomenological distinctions in neurobiological abnormalities in sensory perception, homeostatic appetite, and negative valence systems (for further elaboration see below under "Etiology").

It is important to note that these three presentations are not mutually exclusive, and it is not rare to encounter children whose symptoms fit more than one of these presentations. For example, one paper reported on the case of an 11-year-old boy who showed features of all three ARFID presentations. This child presented with a lifelong history of sensory sensitivity, apparent limited interest in food, and phobia of vomiting, all resulting in him restricting his diet to a single food item (yogurt) for more than 5 years (Dolman et al. 2021). Additionally, Zickgraf et al. (2019a) identified a fourth subgroup of patients who exhibited both poor appetite and selective eating. This group had the longest history of growth faltering and was least likely to present with acute weight loss. Further, the DSM recognizes that there could be additional factors driving the restricted eating, though these are not yet well described. For example, one study of children and adolescents referred to a hospital-based pediatric eating disorder service and diagnosed with ARFID ($N = 102$, ages 8–18 years) identified age, weight, and duration of illness as factors influencing the presentation of ARIFD. In this sample, adolescents (ages 12–18 years) presented with higher rates of depression compared with children (ages 8–11 years); those with chronic ARFID symptoms ($\geq$12 months) presented with significantly lower weight than those with acute symptoms ($<$12 months); and those with acute symptoms endorsed significantly higher suicidal ideation and/or self-harm (Duncombe Lowe et al. 2019). The heterogeneity in ARFID presentation, suggesting distinct etiological and maintenance factors for different restrictive eating patterns, has led to calls for the development of interventions that consider variability in clinical symptoms, demographic characteristics, and appropriate levels of care (Eddy et al. 2019; Zickgraf et al. 2019a).

Prevalence of ARFID

There is a paucity of epidemiological research on ARFID, and prevalence estimates have ranged widely, in both clinical and community samples (Bourne et al. 2020). This could be attributed, in part, to the lack of clear and agreed-upon operationalized definitions of the diagnostic criteria in the DSM, forcing researchers and clinicians to rely on clinical judgment (Harshman et al. 2021).

In community samples, reports of ARFID prevalence range between 0.3% and 3.2%. An Australian population-based study of adolescents and adults ages 15 years and older ($N = 5737$) reported a 3-month point prevalence of 0.3% assessed both in 2013 and in 2014 (Hay et al. 2017). The estimated prevalence of other specific eating disorders was higher in comparison (0.4% and 0.5% for anorexia nervosa, 1.1% and 1.2% for bulimia nervosa). These rates were lower than the estimated prevalence of 3.2% for the heterogeneous group of other specified feeding or eating disorders (OSFED), which includes problems such as atypical anorexia nervosa (anorexia with weight loss that remains within or above the normal range) and atypical bulimia nervosa (subthreshold bulimia with low frequency of binge eating and inappropriate compensatory behaviors). In another self-report community-based study in Switzerland, ARFID was reported in 3.2% of children and adolescents ($N = 1444$; ages 8–13 years; Kurz et al. 2015). Both studies reported similar rates of ARFID in males and females.

Reports of ARFID prevalence in clinical samples of patients in children and adolescent tertiary care centers mostly range between 5% and 14% (Fisher et al. 2014; Norris et al. 2014), with the highest prevalence (22.5%) found in a pediatric partial hospitalization program (PHP) for eating disorders (Nicely et al. 2014). In a sample of 2231 consecutive referrals to pediatric gastrointestinal clinics (ages 8–18 years), the reported prevalence was 1.5% (Eddy et al. 2015). Most reports rely on retrospective chart reviews, documenting encounters from before ARFID was formally and clearly defined in the DSM.

Impact of ARFID

There is little research exploring the outcomes of ARFID, most of which focuses on medical monitoring of the more severe and low-weight ARFID patients admitted to inpatient care (Bourne et al. 2020). Available research suggests serious potential medical and mental sequelae of ARFID. When ARFID is characterized by weight loss or failure to gain weight, this could lead to trouble concentrating, sleep disturbances, and feeling weak, tired, or irritable. It is important to note that children are expected to continuously gain weight. Therefore, for children, maintaining the same weight over extended periods of time is considered weight loss and poses a serious problem (Bryant-Waugh and Higgins 2020). Another possible consequence of restricting food intake is nutritional deficiencies. These commonly include minerals such as iron, calcium, and zinc and vitamins A, C, and D. Deficiencies in these micronutrients can seriously compromise a child's health, leading to problems like anemia, poor bone health, eye and skin problems, and scurvy (Taylor and Emmett 2019).

In some cases, when the child is persistently losing weight and failing to meet energy and/or nutritional needs, it could be deemed medically necessary to introduce tube feeding (also known as nasogastric/gastrostomy feeding tubes). This usually leads to a meaningful improvement in the child's intake and weight and to short-term relief in the concern about the child's health. In the longer term however, tube

feeding may interfere with the body's natural tendency to regulate hunger, and the child may become dependent on the tube feeding and less motivated to eat independently. The insertion of the tube may also restrict the child to the home, leading to disengagement from normal life. For these reasons, it is recommended that when a tube is placed, this step is accompanied with a plan indicating when and how to remove it and encourage independent eating (Dovey et al. 2018).

For some children with ARFID, the main area of impact is in the psychosocial domain, impairing both the child's and the family's functioning. For example, ARFID can impact the child's ability to take part in daily social events such as eating at school or at a restaurant and going to play dates or birthday parties, negatively impacting their relationships with peers and family. ARFID can also have a detrimental impact on the family as a whole. Parents often describe experiencing distress, anxiety, frustration, and conflict between family members at mealtimes. Many parents accommodate the ARFID to alleviate the child's distress and make it easier for the child to eat in the short term (e.g., by providing the child only with their preferred foods). This accommodation, though well-intentioned, usually leads over time to maintenance of the ARFID symptoms and related impairment (Shimshoni et al. 2020; Zickgraf et al. 2019b).

Differential Diagnosis

Arriving at a diagnosis of ARFID involves ruling out other conditions that may better explain the restricted eating. Some examples are gastrointestinal conditions, oral-motor functioning, anxiety, and depression. It is also important to distinguish ARFID from other eating disorders such as anorexia nervosa, bulimia nervosa, and binge eating disorder. A central difference between ARFID and these other eating disorders is that in ARFID, the restriction of food intake is not driven by concerns about weight or shape and the individual with ARFID will not experience extreme anxiety relating to gaining weight (Izquierdo et al. 2019).

Among these eating disorders, anorexia nervosa stands out as a particularly relevant differential diagnosis, especially in children 8 years old and above (Bryant-Waugh and Higgins 2020). While there are some similarities between anorexia nervosa and ARFID, such as restricted food intake, negative impact on family members and relationships, and possibly weight loss or lack of motivation for change, there are also striking and important differences. Aside from the absence of underlying concerns about weight or shape or behaviors intended to promote weight loss in ARFID, studies comparing children with ARFID to those with anorexia nervosa found that children with ARFID were younger and a greater proportion were male (Nicely et al. 2014; Ornstein et al. 2017). Additionally, in ARFID the problematic eating typically dates back to early childhood, whereas in anorexia eating behavior was often normative before the development of the problem (Fisher et al. 2014). Although patients with ARFID and anorexia nervosa both restrict the foods they eat, those with ARFID often prefer energy-dense, high-fat, and high-sugar

foods (e.g., processed foods), whereas those with anorexia usually eat low-calorie, low-fat, and low-sugar foods, such as vegetables (Harshman et al. 2019).

Another difference between ARFID and other eating disorders relates to common co-occurring problems. While both ARFID and other eating disorders frequently co-occur with elevated levels of anxiety and depression (Thomas et al. 2018), some studies report higher rates of co-occurring anxiety disorders in ARFID compared with anorexia and bulimia (Fisher et al. 2014). One retrospective chart review reported generalized anxiety disorder in 50% of adolescents with ARFID ($N = 34$; Norris et al. 2014). Autism spectrum disorder also commonly co-occurs with ARFID, with estimates ranging between 3% and 13% of cases (Cooney et al. 2018; Lucarelli et al. 2017; Nicely et al. 2014). Additional conditions strongly associated with ARFID include oppositional defiant disorder (ODD), obsessive-compulsive disorder (OCD), attention-deficit/hyperactivity disorder (ADHD), gastrointestinal symptoms, and other medical conditions (Bryant-Waugh and Higgins 2020; Eddy et al. 2015; Fisher et al. 2014). Compared with other eating disorders, ARFID was found more weakly associated with mood disorders (Nicely et al. 2014).

Etiology

Why some children develop ARFID, and others do not, is not well understood. In line with the widely accepted biopsychosocial model for understanding heath and illness (Engel 1977), it is probable that several types of factors – biological, psychological, and environmental – and the interactions between them, contribute to the development of this problem (Brigham et al. 2018). Though applicable to most disorders, this complexity is underscored in the case of ARFID, a problem that is heterogeneous and that appears in high frequency alongside other mental and medical conditions, increasing the likelihood that ARFID is caused by the interplay between several different factors (Bryant-Waugh and Higgins 2020; Thomas et al. 2017c).

Some possible environmental contributors to the etiology of ARFID include familial and cultural beliefs and attitudes relating to food and family meal environment and food-related interactions (Satter 1999), as well as maternal food intake during pregnancy and breastfeeding (Mennella et al. 2001). For reviews of environmental factors impacting child eating preferences, see Savage et al. (2007) and Taylor and Emmett (2019). Other contributing factors may include mood, temperament, and arousal levels (Bryant-Waugh and Higgins 2020). Specific attention has recently been given to the role of disgust in the etiology of ARFID, though research is indicated to further understand and support this role (Menzel et al. 2019). Co-occurring problems may also influence the development of ARFID. For example, food allergies or celiac may lead some children to increase their overall food restrictions and avoidance, and autism spectrum disorder, often characterized by heightened sensory sensitivity, might increase sensitivity to smells and sounds associated with food and eating (Thomas and Eddy 2019). Twin studies provide

some indication that genetic factors might also play a role in taste preference (Cooke et al. 2007), though research into this question is scarce in the context of ARFID.

One etiological model that is gaining support is the three-dimensional model of the neurobiology of ARFID, which roots the phenomenological differences in ARFID in neurobiological abnormalities (Thomas et al. 2017c). According to this model, ARFID presenting with lack of interest in food might be associated with differences in activation of appetite-regulating centers in the brain, ARFID presenting with selective eating based on sensory characteristics might be associated with oversensitivity in taste perception, and ARFID characterized by fear of aversive consequences might be associated with hyperactivation of the fear processing brain circuitry. Since children can present with more than one of these three presentations, each individual's severity ratings across these three domains can be quantified and plotted on the three-dimensional model to create a unique ARFID profile.

Assessment of ARFID

Several measures are available for evaluating ARFID, including self-report screening instruments and clinician-administered diagnostic interviews. Screening instruments can indicate the need for further assessment and are not sufficient for establishing a diagnosis. Screening instruments for ARFID include the Eating Disorders in Youth-Questionnaire (EDY-Q; Kurz et al. 2015), intended to detect early-onset disordered eating in children ages 8–13; the ARFID Brief Screener (ARFID-BS; Dinkler et al. 2022), intended for parents of children ages 4–7; and the Nine Item ARFID Screen (NIAS; Zickgraf and Ellis 2018), which is the only screening instrument for adults/parents. A recent study validated the three subscales of the NIAS ("picky eating," "appetite," and "fear") and established recommended cutoff points for each subscale (Burton Murray et al. 2021). Because the NIAS was not able to distinguish ARFID from other eating disorders, the authors recommended using the NIAS as a screening measure for ARFID in combination with other screening measures for eating disorders, such as the Eating Disorder Examination-Questionnaire (EDE-Q; Fairburn and Beglin 2008).

Diagnostic interviews for ARFID include the Pica, ARFID, Rumination Disorder Interview (PARDI; Bryant-Waugh et al. 2019), the Eating Disorder Assessment for DSM-5 (EDA-5; Sysko et al. 2015), and the ARFID module of the Eating Disorder Examination (EDE-ARFID; Schmidt et al. 2019), which are all semi-structured interviews, and the Structured Clinical Interview for DSM-5 Disorders (SCID-5; Chen et al. 2019). For a comprehensive description of available assessment measures for ARFID and their psychometric properties, see Dinkler and Bryant-Waugh (2021).

In addition to determining whether a child meets diagnostic criteria for ARFID, clinical assessment should include a focus on the degree and domains of psychosocial impairment associated with the symptoms. It is also recommended that medical and nutritional assessments be completed by a medical health professional. In complicated ARFID cases, multidisciplinary input may be needed to assess

additional problems, such as gastrointestinal problems, autoimmune diseases, and oral sensorimotor concerns (Bryant-Waugh 2019; Eddy et al. 2019).

Treatment of ARFID

As ARFID was introduced to the DSM only in 2013, there is little research documenting treatment outcomes, and to date there are no well-established psychosocial treatments for ARFID (Bourne et al. 2020; Eddy et al. 2019). Aside from three small-scale pilot randomized controlled trials (RCTs) and three pilot open trials, treatment approaches have been presented through case reports, case series, and retrospective chart reviews. Studies have examined family-based treatment, child-centered cognitive-behavioral therapy, or parent-based interventions, with variability in intended age and setting. Table 1 summarizes psychosocial interventions for childhood ARFID.

Family-Based Treatment

Family-based treatment (FBT) is one of the most documented treatments adapted for childhood ARFID (FBT-ARFID; Lock 2021). FBT for ARFID is usually carried out in an outpatient setting and empowers parents as the primary agents managing behavioral change. This manualized treatment focuses on promoting increased volume of food intake (as in FBT for anorexia nervosa) and on increasing the variety of foods eaten, and applications of this treatment to each of the three common ARFID presentations have been described (Lock et al. 2019b). A pilot RCT in children aged 5–12 years compared FBT-ARFID ($n = 16$) to treatment as usual (TAU; $n = 12$). Participants in the TAU group were free to seek the treatments of their choice, not including FBT-ARFID. Results showed improvement in weight and ARFID symptom severity for children in the FBT-ARFID condition compared with children in the TAU group. Parents in the FBT-ARFID group showed significant changes in parental self-efficacy, and these changes were associated with improved clinical outcomes. These findings led the authors to highlight the importance of parental factors as one potential mechanism of therapeutic change. FBT for ARFID has been applied in combination with other approaches in both outpatient settings and as part of more intensive treatments. For example, one case study of a 9-year-old girl described the combination of FBT with the Unified Protocol for Transdiagnostic Treatment of Emotional Disorders in Children (UP-C; Eckhardt et al. 2019) in an outpatient setting, and in a PHP for children with acute ARFID onset and low body weight, aspects of FBT have been incorporated in a broad family-centered treatment program therapy (Ornstein et al. 2017). Spettigue et al. (2018) reported on a case series ($N = 6$, ages 10–14 years) applying FBT for ARFID in combination with medication in an inpatient and outpatient setting.

Cognitive-Behavioral Approaches

Another promising approach to treating childhood ARFID is cognitive-behavioral therapy (CBT). Most documented adaptations of CBT to ARFID have been

Table 1 Psychosocial interventions for childhood ARFID

Approach	Intervention	Setting	Key intervention components	Who is involved in treatment	Treatment duration and age	Empirical support
Family-based	Family-based treatment for ARFID (FBT-ARFID) (Lock et al. 2019a, b; Norris et al. 2016; Rosania and Lock 2020)	Outpatient	Externalizing, agnosticism, parent-led behavioral changes, focus is on changing eating behavior rather than family process/ dynamics	Child, parents, and siblings (optional)	Up to 22 sessions over 6 moths Ages 5–12 years	Pilot RCT with treatment as usual as comparator ($N = 28$) Case reports
	FBT adapted for ARFID + medication (Spettigue et al. 2018; Naviaux 2019)	Inpatient and outpatient	Medical monitoring, psychoeducation and support for parents, parent-led behavioral changes, relaxation techniques, medication and CBT for comorbid anxiety	Child and parents	4–6 months Ages 10–14 years	Case series ($N = 6$) Case report
	FBT + Unified Protocol for Transdiagnostic Treatment of Emotional Disorders in Children (UP-C) (Eckhardt et al. 2019; Burton et al. 2021)	Outpatient	Collaborative weighing, family engagement, externalizing, parent-led behavioral changes, cognitive restructuring, exposures, behavioral activation, mindfulness (Eckhardt et al. 2019; Burton et al. 2021)	Child and parents	24–29 sessions over 8–11 months Ages 6–11	Case reports

			And additional ASD specific techniques (Burton et al. 2021)			
Cognitive-behavioral	Cognitive-behavioral therapy for ARFID (CBT-AR) (Thomas et al. 2017a; Thomas et al. 2020)	Outpatient	Psychoeducation, monitoring of food intake, establishing regular eating routines, increasing volume of preferred foods or variety of foods, in vivo and interoceptive exposure	Individual or family-supported format depending on the patient's age	20 to 30 sessions Age 11 Ages 10–17 years Treatment intended for ages 10 years and up	Case report (Thomas et al. 2017a) Pilot open trial ($N = 20$) (Thomas et al. 2020)
	Broad CBT approach (Bryant 2013)	Outpatient	Self-monitoring, behavioral experiments, cognitive restructuring, breathing, relaxation	Child and parents	Length of treatment not specified Age 13	Case report
	Cognitive and behavioral treatment (Fischer et al. 2015)	Outpatient	Gradually increasing feeding demands and reinforcing consumption, cognitive restructuring breathing, relaxation, guided imagery	Child and parents	11 sessions Age 16	Case report
	Feeling and Body Investigators-ARFID Division (FBI-ARFID) (Zucker et al. 2019)	Outpatient	Interoceptive and exteroceptive inhibitory learning, exposure to aversive sensations, acceptance	Child and parents	11–15 sessions Age 4 Treatment intended for ages 4–10 years	Case report
	Exposure-based CBT integrating inhibitory	Partial hospitalization	Exposure, behavioral experiments, cognitive	Individual, parent and	4-week intensive day treatment (6–8 hours per day) followed by	Case series ($N = 11$)

(continued)

Table 1 (continued)

Approach	Intervention	Setting	Key intervention components	Who is involved in treatment	Treatment duration and age	Empirical support
	learning principles (Dumont et al. 2019)	program followed by outpatient treatment	restructuring, relaxation	child, and group sessions	4-week low-intensity outpatient treatment Ages 10–18 years	
	Family-centered cognitive-behavioral treatment (Ornstein et al. 2017; Bryson et al. 2018; Lane et al. 2020)	Partial hospitalization program Children with acute onset, low body weight	Meal planning, exposure and response prevention, cognitive restructuring, hierarchical reintroduction of foods in program and at home, contingency management, medication when needed	Child and parent and/or other family members	5 days per week for 8.5 hours per day including 2-hour school component for an average of 7 weeks Ages 7–17 years	Retrospective chart reviews ($N = 130$, $n = 32$ with ARFID (Ornstein et al. 2017); $N = 81$ [17])
Parent-based	Behavioral parent-only group treatment (Picky Eaters Clinic) (Dahlsgaard and Bodie 2019)	Outpatient	Psychoeducation, improving mealtime hygiene, parent-facilitated exposures, habituation, differential reinforcement, contingency management	Parents	7 group sessions. Each group included parents of 2–4 children	Pilot open trial ($N = 21$)
	Parent-based treatment (SPACE-ARFID) (Shimshoni et al. 2020;	Outpatient	Psychoeducation, promoting change in parent behavior: systematic reduction of	Parents	12–16 sessions Ages 6–14 12 weekly sessions Age 7	Pilot open trial ($N = 15$) (Shimshoni et al. 2020) Case report

	Shimshoni and Lebowitz 2020)		food-related stress and family accommodation, increasing supportive responses			(Shimshoni and Lebowitz 2020)
	Behavioral parent-training intervention (Murphy and Zlomke 2016)	Outpatient	Psychoeducation, in vivo parent coaching, parent modeling, differential reinforcement, gradual exposure, contingency management	Child and parents	18 sessions over 6 months Age 6	Case report
	Behavioral parent-training intervention through teleconsultation (Bloomfield et al. 2019)	Outpatient	Contingency management	Parents	Age 8	Case report
Hospital-based feeding programs	Integrated eating aversion treatment (iEAT) (Sharp et al. 2016)	Partial hospitalization program for children with chronic food refusal and dependence on enteral feeding or oral nutritional formula supplementation	Reinforcement, escape extinction, formulized meal structure	Child and parents	5 consecutive days with 14, 40-minute meals Ages 13–72 months	Pilot RCT with wait list as comparator ($N = 20$)
	Nutritional rehabilitation program (Strandjord et al. 2015)	Inpatient	Meal planning, nasogastric tube and nutritional	Child	5–13 days Ages 5–25 years	Retrospective chart review ($N = 318$, $n = 41$ with ARFID)

(continued)

Table 1 (continued)

Approach	Intervention	Setting	Key intervention components	Who is involved in treatment	Treatment duration and age	Empirical support
			supplements when needed			
	CHOP inpatient nutritional rehabilitation protocol (Peebles et al. 2017)	Inpatient	Rest, electrolyte monitoring, gradual increases in nutrition and weight gain, nasogastric tube and nutritional suppliants when needed, as well as psychotherapeutic support and nutritional education	Child, parents as part of treatment team	3–40 days Ages 5–23 years	Retrospective chart review ($N = 215$, $n = 9$ with ARFID)
	Nutritional rehabilitation + pharmacotherapy augmentation (Sharp et al. 2017)	PHP	D-cycloserine (DCS), escape extinction, reinforcement procedures	Child and parents	5 days Ages 20–58 months	Double-blind pilot RCT with placebo as comparator (N = 15)
	Multimodal approach (Dolman et al. 2021)	Inpatient	Multimodal approach combining elements from FBT, CBT, and pharmacotherapy (sertraline and olanzapine)	Child and parents	7 weeks Age 11 years	Case study

Note: ARFID, avoidant/restrictive food intake disorder; FBT, family-based treatment; CBT, cognitive-behavioral therapy; RCT, randomized controlled trial; SPACE, Supportive Parenting for Anxious Childhood Emotions; CHOP, Children's Hospital of Philadelphia

presented thus far through case examples, case series, and retrospective chart reviews (Bryant 2013; Dumont et al. 2019; Fischer et al. 2015; Ornstein et al. 2017; Thomas et al. 2017a) and have been applied in outpatient settings (e.g., Thomas et al. 2017a) as well as integrated in PHPs (e.g., Dumont et al. 2019). These interventions commonly include cognitive restructuring, systematic exposures to increased volume and/or variety of foods, self-monitoring, and relaxation techniques. One open trial examined the application of a manualized cognitive-behavioral treatment for ARFID (CBT-AR) in 20 participants (ages 10–17 years) in an outpatient setting (Thomas et al. 2020; Thomas and Eddy 2019). At posttreatment the authors reported significant reductions in ARFID severity scores, incorporation of new foods (mean = 16.7; SD = 12.1), and significant weight gains for participants in the underweight subgroup. Additionally, 70% of patients no longer met criteria for ARFID. Two retrospective chart reviews reported on the integration of CBT in an intensive family-centered treatment in a PHP ($N = 32$, 81, ages 7–17) and showed posttreatment gains in weight and reductions in eating disorder and anxiety symptoms as well as an increase in the number of foods patients were willing to eat (Lane et al. 2020; Ornstein et al. 2017).

One paper described an application of the Feeling and Body Investigators-ARFID Division (FBI-ARFID) for a 4-year-old girl with ARFID (Zucker et al. 2019). This exposure-based interoceptive treatment focused on exploring and experiencing aversive sensations rather than terminating them, in an acceptance-based framework.

Parent-Based Treatments

Another area of increasing focus examines parent-based interventions in outpatient settings. One pilot open trial examined acceptability, feasibility, treatment satisfaction, and preliminary efficacy of SPACE-ARFID (Supportive Parenting for Anxious Childhood Emotions adapted for ARFID; Shimshoni et al. 2020). The foundation for this adaptation of SPACE, an evidence-based treatment for child anxiety and OCD (Lebowitz et al. 2019), rests on commonly observed shared features between childhood anxiety and ARFID. These include elevated levels of anxiety and avoidance behaviors and the presence of family accommodation (Brigham et al. 2018; Eddy et al. 2019; Norris et al. 2014; Zickgraf et al. 2019b). Family accommodation refers to the ways in which parents and other family members change their own behavior to help their relative with a psychiatric illness avoid or alleviate distress related to the illness. Although family accommodation is usually well-intentioned, it is associated with greater symptom severity and functional impairment (Lebowitz et al. 2016; Shimshoni et al. 2019). SPACE-ARFID is a manualized parent-based treatment aimed at increasing food-related flexibility by helping parents to systematically reduce food-related stress and family accommodation and to increase supportive responses to the child's distress (Shimshoni and Lebowitz 2020). Results of this pilot study ($N = 15$, ages 6–14 years) showed significant reductions in ARFID symptom severity, ARFID-related impairment, and family accommodation and increases in food-related flexibility.

Another pilot open trial examined the acceptability, feasibility, and initial outcomes of a parent-only outpatient group behavioral treatment for childhood ARFID

(Picky Eaters Clinic; $N = 21$, ages 4–11 years). In this study, seven groups of parents (two to four families per group) participated in seven sessions focused on teaching parents to facilitate daily in-home exposures, differential reinforcement, contingency management procedures, and elements of parent management training. Results showed significant reductions in picky eating symptoms after treatment, and gains were maintained at 3-month follow-up (Dahlsgaard and Bodie 2019).

Other accounts of treatments with high parental involvement include a case of a 6-year-old girl who received a behavioral parent-training intervention which was successful in increasing her food intake variety (Murphy and Zlomke 2016) and the case of an 8-year-old boy who increased intake volume of non-preferred foods during a behavioral parent-training intervention delivered via teleconsultation (Bloomfield et al. 2019).

Hospital-Based Feeding Programs

Hospital-based feeding programs usually involve a multidisciplinary team and are of greater intensity compared with outpatient interventions. One prospective pilot RCT compared an intensive multidisciplinary behavioral feeding therapy to a waitlist condition in a 5-day PHP for young children with chronic food refusal and dependence on enteral feeding or oral nutritional formula supplementation ($N = 20$, ages 13–72 months; Sharp et al. 2016). Compared with the waitlist condition, children receiving therapy consumed more food and had fewer mealtime disruptions. Inpatient programs have also described the use of nasogastric tube feeding as part of feeding programs through retrospective chart reviews (Peebles et al. 2017; Strandjord et al. 2015) and case reports (Pitt and Middleman 2018; Schermbrucker et al. 2017). The benefits and negative effects of such procedures remain a contested issue in the field (Dovey et al. 2018).

Pharmacotherapy

In PHPs and inpatient settings, the use of pharmacotherapy (e.g., olanzapine, fluoxetine, mirtazapine, and cyproheptadine) for ARFID has also been examined in addition to other treatment modalities and reported mainly through retrospective chart reviews and case series (e.g., Brewerton and D'Agostino 2017; Gray et al. 2018; Spettigue et al. 2018). A single small-scale double-blind RCT for very young children with ARFID ($N = 15$, ages 20–58 months) compared intensive extinction-based feeding intervention and D-cycloserine (DCS) to the same intensive feeding intervention and placebo (Sharp et al. 2017). Compared with the placebo group, children DCS group showed increased food acceptance and decreased problem behavior during meals. To date, there are no established guidelines for the use of pharmacological treatments for ARFID, though it has been recommended that they be used in addition to other treating approaches and not as a first-line treatment intervention (Bryant-Waugh 2019; Naviaux 2019).

Summary

This chapter reviews findings contributing to the current understanding of ARFID in children and adolescents. Although research demonstrates that ARFID has specific characteristics and clinical profiles distinguishing it from other problems, there are many aspects of this eating disorder that are not yet well understood. For example, ARFID is currently conceptualized as a highly heterogeneous problem, yet little is understood about the nature of this heterogeneity. The DSM offers three examples of forces driving the restricted eating, though it is likely that there are additional drivers that have not yet been explored, such as cognitive inflexibility or a need for control (Bourne et al. 2020). Other questions that are only partially answered by available research include: What is the prevalence of ARFID? What is the impact of ARFID? What is the optimal treatment strategy for ARFID? Accurate epidemiological data are needed and can shed light on the prevalence of ARFID and assist in further characterizing the disorder in terms of age of onset and prevalence of specific ARFID presentations. Systematic research focusing on broader areas impacted by the ARFID, such as implications in the psychosocial domain, will allow for a more comprehensive understanding of the consequences of having ARFID including for those who do not require weight restoration in inpatient settings. And relating to the question of which treatments are best for treating ARFID, large-scale RCTs are urgently required to establish the efficacy of available treatment approaches.

As the field moves forward in studying and treating children with ARFID, it is likely that advances in each of the ARFID-related areas will advance the understanding of other areas. For example, a better understanding of the forces driving restricted eating will help to develop more effective treatment approaches and accurate assessment tools. More accurate and agreed-upon assessment tools will, in turn, provide more precise accounts of the prevalence of ARFID and will enable clinicians and researchers to better distinguish it from other problems and to determine criteria for remission.

Mini-Dictionary of Terms

Anorexia nervosa: an eating disorder characterized by intentional and extreme weight loss driven by concerns about body weight or shape.

Autism spectrum disorder (ASD): a range of neurodevelopmental disorders characterized by difficulties with social interaction and communication and by restricted and repetitive behavior.

Biopsychosocial model: a model that examines the interactions between biology, psychology, and socio-environmental factors to better understand a wide range of health-related conditions and issues.

Binge eating disorder: an eating disorder characterized by uncontrollably eating unusually large amounts of food in a relatively short time. Binge eating is different from bulimia nervosa in that it is not accompanied by behaviors aimed at neutralizing the food intake, such as vomiting, taking laxatives, or excessive exercise.

Bulimia nervosa: an eating disorder characterized by uncontrollably eating usually large amounts of food in a relatively short time, accompanied by behaviors aimed at neutralizing the food intake, such as vomiting, taking laxatives, or excessive exercise.

Cognitive-behavioral therapy (CBT): a type of psychological treatment that focuses on a person's thoughts, feelings, and behaviors which are understood to underlie or maintain the problem. CBT is a short-term and well-established treatment found effective in treating many different mental conditions.

Differential diagnosis: the process a clinician will go through in differentiating between two or more possible conditions characterized by similar signs or symptoms, in an effort to determine which diagnosis is most accurate.

DSM: *Diagnostic and Statistical Manual of Mental Disorders*. It is the mental health problems classification system of the American Psychiatric Association. The current edition of the DSM is the DSM-5.

Enteral feeding: the intake of food through the gastrointestinal tract. This includes the esophagus, stomach, and intestines. Mostly though, in the context of feeding/eating disorders, enteral feeding is used to describe tube feeding.

Epidemiological research: research that investigates the factors that determine the presence or absence of diseases and disorders in the population. Epidemiological research helps to understand how many people have a disease or disorder, if those numbers are changing, and how the disorder affects our society and our economy.

Family accommodation: describes the changes that family members make to their own behavior to help their relative with a psychiatric illness avoid or alleviate distress related to the illness. Although family accommodation is usually well-intentioned, it is associated with greater symptom severity and functional impairment.

Feeding and eating disorder of infancy and early childhood: an eating disorder characterized by failing to eat enough food to maintain weight and grow as expected. Applicable when the difficulties started before age 6 years. This eating disorder appeared in the DSM-4 (the 4th edition of the DSM) and was replaced in the DSM-5 with the introduction of ARFID.

ICD: International Classification of Diseases. It is the World Health Organization's comprehensive classification system for all mental and physical diseases and health problems. The current edition of the ICD is ICD-11.

Nasogastric tube: a plastic tube that is inserted through the nose, past the throat, and down into the stomach. Nasogastric tubes (also known as NG tubes) are often used to facilitate caloric intake when individuals are malnourished and cannot eat independently.

Macronutrients: types of foods needed in large amounts to maintain the body's system and structures. These include fat, carbohydrates, and protein.

Micronutrients: essential elements of our diet that are generally required in small amounts. These include numerous vitamins (such as vitamins A, C, and D) and dietary minerals (such as iron, zinc, and calcium).

Other specified feeding or eating disorders (OSFED): a diagnostic category in the DSM-5, referring to feeding and eating disorders that do not meet diagnostic criteria

for anorexia nervosa, bulimia nervosa, binge eating disorder, ARFID, pica, or rumination disorder. OSFED include atypical anorexia nervosa, atypical bulimia nervosa, and binge eating disorder of low frequency and/or limited duration.

Randomized controlled trial (RCT): a form of scientific experiment used to control for factors not under direct experimental control by randomly assigning participants to different research conditions. RCTs are often used in clinical research to study the efficacy of different treatments and are generally considered high-quality research.

Tertiary care: medical care that is highly specialized involving advanced and complex procedures and treatments.

Summary Points

- ARFID stands for avoidant/restrictive food intake disorder. Individuals with ARFID limit the variety or quantity of foods they eat to the extent that these limitations are associated with marked interference in feeding, growth, or psychosocial functioning.
- Because ARFID was introduced fairly recently, in the 5th edition of the DSM in 2013, there are scarce data on various aspects of ARFID such as assessment, prevalence, correlates, impact, and treatment.
- ARFID is understood to be a highly heterogeneous problem. Emerging evidence supports three distinct, but not mutually exclusive, presentations of ARFID: ARFID driven by lack of interest in eating/food, ARFID driven by sensory sensitivity, and ARFID driven by concerns relating to possible consequences of eating specific foods. It is also hypothesized that there are other driving factors not yet systematically explored.
- ARFID seems to be as prevalent as other eating disorders, and there are serious potential medical and mental implications of having ARFID. These include trouble concentrating, sleep disturbances, feeling tired and irritable, nutritional deficiencies leading to problems like anemia, poor bone health, eye and skin problems, and psychosocial impairment impacting friendships, family relationships, and academic performance.
- ARFID commonly co-occurs with other problems such as gastrointestinal conditions, oral-motor functioning, anxiety, autism spectrum disorders, oppositional defiant disorder, obsessive-compulsive disorder, and attention-deficit/hyperactivity disorder.
- There are several available assessment tools for ARFID including self-report screening measures as well as clinician-administered interviews for establishing a diagnosis of ARFID.
- To date, there are no well-established treatments for childhood ARFID. There is preliminary support for the application of family-based therapy (FBT), cognitive-behavioral therapy (CBT), and parent-based approaches. There is also some support for the use of pharmacotherapy, usually alongside psychosocial therapy.

- Despite research efforts into ARFID, current understanding of this eating disorder is limited. Rigorous research is needed to improve the understanding of the phenomenology, driving forces, assessment, and effective treatments.

Abstract

Prader-Willi syndrome (PWS), a congenital genetic disorder, has received attention due to its features, including hyperphagic behavior with a unique genetic background. While clinical research on this syndrome has focused on the management of the endocrinological and metabolic manifestations, there is growing evidence for the involvement of the brain in the pathogenesis of developmental and behavioral characteristics. Furthermore, researchers have investigated the genetic influence on molecular and cellular processes related to behavior using mouse models. On the other hand, modern advanced magnetic resonance imaging, three-dimensional high-resolution structural imaging, diffusion imaging, and resting-state functional imaging have revealed structural and functional alterations in the brains of individuals with PWS, supported by updated optimization and statistical methods. This chapter discusses research on the brain in PWS and addresses its contribution to hyperphagia, which leads to obesity, as well as the neural mechanisms that may underlie the behavioral phenotypes of this syndrome.

Keywords

Autism · Arginine-vasopressin · Behavior · Brain · Cerebellum · Development · Diffusion · Hyperphagia · Hypothalamus · MRI · Pituitary · Prader-Willi syndrome · Resting state · T1-weighted image

Abbreviations

5-HT	5-hydroxytryptamine
AT	Adipose tissue
AVP	Arginine-vasopressin
cDN	Cerebellar dentate nucleus
DTI	Diffusion tensor imaging
ERP	Event-related potential
GABA	Gamma amino butyric acid
IPWSO	International Prader-Willi Syndrome Organization
MRI	Magnetic resonance imaging
MRS	Magnetic resonance spectroscopy
OXT	Oxytocin

PET	Positron emission tomography
PWS	Prader-Willi syndrome
snoRNA	Small nucleolar RNA
SPECT	Single-photon emission computed tomography
TD	typically developing
UPD	Uniparental disomy

Introduction: Hyperphagia in Prader-Willi Syndrome

Prader-Willi syndrome (PWS) is a relatively rare genetic syndrome characterized by complex multisystem involvement, spanning from endocrinological to neurodevelopmental and psychiatric domains. Excessive eating (hyperphagia) is a prominent behavioral feature of PWS, which may lead to obesity. However, individuals with PWS may face several difficulties and clinical challenges owing to the wide variety of features of this condition. The multifaceted, continuous, and extensive efforts coordinated by international collaborations (International PWS organisation: IPWSO. https://ipwso.org/) are dedicated to expanding knowledge, experience, and best practices in both the scientific and caregiver communities. The recognition of PWS not only as a mere eating disorder but also as a model to investigate the relationship between brain and behavior could lead to a better understanding and treatment of eating disorders. Herein, I will review PWS from the viewpoint of brain pathophysiology as a unique form of neurodevelopmental disorder, whose behavioral and developmental characteristics presumably originate, at least partially, in the brain.

The details of the various aspects of this disease are extensive and beyond the scope of this chapter. This chapter focuses on addressing issues regarding several original or replicated findings that make a significant contribution to the understanding of PWS (Table 1).

Table 1 Clinical findings prompting genetic testing for Prader-Willi, Schaaf-Yang, and associated syndromes

Age	Clinical findings
From birth to 2 years of age	Marked hypotonia with feeding difficulty, typically requiring tube feeding
2–6 years	Hypotonia with poor suck Global developmental delay
6–12 years	History of hypotonia with poor suck Global developmental delay Excessive eating with central obesity (if diet is not managed properly)
From 13 years to adulthood	Intellectual disability (usually mild to moderate) Excessive eating with central obesity (if caloric intake is uncontrolled) Short stature Hypothalamic hypogonadism Characteristic behavioral problems

(Modified with permission from Cassidy et al. 2012)

PWS and Behavioral Phenotypes

PWS Overview

PWS was first described by Prader, Labhart, and Willi in 1956, and subsequent observations have further revealed its endocrinological and neurodevelopmental features (Prader and Labhart 1956). In 1981, the results of a genetic analysis revealed its genetic background as originating from the 15q11–13 region (Ledbetter et al. 1981). Furthermore, genetic imprinting, a unique mechanism, has paved the path for classifying a subtype of PWS, namely, deletion type or uniparental disomy (UPD) (Nicholls et al. 1989). Moreover, growing evidence has revealed differences in the severity of behavioral disturbance, obesity, and susceptibility to psychosis between these subtypes (Aman et al. 2018). Interested readers are invited to read an excellent review on this topic (Cassidy et al. 2012).

Diagnostic Criteria and Neurological Features

Currently, PWS is diagnosed based on multiple criteria including physical features, endocrinological abnormalities, and genetic testing (Holm et al. 1993; Goldstone et al. 2008). Following an initial review of systems and comorbidity screening, clinicians apply a multidisciplinary approach that involves the management of complications and growth hormone supplementation. A multidisciplinary approach has been explored and pointed out as the best practice for PWS by the IPWSO.

The following neurological abnormalities are additional essential features of PWS: severe hypotonia requiring respiratory support or tube feeding in the postnatal period in neonates, global developmental delay from infancy, intellectual disability from preschool, and hypersomnia from school age to adulthood (Cassidy et al. 2012).

Behavioral Characteristics

Hyperphagia and Complex Behavioural Phenotypes

Hyperphagia is a salient and life-threatening behavioral feature that characterizes PWS. PWS patients experience hunger or lack of fullness continuously, which is likely to cause lifelong stress not only in the patients but also their families and caregivers. It typically increases the risk of multiple complications, such as obesity, diabetes, and cardiovascular and respiratory problems. The patients are assessed using the hyperphagia questionnaire, a robust and efficient tool that can measure in vivo food-seeking behavior (Dykens et al. 2007). The management consists of the following dimensions: dietary consultation, behavioral intervention, and severe complications. Moreover, bariatric surgery is also often performed in patients with PWS.

On the other hand, a constellation of behavioral features has been identified and replicated in different studies as an important aspect that may affect health management and reduce the patient's quality of life. Recently, a collaborative team of international experts established a constellation comprised of the following core behavioral features as a consensus for future clinical trials: hyperphagia, temper outbursts, anxiety, obsessive-compulsive behaviors, rigidity, and social cognition (Schwartz et al. 2021). Moreover, other relatively common features include skin picking, hypersomnia, lying, confabulation, and theft, despite being secondary to impulse control disorder or psychological defenses (Curfs 1992; Steinhausen et al. 2004).

Psychiatric Disturbances and Genetic Susceptibility

Researchers have reported high rates of psychiatric manifestations, depression, psychotic episodes, and obsessive-compulsive disorder, which are likely to occur in adolescents to young adults with PWS (Dykens and Shah 2003; Soni et al. 2007; Sinnema et al. 2011; Krefft et al. 2014). Higher rates of psychiatric manifestations in UPD indicate the difference in susceptibility to psychiatric disorders (Whittington and Holland 2018). In contrast, a recent questionnaire-based study demonstrated that while aberrant behaviors decline from a young adult age in the deletion type, food-related behaviors persist, despite aging and growth (Ogata et al. 2018). Future research should determine the specific clinical course, including dementia, in the elderly.

Major Hypothetic Focuses on Brain Developmental Pathophysiology

Hypothalamic Dysfunction with Altered HPA Axis

The hypothalamic dysfunction hypothesis has been long postulated by physicians and researchers in endocrinology. Convergent evidence indicates that the clinical and endocrinological features are best explained by a dysfunction in the hypothalamus, namely, primary (central) homeostatic dysregulation, hypersomnia, altered body temperature, and pituitary hypofunction, which lead to hypothyroidism and hypogonadism. These alterations have also been demonstrated at the molecular and cellular levels, thus providing possible clues for future therapeutic interventions (Swaab 1997; Bochukova 2021).

Gene-Behavior Relationship: "Behavioral Phenotype" Concept

Figure 1 depicts all recognizable genes in and near 15q11–13. Several genes in this region have been delineated, including *MAGEL2* (Luck et al. 2016; Tacer and Potts 2017; Chen et al. 2020), *Snord116* (Lassi et al. 2016; Qi et al. 2017; Polex-Wolf et al.

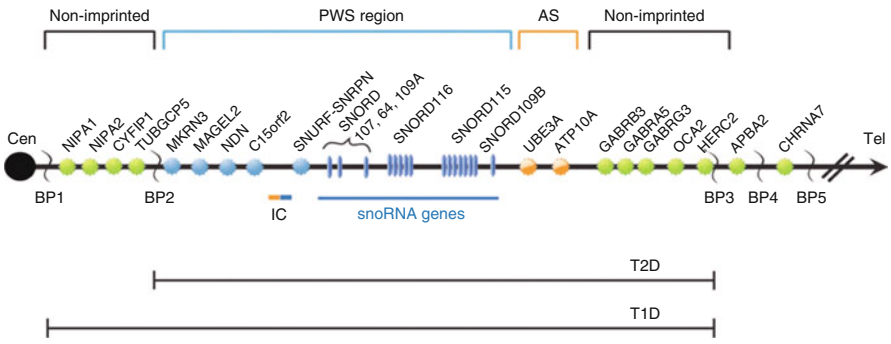

Fig. 1 Summary of the genetic map of chromosomal region 15q11.2-q13. The Prader-Willi syndrome region (shown in blue) has five copy genes that encode each polypeptide and a family of six snoRNA genes, both of which are expressed in a paternal-only manner. The Angelman syndrome region has two copy genes with preferential maternal-only expression, which is limited to certain tissue-specific regions. The jagged vertical lines denote common deletion breakpoints (BP). There are more copies of the *SNORD116* and *SNORD115* genes than are shown, and the map was not drawn to scale precisely. (Taken with permission from Cassidy et al. 2012)

2018), and *NDN* (Necdin) (Zanella et al. 2008; Wu et al. 2020; Yoshikawa 2021). Thus, some researchers have proposed the "behavioral phenotype" in molecular psychiatry as an endophenotype concept determined or constrained by a set of gene series.

Furthermore, genotype-phenotype investigations have successfully delineated various novel syndromes as follows:

Schaaf-Yang Syndrome

A newly proposed clinical form of genetic disorder caused by truncating pathogenic variants in the gene *MAGEL2* located at 15q11-15q13, the Prader-Willi critical region (Schaaf et al. 2013). This syndrome exhibits clinical overlap with PWS in the early stages of life but becomes gradually distinct toward childhood and adolescence, specifically in intellectual disability, language, and motor development (McCarthy et al. 2018).

BP1-BP2 Microdeletion Syndrome

An emerging cytogenetic condition with 15q11.2 Break point (BP)1-BP2 microdeletion (Burnside-Butler susceptibility locus). It is typically confirmed through genetic testing or chromosomal microarray analysis because of behavioral, cognitive, and/or psychiatric problems (Butler 2017). Four non-imprinted genes have been observed in this genomic region. They play a role in a wide spectrum of neurodevelopment and function (Rafi and Butler 2020).

Neurochemical Alterations

While researchers have investigated a wide range of neurochemical alterations that potentially contribute to behavioral characteristics in terms of core elements, PWS-specific and convergent evidence remain limited. It may arise from difficulties associated with a relatively small number of studies and conflicting findings in the same system with different methods. PWS mouse models have been rapidly developed in recent years, and the rapid progress in this research area may provide clues for drug discovery for the better management of hyperphagia and behavior. Due to limited space, I have shown here the major findings on each neurochemical substrate and refer interested readers to an excellent review for a detailed explanation.

5-Hydroxytryptamine and Gamma Amino Butyric Acid

Investigations in mouse models have detected 5-hydroxytryptamine (5-HT or serotonin) alterations in the brain of individuals with 15q11–13 gene deletion (Garfield et al. 2016; Davies et al. 2019). In addition, gamma amino butyric acid (GABA) has been implicated the pathophysiology since its concentration in plasma is changed in these patients (Ebert 1997), together with the fact that the genes encoding three $GABA_A$ receptor subunits are found within the PWS critical region.

Oxytocin and Vasopressin

Oxytocin (OXT) is another candidate that has been postulated as a relevant peptide. An initial neuropathological finding indicated marked reduction in the number of OXT-expressing neurons in PWS (Swaab 1997). Accordingly, a number of clinical trials of OXT supplementation have been performed via nasal spray. Those studies have shown that OXT is well tolerated in individuals with PWS and improves feeding and social skills (Einfeld et al. 2014; Tauber et al. 2017; Miller et al. 2017).

While arginine-vasopressin (AVP) has been less studied, attenuation of the polypeptide 7B2, prohormone convertase PC2, and AVP have been found in the hypothalamus of some individuals with PWS, indicating a processing defect, which may also explain to some extent the combination of behaviors in PWS (Gabreëls et al. 1998).

Ghrelin

Molecular, cellular, and hormonal research has been conducted to determine the causes of obesity and mental illness in PWS. Ghrelin is a gut peptide that exerts a broad spectrum of physiological responses, including appetite stimulation, lipid accumulation via regulating mechanisms in the hypothalamus, increase in gastric motility, regulation of glucose metabolism, and brown fat thermogenesis (Wevrick 2020).

It also modulates stress, anxiety, taste sensation, reward-seeking behaviors, and circadian rhythm (Tauber et al. 2019). The higher-order functions based on these neuroanatomical substrates are discussed in the next section.

Neuroanatomical and Microstructural Structures of the Brain in PWS

Hypothalamus and Pituitary Gland

While the neuropathological alteration is indeed the first objective evidence supporting the hypothesis as the hypothalamic origin of pathophysiology in PWS (Swaab 1997) (Fig. 2a), the pituitary structure is reportedly smaller with altered tissue microstructures, compared with those in PWS (Miller et al. 1996, 2008; Iughetti et al. 2008; van Nieuwpoort et al. 2011). A recent T_1-weighted magnetic resonance imaging (MRI) study demonstrated a correlation between pituitary image contrast and behavioral characteristics, such as autistic, hyperphagia, and obsessive features indexed by questionnaire scores, compared with those in typically developing (TD) controls (Yamada et al. 2021b) (Fig. 3a), which is highly consistent with the neurochemical findings (Gabreëls et al. 1998). Autoimmune or inflammatory processes speculated in recent reports warrant direct visualization (Grugni et al. 2018).

Brain Stem and the Midbrain

Neuropathological alterations have been described in midbrain and brainstem structures, indicating homeostatic and respiratory dysfunctions (Hayashi et al. 2011) (Fig. 2b). However, structural and volumetric alterations that exist in these structures, as well as the limbic structure, remain unclear; therefore, MRI studies are performed more actively.

Cerebellum

The cerebellum has also received some attention from the viewpoint of behavioral learning and cognition. While reduced volume and hypoplasia of the cerebellum have been reported (Titomanlio et al. 2006; Miller et al. 2009), an advanced MRI study using voxel-based morphometry demonstrated that the posterior part of the cerebellum, as well as total cerebellar volume, is smaller in individuals with PWS than in TD controls (Fig. 3b). Moreover, the altered lobular volume ratios (per total volume) were found to be negatively correlated with hyperphagic and autistic characteristics, and positively correlated with obsessive behavior. In contrast, the cerebellar dentate nuclei volume is larger in individuals with PWS and inversely associated with the intellectual quotient (Yamada et al. 2020b) (Fig. 4). These

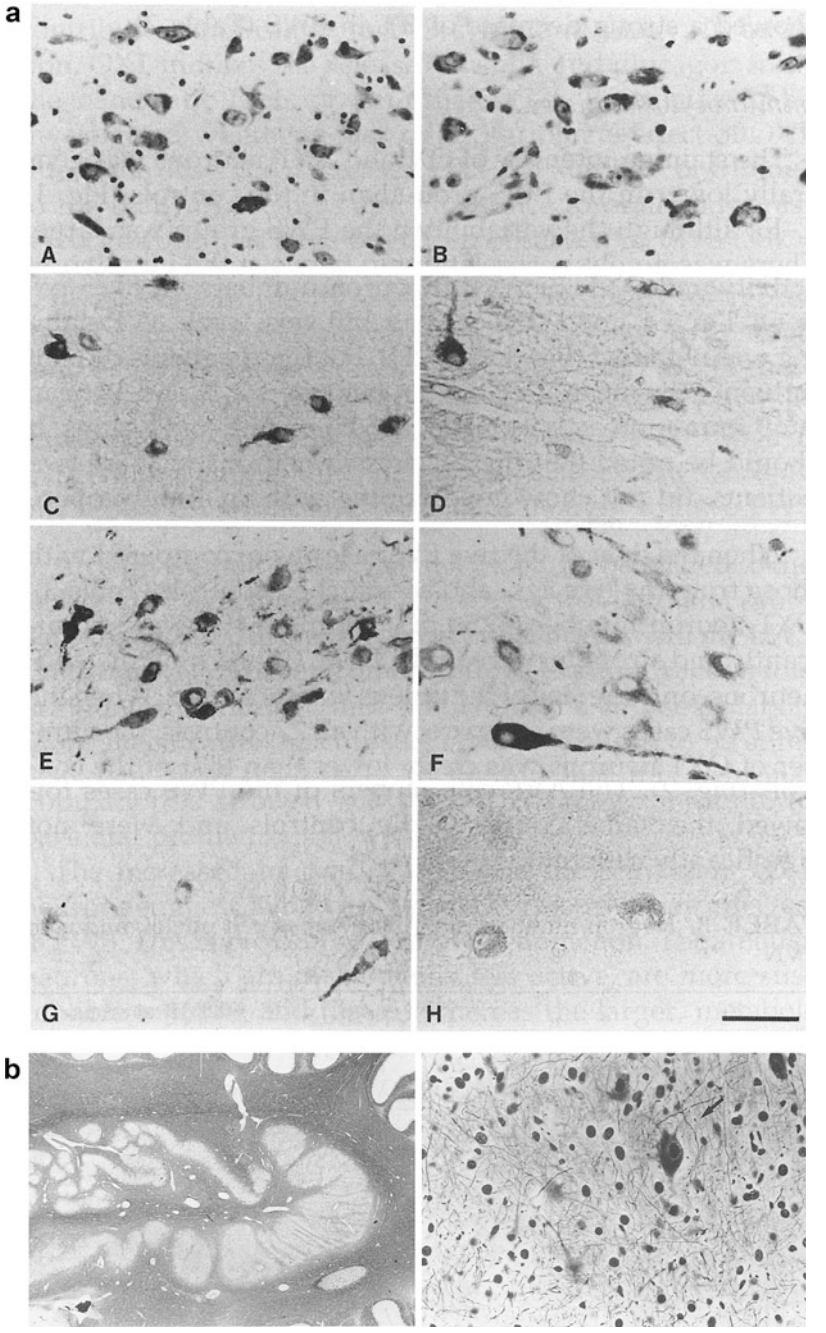

Fig. 2 The neuropathology of the hypothalamus and cerebellum in the brain of individuals with Prader-Willi syndrome. Neuropathological findings in the postmortem brain of individuals with Prader-Willi syndrome (PWS). (**a**) Reduced cell densities with lower immunocytochemical

findings strongly indicate that the cerebellum partially contributes to the behavioral and cognitive characteristics in PWS.

Cerebrum

The major characteristics of cerebral structures in individuals with PWS are as follows: (1) globally and locally reduced cerebral volume together with enlarged ventricles and Sylvian fissure (Miller et al. 2007a, b; Ogura et al. 2011; Honea et al. 2012; Xu et al. 2017; Manning et al. 2018; Yamada et al. 2022); (2) premature aging-related alteration (Manning et al. 2018; Azor et al. 2019), and (3) altered gyrification in the cerebral cortex (Lukoshe et al. 2014). Brain-predicted age difference scores derived from MRI-based machine learning have been found to be higher in the brain of individuals with PWS, thus indicating premature aging (Manning et al. 2018; Azor et al. 2019). This contrasts with a previous hypothesis on arrested brain development (Lukoshe et al. 2013). The details of increasing evidence are summarized in an excellent review (Manning and Holland 2015).

Evidence on Altered Brain Structural and Functional Connectivity

The human brain works as a unit; simultaneously, each part of the brain has a specific contribution, which is known as functional localization. A recent approach, namely, the Research Domain Criteria, seems to be convenient for brain research in PWS because it enables the decomposition of complex functional connections in a domain-specific and systematic manner (Salles et al. 2020).

Structural Connectivity

Structural connectivity was first investigated by diffusion tensor MRI in 2006 (Yamada et al. 2006). Altered white matter microstructure has been identified in multiple representative brain regions in individuals with PWS, including the frontoparietal area, callosal connection, and internal capsule. These are depicted

Fig. 2 (continued) staining intensities were identified. A comparison of the staining of thionine, oxytocin (OXT), and arginine-vasopressin (AVP) of controls (A, C, E) and PWS patients (B, D, F) showed lower staining in PWS patients, while an intense or weak OXT with only negligible AVP staining were observed in two PWS patients. (**b**) Disturbed undulating structures, resembling partial micropolygyria of the cerebral cortex in the cerebellar dentate nucleus in a case of PWS. Kluever-Bartera stain. (**c**) Grumose degeneration in the dentate nucleus. Dendrites were swollen, and a small amount of argyrophilic granular structures was detected. The arrow indicates a neuron showing a grumose-like alteration. Bodian stain. (Taken with permission from (**a**) Swaab et al. 1995, and (**b**, **c**) Hayashi et al. 1992)

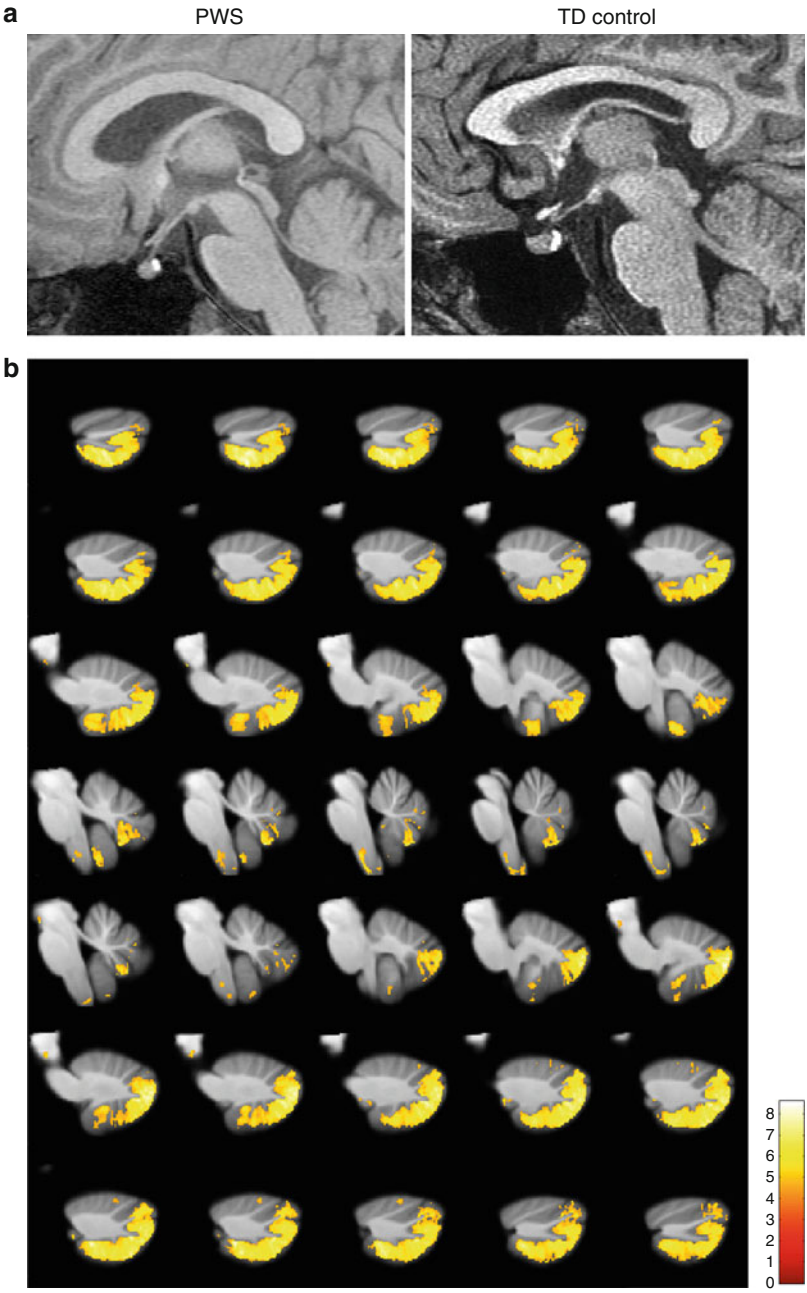

Fig. 3 Magnetic resonance imaging findings of subcortical structures in individuals with Prader-Willi syndrome. (**a**) Representative focused pituitary gland structural T_1 contrast magnetic resonance images (T_1 MRI) showing the anterior and posterior part of the pituitary gland from an adult individual with Prader-Willi syndrome (PWS) and an adult individual with typical

by altered indices suggesting modified brain maturation and connectivity, consistent with clinical features (Lukoshe et al. 2017; Xu et al. 2017; Rice et al. 2017).

Functional Connectivity

Furthermore, multimodal in vivo investigations have been performed to assess functional connectivity alterations of the brain in PWS.

Electrophysiological Studies

The neurophysiological basis for differences in cognitive properties was revealed by event-related potentials (ERP), together with electroencephalogram abnormalities in parietal-temporal brain areas, thereby indicating epileptic susceptibility in PWS. Differences in ERP responses have been reported between individuals with UPD and TD controls, indicating atypical face versus object processes. This might be associated with altered processing, attention and recognition of faces and their expressions (Brandt and Rosén 1998; Stauder et al. 2002, 2005; Halit et al. 2008; Priano et al. 2009; Key et al. 2013; Key and Dykens 2017).

Functional Imaging Studies

Single-photon emission computerized tomography (Ogura et al. 2013; Krishnadas et al. 2018) and position emission tomography studies (Sang et al. 2006; Dimitropoulos and Schultz 2008; Mantoulan et al. 2011; Reinhardt et al. 2016) have revealed altered distributions of cerebral blood volume and metabolic profiles, respectively. MR spectroscopy (MRS) studies have found reduced concentrations of gamma-aminobutyric acid, an inhibitory neurotransmitter, in specific brain regions of individuals with PWS (Hashimoto et al. 1998; Rice et al. 2016). In the future, challenging studies using MRS and manganese-enhanced MRI may reveal metabolic clues in the hypothalamus, albeit in a mouse model of PWS.

Currently, the highest spatial resolution with second-order time resolution can be achieved using functional MR imaging. This technique has been continuously applied to analyze brain connectivity from task-related to resting-state conditions. Food picture visual cues, oral glucose consumption cues, and simple motor task-related alterations have been detected as deactivation in the frontal area, parietal area,

Fig. 3 (continued) development (TD control). (**b**) Cerebellar structure displaying a significantly altered area in yellow color in individuals with Prader-Willi syndrome compared with typically developing controls. and cerebellum, respectively, compared with TD individuals (Shapira 2005; Miller et al. 2007c; Holsen et al. 2009, 2012; Klabunde et al. 2015; Blanco-Hinojo et al. 2019).

Moreover, resting state analysis has enabled the visualization of intrinsic functional connectivity without a task as a hypothetical load (Zhang et al. 2013, 2015; Yamada et al. 2021a). Increasing evidence has revealed enhanced and reduced functional connectivity in a series of convergent brain regions, such as the hippocampus, amygdala, cerebellum, frontal, temporal, and parietal lobe. This has also been detected in frontal areas, particularly the dorsolateral and medial prefrontal cortices, anterior cingulate cortex, and orbitofrontal cortex, which have been reported to be functionally aberrant in task-based studies. These findings suggest that the widespread dysfunction in cortical and subcortical areas, which may be involved in the reciprocal control of motivational drive and inhibitory integration of the characteristic behavior in PWS.

In summary, growing evidence has suggested that, in PWS, altered brain connectivity exists between a wide range of brain regions spanning from lower-order structures and the cerebellum to the cerebral cortex and white matter. An altered topography with enhanced or diminished patterns is substantially consistent with the behavioral features observed in individuals with PWS. While these "hub nodes" share feeding, reward, and homeostatic regulations that are closely involved in hyperphagia, circuits reflecting the characteristics of PWS are yet to be discovered (Fig. 5).

Future Avenues for Research

Molecular, Cellular, and Pharmacological Approaches Combined with Advanced Imaging Technology

Researchers have recently introduced an integrated multiscale approach using noninvasive methods to bridge the pathophysiology from the molecular and cellular scale to visualization. A continuous approach to define mental and behavioral disorders in genetically determined neurodevelopmental disorders can provide a comparative perspective of the cortex pathophysiology in PWS (Holland et al. 2019). Considering an example using relative T_1 shortening in the cerebral cortex that suggests a glial function of aquaporins (Suzuki et al. 2017), these approaches might be informative and applicable in PWS for evaluating interventional effects in clinical trials (e.g., carbetocin, diazoxide choline-controlled release tablets, oxytocin, and cannabidivarin, a naturally occurring homolog of the phytocannabinoid cannabidiol). Moreover, an attempt to establish a system using induced pluripotent stem cells is currently in progress to reproduce the hypothalamus and its functional alteration in PWS (Soeda et al. 2019).

Neuromodulation

Neuromodulation is a novel and alternative approach that allows to regulate the neural connectivity in a noninvasive manner (Poje et al. 2021). Owing to the theory of vagal nerve stimulation and prior clinical application for epilepsy, vagal nerve

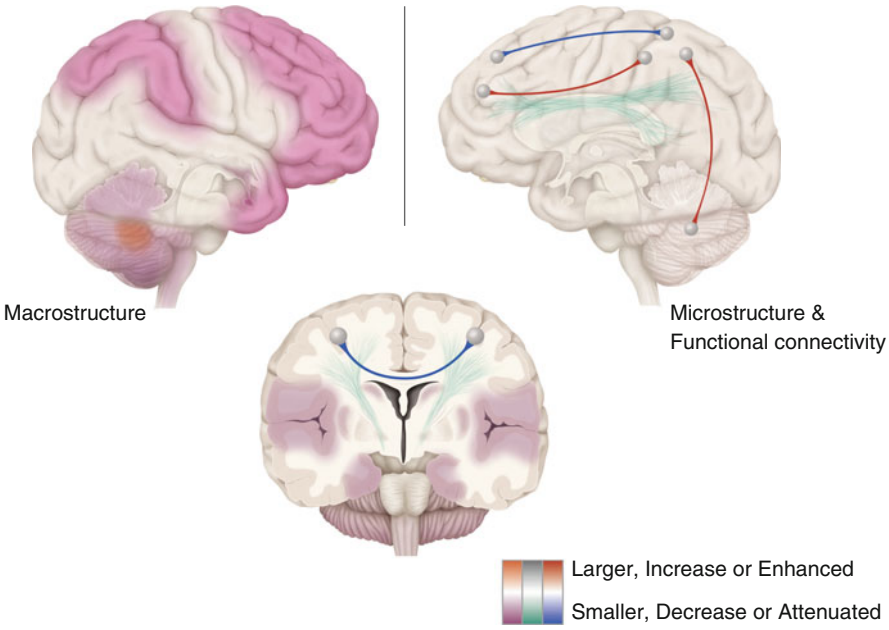

Fig. 5 Graphical summary of brain characteristics in Prader-Willi syndrome. All findings of brain characteristics in individuals with PWS, derived from magnetic resonance imaging studies until now, are graphically summarized. Upper left: macrostructural alteration detected in PWS compared with typically developing controls. Upper right: microstructural and functional connectivity alteration detected in PWS. Lower middle: coronal view showing both macrostructural, microstructural, and functional connectivity alterations detected in the slice containing basal ganglia and amygdala structures. The color bar indicates volume increase (yellow) or decrease (purple), neural fiber integrity increase (yellow) or decrease (green), and enhanced (red) or attenuated (blue) connectivity

stimulation trials in individuals with PWS have shown promising effects in reducing aggressive behavior (Manning et al. 2016). In the future, it is expected that the neuromodulations will be developed in conjunction with transcranial magnetic stimulation, which is both noninvasive and ethically acceptable.

Multidisciplinary Approach Toward Longitudinal Analysis of the Brain and Behavior

A safe, effective, and sustainable approach based on the core principles requires multidisciplinary collaboration (Cobo et al. 2021). Our behavioral choices are considered to be determined by both the biological background and environmental factors. Even if complex economic behavior patterns are constructed from finite, genetically controlled modules of behavior (Stacher Hörndli et al. 2019), environmental factors need to be taken into account carefully in PWS. Preferably, longitudinal analysis from pre- or early nutritional stage to the late stage will have a

significant potential to reveal unique developmental and behavioral trajectories. Advanced neuroimaging using a better preparation without sedation and integrated support will provide a better understanding of the functional and developmental alterations in the brain of individuals with PWS (Yamada et al. 2020a) (Fig. 6).

Suggested Areas to Be Included in the Chapters as Background

Guideline areas:

- Genetic syndrome and behavioral phenotype
- Behavioral characteristics (e.g., autism, obsessive-compulsive disorder)
- Brain function and localization
- Neurotransmitters
- Advanced neuroimaging
- Nutritional factors
- Life stages, such as neonatal period, childhood, adolescence, adulthood, and old age
- Occurrence of these disorders worldwide or in a single country
- Interventions that address the behavioral and developmental aspects
- The role of the parents, family, caregivers, and professionals

Applications to Other Eating Disorders

Cerebellar Contribution to Eating Disorders

In this chapter, we reviewed studies that focused on the cerebellum, in conjunction with other eating disorders leading to obesity. Of interest was the reduced volume of cerebellar structures observed in non-syndromic obesity (Miller et al. 2009), which has implications for other eating disorders in patients with behavior-related obesity. Hitherto, detailed volumetric and morphometric analyses have not yet been performed for other eating disorders because of the lack of specific detailed methods of analysis. We found that substructures of cerebellum contribute to the social and cognitive domain in individuals with PWS (Yamada et al. 2020b). Given the cerebellar alterations in other eating disorders, such as simple morbid obesity, frontotemporal dementia, and anorexia nervosa, the affected pathways might alter hypothalamic functionality.

Neurodevelopmental and Psychiatric Comorbidities in Eating Disorders

Altered or characteristic eating behaviors can be observed in a wide range of neurodevelopmental disorders and psychiatric conditions. While autism spectrum disorder patients may show a limited and obsessive selection of specific food or ingredients, a depressive state makes the patients eager to consume palatable and sweet food, eventually leading to reduced food intake. PWS includes a constellation of multiple neurodevelopmental and behavioral domains; however, it might help in

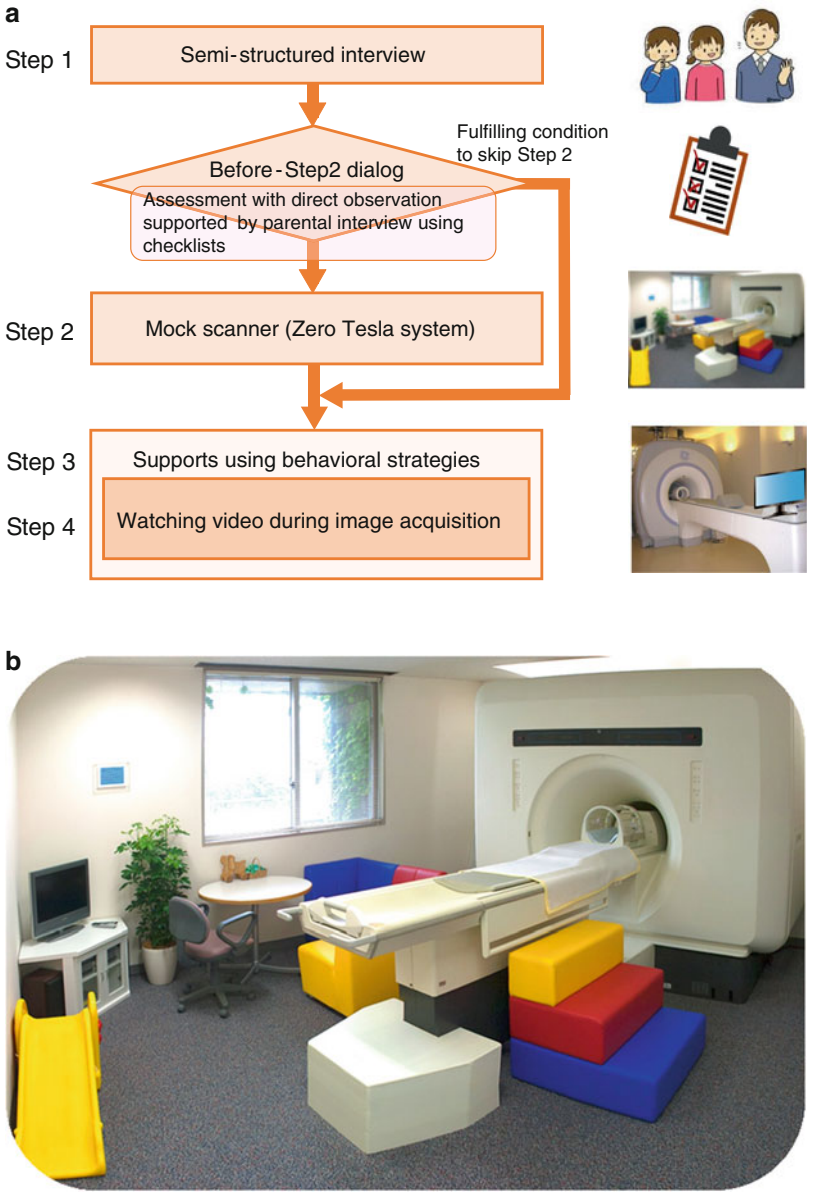

Fig. 6 Simulation protocol for the preparation of magnetic resonance imaging studies for individuals with behavioral and developmental characteristics. (**a**) Flow chart of the simulation protocol. Whether participants met the readiness status for the actual imaging is determined by the participant's responses on the checklist, along with their parents' consensual responses. The behavioral strategies shown in this figure represent the structured verbal or visual explanation of the imaging process, verbal incentives, and countdown of the remaining time in the real scanner. (**b**) "Zero-tesla" preparation system (mock scanner). (Modified with permission from Yamada et al. 2020)

understanding the possible contribution of each domain to other forms of eating disorders and vice versa.

Neuroendocrinological and Musculoskeletal Assessments and Interventions in Eating Disorders

While the multiple interaction of endocrinological abnormalities in PWS makes its pathogenesis complex, such a unique feature has a significant potential to open a new window for alternative approaches to eating disorders. Growth hormone supplementation in PWS has shown alterations of body mass composition and risks of complications associated with obesity, along with increasing body height and constitution in PWS (Pellikaan et al. 2021). In contrast, a recent report using body MRI showed that an altered adipose tissue (AT) composition: a decreased ratio of visceral/subcutaneous AT, in youth with PWS suggests an improved metabolic profile, and elevated ratios of AT to skeletal muscle may be a sign of a sarcopenic obesity-like phenotype (Orsso et al. 2017).

Mini Dictionary of Terms

- **Diffusion tensor imaging (DTI):** An advanced noninvasive imaging technology using MRI to visualize the diffusivity of free water molecules within the brain. Skewed diffusivity in the direction indicates the brain microstructure.
- **Magnetic resonance spectroscopy (MRS):** MRI is used to assess various neurochemical substrates within the brain, such as glutamate, N-acetyl aspartate, choline-containing compound, myoinositol, and GABA.
- **Cerebellar dentate nucleus (cDN):** A nucleus (a cluster of neurons in the central nervous system) in the cerebellum, which behaves like the "gateway" of output from information processed in the cerebellar hemisphere.
- **MAGEL2:** MAGE family member L2. A protein-coding gene that causes a form of clinical feature with autism spectrum disorder. The loss of function can contribute to the clinical aspects observed in PWS and Schaaf-Yang syndrome.
- **Small nucleolar RNAs (snoRNAs):** A class of noncoding RNAs involved in various physiological and pathological cellular processes. Mutations or the aberrant expression of SNORD115 and 116 are reportedly involved in the regulation of alternative splicing.
- **Single-photon emission computed tomography (SPECT):** Imaging modality that requires a radioactive agent to assess cerebral blood flow.
- **Positron emission tomography (PET):** Imaging technique based on positron emission used for the detection of tumors, metabolic alterations, and associated functional alterations.
- **Event-Related Potential (ERP):** Electrophysiological analysis used to detect altered gradients of electric potential associated with cognitive events.
- **Connectivity:** A pattern of neuroanatomical links ("anatomical connectivity") of statistically significant dependencies ("functional connectivity") or possible causal interactions ("effective connectivity") between distinct units within the

brain. The units usually correspond to individual neurons, neuronal populations, or anatomically localized brain regions.

- **Genetic imprinting:** People inherit two copies of their genes, one from each parent. Usually, both copies of each gene are active, or "turned on" in cells. However, in some cases, only one of the two copies gets normally turned on. The active or "turned on" copy depends on the parent of origin: while some genes are normally active only when inherited from the father, others are active only when inherited from the mother. This phenomenon is known as genomic imprinting.
- **Uniparental disomy (UPD):** A form of genetic situation, in which two copies of a chromosome are inherited from one parent, instead of one from each. Both UPD and imprinting mutations have been detected in DNA methylation studies.

Key Facts of Genetic Imprinting in PWS

- Genetic imprinting is a mechanism in which uniparental genetic information gets translated and reflected as a phenotype.
- In PWS, the 15q11–13 region inherited from the mother is translated, while that of paternal origin results in a different phenotype, namely, Angelman syndrome.
- While paternal deletion and maternal UPD account for approximately 65–75% and 20–30%, respectively, imprinting defect accounts for 1–3% of individuals with PWS.
- About half of individuals with imprinting defect have inherited it from an unaffected father with the imprinting center deletion on his maternal inherited chromosome 15, while the other half are de novo deletions on the paternally derived chromosome 15.
- DNA sequence changes are not found in these epimutations; therefore, the imprinting defect is thought to be due to random errors during spermatogenesis in the father or in early embryogenesis.
- For parents with PWS, genetic counselling may be required to understand the mechanism of the disease.

Key Facts of Nutrition in PWS

- Nutritional management is crucial for the health care of individuals with PWS.
- Individuals with PWS typically progress through seven discrete nutritional phases (Miller et al. 2011), namely, phases 0, 1a, 1b, 2a, 2b, 3, and 4.
- While phase 1a is characterized by hypotonia with feeding difficulty and decreased appetite in months 0–9, patients in phase 3 show hyperphagia and rarely reach satiety.
- Phase 3 is believed to be caused by a lack of satiety due to hypothalamic abnormalities, a topic that has not been fully investigated.
- Research and clinical practice have suggested that an increase in physical activity with a well-balanced and nutritionally dense diet can improve weight control in adolescents with PWS.

Key Facts of Behavioral Phenotypes in Genetic Syndromes

- Each genetic syndrome is likely to exhibit unique behavioral and developmental characteristics.
- In the fields of clinical genetics, molecular psychiatry, and behavioral pediatrics, such characteristics are referred to as behavioral phenotype.
- Some well-known examples are self-mutilation in Lesch–Nyhan syndrome, sleep disturbance, aggressive behavior in Smith–Magenis syndrome, and outgoing, engaging personalities with possible attention-deficit and anxiety disorders in Williams syndrome.
- It is important to mention that such characteristics are not fixed by the genetic background but can be reduced or enhanced depending on the environment of the patient.
- Effective collaboration with clinical geneticists, experts in dysmorphology medicine, developmental and behavioral neurologists, and psychiatrists in neurodevelopmental disorders is appreciated in clinical settings.

Summary Points

- Prader-Willi syndrome (PWS) is a congenital genetic syndrome that has received attention as a clinical condition characterized by hyperphagic behavior.
- The brain plays a role in the pathogenesis of the developmental and behavioral characteristics of PWS.
- While the genetic contribution to behavior has been investigated using mouse models, the structural and functional aspects of the brain have been revealed by advanced magnetic resonance imaging.
- Reduced volumes have been observed in the brain stem, pituitary, posterior cerebellum, amygdala, and frontoparietal cortices of individuals with PWS, along with altered integrity in the frontoparietal white matter structure.
- Altered functional connectivity has been detected in frontoparietal and parietocerebellar connections as attenuated and enhanced passages, respectively.
- An integrated multiscale approach with noninvasive methods is warranted to bridge the pathophysiology from the molecular and cellular scale to visualization.

morbid obesity and consequent premature death, if the condition is not diagnosed early and managed properly. It is also characterized by a plethora of other developmental, cognitive, behavioral, and mental health challenges. The purpose of this chapter is to provide an overview of the changing behavioral phenotype of PWS across lifespan and discuss its distinctive features, current understanding, and available interventions.

Keywords

Prader-Willi syndrome · Self-injurious behavior · Behavioral phenotype · Obsessive-compulsive disorder · Hyperphagia · Obesity · Anxiety · Nutrition · Genotype-phenotype correlations · Food security

Abbreviations

ADD	Attention-deficit disorder
ADHD	Attention-deficit hyperactivity disorder
ASD	Autism spectrum disorder
GH	Growth hormone
IQ	Intelligence quotient
mUPD	Maternal uniparental disomy
OCD	Obsessive-compulsive disorder
PWS	Prader-Willi syndrome

Introduction

Prader-Willi syndrome (PWS) is characterized by a specific developmental trajectory and a corresponding behavioral phenotype, understood as a pattern of distinctive behaviors consistently exhibited by people diagnosed with the syndrome (Holland et al. 2003). Typical behavioral profile of patients with PWS encompasses symptoms resulting from hyperphagia, mild intellectual disability, obsessive-compulsive traits, as well as deficits in social functioning. Studies so far have failed to identify a specific age range at which the mental health of PWS patients would significantly deteriorate (Lo et al. 2015). Although there is variation between individuals in terms of clinical picture, i.e., symptom manifestations and their onset and severity (Bellis et al. 2022), the eating disorder is nearly universally present (Holland et al. 2003). Therefore, the behavioral phenotype should be considered as an increased likelihood of certain behaviors in patients with this syndrome (Hodapp et al. 1990) (Table 1). Behavioral features are so significant in PWS phenotype that they have been included in the diagnostic criteria from early on (cf. Holm et al 1993, Table 1) . The following chapter will detail the specific character of behavioral phenotypes across subsequent developmental stages in patients with PWS. It will also include a discussion of most challenging behaviors and their current understanding and impact on functioning.

Table 1 Diagnostic criteria for PWS (behavioral or related features are marked in bold) (Holm et al. 1993)

Major criteria	*Minor criteria*	*Supplemental criteria*
Muscular hypotension/weak suckling reflex	**Poor fetal movements in the third trimester of pregnancy, infantile lethargy, weak cry in infancy**	**High pain threshold**
Eating difficulties/poor weight gain	**Behavior disorders (at least 5): tantrums, obsessive-compulsive behavior, stubbornness, arguments, tendency to manipulate, perseverate**	Decreased vomiting
Excessive and rapid weight gain (12 months of age–6 years of age)	Sleep disturbance/night apnea	Thermoregulation disorders
Features of dysmorphia (at least 3): dolichocephaly, narrow two-sided dimension, amygdala-shaped eyelid gaps, small mouth with a narrow red upper lip, downward corners of the mouth	Low growth, hypopigmentation of skin and hair	Scoliosis and/or kyphosis
Hypogonadism	Small hands and/or feet in relation to body height	Premature pubarche symptoms
Psychomotor development delay/ difficulties at school	Narrow hands with straight ulnar border	Osteoporosis
Excessive appetite/obsessive craving/lack of satiety	Vision defects (myopia, astigmatism, strabismus)	**Exceptional puzzle solving skills**
A characteristic genetic defect	Thick, sticky saliva drying in the corners of the mouth	Normal neuromuscular test results
	Speech defects/nasal speech	
	Skin picking/self-harm	

Behavioral Phenotype in Patients with PWS across Lifespan

Prenatal Period

In an article published in 2020, Srebnik et al. proposed a prenatal phenotype of patients with PWS. It was based on a study of 101 pregnancies, in which the fetuses were later diagnosed with PWS. The study consisted of, inter alia, questionnaires and retrospective interviews with the mothers, comparing the pregnancy with a child, later diagnosed with PWS, against pregnancy with healthy offspring at the closest age. Data obtained from prenatal sonographic examinations was also included. The authors of the study were able to distinguish a number of symptoms the co-occurrence of which at the end of the second or the beginning of the third trimester

should raise concerns and prompt the methylation test for PWS. Among various traits observed in ultrasound scans, a significant diagnostic value was shown by a decreased abdominal circumference, especially when coinciding with polyhydramnios or a considerably decreased fetal movements (Srebnik et al. 2020). Other retrospective studies showed similar characteristics of fetuses with PWS among patients in China (Yang et al. 2020), the USA (Singh et al. 2018), Great Britain (Whittington et al. 2008), and France (Bar et al. 2017), also indicating nonspecific symptoms such as abnormal alignment of hands and feet, lack of vertical fetal movement (non-vertex presentation), and increased frequency of needing assistance during birth or caesarean (Bigi et al. 2008; Cassidy et al. 2012). Researchers involved in studies on prenatal PWS diagnoses point to the importance of implementing proper approach for further patient prognosis, as well as its ethical implications (Goldstone et al. 2008).

Neonatal and Infancy Period

A specific behavioral phenotype is also manifested in the subsequent stage of life of PWS patients – in neonatal and infancy development. Studies by Ge et al. done on a group of 102 Chinese infants recognized a pattern of motor behaviors presenting in over 90% of subjects, consisting of central hypotonia (96.1%), lack of sucking reflex, difficulties in feeding (93,1%), and weak crying (100%), irrespective of the syndrome's etiology. These symptoms showed to be highly indicative for the syndrome, along with the underdevelopment of genitals (Ge et al. 2019). Infants affected by PWS are described as permanently sleepy and having difficulty waking up for feeding. Immediately after birth, they show a decreased or lacking sucking reflex, they may require supplemental feeding via nasogastric tube, and they show a lowered appetite. Increased sleepiness is a characteristic trait in PWS patients, often continuing through their lifespan (Haig and Wharton 2003). Slower motor development results in delayed milestones (taking twice as long as indicated by norms, e.g., walking at 24 months), including those related to speech development (Cassidy et al. 2012).

Early Childhood Period

The onset of uncontrollable appetite is a crucial moment in the life of a patient with PWS. Studies show its occurrence between ages 4, 5, and 8 (Cassidy et al. 2012). Significant differences are shown in the course of this process, with a rapid onset or a gradual development of nonselective eating habits. Children start consequently finishing their meals and then actively seeking and even stealing food, and they tend to eat voraciously and don't experience the feeling of satiety (Haig and Wharton 2003). Studies show that hyperphagia increases with age, which results in a wider range of food-seeking behaviors among older patients (Dykens et al. 2007). The behavioral phenotype connected with the change of appetite also consists of a food-

related obsession and preoccupation with meals. Aberrant behaviors linked to food also include stealing and lying for the purposes of getting more food, eating nonedible items such as pet food, searching for food in trash, stealing money to buy food, or running away to get it (Cassidy et al. 2012; Butler et al. 2019).

Study of food-related behaviors among PWS patients, done by Holland et al. (2003) Lindgren et al. (2000) showed an indicative curve in food consumption in this patient population. A decelerating curve constitutes a typical eating pattern, where the appetite is high at the beginning of the meal, when the patient feels hungry, after which it decreases as the feeling of satiety rises. PWS patients exhibit a non-decelerating curve, indicating a lack of the feeling of satiety. At the same time, it's accompanied by a slower pace of eating at the beginning and overall, than is shown by healthy or obese children. This appears to imply that the abnormality of satiety has a greater impact than uncontrollable hunger on these patients (Lindgren et al. 2000).

Beyond the disrupted behaviors directly connected with hyperphagia and lack of satiety, other specific features of behavioral phenotype of PWS patients have been identified, present even from early childhood and found in 70–90% of patients. This phenotype consists of stubbornness, temper outbursts, mood swings, manipulative and compulsive-like controlling behaviors, as well as difficulty with interrupting or switching activities and actions once they had begun (Cassidy et al. 2012). Compulsive-like behaviors, such as repetitive questioning, stereotypical speech, hoarding behaviors, or symmetrical stacking, are considered as specific developmental delays and appear around age of 2. At this time, their intensity isn't largely deviated from the norm among the general population of children, but lasts longer in PWS patients and may persist even until adulthood suggesting their different role and distinct developmental trajectories involved in their occurrence (Dimitropoulos et al. 2001; Holland et al. 2003). Another aberrant behavior, beginning in childhood, is self-harm, especially skin picking. In the study by Dimitropoulos et al., as many as 40% of children with PWS, aged 4–5, exhibited these behaviors, a third of whom did so even until they started to bleed. Higher pain threshold that is characteristic for PWS patients minimizes negative consequences of self-harm and contributes to this behavior (Holland et al. 2019). This problem increases with the age of the patients and, without proper treatment, may even result in death in the course of the infection (Dimitropoulos et al. 2001; Bellis et al. 2022). The period of increased appetite often coincides with the appearance of temper outbursts. However, the relationship between these two behaviors isn't clear. As they appear later with age than among healthy children, and their aggravation is clinically relevant, a different developmental etiology in PWS patient group should be assumed. Temper outbursts often occur in the response to rejection, interruption of repeated activities, or a request to change activity before it's complete. They tend to be accompanied by verbal aggression, and sometimes physical violence, and may induce subsequent feelings of guilt and regret (Holland et al. 2019). Additionally, temper outbursts may also be a consequence of communication disorders, resulting from delayed speech development, which is also frequent in PWS patients, or as a response to dietary restrictions by caregivers (Dimitropoulos et al. 2001). Aggression, observed during childhood,

manifests by hitting others, while in teenage years tends to have a verbal form. The most frequent psychiatric diagnosis is oppositional defiant disorder, irrespective of genetic subtype (Lo et al. 2015; Feighan et al. 2020).

As children with PWS start school, intellectual disabilities become more and more evident. Although the average IQ values are 60–70 in PWS patients, and even 40% of them have borderline or low intellectual norm, this does not translate into the daily functioning of patients and their academic achievements (Cassidy et al. 2012).

Early childhood is also a period in which the features of autism spectrum disorder (ASD) features begin to appear (Descheemaeker et al. 2006). They are most pronounced in a range of behaviors such as insistence on sameness, attachment to routine, and schematic behaviors (Wigren and Hansen 2005). Research indicates deficits in the theory of mind in patients with PWS, meaning the lack of ability to recognize their own and other people's mental states. Greater intensity of aberrant behaviour is observed in patients with both ASD and PWS diagnosis than in individuals with ASD only (Lo et al. 2013). Autism spectrum symptoms are often accompanied by attention-deficit disorder (ADD) or attention-deficit hyperactivity disorder (ADHD) symptoms along with behavioral disorders (Wigren and Hansen 2005). These symptoms often worsen with age, but tend to partially resolve in adulthood (Cassidy et al. 2012).

Teenage and Adolescent Period

Self-injurious behaviors are widespread in teenage PWS patients, and according to the results of the study by Feighan et al. apart from skin picking, the most common include teeth grinding, body hitting, and self-biting and are most severe in adolescence (Feighan et al. 2020). Aggressive behavior also reaches its peak between the ages of 4 and 18. And among them, the most common are hitting, pushing, pulling others, and verbal aggression. The study also showed a high intensity of anxiety symptoms in patients with PWS in adolescence, with subsequent development of mood disorders. Patients are also often diagnosed with disruptive behavior disorders (DBD), which in some studies were associated with a higher frequency of OCD and skin picking. It is estimated, depending on a study, that 50% to almost 90% of PWS adolescent patients have at least one psychiatric diagnosis (Shriki-Tal et al. 2017; Feighan et al. 2020).

The first episodes of psychotic disorders also occur in adolescence, affecting up to 20–60% of patients with PWS, more often with maternal uniparental disomy (mUPD) etiology. Vogels et al. distinguished a subtype of psychotic disorders in PWS with early age and acute onset, variable course, and the need for hospitalization. The onset of psychotic disorders is often preceded by a prodromal phase in which the patient is affected by stress-related risk factors. Behaviors accompanying psychotic episodes are often strange, characterized by excessive activation or drop in energy, agitation, disturbances in the circadian rhythm, or changes in appetite. Psychotic disorders can often go undiagnosed because abnormal behaviors are attributed to the PWS (Vogels et al. 2004; Cassidy et al. 2012).

Apathy and inactivity, which accompany PWS patients practically from the prenatal period, in the teenage period, and in adulthood, present themselves with spending free time on solitary activities, such as puzzle-solving, idling, and computer gaming (Holland et al. 2019).

The study by Wigren et al. revealed an interesting phenomenon where the insistence on sameness was present in 50% of the studied patients and, despite the teenage age, remained at the level characteristic for children with PWS of preschool age. In previous studies, this symptom, along with skin picking, was classified as part of obsessive-compulsive disorder (OCD) alongside anxiety disorders, which was not replicated by Wigren's study. Skin picking was associated with mood swings, without a clear pattern of repetitive behavior (Wigren and Hansen 2005).

Adulthood

Accounts of behavioral characteristic trajectory in adulthood of PWS patients are somewhat heterogeneous. While some authors attest attenuation of challenging behavioral patterns, others report contradicting results. Elisabeth Dykens and colleagues developed the Hyperphagia Questionnaire, a tool enabling the assessment of food-seeking behaviors in patients with PWS (Dykens et al. 2007). Studies conducted with this tool showed persistence of maladaptive and hyperphagia-related behaviors in older adults with PWS, although their severity was lower than in younger groups. This may be related to the levels of hormones and neuropeptides as they decline with age, but the patients who reach late adulthood also tend to have better symptom control. Additionally, this tool contributed to the in-depth research on the correlation between hyperphagia and maladaptive and emotional problems in PWS patients, e.g., internalizing symptoms such as anxiety and depression (Dykens et al. 2007). On the other hand, population studies conducted on a group of PWS patients by Holland et al. showed an increase in the severity of eating disorders with age, which was associated with decreased parental control in adulthood, diagnosis of the syndrome at a later stage in life, and lack of adequate guidance on nutrition and food intake monitoring at the time of diagnosis (Holland et al. 2003). There is evidence, albeit limited, that in adulthood behavioral symptom severity may abate in some individuals. Dykens compared maladaptive and compulsive behaviors in 45 older adults with PWS (30–50 years) to children, adolescents, and young adults with the same condition, concluding that young adults had the highest risk for behavioral problems, while in older adults, it was significantly less pronounced (Dykens 2004). These results were not replicated by a Dutch study that found no diminishment of behavioral problems in older adults with PWS (Sinnema et al. 2011). The study also points to differences between genetic subtypes in adulthood, with more behavioral problems attested in PWS adults with mUPD compared with deletion.

A systematic review of the literature, published by Tarsimi et al. in 2021, covering 33 articles, revealed the behavioral profile of adult PWS patients as characterized by temper tantrums, autism spectrum, and compulsive behaviors. Mood disorders occurred

in 10–20% of patients and were often accompanied by psychotic symptoms. It should be emphasized that psychiatric disorders occurring in PWS do not always completely fit into the diagnostic criteria, which may lead to diagnostic overshadowing, despite a significant impact on the functioning of the patient and the life of their family; standardized diagnostic methods for this group are required (Tarsimi et al. 2021).

When discussing the behavior of PWS patients, their contribution to the increased mortality should be addressed. Behaviors related to seeking and stealing food, hasty secretive eating, and the lack of a feeling of satiety may result in choking, also due to gastrointestinal dysmotility, gastrointestinal perforation with necrosis, or intoxication. These behaviors are directly related to hyperphagia, regardless of obesity (Butler et al. 2019; Bellis et al. 2022).

The impact of the COVID-19 pandemic deserves its own, separate place in this chapter. According to the research of Wieting et al., it especially negatively affected the well-being and functioning of PWS patients. Lockdown contributed to the exacerbation of anxiety symptoms and behavioral disorders with increased temper tantrums and compulsions, as well as skin picking and behaviors related to food searching. Caregivers of patients reported anxiety about the pandemic situation among their charges, as well as worry about their own health. In addition, studies have shown a particular severity of the described symptoms among patients living at home with relatives, which implies the need for increased support for them during this difficult time (Wieting et al. 2021b). Distinctive features of PWS behavioural phenotype discussed in this section are summarized in Table 2.

Distinctive Features of the PWS Behavioral Phenotype

PWS Phenotype and Intellectual Disability

Three factors determining the behavioral phenotype of PWS patients were distinguished in contrast with a learning disability control group, for which four factors were established (Holland et al. 2003). The PWS factor analysis revealed the following clusters:

1. Eating and associated behaviors, such as lying and theft, limited mainly to food seeking and in some patients to home environment
2. Personality characterized by obsessive behaviors, outbursts of anger, and repetitive and aggressive behavior due to neurodevelopmental delay
3. Emotions, such as mood swings, skin picking, and argumentativeness associated with feeling low, especially when access to food was limited by caregivers

The authors proposed that eating behaviors form a separate constellation of characteristics in PWS, distinguishable from obsessive-compulsive traits. This may indicate a syndrome- specific pathophysiological mechanism related to lack of satiety behind this factor. On the other hand, obsessive and aggressive behavior appears to share a common etiology with developmental delays rather than food-

Table 2 Behavioral phenotype of PWS patients in consecutive life stages

Prenatal period	Neonatal and infancy period	Childhood	Adolescence	Adulthood
Decreased fetal movements	Central hypotonia	Change in appetite with subsequent hyperphagia and lack of satiety	Insistence on sameness	Persistence of food-related behaviors
Abnormal alignment of hand and feet	Lack of sucking reflex	Obsession and preoccupation with food	Mood swings	Maladaptive and emotional problems
Non-vertex presentation	Weak crying	Stealing, lying, wynning away to get more food	Auto-aggressive behaviors: skin picking, teeth grinding, body hitting	Explosive behaviors
	Excessive sleepiness	Eating nonedible items	Aggression toward others: pushing, pulling, verbal aggression	Compulsive behaviors
	Lowered appetite	Stubbornness, temper outbursts, mood swings	Anxiety symptoms	Increased mortality
	Delayed milestones	Manipulative behaviors	Mood disorders	
		Compulsive-like behaviors: repetitive questioning, hoarding	Disruptive behavior disorders	
		Difficulties with interrupting or switching activities	Psychotic disorders	
		Self-harm: skin picking, self-biting		
		Temper outbursts		
		Aggressive behaviors both verbal and physical		
		Autism spectrum features		

related issues, although these factors tend to be confounded in everyday functioning. Furthermore, the obsessive-compulsive behaviors and temper tantrums attested in PWS resemble typical obsessive behaviors found in children, and their rate does not change over time. Moreover, as the researchers propose, some patients seem able to move beyond this developmental stage and develop better coping skills, which lends further support to their link with arrested development. Self-injurious behavior in PWS, on the other hand, such as skin picking, and argumentativeness, seems to be connected with low mood, constituting a separate cluster (Holland et al. 2003).

Self-Injurious Behavior

Self-injurious behavior in PWS deserves a separate note, as this characteristic – even though commonly featured in PWS descriptions – is often underappreciated by the patient environment outside of the family context, which may lead to delayed intervention. For instance, what is known as skin picking is in fact a serious and challenging mental and behavioral issue characteristic of PWS, which in extreme cases may result in serious bodily harm and potentially life-threatening infections (Miller and Angulo 2014). Patients with this syndrome were found to be significantly more likely to engage in skin picking than age- and gender-matched controls with Down syndrome and nonspecific intellectual disability (Dykens and Kasari 1997). In a structured review of literature, Holland and Whittington report very high prevalence of skin picking in PWS, with attested rates ranging from 55% to nearly 100% depending on sampling method and chosen criteria, while the rate of self-injurious behaviors in persons with intellectual disability is estimated at 4.9% (Cooper et al. 2009; Whittington and Holland 2020). In PWS skin picking may take severe forms, leading to open wounds and ensuing complications. The high pain threshold in PWS means that what starts as a reaction to stress and anxiety may soon turn to repetitive behavior, which is difficult to uproot. Picking most often starts in areas where a person experiences discomfort, such as itching due to insect bites, and is more common when no other stimuli that would attract the patient's attention are present (Whittington and Holland 2020). In many cases, skin picking is accompanied by other forms of body-focused repetitive behavior, such as hair, nail, and teeth pulling, head banging, or rectal picking (Symons et al. 1999). Such behaviors are often addressed by environmental and behavioral interventions, but in more severe forms may require pharmacological treatment (Hustyi et al. 2013; Miller and Angulo 2014).

Nutritional Stages

PWS is best known as a syndromic cause of hyperphagia, resulting in early onset morbid obesity and consequent premature death if the condition is not diagnosed early and managed properly. The exact mechanism behind the development of hyperphagia in PWS remains unknown, yet there is a growing understanding of its natural course. In early literature on the syndrome, two nutritional stages were described: Stage 1 characterized by poor feeding and often associated with failure to thrive in infancy, followed by Stage 2, with the onset of hyperphagia and subsequent development of obesity (Gunay-Aygun et al. 2001). Miller and her team demonstrated that the development of hyperphagia and food-related behaviors is far more complex, encompassing seven nutritional phases: five main phases and subphases in phases 1 and 2 (Miller et al. 2011). According to this model, the initial stage Phase 0 in utero should be singled out, which is characterized by decreased fetal movements and retarded growth. Phase 1 is marked by infantile hypotonia, without obesity, or excessive appetite present. In subphase 1a, feeding difficulties

prevail, which may result in failure to thrive (ages birth—15 months). The next subphase 1b is one where a steady growth and weight increase at a normal rate occur (median age of onset: 9 months). In phase 2, weight gain begins, despite lack of increase in consumed calories and initially without a clear change in appetite in subphase 2a (median age of onset: 2.08 years). In subphase 2b, increased interest in food becomes manifest (median age of onset: 4.5 years), while phase 3 is associated with hyperphagia, insatiable appetite, and food seeking (median age of onset: 8 years). Phase 4 was attested in some adults, who apparently gained the ability to feel full following phase 3. This more complex model has implications for both research into pathomechanisms responsible for eating disorders in PWS and family counseling on obesity prevention in this syndrome (Miller et al. 2011).

The Relationship Between the Genotype and Phenotype of PWS

Previously mentioned studies by Dykens et al. with the Hyperphagia Questionnaire, in their preliminary results, showed no differences in hyperphagia in patients with different etiology of the syndrome (deletion or mUPD) (Dykens et al. 2007). Studies show higher verbal intelligence scores and less maladaptive behaviors in mUPD patients (Goldstone et al. 2008). However, mood swings, skin picking, and stubbornness, depending on the study, present either equally frequently regardless of the etiology of the syndrome or more commonly in patients with deletion (Boer et al. 2002; Holland et al. 2003; Wigren and Hansen 2005). Moreover, the severity of compulsions didn't show differences based on etiology (Lo et al. 2013, 2015). The major difference is in the development of psychotic disorders. Research indicates that this risk is significantly higher in patients with mUPD etiology (Boer et al. 2002). In this group, also bipolar disorder and cycloid psychosis are present with greater frequency (Butler et al. 2019). In addition, in an assessment of the prevalence of pervasive developmental disorders by Descheemaeker et al. in a group of PWS patients, mUPD was pointed as an additional risk factor for the development of autism spectrum symptoms (Descheemaeker et al. 2006).

Distinction in symptoms between deletion and uniparental disomy may result from the differences in the ways that loss of imprinted genes affects the neurodevelopment of the brain: haploid deficiency of genes not imprinted in deletion, or excess function of imprinted genes in disomy (Descheemaeker et al. 2006). Manzardo et al. shared an interesting conclusion from their research on genetic subtypes of PWS and neuropsychiatric diagnoses. It was suggested that all PWS subtypes presented a qualitatively similar phenotype, and the differences that did present may be due to the severity of the course of mental disorders, not the diagnosis itself. Differences in the intensity of disturbed, auto-aggressive, or compulsive behaviors and adaptation skills occurred in both types of deletion, with a lighter course and better academic performance presenting when the loss of a part of the chromosome was smaller (Manzardo et al. 2018).

Interventions Targeting Challenging Behaviors in PWS Patients

The basis for the treatment of PWS patients, which contributes to the reduction of disturbed and maladaptive behaviors, maintaining their good health and lowering mortality, is the provision of a food-secure environment (Bellis et al. 2022). Food insecurity contributes to the growth of anxiety and makes people obsessed with looking for food and food sources (Butler et al. 2019). This should be done respectfully of the rights of PWS patients to the highest possible degree of independence, choice, and autonomy while simultaneously strictly controlling the amount of meals and expenses (Goldstone et al. 2008). The patient should be informed of mealtimes, menus, and portions. Knowing the schedule of the day and interweaving activities that are desired (associated with less activity) and those that are not desired, but necessary (such as therapeutic interactions and physiotherapy), allows for the reduction of anticipatory anxiety and undesirable behaviors related to task-shifting (Butler et al. 2019). The most effective measures in improving functioning of PWS patients are summarised in (Table 3), following Dykens et al. 2007 and Goldstone et al. 2008.

Multifaceted therapeutic intervention should be started as soon as possible, preferably soon after birth (Goldstone et al. 2008; Feighan et al. 2020). Apart from maintaining daily routines aimed at regulating the consumption of meals, physical activity, and improving metabolism, it is important to introduce early intervention and then ongoing educational and psychological support. Speech and communication therapy are critical for lifelong functioning of individuals with PWS, as is provision of appropriate support structures, in education and vocational training. Communication with the PWS patient, as well as commands given, should be simple and literal. The patient should have time to process and absorb information, while the educational path should be flexibly adjusted to specific needs, ensuring the possibility of inclusion in the peer group for the purpose of socialization (Goldstone et al. 2008; Lo et al. 2015; Feighan et al. 2020). Such an approach helps reduce levels of anxiety and irritation, and thus manage challenging behaviors. Additionally, due to the deficits in theory of mind mentioned previously, people in the patient's environment should be encouraged to set more realistic expectations concerning exhibition of empathy and overall social-cognitive functioning (Lo et al. 2013). Providing

Table 3 Effective behavioral interventions

The most effective measures in improving functioning of PWS patients (Dykens et al. 2007; Goldstone et al. 2008)
Supervision and control of meals throughout lifetime
Restricted access to food (locked refrigerators, pantries)
Regular physical activity
A reduced calorie diet adapted to hypotension and slow metabolism
Behavioral therapy
Growth hormone supplementation
Psychological and behavioral counseling for families and caregivers

support and psychological counseling for the patient's family or caregivers is also an important element of successful intervention. Studies show that the burden on families and caregivers increases with the severity of hyperphagia as well as with the age of the patient, and severity of behavioral symptoms. Thus, the burden of the disease tends to increase over time (Kayadjanian et al. 2021). The literature emphasizes the negative impact of PWS on the quality of life and burden on both the patient and their family (Meade et al. 2021).

Impact of Pharmacotherapy on PWS Patients' Behavior

Any discussion of phenotypes and behavioral disorders in PWS patients should also take applied pharmacotherapy into account. While no pharmaceuticals improving the global functioning, dedicated to PWS, were found, psychopharmacotherapy allows to alleviate behavioral disturbances, even though it has a negative impact on the somatic burden of patients. On the other hand, drugs used in the pharmacotherapeutic treatments of somatic disorders in the syndrome may cause behavioral side effects (Butler et al. 2019). At the same time, behavioral disturbances related to eating, such as excessive water intake, may, along with undesirable effects of drugs, lead to electrolyte disturbances and be a potential threat to health and life (Butler et al. 2019). The use of psychopharmacotherapy in PWS patients should start with lower than standard doses and take into account the greater susceptibility to side effects in this group of patients (Goldstone et al. 2008).

Meta-analysis published in 2015 identified topiramate as a promising drug in the management of self-harm as well as of impulsive and aggressive behaviors. Among the antipsychotic drugs, the group of atypical neuroleptics is indicated as helpful in management of maladaptive behaviors. Risperidone has been shown to be effective in mUPD-related psychotic disorders. It should be remembered that neuroleptic drugs have well-documented side effects related to increased appetite and weight gain, which in the case of PWS patients requires strict medical control (Bonnot et al. 2016).

Furthermore, drugs from the group of antidepressants may also be found useful in the case of comorbid symptoms of OCD or mood disorders in patients with PWS (Bonnot et al. 2016). In recent studies of Deest el al., special attention was given to sertraline, a drug from the group of serotonin reuptake inhibitors, which significantly decreased the frequency of temper outbursts in 13 out of 14 patients, after 6 months of therapy (Deest et al. 2021).

The use of drugs to improve PWS patient's activation, such as serotonin reuptake inhibitors, aripiprazole, or modafinil, may, as a side effect, exacerbate behavioral disturbances related to agitation, mood lability, or even induced psychosis (Butler et al. 2019).

Supplementation of growth hormone (GH), from infancy through adulthood, proves to have a significant role in improving body composition and metabolism, but also to reduce challenging behaviors and improve cognitive functions (Cassidy et al. 2012). GH also contributes to the improvement of the quality of life, which may translate into reduction of mood disorders in this group of patients (Goldstone et al. 2008).

Hypogonadism found in the syndrome also often requires hormonal supplementation, which translates into an improved well-being and functioning of patients, but at the same time, it may carry the risk of exacerbating the behavioral disorders that occur in even every third patient, especially when they are burdened with mood instability or tendency toward aggression (Goldstone et al. 2008; Pellikaan et al. 2021). This should be taken into consideration especially for male patients in whom hormone replacement therapy may induce inappropriate or even aggressive sexual behavior (Crinò et al. 2003).

Given the high prevalence of skin picking among PWS patients, *N*-acetylcysteine supplementation has been gaining high interest as an effective therapeutic option. Despite initially promising results, the latest study showed only limited usefulness and effectiveness, especially in patients presenting with solitary rectal picking, or in combination with pharmacotherapy with neuroleptic drugs (Wieting et al. 2021a). Additionally, a randomized, double-blind, placebo-controlled study on the effect of probiotic supplementation showed no statistically significant improvement in psychological measurements related to development screening, aberrant behavior, and social and repetitive behaviors, among others. However, a significant statistical change was demonstrated on the Clinical Global Impression, leaving an open path for further research on this topic (Kong et al. 2021).

Application to Other Eating Disorders

As the best known cause of syndromic obesity, Prader-Willi syndrome may provide insights into the mechanisms of obesity and appetite control as well as energy expenditure. It serves as a model for research on disruption in hypothalamic pathways, hyperphagia, and the role of hormones in regulating food intake.

Mini-Dictionary of Terms

- Hyperphagia refers to abnormally increased appetite and urge to consume food, frequently associated with hypothalamic dysfunction.
- Food security is a form of behavioral intervention aimed at removing the temptation to search for edible items outside of mealtimes in persons with PWS. The term was coined by Drs Forster and Gourash. https://pittsburghpartnership.com/handouts/Food%20Security%20Basic.pdf.
- Behavioral phenotype of the genetic syndrome is a pattern of motor, cognitive, language, and social impairments that are consistently associated with its natural course.
- Genotype-phenotype correlation is a relationship between expression of alleles or variants in a particular gene or genetic location and subsequent disease presentation in a person.

- Self-injurious behavior refers to an act of physical aggression toward oneself, intended to (among others) express tension, stress, and anger but also to draw attention.

Key Facts

- Prader-Willi syndrome is a rare genetic condition resulting from loss of function of critical region genes on the long arm of paternally derived chromosome 15.
- Complex neuroendocrine disorder leads to morbid obesity in PWS if untreated.
- The condition is associated with a tendency to self-injury worsened by a high pain threshold.
- Intellectual disability is common in PWS, yet it cannot fully explain the observed behavioral phenotype.

Summary Points

- Prader-Willi syndrome is a complex neurodevelopmental disorder characterized by a specific behavioral phenotype.
- PWS is best known as a syndromic cause of hyperphagia, resulting in early onset morbid obesity and consequent premature death if the condition is not diagnosed early and managed properly.
- Self-injurious behavior is a highly common serious and challenging mental and behavioral issue characteristic of PWS, which in extreme cases may result in serious bodily harm and potentially life-threatening infections.
- Not all symptoms of the behavioral profile will always be present, and not all of them are due to the hyperphagia characteristic for the syndrome.
- Behavioral disorders may result both from the lack of control over food consumption by PWS patients and their frustration caused by overcontrol. Anxiety disorders also play a large part in the occurrence of behavioral disorders (Dimitropoulos et al. 2001).
- The understanding of the behavioral profile of PWS and its implications is crucial for the implementation of early therapeutic interventions which translates into improved patient prognosis and improvement in the quality of life for them and their family.
- Psychoeducation and knowledge of the behavioral profile are important for the families and caregivers of patients as they reduce their burden and improve their quality of life (Goldstone et al. 2008).
- With improved diagnosis, knowledge dissemination among families and access to growth hormone therapy tratment, behavioral disorders now come to the fore as challenging aspects of PWS management.

Body Dysmorphic Disorder: Links with Eating Disorders and Gender-Related Factors

65

Amy Malcolm

Contents

Abstract

Body dysmorphic disorder (BDD) is a mental disorder characterized by a distressing and impairing preoccupation with perceived defects in physical appearance. The disorder shares many clinical similarities with eating disorders (EDs) that involve a core component of disturbed body image, most notably

A. Malcolm (✉)

anorexia nervosa and bulimia nervosa. In particular, the muscle dysmorphia subtype of BDD has close parallels with anorexia nervosa, though is characterized by a drive toward muscularity rather than toward thinness. Due to similarities between the disorders and the reality that BDD can involve concerns with body fat or weight, differentiating BDD from an ED can sometimes be challenging. In addition, BDD and EDs often co-occur; thus, clinicians must routinely screen for BDD among ED patients. Treatments tailored to symptoms of BDD as well as EDs must be used in instances of comorbid BDD and EDs, as treatment responses differ between the disorders.

Introduction to Body Dysmorphic Disorder

Body dysmorphic disorder (BDD) is a mental disorder that is characterized by a preoccupation with one or more perceived defects in physical appearance, which are either very slight or imperceptible to an objective observer (American Psychiatric Association 2013). This preoccupation is further accompanied by repetitive behaviors or mental acts in response to the appearance concerns at some time during the course of the disorder (American Psychiatric Association 2013). Lastly, the diagnosis of BDD cannot be made when the preoccupation is better explained by concerns of body fat or weight in a person whose symptoms meet criteria for an eating disorder (ED) (American Psychiatric Association 2013). This criterion is intended to help clinicians distinguish BDD from an ED and prevent misdiagnosis. Finally, the muscle dysmorphia (MD) specifier is applied to a diagnosis of BDD when the individual is primarily "preoccupied with the idea that his or her body build is too small or insufficiently muscular" (American Psychiatric Association 2013).

While written descriptions of BDD (historically called *dysmorphophobia*, meaning "fear of ugliness") have existed for more than a century, the disorder has received relatively little research and clinical attention (Veale and Neziroglu 2010). However, recent research has begun to demonstrate that BDD has many commonalities with EDs, especially anorexia nervosa (AN) (Phillipou et al. 2019). In addition, there has

been strong discussion about whether the MD subtype of BDD should be considered a standalone ED (Murray et al. 2010). In this chapter, a detailed overview of BDD and MD is provided, accompanied by commentary on associated gender-related factors, and followed by discussion of overlaps and differences between BDD (and MD) and EDs.

Prevalence, Onset, and Course

BDD is common, with large studies estimating a point-prevalence of 1.7–2.4% for BDD in general adolescent and adult populations (Buhlmann et al. 2010; Koran et al. 2008; Rief et al. 2006; Schneider et al. 2017b). While the average age at onset is 16 to 18 years, data suggests that most cases of BDD develop before 18, with early onset being associated with an increased likelihood of lifetime AN or bulimia nervosa (BN) (Bjornsson et al. 2013; Phillips et al. 2005b). BDD typically develops slowly over time, and generally follows a chronic and continuous illness course once established (Phillips et al. 2005b).

Core Symptoms

Appearance preoccupations in BDD may encompass any bodily feature. However, the most common areas of preoccupation are the skin, nose, mouth or teeth, face/facial features, or hair. The specific size, shape, color, texture, or symmetry, or relative proportions of these features, often forms the focus of concern (e.g., facial skin is "too red") (Malcolm et al. 2021). Concerns with other areas, such as body build, breast/chest, hands, genitals, legs, abdominal area, or buttocks, are also common (Malcolm et al. 2021). Furthermore, concerns might also relate to generalized feelings of "ugliness" or "abnormality," or concerns of insufficient masculinity or femininity in appearance (Veale and Neziroglu 2010; Malcolm et al. 2021). Most individuals with BDD will have concerns about multiple bodily areas (5–7, on average), which may change to other areas over time (Phillips et al. 2005b). Typically, thoughts of appearance concerns are present for 3 to 8 h per day (Phillips et al. 1998). Such thoughts about appearance are extremely distressing and difficult to ignore (Kollei and Martin 2014).

Appearance concerns in BDD typically elicit strong urges to engage in excessive, repetitive, time-consuming, or unusual behaviors or mental acts, that are performed with the goal of examining, hiding, or "improving" the area of appearance concern (see Table 1). People with BDD spend one to eight hours per day engaging in behavioral symptoms (Phillips et al. 2005b). While attempts to alter appearance by seeking cosmetic procedures is common, receiving such procedures typically results in a worsening of BDD symptoms or simply leads to a transferral of appearance concerns to a new body area (Veale 2000).

Table 1 Common behaviors associated with body dysmorphic disorder

Behaviors	Examples
Appearance checking	Viewing self in mirrors or other reflective surfaces (e.g., windows, polished cutlery, etc.) Frequent reflection checks, or prolonged gazing Touching or feeling body areas, measuring body areas Taking photographs of the self
Appearance camouflaging	With makeup, hairstyles, accessories (e.g., hat) With body positioning (e.g., hunching, keeping hand over face, controlling facial expressions) With clothing; may also spend extended amount of time changing/choosing clothes
Comparing appearance	Comparing to others, film and media or social media, or to own past appearance (e.g., old photos of self)
Excessive or repetitive appearance routines	Grooming (e.g., washing, hair styling, hair removal) Skin care or beauty treatment routines Meticulous or repeated makeup application
Reassurance seeking	Repeatedly asking others for reassurances about appearance Asking on the Internet for feedback on appearance photos
Attempts to alter appearance	Use of makeup, beauty products, skincare or haircare products Dieting or excessive exercise regimes Seeking cosmetic, dermatological, aesthetic dental, or plastic surgery procedures to change appearance Skin picking with intent to "improve" texture Idiosyncratic methods, which may be diverse or illogical (e.g., chewing gum all day to "tighten jaw muscles")
Information gathering	Obsessive researching of possible appearance-enhancing products, treatments, or procedures
Distraction techniques	E.g., choosing a colorful or bizarre hairstyle to "distract" from nose concerns

Insight

Illness insight in BDD encompasses the degree to which a person can recognize their appearance concern as being excessive or inaccurate and psychological in origin (rather than reflecting a physical reality). Approximately 72% individuals with BDD have poor or absent insight, and commonly endorse delusions of reference (e.g., "that other people are noticing or are disgusted by my appearance") (Phillips et al. 2012).

Comorbidities

Comorbidity is common in BDD, with a majority of individuals having at least one comorbid diagnosis over the lifetime (90%) or concurrently with BDD (81%) (Gunstad and Phillips 2003). Major depression is the most common concurrent comorbidity (e.g., 53% to 87%), followed by social anxiety disorder (31% to

34%), obsessive-compulsive disorder (25%), other anxiety disorders (7% to 16%), EDs (4% to 9.5%), and substance or alcohol use disorders (up to 13%) (Gunstad and Phillips 2003; Phillips et al. 2005b, 2007; Ruffolo et al. 2006; Frare et al. 2004).

Functional Impairment

BDD is, on average, associated with severe functional impairment and poor quality of life across numerous domains (Didie et al. 2007; Phillips et al. 2005a). In particular, BDD involves a high degree of interpersonal impairment, such as experiencing relationship conflicts, social isolation, or becoming housebound (Didie et al. 2007, 2012; Phillips et al. 1998). Moreover, hospitalization, suicidal ideation, and suicide attempts are markedly high in BDD, with some estimates suggesting a rate of completed suicide that is higher than that of major depression, bipolar disorder, or AN (Phillips 2017).

Gender Differences in BDD

Data suggests that BDD impacts men and women in roughly equal proportions and that overall, there are more similarities than differences among men and women with BDD (Buhlmann et al. 2010). Similarities include the average severity of BDD symptoms, average age at onset, and severity of associated depression, stress, anxiety, and social anxiety symptoms (Malcolm et al. 2021). In addition, studies which have examined gender differences in body areas of concern among individuals with BDD have typically found more similarities than differences (Malcolm et al. 2021; Perugi et al. 1997; Phillips and Diaz 1997; Phillips et al. 2006). In particular, concerns with skin and facial features are highly common across both genders. However, these studies have typically found that men tended to be more concerned than women about their genitals (e.g., penis size), their body build (feeling inadequately muscular, or that build is "too small"), and their hair with regard to thinning or balding. Conversely, women were more likely than men to have concerns about their body weight or shape, legs (e.g., calves and/or thighs), stomach, buttocks or hips, and breasts (Malcolm et al. 2021; Perugi et al. 1997; Phillips and Diaz 1997; Phillips et al. 2006). These gender differences seem to coincide with common areas of nonclinical body dissatisfaction among men and women in the general population (Phillips et al. 2006). Though illness insight has not been well-compared between men and women with BDD, one recent study has indicated that women may have slightly poorer insight than men on average (Malcolm et al. 2021).

Men and women with BDD generally show similar patterns of behavioral symptoms in response to appearance concerns, including in the types of behaviors (e.g., mirror checking) and the severity of symptomatic behaviors (Malcolm et al. 2021; Perugi et al. 1997; Phillips and Diaz 1997; Phillips et al. 2006). However, some studies have reported that camouflaging behaviors are more common among women than men with BDD, including use of cosmetics (likely explained by social norms

encouraging cosmetic use among women only), clothing selection, and positioning of the hands to cover areas of concern (Phillips et al. 2006; Malcolm et al. 2021). Although one study also reported more frequent mirror checking by women than by men (Perugi et al. 1997), others have not replicated this finding (Malcolm et al. 2021; Phillips and Diaz 1997; Phillips et al. 2006). Finally, there has not been any comprehensive investigation of BDD among gender-diverse populations, an important research area that requires further attention.

Muscle Dysmorphia (MD): A Subtype of BDD

The DSM-5 describes MD as a specific presentation of BDD that is primarily characterized by a preoccupation with the idea that one's body build is too small or insufficiently muscular (American Psychiatric Association 2013). The condition was initially conceptualized as a form of "reverse anorexia" (or "bigorexia") when it was first identified among male bodybuilders (Pope Jr et al. 1993). This is because, in contrast to individuals with AN who perceive themselves as "fat" despite being of low weight or emaciated, individuals with MD perceive themselves as "small," "puny," or "weak" despite being very large and muscular.

Although no further diagnostic criteria for MD (beyond the criteria for BDD) are included in the DSM-5, Pope et al.' (1997) initial research into the condition produced detailed operational diagnostic criteria for MD that is commonly used by researchers and clinicians today. These criteria require preoccupation with the idea that one's body is inadequately muscular and lean, which may involve characteristically related behaviors of excessive weight lifting and excessive dietary attention, and which meet at least two of the four following conditions: (i) the individual compulsively prioritizes the maintenance of workouts and dietary schedules over important social, occupational, or recreational activities, (ii) the individual avoids situations where the body is exposed or endures such situations with marked distress, (ii) the preoccupation causes clinically significant distress or functional impairment, or (iv) the individual pursues workouts, dietary practices, or use of performance-enhancing substances despite knowledge of associated physical and mental health risks. Finally, the preoccupation with body size or muscularity must not be better explained by fear of weight gain or fatness (as in AN), or by preoccupation with other aspects of appearance (as in other forms of BDD). Among individuals who are diagnosed with BDD, approximately 9.3% meet Pope's criteria for MD (Pope et al. 1997).

Characteristics of MD

Behaviorally, MD is characterized by a pattern of excessive weight training, undertaken with the goal of muscular growth. Individuals with MD often adhere to a rigid training routine which may be maintained through injury or to the extent that social or occupational functioning is impacted, else extreme anxiety may arise if a workout

is missed (Cunningham et al. 2017). Clinically significant symptoms of MD are commonly identified among competitive bodybuilders (e.g., 84%) and recreational weight lifters (Pope et al. 1997). Individuals with MD seem be attracted to these activities due to their goals of increased muscularity, but it remains unclear whether engagement in such activities may also be a risk factor for MD development.

MD typically involves many behavioral symptoms that are common in BDD more broadly, including mirror checking, touching, feeling, or measuring body areas, and use of camouflage behaviors such as wearing loose-fitting clothing. Avoidance behaviors, such as selecting "quiet" hours to attend public exercise facilities or avoiding situations where the body may be exposed (e.g., change-rooms or public bathing/swimming), are also highly common. Relative to more "typical" presentations of BDD, MD is similar in the severity of preoccupations, number of non-muscularity appearance concerns, degree of interference caused by symptom-related behaviors, and a poor degree of insight into symptoms (Pope et al. 2005). However, men with MD may be more likely than men with "typical" BDD to have attempted suicide, have poorer quality of life, and have a higher frequency of substance use disorder and steroid abuse (Pope et al. 2005).

MD typically involves excessive attention to diet within the context of supporting muscle development. Individuals often follow strict diet regimens characterized by extreme protein intake, frequent and/or strictly scheduled food intake, eating beyond fullness, excess use of protein supplements or other nutritional supplements, or liquification of food to make extreme caloric intake easier (e.g., blending/pureeing food), all intended to fuel the growth of trained muscles (Cunningham et al. 2017; Griffiths et al. 2013). Individuals with MD may also make use of "bulk and cut" diets, a two-phase diet popular among competitive bodybuilders but which has little scientific backing (Lenzi et al. 2021; Griffiths et al. 2013; Lavender et al. 2017). The "bulking" phase lasts several weeks to months and involves excess protein and carbohydrate intake, undertaken with the belief that a hypercaloric intake will maximize muscle growth from weight training (Lenzi et al. 2021). However, "bulking" typically leads to increased adiposity due to extreme caloric surplus. As increased adiposity can obscure muscular definition and thus cause dissatisfaction with muscularity, the "cutting" phase is then employed to reduce body fat and enhance muscular definition. "Cutting" involves restricting nonprotein food intake (e.g., carbohydrates) to stimulate fat loss, and may include attempts to maintain a caloric deficit for weeks or months. However, protein intake is typically maintained at an above-average level during this time (Lenzi et al. 2021). The "cutting" phase can result in a loss of lean tissue as well as adiposity, which may cause muscle dissatisfaction and prompt users to begin the "bulk and cut" cycle anew (Lavender et al. 2017).

MD and Steroid Abuse

MD also involves a strong association with anabolic-androgenic steroid abuse. Studies have reported as much as 50% to 100% of participants with MD have used steroids (Lavender et al. 2017). Conversely, steroid use is less common among weight lifters who do not exhibit MD symptoms (e.g., 7%). Data suggests

that the onset of MD symptoms typically precede use of anabolic-androgenic steroids (Olivardia et al. 2000), consistent with the proposal anabolic-androgenic steroid abuse is an attempt to "improve" preexisting body image concerns related to insufficient muscularity (Rohman 2009). Accordingly, data suggests that weight lifters with high MD symptoms are significantly more likely than those with lower MD symptoms to have used anabolic-androgenic steroids excessively (e.g., for 6 to 150 months in total over the lifetime) (Kanayama et al. 2006). However, use of steroids may also perpetuate MD symptoms, as once used, an individual typically gains a level of muscularity that is not naturally achievable. When steroid use is ceased, there is a loss of muscularity as the body returns to a natural state, which could further exacerbate body dissatisfaction and muscle preoccupation (Olivardia et al. 2000).

Gender Differences Associated with MD

Research and discussion of MD has typically been focused on males, yet there is data to suggest that women are also impacted by MD. In a convenience sample of 1150 American military personnel, muscle dysmorphia was identified in approximately 12.7% of men and 4.2% of women (Campagna and Bowsher 2016). Further, a recent study of Australian adolescents reported MD prevalence rates of 2.2% for males and 1.4% for females (Mitchison et al. 2021). In that study, adolescent boys with MD were found to be significantly more likely than girls with MD to have "severe" preoccupation, and to have a weight lifting regime that significantly interfered with their life (Mitchison et al. 2021). However, it is currently unclear whether there are other substantial differences in MD symptomatology between men and women with MD, as most studies to date have recruited male participants only. Recently, sociocultural ideals regarding the female body appear to be moving more toward lean, toned physiques, emphasizing visible muscularity rather than thinness alone (Bozsik et al. 2018; Wagner et al. 2020). As such, the study of MD among women is likely an important yet currently neglected research area.

Relationships Between BDD and Eating Disorders

In the current DSM-5 (American Psychiatric Association 2013) and upcoming draft of ICD-11 (World Health Organization 2019), BDD is currently classified as belonging to the obsessive-compulsive and related disorders family. This classification has been highly controversial, as research to evaluate whether BDD is best situated in this category or alongside other conditions, such as anxiety disorders or EDs, is lacking (Malcolm et al. 2018). In particular, there has been limited research examining relationships between BDD and EDs characterized by body image concern, such as AN (Phillipou et al. 2019). Recent proposals have argued that BDD, AN, and BN should be reclassified together in a new category of "body image disorders," due to the many similarities among these conditions (Phillipou et al. 2016, 2017). In yet

another perspective, it has been argued that MD should be considered a standalone disorder (as opposed to a subtype of BDD), which should be positioned within the EDs family (Murray and Touyz 2013). Regardless of classification debates, there is substantial evidence to show that BDD (including MD) shares many features with AN, which warrant careful attention when screening for or treating comorbid presentations.

Differential Diagnosis: Distinguishing BDD from Eating Disorders

Diagnosis of BDD according to the DSM-5 criteria requires that "the appearance preoccupation must not be better accounted for by concerns with body fat or weight in an individual whose symptoms meet criteria for an ED" (American Psychiatric Association 2013). This criterion ensures that individuals who meet criteria for an ED are not incorrectly diagnosed with BDD instead. However, overlaps between BDD and certain EDs, particularly AN and BN, necessitate very careful exploration of symptoms to ensure that appropriate diagnoses are made. For instance, a person who is primarily concerned with body fat or weight, but who does not meet criteria for any ED, might yet meet criteria for BDD. Diagnoses of both BDD and an ED may be appropriate when there is evidence of both clinically significant concerns with body fat or weight that are associated with disordered eating behaviors and clinically significant preoccupation with perceived defects in other aspects of appearance that are not related to body fat or weight. As such, clinicians who suspect either BDD or an ED must carefully screen for symptoms of both disorders. Moreover, it is important for clinicians to carefully probe for appearance concerns across the entire body when screening for either BDD or an ED. It is very common for individuals with BDD to keep some or all of their appearance concerns secret due to shame or fear of being seen as vain (Veale et al. 2015). As such, failure to ask about broader appearance concerns may result in a missed BDD diagnosis. Box 1 illustrates an example of comorbid eating pathology and BDD concerns.

Box 1 An Example Case of Comorbid Atypical AN and BDD

Sarah is a 29-year-old woman who describes feeling overwhelmed with thoughts that she is "too big," and "ugly," describing concerns with her skin texture and "deep, cut-like" eye wrinkles. On physical examination, Sarah's skin appears healthy, there are only very fine lines around her eyes (normal for her age), and her weight is in a healthy range for her height (BMI = 23). Sarah reports running for 2 h each day to lose weight and eats no more than 800 calories per day. She weighs herself daily and will exercise twice if she feels she exceeded her calorie limit. When asked about her skin and eyes, Sarah describes repeatedly checking her looks in the mirror or touching up her makeup, which has made her for work on several occasions.

(continued)

Box 1 (continued)
She refuses to leave the house without heavy makeup and spends large amounts of money on various skincare and anti-wrinkle creams. At work, she has trouble concentrating on tasks as her thoughts continually return to worries about her body weight and appearance. Sarah describes being unable to make eye contact with customers, as she "can't bear to have them see how fat and ugly [she] is." Sarah avoids social events as she fears that others will reject or humiliate her for her weight and appearance "flaws."

In the example of Box 1, Sarah is likely to meet criteria for both BDD and atypical AN. She shows fears of weight gain and feelings of shame over her body weight and uses severe caloric restriction and excessive exercise to control her weight. Conversely, Sarah's preoccupations with her skin and eyes are likely to be symptoms of BDD. Of note, her concerns about eye wrinkles seemed excessive, as very fine eye wrinkles are not out of the ordinary for an adult woman. Concerns about her weight, skin, and eyes seem to equally preoccupy Sarah for hours each day, feed problematic behaviors (e.g., dietary restriction, excessive exercise, mirror scrutinizing, costly product use, compulsive makeup use), and cause significant avoidance and functional impairments both at work and in her social life.

Comorbidity of BDD and Eating Disorders

EDs commonly co-occur with BDD. For instance, in a large study of 200 individuals with BDD recruited from the community, it was reported that 32.5% of participants had a lifetime ED diagnosis, with 9% reporting AN, 6.5% reporting BN, 5.5% reporting binge ED, and 17.5% reporting an ED not otherwise specified (Ruffolo et al. 2006). Moreover, 9.5% of participants in this study met current criteria for both BDD and an ED. Of note, it was also reported that the majority of participants with a history of ED developed BDD symptoms before the onset of ED symptoms (63.1%), while 16.9% developed both BDD and an ED within the same year (Ruffolo et al. 2006). Regarding MD, it has been reported that up to 29% of men with MD have a history of an ED (Murray et al. 2010). In another study of weight lifters with MD, it was reported that approximately 13% of men and 47% of women had a history of either AN or BN (Pope et al. 1997).

Studies which have screened for BDD among ED patients also report high rates of comorbidity. In an investigation of 158 patients with mixed EDs, 45% screened positive for BDD (Dingemans et al. 2012). Similarly, rates of BDD among individuals with AN have been reported between 9.8% to 39% (Kollei et al. 2013; Grant et al. 2002; Cerea et al. 2018). However, in one study of inpatients with AN, Grant et al. (2002) found that none of the AN patients who screened positive for BDD during the study had been previously diagnosed with the disorder. These data

suggest that the comorbidity of BDD and EDs may be grossly underestimated due to the underdiagnosis of BDD in routine clinical settings (Veale et al. 2016).

Clinical Characteristics Common to BDD and EDs

Differentiating core clinical characteristics of BDD from those associated with an ED can be challenging. Most prominently, BDD shares with AN and BN severe disturbances in body image and dissatisfaction, intrusive negative thoughts about appearance, and an overvaluation of appearance in judgments of self-worth (Hrabosky et al. 2009; Hartmann et al. 2013; Beilharz et al. 2019; Rosen and Ramirez 1998). Often, BDD can be differentiated from an ED on the basis of appearance concerns, as data suggests that individuals with BDD are significantly more likely than those with AN to have concerns centered on facial features, skin, or hair, while those with AN are more likely to be concerned by body areas closely linked to weight concerns (e.g., hips, thighs, stomach, waist) in addition to overall weight (Toh et al. 2020). However, up to 29% of individuals with BDD report experiencing significant weight or shape concerns that are not associated with significant eating pathology (Kittler et al. 2007). Manifestations of BDD can further include concerns related to the shape, feel, or texture of body areas in body areas such as the stomach, thighs or buttocks, arms, or wrists, (e.g., "flabby," "too big," "cellulite-covered") which may seem to mirror concerns linked to body shape or weight among individuals with EDs.

On the other hand, a large proportion of individuals with AN or BN also report non-weight-related appearance concerns, such as concerns with their skin, breasts, teeth, nose, other facial features, or hair, that do not necessarily meet criteria for BDD (Gupta and Johnson 2000; Rosen et al. 1995). However, it is important to differentiate between dysmorphic concerns (i.e., which are objectively imperceptible or very slight) and concerns related to objective, observable changes in appearance that may stem from starvation among ED patients, such as increased hair growth (lanugo), dental lesions, or skin and hair changes (Beilharz et al. 2019).

In sum, clinicians must carefully inquire about appearance concerns across the whole body when suspecting any form of body image disturbance, whether it is BDD or an ED. Any identified areas of concern should then be examined to determine whether the concern has a clearly discernible physical basis, or whether it perhaps may represent a dysmorphic concern (i.e., the concern is imperceptible or very slight, or is within normal variation). Patients should then be asked about the degree of preoccupation and distress associated with each identified concern to aid in determining an appropriate diagnosis.

Both BDD and AN also share patterns of ritualistic, repetitive, or excessive body-focused behaviors. These include mirror checking and self-scrutinizing behaviors (e.g., measuring and weighing oneself), mentally comparing self to others, dieting, and excessive exercise (Grant and Phillips 2004). Both conditions also involve behaviors aimed at "improving" the perceived problem with physical appearance, such as altering weight or shape in AN through eating and exercise behaviors, or

altering the appearance of specific body or facial features in BDD with product use, grooming, exercise, or cosmetic procedures (Phillips 2017). In addition, both BDD and AN involve similar safety behaviors, such as choosing camouflaging clothing and avoiding places, activities, or social situations that exacerbate self-consciousness about appearance (Grant and Phillips 2004). However, individuals with BDD may engage in increased checking and appearance manipulation behaviors relative to individuals with AN (Kollei et al. 2012), and may be more avoidant of social situations (Rosen and Ramirez 1998).

Thus, investigation as to what behavioral reactions arise in response to identified appearance concerns may further aid in distinguishing symptoms of BDD from those of an ED. As noted previously, presence of clinically significant disordered eating behaviors and/or related compensatory behaviors, such as vomiting or use of laxatives, is not characteristic of BDD (American Psychiatric Association 2013). Finally, research suggests that individuals with comorbid BDD and AN may demonstrate more severe illness outcomes than those with AN alone, but not necessarily any more severe than those with BDD alone (Grant et al. 2002). These outcomes include significantly poorer psychosocial functioning, increased likelihood of psychiatric hospitalization, and triple the rate of suicide attempts among those with comorbid BDD and AN as compared to those with AN only (Grant et al. 2002).

Associated Features Common to BDD and AN

Both BDD and AN demonstrate a similar mean age of onset, in a range of approximately 16 to 18 years, though both conditions are also frequently associated with early onset during childhood (Hartmann et al. 2013). Both conditions also tend to exhibit a chronic illness course when left untreated (Hartmann et al. 2013). While both conditions also appear to involve poor insight into the nature of appearance concerns, data suggests that insight may be worse among those with BDD (Phillipou et al. 2019). BDD may also involve a higher risk of suicidal ideation and suicide attempts as compared to AN (Hartmann et al. 2013). Other clinical features that are common among both BDD and AN include perfectionism, tendency to worry, low self-esteem, and negative interpretive biases for ambiguous situations (Hartmann et al. 2013; Phillipou et al. 2019).

Cognitively, both BDD and AN have been associated with poor global visual processing (Lang et al. 2021), and poor performances on tests of executive functioning (Hartmann et al. 2013). Both conditions also show poor recognition of emotional expressions and tendencies to misinterpret emotional expressions as angry (Hartmann et al. 2013). Furthermore, direct neuroimaging comparisons of BDD and AN have demonstrated broadly similar abnormalities, as well as nuanced differences, in the function and structure of brain regions involved in visual processing (Phillipou et al. 2019; Moody et al. 2021). Potentially, abnormalities in visual processing systems may underpin the shared experience of extreme body image distortion that is common to BDD and AN.

Overlaps Between MD and AN

Data suggests that MD and AN involve a similar degree of body image disturbance, abnormal eating behaviors, and engagement in compulsive exercise, but with opposing characterizations (Murray et al. 2012). Individuals with MD demonstrate a significantly increased "drive for muscularity" than do individuals with AN (i.e., reflecting wishes to be larger and bulkier, and associated dietary and exercise behaviors). Conversely, individuals with AN are more concerned with thinness and demonstrate significantly greater dietary restriction and eating concerns than do individuals with MD (Murray et al. 2012). Accordingly, compulsive exercise is considered to be the primary feature of MD, with eating disturbances conceptualized a secondary feature (Pope et al. 1997). However, further research is needed to better understand the nature of eating behaviors in MD, as in both MD and EDs such as AN and BN, non-adherence to planned dietary practices often causes feelings of guilt or anxiety and triggers compensatory behaviors such as additional exercise (Murray et al. 2010).

Overlaps of BDD and EDs: Gender-Related Factors

Across BDD and EDs, gender-related factors seem to play a role in some aspects of illness presentation. EDs such as AN or BN predominately affect women, with estimates suggesting that men represent approximately 25% to 33% of AN or BN cases (Murray et al. 2017). Conversely, just over half of individuals with BDD are women (Buhlmann et al. 2010). However, it seems that men are substantially more likely than women to be affected by MD (Pope Jr et al. 1993). Regarding BDD, there are some subtle differences between men and women in common body areas of concern, which tend to align with normative masculine and feminine gender ideals that are prevalent in Western society (Malcolm et al. 2021; Phillips et al. 2006). In addition, MD has been conceptualized as involving an extreme valuation of the stereotypical masculine ideal, thus feeding a drive for increased muscularity (Lavender et al. 2017). Accordingly, men with MD have been found to show higher adherence to traditional masculinity norms than do men with BDD, such as endorsing the use of violence to solve problems (Blashill et al. 2020). Conversely, it has been argued that adherence to feminine ideals is more closely related to a drive for thinness, which characterizes EDs (Murray et al. 2017). For instance, Murray et al. (2013) reported significantly greater adherence to masculine norms among men with MD as compared to men with AN and gym-using male controls, while men with AN demonstrated significantly greater adherence to feminine norms than men with MD or gym-using men.

Further research in BDD and EDs is also needed among individuals who are transgender or who have nonbinary gender identities, as these groups may also have differing experiences of dysmorphic concern or ED pathology. For instance, transgender people who are not receiving gender-affirming hormone therapy have been found to have increased body dissatisfaction and ED symptoms as compared to those receiving hormone therapy (Jones et al. 2018).

Considering Comorbid BDD and EDs in Treatment

While BDD and AN have a number of similarities, treatments for the disorders have some differences. Treatment for BDD typically involves cognitive behavioral therapy (CBT) tailored for BDD and/or high-dose serotonin reuptake inhibitor (SSRI) medications. CBT for BDD is comprised of psychoeducation, cognitive restructuring, exposure and response prevention, relapse prevention training, and often, perceptual retraining (Wilhelm et al. 2013). Perceptual retraining involves practicing skills in viewing one's reflection objectively and learning how to adaptively use mirrors (i.e., at an appropriate distance and only for brief, purposeful periods). Motivational interviewing techniques are often utilized throughout treatment, especially for individuals with poorer insight (Wilhelm et al. 2013). Where appropriate, additional specialized strategies may be used to address MD, weight/shape concerns, or persistent cosmetic surgery seeking (Wilhelm et al. 2013). For MD, there is a focus on increasing awareness of factors that drive the desire to change body weight or shape, restructuring underlying beliefs or biases, increasing acceptance of the "realistic" or "natural" body, and reducing compulsive dietary and exercise behaviors (Wilhelm et al. 2013). Where relevant, psychoeducation about the health risks associated with steroids is provided, and patients are supported to reduce steroid use.

Other formulations of CBT for BDD emphasize use of mindfulness techniques and emotion-focused approaches, including self-compassion-based skills development and use of imagery rescripting (i.e., restructuring narratives and imagery of painful memories associated with dysmorphic concerns to redefine their meaning) (Veale and Neziroglu 2010). Current data suggests that approximately 40% to 80% of patients show a significant response (e.g., 30% decrease in symptom severity at posttreatment) to CBT for BDD, yet a high degree of specialized training in BDD-specific skills seems most closely tied to improved patient outcomes (Harrison et al. 2016; Wilhelm et al. 2019). In addition, SSRI medications administered at high doses and for extended periods seem beneficial for approximately 53% to 83% of patients (Phillips 2017).

Treatments for EDs often entail different approaches and outcomes. For instance, AN treatments often include ED-specialized family-based therapy, pharmacological interventions (e.g., antipsychotic medications), CBT enhanced for EDs (CBT-E), and ED-specialized inpatient or outpatient programs which may involve refeeding or heavily nutritional-focused components (Murray et al. 2019). In general, interventions for AN are often highly targeted toward weight gain and creating change in eating behaviors, which are essential for the prevention of medical risks related to starvation (Murray et al. 2019). These treatments are efficacious in promoting weight gain in the short term, but demonstrate very little efficacy in promoting long-term weight maintenance or recovery from psychological symptoms of AN (Murray et al. 2019). Further, in contrast to interventions for BDD, data suggests little to no benefit from commonly used pharmacological interventions in AN (e.g., SSRIs, antipsychotic medications), and mixed or moderate benefits from CBT-E or family therapy

(Linardon et al. 2017b). Thus, treatment for an ED with comorbid BDD must include targeted treatments for both disorders.

Role of Dysmorphic Concerns in Comorbid BDD and EDs

Findings suggest that increasingly severe dysmorphic concern is significantly associated with greater severity of eating concerns and shape and weight concerns among individuals with AN (Beilharz et al. 2019). Similarly, disturbances in body image and body dissatisfaction have been found to be consistent predictors of improvement or relapse in AN posttreatment (Murray et al. 2019). Thus, the presence of extreme dysmorphic concern associated with comorbid BDD will likely require intensive focus. Interventions developed specifically to address dysmorphic concern in BDD could be especially useful in these contexts (e.g., imagery rescripting, perceptual "mirror use" retraining, exposure-based approaches, and compassion-based approaches). In addition, clinicians must be attentive to shifts in dysmorphic concerns during treatment for persons with a comorbid ED and BDD. Among individuals with BDD, it is common for appearance concerns to move to other body areas, either spontaneously or after some form of physical change in an area of concern, such as following cosmetic procedure (Veale et al. 1996). Theoretically, physical changes associated with weight restoration during recovery from an ED may also prompt shifting appearance concerns in an individual with comorbid BDD. Thus, clinicians should regularly assess for new or changed appearance concerns among individuals with comorbid BDD.

Future Treatment Research Directions for Comorbid BDD and AN

Research into potential treatments for BDD and AN appear to demonstrate some overlaps, and converged treatments for these disorders may be especially effective in cases of comorbid illness. For instance, emergent research directions that may be beneficial for both disorders include visually focused cognitive remediation therapy, acceptance and commitment therapy-based approaches, or other "third wave" psychotherapies such as dialectical behavior therapy (Beilharz et al. 2017; Hartmann et al. 2013; Linardon et al. 2017a). In addition, comprehensive compassion-focused therapy has separately been proposed as a potentially beneficial treatment for each disorder (Veale and Gilbert 2014; Goss and Allan 2014). In the context of BDD or AN, compassion-focused therapy addresses body image concerns with a focus on shame, self-criticism, and self-hostility while building capacity for self-compassion, distress tolerance, and regulation of affiliative attachment-based emotions (Veale and Gilbert 2014). However, further research is needed to test the efficacy of these treatments in BDD and EDs.

Conclusions

BDD is a severe mental illness that involves many similarities to AN, especially in the severity of body image disturbance, core clinical features, and associated cognitive and neurobiological features. These overlaps may create challenges in

differentiating between BDD and AN, especially when BDD involves weight or shape concerns. However, careful investigation of specific appearance concerns and related behavioral symptoms will help differentiate between the disorders. The MD subtype of BDD further shows particularly strong links with AN in terms of disturbed eating patterns and excessive exercise behaviors, though with an opposing drive toward muscle gain and bulkiness. Across these conditions, gender-related influences seem to intersect with presentations of MD and EDs, though BDD appears more similar than different among men and women. Finally, given that BDD is highly likely to co-occur with AN or BN, it is essential that clinicians screen for BDD in any instance of a potential ED. This is extremely important as BDD symptoms are unlikely to be identified without direct questioning, and the presence of comorbid BDD is associated with significantly more severe psychosocial consequences for individuals with AN. Further, it is important that disorder-specific treatments are jointly utilized for comorbid BDD and EDs, as these disorders often respond to different treatment interventions. However, further research is needed to determine the most helpful course of action treating individuals with comorbid BDD and ED diagnoses, as outcomes for this group of patients are not well reported on.

Applications to Other Eating Disorders

This chapter has reviewed associations between body dysmorphic disorder (BDD) and EDs which involve similarly severe body image disturbance, most notably AN and BN. However, a number of other EDs do not involve any evidence of body image disturbance, and thus may be unlikely to have any strong links with BDD (e.g., pica, rumination disorder, avoidant/restrictive food intake disorder). It has been argued that these aforementioned conditions represent "true" feeding and EDs, whereas AN and BN are, at the core, body image disorders which manifest through problematic eating (Phillipou et al. 2017). This proposal provides a compelling explanation for the numerous close similarities between BDD (including MD) and AN, including overlaps in clinical, cognitive, and neurobiological features (Hartmann et al. 2013; Lavender et al. 2017).

One area of further research interest may be whether BDD has elevated associations with the proposed ED of orthorexia nervosa. Both BDD and orthorexia nervosa are conceptualized to involve obsessive-compulsive characteristics (Malcolm et al. 2018; Brytek-Matera 2012). Theoretically, preoccupation with a "healthy" diet in orthorexia nervosa could coincide with body image concerns related to having a "healthy" appearance in BDD, such as appearing highly fit and toned. Similarly, excessive attention toward the precise nutritional value of food or supplements (e.g., macro- or micronutrient properties) is a common feature of muscle dysmorphia (Lavender et al. 2017), and one which could overlap with orthorexic tendencies. Overall, further research is needed to better understand relationships between BDD, MD, and the EDs. Data comparing BDD and AN is still limited, and there is scant research to evaluate potential links between BDD and other EDs.

Mini-dictionary of Terms

- **Body dysmorphic disorder (BDD)**. A psychological disorder involving a distressing and impairing preoccupation with a perceived defect in physical appearance, which is not observable or appears slight to objective observers.
- **Dysmorphic concern**. Preoccupation with a distorted perception of appearance that is generally not consistent with objective observations (i.e., is imperceptible, or appears very slight, or is within normal variation), and which involves subjectively experienced anomalies in self-perception.
- **Illness insight**. Describes the degree to which a person can recognize disorder-relevant beliefs as being excessive or inaccurate. In BDD, insight relates to beliefs about perceived defects in appearance. In AN, insight relates to beliefs about the body being larger, heavier, or fatter than objective assessments indicate.
- **Muscle dysmorphia (MD)**. A specific presentation of body dysmorphic disorder that is primarily characterized by a preoccupation with the idea that one's own body is not sufficiently muscular. This concern is accompanied by excessive weight training behaviors and excessive attention to a protein-rich diet.

Key Facts of Body Dysmorphic Disorder: Links with Eating Disorders and Gender-Related Factors

- BDD was first named "dysmorphophobia" by the Italian psychiatrist Enrico Morselli in 1891, based on his observations of 78 patients. These patients exhibited persistent, intrusive, and severely distressing fears and beliefs that they had become (or may become) physically deformed, and each spent many hours obsessively checking their appearance. Morselli initially conceptualized BDD as a phobic (anxiety)-based condition involving obsessive and paranoid-delusional qualities.
- Data indicates that BDD is most prevalent among younger adults, with point-prevalence rates up to 4.4% among those aged 18 to 35 years (Koran et al. 2008). Approximately two-thirds of individuals experience BDD onset before age 18. This earlier onset has been associated with increased rates of suicidal behavior and ideation, and greater comorbidity (Bjornsson et al. 2013). Subclinical BDD symptoms often develop around age 12, and rates of subclinical BDD symptoms are estimated to be as high as 3.4% among children aged between 12 and 18 (Schneider et al. 2017a).
- BDD is highly prevalent in cosmetic and plastic surgery settings, with estimates suggesting a weighted prevalence of 5% to 20% in patients in cosmetic dentistry, dermatology, general cosmetic surgery, and rhinoplasty surgery settings. Individuals with BDD are attracted to these settings by hopes that a physical procedure might "fix" their perceived defect in appearance (Veale et al. 2016). However, cosmetic procedures are typically contraindicated for BDD due to poor psychological outcomes (Veale 2000).

- Reports from across the world suggest that BDD is not bound to any one culture, and generally shows similar prevalence rates, sex distribution, and profile of clinical characteristics across nations. However, data suggests that there may be some global differences in terms of specific appearance concerns which may coincide with differences in specific cultural values related to attractiveness. For instance, MD seems more prevalent in Western rather than Eastern cultures. This may be due to a long history of muscularity being closely tied to masculinity in Western cultures, but less so in Eastern cultures (Phillips 2017).
- The high rate of anabolic-androgenic steroid use among individuals with MD represents a significant physical health concern. Steroid use leads to suppression of the gonadal axis, which may result in infertility and changes in physical sex characteristics of both men and women (Anawalt 2019). Use of steroids has also been linked to an increased risk of a variety of cardiovascular consequences, such as atherosclerosis, arrhythmia, and dyslipidemia. In addition, individuals may exhibit increased aggression and impulsivity during active use, while withdrawal may exacerbate symptoms of depression and anxiety.

Summary Points

- Body dysmorphic disorder (BDD) is a mental disorder characterized by a distressing and impairing preoccupation with perceived defects in physical appearance.
- The muscle dysmorphia (MD) subtype of BDD is characterized by preoccupation with concerns of insufficient muscularity, excessive weight training, and excess attention to a protein-rich diet.
- While BDD equally affects men and women, with more similarities than differences in illness presentation, the MD subtype of BDD seems to predominately affect men.
- BDD and MD involve significant overlaps with AN and BN in key clinical characteristics, including having significant body image disturbance.
- BDD can often be differentiated from an ED on the basis of specific body image concerns and types of behaviors that are performed in response to these concerns.
- BDD and MD commonly co-occur with EDs, but are likely underdiagnosed in clinical settings.
- Clinicians must be careful to screen for BDD at any time a patient is being investigated or treated for an ED.
- Treatments for BDD differ from those commonly used to treat EDs; interventions specifically targeting BDD symptoms should be used conjointly with ED interventions in the case of comorbid BDD.

Orthorexic Eating and Addictions: Links with Substance Use, Behavioral Addictions, and Research Gaps

Contents

Abstract

Orthorexia nervosa is described as an obsessive fixation on healthy eating in order to maintain and optimize health. The progressive rigidity of self-imposed dietary rules in orthorexia nervosa may resemble the maladaptive cycle of substance abuse. Phenomenological similarities are high time investment and cognitive and

behavioral preoccupation. Nevertheless, the obvious negative health consequences of substance use disorders are contrary to the aim of orthorexic eating behavior. Moreover, Orthorexia nervosa does not allow the identification of specific foods or food groups which might serve as addictive substances. Based on current evidence, there is no link between Orthorexia nervosa and substance use or abuse. Behavioral addictions, defined as compulsive and excessive non-substance-related behaviors, have also been examined in relation to orthorexia nervosa. Addictive and compulsive exercising was moderately and positively related to orthorexia nervosa. Evidence of a link with food addiction and internet addiction is still too sparse to allow conclusions. Filling research gaps related to addictions and orthorexia nervosa could help to better understand the etiology of orthorexia nervosa and, thus, assess its distinctiveness from established psychiatric disorders.

SES	Socioeconomic status

Introduction

Definition and Clinical Aspects

Health and fitness are key determinants of health and performance. A holistic understanding of health, however, is also becoming a central component of the most diverse lifestyles in our society – causing health to have an elevated source of meaning and health-promoting behaviors being passionately carried out (Crawford 1980). The question arises whether extreme forms of healthy lifestyle have pathological relevance when living healthy becomes a harmful obsession. In this context, the phenomenon *orthorexia nervosa* (OrNe) has received medial interest and is scientifically studied (Håman et al. 2015). This term was coined in 1997 by the American doctor Steven Bratman and composed of the Greek words "*ὀρθός* (orthós)" for right and "*ὄρεξις* (órexis)" for appetite; OrNe describes an obsessive fixation on a diet perceived as healthy and correct (Bratman 1997). Since early case studies describing this new

pathological way of eating, scientific interest has continuously increased. Still, OrNe is not formally recognized as a mental disorder. In 2018, an association of international researchers – the OrNe Task Force – has agreed on three primary diagnostic criteria described in Table 1 (Cena et al. 2019).

From the Healthy Interest in Diet to the Unhealthy Obsession with Diet

In more detail, obsessive preoccupation with healthy eating refers to the amount of time spend for planning, obtaining, preparing, and/or eating one's food. On the other hand, it contains self-imposed rigid and inflexible rules which may be strictly controlled. Thereby, the definition of "healthful eating" might be in accordance with official recommendations, such as those from the World Health Organization (WHO 2000), but may also be incompatible with them. So, the perception of healthy eating may be based on individually varying dietary theories. For example, healthy food is often considered as pure, clean, organic, right, correct, natural, and safe, whereas unhealthy food is often referred to as processed, with added ingredients, prepared, treated, toxic, and contaminated. Those affected consider this to be harmful for their own health (Cena et al. 2019). It might also include any other definition of "healthy" or "unhealthy" according to the individual's superior ideas about foods or to dietary trends (Ferreira and Coimbra 2021) and cultures (Gramaglia et al. 2019). It is proposed that when individuals with OrNe are confronted with food which they consider unhealthy, they tend to suffer from emotional distress and fear of impaired health and disease. In addition, feelings of guilt when violating self-imposed dietary rules cause exaggerated fears and compensatory behaviors (Hayatbini et al. 2021). Dietary restrictions increase over time and food selectivity can contribute to cause nutritional deficiencies, such as anemia, extreme weight loss, global or selective malnutrition, and damage to health. Orthorexia nervosa may lead to symptoms that can also occur in the case of other severe illnesses which are associated with malnutrition, e.g., osteopenia, anemia, hyponatremia, and metabolic acidosis (Koven and Abry 2015).

As orthorexic eating behavior is accompanied by a high amount of cognitive preoccupation and time devoted to diet and nutrition, problems concerning attention and concentration may arise. Relatedly, individuals with OrNe miss time or activities in their personal, vocational, and/or academic lives. This may also result in social isolation and modification of social relationships. Overall, OrNe includes emotional (e.g., feeling guilty after having eating food considered to be unhealthy), cognitive (e.g., problems concerning attention and concentration), and/or social (e.g., social

Table 1 Primary diagnostic criteria of OrNe. (According to Cena et al. (2019))

1	Obsessional or pathological preoccupation with healthy nutrition
2	Emotional consequences (e.g., distress, anxiety) of non-adherence to self-imposed nutritional rules
3	Psychosocial impairments in relevant areas of life as well as malnutrition and weight loss

exclusion) consequences, which impose a negative effect on the individuals' educational, work, or social life (Cena et al. 2019). Despite these consequences on health, relationships, social life, and quality of life, the observance of rigid food rules is maintained in OrNe.

As further criteria, some authors recommend the presence of positive effects from following self-defined healthy eating (Dunn and Bratman 2016) or overvalued ideas about body- and health-related effects of specific foods or food groups (e.g., Barthels et al. 2015). Furthermore, it is discussed whether orthorexic eating behavior might be characterized by a moral or spiritual component leading to a feeling of ethical superiority over the lifestyle and eating habits of others which becomes part of their belief system and identity (Cena et al. 2019).

Epidemiology, Risk Factors, and Clinical Relevance

Reviews estimated that the prevalence of at least some orthorexic behaviors range from 6 to 89% (Dunn and Bratman 2016; McComb and Mills 2019). It is likely that these high numbers can be attributed to psychometrically poor diagnostic tools and their inability to differentiate healthy eating from pathologically obsessive healthy eating. Sound methods suggest rates between 3 and 7% in western countries, numbers that drop below 1% when clinical suffering is also considered (Dunn et al. 2017; Luck-Sikorski et al. 2019). Women seem to be slightly more affected than men although gender as a risk factor remains unclear to date (Strahler 2019). Further proposed risk factors are younger age and higher socioeconomic status (SES). In regard to age, findings are mixed what might be attributed to the methodological heterogeneity (tools, sample) of studies. While some studies suggest younger age to be a risk factor for developing OrNe (McComb and Mills 2019), current research hardly allows a conclusion because usually rather young samples are examined. From theory, it seems comprehensible that higher SES is linked to orthorexic eating. People with a higher level of education are more likely to have the financial resources to purchase high-quality food and are assumed to have easy access to knowledge about certain diets and nutrition (Pollard and Booth 2019). Research, however, has produced inconsistent findings so far. Currently, the samples examined are still very limited (e.g., recruitment primarily in the academic setting), and there is a high demand for more cross-SES and cross-cultural research. For further proposed risk factors, the reader is referred to recent narrative and systematic reviews (McComb and Mills 2019; Strahler and Stark 2019). Notably, proposed criteria reflect on this by adding that the behavior is not better explained by lack of available food or by associated culturally sanctioned practice.

The Current Debate About the Behavior's Pathological Relevance

Although orthorexic eating behavior may negatively affect the health status and quality of life, there is no consensus whether OrNe is of pathological relevance or

not. Present research on negative consequences mainly stems from a few case studies or from studies with poor diagnostic tools and should therefore be considered with caution (Strahler and Stark 2020). While there are possibly harmful consequences of this behavior (e.g., depressive symptoms, fear of negative evaluation, and exhaustion), it remains unclear whether those may be considered as pathological, i.e., whether they lead to individual suffering and significant impairments, and whether these consequences exceed the influence of other also present disorders. For example, OrNe was found to be associated with lower well-being as well as life satisfaction, but this effect was better explained by symptoms of pathological eating (Strahler et al. 2018; Zickgraf et al. 2019). Taking existing literature into account, the clinical relevance of OrNe still remains unclear and needs to be investigated further. In sum, OrNe should be described as a mental health problem associated with distress, impairment, and reduced well-being (Strahler and Stark 2020).

Differential Diagnosis and Differentiation from Other Diseases

To date, orthorexia nervosa has neither been included in the *International Statistical Classification of Diseases and Related Health Problems* (11th ed., ICD-11; World Health Organization 2018) nor the *Diagnostic and Statistical Manual of Mental Disorders* (5th ed., DSM-5; American Psychiatric Association 2013). As the diagnostic validity of OrNe is still uncertain, various disorder categories may be considered for the classification of OrNe on the one hand and for its distinguishability on the other hand. In this regard, two disorder categories are discussed in particular: *eating disorders* (ED) and *obsessive-compulsive disorders* (OCD). Both as well as OrNe seem to share common features such as perfectionism, anxiety, and cognitive rigidity (Koven and Abry 2015).

Orthorexia Nervosa and Obsessive-Compulsive Symptoms

Due to the high amount of cognitive and behavioral occupation, specific similarities with the obsessive-compulsive disorders can be found. In OrNe, thoughts are assumed to revolve around food and health in an intrusive manner. Furthermore, concerns regarding contamination or impurity may occur, while highly ritualized food preparation methods may consume a high amount of time (Bratman and Knight 2000; Koven and Abry 2015). Hence, OrNe might be conceived as an OCD whose obsessive thoughts and actions focus exclusively on food and nutrition. While symptoms of OCDs are experienced as ego-dystonic, those of OrNe are assumed to be ego-syntonic (Strahler and Stark 2020). Overall, the associations between OrNe and OCD are small to moderate and, moreover, insignificant when controlling for symptoms of EDs (Zickgraf et al. 2019; Bartel et al. 2020). Therefore, the placement of OrNe within the spectrum of EDs is favored in literature (Brytek-Matera et al. 2017; Meule and Voderholzer 2021).

Orthorexic Eating Within the Eating Disorder Spectrum

Several similarities with *anorexia nervosa* (AN) can be found. Both share the high need for control, exhibit goal-driven eating behaviors, and follow self-imposed strict dietary rules. When violating said rules, negative cognitive, emotional, and/or behavioral consequences occur, e.g., feelings of guilt and shame, or establishing even more rigid dietary rules. In contrast to AN, those affected primarily refer to the quality of foods instead of quantity. Despite possibly occurring with the rigid diet, weight loss is currently not assumed to be a leading motive for orthorexic eating behaviors. As a significant low body weight and body image disturbances are core features of AN, the lack of weight or shape concerns was suggested to crucially differentiate OrNe from AN (Cena et al. 2019). Current evidence, however, tend to contradict this conceptual assumption (Bartel et al. 2020; Meule and Voderholzer 2021). Since it does not involve body image disturbances as a formal diagnostic criterion, the *avoidant/restrictive food intake disorder* (ARFID) was additionally proposed as a conceptually proximate ED (Moroze et al. 2015). The restriction of diet in ARFID may be exhibited due to various reasons such as sensory characteristics of food or anticipated aversive consequences following food intake, e.g., choking sensations or abdominal pain (American Psychiatric Association 2013). The latter merely refers to immediate or short-term consequences, while orthorexic eating behaviors rather revolve about long-term consequences for the status of health (Zickgraf et al. 2019). Overall, the distinction of OrNe from the EDs remains unclear.

Not only EDs and OCDs are discussed in the context of OrNe. Anxiety disorders are also considered due to possibly similar underlying psychopathological mechanisms. For example, associations with illness anxiety were found, suggesting that OrNe might serve as an inappropriate compensatory behavior (Barthels et al. 2021). Interestingly, this may argue for OrNe as another eating disorder, since anxiety disorders were also found to precede the onset of eating disorders (Swinbourne and Touyz 2007). Moreover, it was also surmised that OrNe shares many features with (behavioral) addictions. This will be explained in more detail in the following section.

Orthorexia Nervosa and Addictive Behaviors

To summarize the existing body of work and identify gaps in knowledge, the following sections are based on a systematic literature search in three main databases, MEDLINE, PsycINFO, and Web of Science. Search terms included ((orthorexia nervosa) or orthorexic) and (addict* or (substance abuse) or (substance use) or compulsive or excessive or alcohol or smoking or (drug abuse) or (medical abuse) or gambling or gaming or (internet disorder) or (behavioral addiction)). As this is a narrative review, there was no predetermined research question and there is no detailed documentation of the search process. We have summarized and synthesized the findings below and in Table 2.

Table 2 Summary of study characteristics included in the narrative review

Authors	Country	Sample	Total sample age (M ± SD)	OrNe measure used (cutoff[a])	Addiction measure used (cutoff)	Main findings[b]
Substance use						
Aksoydan and Camci (2009)	Turkey	44 opera singers (54.5% f) 28 ballet dancers (71.4% f) 22 symphony orchestra (50.0% f)	38.8 ± 10.7 26.8 ± 5.0 30.0 ± 11.2	ORTO-15	Smoking (yes, no) Alcohol (yes, no)	No sig. lower ORTO-15 (=higher OrNe) in nonsmokers ($n = 52$) and non-alcohol consumers ($n = 55$)
Almeida et al. (2018)	Portugal	193 gym members (58.5% f)	32.8 ± 11.6	ORTO-15 (≤35)	Alcohol (yes, no) Tobacco (yes, no) Drugs (yes, no)	No sig. differences between OrNe cases ($n = 100$) and non-cases ($n = 93$) in alcohol consumption, tobacco use, and drug use
Erkin and Göl (2019)	Turkey	118 yoga practitioners (92.4% f)	f: 30.0 ± 9.4 m: 36.3 ± 3.8	ORTO-11	Smoking (yes, no)	No sig. differences between nonsmokers and smokers ($n = 12$) in ORTO-11
Fidan et al. (2010)	Turkey	787 medical students (40.9% f)	21.3 ± 2.1	ORTO-11	Current smoker (yes, no) Cigarettes per day (<1 pack, 1 pack, 1–2 packs, >2 packs)	Lower ORTO-11 (=higher OrNe) in smokers The more packs the lower ORTO-11
Hyrnik et al. (2016)	Poland	1899 high school students (52.5% f)	17.3 ± 1.0	ORTO-15 (≤40, ≤35, ≤33)	Smoking status (yes, no) Alcohol (never, occasionally, 1–5 x/month, 1–5 x/wk, >5	Higher risk for cutoff ≤40 (but not 35 or 33) when nonsmoking (odds ratio = 1.44)

Comorbidity Between Orthorexia Nervosa and Substance-Related Addictions

The obsessivity, marked rigidity, and overcontrol with which individuals with orthorexic tendencies pursue their dietary behaviors despite profound negative consequences are similar to a maladaptive cycle seen in individuals with addictions. Addictive disorders were originally inextricably linked to the use of psychotropic substances. Those are defined as naturally occurring, synthetically produced, or chemically prepared substances that affect the central nervous system resulting in the alteration of perception, cognition, emotion, and behavior as well as the increase of the subjective psychical and physical well-being (American Psychiatric Association 2013). Discussing OrNe as a possible addiction, the question arises on what substance those affected are addicted to? Since the diets, which individuals with orthorexic eating behaviors follow and perceive as healthy, and the beliefs regarding the overestimated effects of foods vary, no specific foods or substances seem to be intertwined with OrNe (Bratman and Knight 2000; Barthels et al. 2015). Hence, there is no substance of abuse in OrNe; rather, some individuals may report emotional reward from the absence of the intake of unhealthy foods (Singh 2014). Individuals with OrNe seem to be "addicted" to the sensation of controlling their health and diet. Thus, excessive control over food intake, self-control in particular, may somehow become reinforcing. This is in stark contrast to substance-related addiction where indulgence of psychotropic substances culminates in high-risk consumption, and a loss of control over the usage may occur. The substance may be used more frequently, in larger quantities, or for longer durations than intended, thus interfering with areas of social or occupational activities and leading to conflicts. Moreover, a substantial time investment may be required to obtain the substance, intoxication, or recovery from said intoxication (American Psychiatric Association 2013). To some extent, the aspect of substance abuse seems applicable to OrNe. Since orthorexic eating behavior is characterized by high cognitive and behavioral occupation, the time invested in meal planning and preparation may lead to impairments in other areas of life. In addition, individuals affected by OrNe may refuse dinner invitations or have conflicts with friends or family because of a sense of moral superiority (Cena et al. 2019). Thus, similar to substance abuse, there is a loss of control over the preoccupation with healthy eating. While attempts to reduce or control usage of psychotropic substances fail, consumption is continued in order to achieve the state of intoxication – despite its negative consequences such as interpersonal conflicts or decrease of mental and physical health. Hence, a *substance use disorder* is considered present when a maladaptive pattern of substance use leads to clinically significant distress or impairment in social, occupational, or other important areas of functioning. Furthermore, *physical addiction* is given in a substance use disorder when tolerance has developed, i.e., an elevated dose is required to achieve the same extent of intoxication, or withdrawal symptoms occur (American Psychiatric Association 2013). Indeed, the diets of individuals affected by OrNe are assumed to get more rigid over time (Bratman and Knight 2000; Barthels et al. 2015). However, there is no study investigating the time course of said dietary

restriction, to date. Overall, the characteristics of OrNe and substance use disorders do not appear to coincide sufficiently to classify OrNe as the latter. Empirical evidence regarding this hypothesis is sparse, and comorbidity between orthorexic behaviors and substance abuse is currently unknown.

Empirical Evidence for a Link Between Orthorexia Nervosa and Substance (Ab)Use

Our literature search revealed only a few reports on legal (and illegal) substance use mostly suggesting similar orthorexic behaviors between smokers and nonsmokers (12 studies) and no relation to alcohol consumption (8 studies). For more study details, the reader is referred to Table 2. For smoking, two further studies reported significant differences, one showing a higher prevalence of orthorexic behaviors (Hyrnik et al. 2016) and one showing a lower prevalence in nonsmokers (Fidan et al. 2010). Two additional reports indicated higher orthorexic behaviors to be related to less alcohol consumption (Varga et al. 2014; Roncero et al. 2017). Furthermore, (illicit) drug use has been examined in four studies producing mainly null findings. The only significant result was a positive but small correlation with illicit depressant drug use ($r = 0.12$). Substance abuse and substance-related addictions have been examined in only two cross-sectional studies. There was no relation with the Fagerström Test for Nicotine Dependence or the Cigarette Dependence Scale, the Alcohol Use Disorders Identification Test, and the brief screen for DSM-5 substance use disorders (Strahler et al. 2018; Oberle et al. 2022).

Considering the characteristics of OrNe, i.e., consuming only foods of highest nutritional quality, makes alcohol, tobacco, medication, or illegal drug use very unlikely in these individuals. Previous null findings are therefore rather unsurprising. Importantly, due to the instruments used, most previous research only allows a limited conclusion on actual orthorexic behavior, which goes beyond the interest in healthy eating. In addition, investigated samples, i.e., students, young adults, and patients of limited age ranges, do not permit generalization.

Comorbidity Between Orthorexia Nervosa and Behavioral Addictions

Somewhat more appropriate than substance-related disorders seem to be the comparison of orthorexic behaviors with the so-called behavioral addictions. In the case of behavioral addictions, a behavior is exhibited excessively and is experienced as "out of control." In analogy to substance use disorders, six components of behavioral addictions can be described as follows: *Salience* refers to the elevated importance the behavior has for the individual. Thus, a high amount of emotional, cognitive, and behavioral preoccupation is involved leading to symptoms such as craving or social isolation. Negative emotional or physical consequences are experienced when the behavior is discontinued or reduced (i.e., *withdrawal*). In contrast, positive changes in mood are the consequences to the additive behavior which may be used as a

coping strategy in emotion regulation (i.e., *mood modification*). Furthermore, *tolerance* develops as the desired effects can solely be achieved by exhibiting more of the behavior. Hence, *conflicts* with others (e.g., friends and family), with other activities (e.g., occupation and education), or with the individuals themselves (intrapsychic conflicts) arise. Despite possible insight to the negative consequences, attempts to reduce the behavior fail or *relapses* to initial problematic quantity or intensity of behavior occur (Griffiths 2005). But not every behavior seems to have the potential to lead to an addiction. So far, evidence for gambling and computer gaming has been sufficient for both to be considered in international classification systems (DSM-5, ICD-11). In addition, other potentially addictive behaviors are currently discussed to be of pathological relevance, e.g., excessive and compulsive exercising or internet use (Griffiths 2005).

Phenomenological Overlap of Orthorexia Nervosa and Behavioral Addictions

Orthorexia nervosa has also been considered as a possible behavioral addiction (Strahler and Stark 2019). While some symptoms of orthorexic eating seem to be compatible with the components of behavioral addictions as healthy eating occupies the highest priority in daily life, there is neither evidence for tolerance nor withdrawal symptoms to date. Withdrawal symptoms in substance-related addictions are rather severe and may comprise physical (e.g., sweating, flushes, nausea, vomiting) as well as psychological symptoms (e.g., depression, anxiety, hallucinations). There are no such reports for orthorexia nervosa so far. Tolerance is theoretically assumed, i.e., increasingly rigid eating, but has not yet been studied. Nevertheless, orthorexic tendencies have been studied in relation to exercise addiction, food addiction, and social media addiction.

The Link Between Orthorexia Nervosa and Exercise (Addiction)

A balanced diet and physical activity are two essential lifestyle factors for maintaining physical and mental health and well-being. Just as for the quality of the diet, regular exercise can become an obsession, and the pursuit of health and fitness can become the focus of one's life. Due to the high importance of health and fitness for people with orthorexia nervosa, it was assumed that this behavior is also associated with increased physical activity and exercise behaviors. For example, studies in at-risk populations show that people who are active in sports, such as gym members, sports students, or yoga practitioners, should be considered as a risk group for developing orthorexic eating behaviors (Eriksson et al. 2008; Rudolph 2018). Correlative studies of individuals from the general population or students paint a rather inconsistent picture with some studies finding exercise and sports activity associated with orthorexia nervosa and others finding no associations. A recent meta-analysis summarized data from 21 studies and quantified the relationship between physical activity behaviors and orthorexic tendencies as $r = 0.09$ to $r = 0.19$ (Strahler et al. 2022). Regular exercise can also evolve from a healthy habit to an excessive, limitless, repetitive addiction to physical activity. In terms of clinical classification, exercise addiction (alternatively also compulsive exercise) should be

classified as a non-substance-related behavioral addiction (Hausenblas and Downs 2002; Griffiths 2005; Colledge et al. 2020). Comorbidity between orthorexic eating and addictive exercise behaviors has been examined in seven studies thus far (summarized in Table 2). Findings predominantly indicate moderate correlations between $r = 0.34$ and $r = 0.59$ (Rudolph 2018; Oberle et al. 2021; Strahler et al. 2021), and only one study found no correlation (Freire et al. 2020). The meta-analysis mentioned above puts the mean effect at $r = 0.29$ (Strahler et al. 2022). There is initial evidence for gender-specific correlations with higher scores in men as compared to women (Strahler et al. 2021) suggesting separate pathological mechanisms among genders. Research on factors contributing to this difference does not exist yet. Theoretical assumptions range from differences in health beliefs (Courtenay et al. 2002) to personality (Strahler et al. 2021), body image (Brytek-Matera et al. 2015; Brytek-Matera et al. 2017), and coping (Matud 2004). Overall, OrNe and exercise addiction appear as overlapping conditions with idiosyncratic clinical hallmarks. Another clinical syndrome that co-occurs with exercise addiction is disordered eating. More precisely, the presence of an eating disorder increases the risk for a comorbid exercise addiction by 3.71 times according to a recent meta-analysis (Trott et al. 2021). Hence, eating pathology seems to be linked with addictive exercising. Additionally, addictive behaviors might co-occur (Sussman 2017).

The Link Between Orthorexia Nervosa and Food Addiction

Hauck et al. (2020) investigated to what extent compulsive exercising and food addiction correlate within an athlete sample. In fact, both behavioral addictions were positively associated. According to the authors, it is questionable, however, whether highly processed and energy providing foods may be used to fuel one's body for the excessive amounts of exercise and optimize performances or whether they were overconsumed due to their addictive potential. It is controversially discussed whether food itself may be addictive at all (Fletcher and Kenny 2018). Bingeing might be equated with excessive consumption under loss of control triggered by craving or confrontation with a food stimulus. Therefore, specific food groups, e.g., highly processed foods or foods high in sugar and fat, seem to potentially be addictive "substances." A neurotransmitter system under suspicion to mediate the addictiveness of both food and psychotropic substances is the dopaminergic system. There are a few findings indicating alterations in the mesolimbic dopaminergic systems altering the reward value of food intake. For example, an association between reduced dopamine receptor density and obesity has been found in some (Wang et al. 2001) but not all studies (Ziauddeen and Fletcher 2013). Next to the assumptions of underlying neuronal processes, some researchers emphasize the proximity of high caloric or processed foods and substances, hence favoring the classification of food addiction as a substance use disorder. In fact, one particular macro food group is suspected of triggering addiction-like craving. *Carbohydrate craving* was established as a construct defined by an overwhelming desire to consume carbohydrate foods in order to increase one's negative mood as a form of self-medication (Wurtman 1990). It has been hypothesized that this effect for

carbohydrate foods occurs due to increased serotonin levels and synthesis that result from heightened tryptophan (Wurtman and Wurtman 1995). Currently, however, this hypothesis must be strongly doubted. A recent meta-analysis of the carbohydrate consumption-mood relationship showed no positive effect on any mood measure at any time after their consumption (Mantantzis et al. 2019). Rather, carbohydrate insertion was associated with higher fatigue and less alertness. Others argue that no specific molecule or substance of food groups clearly identifies as addictive and food addiction is thus to be regarded as behavioral addiction. Third, the validity and added value of the food addiction concept over already established eating disorders is questioned (Ziauddeen et al. 2012). Overall, the ongoing debate does not seem to lead to the inclusion of the concept of food addiction in the international classification systems anytime soon (Meule 2019). In regard to commonalities between food addiction and OrNe, there is only one report in Greek undergraduate students revealing no difference between OrNe cases and non-cases in terms of food addiction (Grammatikopoulou et al. 2018). Food groups discussed in regard to food addiction are predominantly of high fat and sugar. Reducing their consumption is commonly recommended (WHO 2000) which makes a ban more likely in the context of orthorexic eating behaviors. Nevertheless, the beliefs and assumptions about which foods are beneficial and detrimental to health are very subjective in OrNe. Not only scientifically based sources of information are used for this purpose, but others as well, such as social media (Bratman and Knight 2000; Håman et al. 2015).

The Link Between Orthorexia Nervosa and Social Media Addiction

Some authors argue that orthorexia is not a disorder with pathological value but a lifestyle phenomenon (Håman et al. 2015). In the context of this debate, it has been suggested that social media contributes to an unhealthy fixation with health. Whereas the influence of problematic internet use on eating disorders, such as bulimia nervosa and anorexia nervosa, as well as food preoccupation, is already known (Padín et al. 2021), there is little evidence regarding the effect on orthorexic tendencies. In terms of social media use, two previous studies linked more frequent Instagram use with greater level of orthorexic eating (Turner and Lefevre 2017; Lanitis and Raspin 2020). An effect is not found or at a much lower level found for other social media channels, such as Facebook, Twitter, Pinterest, Google+, Tumblr, and LinkedIn. Initial considerations regarding causal mechanisms about the general relation between problematic internet use and orthorexic tendencies proposed an effect called "echo-chamber" (Turner and Lefevre 2017). This effect describes the tendency of people to assess their mindset and worldview as more common than it really is. This is assumed to happen due to selective usage habits, i.e., predominantly consuming contents that support one's own assumptions. In this regard, one study employed a thematic analysis to examine individuals' understanding of the possible links between social media use and eating patterns (Lanitis and Raspin 2020). Qualitative analyses indicated "The Importance of Belonging," "Health as Art," and "Craving" as the three main themes suggesting an appeal of healthy eating practices which could generate an overestimation of orthorexic behaviors (Brytek-

Matera et al. 2015). Furthermore, there are considerations about questionable advices cutting out various food groups. These advices can lead to unbalanced nutrition and even promote the development of an eating disorder (Turner and Lefevre 2017). Using social networks in a nonfunctional way, that is, excessively, experiencing lack of control, and with negative consequences, has parallels with other internet-related behavioral addictions and substance-related disorders. Like OrNe, *social media addiction* has not yet been accepted as a separate diagnosis in the clinical classification systems (Andreassen 2015). Taking the lack of diagnostic certainty into account, global estimates report prevalences of problematic social media use ranging from 8.6% to 41.9% (Guedes et al. 2016). Studies highlight predisposing factors including depression, anxiety, attention deficit hyperactivity disorder, parallel substance abuse, social deficits, feelings of loneliness, lower self-esteem, and also increased stress vulnerability (Clayton et al. 2013; Moreau et al. 2015; Wegmann and Brand 2019). This parallels findings in OrNe. Research on the association between OrNe and social media addiction is sparse with, to our knowledge, only one study on this topic. Yılmazel (2021) found that orthorexic tendencies occur more frequently in nurses and doctors with high or very high social media addiction. To date, there are many theories but a lack of empirical evidence for an association between social media addiction and orthorexic tendencies.

Conclusion

Addictions or substance use disorders are commonly understood as self- and health-harming behaviors. Hence, the missing association of OrNe, in which the optimization of health is aimed through dietary behavior, with substance use and abuse is not surprising. On the conceptual level, known commonalities of OrNe with substance abuse consist in the modulation of anxiety and dysphoric mood as motivational background for obsessive healthy eating and addictive behaviors, respectively (American Psychiatric Association 2013; Koven and Abry 2015; Cena et al. 2019). Whereas the nonconsumption of substances leads to physical and psychological withdrawal symptoms (American Psychiatric Association 2013), the intake of "unhealthy" or forbidden foods is followed by in some way similar negative emotions such as guilt in OrNe (Cena et al. 2019). In contrast, there are no specific "substances" or food groups of interest in OrNe; rather, the control over the subjectively healthy diet itself seems to be addictive even if said diet is inappropriate and malnourishing. Usually, no awareness of the impairment due to orthorexic behaviors arises (Bratman and Knight 2000), while individuals affected by substance use disorders acknowledge the desire to stop substance use and suffer from relapses when impairment becomes noticeable (Raftery et al. 2020). Possibly, but currently unexplored, OrNe is also associated with insight, depending on symptom severity. Moreover, different cultural consequences of performing the behavior occur as maintaining a healthy diet is usually socially accepted and reinforced. In contrast, addictions are particularly stigmatized even compared to other mental disorders (Barry et al. 2014).

Open Questions and Future Directions

But there are still many open questions, the answers to which will contribute to a deeper understanding of the onset and development of orthorexic eating behaviors. For example, are factors that initiate the onset of orthorexic eating distinct from factors that maintain the behavior once started to eat only selected foods (Walsh and Devlin 1998)? Furthermore, the neurobiological mechanisms involved are unknown. Weight loss produced alterations in the neuronal reward system enhancing the reward of weight loss and starvation (Kaye 2008; Keating et al. 2012). Similar effects may contribute to OrNe. Since the reward system is further crucially involved in substance use (MacNicol 2017), this may resemble effects by OrNe and substance abuse. Overall, it is difficult to understand similarities between OrNe and addictions without grater knowledge of the complex etiology and pathogenesis that characterize OrNe. This also applies to the behavioral addictions discussed here in the chapter. While some neurobiological mechanisms are suspected to play a role in exercise addiction and food addiction, their contribution is still unclear and controversial (Hausenblas and Downs 2002; Fletcher and Kenny 2018; McComb and Mills 2019). Nevertheless, OrNe appears to be moderately associated with exercise addiction suggesting the possibility of shared or related underlying mechanisms (Strahler et al. 2022). The evidence on food and internet addiction is too limited to allow any conclusion, but negligible associations currently appear likely (Grammatikopoulou et al. 2018; Yılmazel 2021). In terms of substance-related and behavioral addiction, OrNe is similar in the excessive levels of cognitive, behavioral, and emotional preoccupation. However, there are crucial features of addictions, such as tolerance, lacking empirical evidence in orthorexic eating behaviors. Despite many unanswered questions, the compilation of findings in this chapter makes a close link to addictions unlikely. Rather, OrNe's closeness to the eating disorders suggest its classification within this category (Bartel et al. 2020). Practically, a deeper understanding regarding the etiology of OrNe is not only needed to indicate its clinical relevance and justification as a disorder on its own right but is also necessary to identify appropriate therapy methods and strategies. Nowadays, it is therefore recommended that therapy may be based on the guidelines for eating disorders rather than those for addictions.

Application to Other Eating Disorders

In this chapter, we have systematically reviewed current evidence about the link between orthorexia nervosa and addictive behaviors. Orthorexia nervosa is not included in current psychiatric classification systems, but above all, a closeness to eating disorders is considered most likely (Bartel et al. 2020). Hence, this chapter's question was also based on the assumption from the field of eating disorders, according to which the known eating disorders are also related to substance abuse. For the known eating disorders, a relation with, e.g., smoking has been reported as a strategy to control weight and appetite (Devoe et al. 2021). However, the harmful

consequences of such substances would contrast with the motives for pursuing orthorexic eating behaviors. The goal of maintaining and optimizing long-term health instead of weight loss makes an association seem unlikely.

Based on the present literature review, there was no link between OrNe and substance use and abuse. Behavioral addictions, defined as compulsive and excessive non-substance-related behaviors, have only rarely been studied so far. The most likely conclusion to be drawn here is a link with compulsive and excessive exercise behavior and sports. This corresponds to the known comorbidity of additive exercising and eating disorders. Research on other additive behaviors (food addiction, internet addiction) does not permit any conclusions.

One of the most important research questions, beyond this behaviors' pathological relevance, at present is the establishment of ON as an independent disorder category and thus differentiation from established disorders. The few studies that look at anorectic and orthorexic eating behavior in the course of therapy could also offer an auspicious approach in differentiating eating disorder and orthorexic symptomatology. Such studies demonstrate that while there is improvement of anorexic symptoms, orthorexic eating increases throughout therapy (Segura-Garcia et al. 2015; Barthels et al. 2017). This has been interpreted in terms of orthorexic eating to be a compensatory weight regulation strategy in patients with AN. Clinicians should be aware of orthorexic behaviors as compensatory behaviors in individuals with eating disorders and should consider screening for OrNe. In addition, possible links with social media use provide another relevant aspect not only in understanding risk factors but also in establishing prevention and intervention strategies. Overall, pathological eating behaviors are public health concerns that need to be understood in a multidimensional model of risk factors and determinants, i.e., genetic vulnerability, biological needs, cognitive-affective motives, psychosocial demands, and environmental factors.

Mini-Dictionary of Terms

- **Behavioral addictions.** Defined as a compulsion to engage in rewarding, non-substance-related behavior despite negative consequences and with the presence of functional impairment. The most recent version of the International Classification of Diseases (ICD-11) considers gambling disorder and gaming disorder. A number of other behavioral addictions are proposed, including buying-shopping disorder, pornography use disorder, and social networks use disorder.
- **Carbohydrate craving.** An overwhelming desire to eat carbohydrate foods as a self-medication to increase one's mood.
- **Exercise addiction.** Also exercise dependence or pathological exercising. Excessive volumes and feelings of lost control with exercising and sports, exercise is priority in life and is continued despite injuries and impairments in other important areas of life.

- **Obsessive-compulsive symptoms/disorder (OCD).** A group of symptoms characterized by recurrent unwanted thought (= obsessions) and/or repetitive behaviors that a person feels the urge to do repeat over and over (= compulsions). OCD is an anxiety disorder.
- **Orthorexia nervosa.** The obsessive fixation on healthy eating. Self-imposed rigid dietary rules aim at optimizing and maintaining health.
- **Psychotropic substances.** Substances whose intake alters the perception, cognition, emotion, and behavior as well as increases acute physical and psychological well-being of the consumer. Different psychotropic substances lead to specific states of intoxication.
- **Substance use disorder.** A mental disorder in which the maladaptive pattern of substance use leads to clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Key Facts of Orthorexia Nervosa Within the Debate of Categorization as New Mental Disorder

- Orthorexia nervosa is a newly proposed harmful eating behavior where the individual is obsessed with the quality of diet and restricts his/her diet.
- Orthorexia nervosa can lead to severe weight loss, malnutrition, emotional distress, and impairments in daily functioning.
- Orthorexia nervosa shares features with known eating disorders (e.g., need for control, anxiety, perfectionism, overvalued ideas concerning diet) but is also different (e.g., focus on quality vs. quantity of diet, less consumption of legal drugs).
- Addictive exercise is usually linked to an eating disorder. Similar associations are seen for orthorexia nervosa.
- So far, it is unclear whether orthorexia nervosa is an illness adversely affecting a person or how much it differs from known disorders.
- Current therapeutic approaches resemble those used in the treatment of eating disorders.

Summary Points

- Orthorexia nervosa and substance use disorders seem to share phenomenological commonalities leading to maladaptive cycles: modulation of anxiety and dysphoric mood, high time investment, and cognitive and behavioral preoccupation.
- Since orthorexic eating behaviors are aimed at optimizing health, the consumption of psychotropic substances seems unlikely in orthorexia nervosa.
- The systematic literature search found no evidence for an unequivocal link between orthorexic eating behaviors and substance use or abuse to date.

- Orthorexia nervosa has been suspected to be a behavioral addiction, but its placement within the eating disorder spectrum seems more appropriate.
- Orthorexia nervosa is moderately and positively related to exercise addiction.
- There are research gaps regarding the link of orthorexia nervosa with other behavioral addictions such as food and internet addiction.

Abstract

Orthorexia nervosa is a phenomenon defined as a pathological focus on healthy eating. It is assumed that it shares some common features and possibly overlaps with other mental disorders, especially eating disorders and obsessive-compulsive disorder. Research on orthorexia nervosa has been increasing recently. In this section, the definition of orthorexia nervosa, its clinical and sociodemographic characteristics, and its relationship with other mental disorders, especially obsessive-compulsive disorder, are evaluated.

Keywords

Orthorexia nervosa · Obsessive-compulsive disorder · ED · Ritual · Exercise · Healthy eating

Abbreviations

AN	Anorexia nervosa
ARFID	Avoidant-restrictive food intake disorder
BN	Bulimia nervosa
DSM	*Diagnostic and Statistical Manual of Mental Disorders*
EDs	Eating disorders
OCD	Obsessive-compulsive disorder
OCPD	Obsessive-compulsive personality disorder
ON	Orthorexia nervosa

Introduction

The nature of the relationship between diet and health has long been debated. In recent years, awareness of healthy eating has increased markedly and has become one of the primary concerns of developed and developing societies (Brytek-Matera et al. 2017).

Currently, the World Health Organization recommends reducing sugar, fat, and salt intake, eating plenty of fruits and vegetables, and frequently exercising to lead a healthy life (Norum 2005). The craving for healthy food is not a disorder in itself. However, among some people, interest in healthy eating can turn into obsessive symptoms. The concept of orthorexia nervosa (ON) was first defined by Bratman in 1997 to express the pathological focus on consuming healthy foods and was later elaborated in a book written by Bratman (Bratman and Knight 2000). As a word, "Ortho" means "true, real, complete, valid." The word "Orexis" means "hunger, appetite." Bratman coined the term ON to describe pathological fixation associated

with the consumption of appropriate, healthy food. Bratman, in his book *Health Food Junkies*, defines diets as a disease that people do to feel more attentive and clean (Bratman and Knight 2000). ON was first defined as a "maniacal obsession in pursuit of healthy foods" by Donini et al. (2004). This chapter has given credibility to this case and term used to define ON, implying that ON is a concept worthy of scientific research. In the following years, the term ON has spread all over the world, and the number of studies on ON has increased.

Researchers debated whether ON should be incorporated into DSM-5 (*Diagnostic and Statistical Manual of Mental Disorders* Fifth Edition). However, a conjoint expert consensus could not be reached. As a result, it has not been included in the DSM-5 (2013) due to the absence of necessary and vigorous practical data for proper diagnosis. However, some researchers have established some criteria from their clinical experience (Barthels et al. 2015a; Moroze et al. 2015; Setnick 2013).

Symptoms of Orthorexia Nervosa

ON is defined as a pathological obsession with healthy eating and nutrition. It is characterized by a restrictive diet, marked eating patterns, and intense evasion of foods alleged to be unhealthy or impure. ON's focus is on achieving optimum health through strict dietary control (Lucka et al. 2019). Orthorexic individuals who are concerned about the choice of food regarding its purity, origin, whether it contains artificial ingredients or preservatives, etc. become hugely selective about it (Catalina Zamora et al. 2005). They obsessively avoid foods high in artificial colors, genetically modified components, preservatives, flavors, unhealthy salt, fats, or sugar. Since they want their food to be highly pure and free of additives, they can consume many foods raw. The preparation phase, preparation of kitchen utensils and other utensils, is also part of the obsessive ritual (Bartrina 2007). Orthorexic individuals show obsessive thoughts about food while performing tasks such as rituals for stacking and weighing or measuring food products and planning meals (Lucka et al. 2019). Over time, they develop their own unique food rules and eventually fall into a strict diet regimen. Excessive focus on foods and health can lead to the emergence of particularly complex eating patterns that take an unusually long time to execute (e.g., beliefs that one type of food should be taken after a certain amount of time for optimal digestion) (Koven and Abry 2015). This obsession can increase obsessive food-related anxiety, leading to disruptions in social relationships and emotional problems.

The change in daily behavior in orthorexic individuals has been defined in four stages (Mathieu 2005). In the first stage, people have excessive thoughts about their food that day and the following days. In the next stage, excessive control and criticism of food products occur. In the third stage, efforts are made to prepare meals following the principles of healthy eating. In the fourth stage, a feeling of success or failure is experienced according to the outcome of previous stages. In ON,

while the person's primary purpose is to improve health or lose weight, over time, diet becomes the most central part of their life (Catalina Zamora et al. 2005).

When orthorexic individuals feel they are violating a personal food rule by consuming wrong or unhealthy foods, they suffer under morbid thought and psychological torture, punishing themselves with stricter dietary restrictions. Some may think that sticking to a proper diet will help them achieve a sense of perfection by feeling better, pure, or clean (Chaki et al. 2013). This behavior pattern affects a person's quality of life over time and plays a restrictive role. Finally, the controlled diet they apply to change their lives becomes something that controls their whole life (Getz 2009).

Negative Effects of Orthorexia on Health and Functionality

Compulsive obsessions with certain types of food present in ON influence the physiological health of those affected and have significant psychosocial consequences. Orthorexic individuals often spend an excessive amount of time researching their food concerns. They may exhibit behaviors such as long-term research on food and health on the Internet; buying and reading excessive amounts of food, health, and nutrition books; and almost constantly reviewing food labels while shopping at the grocery store (OCD Center of LA 2011). So much so that the quality of the food they consume may become more critical than personal values, interpersonal and social relationships, and career plans (Bağcı Bosi et al. 2007).

Bratman noted that orthorexic individuals tend to maintain their diet based on a theory (e.g., macrobiotic diets or diets created for a particular blood type). When diet becomes more restrictive and complex, it will severely affect the person (Bratman and Knight 2000). The strict diet dependency in ON can lead to the removal of many essential nutrients from the diet and various nutrient and mineral deficiencies that may harm the health of individuals and ultimately reduce their quality of life (Bağcı Bosi et al. 2007). Depending on the individual's beliefs about healthy eating, the resulting diet may follow a vegetarian, gluten-free, or any other diet type (Bratman 2017). Extreme cases of ON may choose to starve rather than eat foods they consider tainted, unsanitary, and unhealthy (Bratman and Knight 2000).

Orthorexic individuals dislike letting go of control when it comes to food. They also follow strict, self-imposed rules that determine which and how the combination of foods can be eaten at certain times of the day (Varga et al. 2013). Such rigid eating habits can make it challenging to participate in social activities that revolve around food, such as dinner parties or dining out. This perspective can influence one's interpretations of others. It may cause different evaluations of people who do not have the same food habits as themselves. Orthorexic individuals do not share the same eating habits as other people and carry certain foods wherever they go. For this reason, social isolation may be inevitable in these individuals over time (Bratman and Knight 2000).

An intense feeling of guilt may occur in orthorexic individuals, sometimes when they think they have failed to maintain their rigid eating habits. Over time, food

choices can become very limited in both variety and calories. These choices may endanger the health of the individual (Costa et al. 2017). Various health problems can be seen after dietary restriction, ranging from nutrient deficiencies to osteopenia, hyponatremia, metabolic acidosis, reduced testosterone levels, and heart rate, as in severe anorexia nervosa (AN) cases (Moroze et al. 2015).

One of the most worrisome situations associated with ON is when children inherit orthorexic tendencies similar to their parents. Children who observe their parents' obsession with certain types of food might imitate this behavior. Sometimes, parents harshly limit their children's sugar intake or feed their children only with organic food. These restrictions may raise fears in children's minds that some foods are "bad and dangerous" and that eating these foods can cause damage to them (Getz 2009). Several case studies reported children with orthorexic parents who developed metabolic problems due to orthorexic feeding behavior (Hunter and Crudo 2018).

Prevalence of Orthorexia Nervosa

In the general population, AN has a lifetime prevalence rate of 0.5–0.9%, and for bulimia nervosa (BN), this rate is approximately 1.5% (Favaro et al. 2003; Hudson et al. 2007). Since ON is still not accepted as a separate psychiatric diagnosis and there are currently no specific widely accepted diagnostic criteria, we do not know its frequency with certainty. Prevalence rates vary widely based on the scales used and the sample. Most of the studies were conducted using the ORTO-15 scale, and prevalence rates in these studies ranged from 6.9% to 75.2% (Donini et al. 2004; Haddad et al. 2019). The prevalence of ON reaches 90.6% in some groups (Turner and Lefevre 2017). Previous studies primarily evaluated the prevalence of ON in high-risk groups. Kinzl et al. (2006) evaluated ON in dietitians using the Bratman orthorexia test and found the level of orthorexic tendency to be 34.9% and showed that 12.8% of the sample had a higher risk of developing ON. Bağcı Bosi et al. (2007) determined a 45.5% ON trend in Turkey in his study with the ORTO-15 scale. In a study with ORTO-15 scale, Aksoydan and Camci (2009) reported ON prevalence rate as 56.4% among performance artists, 81.8% among opera singers, 32.1% among ballet dancers, and 36.4% among symphony orchestra musicians. Fidan et al. (2010) calculated the ON risk rate in medical students as 43.6% with the ORTO-11 scale. Ramacciotti et al. (2011) found the prevalence rate of ON to be 57.6% in the general population with the ORTO-15 scale. This figure, which is much higher than the prevalence of other EDs, might be because of the inability of the ORTO-15 scale to differentiate healthy eating from orthorexic behaviors (Fig. 1) (Table 1).

Later, many scales evaluating ON were developed, and prevalence rates were examined. In studies conducted with the Düsseldorf Orthorexia Scale in a healthy population, consistent results were observed between 2.5% and 6.9% in Germany (Barthels et al. 2015a; Depa et al. 2017; Luck-Sikorski et al. 2019; Rudolph et al.

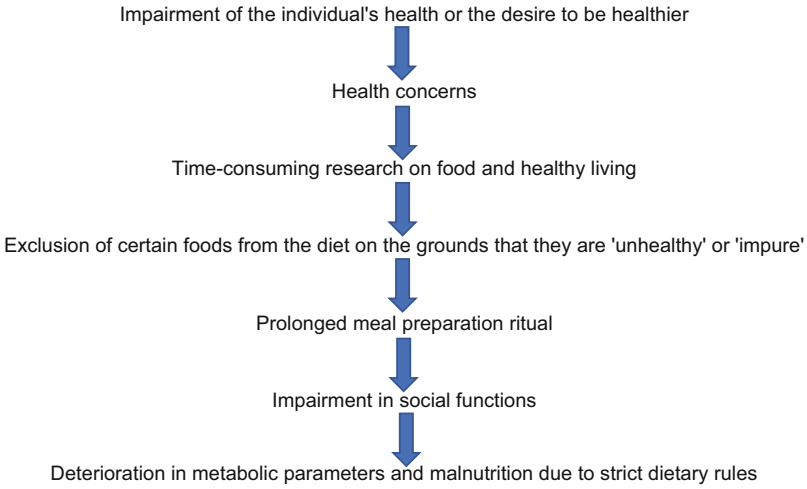

Fig. 1 Pathways to orthorexia

2017; Strahler et al. 2018) and as 8% in the UK (Chard et al. 2019). In another study with the Orthorexia Nervosa Inventory, the prevalence was found to be 4.5% (Oberle et al. 2021).

Orthorexic tendencies might be more common in some specific groups. The literature reports a higher prevalence of ON in specific groups, such as professional artists and ashtanga yoga practitioners (Herranz-Valera et al. 2014). The risk of ON might be higher in physicians, medical students, and dietitians (Herranz-Valera et al. 2014; Segura-Garcia et al. 2012). Besides, regular sports individuals have a higher orthorexic tendency (Bağcı Bosi et al. 2007). In many studies, ON symptomatology was higher among vegetarians and vegans than omnivorous individuals (Brytek-Matera et al. 2019; Brytek-Matera 2021). In addition, there are no consistent results on the relationship between ON and age, sex, level of education, and BMI (body mass index), suggesting the presence of cultural influences on orthorexia (Arusoğlu et al. 2008; Varga et al. 2013).

Diagnostic Criteria of Orthorexia Nervosa

ON does not yet have a widely accepted clinical definition and diagnostic criteria. However, some researchers have suggested possible valid diagnostic criteria for ON (Barthels et al. 2015b; Dunn and Bratman 2016; Moroze et al. 2015; Setnick 2013).

Studies that propose diagnostic criteria for ON include the following standard criteria: (a) obsessive thoughts, preoccupation with healthy eating, and strictly following a restrictive diet (which is believed to be healthy) while strongly evading foods thought to be unhealthy; (b) feelings of high emotional distress accompanying feelings of guilt, shame, and/or anxiety when restrictive dietary guidelines are

violated; (c) physical disorders in which nutritional deficiencies can result in substantial weight loss, malnutrition, and complications of physical health; and (d) psychosocial disorders related to social, occupational, and academic functioning that may result from other diagnoses (Dunn and Bratman 2016; Moroze et al. 2015; Setnick 2013).

According to Dunn and Bratman (2016), diagnostic criteria for ON should be as follows in Tables 2, 3, and 4).

Table 2 Diagnostic criteria for orthorexia nervosa according to Dunn and Bratman (2016)

A. Presence of excessive mental preoccupation with healthy eating, a diet theory, or a set of beliefs whose details may vary individual to individual; overstated emotional distress associated with food choices considered unhealthy; and weight loss, which might occur as a result of dietary choices (this should not be the primary goal):
1. Compulsive behavior and preoccupation with positive and restrictive eating patterns that the individual believes best promote health
2. Violation of the dietary instructions that the individual imposes on himself leads to exaggerated illness fear, a sense of contamination, and negative physical sensations, along with feelings of anxiety and embarrassment
3. Restrictions on nutrition that a person imposes on himself increase over time. Such restriction may involve eliminating all nutrition groups and increasingly frequent "cleanses" (partial fasts) that are considered cleansing/detox. There is no desire to lose weight, but this often leads to weight loss
B. Compulsive behavior and preoccupation is defined as a clinical disorder with one of the following:
1. Malnutrition, severe weight loss, and/or other medical complications resulting from a restrictive diet
2. Disruption of social, academic, or professional functioning due to beliefs and behaviors related to healthy eating
3. Evaluation of positive body image, self-esteem, identity, and/or satisfaction with compliance with self-determined "healthy" eating behavior

Table 3 Common and distinguishing features of orthorexia nervosa and OCD

Orthorexia nervosa	Common features	OCD
Symptoms associated with healthy eating	Intrusive thoughts (e.g., preparing food) and repetitive behaviors	Nonspecific obsessions and compulsions that may be unrelated to food
Egosyntonic intrusive thoughts and repetitive behaviors	Excessive time spent on thoughts and behaviors (e.g., on food selection and preparation)	Obsessions and compulsions that are often perceived as egodystonic
The main motivation is for pure and healthy nutrition	Impairment in social functioning	
	Perfectionism	
	Need to exert control	
	High anxiety levels	

Abbreviation: *OCD, obsessive-compulsive disorder*

Table 4 Common and distinguishing features of orthorexia nervosa and eating disorders

Orthorexia nervosa	Common features	Eating disorders
No fear of weight loss	Excessive worry about food and eating	Fear of gaining weight
Focus on the quality of the food	Life and behaviors are arranged to serve special eating habits	Focus of quantity of food
Clear, rationalized rules about eating	Impairment in social functioning	Secret rules about eating
No disturbances in body image	Malnutrition and weight loss	Disturbances in body image
No gender differences	Egosyntonic intrusive thoughts and repetitive behaviors	Female>male
	Perfectionism	
	Cognitive rigidity	
	High anxiety levels	

Definition of Obsessive-Compulsive Disorder and Its Relationship with Eating Disorders

Obsessive-compulsive disorder (OCD) is characterized by time-consuming, usually chronic, and sometimes episodic course, accompanied by obsessions and compulsions (Rasmussen and Tsuang 1986). OCD is usually comorbid with other psychiatric disorders such as depression, anxiety disorders, EDs, OCPD (obsessive-compulsive personality disorder), and suicidal thoughts (Costa and Hardan-Khalil 2019). OCD is a common psychiatric disorder like phobias, major depressive disorder, and substance use (El-Sayegh et al. 2003). The lifetime prevalence rate of OCD is 2.3%, and a 12-month prevalence is 1.2% (Ruscio et al. 2010). The lifetime prevalence of OCD comorbid with EDs was 13.9%, and the current prevalence rate was 8.7%. In fact, cases diagnosed with ED are at 8.9 times more lifetime risk for OCD than healthy controls (Drakes et al. 2021). The lifetime prevalence of comorbid AN among OCD cases ranges from 3 to 17%, and the current prevalence rate ranges between 0% and 2.4% (du Toit et al. 2001; LaSalle et al. 2004; Pinto et al. 2006). The prevalence of comorbid BN among OCD has not been studied extensively as AN, but lifetime prevalence rates range from 3.1% to 10%, and reported current prevalence rates are between 1% and 3.5% (Altman and Shankman 2009).

Murphy et al. (2004) found that cases with comorbid OCD and EDs have higher cerebral glucose metabolism, preventing them from effectively completing tasks requiring the prefrontal cortex and caudate nucleus work. They reported similar neurophysiological functioning in OCD and orthorexia. Available data suggest that EDs, including ON, and OCD may share some common underlying features (Table 5).

Table 5 The relationship of orthorexia with obsessive-compulsive symptoms and eating attitude in clinical samples

Study				Material		Relationship with ON	
Source	Patient group	Year	Country	Sample size	Tool	OC symptomatology	ED
Poyraz et al.	OCD, panic disorder, and generalized anxiety disorder	2015	Turkey	OCD: 49 PD: 44 GAD: 37	ORTO-11	Checking and dressing/grooming compulsions. There was significant difference between OC symptom severity and orthorexia nervosa. There was no significant difference between patient groups in the mean scores of orthorexia symptom severity	Orthorexic tendencies were found to increase as impaired eating attitudes increased in patient groups
Segura-Garcia et al.	ED	2015	Italy	32 (AN, 18; BN, 14)	ORTO-15	Longitudinal study. OC symptom severity was higher in eating disorder patients than the control group. After 3 years of follow-up, OC symptoms regressed despite an increase in orthorexic tendencies	Eating disorder patients were followed for 3 years, and a significant increase in orthorexic tendencies was found after treatment
Barthels et al.	OCD and ED	2017a	Germany	OCD: 30 ED: 40	DOS	The prevalence of orthorexia in OCD patients was similar to the healthy control group	The prevalence of orthorexia was found to be higher in the patient group with ED compared to the patient group with OCD

Yılmaz et al.	OCD	2020	Turkey	63	ORTO-11	Current order symmetry obsessions. There was no significant difference between OC symptom severity and orthorexia nervosa	Orthorexic tendencies were found to increase as impaired eating attitudes increased in patients with OCD
Vaccari et al.	OCD and anxiety-depressive spectrum disorder	2021	Italy	OCD: 50 Anxiety-depressive spectrum disorder: 42	ORTO-15	There was no significant difference between patient groups in the mean scores of orthorexia symptom severity	It was found to be associated with a restrictive dietary regime
Barthels et al.	Somatoform disorders	2021	Germany	31	DOS	Not evaluated	The patients displayed higher levels of orthorexic eating behavior than the control group

Abbreviation: ON, orthorexia nervosa; OCD, obsessive-compulsive disorder; DOS, Dusseldorf Orthorexia Scale; EDs, eating disorders; AN, anorexia nervosa; BN, bulimia nervosa; GAD, generalized anxiety disorder; PD, panic disorder; OC, obsessive-compulsive

Association of Orthorexia Nervosa with Obsessive-Compulsive Disorder

ON shares some common features with other psychiatric disorders such as OCD, AN, OCPD, illness anxiety disorder, somatic symptom disorder, and psychotic disorders (Koven and Abry 2015). Obsessive-compulsive tendencies are one of the most valuable and reliable features of ON. The previous studies consistently show that as obsessive-compulsive tendencies increase, orthorexic symptoms also increase. This trend is independent of the relationship of obsession and compulsion content with food (Poyraz et al. 2015; Roncero et al. 2017; Segura-Garcia et al. 2015).

Nevertheless, Moroze et al. (2015) suggested that obsession may be the root of ON. They stated that there might be a continuum between obsessive preoccupation with health and the distress caused by obsessive thoughts and beliefs about healthy eating. Koven and Abry (2015) reported that a potential relationship between ON symptoms and OCD might be considered if repetitive and ritualistic behaviors focus primarily on eating. The symptomatology of ON may be present when a person with an obsessive-compulsive tendency tends to ritually check their nutritional knowledge and increasingly has repetitive thoughts about attaining a better diet (Costa and Hardan-Khalil 2019).

ON was defined by the Los Angeles OCD Center (2011) as a hybrid of ED and OCD. Like OCD, ON is characterized by obsessive thoughts (thoughts about certain foods that are dangerously unhealthy) and compulsive behaviors (in this case, avoiding food, doing more research) to minimize the anxiety caused by these obsessive thoughts.

Similar to individuals with OCD, repetitive, intrusive thoughts about food and health, excessive worry, order symmetry, contamination and cleanliness obsessions at inappropriate times, as well as dressing, following ritualized and rule-based patterns, arranging food, washing, and controlling compulsions can be seen (Hayles et al. 2017; Yılmaz et al. 2020). Obsession with food intake is the most prominent behavioral association between ON and OCD (Costa et al. 2017). Also, as in individuals with OCD, the frequency of ON in men and women is similar (McComb and Mills 2019) (Table 6).

Table 6 Some magical thoughts about diet and eating

If we don't clean our body somehow, harmful toxins remain inside
It's good for a person to detoxify their body once in a while
An incorrect diet causes food to rot in the body
The idea that red foods raise hemoglobin is probably valid
Since 70% of our body is water, we should have a diet that is approximately 70% water
Vegetarian food is spoilt if it has been in contact with meat
Animal blood contaminates food

Obsessive-Compulsive Disorder-Related Cognitive Features of Orthorexia Nervosa

Orthorexic individuals have cognitive characteristics similar to individuals diagnosed with AN and OCD. In particular, themes of anxiety, perfectionism, impairment in external observation, and cognitive rigidity are common features of ON, EDs, and OCD. Like patients with OCD, orthorexic individuals devote most of their time to firm rules and overwork, and therefore, a decline in social functions may occur over time. In orthorexic individuals, meal preparation can take much time and may involve ritualistic features such as preparing food to represent compulsive behaviors, whether wood or ceramic materials are used. Similarly, a feature of OCD is the thought that if rituals are not completed, catastrophic consequences will occur in proportion to the perceived threat (Altman and Shankman 2009). This feature can also appear in orthorexic people because they might be uncomfortable when they think they are not following healthy eating instructions adequately. Like patients with OCD, orthorexic cases have restricted time for other activities because adherence to an inflexible eating style affects regular agendas (Dunn and Bratman 2016).

In contrast, patients with OCD exhibit obsessions and compulsions that are not limited to eating or food and generally have egodystonic features (Koven and Abry 2015). DSM-5 (2013) stated that the symptoms should not be better explained by the ritualized eating behavior observed in EDs to diagnose OCD. However, although a relationship was found between orthorexic symptoms and obsessive-compulsive tendencies in many studies among the general population, there was no significant increase in orthorexic symptoms in any of the studies conducted with OCD groups (Poyraz et al. 2015; Vaccari et al. 2021; Yılmaz et al. 2020).

Association of Orthorexia Nervosa with Eating Disorders

Association of Orthorexia Nervosa with Anorexia Nervosa and Bulimia Nervosa

There is some symptomatic overlap between ON and EDs, such as AN and BN. Catalina Zamora et al. (2005) emphasize that in orthorexic individuals, there are obsessive-compulsive mechanisms (rigidity, perfectionism, need to control one's life overeating), phobic mechanisms (intense anxiety about certain foods and avoidance of these foods), and hypochondriac mechanisms with personality traits similar to restrictive anorexia. In both orthorexic and anorectic individuals, lack of pleasure and control over one's life shifts to food when it comes to eating. Eating-related behavior dominates one's life, and one is overly concerned about it. They regulate their behavior and life to serve their particular eating habits. They face weight changes and malnutrition. Both orthorexic and anorectic individuals are achievement-oriented. They interpret sticking to their diet as a sign of self-discipline

and noncompliance as a failure of self-control. Obsessive-compulsive symptoms in ED and orthorexic individuals are egosyntonic and often do not accept functional disorders associated with their disease (Varga et al. 2013). It has been shown in many studies that as the worsening in eating attitude increases, orthorexic symptoms increase (Arusoğlu et al. 2008, Poyraz et al. 2015, Yılmaz et al. 2020).

However, orthorexic individuals focus on food quality, display unrealistic beliefs about food, and exhibit behaviors and desires to maximize health, while anorexic individuals focus on food quantity, and by the time, body image deteriorates and weakens (Brytek-Matera et al. 2015a). However, some authors state that fixation on food quality and type can also be seen in AN because these patients may follow specific strict dietetic instructions (Kummer et al. 2008; Misra et al. 2006). Therefore, adherence to the type of food might not be an essential criterion for ON. In addition, severe weight loss and malnutrition can occur in ON due to selective eating, which may follow a similar course to AN (Brytek-Matera 2012). On the other hand, while AN cases are prone to hide their anorexic behavior, orthorexic individuals are characteristically pleased with their lifestyle and eating choices and often do not hesitate to show it because of their sense of moral superiority (Koven and Abry 2015). In ON, individuals are reported to be motivated by the necessity to accomplish a sense of personal perfection or pureness, in contrast to AN, in which primary motivation is weight loss (Bratman and Knight 2000). However, some studies have suggested that motivation to achieve perfection is also the case for AN (Lilenfeld et al. 2006; Shafran et al. 2002).

Distinguishing Features of Orthorexia Nervosa from Anorexia Nervosa and Bulimia Nervosa

Unlike other EDs, ON is not associated with the desire to be thin. The underlying urge appears to be the desire to follow an excellent, healthy, or untainted diet. For example, organic vegetables and fruits might be considered safe foods for both anorexic and orthorexic individuals because they are viewed as healthy and low-calorie foods. However, frozen diet meals often seem acceptable for anorexic individuals but not for cases with orthorexic tendencies. Conversely, while pressed canola oil is an acceptable food for orthorexic individuals, it is seen as an unacceptable food for anorexic individuals who are afraid of gaining weight when they eat it due to its fat content (Getz 2009). In addition, ON differs from AN concerning BMI and gender variables. According to DSM-5 (2013), AN cases have low body weight. AN is more common in women than men, with a ratio of 9:1. On the contrary, symptoms of ON are not negatively correlated with BMI, and there are no differences in prevalence with regard to gender (Mccomb and Mills 2019).

Some studies indicate that ON and AN should be considered as disorders at various levels in the continuum of the same psychopathological dimension (Segura-Garcia et al. 2015). It has been proposed that ON symptoms are common among ED patients after treatment. These shared symptoms may be defined as the

transformation of ED, an undesirable side effect of psychotherapy, or the intellectualization of symptoms evolving into a socially acceptable behavior (Segura-Garcia et al. 2015). Another problem with the relationship between ON and EDs is that they occur together or in succession over time. ON may occur before the onset of ED or may manifest during remission and recovery.

On the other hand, ED experts in the UK argue that ON is not currently defined as ED because patients initially do not have low self-esteem, but can lead to eating disorders over time as dieting becomes more challenging (Mac Evilly 2001). Eating habits observed during the course of ON can lead to EDs as they become more restrictive and compulsive. One study suggested that ON is a risk factor for developing an ED, and it should be considered an initial stage rather than a separate disorder (Mac Evilly 2001). Other studies indicate that ON may be a comorbid disorder or a coping strategy to deal with an ED (Brytek-Matera et al. 2015b; Barthels et al. 2017b; Segura-Garcia et al. 2015). According to this view, focusing on healthy foods and reducing reliance on calorie intake may paradoxically lead to increased food variety and reduced risk of weight loss. Although patients continue to be meticulous when choosing their food, they begin to eat more calories which may be the first step toward recovery in EDs.

Association of Orthorexia Nervosa with Avoidant-Restrictive Food Intake Disorder

Several studies classified ON as an avoidant-restricted food intake disorder (ARFID) (Moroze et al. 2015, Brytek-Matera et al. 2015b). Both ARFID and ON may be associated with weight loss, malnutrition, and impairment in psychosocial functioning. Some findings common to both ARFID and ON may include increased stress at mealtimes, avoidance or feeling nervous when eating with relatives or friends, inability to maintain relationships due to conflicts about eating habits, and impairments in psychosocial functioning. The ED features in ARFID do not occur during AN or BN, and similar to ON, there is no evidence of body image disturbance or weight anxiety. Like ON, there is no difference in gender prevalence of ARFID, and common comorbidities are anxiety disorders and OCD (APA 2013).

These findings partially support the claim that ON might be a subtype of ARFID. However, clinical definitions of ARFID suggest that this disease develops in infancy or early childhood, usually after a traumatic experience with eating. Besides, ON appears to be more influenced by cultural health models learned in early adulthood. ARFID is characterized by avoidance of certain types of food (based on shapes, colors) and fear of the consequences of eating (Kreipe and Palomaki 2012). However, in ARFID, anxiety associated with eating may be the consequence of a traumatic experience (e.g., drowning) or an aversive experience (e.g., regular vomiting) rather than a result of the focus on improving health seen in ON (Bryant-Waugh and Kreipe 2012). The aforementioned risk factors of ARFID are not comprehensive; therefore, the possibility that the addition of food quality-related

factors or concerns about health loss encountered in ON to future updates of ARFID should not be disregarded.

Association of Orthorexia Nervosa with Other Mental Disorders

Association of Orthorexia Nervosa with Obsessive-Compulsive Personality Disorder

ON shares some features that overlap with other diagnostic categories, including OCPD. OCPD is a personality disorder manifested by fear and behavioral inhibition. It has prominent similarities with ON like perfectionism, rigid thinking, excessive commitment, extreme morality, and preoccupation with details and perceived rules (Koven and Abry 2015). No studies have examined association rates between OCPD and ON to date, but comorbidity between OCPD and OCD and between OCPD and ED has been comprehensively studied. Studies have shown that OCPD symptoms are closely related to EDs, especially AN, and noticeably predict the development of pathological eating habits (Anderluh et al. 2003; Lilenfeld et al. 2008).

Perfectionism, a feature of OCPD, has been accused in the psychopathology of AN and BN (Bardone-Cone et al. 2007). Perfectionism also plays a role in the course of developing and maintaining EDs (Bardone-Cone et al. 2007; Barnes and Caltabiano 2017). The previous studies suggest that cases with ON are also characterized by perfectionism and that perfectionism is a potential risk factor for ON (Koven and Abry 2015; Mathieu 2005; McComb and Mills 2019). The individuals with ON aim to have a perfect diet and to follow strict dietary instructions. Thus, it seems reasonable to think they have perfectionist character traits. Adherence to eating instructions was found to mediate the relationship between perfectionism and EDs (Brown et al. 2012).

Association of Orthorexia Nervosa with Somatoform Disorders

The symptoms of ON may also be similar to the health anxiety seen in somatoform disorders. In somatic symptom disorder, patients experience one or more chronic somatic symptoms which can or cannot be explained by medical evaluations, about which they are disproportionately preoccupied or fearful, leading to recurrent use of conventional and sometimes unconventional healthcare services. In illness anxiety disorder, individuals may experience bodily sensations and are extremely worried about the likelihood of an undiagnosed illness, often spending disproportionate time and energy on health problems. Either way, preoccupation with illness can lead to a secondary preoccupation with food and diet to deal with real or perceived illness. The individual may get into a compensatory dietetic program upon dissatisfaction with the conventional medical institutions or on specific advice from healthcare professionals to manage the disease with diet. Although there are few studies investigating the link between somatoform disorders and ON, it is known that health

anxiety is positively associated with food preoccupation, and there is evidence that health anxiety leads to significant problems in eating patterns (Koven and Abry 2015; Quick et al. 2012). However, longitudinal studies are warranted to further investigate whether health anxiety and somatic symptoms are risk factors for orthorexic eating behavior.

Association of Orthorexia Nervosa with Psychotic Disorders

Although there are no robust empirical data on this subject, ON is likely to indicate more severe psychopathology such as psychotic disorders. It is estimated that comorbidity of schizophrenia and eating disorders is generally low. However, the large number of anecdotal cases reporting the development of AN before the first psychotic episode has led to theories stating that the obsessive features of anorexia have the potential to evolve into more precise delusions over time. These theories also claim that nutritional deficiencies from food restriction might trigger psychosis. As ON is a relatively novel concept, prospective studies are needed to decide to what extent ON increases the likelihood of developing schizophrenia, delusional disorder, and related disorders. However, one of the most distinctive features of ON is control over food, which is considered as an attempt to possibly neutralize the loss of internal control experienced in the prodromal phase of schizophrenia (Møller and Husby 2000). In addition, some researchers thought disordered eating might act as a defense mechanism against psychosis (Hugo and Lacey 1998). At the theoretical level, the most related feature of ON with psychotic spectrum is magical thoughts about food, erroneous beliefs based on instinctive laws of contagion (i.e., real or imagined contact with objects continues to influence each other over time or space) (Aarnio and Lindeman 2004; Lindeman et al. 2000). Regardless of their origins (cultural or religious), magical beliefs about food are a medical concern as they can lead to severe nutritional deficiencies through the exclusion and rejection of food. Koven and Abry (2015) stated that independent of its content, high magical thinking is a commonly seen symptom of schizotypal personality disorder and might be a good indicator for possible psychosis.

Unique Features of Orthorexia Nervosa

While ON has some commonalities with OCD, EDs, and many other mental illnesses, some emergent symptoms are unique and equivocal to ON. Prominent among the specific symptoms of ON is an extreme obsession with regaining health or getting healthier. People with this disorder are unaware or may not accept the idea that this healthy diet may not be as beneficial for their health as they think. Another unique symptom of ON is that orthorexics are not obsessed with being thin or losing weight. Finally, as Bratman (2000) defines, the notion of being more accurate and superior to other individuals is a symptom not associated with other EDs or OCD.

Orthorexia Nervosa and Healthy Living Behaviors

Orthorexia Nervosa and Exercise

In the description of ON, the focus is mostly on eating habits, while other aspects of a healthy lifestyle indicative of ON have not been stated. For example, regular sports activities indisputably play an essential role in maintaining a healthy life, weight management, improving heart function, lowering cholesterol levels, and lowering stress and depression levels. However, its extreme forms may sometimes be associated with EDs (Bratland-Sanda et al. 2010; Ströhle, 2009). Considering that thoughts and behaviors in ON stem from the desire to be in excellent physical health, a commitment to healthy eating may also lead individuals to cover exercise activity as part of a more broad healthy lifestyle. More frequent and moderate physical activity may reveal motivation to pursue a healthy lifestyle. However, it is still possible to consider exercise as a part of the symptom cluster of ON (Kiss-Leizer et al. 2019).

Obsessive thought content of ON may be related to sport activities along with healthy eating (Kiss-Leizer et al. 2019). Indeed, higher levels of sport and physical activity are observed among ON symptomatology, which can also transform into exercise dependence to follow a compulsively rigid exercise regimen even during physical illness, injury, or other problems (Malmborg et al. 2017; Segura-García et al. 2012; Varga et al. 2014). Excessive preoccupation with standards, duties, and instructions and need to follow a firm order contribute to the development of both ON and exercise addiction (Strahler and Stark 2019). Interestingly, however, it was revealed that orthorexic people's motivation to exercise was to manage stress, rejuvenate, and increase positive impact by using exercise as a tool to improve physical health and avoid illness and improve their psychological health (Oberle et al. 2018). However, the association between ON and exercise is very complex and longitudinal studies are needed.

Orthorexia Nervosa and Social Media

Several mental health issues are closely related to Instagram and social media use. For example, higher levels of depression, EDs, and related behaviors are seen in young adults compulsively using social media (Carrotte et al. 2015; Lin et al. 2016). Without any scientific evidence, individuals are encouraged to eliminate several food groups from their diets on social media, potentially leading to an unbalanced diet and nutritional problems. In addition, this condition can aggravate psychological complications related to recommended food and, in some cases, lead to EDs such as AN or ON (Turner and Lefevre 2017).

The researchers note that Instagram use can result in ON as Instagram allows users to follow mostly food accounts based on their selections. Such selective exposure may make users believe healthy eating is more normative than it is and feel the need to conform to eating habits promoted on Instagram (Turner and Lefevre 2017). Instagram

users can use different diets (such as Paleo, vegan diet) to meet their compulsive control needs over original eating habits (Santarossa et al. 2019b).

Research suggests that ED groups create an environment where they connect and support each other through social media. Attitudes and behaviors of individuals with an unhealthy diet can be endorsed and promoted on social networks and eating-related websites. Such attitudes may lead individuals to develop EDs (Borzekowski et al. 2010). Social networking sites provide an almost limitless source for social comparison. Research indicates that especially young and female social media users compare their bodies with the bodies of celebrities and athletes and give them inspiration for a slim and ideal body (Santarossa et al. 2019a; Tiggemann and Zaccardo, 2015). However, studies on the relationship between ON and social media use are still in infancy, and more research is needed in the future.

Smoking and Alcohol Use

The obsession with wellness will likely require avoiding smoking and alcohol and including nutritional supplements and other complementary medicine ingredients into the diet. Studies supporting this hypothesis show that ON symptoms are observed more frequently in people who use nutritional supplements, do not smoke, and drink alcohol (Hyrnik et al. 2016; Varga et al. 2014). However, several other studies did not find any relationship between smoking and orthorexic symptoms (Aksoydan and Camci 2009; Fidan et al. 2010). In conclusion, studies to date did not report conclusive findings of a relationship between smoking and alcohol and ON.

Vegetarian Diet

The majority of studies show that vegetarians have more orthorexic behavior than those following an omnivorous regime (Brytek-Matera 2021; Brytek-Matera et al. 2019). Elimination of large micro- and macronutrients from a vegetarian diet may cause an increased risk of developing orthorexic behavior (Bratman and Knight 2000). A vegetarian diet is also another acceptable way to cover up disordered eating behaviors in public (Barnett et al. 2016). However, we should conduct more longitudinal studies to find out the role of a vegetarian diet in the development of ON.

Is Orthorexia Nervosa a Separate Mental Disorder?

Many people, especially in developed countries, have increased awareness of healthy nutrition, which becomes their primary focus. The increasing incidence of obesity has led to a significant increase in cardiovascular diseases, diabetes, hypertension, osteoarthritis, cancer, and many other health problems, mainly due to a

sedentary lifestyle. Therefore, concerned people start to be selective about the quality, quantity, and type of food they consume as a key to stay fit and healthy. But there is a subtle difference between being selective about food consumed and developing an obsession with a diet to be healthier. The development of such obsessions about the amount or type of food often leads to abnormal eating patterns and, in some cases, to psychological EDs (Chaki et al. 2013).

Orthorexic tendencies can be mentioned when a person restricts himself to a specific diet regimen with an obsessive urge to eat healthy (Getz 2009). In general, ON may come to mind when this condition is long-lasting, and this behavior has serious adverse effects on the person's quality of life (Bratman and Knight 2000).

With the growing media attention to ON, researchers have investigated the validity of ON as a unique disorder. Many have chosen to define ON as a variant of anxiety disorders or EDs (Mathieu 2005). Nevertheless, Bratman has proposed ON to be categorized as a specific ED. Bratman stated that ON and current EDs share many common features, but ON also has several important differences from other EDs (Bratman and Knight 2000).

The diagnostic classification of ON is currently unknown. However, Robins and Guze's (1970) seminal article suggests several steps for a mental disorder to reach diagnostic validity. The first step is the clinical definition currently available for ON. The second step is laboratory studies in which chemical, physiological, anatomical, and radiological findings are included, and psychological tests can be evaluated in this context. There is no generally accepted psychometric scale for ON and more research is needed on this topic. In addition, the neurobiological and neurophysiological basis of orthorexic eating has not been searched thoroughly, and like many other mental disorders, there is no specific laboratory test for diagnosing ON. The third step is differential diagnosis to prove the distinctiveness of a newly proposed diagnostic category and exclusion of other disorders. There has been an overlap between ON, EDs, and OCD in previous studies (Mccomb and Mills 2019). However, mental disorders could often exist together (Kessler 1994). Therefore, the simultaneous comorbidity of different disorders does not eliminate their distinctiveness. Thus to exclude other disorders, the person's distress should be proved to be caused by ON, not another mental disorder. The fourth and fifth steps, respectively, include follow-up and family studies, none of which were performed for ON. In summary, caution is advised when extending the diagnosis to ON based on the available evidence.

Discussions continue in the literature to decide whether ON, for which there are no formal diagnostic criteria yet, should be considered a separate disorder, a variant of another ED, an OCD-related disorder, or just an impaired eating habit (Brytek-Matera 2012; Ryman et al. 2019).

Treatment and Management

Although there are some recommendations for ON treatment, no studies have been conducted to date on treatment efficacy, other than case studies. The question regarding the classification of ON (a separate syndrome or a manifestation of another

disorder group) remains unresolved. However, the best intervention requires a multidisciplinary team approach that should include physicians, psychotherapists, and dietitians (Bartrina 2007; Koven and Abry 2015). A combination of drug therapy, psychoeducation, and cognitive-behavioral therapy could be implemented in outpatient settings with close monitoring (Mathieu 2005). In cases of significant malnutrition and weight loss, inpatient treatment may be required (Moroze et al. 2015).

During treatment, the individual is encouraged to eat a healthy diet. Orthorexic individuals may believe that giving up orthorexic eating behavior is the same as eating a bad diet. The goal is not to help the individual learn that all foods are healthy. Indeed, there are also foods that can harm health, especially if eaten in excess. The main purpose is to help the individual have a more balanced perspective toward food and learn to eat healthily and with pleasure. In other words, the goal is not to teach the individual to consume potato chips or sodas but to enable them to eat by choice rather than fear.

Regarding psychotropic drugs, selective serotonin reuptake inhibitors are reported to be beneficial for ON (Mathieu 2005), which also show some efficacy for both AN and OCD (Simpson et al. 2013). In one study, olanzapine was successfully used to reduce the obsessive nature of thoughts about magic food, and mirtazapine was successfully used in another case study followed up with a diagnosis of ON with comorbid depression (Moroze et al. 2015; Lopes et al. 2020). However, it should be noted that patients with ON may reject psychotropic drugs as they may be viewed as unnatural substances.

In psychotherapy, individualized interventions should be used by targeting the symptoms that are evident to the patient. Goals should focus on what patients eat, how they shop, and how they feel about the food they prepare and consume. Exposure and response prevention, together with habit reversal training, may be the most successful approach for treating the obsessive and compulsive aspects of ON (Koven and Abry 2015). Apart from that, providing psychoeducation about valid, current dietary science can help discourage orthorexic individuals from false beliefs about food.

According to LA OCD Center (2012), some parts of exposure and response prevention, which is the primary behavioral component of ON therapy, may be as follows:

- Gradually adding more types of food to the individual's diet, comprising healthy foods that she formerly deemed improper
- Reducing and eventually eliminating time spent investigating food
- Reducing and eventually eliminating the time spent arguing the health impact of food
- Return to everyday social life, including eating with others

Attention should be paid to refeeding syndrome, which is caused by disturbances in fluid and electrolyte balance. This syndrome occurs when nutrition is quickly reinstated after the body has adapted to hunger and malnutrition in patients who were

treated as inpatients due to significant weight loss and malnutrition. Refeeding syndrome can progress with sudden cardiac death and seizures and can be fatal. Other symptoms in this syndrome are hypertension, dyspnea, fatigue, weakness, confusion, and arrhythmias. Symptoms typically appear within 4 days of resumption of food intake. The first clinical manifestation of refeeding syndrome is low phosphate level (refeeding hypophosphatemia). Clinicians should be familiar with the signs and symptoms of fatal refeeding syndrome (Zickgraf 2020).

Conclusion

ON is an important and growing problem that needs serious consideration. While ON is not yet officially recognized as a disorder, failure to properly identify and treat the condition will cause serious problems for many people who suffer from these symptoms. However, making the patient aware of the extreme and distorted nature of their thoughts and behaviors regarding food purity may respond well to treatment with cognitive behavioral therapy.

Applications to Other Eating Disorders

In this section, ON symptoms are defined, and the relationship of ON with OCD and other mental disorders is discussed. ON is a unique phenomenon with distinct features. The obsessive-compulsive mechanisms underlying ON are interesting. Obsessive-compulsive mechanisms have been shown in other EDs, especially in AN and BN. However, it is interesting how critical obsessive mechanisms are under ARFID, which draws attention with some similar aspects to ON. It has been reported that ON can be seen together with other EDs. It is intriguing what the initiating factor is, which mechanisms sustain the process, what are the treatment options in comorbid conditions, or whether ON is a step in the recovery process. Although research on ON has increased, studies on the neurobiological aspects of ON are limited. In the future, revealing the neurobiological basis of ON and showing whether it is associated with OCD and EDs may help to illuminate the place of ON in classification systems. Conducting family and genetic studies related to ON may contribute to elucidating its relationship with other EDs. The prevalence of ON was evaluated in different populations with diverse rating scales and showed inconsistent results. ON prevalence rates seem inconsistent when considering other EDs with more balanced prevalence rates. When standardized assessment tools are developed for ON, prevalence rates of ON can be determined consistently, and the prevalence rates can be compared with other EDs. Consequently, more research conducted with a similar methodology on ON will define the diversity and changes in different cultures and populations.

Key Facts of Orthorexia Nervosa with Obsessive-Compulsive Symptoms

- Orthorexia nervosa is not currently included in the DSM-5. However, research continues to determine its place in diagnosis and classification systems.
- The main goal of orthorexia nervosa is to reach optimum health with a healthy and pure diet.
- Obsessive-compulsive symptoms are present in many eating disorders, including ON.
- It was found that as the severity of obsessive-compulsive symptoms increased, orthorexic symptoms also increased.
- The most prominent behavioral association between orthorexia nervosa and OCD is obsessions about food intake.

Summary Points

- Orthorexia nervosa is associated with impairment in social, occupational, and academic functioning and physical ailments due to nutrient deficiencies.
- Orthorexia nervosa shares some behavioral and cognitive features with OCD and EDs.
- Some important common features of orthorexia nervosa and OCD are perfectionism, impaired external observation, high anxiety levels, and deterioration in social functions.
- Some overlapping points of orthorexia nervosa with eating disorders are lack of enjoyment of eating, shifting control over life to food, weight changes, and facing malnutrition.
- The distinguishing features of orthorexia nervosa are that the main motivation for eating is a sense of perfection and purity, and they see themselves as superior to other people.

evaluative parameter of emotional regulation indicates that the decrease of the vagal tone in the HRV is positively related to deficient self-regulation that might be associated with dysfunctional styles such as emotional eating. The explanatory emotional eating theory sustains this physiological mechanism by suggesting the sympathetic nervous system's activation and the existence of physiological incompatibilities between the action of eating and the presence of negative emotions which, instead of inhibiting the intake, boosts it. Nevertheless, evidence on the relation between the HRV and emotional eating demonstrates a predominance of the vagal response against the lower food stimulus under stress conditions.

Keywords

Emotional eating · Heart rate variability · Cardiac autonomic imbalance

Introduction

Emotional eating is characterized by an excessive food intake in states of emotional excitement or stress (Evers et al. 2010; Ouwens et al. 2003; Torres and Nowson 2007). This eating style is conceived as a maladaptive generalized behavior that operates as a momentary response to the regulation of emotions; however, it usually leads to different health problems such as weight gain, obesity, and behavioral eating disorders (Frayn and Knäuper 2018; van Strien et al. 2013). From a physiological point of view, emotional eating has been described as a surprising behavior considering that negative emotions are expected to induce states similar to satiety since they activate the autonomic nervous system (ANS) and appetite-suppressing hormone release. This is the proposal of Kaplan and Kaplan's psychosomatic hypothesis (1957) which poses that a normal response toward emotional excitement or stress is loss of appetite. Schachter (1968) sustained the same when explaining that negative emotions induce an increase in appetite-suppressing hormones such as catecholamine. Notwithstanding, some people tend to overeat when facing stress conditions or discomfort (Ouwens et al. 2003), contrary to the signals of the organism. Among the explanatory hypotheses of this phenomenon, there are proposals of psychological nature that suggest that food intake induced by uncomfortable emotions derives from a confusion between internal excitement states and hunger, probably due to neglected signals from the organism in early learning experiences during early childhood (Bruch 1964). In this same line, van Strien (2000) claims that among the predictors of emotional eating would be the lack of interoceptive awareness or complications in the identification and recognition of the internal signals of the organism, in this case, hunger or satiety and being able to overeat in front of a certain state of excitement. Another proposal comes from Heatherton and Baumeister (1991), who states the escape theory in which food and eating would be the mechanisms used to escape or divert attention during a negative self-evaluation redirecting it toward more pleasurable stimuli or experiences as the ones that come

from eating. Besides, a different approach to emotional eating has been described as an inhibited behavior that occurs under dietary restrictions. Polivy and Herman say that dietary restriction sustained over time is translated as exaggerated responsiveness toward external cues such as food characteristics and limited responsiveness toward the external signals of the organism. That is, when intake is permanently under cognitive control (rather than physiological) and is restricted, the sensitivity to the internal cues of hunger and satiety is reduced, resulting in disinhibition and overeating in situations where cognitive control is hampered (Herman and Polivy 1980). Emotional activation, such as stress or negative mood states, would act as inhibitors or disruptors of the restriction. This disinhibition not only occurs when facing dysphoric emotions but also as a response to sensory cues from palatable foods and alcohol consumption or in situations where self-regulatory abilities are reduced with high-stress moments, for instance (Ouwens et al. 2003).

There are parameters of physiological nature that function as emotional dysregulation predictors when anticipating maladaptive eating behavior. In this sense, heart rate variability (HRV) is positioned as one of the noninvasive and highly useful measures in clinical research, which allows the analysis of the changes that occur in the balance of the ANS, which facilitates information about certain abnormal physiological conditions (Task Force of the European Society of Cardiology and the North American Society of Pacing and Electrophysiology 1996). HRV assessment has been conceived as the beat-to-beat rate variation within the heart rate, measured through the R-R intervals of the electrocardiogram over 24 h (Billman et al. 2015). Two indicators of the frequency domain emerge from this analysis: high-frequency power (HF) as an indicator of vagal activity and low-frequency power (LF) as a marker of sympathetic activity. However, LF has gained controversial appreciation since it has also been considered a parameter that includes sympathetic and vagal influence (Task Force of the European Society of Cardiology and the North American Society of Pacing and Electrophysiology 1996; Reyes del Paso et al. 2013). In general terms, sympathetic activation has been associated with an increase in the LF and a decrease in HRV (Reyes del Paso et al. 2013). This reduction in HRV has been reported in several abnormalities in stress-related emotional regulation (Rodas et al. 2008). According to this, the presence of a link between eating behavior disorders and the presence of cardiac dysautonomia has been proposed (Jelinek et al. 2018; Mazurak et al. 2011), with a connection between this biological maladjustment and the emotional disturbance that leads to food intake. Thus, the diagnostic capacity of HRV allows us to understand the emotional dysregulations of behaviors concerning the decreased ability to regulate cardiac function, which leads to emotional eating (Moore 2018).

Emotional Eating and Body Mass Index (BMI)

A relationship between BMI, depression, and emotional eating has been found and is the last one that acts as a mediator which, at the same time, is related to future body weight gain. Likewise, people with dietary difficulties normally present a higher BMI and are more likely to acquire emotional eating disorders (Lazarevich et al.

2016). In this regard, the dysregulation of emotions exerts an indirect effect on BMI through emotional eating. Therefore, higher levels of emotional dysregulation might be associated with higher levels of emotional eating, which is also associated with higher levels of BMI (Jones et al. 2019). These results are consistent with different studies that suggest that emotional eating is tightly related to emotional dysregulation (Gianini et al. 2013) and weight gain (Grant and Boersma 2005; Koenders and van Strien 2011; Sung et al. 2009; van Strien and Koenders, 2012, 2016). Even though obese people usually present higher rates of emotional eating, this dysfunctional eating style is not exclusive to people with obesity since it is also present in normal-weight population (Palomino Pérez 2020). Other relationships have been established between emotional eating in people who are overweight and a series of negative emotional states such as depression, stress, anxiety, attention deficit, and dysfunctional regulation of emotions. In addition to this, symptomatology in certain eating disorders, body acceptance difficulties, eating self-regulation, and eating self-efficacy in the presence of obesity can be named (Nightingale and Cassin 2019). This indicates a higher susceptibility in people with obesity toward uncontrolled emotional eating provoked by a subjective perception of stress (Wilson et al. 2015). In the analysis of the physiological responses to stress, higher levels of impulsivity, cognitive restraint, uncontrolled emotional eating, and a higher reduction in the HRV have been reported as a response to food stimuli in patients with obesity. The urge for food in the absence of caloric need is thus construed as a vagal disbalance and lack of inhibitory control. These difficulties lead to the perpetuation of unhealthy eating behaviors associated with low HRV in response to stimuli relevant to subjects with psychopathological disorders and obesity (Spitoni et al. 2017) (Fig. 1).

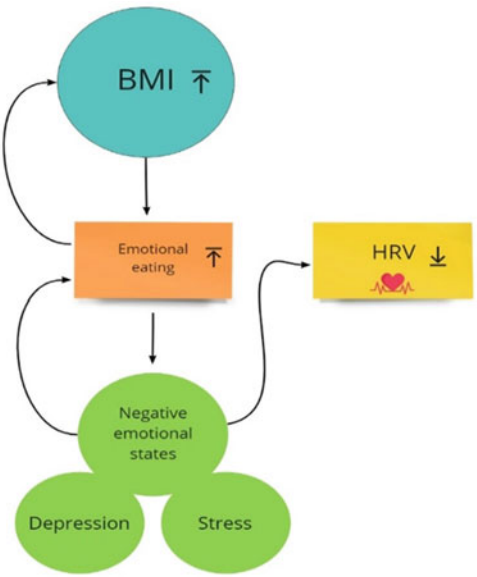

Fig. 1 HRV in the relationship between BMI and emotional eating

Emotional Eating and Food Image Stimuli

Visual food stimuli produce brain responses in the limbic centers (Ziv et al. 2020) as well as the activation of SNS under abnormal dietary conditions inducing emotional states in the subject, some of which should inhibit the eating response. By comparing a group of healthy women to others with bulimia nervosa, high caloric food craving in the clinical sample was bigger under the induction of negative emotions. Therefore, a negative mood was associated with higher brain activity in reward-related brain areas when anticipating food intake. In this way, bulimia nervosa is linked to eating in response to negative emotions during the induction of negative emotional stimuli (Lutz et al. 2021). In the analysis of biological and psycho-affective correlates of food image processing in emotional eating and as a response to the induction of negative images, an increased desire for food occurs in individuals with high levels of intake compared to individuals with low levels of intake. Additionally, the image of appetizing food influences the improvement of the emotional state, reducing negative affect (Blechert et al. 2014). It indicates that craving for food increases due to stress, which is contradictory considering that the sympathetic nervous system (SNS) is a suppressor of the digestive response regarding food intake. On the other hand, when relating BMI with food cue responses and HRV, a significant increase in food reactivity of HRV with a sympathetic predominance regarding highly caloric content in subjects with high BMI compared to subjects with low BMI. It proposes that subjects with high BMI have weaker cognitive restraint to food stimuli with high caloric content being more susceptible to food intake in response to appetizing characteristics of food, which is also common in emotionally induced feeding. It may indicate that people who are overweight are more vulnerable to identifying hunger cues and experience dysregulations in eating behaviors; this is verified through HRV (Chang et al. 2021) (Fig. 2).

Emotional Eating and Food Craving

Food craving is understood as an intense desire for one specific food (Meule 2018). Several studies report a relationship between highly palatable food cravings, external eating, and emotional eating behaviors (Blau et al. 2018). Different studies have established associations between emotional eating and food craving in individuals at risk of eating disorders, specifically in subjects with binge eating disorders and anorexia nervosa. Also, food craving can be linked to external eating behaviors in people with symptoms of anorexia nervosa, bulimia nervosa, and binge eating (El Archi et al. 2020). Hence, what eating styles such as food craving, emotional eating, external eating, and have in common is the pursuit of emotional rewards instead of responding to biological needs. Thus, an increment in emotional eating might boost a significant increase in the frequency of food cravings (Shnepper 2020). On the other hand, it is coherent with biological cues that food intake gets properly motivated by interoceptive cues of hunger or satiety since it does not depend on inaccurate mechanisms influenced by mood to be triggered. Concerning

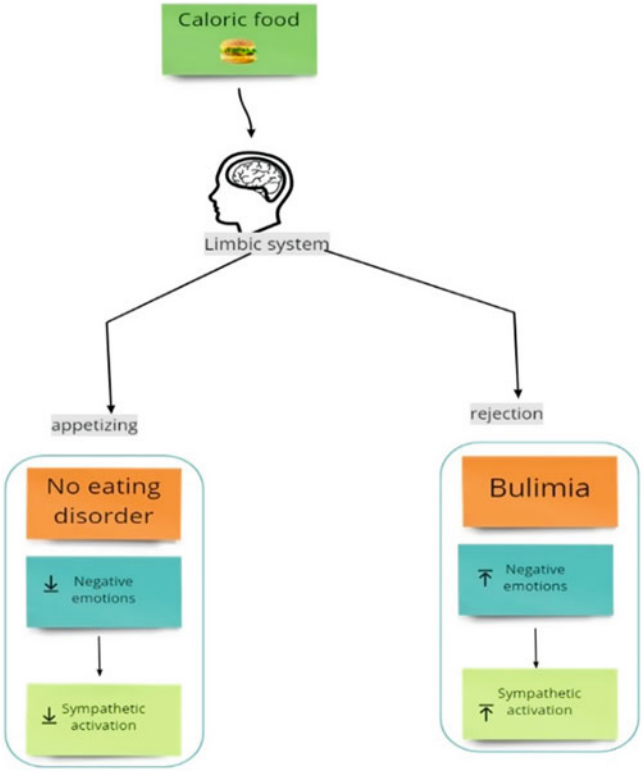

Fig. 2 Relationship between food stimuli and eating behavior. Autonomic response

HF values of HRV in the analysis of maladaptive style, Wu et al. (2020) discovered significant relationships between loss of control in eating and food craving. In this respect, an increased food craving is associated with a lower HF-HRV. This phenomenon responds to the influence that stress exerts on SNS activation over the parasympathetic nervous system (PSNS) in which the individual becomes motivated by the intake instead of suppressing the desire for food. Moreover, food craving has also been found to be associated with this HRV pattern through the lack of control over food intake. In palatable food like chocolate, a lower HRV has been found which precedes increased craving. It means that, due to a lower HRV, deficient automatic regulation plays an important role, relevant in food craving and uncontrolled eating behaviors (Rodríguez-Ruiz et al. 2009) (Fig. 3).

Emotional Eating and Loss of Control Eating

Loss of control eating is often a feature in individuals with binge eating episodes. These individuals are characterized by two different components: (a) eating an unusually large amount of food, known as overeating, and (b) feeling unable to

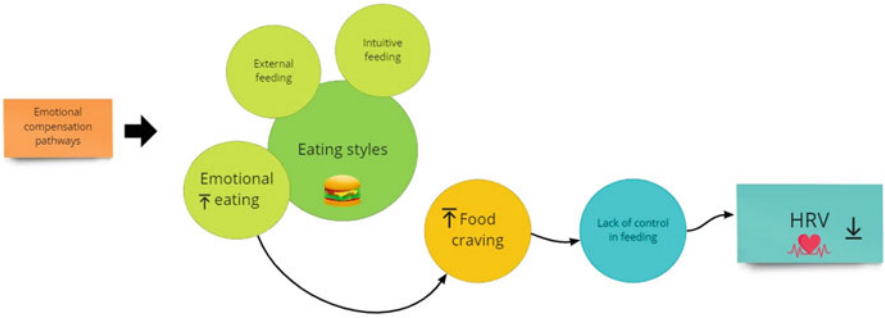

Fig. 3 Relationship between eating styles and food craving. Autonomic response

stop or resist eating, which is called "loss of control eating" (LOC) (American Psychiatric Association 2013; Vannucci et al. 2013). Emotional eating has been linked to LOC eating when predicting binge eating behavior. Also, emotional eating is usually associated with higher levels of depression, anxiety, and stress (Conceição et al. 2018). Such emotional alterations underlying food intake are commonly driven by the lack of control in eating to avoid negative emotions. In this sense, it has been identified that emotional eating is moderated by LOC eating in association with a significant increase in disordered eating patterns, BMI, and long-term adiposity (Stojek et al. 2017). Responding to stress, HRV informs how emotional regulation behaves concerning LOC eating which may lead to binge eating episodes. In this way, overeating has been associated with a lack of emotional balance and LOC as well as the nonacceptance of emotions. The high severity of these conditions is related to poor flexibility in the ANS with increased LF-HRV and decreased HF-HRV (Godfrey et al. 2019). Young et al. (2017) analyzed LOC eating as the mediator between negative emotional states and HRV. A depressed mood was connected to a lower HF-HRV rate with higher levels of disinhibited eating. For entropy effects, findings were similar to HF-HRV, connecting a reduction of it to emotional states and disinhibited eating. It is important to highlight that minor entropy indicates a minor regulatory capacity of the organism which will affect self-regulation and the control of emotions that leads to eating. It evidences HRV capacity as a stress biomarker in the identification of dysfunctional patterns of emotional regulation and food intake. Lastly, Ranzenhofer et al. (2016) determined that a critical low HRV during the 30 min before emotional eating is associated with eating and LOC (Fig. 4).

Emotional Eating and Hunger Inhibitory Control

Lack of inhibitory control impacts the suppression of food cues which causes an inability of individuals to recognize hunger cues and becomes influenced by emotions to execute food intake. The latter can be expressed by an impulsive behavior as a hasty response toward the stimuli or the lack of competence to amend inadequate

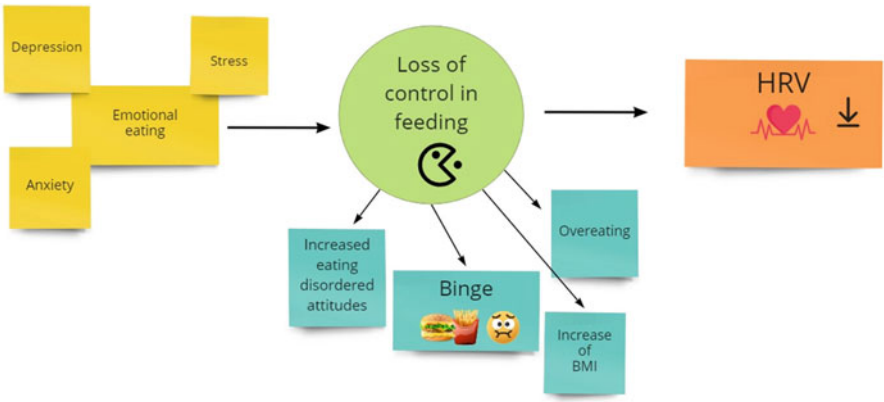

Fig. 4 Relationship between loss of control in feeding and emotional eating. Autonomic response

behaviors (response inhibition). So, this pattern has been associated with obesity and low self-control during food intake (Spitoni et al. 2017). More specifically, a higher negative affect predicts an inability to suppress desirable food cues, implying disinhibition in eating or loss of control associated, at the same time, with a higher level of emotional eating (Zhang et al. 2020). On another side, van Strien et al. (2014) found that inhibitory control moderates emotional eating over food intake. This pattern perpetuates in people who did not experience the typical hunger-reduction response after a stress episode. In this regard, inhibitory control has been related to emotional eating (Nelson et al. 2020). Different findings support these assumptions stipulating that emotional eating is connected to major behavioral inhibitory control difficulties, while negative emotions are being suppressed. Aligned to this, it is concluded that inhibiting behavioral responses during the regulation of negative emotions would contribute to a disinhibited intake (Wolz et al. 2021). Rodríguez-Ruiz et al. (2011) examined the loss of inhibitory control through food stimulation to evaluate physiological reactivity in HRV. The results confirmed a lower HF leading to a higher defensive and appetitive reflex toward food stimuli assessed as threatening (high-calorie foods) for women with bulimia nervosa. In this sense, HRV appears to modulate these reactions, which include appetite, food aversive reflex, and loss of control over eating, and supports the assumption that poor emotional and autonomic regulation plays a significant role in lack of inhibitory control (Fig. 5).

Neural Basis of Emotional Eating

Emotional eating is related to the hedonic dimension of eating behavior which has its structural and functional basis in the appetite reward systems located in the cerebral cortex and subcortex. From this neural mechanism, the search for gratification follows through food in order to relieve emotional discomfort, which is associated

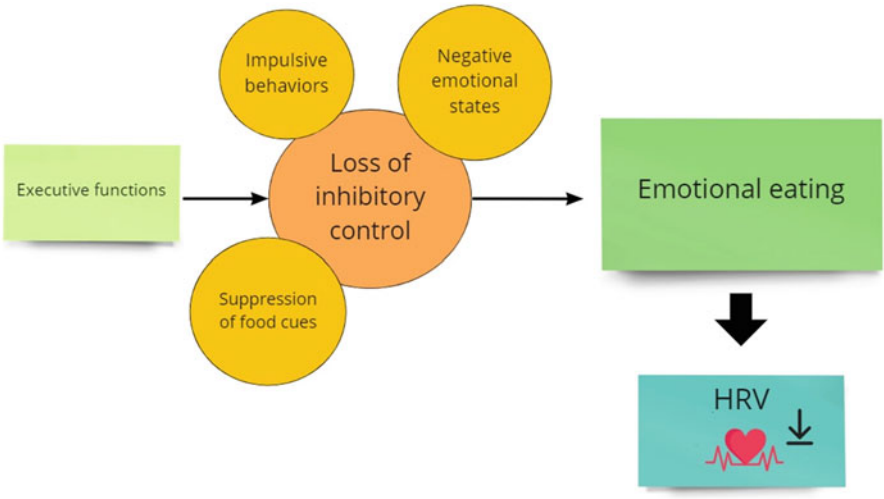

Fig. 5 Relationship between loss of inhibitory control and emotional eating. Autonomic response

with a deficit in the capacity for self-control (Suárez Palazón and Mayoral Babiano 2019). Considering this, the findings suggest that it is a tendency in people with emotional eating behaviors to have higher neural activation in response to rewards in front of food stimuli and rewards reinforcing food intake (Bohon et al. 2009). This is evident during the experience of negative emotions and during the anticipation of rewards, where activation of the right frontal lobe has been found, which could reflect the learned resource of food craving as an emotional regulator (Bletcher et al. 2014). During highly appetizing food choices, the visual system is the principal role-player, which reacts to food stimuli so the received information can travel through afferent pathways vias and activates structures such as bilateral posterior fusiform gyrus (FG), left orbitofrontal cortex (OFC), and the left mid-insula (van der Laan et al. 2011). Besides, different activation patterns have been discovered specifically in the anterior cingulate cortex (ACC), globus pallidus (GP), thalamus (Bohon et al. 2009), medial OFC, insular cortex (Killgore and Yurgelun-Todd 2006), dorsolateral prefrontal cortex (DL-PFC), and bilateral prefrontal cortex (Wood et al. 2016). Specifically, the activation of the insular cortex has been directly linked to information processing related to food's taste and its hedonic assessment, and, at the same time, it is involved in impulse control deficit in response to food incentives (Kenny 2011; Wood et al. 2016). Also related to self-control, the activation of subcortical structures such as the tonsil and basal ganglia occurs (Chechlacz et al. 2009; van Bloemendaal et al. 2015). In emotional eating condition there is styles, higher functional connectivity between the OFC - lateral hypothalamus (LH), ventral striatum, anterior insula, and medial temporal lobe networks - medial hypothalamus (MH), LH networks - nucleus accumbens, and the LH of the mesencephalon or midbrain has been detected, with the latter being also associated with the stress response. Moreover, a higher connection in the LF of the mesencephalon has been

related to a greater presence of an emotional eating style. Thus, the relationship between functional connectivity alterations in both networks, LH and MH, in eating patterns induced by emotions, particularly LH network alterations, has also been associated with higher levels of response toward stress (Martín Pérez et al. 2019). To summarize, evidence demonstrates a tendency to increase neural reactivity under induced stress conditions in the presence of food cues, which, at the same time, appears to be the basis of different background information related to binge eating as clinical symptomology (Fischer et al. 2017) (Fig. 6).

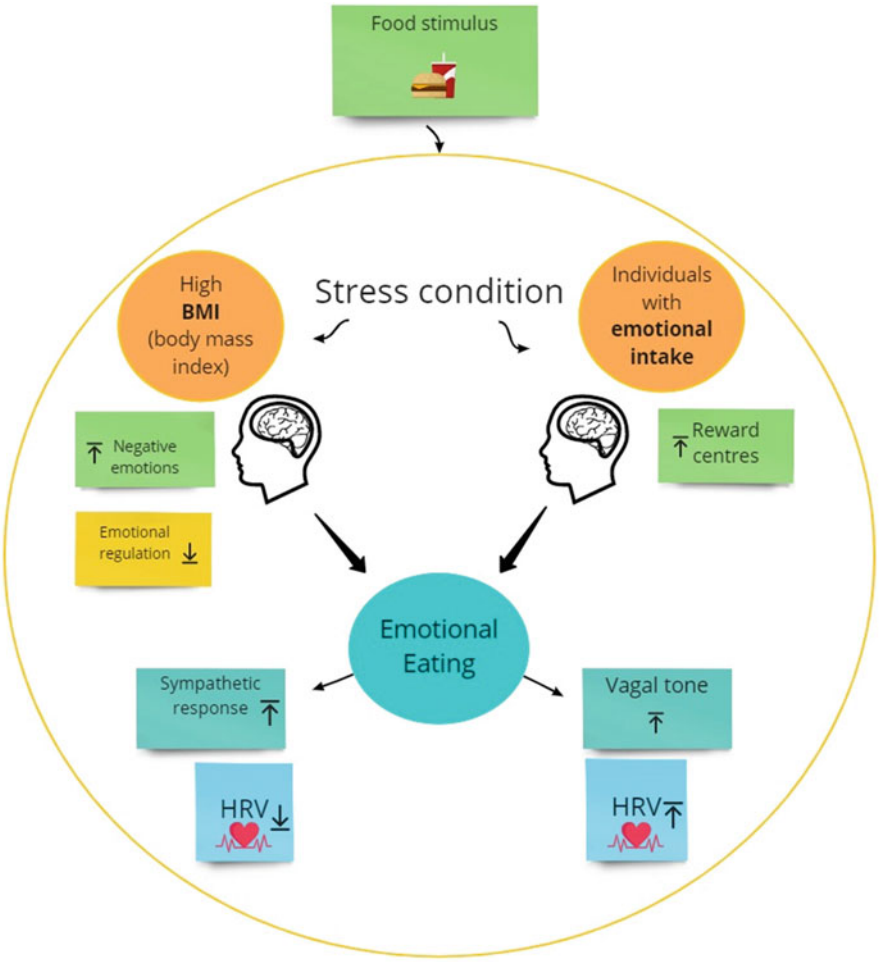

Fig. 6 Relationship between emotional eating with and without BMI mediation. Autonomic response under stress condition

Emotional Eating and HRV

In the theoretical approach to emotional eating, Kaplan and Kaplan's (1957) psychosomatic approach is positioned as one of the main explanatory theories. From this point of view, it can be established the existence of a tendency to handle negative emotions through eating concerning people who are overweight. In this regard, reference is made to SNS activation (Kaplan and Kaplan 1957), which is associated with a reduction in vagal tone, being the physiological process that would explain an adaptive difficulty of the organism when dealing with stress and that would be related to this dysfunctional eating style (Thayer and Lane 2000). Consistent with this approach, the neurovisceral integration model poses that HRV is an indicator of the self-regulation capacity in the organism in response to external demands meaning that the vagal tone reduction in HRV is connected to a deficient emotional regulation, which might be associated with dysfunctional behaviors such as emotional eating (Thayer and Lane 2000). Nonetheless, considering current findings when HRV is analyzed in people with emotional eating disorder, their physiological response is associated with an activation of the PSNS instead of the SNS. This is demonstrated through the HF band predominance in the HRV (González Velázquez et al. 2020). On another hand, Juarascio et al. (2020) found similar results in relation to changes associated with HRV in response to emotional eating episodes. In this respect, HF bands were predominating in previous moments of emotional eating episodes, suggesting vagal predominance and emerging as a principal and mainly predictive characteristic (Juarascio et al. 2020). This paradoxical response toward a stressful factor could be interpreted as a coping strategy and inadequate compensation associated with positive emotional responses in food intake (González Velázquez et al. 2020). Also, these results imply that people with emotional eating disorders apparently have higher activation of the reward centers in front of food stimuli and negative emotions induced intake (Bohon et al. 2009), explaining that the parasympathetic predominance would be linked to hedonism considering emotional eating behaviors. Likewise, the results remind us that when emotional eating is studied without BMI mediation, the psychophysiological response addressed by these theoretical references is not successfully obtained (Kaplan and Kaplan 1957; Thayer and Lane 2000). Contrary to these assumptions, the vagal response predominates from the activation of the PSNS, which would question the paradigm of psychosomatic theory in the analysis of emotional eating behaviors. Other results support Kaplan's approach (1957), where the BMI appears to mediate the relationship between food stimuli reactions and HRV, resulting in a predominance of the SNS and a reduction in HRV. In this way, these psychophysiological responses is a mechanism of emotional eating. However, this finding got restrained to people with a high BMI (Chang et al. 2021) resulting in a discrepancy between empirical evidence and theoretical information when trying to explain the psychophysiological mechanism of emotional eating behaviors. On the one hand, the psychological mechanisms involved in the interaction between HRV and emotional eating, which are associated with the self-regulation of emotions, interoception, and inhibitory control, have not yet been studied in depth. On the other hand, the approach to

emotional eating and the psychophysiological response associated with this eating disorder is restricted to people with obesity. Thus, it is concluded that explanatory reasons for emotional eating are not yet clear, and this explanation remains pending considering the limitations named above (Suárez Palazón and Mayoral Babiano 2019).

Applications to Other Areas

Los hallazgos actuales permiten sentar las bases para comprender el mecanismo a través del cual la VFC repercute en la autorregulación que conlleva a la ingesta alimentaria (Meule et al. 2012). En relación a las implicaciones clínicas, este conocimiento permite el diagnóstico de las desregulaciones emocionales que conllevan a comportamientos alimentarios compulsivos como el comer emocional. En este sentido, a través del uso de las nuevas tecnologías como es el caso de los sensores de machine learning, se incluyen métodos eficaces para detectar en tiempo real, los cambios en la VFC y el riesgo de episodios de comer emocional y de conductas alimentarias desadaptativas (Juarascio et al. 2020). Además, se pueden diseñar e implementar intervenciones como biorretroalimentación del hambre como estrategia de afrontamiento que permite a las personas con alimentación emocional, identificar sus sensaciones físicas de hambre (Kalogiratou et al. 2021; Ledoux et al. 2014). En consonancia con esto, la HRV-biofeedback podría ser una herramienta beneficiosa para atenuar el comportamiento alimentario disfuncional (Meule et al. 2012), pues posibilita el desarrollo de estrategias de regulación emocional y locus de control, lo que a su vez genera cambios favorables en el control del peso, teniendo en cuenta el alto índice de obesidad y el riesgo de enfermedades crónicas que existe hoy en día (Ledoux et al. 2014; Meule et al. 2012).

Mini Dictionary of Terms

- **Biofeedback**: Es una técnica de reconocimiento del hambre desarrollada por Mario Ciampolini. Consiste en la le administración de dispositivos portátiles de autocontrol con el que se les indica a los individuos que coman cuando confirmen el hambre física, con el objetivo de controlar el estado de peso.
- **Comer emocional**: Se considera como una tendencia a comer en respuesta a emociones negativas, siendo los alimentos elegidos principalmente ricos en energía y palatables.
- **Estrés**: Se define como una perturbación de la homeostasis e incluye el estresor, la respuesta al estresor y los cambios fisiológicos entre el estresor y la reacción corporal.
- **Índice de Masa Corporal (IMC)**: Valor que se obtiene del cálculo en base al peso y la talla y que funciona como indicador para establecer las categorías de peso.

- **Variabilidad de la Frecuencia Cardiaca (VFC)**: Es un índice de la actividad de la actividad del SNA. Se refiere a la variación latido a latido en la frecuencia cardíaca o la duración del intervalo R-R.
- **Machine learning**: Se basa en el algoritmo de funciones estadísticas a partir de conjuntos de datos multidimensionales que permiten hacer predicciones generalizables sobre individuos.

Summary Points

- The psychological mechanisms involved in the interaction between heart rate variability (HRV) and emotional eating are associated with the self-regulation of emotions, interoception, and inhibitory control.
- The approach to emotional eating and the psychophysiological response associated with this eating disorder are restricted to people with obesity.
- The evidence on the relation between the HRV and emotional eating demonstrates a predominance of the vagal response against the lower food stimulus under stress condition.

Biologic Aspects of Rumination Syndrome, Eosinophils, and Beyond

69

Hunter J. Friesen, Jennifer V. Schurman, and Craig A. Friesen

Contents

Abstract

Rumination syndrome is characterized by repeated regurgitation with re-swallowing or spitting. It is associated with both medical and psychosocial complications. It is a disorder of gut-brain interaction resulting from complex and heterogenous interactions across biologic, psychologic, and social systems. Diaphragmatic breathing to compete with abdominal wall contractions is the current mainstay of treatment but is often only associated with partial improvement and high relapse rates. As such, there is a need to develop other treatments to supplement the current behavioral approach, particularly addressing other targets of therapy as defined within the biopsychosocial model. The purpose of this chapter is to describe current knowledge of the biology of rumination syndrome, suggesting other potential therapeutic targets including both mechanical and

immune dysfunction. Frequent coexistence of GERD and functional dyspepsia has been demonstrated in both adults and children with rumination syndrome, and both may be triggers for rumination. Thus, the biology of both is relevant to rumination, and, as such, the biologic mechanisms of both may represent viable treatment targets in rumination syndrome. Immune dysfunction is now highly implicated in other disorders of gut-brain interaction with emerging data implicating a role in rumination syndrome independent of the presence of functional dyspepsia.

Rumination syndrome · Gastroesophageal reflux · Functional dyspepsia · Diaphragmatic breathing · Mast cells · Eosinophils · Biopsychosocial model

Introduction

Although some variability exists across criteria defining rumination syndrome (see Table 1), rumination syndrome is generally characterized by repeated regurgitation with re-swallowing or spitting of the regurgitated material (Drossman 2016; APA 2013; Hyams et al. 2016). It usually begins shortly after eating, does not occur at

Table 1 Rome and DSM-5 criteria for rumination syndrome

Adult Rome IV:
All of the following:
1. Persistent or recurrent regurgitation of recently ingested food into the mouth with subsequent spitting or remastication and swallowing
2. Regurgitation is not preceded by retching
Supportive: effortless regurgitation events are usually not preceded by nausea; regurgitant contains recognizable food which may have a pleasant taste; the process tends to cease when the regurgitated material becomes acidic
Pediatric Rome IV:
All of the following:
1. Repeated regurgitation and rechewing or expulsion of food that:
(a) Begins soon after ingestion of a meal
(b) Does not occur during sleep
2. Not preceded by retching
3. After appropriate evaluation, the symptoms cannot be fully explained by another medical condition. An eating disorder must be ruled out
DSM-5:
Criteria for rumination disorder are:
1. Repeated regurgitation of food for a period of at least 1 month. Regurgitated food may be rechewed, re-swallowed, or spit out
2. The repeated regurgitation is not due to a medication condition (e.g., gastrointestinal condition)
3. The behavior does not occur exclusively in the course of anorexia nervosa, bulimia nervosa, BED, or avoidant/restrictive food intake disorder
4. If occurring in the presence of another mental disorder (e.g., intellectual developmental disorder), it is severe enough to warrant independent clinical attention

night, and is not preceded by retching. Like other conditions defined by Rome criteria, it is believed to be a disorder of gut-brain interaction. Previously referred to as functional gastrointestinal disorders under Rome criteria, disorders of gut-brain interaction are defined as unique symptom clusters of gastrointestinal symptoms which result from any combination of dysmotility, visceral hypersensitivity, altered mucosal barrier, immune dysfunction, dysbiosis, and/or aberrant central nervous system processing (Drossman 2016). As such, they are the result of complex interactions across biologic, psychologic, and social systems.

Rumination syndrome is believed to be underdiagnosed and quite often misdiagnosed as another gastrointestinal condition, particularly gastroesophageal reflux disease (GERD). Reported prevalence in community samples varies from 0.8% to 10.6% in adults and 0% to 9.7% in children and adolescents (Murray et al. 2019; Martinez et al. 2021). The prevalence appears to be much higher in patients seeking evaluation for gastrointestinal symptoms, particularly in pediatrics. Rumination syndrome has been found in 12.8% of adults presenting with "gastric symptoms" (Murray et al. 2019). Rumination syndrome has been reported in 44% of children believed to have treatment-refractory GERD and in 60% of children with chronic vomiting (Nikaki et al. 2020; Malik et al. 2020). These studies suggest that rumination should be considered in all patients seeking care for reflux or dyspeptic symptoms.

There is often a large delay between onset of symptoms and diagnosis of rumination syndrome with associated high costs for medical tests and ineffective treatments (O'Brien et al. 1995; Chial et al. 2003; Alioto et al. 2017). There are also high psychosocial costs with school absenteeism and avoidance of work and social settings (Murray et al. 2019; Chial et al. 2003; Malik et al. 2020; Alioto et al. 2017). Additionally, there are medical complications including dental erosions, weight loss, and electrolyte disturbances (Murray et al. 2019; Chial et al. 2003; Malik et al. 2020; Alioto et al. 2017).

Disorders of gut-brain interaction are best understood through a biopsychosocial model which states that they are the result of biologic, psychologic, and social factors which are all interactive with each other (see Fig. 1), communicating through neurologic, immunologic, and endocrinologic pathways. These disorders are more likely to respond to treatment packages that identify and treat multiple factors across the full spectrum of the biopsychosocial model. To date, most treatment approaches to rumination syndrome have been directed at psychologic aspects with behavioral interventions to create responses that compete with the abdominal contractions that initiate a rumination episode (as will be discussed).

Diaphragmatic breathing is considered the mainstay of treatment for rumination syndrome with very few studies to support other treatments currently (Murray et al. 2019). Diaphragmatic breathing, also known as abdominal breathing, involves engaging the abdominal wall muscles and diaphragm while breathing. As will be discussed, rumination episodes follow strong contractions of the abdominal wall muscles pushing stomach contents into the esophagus and mouth. Diaphragmatic breathing is believed to create a competing response to these contractions (Murray et al. 2019). The evidence for diaphragmatic breathing is meager, including three

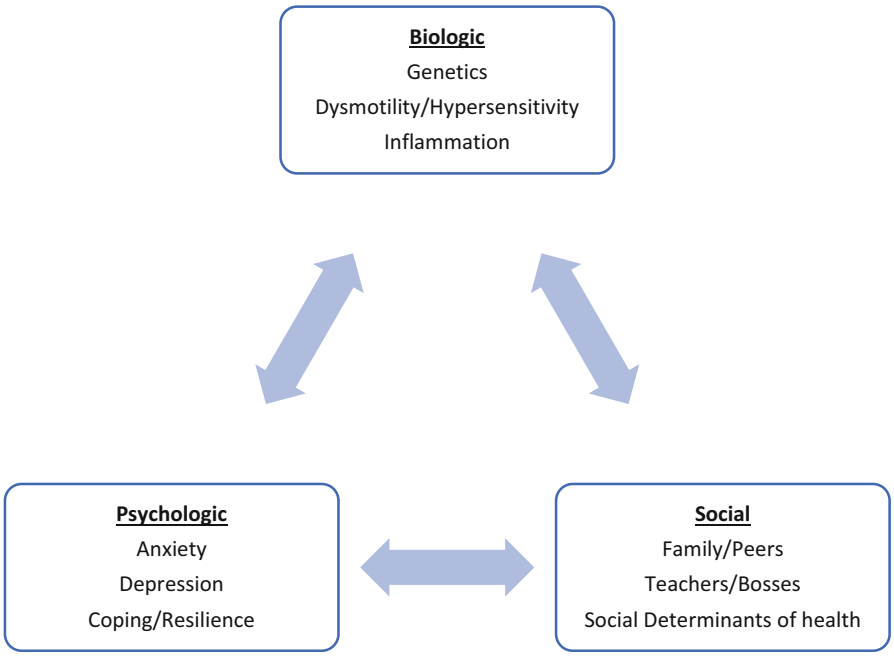

Fig. 1 The biopsychosocial model involves interactions between biologic, psychologic, and social factors in the generation of symptoms

prospective trials: two open trials containing a total of 38 patients and one randomized trial of 23 patients (Murray et al. 2019). Diaphragmatic breathing results in a decrease in rumination episodes, but most often some rumination continues, and the relapse rate is rather high, particularly in pediatrics (Murray et al. 2019; Chial et al. 2003; Malik et al. 2020; Alioto and Di Lorenzo 2018). Thus, there is a need to develop other treatments to supplement the current behavioral approach, particularly addressing other targets of therapy as defined within the biopsychosocial model. To date, there has only been one prospective trial of a medication directed at biological aspects of rumination syndrome (Pauwels et al. 2018). The purpose of this chapter is to describe current knowledge of the biology of rumination syndrome.

Physiology of a Rumination Episode

The physiologic changes which occur during a rumination episode have been well described in youth and adults during antroduodenal motility evaluations and more recently high-resolution esophageal manometry (Singendonk et al. 2017; Grunder et al. 2017; Rosen et al. 2017; Halland et al. 2020; Tucker et al. 2013; Rommel et al. 2010). Although the trigger for rumination may vary (as discussed later), the final events resulting in regurgitation are quite consistent. Episodes result from strong

voluntary (but generally unconscious) contraction of abdominal muscles which significantly increases intragastric pressure. An intragastric pressure increase greater than 30 mmHg is specific for rumination, differentiating it from a reflux episode, though a lower pressure may be seen in pediatric patients (Singendonk et al. 2017; Grunder et al. 2017; Halland et al. 2020; Tucker et al. 2013; Rommel et al. 2010). This pressure increase propels gastric contents into the esophagus and into the mouth. On manometry, rumination episodes appear as "R" or retrograde waves.

Other features seen on manometry demonstrate overlapping physiology with GERD but also differentiating features. Additionally, reflux may be a triggering event for rumination. Rumination is generally divided into primary rumination, where rumination is not associated with reflux, and secondary rumination where rumination is preceded by reflux which presumably triggers the rumination episode (Rosen et al. 2017; Tucker et al. 2013; Rommel et al. 2010). In adults with rumination syndrome, Rommel and colleagues demonstrated a consistent pattern in 86% of episodes where an initial small increase in gastric pressure was followed by retrograde flow of gastric contents with a subsequent large increase in gastric pressure due to abdominal wall muscle contraction (Rommel et al. 2010). In youth, Rosen and colleagues reported primary rumination in 55.5% and secondary in 44.5% of rumination episodes (Rosen et al. 2017). However, even in those episodes not preceded by reflux, there was often physiology similar to GERD, specifically relaxation of the lower esophageal sphincter (LES). Three patterns were noted in those with primary rumination: LES relaxation followed by an R wave before regurgitation in 51%, an initial R wave followed by LES relaxation in 20%, and an R wave without LES relaxation in 29% (Rosen et al. 2017). Whether different patterns have clinical significance remains to be determined. Rumination episodes differ from reflux episodes in that they are more likely to reach the proximal esophagus and mouth, are more frequently nonacidic postprandial events, and are more likely to be sensed by the patient and associated with symptoms (Nikaki et al. 2020).

As the physiology of a rumination episode has been well described, one pathway for treatment involves interventions to disrupt the episodes by inducing competing responses to abdominal wall contractions or to retrograde waves. This is the strategy behind diaphragmatic breathing which is performed to counteract the abdominal contractions. Hard swallows or inducing swallowing by sucking on mints or hard candy or chewing gum has been used to counteract retrograde waves. An alternative strategy would be to attempt to disrupt the pathophysiology that precedes the initiation of the abdominal wall muscle contractions.

Pathophysiology of Rumination

Three primary pathways have been proposed for development and maintenance of rumination including (1) a primary pathway where premonitory urges (uncomfortable psychologic or physical symptoms) precede and are relieved by rumination; (2) a pathway involving comorbid pathology, such as GERD; and (3) a pathway

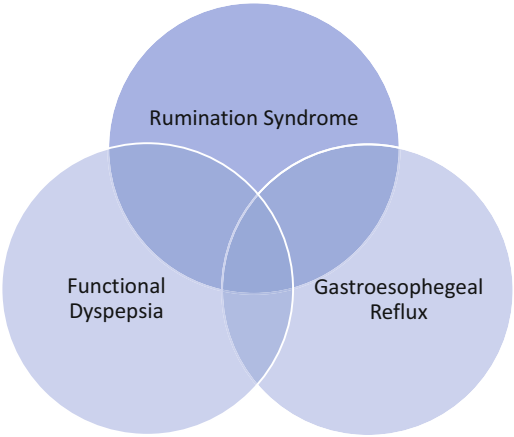

Fig. 2 There is significant overlap in the occurrence of rumination syndrome with functional dyspepsia and/or gastroesophageal reflux

involving psychosocial mechanisms where rumination initially relieves an unpleasant physical sensation due to a related condition, such as functional dyspepsia, and continues after the related condition resolves as a learned behavior to contextual clues, such as eating (Murray et al. 2019).

There is significant overlap in the presence of rumination syndrome, GERD, and functional dyspepsia which would suggest shared pathophysiology or that GERD and FD are triggers for rumination (see Fig. 2). There is evidence that both are true to differing degrees.

Frequent coexistence of GERD and functional dyspepsia has been demonstrated in both adults and children (Geeraerts et al. 2020; Fujiwara and Arakawa 2014; De Bortoli et al. 2018; Friesen et al. 2016). In adults with GERD symptoms occurring at least weekly, there is a nearly sevenfold increase in the prevalence of dyspepsia (Eusebi et al. 2018). Overlap is associated with worse physical and mental health, including increased sleep disturbance, anxiety, and depression (Lee and Chang 2021; Colombo et al. 2021). Significant overlap has been demonstrated between rumination syndrome and GERD with a substantial proportion of rumination syndrome patients having rumination secondary to reflux (Rosen et al. 2017). Significant overlap between rumination syndrome and functional dyspepsia has been demonstrated in population studies (Zand Irani et al. 2021a). In one study of children with rumination syndrome, 18% fulfilled Rome criteria for another functional gastrointestinal disorder (Rajindrajith et al. 2012). In youth with rumination syndrome, concurrent abdominal pain is reported in 23–38%, nausea in 17–30%, and constipation in 21–28% (Chial et al. 2003; Malik et al. 2020). Adults with rumination syndrome report increased postprandial nausea and discomfort as compared to healthy controls (Hoshikawa et al. 2020). Also, in adults with rumination syndrome, postprandial dyspepsia has been reported in 29% and treatment-resistant GERD in 24% (Tucker et al. 2013). As GERD and functional dyspepsia may provide the

stimulus for rumination episodes, the two conditions represent viable treatment targets in patients with rumination syndrome.

As will be discussed, GERD and rumination syndrome share common mechanical features and rumination syndrome, and GERD and functional dyspepsia share common features related to mucosal inflammation. Additionally, reflux and post-prandial symptoms seen in functional dyspepsia may be triggers for rumination, with regurgitation providing temporary symptom relief. For example, over 70% of adults report symptoms such as dyspepsia before onset of a rumination episode, symptoms which resolve once the regurgitant reaches the mouth (Tucker et al. 2013). Given the significant links between rumination syndrome, GERD, and functional dyspepsia, further discussion of GERD and functional dyspepsia is warranted.

GERD

Rumination syndrome significantly overlaps with GERD in terms of both symptoms and pathophysiology. Most often, patients with rumination syndrome are initially diagnosed with GERD and treated with acid-reducing medications (Murray et al. 2019). The clinical similarities prompted pediatric Rome III criteria to include the requirement that patients not respond to GERD treatment; this requirement was dropped under the current Rome IV criteria (Hyams et al. 2016; Rasquin et al. 2006). "GERD" patients who continue to have symptoms despite treatment are often labeled as refractory GERD before the diagnosis of rumination syndrome is entertained.

There are multiple possible explanations for why patients presumed to have GERD may be refractory to acid reduction therapy. Symptoms may be unrelated to GERD. For example, they may be the result of esophageal hypersensitivity (Clarke et al. 2018). This may be more likely with concurrent functional dyspepsia or irritable bowel syndrome which is associated with a decreased rate of symptomatic response to acid-reducing medications (e.g., proton pump inhibitors, PPIs) (Zerbib et al. 2021). As medications are not perfect, acid reflux may continue despite aggressive acid reduction therapy (e.g., twice daily PPIs) (Zerbib et al. 2021). Ultimately, a significant proportion of treatment-refractory "GERD" patients with predominantly post-prandial regurgitation will have rumination syndrome, either primary or secondary to reflux.

Up to 90% of gastroesophageal reflux episodes are initiated by transient lower esophageal sphincter relaxations (TLESRs) (Tack and Pandolfino 2018). These are both myogenic and neurogenic phenomena, most often resulting from a vagal-mediated reflex initiated by distension of the gastric fundus (proximal stomach) (Clarke et al. 2018; Tack and Pandolfino 2018). TLESRs are also influenced by intra-abdominal pressure, neuro-mediators, hormones, and dietary components (Tack and Pandolfino 2018). $GABA_B$ receptors, which can be moderated by baclofen (a $GABA_B$ agonist), have been assessed in several studies; baclofen decreases TLESRs and increases LES pressure (Clarke et al. 2018; Pauwels et al. 2018;

Blondeau et al. 2012). Baclofen has been reported to be beneficial in pediatric GERD patients with a sustained response in 81% (Vadlamudi et al. 2013).

GERD may also be associated with gastric motor dysfunction. GERD is associated with delayed gastric emptying in up to 45% of patients (Jehangir and Parkman 2020; Gonlachanvit et al. 2006). GERD is associated with proximal gastric retention of both solids and liquids and has been associated with altered gastric accommodation in some, but not all, studies (Gonlachanvit et al. 2006; Penagini 1998; Patcharatrakul et al. 2020; Pauwels et al. 2014). One method for assessing accommodation and gastric sensitivity is to inflate a gastric balloon to increasing volumes in the proximal stomach while measuring pressure and assessing symptoms. With gastric balloon distension, patients with GERD report fullness and discomfort at lower pressures and/or volumes than do controls (Penagini et al. 1998).

GERD is also associated with increased esophageal sensitivity which may be relevant given that a significant proportion of rumination episodes are preceded by reflux. Sensitivity plays an important role in symptoms generated by reflux (Tack and Pandolfino 2018). GERD is associated with disruptions in the esophageal epithelial barrier, increased nerve fiber density, and increased expression of TRPV1, a channel associated with hypersensitivity in patients with other functional gastrointestinal disorders (Tack and Pandolfino 2018). Together, these result in hypersensitivity to esophageal distension (Tack and Pandolfino 2018).

GERD can also be associated with inflammation, both in the esophagus and downstream within the gastrointestinal tract. While gastric acid may induce a chemical burn, much of the reaction resulting in esophagitis appears to be immune mediated with T cells central to the inflammatory mechanism (Rieder et al. 2007, 2010; Zavala-Solares et al. 2021; Souza et al. 2009; Zand Irani et al. 2021b; Moiseff et al. 2021). The immune response is associated with production of cytokines that can reduce esophageal muscle cell contractions (Rieder et al. 2007). It is likely that inflammation contributes to the altered mucosal barrier and increased sensitivity.

GERD has also been associated with duodenal inflammation with eosinophils, in particular, and as will be discussed, this represents an area of commonality with functional dyspepsia and rumination syndrome. In patients with functional dyspepsia, duodenal eosinophilia is associated with up to a sixfold increase in GERD (Ronkainen et al. 2019).

Functional Dyspepsia

Like GERD, rumination syndrome significantly overlaps with functional dyspepsia in terms of both symptoms and pathophysiology. Dyspeptic symptoms are frequently reported by patients with rumination syndrome; often, patients report these symptoms before a rumination episode with symptom relief once the regurgitant reaches the mouth (Tucker et al. 2013).

Functional dyspepsia has been associated with a variety of mechanical disturbances including delayed gastric emptying, decreased gastric accommodation, and visceral hypersensitivity (Rosen et al. 2014; Tack and Pandolfino 2018; Simrén et al.

2018). Approximately half of adults with FD exhibit delayed gastric emptying, and patients tend to exhibit increased retention in both the proximal and distal stomach (Park et al. 2017; Gonlachanvit et al. 2006). Delayed gastric emptying can be associated with nausea, pain, early satiety, and fullness (Vijayvargiya et al. 2019). Abnormal accommodation has been reported in over 40% of adults with functional dyspepsia and can be associated with early satiety (Park et al. 2017; Tack and Pandolfino 2018). Over 20% of adults with functional dyspepsia have both abnormal accommodation and delayed gastric emptying (Park et al. 2017).

Functional dyspepsia has been associated with inflammation including chronic inflammation involving Th17 cells (Singh et al. 2020). A large and continually growing body of literature has demonstrated increased density and activation of eosinophils and mast cells in the antrum and duodenum of both adults and youth with functional dyspepsia (Wauters et al. 2017; Friesen et al. 2013, 2021a; Singh et al. 2018; Du et al. 2018). Pesek and colleagues found mucosal eosinophilia in over 80% of patients undergoing endoscopy for moderate to severe gastrointestinal symptoms (Pesek et al. 2020). This increase occurs even in patients with mucosa that appears normal on gross endoscopic examination (Dellon et al. 2021). In particular, early satiety has been associated with mucosal eosinophilia. Nausea is also associated with increased mast cell density in children with dyspepsia, independent of abdominal pain (Friesen et al. 2020).

Inflammation appears to be an important link between functional dyspepsia and known triggers including stress and infections. Anxiety and stress have been highly implicated in the development and maintenance of disorders of gut-brain interaction, including functional dyspepsia. The stress response results in inflammation, dysmotility, visceral hypersensitivity, and alteration of central nervous system processing of nociceptive signals (Friesen et al. 2013). Corticotropin-releasing hormone (CRH) is the major mediator of the stress response. CRH receptors are widely expressed on the surface of mast cells, and CRH receptors may be expressed on the surface of eosinophils under stress conditions (as demonstrated in a rodent model), or eosinophils may be recruited and activated by mediators released from mast cells (Wallon 2009; Zheng et al. 2009). Antral mast cell density is positively correlated with anxiety and depression scores in youth with functional dyspepsia (Schurman et al. 2010b). Anxiety is common in patients with mucosal eosinophilia, and duodenal eosinophilia is associated with anxiety independent of functional dyspepsia (Reed et al. 2021; Ronkainen et al. 2021). Biofeedback-assisted relaxation training has been shown to enhance the clinical response in youth with functional dyspepsia and duodenal eosinophilia with decreased pain intensity and decreased duration of pain episodes providing further evidence for a link between eosinophilia and stress (Schurman et al. 2010a).

Mast cells appear to be an important pathway between stress and pain in adults as well (Wouters et al. 2016; Santos et al. 1998). Under physical stress conditions, adults have demonstrated jejunal intraluminal release of tryptase and histamine at a magnitude similar to that released by antigen exposure in food allergic patients (Santos et al. 1998). Upon activation, mast cells and eosinophils can release mediators which induce gastrointestinal symptoms (Friesen et al. 2013). Mast cell

infiltration and activation has been shown to induce hypersensitivity with histamine as an important mediator (Zheng et al. 2009; Wouters et al. 2016; Hou et al. 2001). Mast cell-derived histamine, which is released at biologically important rates in adults under stress, may be of particular importance as it can directly stimulate sensory nerves or lead to hypersensitivity (Coruzzi et al. 2012; Wouters et al. 2016; Santos et al. 1998).

Functional dyspepsia can be induced by an enteric infection with higher reported prevalence following both bacterial and parasitic infections (Zanini et al. 2012; Saps et al. 2008; Hanevik et al. 2009). Postinfectious functional dyspepsia appears to be due to an inability to end the inflammatory response after the pathogen is eliminated (Zanini et al. 2012). Postinfectious functional dyspepsia is associated with chronic inflammation as well as increased duodenal eosinophils, increased gastric mast cells, and increased gastric release of histamine and 5-hydroxytryptamine (Walker et al. 2011; Li et al. 2010; Lan et al. 2011; Futagami et al. 2010).

Rumination Syndrome

The overlap between GERD, functional dyspepsia, and rumination creates challenges in distinguishing which motility and inflammatory processes are directly related to rumination and which are due to an associated condition. As previously discussed, rumination episodes are frequently triggered by gastroesophageal reflux and share pathophysiology related to TLESRs. Like GERD, rumination episodes can be decreased by baclofen which decreases TLESRs and increases LES pressure (Blondeau et al. 2012; Pauwels et al. 2018). Other pathophysiologic motility processes reported in GERD and particularly in functional dyspepsia have been evaluated in several studies with mixed or inconclusive results. This should not be surprising as findings could be significantly altered by whether patients have overlapping GERD and/or functional dyspepsia.

Most often, gastric mechanical function is normal in patients with rumination, and there is a belief that medications to increase accommodation or emptying are ineffective; however, placebo-controlled trials are lacking (Murray et al. 2019; Absah et al. 2017). In one study, impaired accommodation was reported in less than 10% of adults with rumination syndrome (Bredenoord et al. 2003). In adults with rumination, balloon distension in the proximal stomach was associated with increased nausea and bloating as compared to healthy controls with no differences in accommodation at a group level (Thumshirn et al. 1998). However, decreased accommodation was demonstrated in 50% (6/12) of patients, and these patients reported increased pain with distensions (Thumshirn et al. 1998). Rumination syndrome patients do not appear to be a homogeneous group with regard to accommodation, and at an individual patient level, decreased accommodation may contribute to rumination in some patients. This is an important area for future research. Delayed gastric emptying is not uncommon in rumination syndrome and has been reported in 30–46% of children and adolescents (Chial et al. 2003; Alioto et al. 2017). It is not known whether delayed gastric emptying as measured by a

scintigraphic emptying study represents decreased gastric motor function or is an artifact created by excessive regurgitation. Again, there are no controlled trials of gastric pro-motility agents in rumination syndrome.

Similar to GERD, an altered mucosal barrier has been reported in rumination syndrome (Halland et al. 2020). Inflammation has also been more recently implicated in rumination syndrome. Abnormal upper endoscopic findings have been reported in over 30% of youth with rumination syndrome (Alioto et al. 2017). In another pediatric series, esophagitis (generally consistent with reflux esophagitis) was found in 32%, gastritis (generally chronic gastritis) in 32%, and eosinophilic duodenitis in 18% of patients (Friesen et al. 2021b). In functional dyspepsia, though there is not universal agreement in the upper limit of mucosal eosinophils, an increase in gastric or duodenal eosinophils appears to be common even in the absence of a formal pathologic diagnosis of eosinophilic gastritis or duodenitis; histologic criteria continue to evolve, and thus the 18% prevalence may represent an underestimation of the prevalence of duodenal eosinophilia in rumination syndrome (Dellon et al. 2021). Halland and colleagues studied mucosal inflammation in adults and found an increase in eosinophil density and intraepithelial lymphocytes in rumination syndrome patients as compared to controls (Halland et al. 2019). It was not known whether this was accounted for by overlapping functional dyspepsia which is highly associated with increased mucosal eosinophils (Halland et al. 2019; Du et al. 2018). A subsequent pediatric study confirmed these increases in duodenal eosinophils and intraepithelial lymphocytes while also demonstrating increases in eosinophil and mast cell densities in the gastric antrum (Friesen et al. 2021b). This study also demonstrated that increased inflammation occurred independent of the presence of abdominal pain or early satiety, hallmark symptoms of functional dyspepsia (Friesen et al. 2021b). The significant prevalence of chronic gastritis in these patients may also be relevant as chronic gastritis in children is associated with increases in mucosal eosinophils and mast cells (Singh et al. 2020).

Immune activation involving mast cells and eosinophils may be a pathway for factors that can exacerbate rumination, particularly known triggers of illness and stress (Alioto and Di Lorenzo 2018). Rumination syndrome is associated with anxiety and depression (O'Brien et al. 1995; Amarnath et al. 1986; Barba et al. 2015, 2016). Inflammation may be an important path between stress and rumination as has been demonstrated in other disorders of gut-brain interaction. As previously discussed, stress may be of particular importance in patients with concomitant rumination syndrome and functional dyspepsia. The role of inflammation in stress exacerbation of rumination syndrome is another important area for future research.

Summary

Like most disorders of gut-brain interaction, rumination syndrome is a complex and heterogenous entity. There is significant variability regarding mechanical functioning, both gastric motor function and functioning of the LES, particularly with its relationship to the onset of abdominal wall muscular contractions. Additional

heterogeneity is introduced by whether there is concomitant GERD or functional dyspepsia. It also seems likely that variation is introduced by varying triggers and differences in psychosocial factors. Consequently, patients may develop rumination syndrome by widely divergent pathophysiologic processes which may impact treatment responses. The paucity of controlled trials along with the pathophysiologic variability between patients which has not been controlled for in these studies limits the options for treating rumination syndrome in an evidence-based fashion.

There currently appear to be two treatment strategies: one directly targeting rumination episodes with competing responses (directed either at abdominal wall contractions or counteracting retrograde waves) and another identifying associated conditions with an attempt to identify relevant biologic, psychologic, and social factors. The two strategies are not mutually exclusive, and frequently both strategies are utilized, in part, in clinical practice. Diaphragmatic breathing has the most literature support, although somewhat meager, as a competing response. Other competing responses utilized in clinical practice (e.g., hard swallows, sucking on mints or hard candy, chewing gum), which are directed at counteracting retrograde waves, have not been studied prospectively nor compared to diaphragmatic breathing in treatment trials. Unfortunately, with diaphragmatic breathing, many or most patients have some residual rumination, albeit at a reduced rate, and relapse can be high. The other intervention which has been studied in a controlled trial is baclofen which improves LES function, preventing TLESRs as a trigger for some patients (Pauwels et al. 2018). With baclofen, although improvement has been noted in rumination syndrome, a significant proportion of patients continue to have symptoms. No studies have assessed combined treatment with diaphragmatic breathing and baclofen to determine if they have complementary effects. There have also not been controlled trials assessing either intervention in association with relaxation training although diaphragmatic breathing may induce a relaxation response in some patients if done properly. Teaching diaphragmatic breathing utilizing biofeedback may have the added benefit of being able to assure that it is also inducing relaxation.

Treatment utilizing a biopsychosocial model, identifying and treating relevant biologic, psychologic, and social factors, might represent a more efficacious pathway (as appears true for other disorders of gut-brain interaction), but this remains to be proven in this patient group. We have found it useful to classify patients by whether associated GERD and/or FD is still present or whether rumination syndrome represents a residual set of symptoms following adequate treatment and resolution of GERD and/or functional dyspepsia. In some patients, treatment of GERD or functional dyspepsia may be able to resolve rumination syndrome. In others, it may be helpful or even necessary but not sufficient to eliminate it. Within the biopsychosocial model, there is an implied need to identify relevant biologic contributors which is the focus of the present chapter. Similar to other disorders of gut-brain interaction, mechanical dysfunction (visceral hypersensitivity, accommodation defects, and possibly delayed gastric emptying) may be relevant in some patients and represent therapeutic targets. Immune dysfunction, particularly increased density and activation of mucosal eosinophils and mast cells, is now highly implicated in other disorders of gut-brain interaction, particularly functional

dyspepsia and irritable bowel syndrome, with emerging data implicating a role in rumination syndrome independent of the presence of functional dyspepsia (Du et al. 2018; Friesen et al. 2021a; Halland et al. 2019; Friesen et al. 2021b). Treatments targeting mast cells and eosinophils have shown benefit in other disorders of gut-brain interaction and are an important area for future studies in rumination syndrome (Dellon et al. 2020). Much of the current knowledge pertaining to rumination syndrome is related to pathophysiology; studies assessing treatments targeting the wide variety of maintaining pathways across biopsychosocial factors are strongly needed.

Mini-Dictionary of Terms

Rumination syndrome: A syndrome characterized by repeated regurgitations with swallowing or spitting which begins shortly after eating and is not preceded by retching.

Disorders of gut-brain interaction: Gastrointestinal symptom clusters resulting from any combination of aberrant motility, sensitivity, microbiome composition, intestinal barrier function, and neural processing.

Biopsychosocial model: A model explaining symptoms as resulting from variable contributions from and interactions between biologic, psychologic, and social factors.

Competing responses: Motor behaviors that oppose a habit in order to suppress the habit.

Gastroesophageal reflux: The return of stomach contents into the esophagus generally due to an incompetent sphincter or, most often, transient relaxation of the LES.

Functional dyspepsia: A disorder defined by the presence of epigastric pain, epigastric burning, early satiety, and/or postprandial bloating without a clear medical cause.

Summary Points

- The physiology of rumination episodes is well described with strong abdominal wall muscle contractions initiating retrograde or R waves; both muscle contractions and R waves are targets of current therapies utilizing competing responses
- Diaphragmatic breathing is the current mainstay of treatment but only has meager support from controlled studies, often leaves residual rumination, and is associated with significant rates of relapse
- GERD and functional dyspepsia frequently coexist with rumination syndrome and may trigger rumination episodes; as such, they represent viable treatment targets utilizing a biopsychosocial framework
- A growing body of evidence supports a role for mast cells and eosinophils in other disorders of gut-brain interaction including functional dyspepsia; emerging

data may implicate a role for inflammation in the pathophysiology of rumination syndrome
- There is a great need for controlled studies of current commonly utilized treatment strategies as well as interventions targeting biologic contributors to rumination syndrome

Picky Eating in Normally Developing Children and Young Adults

70

Ada H. Zohar

Contents

Abstract

This chapter deals with picky eating (PE) in normally developing children and adults. PE is a central component of avoidant/restrictive food intake disorder (ARFID) but not an eating disorder in itself. A large proportion of children go through a phase of PE, which usually resolves itself. A minority of children continue to be highly selective and neophobic. Extreme and consistent restricted eating in children can arrest development and cause severe health problems. There is (arguable) evidence that consistent picky eating from early childhood

into preadolescence is a risk factor for restrictive eating disorders such as ARFID and anorexia nervosa. There is a growing body of research on PE in young adults; there is some evidence that adult PE is related to a less healthy lifestyle and is associated with emotional and social dysfunction and distress. This chapter reviews the definition, extent, duration, precursors, and repercussions of PE in children and young adults. It uses vignettes of picky eaters to illustrate some of the points raised in the review. In conclusion, it summarizes some of the less-studied issues that require further research and offers practical advice.

Keywords

Picky eating · Neophobia · Food fussiness · Intergenerational transmission · Children · Young adults · Parental feeding practices · Pressure to eat · Appetitive tendencies

Abbreviations

AN	Anorexia nervosa
ARFID	Avoidant restrictive food intake disorder
BMI	Body mass index
FF	Food fussiness
Pe	Picky eater
PE	Picky eating
Pes	Picky eaters

Introduction

Picky eating may constitute a health hazard, and at the very least can permeate the parent–child relationship with frustration, distrust, guilt, and anger, which may generalize to other aspects of the parent–child relationship and alter family dynamics. It is a nondiagnostic but salient problem in autism spectrum disorder (ASD); and in the absence of language in children and adults with ASD can be particularly tragic and difficult to deal with. There is a wealth of research on picky eating in the context of ASD. However, this chapter focuses on typically developing children and young adults, which is in itself a field of study that is gaining momentum and is worthy of review.

Definitions of Picky Eating

The criterion of avoidant restrictive food intake disorder (ARFID) in the DSM5 (APA 2013) includes apparent lack of interest in food, avoidance of foods based on their sensory characteristics, and concern about aversive consequences of eating, which leads to a significant weight loss or to nutritional deficiencies. Some of these have been suggested as elements of picky eating (PE). Dovey et al. (2008) include in

their definition of PE an inadequate variety of foods, rejecting many familiar and unfamiliar foods, and an aversion to specific food textures. A different definition was suggested by Brown and Perrin (2020) to include the refusal to taste new foods (neophobia), eating very little, and having one's food prepared separately or differently from other people present at the meal. Other definitions of PE include emotional responses having to do with food – such as showing no interest in food or meals, or displaying negative emotions before or during eating. These behaviors are better described as emotional undereating, although they are usually associated with PE (Tharner et al. 2014; Zickgraf and Ellis 2018; Zohar et al. 2020; Wolstenholme et al. 2020). In a systematic review of child PE and neophobia, Brown et al. (2016) conclude that the inconsistency of the definition of PE leads to great difficulty in drawing conclusions about prevalence of PE and its relationship to BMI and obesity in children.

Measurement of Picky Eating

The measurement of picky eating has evolved as interest in the phenomenon has grown. Some studies of young children (e.g., Cardona Cano et al. 2015; Zohar et al. 2019) rely on parental report via the Pre-School Child Behavior Checklist (Achenbach 1992), which includes an item on eating problems answered on a 3-point severity scale, and an open item for describing the eating difficulties. A more detailed parental report is the Child Eating Behavior Questionnaire (Wardle et al. 2001), which includes the six-item Food Fussiness (FF) subscale, with a focus on refusal to taste new foods, and can be used for children up to the age of 18. The FF score is sometimes used to define a cutoff point above which the child is defined as a picky eater (Sandvik et al. 2019; Zohar et al. 2020). Another measure is the objective tool for assessing picky eating (OTAPE; Finder 2020) for parental report on children 3–6 years of age. Parents report on the availability of various food items from a frequent foods list at meals in their home, and then on which of these were actually eaten by their child. Since it yields a quantitative ratio, it is deemed objective. However, since all these measures depend on parental report, there is potential for bias.

Observational tools are used in some studies and have the highest face validity. However, the observed behavior is study-specific, and the expense and labor involved limit the sample size studied (e.g., Abebe et al. 2017; Adamson and Morawska 2017; Jordan et al. 2020).

As children grow older, self-report becomes possible. Zohar et al. (2020) developed a scale based on a frequent foods list presented by name and picture. Children 7–9 years of age self-reported online to produce two variables: "never," the number of food items the child scores as not to be eaten; and "last week," the number of items the child endorses as having eaten over the last week. The two variables are negatively correlated and are strongly related to maternal reports of PE at earlier developmental stages as well as concurrently. Ellis et al. (2017) developed a 16-item self-report adult picky eating questionnaire (APEQ), with excellent psychometric

properties measuring sensitivity to meal presentation, the limitation of food items eaten, lack of appetite or interest in food, and aversion to sour and bitter tastes, which is in wide use in the growing research on adult PE. Zickgraf and Ellis (2018) composed a nine-item avoidant/restrictive screen (NIAS), with three items on PE, three on low appetite (Appetite, A), and three on anxiety pertaining to the gastrointestinal consequences of eating (Fear, F). The items on PE are "I am a picky eater"; "I dislike most of the foods that other people eat"; and "The list of foods that I like and will eat is shorter than the list of foods I won't eat." Each of the items is rated on a 6-point scale from strongly disagree (0) to strongly agree (5). The score on the PE subscale of the NIAS is the sum of responses, ranging potentially from 0 to 15. The NIAS has excellent psychometric properties, but as yet a cutoff point for PE has not been identified. The PE score correlates positively with food neophobia and with the food fussiness subscale of the adult eating behavior questionnaire, and negatively with the food enjoyment subscale. It does not correlate with measures of anxiety, depression, and stress (Zickgraf and Ellis 2018).

What Is Not Eaten by Picky Eaters?

Although the definitions of PE offered at the beginning of this chapter did not include what picky eaters (Pes) are not eating, this is of course of medical and health concern. By definition, the more selective a picky eater (Pe) is, the more foods she will not eat. However, a recurring theme in PE is avoiding vegetables and fruit. Most children who are Pes will not eat vegetables of any kind (Zohar et al. 2019) or will only eat a restricted range or amount of raw vegetables (van der Horst et al. 2016) and fruit. Because vegetables and fruit are crucial for vitamins and dietary fiber, this may have developmental repercussions and may also contribute to constipation (Taylor et al. 2016), which in turn will affect appetite and food enjoyment, thus constituting a positive feedback loop for PE. Ellis et al. (2018a) found that college students who self-reported as Pes were more likely to eat less vegetables and fruits. Thus, the association between PE and low vegetable and fruit consumption is found throughout the developmental span studied. Many PE interventions are targeted at extending the consumption of vegetables and fruit (e.g., Bennett et al. 2020; Jordan et al. 2020).

The avoidance of all or most vegetables and fruit is mentioned in all five vignettes included at the end of this chapter.

Prevalence of Picky Eating

Prevalence estimates of transient picky eating, present in one phase of childhood and not in another, vary from study to study, possibly because of cultural influences. A meta-analysis concluded that about 22% of children go through a picky eating phase (Cole et al. 2017a). There is some consistency, however, in the estimate of persistent picky eating over childhood, which derives from longitudinal studies. Zohar et al.

(2020) found that 3.9% of typically developing children in Israel were persistently Pes between 3 and 8 years of age. Taylor et al. (2015) found in a longitudinal study in the west of England that 3.5% of children 2–7 years of age were persistently Pes. In the Netherlands, a longitudinal study that followed children from their first year of life until they were 6 found that 4% of the children were persistent Pes (Cardona Cano et al. 2015). The prevalence of PE in young adults has been less studied. However, He et al. (2020) found that 19.4% of the Chinese college students studied could be defined as picky eaters and 3.3% as severe Pes. Ellis et al. (2018b) studied young adults in the United States and found that 18.1% could be described as picky eaters; this group also reported more social anxiety related to eating and more depressive symptoms. Thus, currently, there is a discrepancy in the prevalence estimates of PE in children and adults. While less than 5% of children are persistently picky eaters from infanthood to school age, about a fifth of young adults self-report as picky eaters. It is likely that different criteria are being used at different developmental stages; however, only extended longitudinal studies, with well-defined criteria for picky eating at the different developmental stages, can resolve this discrepancy.

Continuity from Childhood to Young Adulthood

Do individuals who are persistently picky as children become adult picky eaters? Or, are they at increased risk to develop restrictive eating disorders such as ARFID or restrictive AN? Van Tine et al. (2017) followed a small sample of children from infancy until the age of 23 and found continuity between persistent picky eating at 11 and remaining a selective eater at 23, with no evidence for increased eating pathology or obesity in the persistent picky eaters. Retrospective studies of adolescents diagnosed with ARFID (Menzel 2019) or AN (Dellava et al. 2012) suggest that childhood PE increases the risk for developing these disorders; however, there are no prospective studies showing this association. Moreover, a retrospective qualitative study of adolescents with restrictive AN (Scolnick et al. 2015) found that as children they were particularly good eaters, eating healthy, varied, vegetable-rich diets. The onset of their eating disorder could best be attributed to school-based obesity intervention programs. In young adults, PE is associated with more disordered eating, obsessive-compulsive symptomatology, and social anxiety surrounding eating (Wildes et al. 2012). Barnhart et al. (2021) found that PE as self-reported by undergraduates was correlated with overall eating pathology, with binge eating, as well as with social anxiety about eating, and symptoms of stress, anxiety, depression, and OCD. However, Zickgraf and Ellis (2018), in their validation of the NIAS, did not find that PE correlated with any measures of psychopathology in healthy young adults.

For the adult picky eaters represented in the vignettes in this chapter, there does not appear to be associated psychopathology, but there is discomfort around social eating.

Trajectories of PE

Different lines of research find partial support for a variety of antecedents and risk factors that can best be grouped as distinct trajectories to PE. In reality, they may not be mutually exclusive, but are described separately for clarity.

Parental Feeding Practices: Pressure to Eat

The dance of feeding and eating begins in the first few hours of the baby's life as both mother and child are recovering from the trauma of birth (Brody and Siegel 1992).

Some studies support the protective role of exclusive breastfeeding until 6 months of age against PE in later childhood (Shim et al. 2011; de Barse et al. 2017; Emmett et al. 2018); however, systematic review does not bear out this association (Bąbik et al. 2021). Self-weaning, letting the infant pick up and eat solid and lumpy foods when over 6 months of age rather than spoon-feeding her smooth pureed food, in the process of weaning the infant from an exclusive diet of milk or milk substitutes, is also found to be protective against later picky eating (Bąbik et al. 2021). However, waiting to begin doing so until the child is over 9 months of age is a risk factor for PE (Emmett et al. 2018), particularly so if the mother is worried or very worried about the child's eating. A possible integration of these early feeding findings is that babies and toddlers do best when they can regulate their food intake to suit their actual needs and appetite: Therefore, breastfeeding has an advantage over bottle feeding; self-weaning over spoon-feeding, but these are proxies and thus found in some studies and not in others, because the underlying protective factor is the absence of parental worry or fussing, trusting the baby/toddler to eat what and how much she needs. In an extraordinary longitudinal study of maternal feeding that followed mother–child dyads from the first year of life until the children were 18, Brody and Siegel (1992) found that mothers who were relaxed and enjoyed breastfeeding had long-term better outcomes for their children and for their children's eating behavior when they were young adults. Steinsbekk et al. (2017) found that parents offering their Pe child new foods in a calm, assertive way helped against continued PE; while responding emotionally to the child's food rejection "parental sensitivity" and accommodating to the child's food avoidance increased the risk of continued PE. This conclusion, that a relaxed confident parent who feeds her child without too much worry, fuss, or pressure has the greatest odds of not having a child who is a PE, has further corroboration in that first-born children are more likely to be described by their mother as PE than non-first-born children (van der Horst et al. 2016; Zohar et al. 2019), so that inexperienced and more anxious parenting may be the underlying factor.

Parents who identify their children as Pes self-report that they pressure their child to eat (e.g., Kutbi 2020). Common sense dictates that if the child eats less than the parent or the culture deems appropriate, or rejects many of the foods that are readily available in the home environment, a parent will try to discharge her responsibility toward the child by trying to increase the child's food intake or the range of foods the

child will eat. However, a low-appetitive child who is pressured to eat might respond to pressure by further reduced appetite and develop the attitude that eating is a chore that must be undertaken to satisfy the parent. Zohar et al. (2021) found that mothers of 6-year-old children, who were authoritarian, and practiced overt control of their child's diet, pressured their child to eat more, while the children ate less (high food satiety), had a more restricted diet (food fussiness), were slower eaters, and did not enjoy their food as much. Authoritative parenting, both loving and structured, is protective against PE (Steinsbekk et al. 2017; Jordan et al. 2020; Zohar et al. 2021).

There is also evidence that parental pressure to eat in childhood is a stronger predictor of adult PE than childhood PE (Ellis et al. 2016); this ironic reversal was noted in a retrospective study of adult eating behavior, BMI, and body image (Lev-Ari and Zohar 2013). Parental pressure to eat on children is a major predictor of adult PE (Cole et al. 2018). So, although pressure to eat is a common and understandable parental response to a child who is eating or is perceived to be eating very little, it does not seem helpful in the long run. In the short term, if meals become conflictual, with parents seeking to forcefully control their children's eating behavior, the parent–child relationship is negatively affected and the risk for continued PE and the development of eating disorders is elevated, while maintaining a positive atmosphere at family meals is moderately protective (Cole et al. 2018; Emmett et al. 2018).

It is unfortunate that particular parental feeding practices, including pressure to eat, undergo intergenerational transmission (Lev-Ari et al. 2021); so, young adults who were adversely affected by being pressured to eat when children find themselves in turn pressuring their own children to eat.

Sensory Sensitivity

Sensory sensitivity can be described as having an aversive or lacking response to stimuli that are tactile, visual, auditory, kinetic, the body's spatial orientation (proprioception), as well as to taste, smell, and food texture (Schoen et al. 2008). In the context of PE, sensory sensitivity is measured in all these domains **excluding** those that pertain directly to food (taste, smell, and food texture). Children who react aversely to sensory stimuli are more likely to be Pes at age 4, and sensory sensitivity at age 4 predicts continued PE at age 6, even when controlling for PE at age 4 (Steinsbekk et al. 2017). Sensory sensitivity seems to be congenital or genetic to some degree (van Hulle et al. 2012; Kalig-Amir et al. 2019), as does neophobia (Cooke et al. 2007; Smith et al. 2017). Pes are more prone to disgust, probably mediated by sensory sensitivity (Harris et al. 2019).

It has been suggested that individual differences in sensitivity to bitter taste may mediate PE (Jani et al. 2020; Patel et al. 2020). These differences are partly genetically determined as the ability to taste 6-n-propylthiouracil (PROP) is a Mendelian trait (Wooding et al. 2004). Cole et al. (2017b) found that variations in chemosensory genes were associated with elevated PE in preschool children. Bell and Tepper (2006) found that preschool children who were phenotypically

non-PROP tasters consumed more vegetables such as raw broccoli and black olives than PROP tasters. Moreover, Bell and Tepper (2008) found that parents of tasters and nontasters were no different in their feeding practices, suggesting that sensitivity to bitter taste contributes to PE in young children irrespective of parental influence. This line of research seems promising, but is relatively undeveloped.

This relationship between sensory sensitivity and PE has been found in preschool children (Steinsbekk et al. 2017), school-age children, adolescents, and young adults (Zickgraf and Ellis 2018). In school-age children with a diagnosed anxiety disorder, Zickgraf and Ellis (2018) found that aversive sensory sensitivity mediated completely between anxiety levels and PE; they found a similar pathway in healthy college students in their early twenties – the young adults' aversive sensory sensitivity mediated between their anxiety level and their PE. Kauer et al. (2015) found that adult Pes had more obsessive-compulsive symptoms and disgust propensity. To summarize, across development from young childhood to young adulthood, having strong aversion to sensory stimuli in realms unrelated to food is a considerable contributor to PE.

Sensory sensitivity is quite marked in vignettes I and III; in the other accounts, the sensory sensitivity is limited to taste and smell.

Temperament, Fearfulness, and Inhibition

An initial influence on the child's appetitive behavior can be due to temperament. Negative emotionality in toddlers is predictive of PE in later childhood (Hafstad et al. 2013) and cross-sectionally differentiates between toddlers who are PE and those who are not (Zohar et al. 2019). Obesity-prone children who exhibit high levels of PE have many more behavioral and emotional difficulties (Lepinioti et al. 2021).

Behavioral problems are elevated in young children who are described as PE. These include externalizing behavioral problems (Jacobi et al. 2008), as well as internalizing behavioral problems, and in particular affective problems (Zohar et al. 2019). This is also true in school-age children (Machado et al. 2016) and adolescents up to the age of 18 (Machado et al. 2021).

Typically developing children develop fears of imaginary characters, of harm to themselves or others, fear of strangers and strange situations, and may also suffer from night terrors (Zohar and Felz 2001). Children who were identified as PE at age 3 were elevated for all these normative childhood fears compared to typically developing children who were not PE (Zohar et al. 2019).

Deficiency in executive function, particularly in emotional regulation and shifting, differentiates children with PE at 3 from children without PE (Zohar et al. 2019) and predicts the persistence of PE to 8 years of age (Zohar et al. 2020). Although executive function is crucial for behavior regulation (Isquith et al. 2004), it has not been much studied in relationship to PE in children, and not at all in adults.

Children who are Pes and young adults who self-report as Pes may have a greater tendency to be shy, inhibited, anxious, and/or depressed, and these tendencies may characterize the individual and contribute to low appetite and PE.

Less-Studied Issues

Although the literature on PE is large and growing, there are several outstanding issues that bear additional scrutiny. Although there is a plethora of research on risk factors, there is less on protective factors. It is still difficult when examining a 3-year-old Pe child to predict if the individual child will outgrow this PE phase or whether the child is set on a trajectory of persistent and potentially dangerous PE. In vignette I, the mother assumed that her baby son's extreme pickiness was a phase; sadly, she was mistaken. There is a need to better understand the continuity between childhood PE and adult PE. The sensory and genetic underpinnings of PE and neophobia bear further study. And the contribution of difficulties with executive function, in children and young adults to PE, is a promising line of research that has not been pursued.

Practical Advice

For children who are low in appetite and restrictive in their food choices, and are low on their developmental trajectory, parents should first seek a medical evaluation to rule out health complications. When and if ruled out, parental common sense should prevail. Parents should avoid keeping foods in the house that they prefer their children not to eat. Parents should avoid power struggles over food and let the children lead in what and how much they eat out of the available foods that the parents deem healthy. If parents find themselves regularly pressuring, cajoling, or preparing special and different meals for their child, or for each of their children, then they are accommodating their children's pickiness and reinforcing it (Shimshoni et al. 2020). Treatment of extreme PE in children and adults can be sought in serious cases, and treatment follows the general principles of exposure (to more foods) and anxiety reduction. Young adults who seek treatment for their PE can be treated by dieticians who specialize in PE along the same principles. In the absence of distress or adverse health implications of PE, Pes should be left to enjoy their choices and their PE should not turn into a personal or social issue.

(1) A mother's account.

The only picky eater among my children was and is my youngest and fourth child. When he started sitting in a high chair and eating solids, I would put different vegetables on his tray for him to pick up and eat. He would try to pick them up and was obviously repelled by their texture. When I tried to spoon feed him he would look disgusted, and push the food out with his tongue. He absolutely rejected all vegetables and fruit, and to this day (at 26 years of age) will not eat any fruit. He was very sensitive to textures – of food and other things. He would not wear anything

with a label. I didn't concern myself too much about his diet – he was a fourth child, I was an experienced mother, and I expected it was just a phase. Our family is not particularly focussed on eating a healthy diet, and I didn't enter into conflicts with him or go to extraordinary lengths to look for vegetables and fruit that he would eat. There was a process of adaptation in which we discovered the limited list of foods that he was willing to eat, and made sure that some of them were available at meals. Sometimes I feel guilty I didn't try harder, and think he would have grown taller if he had eaten a more varied and nutritious diet. Even as an adult man, he eats very few vegetables and no fruit, but any kind of meat. I don't think he is much inconvenienced by his limited diet, except when people start fussing about it, or when he is out of the house and has difficulty finding foods that he can eat.

(II) A mother's account.

My eldest (now 27) was a very good eater as a baby and a young child. She nursed well, and loved the pureed food which at that time was the first non-milk food offered to very young children. To this day one of her favourite foods is apple puree. When she was in nursery school and kindergarten she ate with the other children and the staff never complained about her eating. I first noticed how restricted her diet was when she was a schoolchild (over 6). She would not eat any raw vegetables, very few fruits, and preferred potatoes, (white) rice, pasta and (white) bread. She would eat some proteins, chicken or beef if they were processed and had a smooth texture, and eggs in any form. Some hummus and tahini. She would eat vegetable soup if it was pureed, and particularly liked pumpkin. The restriction of her diet was a problem for her mainly when adults tried to pressure her to eat "healthy" food she could not eat. Then as now, she loved fried food. I worried about her nutrition and health. When she was about 10 or 11 years old, I consulted our paediatrician as well as a dietician. They did not have much constructive advice. As she matured, she was able to extend her diet. She has adopted tomatoes, raw, cooked, chopped and pureed. She loves basil pesto. She eats onions. She can mostly get by with food she cooks herself and eating with friends is part of her very active social life. She is very overweight, but I think this is mostly the result of not having enough physical activity, and does not result from her picky eating.

(III) A picky eater's account (30 years old at interview)

I was a picky eater from day one – my mother likes to say from the moment I was hatched. There was a wide range of things I couldn't eat – most fruit and all vegetables repelled me. When I first went to kindergarten my mother told the teacher that I could not eat tomatoes. The teacher was not deterred but several hours later had to call my mom to come and pick me up because I was vomiting so violently. Our house had a traditional cuisine, with a lot of meat, rice, and fried food, which I loved. There wasn't great emphasis on healthy eating, or on fruits and vegetables. I was a plump child, with a preference for processed food, dry hard food, and an aversion from anything that was or felt wet. Cucumbers I cannot stand to this day- they are wet and they smell. The smell of melon, watermelon, banana, can make me gag. The texture of soft fruits like plum or peach is unbearable for me. I can eat hard cheese, but it leaves my mouth feeling like sandpaper. I remember the adults around me being frustrated and angry about my pickiness, and also worrying that I was

gaining weight because I was eating a lot of junk food, and rejecting fruit and vegetables. I think it affected my body image even as a child; I also felt I was harming myself by not eating most of the foods. In the family I was ridiculed and tagged as a problem eater. When I left the house as a young adult I started working to extend my diet. I can now eat tomatoes; I can eat strawberries, and certain sautéed vegetables like broccoli. My boyfriend and his family are into healthy eating and that exposed me to more foods, some of which I now eat. My sensitivity is not restricted to food – loud sounds and especially loud talking actually hurt my ears; Although I enjoy being touched I am also extremely sensitive to touch, and this may mean that I will not be able to nurse my baby when she is born. I worry now that I am pregnant that the baby may not be getting the nutrition she needs and will suffer because of my pickiness.

(IV) An adult man's picky eater's account (55 years of age)

I am second out of four children, and although my sister is also picky, I have always been, and still am the most extreme picky eater in the family. As a child I was very sensitive and prone to moods. I would only eat a very limited number of foods; no vegetables, for fruit – only apples and carrots (laughs). I would eat processed meat, rice, and potatoes. Bread with chocolate spread. Very little else. There is a big category of foods that I call sour; I cannot abide sour food. Melon and watermelon are sour, as are many other things. When I was twelve we moved to a Kibbutz with a communal dining room. So not only was I a skinny runt (he is still extremely thin, AHZ), but there was no accommodation for my restricted diet and I had great difficulty finding things I could eat. My pickiness made me even less acceptable to my new peers and I was bullied by them. When I was in college living in the dorms I extended my diet a little – I learned to eat eggs cooked in certain ways as well as toasted cheese sandwiches. When I taste food that is unacceptable to me, I gag and spit it out. Today, my picky eating is less of a problem because I can usually determine what I will eat. I have problems when attending a social event, when I have to find things that I can eat. Being a guest in someone's home requires a lot of preparation and explanation, and sometimes is embarrassing for me and disappointing or hurtful to my hosts. However, when I go out to a restaurant with friends I can nearly always find something on the menu to eat.

(V) A young woman's account (26 years of age)

I have always been a picky eater. The list of things I can eat is very limited. My younger brother – is the opposite, he is omnivorous and a very large man. I have always been very small and skinny for my age. To be drafted into the army I made a special effort and gained weight to meet the minimal weight – 37 kilograms (81.6 pounds). I am known as a problem eater in the family. I cannot eat beef, only chicken breast; I can eat rice and potatoes. I avoid most vegetables and fruit. I love sweet processed foods like breakfast cereals, and certain candy bars. I am not very motivated to eat – I can forget to eat or not be bothered to for a whole day. During corona, when studies were on zoom, I forgot to get out of my chair and eat for entire days. But I am a nibbler and always have snacks in my backpack (shows a bag of cereal she has taken along). My best cooked food is pasta, and I can eat it with tomato sauce or with a cream sauce as long as no vegetables are included. That is

what I ate during my army service. When the family goes out for a meal, I try to study the menu in advance to identify things that I can eat. Sometimes there is a children's meal that is appropriate. My family complains a lot about my limited eating and the difficulties it poses for family events. I do not like to have my eating focused on, and find it unpleasant at family meals and social events when my restricted eating is noticed. I don't know if it effects my health, I am phobic about needles I am not monitored regularly.

Applications to Other Eating Disorders

Picky eating is not an eating disorder, yet it is linked to the restrictive eating disorders. ARFID includes aspects of picky eating in its first diagnostic criterion. AN is characterized by eating very limited amounts of food within a highly restricted range. So, picky eating can be conceived as a component of these disorders. There is some literature linking picky eating in childhood to eventual obesity, but the evidence is weak and arguable. The impulsive urges salient in bulimia and binge eating disorder seem to be in direct contradiction to the inhibited behavior seen in picky eating, and there is no research linking picky eating to the bingeing disorders. Picky eating in children is often the focus of parental feeding practices that do not promote healthy eating habits and can increase risk for the development of restrictive eating disorders.

Mini Dictionary of Terms

Appetitive tendency

- A tendency present early in development to approach and consume food; children with a low appetitive tendency are likely to eat small amounts, enjoy food less, and eat slowly, while children with a high appetitive tendency will do the reverse.

Picky eating

- Eating behavior characterized by low intake of food, rejection of new foods, food rejection because of texture or smell, and is usually exhibited by individuals with low appetitive tendencies.

Pressure to eat

- Parental feeding behavior intended to influence the child to eat greater amounts or to eat particular foods that the child rejects. The pressure might manifest in exerting parental authority, evoking guilt and shame in the child, or using food as reward or punishment,

Key Facts of Picky Eating in Children and Young Adults

- Picky eating is one of the most common presenting problems brought to the clinical attention of pediatricians in wealthy countries.
- It is difficult to untangle parental feeding behavior from child eating behavior in regard to child picky eating.
- It can cause social and emotional impairment in both children and young adults.

Summary

- About 20% of children go through a phase of picky eating, although there is great cultural variation.
- Most children will outgrow this behavior over development.
- Although cross-sectional studies show that children with picky eating are more prone to emotional and behavioral problems than their nonpicky peers, these problems tend to remit as picky eating wanes.
- Only about 4% of children persist in picky eating throughout childhood.
- Self-described picky eating is common in young adults and is associated with emotional and social dysfunction.
- There is retrospective evidence that persistent picky eating throughout childhood increases risk for restrictive eating disorders.
- Individuals who are consistently picky eaters from childhood into adulthood tend to be either under- or overweight as adults.
- Adults picky eating is a relatively new but fast-growing field of study.

Part VI

Diagnosis, Delective Questionnaires, and Resources

Assessing Orthorexia Nervosa by Questionnaires

71

Melda Pelin Yargic and Murat Cenk Celen

Contents

Abstract

With a growing research interest directed at orthorexia nervosa (ON), specifically at measuring it accurately, today there are many measurement tools available in the scientific literature. Due to the lack of a consensus on the diagnostic criteria of ON for many years, the early scales, which are the most commonly used ones, lack questioning some key features of the disease, in addition to lacking adequate

validity. Researchers who noticed this shortcoming started working on developing new measurement tools. In this chapter, we will review these 10 ON measurement tools and their properties: Bratman Orthorexia Test (BOT), ORTO-15, Body Image Screening Questionnaire (BISQ), Düsseldorf Orthorexia Scale (DOS), Orthorexia Nervosa Scale (ONS), Burda Orthorexia Risk Assessment (B-ORA), Teruel Orthorexia Scale (TOS), The Barcelona Orthorexia Scale (BOS), Orthorexia Nervosa Inventory (ONI), and Test of Orthorexia Nervosa (TON-17). Our aim is to provide researchers and clinicians with the information they require regarding the content, validity, reliability, and other distinct properties of the questionnaires.

TON-17	Test of Orthorexia Nervosa
TOS	Teruel Orthorexia Scale

Introduction

Orthorexia nervosa (ON), which is often referred to as a lifestyle syndrome, is a disordered eating behavior. The word "orthorexia" was put together by Bratman in his article "Health Food Junkie" which was published in Yoga Journal in 1997 (Bratman 1997). The term implies an unhealthy preoccupation with healthy eating. There is an ever-growing interest in orthorexia nervosa, although it lacks the proper recognition in the current diagnostic classifications.

Questionnaires are a set of previously determined questions to determine the attitude, behavior, or situation on a particular topic. This topic can be related to all areas of life, as well as human health. For many years, questionnaire research has been used for many of the studies in the field of medicine and has been especially preferred by epistemologists in examining the attitude and behavior dimension of disease and health (Mandal et al. 2000). In general, questionnaires are not a preferred

Fig. 1 Orthorexia nervosa is an unhealthy preoccupation with healthy eating. (Image: Freepik)

method in the diagnosis phase of patients. It is mostly used in the self-reported, systematic determination of the factors that cause the formation of the disease (Fig. 1).

The *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (*DSM-5*), published by the American Psychiatric Association is the most up-to-date manual accepted as a reference when defining certain psychiatric conditions as a psychiatric disease (American Psychiatric Association 2013). Although orthorexia nervosa is a condition that is increasingly recognized and of interest as a research topic, it is still not defined as a disease in the *DSM-5*. Therefore, it is not possible to use the *DSM-5* diagnostic criteria for orthorexia nervosa, as we do for other eating disorders. Even so, Dunn and Bratman have suggested diagnostic criteria for the condition: an obsessive focus on "healthy" eating (Criterion A) and clinically impairing compulsive behavior and mental preoccupation (Criterion B) (Dunn and Bratman 2016). In this context, questionnaires assessing orthorexia nervosa are very much needed, not necessarily for making a diagnosis, but to clarify which populations are under higher risk for ON, which clinical conditions are often associated with it, and its many unknown properties (Fig. 2).

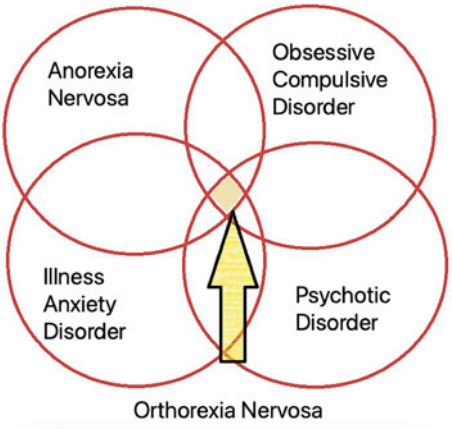

Fig. 2 Association of orthorexia nervosa with other eating-related disorders

In this section, the questionnaires used in studies on orthorexia nervosa, their compatibility with each other, and how inferences are made from the information obtained from these questionnaires will be discussed.

Which Questionnaires Are Used in Orthorexia Nervosa Studies?

The number of orthorexia nervosa questionnaires used in current studies is relatively high. The first of these questionnaires was conducted in 2000 by Bratman, who described this eating disorder condition as orthorexia nervosa (Bratman 2000). At least 10 different questionnaires appear to be used to measure ON nowadays. Although some of these questionnaires are about eating disorders in general, studies show that they can be used in the detection of ON. Important details such as the scope of the questions and the explanations suitable for the person to answer affect the reliability and validity of the scales. Translations of the questionnaires in various languages require new reliability and validity studies, in some cases resulting in extracting certain questions from the scale. Each scale used for the measurement of ON has its strengths and weaknesses. It should not be aimed to decide on one single scale which is "the best" measurement scale for ON in general but to find the best scale for each varying study purpose and condition (Table 1).

Bratman Orthorexia Test

Bratman Orthorexia Test, also referred to as Orthorexia Self-Test, was developed by Bratman and Knight, and it consists of 10 questions in dichotomous response format (Bratman 2000). Each positive answer is recorded as one point, and a higher sum score shows a higher tendency towards ON. Although the cutoff value does not have

Table 1 The scales that will be reviewed in this chapter

Name of scale	Abbreviation	Reference
Bratman Orthorexia Test	BOT	(Bratman 2000)
ORTO-15	ORTO-15	(Donini et al. 2005)
Body Image Screening Questionnaire	BISQ	(Jenaro et al. 2011)
Düsseldorf Orthorexia Scale	DOS	(Barthels et al. 2015)
Orthorexia Nervosa Scale	ONS	(Kramer 2016)
Burda Orthorexia Risk Assessment	B-ORA	(Burda 2018)
Teruel Orthorexia Scale	TOS	(Barrada and Roncero 2018)
The Barcelona Orthorexia Scale	BOS	(Bauer et al. 2019)
Orthorexia Nervosa Inventory	ONI	(Oberle et al. 2021)
Test of Orthorexia Nervosa	TON-17	(Rogowska et al. 2021a)

a valid basis, patients who score four and higher are considered to suffer from ON by Bratman. Some studies have used the BOT with a 4-point Likert scale instead of a yes/no format, to have more comparable results with other measurement tools (Meule et al. 2020). A good internal reliability was shown for BOT (Cronbach α: 0.79), but its test-retest reliability has not been measured yet. German and Swedish translations are available for the scale (Rössner 2004; Kinzl et al. 2005).

BOT is the oldest ON measuring tool available, which makes it difficult to catch up with the conceptual changes about ON. Recognizing this shortcoming, Steven Bratman updated the scale by associating it with the new diagnostic criteria, which were also set forth by him, and published ABOST (Authorized Bratman Orthorexia Self-Test) (Dunn and Bratman 2016; Rogowska et al. 2021b). The ABOST has six items instead of 10, and even one positive answer points out an increased risk of ON. One study investigated the reliability and validity of the ABOST with two answering formats (a dichotomous format and a continuous 5-point Likert scale). The latter showed a good validity and reliability, whereas the former did not meet the reliability and validity criteria (Rogowska et al. 2021b).

There has been no validity or reliability studies published regarding the ABOST yet, other than its Polish adaptation study (Rogowska et al. 2021b).

ORTO-15

ORTO-15, a 15-item questionnaire developed by Donini, is scored on a 4-point Likert scale (Donini et al. 2005). ORTO-15 uses some items of the BOT by changing the wording and adding new items to them. Therefore, there is no harm in saying that ORTO-15 was heavily inspired by the BOT. ORTO-15 has six items focusing on the cognitive factors related to eating behavior, five items related to clinical factors, and four items related to emotional factors. However, a sum score is evaluated rather than calculating separate scores for each dimension (Table 2).

Items 2, 5, 8, and 9 are scored as always 4, never 1. The rest of the items other than 1 and 13 are scored in reverse. Items 1 and 13 are scored as such: Always = 2,

Table 2 Number of questions and used Likert scale in questionnaires

Name of scale	# of questions	Likert scale
Bratman Orthorexia Test (BOT)	10	4-point
ORTO-15	15	4-point
Body Image Screening Questionnaire (BISQ)	24	5-point
Düsseldorf Orthorexia Scale (DOS)	10	4-point
Orthorexia Nervosa Scale (ONS)	47	5-point
Burda Orthorexia Risk Assessment (B-ORA)	21	4-point
Teruel Orthorexia Scale (TOS)	17	4-point
The Barcelona Orthorexia Scale (BOS)	64	Self-statement
Orthorexia Nervosa Inventory (ONI)	24	4-point
Test of Orthorexia Nervosa (TON-17)	17	5-point

Often = 4, Sometimes = 3, and Never = 1. Higher sum scores indicate a lower tendency towards ON behavior (Donini et al. 2005).

Creators of the ORTO-15 have also attempted to set a cutoff value for ORTO-15, trying out three different values (<35, <40, and <45). They observed increasing sensitivity and decreasing specificity and efficacy with increasing threshold values, so much that at the threshold value of 45, efficacy of the test was as low as 37.4%, which made it unreliable. However, when the threshold was set at 35, the sensitivity and positive predictive value were 0%. Therefore, the threshold was set at 40, where it confirmed substantial validity. A very problematic issue with ORTO-15 and its threshold is that its predictive capability covers healthy eating behavior but fails to differentiate any obsessive traits (Donini et al. 2005). The use of any cutoff values was later criticized heavily for resulting in erroneous inferences, and it was suggested that researchers should not utilize cutoff values and should not report prevalence rates with regard to these cutoff values (Rogoza and Donini 2021). This criticism was based on the many unrealistic reports of ON prevalence across different populations (many of them higher than 50%, one study even 88.7%) (Aksoydan and Camci 2009; Ramacciotti et al. 2011; Souza and Rodrigues 2014; Segura-Garcia et al. 2015). Although ORTO-15 is the most widely used measurement tool in ON research and has the most language adaptations, such as Turkish, Russian, Arabic, Polish, French, Greek, German, Spanish, and Italian (Arusoğlu et al. 2008; Alvarenga et al. 2012; Brytek-Matera et al. 2014; Missbach et al. 2015; Stochel et al. 2015; Parra-Fernandez et al. 2018; Babeau et al. 2020; Haddad et al. 2020; Gonidakis et al. 2021; Zemlyanskaya et al. 2021), its validity and reliability are very questionable. In fact, many studies reported very low internal consistency reliability and poor validity for ORTO-15 (Missbach et al. 2015; Heiss et al. 2019; Mitrofanova et al. 2021). In one study ORTO-15 had a Cronbach α value of 0.23, whereas a limited version of it (ORTO-11) had 0.74 (Roncero et al. 2017). The language adaptation studies have extracted items that had low factor loadings, and this resulted in different questionnaires with varying numbers of items included, such as ORTO-11, ORTO-9, and ORTO-6. Two recent studies addressed the factor stability issue of the ORTO-X's available and proposed two new scales: ORTO-7

and ORTO-R. Moller et al. suggested that ORTO-15, ORTO-11, and ORTO-9 have poor model fits and developed a new version consisting of seven items using exploratory factor analysis and confirmatory factor analysis in combination. Authors have reported that ORTO-7 has a strong, stable factor structure in contrast to the previous versions (Moller et al. 2019). Another revised version of ORTO-15 is the ORTO-R, which was developed using the very original data of Donini. ORTO-R also addresses the same problem, namely, the factorial instability of ORTO-15. It consists of six items, none of the items are coded reversely, and a higher score indicates a higher tendency of ON (Rogoza and Donini 2021). All versions of ORTO-15 are still being widely used in the scientific literature across various populations such as university students, athletes, artists, patients who suffer from other eating disorders, etc.; yet it is fair to suggest the use of the two newly proposed versions (ORTO-R and ORTO-7) in forthcoming research instead, which have proven factorial stability (Vuillier et al. 2020; Özdengül et al. 2021; Rodgers et al. 2021; Hallit et al. 2021b).

Body Image Screening Questionnaire (BISQ)

In 2011, the Body Image Screening Questionnaire was first used by Jenaro et al. in Spain (Jenaro et al. 2011). According to this study conducted with 395 participants, results show that the questionnaire could be used in the assessment of eating disorders such as orthorexia, anorexia, obesity, and bigorexia. Only Romanian adaptation of the mentioned assessment technique was made. This study, in which a 24-item version was applied to 156 participants, was used to evaluate the psychometric properties of the scale and reported adequate internal consistency (Tomsa et al. 2012). This questionnaire was originally made in Spanish. There is no English adaptation study. Therefore, there are very few original studies on ON assessment using this scale in the literature. Although its validity and reliability have been demonstrated, when using BISQ in your research, it should be kept in mind that there is very limited literature to compare the results. Also, BISQ's test-retest reliability has not been examined yet (Table 3).

Düsseldorf Orthorexia Scale (DOS)

Düsseldorf Orthorexia Scale consists of ten items, which are answered on a 4-point Likert scale: This does not apply to me = 1, This does rather not apply to me = 2, This does somewhat apply to me = 3, and This applies to me = 4. It was originally developed in German. It shows a good internal consistency with a Cronbach α value of 0.84 (Barthels et al. 2015). As it has a much better internal consistency, some authors suggest the use of DOS instead of ORTO-15 (Meule et al. 2020). It has Chinese, Polish, English, Italian, French, and Arabic language adaptation available (Chard et al. 2019; He et al. 2019; Brytek-Matera 2021; Cerolini et al. 2021; Hallit et al. 2021a; Lasson et al. 2021).

Table 3 Evaluation standard and Cronbach α values of questionnaires

Name of scale	Evaluation standard	Cronbach α value
Bratman Orthorexia Test (BOT)	4 or higher	0.79
ORTO-15	Higher sum lower tendency	0.23
Body Image Screening Questionnaire (BISQ)	Higher sum score higher tendency	Not found
Düsseldorf Orthorexia Scale (DOS)	Higher sum score higher tendency	0.85
Orthorexia Nervosa Scale (ONS)	Higher sum score higher tendency	.
Burda Orthorexia Risk Assessment (B-ORA)	Higher sum score higher tendency	0.97
Teruel Orthorexia Scale (TOS)	Higher sum score higher tendency	0.87
The Barcelona Orthorexia Scale (BOS)	Higher sum score higher tendency	Not found
Orthorexia Nervosa Inventory (ONI)	Higher sum score higher tendency	0.84
Test of Orthorexia Nervosa (TON-17)	61 or higher score higher tendency	Not found

Orthorexia Nervosa Scale (ONS)

Orthorexia Nervosa Scale was developed by Kramer in 2016, and it was further updated in 2019 (Kramer 2016, 2019). ONS consists of 47 items, answered on a 5-point Likert scale where 1 = Strongly Disagree, 2 = Disagree, 3 = Neither Agree or Disagree, 4 = Agree, and 5 = Strongly Agree. The purpose of the scale is to accurately measure ON in the US sample, as most of the other measurement tools are valid for European populations. Its psychometric properties were studied by Conrad, suggesting a two-factor solution after an exploratory factor analysis: behavioral dysfunction and social dysfunction. The scale has a high internal consistency (Conrad 2019).

Burda Orthorexia Risk Assessment (B-ORA)

BORA, developed by Lilo Burda, explores orthorexic tendencies. It consists of 21 questions. All questions are scored based on a 4-point Likert scale (strongly agree = 1, somewhat agree = 2, somewhat disagree = 3, strongly disagree = 4). The highest total score attainable is 84 and the lowest 21, with a higher score indicating less orthorexic tendencies. It has a good internal consistency (Cronbach $\alpha = 0.97$), which is a property that more commonly used scales often lack (Burda 2018). However, it does not have a test-retest reliability result. It was developed among

college students and has not yet been validated among other populations or cultures. Also, the lack of original studies making use of BORA is a major disadvantage when it comes to comparing your results.

Teruel Orthorexia Scale (TOS)

Teruel Orthorexia Scale, the first version of which was developed in Spanish by Barrada and Roncero in 2018, is a promising tool for distinguishing healthy orthorexia and orthorexia nervosa (Barrada and Roncero 2018). TOS is used to illuminate the relationship between psychological constructs and disorders like obsessive-compulsive disorder symptoms, negative affect, and perfectionism with orthorexia nervosa. The questionnaire includes 17 items rated on a 4-point Likert scale with Cronbach α value of 0.87 (Barthels et al. 2019). The first nine items question the healthy orthorexia and orthorexia nervosa, whereas the last eight items question the pathological dimension of orthorexia nervosa. Adaptation studies have been carried out in several languages due to its distinctive features (Chace and Kluck 2021; Mhanna et al. 2021; Roberto da Silva et al. 2021). The fact that the English adaptation study has been carried out might accelerate the research using TOS in the coming years. In the English adaptation study, with the concerns of poor differentiation, one item was extracted. The modified TOS showed a good model fit and was accepted; therefore, the English version of TOS is called TOS-16 instead of TOS-17 (Chace and Kluck 2021) (Table 4).

Table 4 Language revisions of questionnaires

Name of scale	Language revisions
Bratman Orthorexia Test (BOT)	German, Swedish
ORTO-15	Turkish, Russian, Hungarian, Arabic, Polish, French, Greek, German, Spanish, and Italian
Body Image Screening Questionnaire (BISQ)	Spanish, Armenian, no English ver.
Düsseldorf Orthorexia Scale (DOS)	Chinese, Polish, English, Italian, French, and Arabic
Orthorexia Nervosa Scale (ONS)	No other version
Burda Orthorexia Risk Assessment (B-ORA)	No other version
Teruel Orthorexia Scale (TOS)	English
The Barcelona Orthorexia Scale (BOS)	English, Spanish
Orthorexia Nervosa Inventory (ONI)	Turkish
Test of Orthorexia Nervosa (TON-17)	No other version

The Barcelona Orthorexia Scale (BOS)

The Barcelona Orthorexia Scale was developed using the Delphi method. 58 experts from 17 different countries participated in the study, and an initial item pool consisting of 105 items was evaluated in 3 rounds. Finally, 64 items were obtained. Items are grouped into 6 domains: cognitive domain (14 items), emotional domain (16 items), behavioral domain (14 items), negative consequences – health (6 items), impairment in social or academic functioning (9 items), and differential diagnosis (5 items). These items are selected due their content validity according to expert opinion, but they lack any study on their psychometric properties. Therefore these selected 64 items are not the final version (Bauer et al. 2019). BOS has two versions in Spanish and English. It is a very promising measurement tool for ON, which is currently under development.

Orthorexia Nervosa Inventory (ONI)

ONI consists of 24 items, of which 9 assess behaviors and preoccupation with healthy eating, 10 assess physical and psychosocial impairments, and 5 assess emotional distress. Items are scored on a 4-point Likert scale (very true = 4, mainly true = 3, slightly true = 2, not at all true = 1). Higher scores indicate a higher tendency towards ON. One of the strengths of ONI is that it has a very high internal consistency (Cronbach $\alpha = 0.94$) and 2-week test-retest reliability (ICC = 0.91) (Oberle et al. 2021). What makes ONI further advantageous is that it takes the physical impairments associated with ON into account. Although these impairments are agreed to be a key component of the disease, none of the previous measurement tools evaluated this aspect.

On ONI, items 10, 24, 12, 5, 19, 14, 3, 20, 7, and 16 belong to the "impairments" factor; items 17, 11, 8, 6, 22, 8, 15, 4, and 2 belong to the "behaviors" factor; and items 9, 13, 1, 23, and 21 belong to the "emotions" factor.

ONI already has a Turkish language adaptation (Kaya et al. 2021). As it is a very newly developed scale, it certainly lacks results in different populations and cultures.

Test of Orthorexia Nervosa (TON-17)

TON-17, which was initially TON-40 but was reduced to TON-17 as a result of the structural analysis, was developed in response to the need for a reliable and new method to measure ON emphasized in the literature (Valente et al. 2019; Rogowska et al. 2021a). It consists of 17 items, in 3 subscale factors (control of food quality, fixation of health and healthy diet, and disorder symptoms). Each item is answered on a 5-point Likert scale and scored as follows: 1 = Strongly disagree, 2 = Rather disagree, 3 = Undecided, 4 = Rather agree, and 5 = Strongly agree.

The authors suggest the use of a cutoff value of 61 points as an indicator for high ON risk. TON-17 currently has English and Polish versions, and this promising measurement tool for ON requires to be used in different populations and cultures.

In summary, there are many options for researchers and clinicians when it comes to assessing ON. But it should be kept in mind that most measurement tools fall somewhere in between measuring "healthy eating" and "being obsessed with healthy eating." This is especially important when using the older scales. Also, it is very interesting to see that the most commonly used tools have the poorest validity and reliability values among all. Researchers and clinicians should pay attention to the newly developed measurement tools and always make sure they check the psychometric properties of the tools they choose to apply.

Application to Other Eating Disorders

In this chapter, we have reviewed questionnaires that can be used to evaluate orthorexia nervosa. However, a similar approach is also widely used when assessing all eating disorders. For example, scoring 2 or higher in the SCOFF questionnaire (which is an acronym for Sick, Control, One, Fat, Food) raises suspicion of anorexia nervosa or bulimia. It consists of five simple questions answered with yes or no. Being developed in 1999, it has been adapted to more than 10 languages and was used among various populations, such as children, adolescents, athletes, depressed patients, and so on (Morgan et al. 1999). An even older questionnaire is the Dutch Eating Behaviour Questionnaire, which consists of 33 items and measures 3 different psychologically based eating behaviors: emotional eating, externally induced eating, and restrained eating (Wardle 1987; Bozan et al. 2011). Similarly, EDE-Q (Eating Disorders Examination Questionnaire) is a 36-item questionnaire that assesses the specific psychopathology of eating-disordered behavior (Mond et al. 2004). The Eating Disorders Inventory (EDI) and EDI-2, which is an adapted version of EDI, are also widely used self-reported measures of symptoms of eating disorders (Garner et al. 1983). A more recent questionnaire developed to examine eating disorders is the Survey for Eating Disorders (SEDs), which is another valid and reliable tool with a high positive predictive value. In summary, questionnaires have been widely used for decades in the evaluation of all eating disorders and will continue to be used due to their advantages such as ease of application, objective evaluation, and allowing for comparison of results.

Mini-Dictionary

- **Validity**: The degree to which a construct is accurately measured.
- **Reliability**: The consistency of a measure. It includes aspects such as internal consistency and stability.

- **Internal consistency**: The degree to which all items included in a test are consistent with each other. To test internal consistency, the correlation is checked one by one between all the items.
- **Stability**: The correlation between the answers of the same subject to the measure at two different times. Also called test-retest reliability.
- **Cronbach α value**: Indicates the level of internal consistency (shows excellent reliability when >0.90).

Key Facts of Assessing Orthorexia Nervosa by Questionnaires

- There are some statistical methods to make sure that questionnaires successfully measure what they aim at. With these methods, the validity and reliability of the questionnaires can be determined. If the questionnaires are used in research without paying attention to these features, it can lead to erroneous inferences and even misdiagnosis.

Summary Points

- There is an ever-growing research interest in ON; most of it focused on measuring ON accurately.
- There are numerous available scales to evaluate orthorexia nervosa.
- It is necessary to pay attention to their psychometric properties when deciding which one to use in your research or clinical practice.
- Some scales were developed before a consensus was reached on the diagnostic criteria of the disease; therefore, they do not question all the clinical features of ON.
- Some of the newly developed scales are very promising as they are based on the conceptual background of the disease, question all clinical features, and have a high validity and reliability.

The Eating Disorder Quality of Life (EDQoL) Scale 72

Methods and Applications

Paolo Meneguzzo, Enrico Collantoni, Valentina Meregalli, Elena Tenconi, and Angela Favaro

Contents

Abstract

Patients with an eating disorder present a severe reduction of their quality of life (QoL) during the acute phase, which could also impact their treatment outcome. Different studies have pointed out the role of QoL in both physical and psychological well-being, and slight differences have been pointed out between eating disorder diagnoses, showing a transdiagnostic impairment in this specific aspect of patients' lives. Different domains have been included in the evaluation of the QoL: psychological, physical, cognitive, financial, work/school, and

interpersonal. The relevance of the interpersonal domain is profoundly discussed in the chapter and how it has been included in the original version of the EDQoL questionnaire. Despite the role of this aspect in the patients' lives, the literature's evidence is limited, and possible future directions are discussed.

HRQoL	Health-related quality of life
QoL	Quality of life

Introduction

In recent decades, eating disorders (EDs) have presented an increased epidemiological impact in young women and girls and a progressively decreased age of onset (Favaro et al. 2009). Recent evidence has also underlined the underestimation of the incidence of EDs in males, especially during adolescence, when one-third of patients are boys (Murray et al. 2017). These psychiatric disorders have consistent effects on physical, psychological, and social facets of life, especially given their tendency to evolve into chronic disorders or partial recovery, with possible relapses (Steinhausen 2002, 2009). These physical, mental, and social impairments can be long-lasting and evolve into severe difficulties in different facets of patients' lives. The medical complications of EDs have an impact on almost all organ systems. These complications are life-threatening and potentially irreversible, and they are consequences of starvation, binge eating, or purging behaviors (Rome and Ammerman 2003).

In recent decades, researchers and clinicians have moved from measures of psychopathology to looking at the impairment caused by disorders, taking into account the change of perspective suggested by patients with a long history of ED. Indeed, due to the possible roles of EDs in the everyday lives of patients, growing importance has been placed on the measurement of quality of life (QoL). Quality of life is defined as a person's perception of their position in life regarding their goals, expectations, and concerns and their quantitative evaluation of how they experience their life overall (Engel et al. 2009). The evaluation of QoL in ED patients provides indicators of their satisfaction with their lives and recovery levels (Mitchison et al. 2016). To allow the evaluation of the effects of EDs on patients' lives and the effects of psychosocial treatments, specific self-report questionnaires about health-related quality of life (HRQoL) have been validated. These instruments allow clinicians and researchers to obtain standardized data for comparison and

objective evaluation. Dedicated questionnaires also allow to find out aspects specifically linked to the symptomatology of a disorder, increasing data robustness.

Quality of Life in Eating Disorders

Even if several papers focused on QoL in EDs, the literature still seems very limited, with a predominance of cross-sectional approaches and few speculations about specific aspects linked to QoL. In a comprehensive overview, QoL appears to be compromised in EDs. Still, it is also significantly related to the different levels of insight of the patients about the existing impacts of ED symptoms on their lives.

Looking at the specific effects of EDs on the QoL of patients, a systematic review of the existing literature has suggested that there are no marked differences between diagnoses in the impairment of QoL of ED patients (Ágh et al. 2016). This evidence corroborates the results of a previous meta-analysis that showed a substantial decrease of the QoL throughout the entire ED spectrum, regardless of diagnosis (Winkler et al. 2014). The literature also underlines the shared increased healthcare system use and costs compared to controls (Agh et al. 2015). However, these results have to be taken with the consideration that the number of studies is limited and different questionnaires have been applied, with a possible bias effect on results. Moreover, ED patients – especially in patients with anorexia nervosa (AN) – have shown the presence of a reduction of the insight of the disorder. This aspect could bias the results of self-reported questionnaires due to the absence or the reduction of the patient's awareness of the negative impact of their health status (Mond et al. 2005). Indeed, in AN patients, momentary ecological assessments have found a robust relationship between ED symptomatology and QoL, showing a specific role for binge eating behaviors in worsening the perception of their life quality (Mason et al. 2018). Moreover, analysis of the published studies pointed out the need for a distinction in the binge eating spectrum between patients with bulimia nervosa (BN) and binge eating disorder (BED) due to the presence of obesity and its consequent comorbidities (Ágh et al. 2016). Looking into different domains of the QoL evaluation, patients with AN and BN have shown higher scores on social well-being (van Hoeken and Hoek 2020), with patients with AN reporting the highest impairment (Meneguzzo et al. 2020). Another interesting aspect that previous reviews have highlighted is the possibility of a reduced impact on QoL in patients with a diagnosis that do not meet the diagnostic criteria, possibly due to a modest distress (Baiano et al. 2014).

Looking at the literature, robust evidence has suggested the use of ED-specific questionnaires for the evaluation of QoL over generic ones – like the Short-Form Health Survey 36 (SF-36) – due to the possible underestimation of specific behaviors or thoughts that could have relevant roles in the assessment of self-perceived QoL, for example, in AN patients (Muñoz et al. 2009) (Table 1).

Regarding the interpersonal effects of EDs, only one study has evaluated the people who lived with patients (de la Rie et al. 2005). Caregivers and relatives of ED patients reported decreased QoL and a reduction in their psychological well-being,

Table 1 Summary of evidence on quality of life

	Global QoL	Psychological domain	Physical/ cognitive domain	Financial-work/ school domains	Interpersonal/ social domain
Anorexia nervosa	Impaired compared to general population and other EDs. Insight might have a specific role in the reliability of the results	No clear differences across ED spectrum	Impaired compared to general population and other EDs	Impaired compared to general population and to BN, BED, and OSFED	Impaired compared to general population. Some evidence of worse score than patients with BN
Bulimia nervosa	–	No clear differences across ED spectrum	–	–	Impaired compared to general population
Binge eating disorder	–	No clear differences across ED spectrum	Evidence of worse scores due to medical comorbidities	–	No clear evidence of a strong impairment of social domain
Other eating and feeding disorders	Reduced when compared to general population. Little evidence of a reduced burden than other EDs	No clear differences across ED spectrum	–	–	–

with the increase of family conflicts after the development of the disorder by their relative. The QoL of patients' relatives is a less explored aspect of QoL and EDs, even if relatives and caregivers of patients with an ED could have an essential role in treatments (de la Rie et al. 2005).

An interesting relationship between QoL and psychological distress was found in a community-based study that pointed out the bidirectional relationships between QoL and ED symptoms (Mitchison et al. 2015). The authors found that lower levels of QoL and higher psychological distress predict increases in ED symptomatology after 9 years from the first evaluation. Moreover, ED symptoms predict a reduction in QoL at the follow-up. These bidirectional relationships could help clinicians and researchers to move away from symptom-centered approaches in the evaluation of QoL. Indeed, this study helps to point out the complexity of the relationships between QoL and psychopathology and could also suggest the need for more studies

focused on possible latent variables. Moreover, these data reinforce the idea that specific interventions are needed for the improvement of QoL.

Applications to Other Eating and Feeding Disorders

Looking at the existing literature, few data is available about other eating or feeding disorders, mainly because these diagnostic categories were introduced with DSM-5. A reduction of the QoL in individuals with these diagnoses is linked to the presence of a psychiatric or psychological condition, but the levels of burden are still not clear. Indeed, going beyond merely considering them as one non-specified group, we may find different facets of impaired QoL, and, for this reason, future studies should consider this aspect in their research planning. Here is a summary of the preliminary evidence in the literature with a comparison between diagnoses, if available.

People with avoidant/restrictive food intake disorder (ARFID) have reported a reduction of their QoL compared to the general population, but with a reduced compromission of the physical domain if compared to patients with BED (Hay et al. 2017). Pica may have a negative effect on the QoL of the patients and parents, both from stigmatization that may occur and from clinical effects related to the consumption of toxic, contaminated, or inedible substances (Leung and Hon 2019; Liu et al. 2021). However, no study has been specifically conducted for the evaluation of QoL in patients with pica. Rumination disorder impaired QoL of patients due to the effects of their symptomatology on social activities, interpersonal involvement, school absence, and physical health (Mousa et al. 2014). Individuals with purging disorder are characterized by an impairment of physical, psychological, and social domains (Forney et al. 2021). However, no studies are available with a direct comparison of individuals with purging disorder and other EDs like anorexia or bulimia nervosa (Smith et al. 2017). Individuals with night eating syndrome may present an impaired quality of life due to the disruption of the circadian circle, with effects on mood and perceived stress (Vander Wal 2012). The QoL of these patients is compromised, and it has an effect on their ability to reduce their weight during treatment (Calugi et al. 2009). Finally, also individuals with orthorexia nervosa showed an impairment of their QoL in its physical and environmental domains, but the results need confirmatory studies (Strahler and Stark 2020; Sfeir et al. 2021).

Comorbidities

In recent years, there has been a growing concern about pro-eating disorder website communities, which have been cited as possible reinforcing factors in the development and maintenance of EDs (Peebles et al. 2012). In evaluating users of these sites, authors have found a relationship between time spent online in these communities and decreases in QoL and increases in dysfunctional eating behaviors even in individuals without an ED diagnosis according to international criteria. These results

could underline the role of interpersonal reinforcement in EDs, and this is a potential aspect that might be evaluated in future studies, looking for potential ways to improve patients' QoL.

Medical comorbidities like obesity in BED patients have been found to be negative factors for QoL, suggesting the possible role of psychological elements like social exposure or depression in addition to physical factors (Singleton et al. 2019). Moreover, it has been demonstrated that the presence of irritable bowel syndrome, but not functional gastrointestinal-like disorders, is highly related to the QoL reported by patients, with a significant decrease in QoL correlating with increases in intestinal symptomatology (Abraham and Kellow 2011). Similarly, psychiatric comorbidities like obsessive-compulsive behaviors have shown a moderate association with poorer QoL in AN (Young et al. 2018), as well as emotional distress in BN (Ágh et al. 2016).

Looking at demographic data, sex has been found to be a moderator for the relationship between QoL and body objectification (Sanftner 2011). Still, no studies are available with sexual orientation as a variable. Moreover, no study has looked at the possible changes in QoL in different stages of life. So little evidence is available about the demographic aspect linked to QoL.

Treatments and Quality of Life

Looking at the effects of treatments in improving perceived QoL, studies reported that current psychological approaches had modest effects in the improvement of the perceived QoL in ED patients (Linardon and Brennan 2017), and their effects are similar to other psychiatric conditions. Indeed, cognitive-behavioral approaches are tailored to improve eating psychopathology more than QoL, and this aspect should be improved in future studies (Linardon and Brennan 2017). Inpatient treatment has been found to be effective in improving the HRQoL scores in ED patients (Weltzin et al. 2015), but the number of studies is limited, and there is no definitive evidence (Linardon and Brennan 2017). Indeed, other studies have pointed out that dysfunctional elements persist after treatment in patients with EDs despite improving the perceived QoL (Padierna et al. 2000).

In severe and enduring patients with AN, QoL has been the critical element of several studies about its role in treatment approaches, especially regarding the idea that it should focus on the improvement of long-enduring disorders. Study results have reinforced this position, showing that improving patients' QoL after a long duration of the disorder is also linked to weight gain and reductions in ED symptomatology (Bamford et al. 2015). The existing connection between QoL, eating psychopathology, and weight underlines that these three elements could not be treated alone, especially in patients with a long history of disorder.

The Eating Disorder Quality of Life (EDQoL) Questionnaire

One of the first and most used HRQoL questionnaires is the eating disorder quality of life (EDQoL) scale, constructed and validated for the first time by Engel and colleagues in 2006 with the goal of introducing in the literature a validated instrument focused on the domain of QoL as it relates to the clinical impairments of patients (Engel et al. 2006). Previous studies had been conducted with generic QoL questionnaires, obtaining data with smaller effect sizes and fewer specifically related results. An interesting aspect of the transdiagnostic nature of the EDQoL, based on the theoretical perspective on EDs, is that for all the ED diagnoses, clinicians are allowed to evaluate patients across time and determine the diagnostic changes that are common in patients' lives. The EDQoL has demonstrated good psychometric properties with test-retest validity and sensitivity between patients and controls in different languages and ages. In addition, it shows a robust correlation with other psychological constructs more focused on psychosocial impairment in areas like self-perception, cognitive functioning, interpersonal functioning, and work performance. The questionnaire has been translated into different languages, including Italian and German, and all the translations have maintained good psychometric proprieties (Tagay et al. 2010; Meneguzzo et al. 2020).

The EDQoL Domains

Subjective QoL can be reported as a global measure of well-being or satisfaction, or it can be broken down into distinct domains (e.g., psychological well-being). In the development of the EDQoL domains, researchers decided to evaluate different possible domains due to the complexity of the QoL domain in patients with ED (Engel et al. 2006). The authors of the original EDQoL scale pointed out the possible areas where ED patients could be more impaired and produced a large number of items (Engel et al. 2006). The statistical validation of the scale produced four domain areas: psychological, physical/cognitive, financial, and work/school. The authors also included social and legal domains in the original version of the questionnaire, but data did not support their inclusion in the final questionnaire. This aspect could be linked to the items included in the original questionnaire, as well as in the participants of the original evaluation. Indeed, authors of different QoL scales for ED patients have pointed out the possible role of interpersonal domain in patients and included specific items in their questionnaire (Padierna et al. 2000).

Regarding the different domains, the psychological subscale of the EDQoL is focused on emotional states and feelings related to the self and one's everyday activities. The physical/cognitive subscale is related to the physical and cognitive effects that EDs could have on patients, investigating the presence of symptoms like reduced attention or concentration and headaches or weakness. The financial domain evaluates the presence of economic effects of EDs in patients' lives, which could be due to increases in spending or reductions in income. Finally, the work/school domain evaluates the effects of EDs on daily activities. In the Italian version of the

EDQoL (Meneguzzo et al. 2020), the authors increased the number of items on the physical/cognitive subscales, including, for example, teeth pain or problems, constipation, and weight. The result showed good reliability and psychometric values. Therefore, they suggest that items should also be included in different language versions of the questionnaire.

Some differences have been found looking at the impairment of the QoL domains across the ED spectrum. No differences emerged between diagnoses as regards psychological impairment, while in physical/cognitive and financial domains, the results showed worse scores in AN compared to BN, BED, and OSFED (Meneguzzo et al. 2020).

Interpersonal Domain

The interpersonal domain was included in the Italian translation of the EDQoL questionnaire (Meneguzzo et al. 2020) due to the need to evaluate the social interactions of patients, their effects on eating psychopathology, and their role in perceived QoL. The interpersonal domain has a specific role in the development and maintenance of ED psychopathology due to the role of negative social evaluation reported by patients and the effects on self-evaluation (Rieger et al. 2010). Patients reported social isolation linked to interpersonal difficulties. Dysfunctional behaviors could increase the disruption of social connections (Björck et al. 2003; Ivanova et al. 2015; Treasure et al. 2020).

For this goal, questions about interpersonal difficulties were elaborated on using ED research and clinical experts and then rated by three experts to find a consensus between ED researchers. The new items were then included in the Italian EDQoL and validated using an exploratory factor analysis approach. The result was a valid questionnaire with robust psychometric values that showed good convergence with other well-known questionnaires used for the evaluation of different life aspects like the clinical impairment assessment questionnaire (Bohn et al. 2008). The results of the first Italian application of the new EDQoL were the presence of an impaired QoL linked to the interpersonal domain, with AN patients reporting the highest (worst) scores.

The Italian authors have proposed an English version of the new EDQoL questionnaire. However, validation has not yet been performed (Meneguzzo et al. 2020).

Application to Other Areas

The EDQoL has assumed a relevant role in evaluating the ED burden, showing its centrality in clinical and health psychology as one of the main elements of the individual's well-being [1]. Today, the recent literature has pointed out new evidence

of the existing connections that may be pointed out in patients and that may have a relevant role in the treatment pathways.

Recently, in a large clinical sample of individuals with EDs, researchers have evaluated the connection between QoL and the insight of the disorder as a relevant role in the self-assessment of ED psychopathology, showing different evaluations between patients and clinicians [2]. There is still something missing in ED psychopathology that QoL might allow us to evaluate [3]. These data underlined the possible role of QoL in the definition of recovery in ED and the need for a standardized approach to QoL in the definition of treatment pathways. Indeed, the connection between QoL and health service use has already been reported, showing that even before an official ED diagnosis, patients reported a decreased QoL and higher use of services, with more drug prescriptions and medical consultations [4]. However, the literature needs specific studies about the economic and organizational aspects linked to QoL, and EDQoL may be the specific tool that could be applied due to the presence of a specific subscale.

Future Directions

The literature about QoL in patients with ED is still insufficient. More studies are needed to evaluate the relationships between these psychological constructs and different psychopathological aspects like depression, anxiety, cognitive functioning, and specific eating behaviors. The literature has proposed QoL as a possible "back-door" approach in order to improve ED symptomatology and promote recovery in patients who did not respond to other treatment approaches by increasing insight into the effects of the disorder (Mitchison et al. 2016). However, clinical data on this hypothesis is still missing.

Mini-dictionary of Terms

- **Financial-work/school domains**. These are two different domains that are connected. Financial domain evaluates the loss of money, while the work/school domain evaluates the adverse effects of ED on everyday activities.
- **Health-related quality of life (HRQoL)**. The specific evaluation of the own QoL related to mental and physical health.
- **Interpersonal domain**. This domain evaluates the presence of social connections with friends, fiancé, and sexual experiences.
- **Physical/cognitive domain**. It is related to all the physical effects that EDs could cause, as well as to mental performances. In the statistical validation of the EDQoL, cognitive and physical aspects fall in the same domain, corroborating a psychosomatic approach to these aspects.
- **Psychological domain**. It is related to all the ideas and concerns due to the eating psychopathology that could be negatively affected in patients. It is related to past, present, and future scenarios that could be affected by specific psychopathology.
- **Quality of life (QoL)**. The degree to which individuals perceive themselves in relationship with their goals, standards, concerns, and expectations.

Key Facts on Quality of Life in EDs

- Despite the evidence that the majority of the patients have an impaired QoL, studies are still limited and with preliminary results.
- Some studies reported that patients with AN have the worst scores in QoL, and other studies reported no differences across diagnoses.
- Patients with subthreshold ED diagnosis report less impaired QoL.
- Comorbidities and insight have specific roles in the evaluation of QoL.

Summary Points

- Patients with EDs have a reduced quality of life versus their healthy peers.
- Psychological, physical, cognitive, financial, and work/school domains could be compromised by an eating disorder.
- The interpersonal domain should be included in the evaluation of the health-related quality of life of patients due to its role in the development and maintenance of the disorder.
- The evaluation of the effects of treatments on patients' QoL is still preliminary.
- More studies are needed to understand better the possible role of quality of life in treating eating disorders.

Binge Eating Scoring Systems

73

Applications to Bariatric Surgery

Natália Luiza Kops and Rogério Friedman

Contents

Abstract

Bariatric surgery limits the amount of food consumed in a short period of time, and, since this is one of the diagnostic criteria for binge eating disorder (BED), the experience of loss of control (LOC) continues to be reported postoperatively. Therefore, the tools and questionnaires used to assess binge eating in these patients need to be discussed. Data regarding the presence of eating disorders in the postoperative period are scarce, due to lack of comprehensive follow-up data, screening, or standardization in the evaluation of these comorbidities. The chapter aims to discuss binge eating scoring systems in patients seeking or undergoing bariatric surgery.

Introduction

The global prevalence of obesity has tripled in more than 70 countries since 1975, and it is projected to continue increasing ("obesity and overweight" n.d.). Clinically severe obesity has increased at a more pronounced rate than less severe obesity. More severe forms of obesity represent a great risk for noncommunicable diseases, including approximately 200 comorbidities such as type 2 diabetes, hypertension, heart disease, sleep apnea, osteoarthritis, and several forms of cancer (Apovian 2016). Individuals with body mass index (BMI) $\geq$ 45 kg/m^2 show a decrease in life expectancy and an increase in mortality from cardiovascular causes ("Associação Brasileira para o Estudo da Obesidade e da Síndrome Metabólica Diretrizes brasileiras de obesidade 2016/ABESO - Associação Brasileira para o Estudo da Obesidade e da Síndrome Metabólica. – 4.ed. - São Paulo, SP" n.d.).

Obesity is a complex whole-body disease that involves the brain, gut, hormones, and emotions. Finding personal strategies that unlock the root causes of obesity and finding the path to sustainable health is crucial for long-term success of weight loss. The treatment must necessarily promote healthy lifestyle behaviors, and, in individual cases, the association of pharmacotherapy can be adopted. However, when these

measures do not imply improvement of severe obesity and associated diseases, bariatric surgery is a consistent option ("Associação Brasileira para o Estudo da Obesidade e da Síndrome Metabólica Diretrizes brasileiras de obesidade 2016/ ABESO – Associação Brasileira para o Estudo da Obesidade e da Síndrome Metabólica. – 4.ed. – São Paulo, SP" n.d.).

Concomitantly with the increase in obesity, the number of bariatric surgeries also increased (Ramos et al. 2019.). There has been an overall increase of approximately 60%, since 2011, in the number of metabolic and bariatric procedures (English et al. 2020). The surgery can lead to weight loss on average 26 kg greater than nonsurgical treatment (Finkelstein et al. 2009). However, the outcomes, although expressive, are not universal, varying between patients and types of surgical procedures.

Bariatric Surgery and the Prevalence of Disorders

Symptoms of stress, anxiety, depression, nervousness, and emotional problems are common in patients with obesity. There are strong associations between obesity and a range of mental disorders, such as depressive and bipolar disorders, schizophrenia, and binge eating disorder (BED) (American Psychiatric Association 2013), especially in those undergoing bariatric surgery (Horvath et al. 2015; Sarwer et al. 2021). However, the relationship between psychopathologies before bariatric surgery and postoperative results is less robust (Dawes et al. 2016).

Mood and substance use disorders, such as binge eating, share common characteristics of impulsivity. That is, the inability to inhibit automatic behavior and the tendency to discount future consequences in favor of immediate results (Sarwer et al. 2021). Lack of control can reduce the ability to inhibit automatic behavior (such as the consumption of highly palatable foods) and may increase preference for immediate rewards (as a healthier option) affecting the results of bariatric surgery (Sarwer et al. 2021).

Despite several common psychological and behavioral aspects, the disorders differ in terms of clinical course, outcome, and need for treatment (American Psychiatric Association 2013). The effects of disordered eating behaviors may differ if they occur over a time-limited versus prolonged period, for example. Therefore, it can be problematic if assessments do not address chronicity or focus only on recent experiences (Lavender et al. 2020).

Valid postsurgical assessment and monitoring have a critical role in identifying disordered eating following bariatric surgery (Parker et al. 2014). In the presurgery period, it is known that the prevalence of disordered eating behaviors is high (Sarwer et al. 2021). Among patients seeking and undergoing bariatric surgery, BED is the second most common psychiatric disorder (17% [95% CI, 13–21%]), following major depressive disorder (19% [95% CI, 14–25%]) (Dawes et al. 2016). On the other hand, data regarding the presence of eating disorders in the postoperative period are scarce, due to lack of comprehensive follow-up data, screening, or standardization in the evaluation of these comorbidities (Parker et al. 2014).

BED Diagnosis

The diagnostic criteria of BED have changed over time. Binge eating was described more than 50 years ago by Stunkard (1959). However, it was only in the fifth edition of Diagnostic and Statistical Manual of Mental Disorders (DSM-5), published on May 2013, that BED was no longer listed as an "eating disorder not otherwise specified." In DSM-5, diagnostic criteria were consistent with the previous edition, but both the frequency of episodes and the duration of eating behaviors were reduced (American Psychiatric Association 2013). In DSM-5, it is required that binge eating episodes occur at least once a week for 3 months (American Psychiatric Association 2013). These recurrent objective binge eating episodes must occur in the absence of compensatory behaviors (e.g., self-induced vomiting), accompanied by a sense of loss of control (LOC). They are defined as eating an unusually large quantity of food in a discrete period. In addition, a diagnosis requires experiencing three of five associated symptoms: (1) eating much more rapidly than normal, (2) eating until feeling uncomfortably full, (3) eating large amounts of food when not feeling physically hungry, (4) eating alone due to embarrassment, and (5) feeling disgusted with oneself or very guilty after overeating (American Psychiatric Association 2013).

Despite the difficulty in eating large amounts of food after surgery, the experience of LOC continues to be reported postoperatively. LOC is common among bariatric patients, with rates ranging from 13.3% to 61.0% prior to surgery (Colles et al. 2008; White et al. 2010) and from 16.9% to 39.0% postsurgery (Conceição et al. 2014; White et al. 2010). Evidence suggests that the experience of LOC, regardless of the amount of food ingested, may be the most important indicator in defining BED postsurgery (Mond et al. 2010). Thus, because LOC is most predictive of the level of impairment, distress, and psychopathology associated with disordered eating behaviors (Colles et al. 2008).

Currently, the diagnostic criteria for BED are the same for bariatric and non-bariatric patients. However, we leave a reflection about the amount of food ingested after surgery and how much this factor can interfere in the assessment of postsurgical patients.

Effect of BED in Pre- and Postsurgery Patients

The impact of preoperative BED in the outcomes of bariatric surgery has been a question of interest to the field. Some studies suggest an association between BED and poorer outcomes, although most have not found this association (Kops et al. 2021; Meany et al. 2014). Data from the Longitudinal Assessment of Bariatric Surgery (LABS) study showed that presurgery BED was not associated with weight change over 7 years of follow-up (Kalarchian et al. 2019). Nevertheless, patients presenting BED presurgery have higher rates of other psychopathologies, which have been associated with poorer surgical outcomes. The disorder is not a

contraindication for surgery, and its presence may not be very significant in terms of surgical success, although an indication remains to follow each case carefully.

On the other hand, the impact of BED during the postoperative period is more controversial. Little is known about the continuation of preexisting BED, incidence, or remission of the disorder. Inaccurate measures may lead to misdiagnosing symptoms and failure to identify clinically significant symptoms that have the potential to impact postsurgical psychological well-being, weight loss, and complications (Conceição and Goldschmidt 2019). As expected, after bariatric surgery, the frequency of objective binge eating episodes seems to fall, and the prevalence of full BED is lower. This prevalence depends on the diagnostic criteria of BED employed and on different assessment measures. Thus, inadequate measures also contribute to the lack of evidence in the research literature and to inconsistency in reported findings. Furthermore, they impact the evaluation of disordered eating treatments.

Undoubtedly, the anatomical alterations imposed by bariatric surgery influence the patients' ability to consume large quantities of food, as well as the types of food that can be consumed, especially in the first months after surgery (Kops et al. 2021). The postsurgical physiologically imposed restriction impacts the ability to eat unusually large amounts of food, an event that is required for the diagnosis of binge eating. Furthermore, postsurgery recommendations, including reducing portion sizes, eating slowly, and chewing thoroughly, mimic some disordered eating behavior. In addition, maladaptive eating symptoms including vomiting, regurgitation, diarrhea, and other gastrointestinal complications such as dumping syndrome can arise from a failure to adhere to postsurgical eating recommendations and may appear very similar to disordered eating (Conceição et al. 2015).

Although the predictive effect of presurgical BED is controversial, the literature that addresses the effect of BED in the postoperative period is more consistent. Still, it is unknown why the disorder recurs in some people and not others. Even so, psychosocial interventions can improve psychosocial disorders among bariatric surgery patients. The surgery alone will not improve compulsive behaviors, and patients need to understand the importance of this for effective long-term results.

Types of Bariatric Surgery and the Effect on Eating Behavior

Currently, different surgical techniques can be used. The most frequently performed procedures are either purely restrictive, such as laparoscopic adjustable gastric band (LAGB) and laparoscopic sleeve gastrectomy (LSG), or restrictive-malabsorptive, such as the Roux-en-Y gastric bypass (RYGB). Knowing the type of procedure is important since anatomical changes may modify the production of hormones responsible for satiety signals and eating until feeling uncomfortably full is one of the criteria for binge eating Fig.1.

The RYGB is the "gold standard" and most widely studied procedure (Welbourn et al. 2018). This surgery reduces food intake through the "creation of a small pouch in the top portion of the stomach which is separated from the remaining stomach." The small intestine is connected to the pouch to allow for the passage of food, while

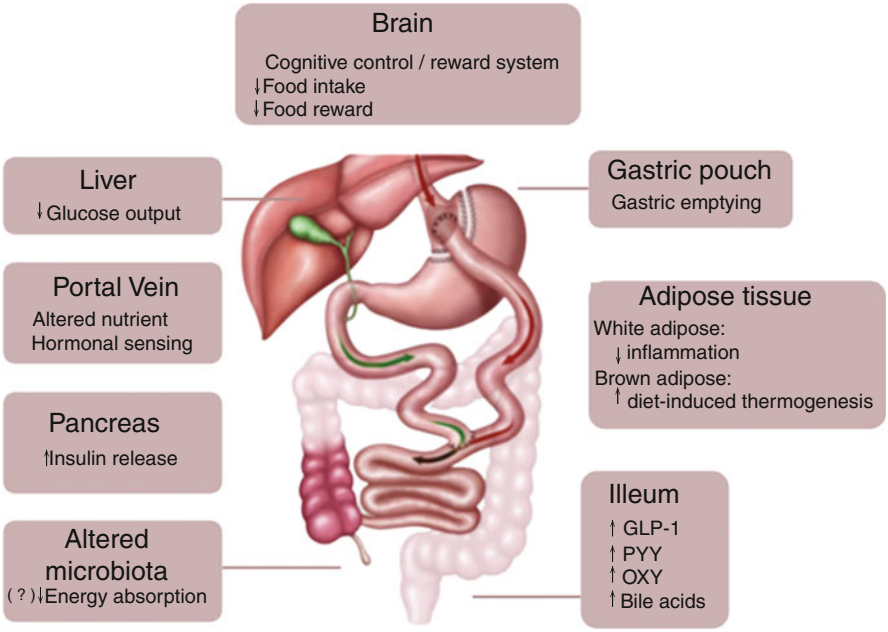

Fig. 1 Anatomical changes and representation of the physiological mechanisms after bariatric bypass surgery. The anatomical change of the gut is a major source of altered signaling to the brain, liver, pancreas, and adipose tissue. These changes lead to reduction of hunger, increase in satiation, shift in food preferences away from high-calorie foods, increase in diet-induced thermogenesis, reduction in inflammation, and improved glycemic control. Abbreviations: *GLP-1* glucagon-like peptide-1, *PYY* peptide YY, *OXY* oxyntomodulin

the remnant stomach is reattached further down the intestinal track (Mitchell and Gupta 2020). The redirection of food produces changes in intestinal hormones that promote satiety and suppress hunger. In addition to favorable changes in gut peptides and appetite hormones, the restriction of total food intake and malabsorption of macronutrients induces weight loss (Mitchell and Gupta 2020).

Energy balance requires an ability of the brain to match energy intake with expenditure. Signals from sensory organs such as vision, smell, and taste and from peripheral tissues such as gastrointestinal tract and adipose tissue, as well as signals from other central areas such as the cortex and reward system, converge on the hypothalamus (Sohn 2015). In the hypothalamus, there are two groups of neuropeptides involved in orexigenic and anorectic processes. The first increases the feeling of hunger: neuropeptide Y (NPY) and agouti-related peptide (AgRP). The other suppresses the appetite, such as pro-opiomelanocortin (POMC) neurons. Both have the function of controlling feelings of hunger or satiety and triggering endocrine, autonomic, and behavioral responses in order to maintain homeostasis (Sohn 2015).

Knowing the procedure performed on each patient is also essential to determine the postsurgical follow-up. Despite the effectiveness of bariatric surgery, weight regain may occur over time. Maximum weight loss usually occurs between 1 and

2 years after the surgery (Sjöström 2018). And long-term weight stabilization is still one of the greatest challenges as it is known that only 76% of patients receiving RYGB surgery maintain at least 20% weight loss 6 years after surgery (Adams et al. 2012). The reasons for weight regain are not fully understood but likely involve psychological, behavioral, and physiological processes.

Sanmiguel et al. (2017) showed that sleeve gastrectomy also decreased both appetite and hedonic eating, causing structural changes in various regions of the brain's reward system (Sanmiguel et al. 2017). Therefore, regardless of the type of surgical procedure performed, the anatomical and physiological changes suggest an important role in the effectiveness of weight loss. The velocity and amount of weight loss will differ between the types of surgeries; however, it is unknown if BED patients would benefit more from one procedure over another.

Binge Eating Assessment in Bariatric Patients

Tools and measures originally developed for patients outside the context of bariatric surgery may not adequately address the clinical presentation of disordered eating behaviors after bariatric surgery (Conceição et al. 2015). Validated measures are fundamental to identify and prevent the disorders and consequent poor biopsychosocial outcomes (Parker et al. 2014). Moreover, methodological inconsistencies in the literature make it difficult to determine the prevalence of the disorders and their impact on treatment outcomes.

A lack of consistency between terms and definitions has been used to describe problematic eating behavior across studies. These definitions such as "binge eating," "LOC," "hyperphagia," "craving for food," "nibbling," "picking," "grazing," and "frequent snacking" are isolated characteristics of a possible disorder and cannot be compared with the diagnosis of BED. Grazing, for example, "involves eating small/modest amounts of food in an unplanned and repetitious manner, and not in response to hunger/satiety sensations" (Conceição and Goldschmidt 2019) and is present in 33.20% of patients with obesity and 67.77% of BED patients (Heriseanu et al. 2017).

There is mixed evidence to suggest that grazing is associated with worse outcomes in weight loss treatment (Heriseanu et al. 2017) and greater weight regain (Pizato et al. 2017). After 10 years of follow-up of patients included in the Swedish obese subjects, presurgery eating behaviors were not related to subsequent weight changes (Konttinen et al. 2015). Including 26 studies, the prevalence of grazing presurgery was 33.2% (95% CI, 27.5–39.1), 28.2% (95% CI, 17.9–39.7) post-surgery, and 23.3% (95% CI 3.1–52.0) in the general population (Heriseanu et al. 2017). The Longitudinal Assessment of Bariatric Surgery-2 (LABS-2) study also showed that grazing and BED reduced right after gastric banding or RYGB but increased again with a remarkable number of new cases (25.6% e 4.8%, respectively) (Smith et al. 2019).

Besides the different terminologies, considerable variation in BED assessment measures is evident among the studies (Tess et al. 2019). A systematic review of the methods used to diagnose disordered eating in presurgical assessments identified

35 questionnaires and 23 interviews. From the 35 questionnaires identified, the Dutch Sweet-Eating Questionnaire was the only measure developed for bariatric surgery patients (however, it was not developed to evaluate BED but sweet eating) (van den Heuvel et al. 2011). From the 23 interviews identified, the only interview specific to the bariatric surgery population was the Eating Disorder Examination-Bariatric Surgery Version (EDE-BSV) (de Zwaan et al. 2004).

Other frequent methods of evaluation are the Eating Disorder Examination-Bariatric Surgery Version (EDE), Three-Factor Eating Questionnaire (TFEQ), Binge Eating Scale (BES), and Questionnaire on Eating and Weight Patterns-Revised (QEWP-R) (Parker et al. 2014):

EDE is a tool to help diagnose eating disorders in general. It addresses various food and self-image issues (e.g., objective binge eating, subjective binge eating, and LOCE) through self-reported questionnaires. The questionnaire assesses disordered eating attitudes and behaviors over the previous 28 days (Fairburn and Beglin 1994). The measure provides four subscale scores: restraint (5 items), eating concern (5 items), shape concern (8 items), and weight concern (5 items). The global score is obtained by averaging the four scores. Higher scores reflect greater eating- or body-related concerns or behaviors. Frequencies of disordered eating behaviors (e.g., binge eating and compensatory behaviors) are also assessed. The revised version of the EDE questionnaire is recommended for use in both bariatric surgery candidates and patients (Parker et al. 2015).

The TFEQ is a scale that measures three types of eating behavior: cognitive restraint, uncontrolled eating, and emotional eating (Stunkard and Messick 1985). It contains 51 items, and higher scores indicate higher levels of the factor, respectively.

The BES is a widely used self-report instrument that measures the behavioral and emotional/cognitive symptoms associated with binge eating. Each of the 16 items contains three to four response options reflecting the severity for each characteristic measured. It was validated by Grupsky (2016) for patients seeking bariatric surgery, but it must be administrated as part of a comprehensive psychological evaluation (Grupski et al. 2013). Individuals can be categorized into three groups, based on the BES total score: no binge eating (score $\leq$ 17), mild to moderate binge eating (score of 18–26), and severe binge eating (score $\geq$ 27). The cut score of 17 classifies correctly 78% of patients with BED. A higher score improved this statistic but increases the number of false negatives (Grupski et al. 2013).

The 28-item QEWP-R also assesses behavioral components of disordered eating, including frequency of objective binge eating and diagnostic information (Yanovski et al. 2015). This measure does not include additional constructs or provide a scaled severity score of disordered eating but has been shown to have reasonable agreement with interview-based measures and the EDE. However, the QEWP generally is more sensitive and less specific and, therefore, should only be used to screen for BED with its confirmation by interview (Yanovski et al. 2015) Table 1.

Among these questionnaires, the EDE is the most appropriate to be used in the pre- and postoperative surgery (Parker et al. 2015). The criteria of objectively large amount of food for BED are not always clear, which makes it difficult to interpret findings across studies (Conceição et al. 2015). For this reason, the tools in their

Table 1 Scoring questionnaires to assess binge eating

Instrument	Details
Dutch Sweet-Eating Questionnaire	Ten questions and a list of 16 sweet foods and beverages to measure intake frequency. The questions had three to maximally five options. Intake frequency varied from never to three or more times per day and had ten options
Eating Disorder Examination-Bariatric Surgery Version (EDE-BSV)	A semi-structured clinical interview adapted for bariatric patients
Eating Disorder Examination (EDE)	Four subscale scores
Three-Factor Eating Questionnaire (TFEQ)	51 items; three types of eating behavior
Binge Eating Scale (BES)	16 items containing three to four responses
Questionnaire on Eating and Weight Patterns-Revised (QEWP-R)	27-item self-administered questionnaire

adapted forms are more reliable. Furthermore, inclusion of items assessing objective and subjective binge eating and grazing enables comparison between measures of disordered eating more relevant to a postsurgical population (Parker et al. 2015).

Pros and Cons of Instruments for the Assessment of Eating Disorders

Although there are several instruments for the assessment of eating disorders, clinical interviews are the gold standard for the diagnosis of BED. However, their application is not always feasible as they are laborious and must be performed by trained mental health professionals. Therefore, self-report questionnaires are preferred as a screening method. Ideally, a good screening instrument should be highly sensitive in order to identify the majority of affected patients with BED (Tess et al. 2019). On the other hand, its specificity is less relevant, since a preliminary diagnosis of an eating disorder must be confirmed by a clinical interview – responsibility of the psychologist or the psychiatrist.

The lack of consistency impedes recognition of disordered eating behaviors and appropriate continuity of treatment by clinicians (Conceição and Goldschmidt 2019). The correct assessment could greatly improve the detection of eating disorders and behaviors and, thus, contribute to a better postoperative result. Since the effects of binge eating in the postoperative period are more recognized (related to poorer weight outcomes, psychological well-being, and greater postsurgical complications) than the preoperative period, the accurate identification at this time is perhaps even more important.

In addition, the wide range of questionnaires for the assessment of binge eating made comparison between different studies and procedures difficult. The psychometric properties, validity, and utility of these measures in bariatric surgery patients are not established. The investigators should use the same assessment measures to

ensure accuracy and comparability of findings in future studies. Further development of measures is required to find consistent and psychometrically acceptable measures for pre- and postsurgery patients.

In conclusion, bariatric surgery is recognized as an important option for obesity treatment. Although most surgical patients have disturbed eating behaviors, little is known about the effect of this in the surgery. Furthermore, the studies have important methodological limitations to evaluate the development or recurrence of eating disorders. Thus, a standardized assessment is crucial to identify these disorders considering the unique eating context created by the surgery. Meanwhile, we emphasize the importance of a clinical assessment by qualified professionals for the disturbed eating behaviors and a postsurgery follow-up by a multidisciplinary team.

Applications to Other Areas

Binge eating scoring systems are also used in other areas than bariatric surgery. Although most studies are performed in patients with obesity or undergoing weight loss treatments, the general population of different age groups, as well as clinical and nonclinical patients, can also be evaluated despite contradictory results.

Studies conducted on obese patients have demonstrated that the BES has high sensitivity and specificity for discriminating between binge eaters and non-binge eaters (Grupski et al. 2013). These findings show scales presenting similar results to those obtained by reliable and supported semi-structured interviews (Robert et al. 2013). Furthermore, a growing body of research has been showing that the BES presents good validity both in clinical and in nonclinical samples (Duarte et al. 2015), including in the youth population (Cardoso et al. 2020; Escrivá-Martínez et al. 2019; Mina et al. 2021). However, in a study with 553 non-clinical subjects, BES was not a useful tool in underweight and optimal-weight subjects (Brunault et al. 2016). Therefore, there is a need for more evidence about the scale and additional psychometric properties in this population.

A large amount of research has established a well-defined relationship between BED and addiction disorders. Impulsivity has been positively associated with BED (Mason et al. 2018) and could play an important role in comorbidity. Although there is a positive correlation between the presence of BED and food addiction (Imperatori et al. 2014), use of alcohol, and binge drinking (Fouladi et al. 2015), the applicability of each instrument cannot be confused.

The evaluation of binge eating offers some challenges due to the private nature and the difficult aspects to declare and to recall, such as shame and severity of the episodes. These challenges are even greater when evaluated by scoring systems. It is consensual that investigator-based interviews are the most valid method to accurately assess disorders regardless of the area or studied population.

Mini-Dictionary of Terms

- ***Loss of control:*** *Constantly exaggerate. Eating an unusually large amount of food in a discrete period*
- ***Grazing:*** *The habit of "pinching." Eating small amounts of food over time*
- ***Bariatric surgery:*** *Surgical procedure for weight loss and improvement of associated comorbidities*
- **Scoring systems:** Assessment instruments and questionnaires that use a score as a diagnostic criterion
- **Orexigenic neuropeptides:** They are transmitters that stimulate appetite
- **Anorexigenic neuropeptides:** They are transmitters that inhibit appetite

Key Facts of Scoring Systems for Bariatric Patients

Bariatric surgery limits the amount of food consumed in a short period of time.

The experience of LOC continues to be reported postoperatively.

Valid postsurgical assessment and monitoring have a critical role in identifying disordered eating following bariatric surgery.

Considerable variation in BED assessment measures is evident among the studies.

The wide range of questionnaires for the assessment of binge eating made comparison between different studies and procedures difficult.

Scoring systems are practical and inexpensive to apply but need attention.

Summary Points

- *The gastrointestinal rearrangement after bariatric surgery plays a role in the metabolic changes observed after surgery*
- *Valid postsurgical assessment and monitoring have a critical role in identifying disordered eating following bariatric surgery*
- *Data regarding the presence of BED in the postoperative period are scarce, due to lack of comprehensive screening or standardization*
- *Despite the difficulty in eating large amounts of food after surgery, the experience of LOC continues to be reported postoperatively*
- *Tools originally developed for patients outside the context of bariatric surgery may not adequately address the clinical presentation of disordered eating behaviors after the surgery*
- *Inclusion of items assessing objective and subjective binge eating and grazing enables comparison between measures of disordered eating more relevant to a postsurgical population*

Abstract

Orthorexia can be understood as a drive for eating foods perceived to be health-promoting. When this drive includes obsessive thoughts and rigid behaviors about food choices, a person can suffer physical, psychological, and social harms. In the literature, this symptomatology is known as orthorexia nervosa, as it can cause damage in different areas of people's lives. On the other hand, a drive for healthy eating can also be experienced as a guide to help people make food choices aiming to establish a health-promoting eating habit. This has been named in the literature as healthy orthorexia, but it is not clearly understood yet. The aim of this chapter was to conceptualize healthy orthorexia and explore its forms of evaluation, providing discussion about empirical evidence and practical implications. For that, a background about orthorexia nervosa was also necessary to understand how healthy orthorexia fits into this phenomenon that is still under debate in the clinical and scientific community.

Introduction

The beneficial effects of a nutritionally adequate eating (e.g., supplying adequate macro- and micronutrients) are undeniable (Bazzano 2006), which supports global strategies focused on promoting health through food, aimed mainly at the prevention of noncommunicable diseases (World Health Organization 2003, 2020). However, while this appeal is seen as protective and important, biological approaches focused only on health promotion (e.g., a medical recommendation) ironically may have negative implications on autonomous choices, individual values, group experiences, and others (Barnhill et al. 2014). In addition, internalizing an eating behavior with a premise to exclude all foods labeled "unhealthy" can turn into an obsession (i.e., a persistent and disturbing thought) with consequent fixation (i.e., a stereotyped behavior related to an obsessive and unhealthy preoccupation or attachment) and subsequent biological and psychosocial harm (McComb and Mills 2019; Strahler et al. 2018; Cena et al. 2019). As a result of health-focused reductionist approaches, a growing number of individuals are seeking help from psychologists, nutritionists/dietitians, and other professionals and reporting maladaptive behavior focused on "ideal eating" to promote health (Bratman 2017). This seems to be a paradox represented by the modern preoccupation with health (Devcich et al. 2007), which may result from inconsistent interpretations of official dietary recommendations that actually suggest having a diet that promotes health, psychological well-being, social interaction, and environmental sustainability, as well as respects culture (McCartney 2016; Brazil 2014; World Health Organization 2020).

The unhealthy preoccupation with healthy eating has been understood as a phenomenon called orthorexia (Mathieu 2005). Etymologically, this word derives from the Greek words *orthós* and *orexsis*, meaning "correct" and "appetite," respectively (Bratman 2017). Orthorexia-like behaviors seem to stem from global motives, values, and beliefs based on the ideological theory that food promotes good health per se (Bratman 2017), which is not an absolute truth (Barnhill et al. 2014). In 1997, Steven Bratman, an American physician who at the time practiced alternative medicine, published a manuscript in the *Yoga Journal*, where he coined initially – based on his personal and clinical experiences – the term "orthorexia nervosa (OrNe)". The use of the word "orthorexia" to represent "correct appetite" was intentional to refer to an eating practice considered healthy. Furthermore, this word would be different from "anorexia," which represents "absent appetite." The addition of the word "nervosa" to "orthorexia" forms the term OrNe representing a pathological fixation on healthy eating characterized by overconcentration on specifics of food choices, including quality, preparation, and adherence to one or another particular theory of eating. These may be conceptualized as improving everyday health, addressing specific health concerns, or reducing risk of life-threatening diseases (Bratman 1997; Hallit et al. 2021). After Bratman's first publication, a considerable number of studies sought to understand OrNe phenomenon. However, some of these studies began to conflate OrNe with adherence to a theory of healthy eating per se, such as the desire to avoid ultra-processed foods and the adoption of

eating styles, such as veganism (Bratman 2017). In part the present work is designed to address this confusion.

The present biopsychosocial understanding of OrNe indicates that it represents an extreme fixation on healthy eating, which can influence the choice and consumption of foods and, consequently, people's lives (Douma et al. 2021; Bratman 2017). Individuals who exhibit OrNe behaviors are "inflexible eaters" (i.e., they only eat what they judge to be appropriate) avoiding certain type of foods based on whatever theory of healthy eating they may follow. For example, vegans avoid all animal products, followers of the paleo diet eschew legumes and grains, and adherents of "clean eating" avoid additives (e.g., artificial colors, pesticides, and preservatives). Thus, food choice is based on self-perception of unhealthy characteristics. Concepts such as the "naturalness" of foods, their purity, and their production by certain means (such as organic farming) are often but not always employed. In addition, it is has been observed that individuals with OrNe may switch dietary theories, sometimes rather rapidly, and therefore move from one set of rigid rules to another (Bratman and Knight 2000). However, it should be noted that choosing foods believed to be healthy is not a problem per se. Most people who exhibit healthy eating preoccupations do not subject themselves to direct physical harm. The real issue emerges when the "drive for healthy eating" becomes problematic, and understanding this transition is a challenge (Koven and Abry 2015; Moroze et al. 2015).

From a psychodynamic point of view, when healthy eating becomes a permanent preoccupation and demands an inflexible choice, it provides a sense of control over the body, hunger, and health, masking anguish and acting as a kind of defense (Dolto 2014). When a person adopts an overcontrolled eating behavior, they may feel safe, but this can have a negative impact on different areas of their life, such as social (e.g., isolation to avoid eating out), psychological (e.g., feelings of guilt when eating a self-imposed forbidden food), occupational (e.g., spending a lot of time acquiring and preparing specific types of food), and biological (e.g., nutritional deficiencies due to monotonous eating and fasting as self-punishment for breaking rules). As society plays a key role in people's lives, maladaptive eating behaviors (e.g., restrict all foods supposed to be "unclean") could occur in response to societal pressure (e.g., being as healthy as possible), and this may trigger a disorder (e.g., obsessive-compulsive disorder). Therefore, a behavior that was supposed to be healthy can become a coping strategy with negative outcomes (Moroze et al. 2015; Koven and Abry 2015). However, this hypothesis has not been completely validated (Greville-Harris et al. 2020; McGovern et al. 2021; Mitrofanova et al. 2021).

At present, there is still no consensus in the literature whether OrNe is an independent mental disorder, a subtype (e.g., obsessive-compulsive disorder), or merely a behavioral or lifestyle phenomenon (Koven and Abry 2015; Strahler et al. 2018). Both the Diagnostic and Statistical Manual of Mental Disorders, fifth edition (DSM-5), and the International Statistical Classification of Diseases and Related Health Problems, eleventh revision (ICD-11), do not recognize OrNe as a mental disorder, as there are no official diagnostic criteria. Based on this, individuals who are obsessed about food to achieve good health may exhibit risky behaviors, but so far there is no sufficient evidence to describe OrNe as a disease (Cena et al. 2019;

Dunn and Bratman 2016). Nevertheless, it is still possible to identify some characteristic aspects of OrNe.

Evidence suggests that OrNe is focused on *what to eat* (i.e., quality) driven by the goal of being as healthy as possible, while eating disorders (EDs) such as anorexia nervosa (AN) are focused on *how much to eat* (i.e., quantity) in an attempt to change body shape. However, this distinction is not always so pragmatic (Domingues and Carmo 2021). For instance, an individual with AN may move their focus from quantity to the quality of food (Barrada and Roncero 2018; Segura-Garcia et al. 2015). On the other hand, a person that is primarily preoccupied with food quality may also control the food quantity (Strahler et al. 2018). Furthermore, a simultaneous preoccupation with the quality and quantity of food can occur. In this way, it is speculated that OrNe can precede, succeed, or coexist with EDs (Barthels et al. 2017; Segura-Garcia et al. 2015; McGovern et al. 2021). Individuals with AN generally hide their behaviors, while those with OrNe are proud of their conduct, and these differences are important (McComb and Mills 2019; Mitrofanova et al. 2021; Greville-Harris et al. 2020). Therefore, future research should be encouraged to better understand OrNe in the context of EDs.

When Bratman coined the term OrNe (Bratman 1997), he did not intend to determine a new ED; however, this was not clear in the literature. Thus, years later, Bratman clarified this point by reporting that orthorexia encompasses two stages (Bratman 2017). The first involves an "innocent" interest in changing eating to reduce diseases and improve overall health without physical and mental negative consequences. The second, understood as OrNe, is characterized by a further progression focused on extreme fixation with healthy eating, generating a rigid, fearful, and self-punishing lifestyle, which is the problematic component of orthorexia (Bratman 2017). From this perspective, Barrada and Roncero (2018) brought to light the bidimensionality of the orthorexia by proposing to investigate this phenomenon considering an already known pathological dimension (i.e., OrNe) and a non-pathological one called "healthy orthorexia" (HeOr).

It is worth commenting that Bratman is opposed to the use of the term healthy orthorexia and instead wishes to describe this as an interest in health. In Bratman's conception, "orthorexia" should only be used as a shorthand for OrNe, just as "anorexia" is a shorthand – at least when EDs are concerned – for anorexia nervosa. He argues that since the term "anorexia" is also used, especially in association with cancer treatment, as an indicator of lack of appetite, "orthorexia" could conceivably be used in a parallel manner as a mere indicator of healthy eating. Despite these objections to use of the term HeOr, this work will follow the general literature and employ it. Importantly, the term "non-orthorexia nervosa (non-ON)" is also used to represent signs and symptoms related to interest in healthy eating (Strahler et al. 2018; Barrada and Roncero 2018), but the term HeOr is more commonly used in the literature. However, regardless of the term used, it is important to know this dimension, as well as the whole continuum, to verify the usefulness of recognizing the symptoms of orthorexia.

The focus of this chapter is to discuss orthorexia as a phenomenon that lies on a continuum as illustrated in Fig. 1. This continuum begins with no concern for

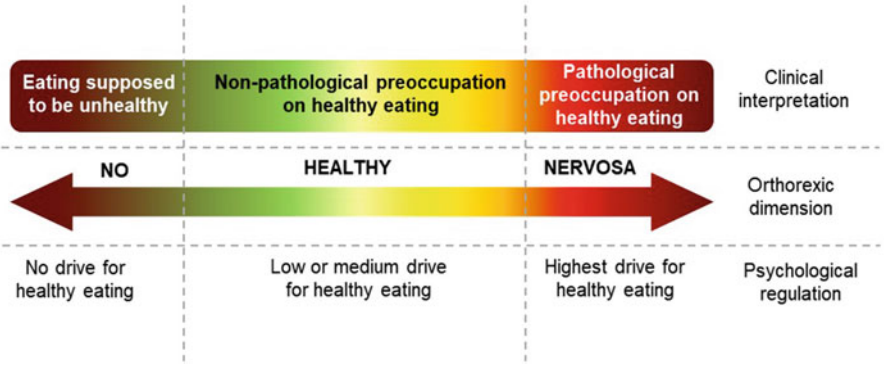

Fig. 1 The continuum of orthorexia. Note. Orthorexia is a state of excessive preoccupation with healthy eating. Here it is conceived as a continuous phenomenon ranging from none to high drive (i.e., arousal influencing beliefs and behaviors) toward healthy eating. When there is no drive for healthy eating, orthorexia is absent (this can be problematic, as it represents disinterest). When there is a low/medium drive for healthy eating, but it is not obsessive, healthy orthorexia may be found. When there is a high drive as an obsession for healthy eating, orthorexia nervosa may be found, which can cause damage in different areas of a person's life. (This figure was created by the authors of this chapter)

healthy eating, which can be seen as a maladaptive eating behavior, but it is clearly not orthorexia. Then, there is a point of balance where food choices are made consciously to promote health but without obsessive preoccupation. Note that this may involve the adoption of a nonstandard theory of healthy eating; rather than simply promoting consumption of fruits, vegetables, whole grains, and protein sources, the theory may extol raw food and eschew meats. All theories of healthy eating are equivalent from this perspective provided they supply adequate micro- and macronutrients. Finally, a stage in which extreme fixation is reached is found, and here there is a maladaptive eating behavior, as it causes significant damage. From this perspective, some drive for healthy eating may be good, but a total absence or extreme level is not. The balanced drive for healthy eating can be seen as HeOr. The aim of this chapter is to conceptualize HeOr and explore its forms of evaluation to discuss empirical evidence and practical implications. For this, it was necessary to provide a background about OrNe to understand how HeOr fits.

Conceptualizing Orthorexia

One of the first scientific articles explaining orthorexia was published by Mathieu (2005). The author described the phenomenon based on pathological dimension as a fixation on righteous eating. This was supported by an interview conducted with Bratman, who proposed the term OrNe. In addition, experts in mental disorders who cared for people with different obsessions around food were interviewed for the article. At that time, experts were not completely sure whether orthorexia should be

considered a disorder, since having a healthy eating is something positive in society (Mitrofanova et al. 2021). Despite the effort to provide a clear definition for OrNe, the article also highlighted the need of further investigation and evidence gathering, both in clinical and research settings.

Currently, OrNe encompasses an intensification of the preoccupation with healthy eating that leads to persistent and disturbing thoughts (obsession) and stereotyped behaviors (fixation), such as eating only highly specific foods, eliminating those perceived to have unhealthy properties (e.g., "highly refined" foods), constantly thinking about the origin of the food, and choosing holiday destinations based solely on local foods chosen for their supposed health-promotion properties, rather than mere regional tastes (Mitrofanova et al. 2021). Knowing this is useful for therapists to be able to recognize OrNe symptomatology, although it is worth emphasizing that official diagnostic criteria do not yet exist (Cena et al. 2019).

Twenty-one years after its initial concept, orthorexia gained a new perspective. Barrada and Roncero (2018) observed a need to clarify when the preoccupation with healthy eating ceases to be a sign of care and becomes a fixation. This approach does not appear to represent a division of orthorexia into two parts but considers it as a continuum, ranging from no concern about healthy eating to extreme fixation passing by a midpoint represented by the interest based on preoccupation (see Fig. 1). Thus, HeOr was proposed as a non-pathological dimension for orthorexia. It emerged to represent an "adaptive preoccupation," such as an interest in the consumption of nutritionally adequate and health-promoting foods. This interest involves the tendency to self-control and the ability to focus attention on food choices, as a manifestation of a health care, without overconcern, being interpreted as a protective behavior. Hence, individuals who exhibit HeOr behaviors usually have healthy eating as an important part of their lives, take responsibility for their actions, and persist in their commitment, but without exaggeration. In summary, HeOr represents the tendency to eat healthy food as an integrated part of one's life (Barrada and Roncero 2018; Zickgraf and Barrada 2022).

Unlike the extreme fixation on healthy eating, HeOr encompasses the interest in eating to promote health, but the preoccupation does not trigger behaviors that objectively cause psychological, physical, occupational, or other harm. Thus, Barrada and Roncero (2018) shed light on the understanding of orthorexia by expanding it to include two dimensions, one represented by the interest in healthy eating (HeOr) and the other represented by extreme preoccupation (OrNe), which are part of the continuum seen in Fig. 1. Some studies (Depa et al. 2019; Silva et al. 2021; Zickgraf and Barrada 2022; Yakin et al. 2022; Strahler 2020, 2021; Barthels et al. 2019; Mhanna et al. 2022) bring up this supposed bidimensional nature of orthorexia, providing further support for decipher it. However, this understanding remains difficult, as most research focuses on investigating only OrNe (McComb and Mills 2019). In addition, with the strengthening of official guidelines to promote health through food (Walker-Swanton et al. 2020), the concern about healthy eating seems to be something natural and acceptable, regardless of whether it is exaggerated. Thus, it is important to know the extent to which people's concerns about

healthy eating are "normal," that is, including adaptive eating behaviors based on food choices that promote physical health and psychosocial well-being.

Knowing Orthorexia Symptomatology

Research about orthorexia is growing year by year (McComb and Mills 2019; Dunn and Bratman 2016; Cena et al. 2019). However, today the body of scientific evidence is still fragmented about its etiology and clinical implications, being especially scarce in terms of investigation of HeOr. Some articles (Dunn and Bratman 2016; Barthels et al. 2015b; Moroze et al. 2015; Donini et al. 2004; Setnick 2013) have suggested diagnostic criteria to guide the clinical community to identify signs and symptoms of OrNe. Cena et al. (2019) carried out a review study and gathered the diagnostic criteria suggestive of OrNe presented in four previous studies. Based on these, "consensual" diagnostic criteria for OrNe can be found, as presented in Fig. 2. The "consensual" criteria are not exactly the same in the studies, but there are key elements (e.g., obsessive behaviors, drive for health, and psychosocial and nutritional deficiencies), which allow characterization of OrNe. These can be useful as a

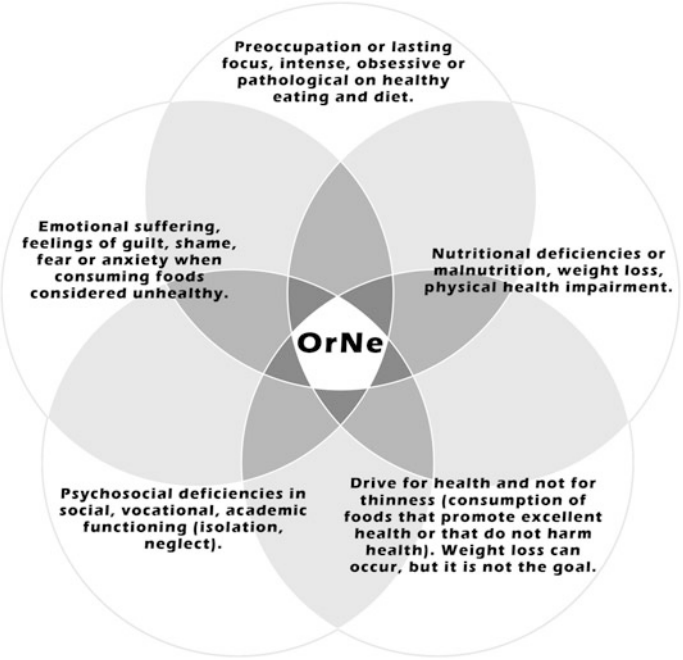

Fig. 2 Consensus criteria found in the literature for diagnosis suggestive of orthorexia nervosa (OrNe). (Note. Adapted from Cena et al. (2019) based on the criteria of Setnick (2013), Moroze et al. (2015), Barthels et al. (2015b), and Dunn and Bratman (2016). This figure was created by the authors of this chapter)

starting point for developing official diagnostic criteria that are still under debate. Despite the gaps in the literature, OrNe may already be well recognized and distinguished from eating behaviors (Cena et al. 2019).

Knowing the non-pathological dimension of orthorexia and identifying the point on which the drive for healthy eating becomes too high and negative can provide clinical benefits. Hence, recognizing signs and attitudes of HeOr is necessary. People with HeOr behaviors may be attentive to healthy eating and spend a considerable amount of effort on it, but this per se is not enough to determine that a psychopathology exists, since no extreme preoccupation emerges when it is not possible to "eating properly." Subsequent literature (Depa et al. 2019; Silva et al. 2021; Zickgraf and Barrada 2022; Yakin et al. 2022; Strahler 2020, 2021; Barthels et al. 2019; Mhanna et al. 2022) has shown consensus that HeOr is a dimension of orthorexia and this involves the general interest about healthy eating that produces behaviors as part of one's identity.

Yakin et al. (2022) mentioned that HeOr behaviors may include elimination of ultra-processed foods, as they are believed by some to negatively impact health and the environment. This can be interpreted as a lifestyle choice given that the dietary changes include the individual and the collective. According to Roncero et al. (2021), people who exhibit HeOr behaviors are able to plan the meal knowing that their food choices can have an impact in the long, medium, and short term, but they bet more on the effort that will have future and not immediate effects. In addition, the authors report that these individuals have a specific personality pattern including a tendency for responsibility, self-control, and the ability to focus, allowing them to critically evaluate guidelines, beliefs, and experiences that supposedly influence their behavior. Therefore, knowing how to differentiate individuals with HeOr behaviors from those with OrNe behaviors becomes important in terms of clinical implications, to contribute to the development of prevention or treatment strategies (Yakin et al. 2022).

Strahler et al. (2020) suggest that there are gains in the therapeutic approach when identifying HeOr behaviors. The authors showed that high scores for OrNe were significantly correlated with poor mental health, but this relationship was attenuated when there were also high scores for HeOr. This means that there was a "buffering," as the "interest" in healthy eating mitigated the obsession/fixation with eating specific foods. For example, a person who is preoccupied with healthy eating may recognize that certain behaviors are not beneficial and seek to avoid them. However, this self-awareness is not present all the time, and for this reason the individual needs help to maintain the interest in healthy eating (as absence may be also a problem), but without this becoming an extreme fixation (Hallit et al. 2021; Yakin et al. 2022). Yakin et al. (2022) showed that distinguishing between individuals with pathological and non-pathological orthorexia behaviors is significant, but also the awareness of the existence of groups of individuals with "low orthorexia" (i.e., no particular interest in healthy eating) and "in-between orthorexia" (i.e., symptomatology for OrNe and HeOr experienced together) is important to implement the most parsimonious therapeutic strategy. From this perspective, different behaviors can be seen as associated with orthorexia, and this may indicate that the concept appears to be a

multidimensional phenomenon rather than bidimensional. However, this is just a speculation that needs to be validated by future scientific evidence in different contexts.

Investigating the Frequency and Risk Factors of Orthorexia

Rates of OrNe behaviors have already been shown in different samples around the world, ranging from less than 1% to 90% (McComb and Mills 2019; Chard et al. 2019). This wide variation seems to be uncertain and may be associated with the different ways of measurement, such as instruments (e.g., scales) with poor psychometric properties (Valente et al. 2019; Chard et al. 2019) and suggestive clinical evidence based on preliminary diagnostic criteria (McComb and Mills 2019). Rates of HeOr behaviors are practically nonexistent, with few studies finding it (Silva et al. 2021; Awad et al. 2022b). This indicates that studies are focused on identifying maladaptive behaviors, and this strategy may not be the best way to understand orthorexia, as it separates the findings into the presence or absence of a problem. As mentioned previously, knowing whether there is an interest in healthy eating can be useful for preventive therapeutic plans that seek to prevent maladaptive behaviors from appearing. Thus, knowing the number of people interested in healthy eating and the number of individuals obsessed with the quality of their food provides room for the development of more assertive public health intervention plans.

Besides knowing the frequency and type of behavior found, knowing whether specific characteristics can be considered a risk factor may be interesting to prevent attitudes driven by extreme fixation on healthy eating. Table 1 shows a distinction between OrNe and HeOr considering the main predictors for symptomology and relationships found in the literature (Astudillo 2021; Cena et al. 2019; McComb and Mills 2019; Awad et al. 2022b; Hallit et al. 2021; Roncero et al. 2021; Strahler 2021; Zickgraf and Barrada 2022; Mitrofanova et al. 2021). In general, OrNe covers positive relationships with aspects that can compromise people's physical and mental health (e.g., restrained eating and maladaptive personality traits), as well as reducing well-being (e.g., impulsivity), while HeOr seems to be inversely associated with these aspects or leads to outcomes without significant harms. A significant relationship between OrNe and the drive for thinness and dysfunctional attitudes toward physical appearance was found in previous studies (Depa et al. 2019; Domingues and Carmo 2021), but this is not fully validated in the literature. Some relationships are unclear, such as HeOr vs. EDs. Other relationships are inconclusive, such as demographic characteristics, like sex and age, vs. OrNe and HeOr. Furthermore, somatic symptoms (e.g., anxiety, guilt feelings, and obsessive thoughts) seem to be present in OrNe, making the individual's clinical condition worrying.

Douma et al. (2021) studied the experience of Dutch health professionals to assess how OrNe develops and who typically develops it. Data showed young age, female, high level of education, perfectionism, and use of social media as baseline risks for OrNe. The authors also found that weight loss, inactive social life, and

Table 1 Distinction between pathological and non-pathological dimensions of orthorexia and the main predictors for symptomology

	Pathological dimension (orthorexia nervosa)	Non-pathological dimension (health orthorexia)
Focus	In the food quality that must be as healthy and "clean" as possible	In the food quality that is nutritionally balanced
Eating disorders	Positive relationship	Positive relationship, but weak*
Restrained and emotional eating	Positive relationship	Negative relationship
Body image disturbance	Positive relationship	Negative relationship*
Obsessive-compulsive symptoms	Positive relationship	Uncorrelated
Maladaptive personality traits and impulsivity	Positive relationship	Negative relationship
Poor mental health	Positive relationship	Negative relationship
Good mental health	Negative relationship	Positive relationship
Well-being	Negative relationship*	Positive relationship*
Mindfulness	Negative relationship*	Positive relationship*
Social media use	Positive relationship*	Untested
Exercise engagement	Inconclusive	Uncorrelated*
Body mass index	Inconclusive	Inconclusive
Age	Inconclusive	Inconclusive
Gender	Inconclusive	Inconclusive
High level of education	Positive relationship*	Untested
Socioeconomic status	Inconclusive	Inconclusive
Health-related programs/ occupations	Inconclusive	Positive relationship*
Dieting	Positive relationship	Untested
Adoption of vegetarian/ vegan food style	Inconclusive	Untested
Alcohol, tobacco, and drug use	Positive relationship*	Inconclusive
Vegetable and fruit consumption	Positive relationship*	Positive relationship*
Meat consumption	Negative relationship*	Untested

Note. Asterisk indicates that only or a small number of studies have found the relationship. Inconclusive means that the studies are not consensual about the relationship.

environment were inconclusive for OrNe, corroborating Bratman's (2017) idea that weight and exercise are not primary motivations for exhibiting high levels of OrNe. Zickgraf and Barrada (2022) found differing patterns of associations between OrNe and HeOr and ED symptoms, food intake, diet quality, nutrition knowledge, and lifestyle variables, with negative consequences for OrNe. Some studies show that OrNe is positively associated with poorer mental health (Barthels et al. 2019; Strahler et al. 2020; Awad et al. 2022a; Yakin et al. 2022), while HeOr is positively

linked to better mental health (Awad et al. 2022b; Strahler 2021; Yakin et al. 2022). Therefore, the literature is still inconsistent in terms of risk and protective factors for orthorexia dimensions.

A relationship that could be explored in greater depth in the future is whether orthorexia is associated with socioeconomic status. Some studies (Mathieu 2005; Varga et al. 2013; Hyrnik et al. 2016) suggest that it is expensive to eat the kinds of foods classified as healthy. According to McComb and Mills (2019), it is possible that OrNe is more prevalent among high-income individuals. In this way, would people who cannot afford to shop at an organic health food store be less likely to develop orthorexia? Perhaps, as people with lower or lack of income generally make food choices based on price and not on the desire to be healthier per se. Furthermore, low socioeconomic status may be associated with other problems that are more relevant than just healthy eating. However, the answer to this question is not yet clear, which requires further investigation to determine whether income influences orthorexia-like behaviors.

Evaluating Orthorexia from Psychometric Instruments

To screen orthorexia-like behaviors, it is essential to have adequate tools to produce valid and reliable data. In this chapter, only psychometric instruments with a suggestive capacity to simultaneously investigate both OrNe and HeOr symptomatology will be explored. At the time of this writing, most tools do not allow a clear interpretation about the dimensions of the orthorexia (Valente et al. 2019; Hallit et al. 2021; Niedzielski and Kazmierczak-Wojtas 2021). However, the Teruel Orthorexia Scale (TOS) (Barrada and Roncero 2018), the Eating Habits Questionnaire (EHQ) (Gleaves et al. 2013), the Düsseldorfer Orthorexia Scale (DOS) (Barthels et al. 2015a), and the Orthorexia Nervosa Inventory (ONI) (Oberle et al. 2021) seem to include items that may be able to identify both OrNe and HeOr behaviors. The following information about these instruments is to help clarify to the reader their reasoning and usefulness.

TOS. The TOS was developed by Barrada and Roncero (2018) in the Spanish culture based on key elements extracted from literature. The researchers constructed the items as statements (e.g., "Thoughts about healthy eating prevent me from concentrating on other tasks") and found from exploratory factor analysis (EFA) two balanced item sets, one with eight items to investigate the negative consequences of extreme fixation on healthy eating, i.e., OrNe (e.g., "If I ever eat something I consider unhealthy, I punish myself for it"), and the another with nine items to investigate the interest, but not obsessive, in following an eating style considered by the individual as healthy, i.e., HeOr, (e.g., "I mainly eat foods that I consider healthy"). Table 2 shows the distribution of items for each factor of the TOS. A 4-point *Likert*-type response scale ranging from 0 (completely disagree) to 3 (completely agree) is used, and higher scores indicate greater likelihood of presenting OrNe and/or HeOr. Importantly, when there is evidence about the multidimensionality of an instrument, as in the case of the TOS, it is necessary to compute

Table 2 Potential instruments to assess the bidimensionality of orthorexia

Instrument	Items[a]	
	Health orthorexia dimension	Orthorexia nervosa dimension
Teruel Orthorexia Scale (TOS)[b]	1, 2, 3, 6, 7, 8, 11, 13, 15	4, 5, 9, 10, 12, 14, 16, 17
Eating Habits Questionnaire (EHQ)[c]	1, 2, 3, 11, 12, 15, 19	6, 7, 8, 10, 13, 17, 18, 20
Dusseldorf Orthorexia Scale (DOS)[c]	1, 2, 3	4, 6, 7, 8, 9, 10

Note

[b]Barrada and Roncero (2018)
[c]Hallit et al. (2021)

Table 3 Classification used in Silva et al. (2021) to interpret scores of "orthorexia nervosa" (pathological) and "health orthorexia" (non-pathological) using the Teruel Orthorexia Scale

Percentile	Mean score	Likelihood for presenting health orthorexia- and orthorexia nervosa-like behaviors
≤25	≤0.75	Extremely unlikely
25–50	0.75–1.50	Unlikely
50–75	1.50–2.25	Likely
>75	>2.25	Extremely likely

Note. Silva et al. (2021)

a score for each latent factor (i.e., dimension). The TOS has been tested in different contexts, such as Spanish college students (Barthels et al. 2019; Depa et al. 2019; Barrada and Roncero 2018), German and/or Lebanese community (Strahler et al. 2020; Strahler 2020, 2021; Awad et al. 2022a, b), US college students (Chace and Kluck 2021), English-speaking adults from different countries (Domingues and Carmo 2021; Zickgraf and Barrada 2022), adolescents residing in Lebanon (Mhanna et al. 2022), French female adults (Yakin et al. 2022), and Brazilian gym users (Silva et al. 2021).

Despite the advance brought by the TOS with the bidimensional approach, the methodology to determine HeOr scores is unclear. At the present, only two studies (Silva et al. 2021; Awad et al. 2022b) used the TOS to show the frequency of HeOr behaviors among participants with distinct approaches. Awad et al. (2022b) indicated the frequency of HeOr for each independent variable studied (e.g., presence of HeOr separated by gender: male = 37.6%, female = 45.2%) based on mean scores; however, the allocation of participants in present/absent HeOr was unclear. Silva et al. (2021) calculated the mean scores for each factor of the TOS and classified participants according to the likelihood of presenting HeOr and OrNe behaviors using percentiles (P) of *Likert*-type response scale. Table 3 shows this classification. Importantly, the authors emphasized that the strategy used was for the study, which requires future evaluation to verify whether the suggested classification is adequate in other contexts, as this may change when there is a "gold standard," i.e., an official

diagnostic criteria. Using their classification, Silva et al. (2021) found that 5.3% of participants were more likely (>P50) to present OrNe. These individuals were extremely preoccupied with healthy eating, and clinical follow-up would be very helpful to confirm and understand the symptomatology. On the other hand, 41.2% of participants were more likely (>P50) to present HeOr. They are people who are interested in healthy eating and seek to follow it but without exaggerations. In addition, the study found that 4.4% of participants exhibited both OrNe and HeOr behaviors (>P50). This overlap may indicate the validity of considering orthorexia as a continuum phenomenon (Strahler 2020), as participants with high OrNe and HeOr scores are probably people interested in healthy eating, but at certain times they may be more preoccupied than usual with the quality of food.

EHQ. The EHQ was developed in a US context by Gleaves et al. (2013) based on evidence about orthorexia indicated by Bratman and Knight (2000) and on the importance attributed to healthy eating by undergraduate students in introductory psychology and nutrition classes and apparent symptoms of the phenomenon reported by graduate students in clinical psychology. A pool of 21 items composed the final version of the EHQ, which included 12 items to measure problems associated with healthy eating (e.g., "I am distracted by thoughts of eating healthily"), five items to measure knowledge of healthy eating (e.g., "I am more informed than others about healthy eating"), and four items to measure positive feelings about healthy eating (e.g., "I feel in control when I eat healthily"). A 4-point *Likert*-type response scale ranging from 1 (*false, not at all true*) to 4 (*very true*) is used to the EHQ items. Individuals with higher scores on the three factors exhibit greater preoccupation with healthy eating. Subsequent studies (Mohamed Halim et al. 2020; Godefroy et al. 2021) evaluated the EHQ in different samples (Australian and French) and found factorial structures and distribution of items per factor not equivalent to the original study, which may indicate some factorial instability of the instrument.

DOS. The DOS was created by Barthels et al. (2015a) in Germany. Data for the items came from an inductive procedure that included discussions on different subject areas, such as knowledge about the composition and components of food, nutritional supplements, effects of food on bodily functions, psyche and diseases, and general opinions about health. The authors also used the ideas presented by Bratman and Knight (2000) to create the DOS items. A single-factor final model with 10 items (e.g., "I have the feeling of being excluded by my friends and colleagues due to my strict nutrition rules") was designed to measure orthorexia-like eating behaviors. A 4-point *Likert*-type response scale ranging from 1 (*this does not apply to me*) to 4 (*this applies to me to*) is used in the DOS, and a higher score reflects greater OrNe-like behavior. Psychometric studies (Chard et al. 2019; He et al. 2019) have evaluated the DOS and found inconsistencies regarding the adequacy of the single-factor model, which raises doubts about its dimensionality.

Considering the inconsistent data on the dimensionality of both EHQ and DOS, Hallit et al. (2021) conducted a study with a sample of Lebanese adults and found for both instruments two correlated factors interpreted as HeOr and OrNe. Table 2 shows the distribution of items and each factor. The multidimensionality of these

instruments was discovered from the EFA, which was conducted in a sample of participants. However, to date, psychometric evidence of the bidimensional structure of the EHQ and of the DOS has not been showed in different samples to support the adequacy of the models; therefore, this limitation must be taken into account. Importantly, to elaborate the items of an instrument, a clear theoretical rationale is the main guide for the formation of latent factors (Marôco 2021; Kline 2016). From this perspective, developing items with specific content to capture the symptomatology of each dimension of orthorexia would be the most parsimonious way.

ONI. The ONI was proposed in an American context by Oberle et al. (2021) to screen orthorexia-like behaviors from physical, psychosocial, and emotional aspects included in consensual diagnostic criteria for OrNe (Cena et al. 2019). As this instrument was also based on modified items of the EHQ and DOS, speculation emerges as to whether it would also be able to assess HeOr. The ONI encompasses a three-factor model composed of 10 items to assess physical and psychosocial impairments (e.g., "Health professionals have expressed concern that my diet is too restrictive"), nine items to capture behaviors and preoccupation (e.g., "I follow a healthy diet with many rules"), and five items to investigate emotional distress (e.g., "When I stray from my healthy diet, I can only think about what a failure I am"). A 4-point *Likert*-type response scale, which ranges from 1 (*definitely not true*) to 4 (*definitely true*), is used in the ONI with higher scores indicating OrNe symptomatology. The authors proposed a cut-off point using the mean value of >3 to indicate having OrNe (or at least being at high risk for OrNe). What is not clear so far is whether the ONI is an instrument capable of evaluating HeOr, and if it is, it is important to determine how to do this.

What Is the Best Way to Investigate HeOr Symptomatology?

At this point, you should be asking yourself this question. In an epidemiological context, the psychometric instruments seem to be the most prominent tools to screen orthorexia-like behaviors in the population, but caution is essential when using these as all have limitations. This is not surprising, because given that there are no official diagnostic criteria for orthorexia, it is unlikely that any instrument will be considered the best to assess the phenomenon. Psychometric evaluation of the existing attitude scales should continue. Future research should focus on clarifying differences and similarities between the TOS, DOS, EHQ, and ONI for screening OrNe and HeOr. Importantly, no psychometric instrument produces results to determine the presence/absence of orthorexia, as this would require cutoff values to be establish from diagnostic tests. For now, the TOS seems to be the most prominent psychometric tool available.

Investing in reviews of available instruments to investigate the dimensions of orthorexia may be more plausible than creating new ones without knowing exactly where HeOr fits. As the understanding of HeOr advances, the possibility of adjusting existing instruments becomes more tangible, such as improving items and factors. In addition, HeOr investigations with qualitative research design – including clinical

interviews – on healthy eating styles and other related eating habits can be substantially important to generate information to improve the instruments. These data, together with longitudinal and experimental studies (with qualitative and quantitative approaches), may help to increase knowledge about orthorexia, clarify risk factors, and determine the extent to which a pathological obsession exists. This could make preventive and therapeutic intervention strategies more successful (Douma et al. 2021).

What Is the Best Way to Management Symptomatology of Orthorexia?

The answer to this question is not clear and objective. As OrNe is not an officially recognized disorder, elaborating a therapeutic plan is a challenge. A pertinent hesitation that emerges is whether both OrNe and HeOr should be treated considering that they refer to pathological and non-pathological dimensions, respectively. In practical terms with the background of the literature, treating OrNe is probably clear and necessary, as it harms different areas of the person's life. On the other hand, treating HeOr does not seem to be appropriate.

Before guiding a patient with symptoms suggestive of orthorexia, it is important to know if you are the "right professional" for this. For example, people commonly go to a nutritionist in search of more information about food and nutrition but with a focus on receiving a "perfect diet (e.g., a list of foods written on a sheet)" that promotes several benefits, especially the control of body weight. If "diet" is the unique therapeutic approach to be followed in a case of orthorexia, treatment is not in line with projections of improvement in the disturbance. Now, if the therapeutic approach includes techniques to change maladaptive eating behaviors, this needs to be clear for that patient to evaluate their level of involvement. Individuals with OrNe symptomatology must be assisted by nutritionists aligned with this phenomenon, i.e., those trained and able to recognize healthy eating practices and when these practices cross the line toward obsession (Mathieu 2005).

A multidisciplinary team (e.g., nutritionist, psychologist, psychiatrist, physical education teacher, and social worker) is important for the management of orthorexia, as maladaptive traits can affect different areas of people's lives. This also allows for the complete treatment of the phenomenon, since "people don't stay in one spot," as they may have more than one disorder, as well as change categories such as recovering from bulimia nervosa and manifesting orthorexia-like behaviors together with symptoms of stress and anxiety (Mathieu 2005; McGovern et al. 2021). To date, studies on the effectiveness of treatment have not been identified in the literature, but some works have suggested that cognitive-behavioral therapy, exposure therapy, and group therapy can be useful to reduce extreme fixations with healthy eating. These therapies can be applied by well-trained nutritionists and psychologists who should know what patients eat, how they buy and prepare food, and what they think is important to guide/advise change of habits (McGovern et al. 2021; Walker-Swanton et al. 2020; Mitrofanova et al. 2021). In some cases, the prescription of medication –

by a properly qualified physician – may be necessary to reduce debilitating sensations, but this strategy is challenging, as the obsession with "purity" or "naturalness" can prevent the consumption of drugs. On the other hand, individuals who experience orthorexia symptomatology might be a bit more responsive to treatment because they are actually concerned about their health (Mathieu 2005; Douma et al. 2021).

As for HeOr, what therapeutic approach should be followed? Is this plausible? If a "normal" drive for healthy eating is not a problem per se, when should the therapist act? If the risk factors for OrNe and HeOr were elucidated, the answer to these questions would be clearer. For now, it is believed that public health campaigns aimed at promoting health and individual guidance carried out by trained professionals to understand the guidelines are the best paths. These are not therapeutic approaches but preventive and counseling strategies that may avoid the drive toward healthy eating as an extreme preoccupation on the edge of OrNe.

Regardless of whether or not it receives its own diagnostic category, orthorexia appears to be increasingly prominent in society. Knowing the symptomatologic framework involved in this phenomenon is important; however, helping those who suffer from a maladaptive relationship with food is also valuable. Therefore, those involved in the therapeutic process of patients who have healthy eating concerns should be constantly updated on the evolution of the concept of orthorexia. However, they must also be sensitive and empathetic to provide care that goes beyond diagnosis and biomedical therapy, being able to tap into beliefs and emotions that influence and/or determine eating behavior aiming to changing it, when relevant.

Final Considerations

Although the focus of this chapter was to describe the non-pathological dimension of orthorexia (i.e., HeOr), it was necessary to introduce the reader to the characteristics of the pathological dimension (i.e., OrNe). The background presented demonstrates a growing effort of the academic community to understand the negative consequences of OrNe and the dearth of data about HeOr. A better understanding of the non-pathological dimension would be useful in managing people's conscious eating behaviors, offering opportunities to develop prevention and intervention, when the preoccupation with health crosses the line of interest and becomes an obsession.

A focused interest on food is not inherently problematic unless maladaptive behaviors occur and cause distress or lead to impairments. In this way, OrNe and HeOr seem to be separable dimensions that individuals may experience to different degrees. Individuals with symptoms of OrNe have food as the center of life and, due to the ability to control, experience a sense of pride and superiority creating identity. This commonly leads to fixation and obsession with physically, socially, and emotionally negative impacts. On the other hand, people with symptoms of HeOr see eating as a way to promote health, but not the only way, so they are interested in eating to change maladaptive eating behaviors. These changes do not cause

significant damage to these people's life and should not be considered potentially pathological.

Importantly, it is still unclear whether orthorexia represents a disorder, the progression of a disorder, or a lifestyle. It is also unclear whether orthorexia is a multidimensional phenomenon. Therefore, understanding, conceptualizing, and showing how to assess this phenomenon is a challenge that the scientific community will have to unravel, thus making clinical practice assertive and effective. There is still much to discover about orthorexia, especially about HeOr. The conceptualization of this seems to be close to a consensus, finding no associated pathological characteristics. On the other hand, the forms to assess HeOr are still quite unclear, and few tools are available to investigate non-pathological symptoms, with the TOS being the scale that seems to be the most promising. For now, it is worth remembering that following a healthy eating is good, but if obsessive thoughts and fixation behaviors exist, the effects can be reversed, making the person's life more complicated and less long-lasting.

At this point, a final remark is important. Naming HeOr as a non-pathological healthy eating brings it too close to a pathological one. The use of the suffix "orexis" with a negative bias is so common (given to its use to name EDs) that this happens unintentionally. Note in Fig. 3 that when a group of Brazilian students was asked

Fig. 3 Word cloud associated with the terms "healthy eating" (A) and "healthy orthorexia" (B). *Note*. Answers given by Brazilian students to the questions: "When I say healthy eating, what word comes to your mind?" (A) and "When I say healthy orthorexia, what word comes to your mind?" (B). (This figure was created by the authors of this chapter)

about the meaning of "healthy eating" and "healthy orthorexia," the words "health" and "preoccupation" were present in both. Furthermore, the words used by students to characterize HeOr were mostly associated with something problematic. When Bratman (1997) first proposed the existence of orthorexia, he only made reference to what is called today as OrNe to indicate an excessive preoccupation about healthy eating. In research settings, scientists may use the terms OrNe and HeOr to operationalize the supposed bidimensionality of orthorexia in a didactic way. However, despite the theoretical enthusiasm to understand the particular dynamics about orthorexia, the impact that words may cause in the general population should be noted. The use of the term HeOr should always be used with caution, as the suffix *"*orexsis" may be misinterpreted as something harmful. Therefore, for the general public, HeOr might be translated as interest in healthy eating in order not to cause feelings of inadequacy.

Applications to Other EDs

In this chapter, we review the phenomenon of orthorexia focusing on its presumed non-pathological dimension, called healthy orthorexia (HeOr). However, we also had to explore the pathological dimension, called orthorexia nervosa (OrNe), and through this we found suggestions for therapeutic approaches that can reduce extreme fixation on healthy eating. Although OrNe is not recognized as a mental disorder, it is already possible to identify some characteristic aspects of OrNe in the context of EDs. Hence, as more about OrNe is understood, more clinicians and health professionals may add this to their body of knowledge about eating, becoming more resourceful to plan and implement therapeutic plans. Some evidence suggests that OrNe is focused on the quality of food driven by the goal of being as healthy as possible, while EDs can be focused on the quantity of food aiming at body change; however, these two focuses can coexist. Among the therapeutic and preventive approaches mentioned in this chapter for OrNe, psychotherapeutic and psychoeducational strategies stand out, which are also very relevant for the treatment of EDs. The cognitive-behavioral approach is an example of a useful therapy to reduce maladaptive thoughts about healthy eating and, consequently, promote new adaptive eating behaviors, applying to people who exhibit OrNe behaviors, and an official ED (e.g., anorexia nervosa), as they can coexist. Regarding preventive approaches, the chapter provides evidence that may also be considered for other EDs, since it is not clear yet if the controlled and fixated food selection characteristic of OrNe can act as a first sign of other EDs. If OrNe risk factors are divulged, they also may be considered in other ED investigation studies. The chapter also sheds light on a non-pathological healthy eating behavior, HeOr. Although it is conceptually associated with OrNe, the dedication, care, and commitment to healthy eating should not be seen as pathological – even if someone has some weird beliefs regarding what is a good food – if this care and commitment do not cause physical, social, and psychological impacts on one's life. Therefore, it is recommended that in clinical practice (e.g., during an appointment with a psychologist) people are not labeled as

"orthorexic" just because they take care with what they eat, as this label carries a negative perception and may cause psychological distress. People diagnosed with EDs may have excessive preoccupation with healthy eating, and in these cases the therapeutic approaches suggested in this chapter for OrNe may be useful.

Mini-Dictionary of Terms

- **Concern**: A state of interest blended with apprehension or uneasy.
- **Drive**: An arousal state that influences beliefs and behaviors related to its aim.
- **Eating behavior**: A set of cognitions and affections that support actions in relation to the act of eating and are strongly related to biological, psychosocial, cultural, and environmental aspects.
- **Fixation:** An obsessive preoccupation or attachment to making something firm or stable.
- **Healthy orthorexia**: A non-pathological interest in healthy eating behavior.
- **Maladaptive behavior:** An action that interferes with everyday activities with potential harmful effects.
- **Non-orthorexia nervosa**: Synonymous with healthy orthorexia.
- **Obsession:** A persistent and disturbing idea or thought.
- **Orthorexia nervosa**: A possible pathological fixation on healthy eating.
- **Preoccupation**: Synonymous with concern with a likely higher degree of alarm.
- **Psychometric properties**: Validity (e.g., factorial) and reliability (e.g., internal consistency) estimates that allow showing data on the capacity of an instrument to measure latent construct(s).
- **Score**: A numerical value that can be used to interpret the magnitude of a phenomenon.
- **Trigger**: Something that sets off a mechanism.

Key Facts of Orthorexia

- Orthorexia is represented by the concern with healthy eating that can be obsessive or not.
- The term orthorexia nervosa has been used to represent an extreme fixation on healthy eating that can damage various areas of a person's life.
- Orthorexia nervosa is not yet recognized as a mental disorder included in the DSM-5 and ICD-11.
- People with pathological behaviors to achieve a healthy diet can experience physical and mental impairments; therefore, therapeutic approaches used in official mental disorders can be useful.
- The term healthy orthorexia has been used to represent an interest in healthy eating without obsessive behavior; however, it is not yet consolidated in the literature.

- People who are interested in eating healthy can benefit from guidelines to direct their eating behaviors; however, these individuals do not have pathological symptoms that require intervention therapy.

Summary Points

- Orthorexia is a phenomenon that lies on a continuum, which goes from an interest in healthy eating (non-pathological) to an extreme preoccupation and control (pathological).
- Knowing the drive for healthy eating can be helpful for clinical management.
- Orthorexia nervosa encompasses an intensification of the preoccupation with healthy eating with disturbing thoughts and stereotypical behaviors.
- Healthy orthorexia involves an interest in healthy eating that does not harm the person's life.
- This chapter focuses on the conceptualization of healthy orthorexia and explores its forms of assessment and empirical evidence.
- Much is known about orthorexia nervosa behaviors, but little is known about healthy orthorexia.
- The use of proper assessment tools is necessity in the field, which is more focused on orthorexia nervosa, but a special look at healthy orthorexia is also helpful.

The Binge Eating Scale

75

Features and Applications

Sagar Karia, Shorouq Motwani, and Avinash Desousa

Contents

Abstract

Binge eating disorder (BED) is a type of ED that is characterized by recurrent episodes of binge eating (BE) without subsequent compensatory behaviors, such as self-induced vomiting or over-exercising. The Binge Eating Scale (BES) is one of the most common instruments used to screen binge eating severity. The BES has been found to demonstrate a very good internal consistency (between 0.85 and 0.90) and a good construct validity. There have been various versions developed of BES like French, Persian, Arabic, Spanish, etc.

Introduction

Eating disorder (ED) most frequently affects young Western females within high-income and industrialized Western Europe and North America, but can also occur in diverse countries and cultures worldwide to a lesser extent. The disorder is found to be more common in the population suffering from obesity, and it is usually associated with several psychiatric (anxiety, depression, obsessive-compulsive disorder) and physical comorbidities (diabetes, hypertension). It has been seen that anxiety is the most important associated factor with ED, followed by stress, body image, and depression.

Binge eating disorder (BED) is a type of ED that is characterized by recurrent episodes of binge eating (BE) without subsequent compensatory behaviors, such as self-induced vomiting or over-exercising (Zeidan et al. 2019). Very high BED prevalence rates have been reported in adolescents and young adults, with higher prevalence rates in women than in men, and recent neuroimaging studies suggest that this sex differences in binge eating may be due to the presence of some alteration in the female brain's reward system, such as the lower ability to suppress hunger in women (Escrivá-Martínez et al. 2019; Imperatori et al. 2016). Smink et al. showed that BE has two peak ages of onset, one immediately after puberty at an average age of 14, and the other at the end of adolescence (19–24 years). Average lifetime prevalence is estimated to be 1.9% for BED, making it the most common ED (Escrivá-Martínez et al. 2019).

The risk factors associated with BED are similar to those with psychiatric disorders and obesity. The most common risk factors associated with BED are as follows (Zeidan et al. 2019):

1. Adverse childhood experiences such as sexual/physical abuse.
2. Parental problems like depression.
3. Negative self-evaluation.
4. Vulnerability to obesity.
5. Repeated exposure to negative comments about shape, weight, or eating is associated with BED.
6. A positive correlation has been found between BE and food addiction.
7. Emotional eating has also been found to be positively related to BE. In fact, overeating just for emotional reasons and cravings may turn quickly into BED.
8. Family history of eating disorders is associated with higher BE. BED is found to aggregate strongly within families, which may reflect genetic influences.

Tuschen-Caffier and Hilbert model has integrated the triggering and sustaining factors of the BED in addition to the risk factors. Based on this model, different external and internal stressors like relationship conflicts, exposure to food, impulsivity, low self-esteem, and tensions have been identified that can trigger BE. BED also shares characteristics with substance use and addictive disorders (Zeidan et al. 2019).

Recent research indicates the presence of comorbidity between BE and the use of alcohol and binge drinking in young people. Impulsivity can play an important role in the comorbidity between disordered eating behavior and excessive alcohol consumption in young students and has also been positively associated with BE (Escrivá-Martínez et al. 2019).

Despite data suggesting that only a small subset of adolescents 10–13 and even fewer children 14–16 meet full DSM-IV-TR criteria for BED, binge eating and the experience of loss of control (LOC) while eating (regardless of the amount of food ingested) appear to be quite common among youth (Tanofsky-Kraff et al. 2007).

Diagnosis and Scales

Diagnosis of BED according to the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (*DSM-5*), is based on the occurrence of at least one BE episode per week for three consecutive months; these episodes are characterized by the consumption of larger amounts of food in a short period when compared to the typical amounts for most people under similar circumstances, accompanied by a sense of loss of control over eating and a marked distress during these episodes (Zeidan et al. 2019).

Eating Disorder Examination (EDE) interview provides a comprehensive scheme for classifying episodes of overeating using perceived lack of control and amount of food consumed as criteria to distinguish between different types of overeating. Based on these criteria, four different types of overeating are identified: (a) objective binge eating: loss of control and objectively large amount consumed; (b) subjective binge eating: loss of control and small amount consumed even though the individual views intake as excessive; (c) objective overeating: no loss of control and objectively large amount consumed; and (d) subjective overeating: no loss of control and small amount consumed, but individual views amount consumed as excessive. Objective binge eating is used as part of the *DSM-IV* diagnostic criteria for Binge Eating Disorder (BED; American Psychiatric Association 1994; Timmerman 1999).

To assess any psychological disorder including binge eating, structured clinical interview is considered as gold standard. However, it is time-consuming, requires training, and can only be administered to one subject at any particular time (Robert et al. 2013).

Several self-report questionnaires have been developed to assess BED to replace the interview and save time. Gormally et al. (1982) developed the BES, Yanovski (1993) developed the Questionnaire on Eating and Weight Patterns (QEWP-R), and Fairburn and Beglin (1994) developed the Eating Disorder Examination Questionnaire (EDE-Q).

The Binge Eating Scale (BES) is one of the most common instruments used to screen binge eating severity.

Binge Eating Scale

The Binge Eating Scale (BES) was developed by Gormally et al. to measure severity of binge eating, the uncontrolled consumption of a large amount of food, in overweight binge eaters (Timmerman 1999). It is an interesting tool both in terms of evaluation and monitoring of these patients, as it can be used for the purposes of screening, evaluation of severity, and monitoring of the disorder (Zeidan et al. 2019). Since its inception, the BES has been used widely in research to measure binge eating severity in the non-purge binge eating population and to determine whether potential research participants meet the inclusion criteria of binge eating (Timmerman 1999).

Importantly, the BES is not intended to detect presence of Binge Eating Disorder (BED) as it was created before binge eating disorder (BED) was officially recognized as a psychiatric diagnosis (American Psychiatric Association 1994). Rather, it can be used as a brief screening tool to identify the severity of binge eating behavior in overweight and obese adults, to tailor obesity interventions, and to track treatment outcomes (Cotter and Kelly 2015).

The BES was designed as a measure of severity rather than diagnosis of BED, with the additional property of evaluating its affective, cognitive, and behavioral manifestations. It has an outstanding role as a screening measure in clinical and nonclinical populations to evaluate BE severity and intervention outcomes (Escrivá-Martínez et al. 2019). It does not specify a time frame and presents a series of differently weighted statements for each item, from which respondents select the statement that best describes their attitudes and behaviors (Celio et al. 2004).

Studies carried out in the past decade, mainly with obese patients, have shown that the BES is very sensitive and specific in distinguishing between compulsive and normal eaters (Escrivá-Martínez et al. 2019).

The BES has been found to demonstrate a very good internal consistency (between 0.85 and 0.90) and a good construct validity (Zeidan et al. 2019).

The BES items were created in accordance with the "Diagnostic and Statistical Manual of Mental Disorders, 3rd edition," criteria for binge eating. Although the BES is not designed to assess for the presence of binge eating disorder (BED), in one of the few studies that evaluated the concordance between the BES and BED in bariatric surgery candidates, BES was found to have a high sensitivity and adequate specificity in identifying those with BED (Cotter and Kelly 2015). Estimated internal consistency of the measure is generally acceptable across samples, including men and women from the community, college students, treatment-seeking adults, and racially/ethnically diverse groups (Hood et al. 2013).

The BES demonstrates a significant association with several indicators of subjective binge eating (SBE) like calories consumed during SBEs, number of SBEs, and number of SBE days. Small-to-moderate, significant correlations have also been noted between the BES and similar indicators of objective binge eating. BES scores do not correlate with overall caloric intake and is not successful in discriminating between SBEs and OBEs, but appears to be a good indicator of severity of LOC eating (Cotter and Kelly 2015).

The BES is a 16-item self-report measure designed to assess two components of binge eating: behavioral manifestations (e.g., eating quickly, overeating) and emotions/cognitions that precede or follow a binge (e.g., feeling out of control, guilt) (Hood et al. 2013).

The initial development of the scale yielded two eight-item factors representing the behavioral and cognitive/emotional aspects of binge eating. More recent examinations of the scale further support this two-factor solution, suggesting that the existing subscales remain appropriate across a range of samples (Cotter and Kelly 2015).

Scoring

The BES consists of 16 items, eight describing the behavioral manifestations of binge eating and eight describing feelings and cognitions associated with binge eating. Each item consists of four statements that reflect a range of severity (0 indicates no binge eating problem and 3 indicates a severe binge eating problem). Subjects choose the statement that best describes their perceptions and feelings about their eating behavior. The BES is scored by adding the individual values for the 16 items with the possible range of scores from 0 to 46 (Timmerman 1999).

Based on BES scores, the uncontrolled eating behavior is graded into three different levels of severity: subjects scoring 17 and less were considered non-binge eaters, those scoring between 18 and 26 were moderate binge eaters, and those scoring 27 and above were considered severe binge eaters (Robert et al. 2013).

Thus, the total score is used to differentiate among those with absent to minimal binge eating, mild to moderate binge eating, and severe binge eating (Hood et al. 2013).

Based on the BES total raw scores, Marcus et al. (1988) identified three different levels of severity: individuals scoring 17 or less were considered not reporting significant binge eating, those scoring between 18 and 26 were considered moderate binge eaters, and those scoring 27 and above were considered severe binge eaters. These categories had a 98% concordance rate with a diagnosis using a semi-structured interview (Imperatori et al. 2016).

Other Uses of BES

BES has been used as a screening measure in prebariatric surgery psychological evaluations (Hood et al. 2013). Administering the BES as part of a comprehensive psychological evaluation can help improve the assessment and treatment of patients presenting for bariatric surgery (Celio et al. 2004). BES is a reliable measure that identifies approximately one third of patients seeking bariatric surgery (Hood et al. 2013). When prescreening potential bariatric surgery patients, clinicians are likely to be interested in identifying patients who endorse significant binge behaviors, even if

they do not meet full criteria for BED. In other words, identifying false positives is often acceptable as further evaluation and appropriate presurgical cognitive/behavioral interventions can be recommended. Timmerman reported an adequate 2-week test–retest reliability of the BES in a behavioral weight loss sample. BES is an appropriate measure to screen for binge eating behaviors in nonsurgical weight loss treatment, although false positives may be common (Celio et al. 2004).

Limitations

1. Gormally et al. originally proposed a two-dimensional structure, dividing the items of the BES into cognitive and behavioral BE, but the results on its two-dimensionality use are contradictory (Zeidan et al. 2019). Most of the times it is exclusively used as a unidimensional measure of binge eating severity through the measure's total score, but studies have shown that both the unidimensional and the two-factor models provide an adequate fit to the data, in fact the fit of the two-factor model maybe better (Hood et al. 2013). Of all the models compared, the bi-factor model is more superior in its potential for replication. Various studies have cast doubt on the utility of calculating the behaviors and feelings/cognitions factors as separate scores on the BES (Imperatori et al. 2016; Hood et al. 2013).

2. Though BES questionnaire has been widely used, there is limited research on the factors and properties of the BES in the general population. There is no study examining its psychometric properties in general populations of young men and women. Research has been done to assess the validity in specific samples like clinical samples or samples of women, especially obese women who undergo bariatric surgery to lose weight (Hood et al. 2013; Marek et al. 2016), or obese and overweight patients seeking weight loss treatment (Imperatori et al. 2016).

3. BES may be adequate for screening purposes but its use solely for the diagnosis of BED is not recommended due to the high percentage of misclassifications (Celio et al. 2004).

Other Versions

The BES has been translated into a variety of languages and validated in multiple international samples.

Spanish version: Spanish version of the BES is a valid and reliable scale for the assessment of BE in a youth sample. This brief, easy-to-administer, self-report questionnaire consists of 16 items on one scale. It provides relevant information about clinically significant symptoms of BE, and it may be especially useful in prevention programs and community interventions for disordered eating behaviors (Escrivá-Martínez et al. 2019).

Persian version: The BES showed acceptable reliability and considerable sensitivity (84.8%) and specificity (80.8%). BES, also, effectively distinguished the obese participants from the normal weight subjects. These results suggest that the

Persian version of BES is a sensitive instrument for screening binge eating among the nontreatment-seeking obese population (Mootabi et al. 2009).

Indonesian version: The Indonesian version of BES has good validity. The two-factor BES was revealed to be important in Indonesia, cross-culturally. There were language and cultural differences among Indonesian ethnics, which required a scale that uses standard language. This Indonesian version of BES can be used immediately. Thus, it can help improve planning of health promotion, prevention, and treatment of binge eating (Kusbiantari et al. 2020).

French version: The psychometric properties of the French version of the BES are comparable to its original version with a one factor structure. The BES is a useful tool to assess binge eating disorder in obese patients but might not differentiate binge eating disorder and bulimia nervosa in underweight and optimal weight subjects (Brunault et al. 2016).

Arabic Version: The Binge Eating Scale in its Arabic version is a suitable instrument to screen for binge eating among the Lebanese population. Some factors (body dissatisfaction, having a history of sexual abuse, a family history of binge eating, greater depressive/anxiety symptoms, and lower self-esteem) seem to be associated with higher binge eating (Zeidan et al. 2019).

Malaya Version: A study demonstrated high levels of sensitivity (84.6%) and specificity (94.9%) of the Malay version of BES in detecting binge eating behavior within a Malay-speaking adult population, with a positive predictive value of 81.8%, negative predictive value of 95.7% and Cronbach's alpha of 0.89. Therefore, the Malay version of the BES is useful as it has been demonstrated to be a valid and reliable instrument that is easy to administer (Robert et al. 2013).

Only five of the 16 items were correlated when studies were carried out to determine possible ways to strengthen concordance of the BES with a BED diagnosis. The items that were significantly associated with a BED diagnosis measured preoccupation with eating (item 14), guilt after overeating (item 6), difficulty controlling eating (item 10), preoccupation with food (item 15), and eating when not hungry (item 5) (Celio et al. 2004).

When using the BES clinical cutoffs there is tendency to over diagnose BED so it is suggested that the BES be used as a brief screening device and not as a diagnostic indicator (Cotter and Kelly 2015).

Modified Versions of BES

1. **The Children's Binge Eating Disorder Scale** (C-BEDS) is a 7-item measure which includes Marcus and Kalarchian's criteria. For example One item asks, "Do you ever eat because you feel bad, sad, bored, or any other mood?" to which children respond "yes" or "no" (Tanofsky-Kraff et al. 2007).

This scale was developed to measure BED in children according to the provisional criteria. Both the provisional criteria and the C-BEDS may be developmentally appropriate for use with children, although the C-BEDS may be a better screening

instrument as it quickly identified children with subsyndromal BED. If used by physicians and other health providers, this brief measure may assist with identifying early onset binge eating behaviors and avoiding the associated consequences, including adult BED, obesity, and other comorbidities (Shapiro et al. 2007).

2. **The Adolescent Binge Eating Scale** questionnaire is a potential screening tool to identify adolescents with obesity at high risk of BED and guide referral to a specialist to clarify the diagnosis and provide adequate care. Binge eating disorder (BED) is associated with obesity and high rates of medical and psychopathologic comorbidity, as well as increased healthcare use. Research involving children and adolescents has shown that few meet all the criteria for BED, as described by the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders*. The ADO-BED auto-questionnaire demonstrated a good association with the clinical interview for BED, particularly for question 1, "food seeking in the absence of hunger or after satiation," which was efficient to exclude adolescents without BED when answered negatively. The first question was more indicative than the second relative to the sense of lack of control over eating (sensitivity 85.7%). This may be explained by the subjectivity of this question and the adolescents' limited capacity to recognize such a behavior, even when illustrated by a concrete example such as, "Has it ever happened that you started eating biscuits and could not stop before the end of the packet?" However, answering positively to one of these two questions was not in itself predictive of BED (specificity 27.4%) (Chamay-Weber et al. 2017).

Applications to Other Eating Disorders

The Binge Eating Scale (BES) has no direct role in the assessment of other eating disorders but may be used as an add-on scale when scales for other eating disorders are applied. This is more so as binge eating behavior may be part of other eating disorders like Bulimia and is worth evaluating in those patients. The BES may provide insights into the binge eating behavior patterns in those patients and may also provide insights into the comprehensive management of these patients. The BES may be of use in patients with obesity where there are binge eating issues, and as a result, there is weight gain and there are many instances that these patients may have guilt and shame related to binge eating. The scale may help in the management of binge eating behavior in patients with obesity and looking at weight management as a part of their treatment. The BES may be useful in patients with borderline personality disorder that may have binge eating as a coping mechanism in these patients. The scale may also be useful in adolescents that have binge eating as mechanism of coping. There is a need to study the usefulness of BES in these populations so that we are able to deduce its utility in these cases and decipher its exact applications. Detailed literature in these conditions is sparse.

Mini-Dictionary

1. **Adolescence:** Adolescence is the transitional phase of growth and development between childhood and adulthood. The World Health Organization (WHO) defines an adolescent as any person between ages 10 and 19.
2. **Binge:** a period of excessive indulgence in an activity, especially eating, drinking, or taking drugs.
3. **Disorder:** a disturbance of normal functioning of the mind or body.
4. **Eat:** put (food) into the mouth and chew and swallow it.
5. **Obesity:** A disorder involving excessive body fat that increases the risk of health problems.
6. **Overeat:** Eat too much.
7. **Screening:** the evaluation or investigation of something as part of a methodical survey, to assess suitability for a particular role or purpose.

Key Facts

- The Binge Eating Scale (BES) is one of the most commonly used instruments to screen binge eating severity.
- There are many versions of scale in many languages like French, Persian, Arabic, Spanish, etc.
- The BES has been found to demonstrate a very good internal consistency and reliability.
- The scale aids in screening, diagnosis, and to judge improvement in children and adults with binge eating problems.
- Apart from binge eating disorder, the BES has uses in other eating disorders and obesity as well as patients undergoing bariatric surgery.

Key Summary Points

- The BES is one of the most widely used scales in the screening and diagnosis of binge eating behavior and binge eating disorder.
- The scale has greater use in the measurement of severity rather than diagnosis of binge eating disorder.
- The BES has a version to assess binge eating severity in children and adolescents as well.
- Further studies of the BES in diverse populations of eating disorders are needed to validate its use better.
- The BES also has versions in many languages that allow it to be used in national and international populations across research studies.

Conclusion

The BES may identify a significant number of patients with moderate/severe binge eating who do not meet criteria for BED; this is acceptable for a screening instrument, where false positives are more desirable than false negatives. Finally, clinicians can be very confident that a patient with a negative BES screen most likely does not have BED (Grupski et al. 2013).

Questions in Binge Eating Scale and Scoring

1. Self-conscious about weight:
   - I do not think about my weight or size when I'm around other people.
   - I worry about my appearance, but it does not make me unhappy.
   - I think about my appearance or weight and I feel disappointed in myself.
   - I frequently think about my weight and feel great shame and disgust.
2. Eat Quickly:
   - I have no difficulty eating slowly.
   - I may eat quickly, but I never feel too full.
   - Sometimes after I eat fast I feel too full.
   - Usually I swallow my food almost without chewing, then feel as if I ate too much.
3. Difficulty controlling Eating Urges:
   - I can control my impulses towards food.
   - I think I have less control over food than the average person.
   - I feel totally unable to control my impulses toward food.
   - I feel totally unable to control my relationship with food and I try desperately to fight my impulses toward food.
4. Eat when bored:
   - I do not have a habit of eating when I am bored.
   - Sometimes I eat when I am bored, but I can often distract myself and not think about food.
   - I often eat when I am bored, but I can sometimes distract myself and not think about food.
   - I have a habit of eating when I am bored and nothing can stop me.
5. Eat when not hungry:
   - Usually when I eat it is because I am hungry.
   - Sometimes I eat on impulse without really being hungry.
   - I often eat to satisfy hunger even when I know I've already eaten enough. On these occasions I can't even enjoy what I eat.
   - Although I have not physically hungry, I feel the need to put something in my mouth and I feel satisfied or only when I can fill my mouth (for example with a piece of bread).

6. Guilt after overeating:
   - I do not feel guilty or regretful at all.
   - I sometimes feel guilty or regretful.
   - I almost always feel a strong sense of guilt or regret.
7. Diet and Binge:
   - When I'm on a diet, I never completely lose control of food, even in times when I eat too much.
   - When I eat a forbidden food on a diet, I think I've failed and eat even more.
   - When I'm on a diet and I eat to much, I think I've failed and eat even more.
   - I am always either binge eating or fasting.
8. Eat tilled stuff:
   - It is rare that I eat so much that I felt uncomfortably full.
   - About once a month I eat so much that I felt uncomfortably full.
   - There are regular periods during the month when I eat large amounts of food at meals or between meals.
   - I eat so much that usually, after eating, I feel pretty bad and I have nausea.
9. Diet/restrict and binge:
   - The amount of calories that I consume is fairly constant over time.
   - Sometimes after I eat too much, I try to consume few calories to make up for the previous meal.
   - I have a habit of eating too much at night. Usually I'm not hungry in the morning and at night I eat too much.
   - I have periods of about a week in which I imposed starvation diets, following periods of when I ate too much. My life is made of binges and fasts.
10. Difficulty controlling eating:
    - I can usually stop eating when I decide I've had enough.
    - Sometimes I feel an urge to eat that I cannot control.
    - I often feel impulses to eat so strong that I cannot win, but sometimes I can control myself.
    - I feel totally unable to control my impulses to eat.
11. Eat till stuffed or sometimes vomit:
    - I have no problems stopping eating when I am full.
    - I can usually stop eating when I feel full, but sometimes I eat so much it feels unpleasant.
    - It is hard for me to stop eating once I start, I usually end up feeling too full.
    - It is a real problem for me to stop eating and sometimes I vomit because I feel so full.
12. Conceal eating:
    - I eat the same around friends and family as I do when I am alone.
    - Sometimes I do not eat what I want around others because I am aware of my problems with food.
    - I often eat little around other people because I feel embarrassed.
    - I'm so ashamed of overeating; I only eat at times when no one sees me. I eat in secret.

13. Eat continually:
    - I eat three meals a day and occasionally a snack.
    - I eat three meals a day and I usually snack as well.
    - I eat many meals, or skip meals regularly.
    - There are times when I seem to eat continuously without regular meals.
14. Preoccupation with eating:
    - I don't think about impulses to eat very much.
    - Sometimes my mind is occupied with thoughts of how to control the urge to eat.
    - I often spend much time thinking about what I ate or how not to eat.
    - My mind is busy most of the time with thoughts about eating.
    - I seem to be constantly fighting not to eat.
15. Preoccupied with food:
    - I don't think about food any more than most people.
    - I have strong desires for food, but only for short periods.
    - There are some days when I think of nothing but food.
    - Most of my days is filled with thoughts of food. I feel like I live to eat.
16. Uncertain how much food is normal:
    - I usually know if I am hungry or not. I know what portion sizes are appropriate.
    - Sometimes I do not know if I am physically hungry or not. In these moments, I can hardly understand how much food is appropriate.
    - Even if I knew how many calories should I eat, I would not have a clear idea of what is, for me, a normal amount of food.

Non-binging; less than 17
Moderate binging; 18–26
Severe binging; 27 and greater

Contents

Abstract

People suffering from eating disorders (EDs) are affected both on the somatic and psychological and social aspects. The World Health Organization used the term quality of life to define individuals' perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals,

Dunja Stankic and Dona Stefanovic contributed equally with all other contributors.

expectations, standards, and concerns to express the broad range of changes in a person's life. Some of these changes are either triggered or suffer consequences from eating habits that are often a form of EDs. In the last few decades, there is an increasing interest in finding adequate questionnaires to help identify and measure the severity of EDs, as well as questionnaires to examine the quality of life in these patients. Several studies have been conducted on this subject, and the evolution and scientific advancement will be elaborated and discussed in the following text in order to identify the most appropriate questionnaire that will aid clinicians in their therapeutic practice. Among the first questionnaires used in practice to assess the quality of life of patients with an ED were Short Form-36 (SF-36) and the Eating Disorder Examination-Questionnaire (EDE-Q). Although the generic questionnaires were applied and yielded good results, a specific questionnaire on the quality of life of individuals with EDs is still lacking in this field. New discoveries are made as the search for highly specialized and sensitive questionnaires continues. Several instruments and questionnaires are used to obtain a final result in several studies investigating the association between the intensity of symptoms induced by EDs and quality of life. The most recent questionnaires specific to the quality of life of a patient with an ED are the Eating Disorders Quality of Life Scale (EDQLS) and the Eating Disorders Quality of Life Scale (EDQOL). We conclude that there has been great progress in evaluating and designing appropriate questionnaires to help clinicians and researchers in the diagnosing, developing treatment strategies, and prognosing EDs, as well as assessing quality of life in these patients.

Introduction

People suffering from eating disorders (EDs) are affected both on the somatic and psychological and social aspects. Eating problems are increasingly demonstrating potentials to cause substantial medical, mental, and social consequences. The WHO defines quality of life as the World Health Organization (WHO) defines QoL as an

individual's perception of their position in life in the context of the culture and value system in which they live and in relation to their goals, expectations, standards, and concerns (Orley et al. 1998). As a result, a wide range of related domains, such as the connection of physical health with social and psychological functioning, have an impact on quality of life. If EDs progress to a chronic stage, they can have a substantial influence on the patient's physical, social, psychological, and other aspects of life. As a result, assessing the quality of life of ED patients is an important part of the treatment process and should be incorporated into therapeutic practice.

In the last few decades, there has been more and more interest in finding adequate questionnaires to help identify and measure the severity of EDs, as well as questionnaires to examine the quality of life of these patients. Several studies have been conducted on this subject, and the evolution and scientific advancement will be elaborated and discussed in the following text in order to identify the most appropriate questionnaire that will aid clinicians in their therapeutic practice (Fig. 4).

Among the first questionnaires used in practice to assess the QOL of patients with an ED were Short Form-36 (SF-36) and the Eating Disorder Examination-Questionnaire (EDE-Q).

The Short Form-36 (SF-36)

A generic health-related quality of life questionnaire, the Short Form-36 (SF-36), examines quality of life (Fairburn and Wilson 1993). The SF-36 comprises questions concerning an individual's functioning and contentment in several areas of life. The SF-36 is a 36-question survey that examines a person's happiness with their physical, mental, social, and emotional well-being. The SF-36 scale has a range of 0 to 100 points. A higher score suggests a better quality of life (Fairburn and Wilson 1993) (Fig. 1).

Although the generic Short Form-36 (SF-36) questionnaire was applied and yielded good results, a specific questionnaire on the quality of life of individuals with EDs is lacking in this field. The questionnaire was used to assess the quality of life of patients with EDs; nevertheless, issues were found that obscured the true image of the quality of life of these patients. The fundamental concern is that the Short Form-36 is not sensitive or specific enough for patients with EDs – in other words, it does not address enough aspects relevant to how EDs can affect a patient's quality of life. Specific concerns and common symptoms associated with certain disorders, such as EDs, are assessed using disease-specific questionnaires. Disease-specific questionnaires are more likely to show substantial differences than generic questionnaires because they are more sensitive. Scientists were inspired by the challenge to create and evaluate new, more sensitive quality of life questionnaires.

Eating Disorder Examination-Questionnaire (EDE-Q)

The Eating Disorder Examination-Questionnaire (EDE-Q) is a self-assessment questionnaire adapted by Fairburn (Ware et al. 1993). The questionnaire is structured

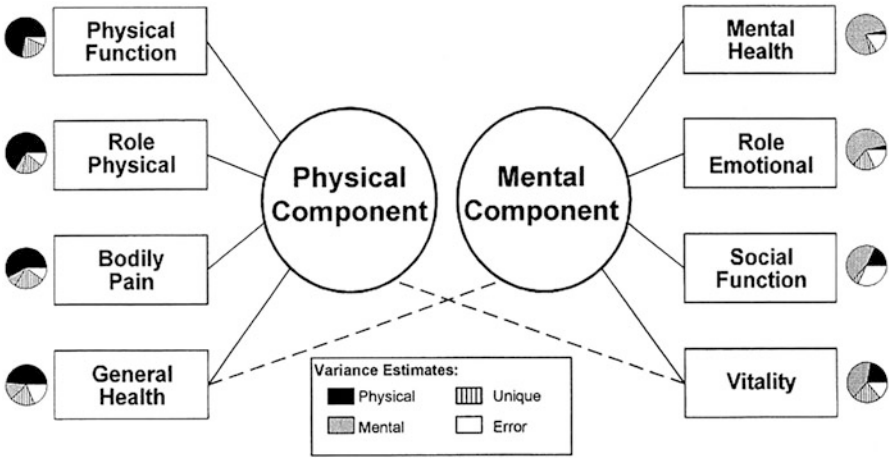

Fig. 1 Components of the Short Form-36 questionnaire. A generic health-related quality of life questionnaire (SF-36) which includes both physical and mental component (Ware and Gandek 1998)

into 36 questions about the patient's eating habits during the previous 28 days. It includes questions based on DSM-IV criteria for EDs. Feeling obese, fear of gaining weight, bulimic episodes, certain dietary restrictions, compensatory behaviors such as self-induced vomiting or laxative abuse, irrational desire to lose weight, obsessive need for a healthy diet, and the impact of physical appearance on self-esteem are all covered by the questionnaire. In regard to the frequency of symptoms in the previous 28 days, the questions were assessed on a scale of 6 points (Fig. 2).

A study published by S. Engel in 2006 was conducted on the development and validation of questionnaires designed to combine the symptoms of EDs with quality of life. In this study, the EDE-Q questionnaire proved to be more specific than the SF-36 questionnaire for determining the severity of the stage of an ED and the consequences that these disorders can contribute to the quality of life of patients (Engel et al. 2006). The EDE-Q questionnaire provides an opportunity for clinicians and researchers treating EDs to assess the degree of reduced quality of life since the questionnaire is designed to address the issues and concerns of people with EDs, and it can be very useful in clinical research to assess treatment outcomes (Figs. 3, 4, 5, and 6).

New discoveries are made as the search for highly specialized and sensitive questionnaires continues. Several instruments and questionnaires were used to obtain a final result in several studies investigating the association between the intensity of symptoms induced by EDs and quality of life. What led researchers and scientists to this approach is that a substantial percentage of patients with EDs suffer from other mental disorders in addition to EDs, most often anxiety disorders, mood disorders, depression, and others. A study conducted in 2014 looked at the

	On how many of the past 28 days	No days	1-5 days	6-12 days	13-15 days	16-22 days	23-27 days	Every day
1	Have you been deliberately trying to limit the amount of food you eat to influence your shape or weight (whether or not you have succeeded)?	0	1	2	3	4	5	6
2	Have you gone for long periods of time (8 waking hours or more) without eating anything at all in order to influence your shape or weight?	0	1	2	3	4	5	6
3	Have you tried to exclude from your diet any foods that you like in order to influence your shape or weight (whether or not you have succeeded)?	0	1	2	3	4	5	6
4	Have you tried to follow definite rules regarding your eating (for example, a calorie limit) in order to influence your shape or weight (whether or not you have succeeded)?	0	1	2	3	4	5	6
5	Have you had a definite desire to have an empty stomach with the aim of influencing your shape or weight?	0	1	2	3	4	5	6
6	Have you had a definite desire to have a totally flat stomach?	0	1	2	3	4	5	6
7	Has thinking about food, eating or calories made it very difficult to concentrate on things you are interested in (for example, working, following a conversation, or reading)?	0	1	2	3	4	5	6

Fig. 2 Eating Disorder Examination-Questionnaire EDE-Q. An example of questionnaire (EDE-Q) (Rø et al. 2015)

quality of life of a large group of people with EDs and discovered potential predictors of quality of life. The Eating Disorder Examination-Questionnaire (EDE-Q), Short Form-12 Health Status Questionnaire (SF-12), the Weissman Social Adjustment Scale, and the Beck Depression Inventory (BDI) were the four types of questionnaires that were utilized in this study (Bamford et al. 2015).

Short Form-12 Health Status Questionnaire (SF-12)

The Short Form-12 Health Status Questionnaire (SF-12) (Ware Jr et al. 1996) is a standardized measure that assesses the respondents' physical and psychological well-being. It is made up of 12 questions separated into two parts: the Physical Component Summary Scale (PCS) and the Mental Component Summary Scale (MCS). The physical component of the health condition questions assesses if the patient's physical health limits his daily physical activities, as well as his ability to function in society and whether it impacts his productivity at work and in other activities. The mental component of the questionnaire includes questions that examine how an individual's mental and emotional health affects social functioning and productivity at work, as well as how nervous, sad, or lethargic they are.

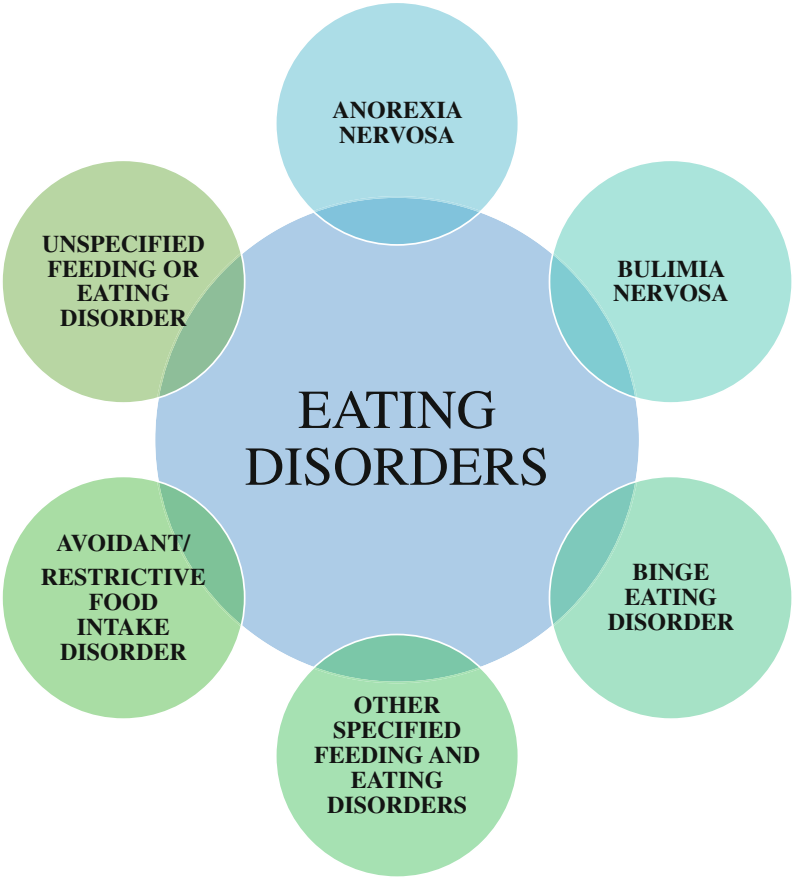

Fig. 3 Eating disorders

Weissman Scale of Social Adjustment

The Weissman Social Adjustment Scale (Weissman and Bothwell 1976) assesses an individual's social adjustment in a number of different areas of functioning, including marital, family, work, and leisure. The Weissman scale is a five-item self-assessment measure that assesses the extent to which physical or mental disorders have affected an individual's work, social and leisure activities, interpersonal relationships, and home management skills. Each item is scored on a scale of 5 points with higher grades, which indicates poorer functioning. The reliability and validity of the questionnaire was well established and used in a wide range of populations.

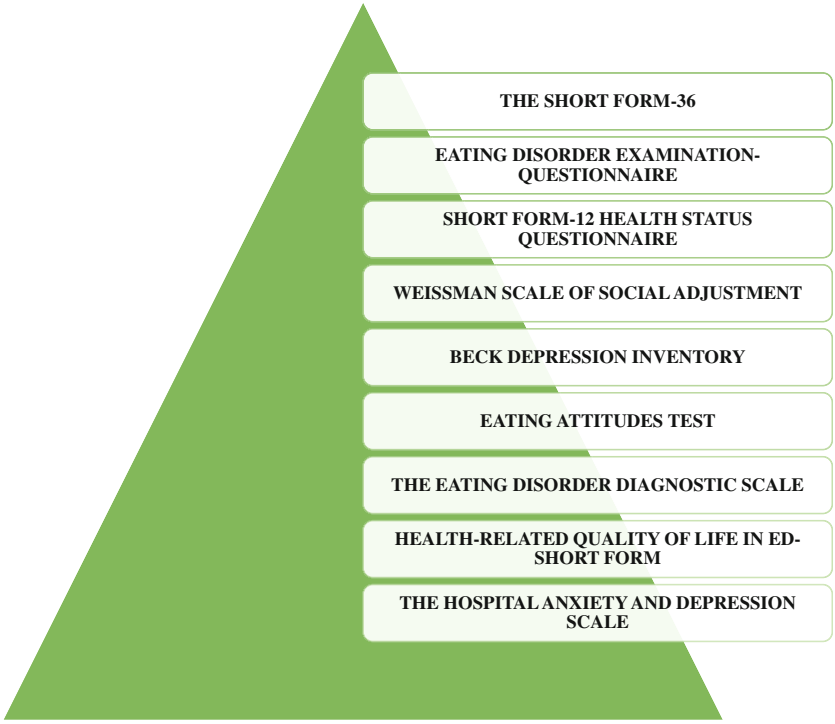

Fig. 4 Questionnaires that are used today

BDI

The BDI (Beck 1981) is a 21-question self-assessment questionnaire designed to assess depressive symptoms. Higher overall scores reflect greater depressive symptomatology.

More research into questionnaires for the discovery and prognosis of EDs, as well as the assessment of these patients' quality of life, leads to the development of new, more specific, and sensitive instruments.

Eating Attitudes Test (EAT-26) (Garner et al. 1982) evaluates behavioral and cognitive characteristics of patients with EDs. It comprises of 26 questions divided into three categories: diet, bulimia, and food worries and oral control. The result of the questionnaire might range from 0 to 76. The existence of actions or thoughts typical of people with an ED is indicated by a score of more than 20.

The Eating Disorder Diagnostic Scale (EDDS)

The Eating Disorder Diagnostic Scale (EDDS) (Castro et al. 1991) consists of 22 questions that assess the DSM-IV diagnostic criteria for anorexia, bulimia, and

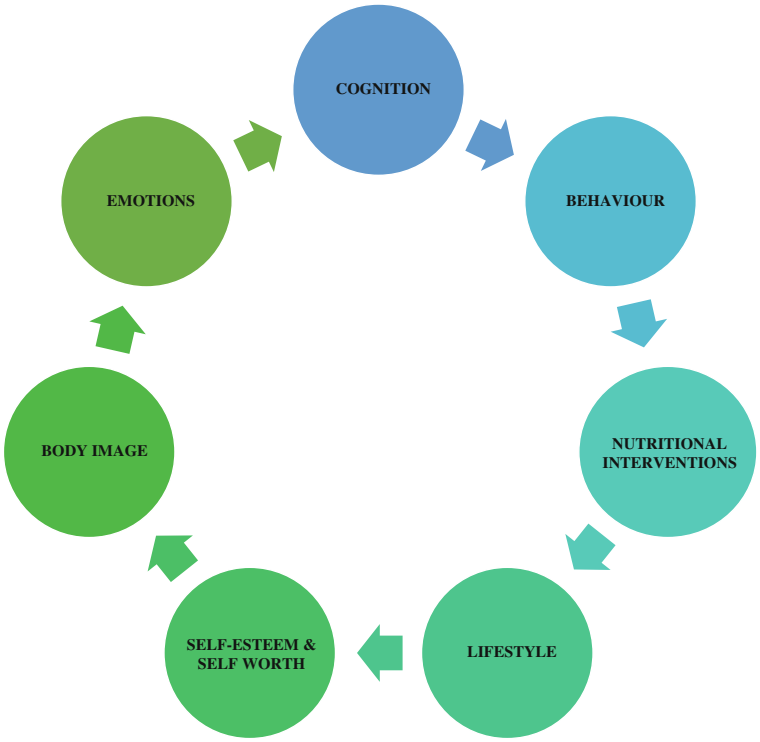

Fig. 5 Aspects affected by EDs

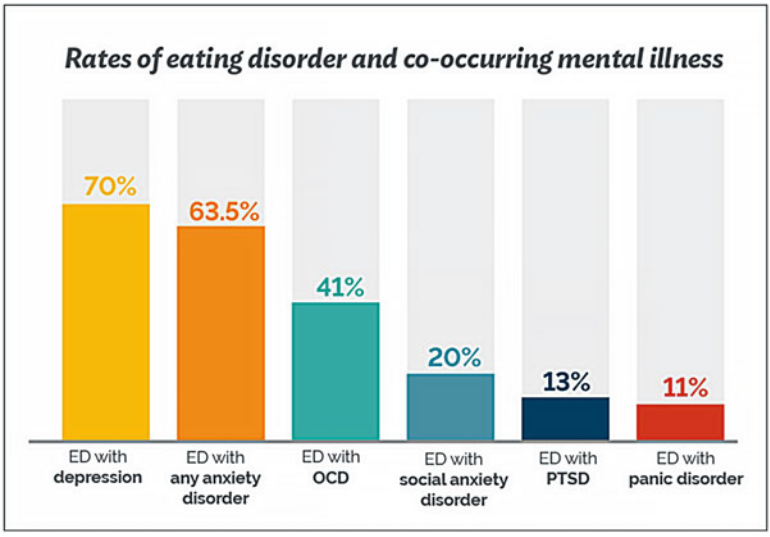

Fig. 6 Eating disorders and co-occurring mental illness (Bould et al. 2014)

binge-eating disorder. The answers can be used to make a DSM-IV diagnosis of these three disorders. There are both closed and open questions (e.g., questions about height, weight, use of contraceptive pills, etc.). This questionnaire's benefit is that it has been demonstrated to be trustworthy and valid in a population that includes both adolescents and adults (Stice et al. 2000).

Health-Related Quality of Life in ED-Short Form (HeRQoLED-S)

HeRQoLED-s (Las Hayas et al. 2010) has 20 items that are divided into two categories: social maladaptation and mental health and functioning. The higher the result of the questionnaire, the lower the quality of life related to the health condition.

The above questionnaires (Eating Attitudes Scale (EAT-26), the Eating Disorder Diagnostic Scale (EDDS), HeRQoLED-s, and the Short Form-12 Health Status Questionnaire (SF-12) described earlier in the text with the Hospital Anxiety and Depression Scale (HADS) were used in a study conducted in 2017, which looked for predictors of quality of life in patients with EDs (Martín et al. 2017). The anxiety and depression scale was employed in the study to detect anxiety and depression symptoms in ED patients in earlier stages.

The Hospital Anxiety and Depression Scale (HADS) (Zigmond and Snaith 1983) is a 14-item questionnaire that is used to test for anxiety and depression in the nonpsychiatric population (those who haven't been diagnosed with a mental illness). It's divided into two subscales. An absence of anxiety or depression symptoms is indicated by a score of 0 to 7 on any subscale, a score of 8 to 10 indicates a likely case of anxiety or depressive symptoms, and a score of 11 or higher indicates the presence of anxiety or depressive symptoms.

Further research suggests that different types of EDs cannot be defined using generic QoL questionnaires like the SF-36 and that ED-specific QOL questionnaires should be used in clinical trials to help clinicians identify behavioral patterns that are common in diseases that meet the definition of EDs. The most recent questionnaires specific to the quality of life of a patient with an ED are the Eating Disorders Quality of Life Scale (EDQLS) and the Eating Disorders Quality of Life Scale (EDQOL). The Eating Disorder Quality of Life Scale (EDQOL) has 25 items and four subscales: psychological, physical/cognitive, financial, and school/work. The EDQLS (Adair et al. 2007) is a 40-item questionnaire that assesses 12 aspects of disordered eating-related quality of life: cognitive, educational/vocational, family and close relationships, interpersonal relationships, future outlook, appearance, leisure, psychological, emotional, values and beliefs, physical, and eating. On a 5-point scale, items are scored from (Orley et al. 1998) strongly disagree to (Bamford et al. 2015) strongly agree. Higher ratings imply a better quality of life.

Before we move on to the conclusion, there is one more point to consider when assessing the quality of life of individuals with EDs. Patients were evaluated by

several specialists in most studies that evaluated the quality of life of patients with an ED prior to the beginning of the research. All patients must undergo a comprehensive physical examination, which involves determining body weight, height, and BMI, as well as discovering any organic chronic diseases such as diabetes, hypertension, obesity, heart diseases, lung diseases, and others. In order to diagnose psychiatric comorbidities such as mood disorders, anxiety disorders, substance addiction disorders, psychotic disorders, and others, a complete psychiatric assessment is also required.

Conclusion

There has been great progress in evaluating and designing appropriate questionnaires to help clinicians and researchers in the diagnosing, developing treatment strategies, and prognosing EDs, as well as assessing quality of life in these patients. What emerges in most studies and research is the knowledge that the combination of several questionnaires at the same time is the best choice for detecting and preventing impairment in quality of life in patients with EDs, as well as considering predictive factors related to quality of life. It is important to emphasize that the simultaneous occurrence of other mental illnesses, such as depression and anxiety, is very common and that instruments that help in the early detection of these accompanying disorders must be implemented in the examination.

Mini-Dictionary of Terms

- **QOL** – An individual's perception of their position in life in the context of the culture and value system in which they live and in relation to their goals, expectations, standards, and concerns.
- **Questionnaire** – A list of questions, usually printed, submitted for replies that can be analyzed for usable information.
- **Impairment** – The state of being diminished, weakened, or damaged, especially mentally or physically.
- **Instrument** – A device for measuring the present value of a quantity under observation.
- **DSM-IV** – A publication by the American Psychiatric Association for the classification of mental disorders using a common language and standard criteria.
- **Mental disorders** – Conditions that affect your thinking, feeling, mood, and behavior. They may be occasional or long-lasting (chronic).
- **Predictive factor** – As any patient characteristic that is predictive of the patient's response (outcome) to a specified treatment.

Key Fact of Health-Related Quality of Life Questionnaires: Applications to EDs

- Quality of life expresses the broad range of changes in a person's life as a result of an eating problem; it defines as an individual's perception of their position in life in the context of the culture and value system in which they live and in relation to their goals, expectations, standards, and concerns.
- Questionnaire: A research instrument consisting of a series of questions (or other types of prompts) for the purpose of gathering information from respondents through survey or statistical study.
- Evaluation of questionnaires is conducted through many of clinical research and studies in order to find the most suitable questionnaire that could help the clinicians and researchers in future treatment of EDs.
- Mental comorbidity is the presence of one or more additional mental conditions co-occurring with a primary condition – ED. Comorbidities are often coexistent with each other.
- Instrument represents a tool, often in the form of questionnaire, that is used to aid in diagnosing a variety of symptoms through the questions.

Summary Points

- People with EDs are impacted in a variety of ways by a variety of disciplines. There has been a growing interest in identifying appropriate questions to help detect and measure the severity of EDs, as well as questionnaires to assess the quality of life of these patients, throughout the previous several decades.
- The Short Form-36 (SF-36) and the Eating Disorder Examination-Questionnaire were among the first questionnaires used in practice to assess the QOL of patients with an ED (EDE-Q).
- Significant progress has been made in analyzing and constructing relevant questionnaires to assist clinicians and researchers in diagnosing, developing treatment strategies, and prognosing EDs.
- The best method for diagnosing and avoiding deterioration in quality of life in patients with EDs is to use a combination of many surveys at the same time.
- It's crucial to think about the factors that influence the outcome.

Abstract

Eating disorders are characterized by abnormal eating behavior which may also be associated with a preoccupation with body shape, size, and weight. They cause significant morbidity and mortality. Of all mental disorders, the mortality rate of anorexia nervosa is among the highest. In 1992, The World Health Organization (WHO) published the tenth revision of the International Classification of Diseases and Related Health Problems (ICD; ICD-10. The guidelines on eating disorders in the ICD-10 had several limitations. In 2022, the 11th revision (ICD-11) was

officially released. Many changes had been made in an attempt to rectify these shortcomings. During the intervening 30 years between the release of ICD-10 and ICD-11, the literature on eating disorders and the evidence to inform clinical practice advanced greatly and eating disorders are still actively being studied. Thus, the knowledge and understanding of eating disorders has progressed rapidly in recent years. However, keeping abreast of current research can be difficult so we have compiled tables of the resources recommended by active practitioners and researchers. These include information on regulatory bodies, societies, organizations, and other resources.

WHO	World Health Organization

Introduction

Eating disorders are characterized by abnormalities of eating behavior (World Health Organization (WHO) 2022). They may also be associated with a preoccupation with body shape, size, and weight. Examples of eating disorders include binge eating, bulimia, and anorexia nervosa. Eating disorders cause significant morbidity and mortality (Arcelus et al. 2011; Field et al. 2012). Those suffering from eating disorders are at increased risk of death by suicide (Arcelus et al. 2011). Indeed, of all mental disorders, mortality rate of anorexia nervosa is among the highest (Zerwas et al. 2015).

The World Health Organization (WHO) published the tenth revision of the International Classification of Diseases and Related Health Problems (ICD; ICD-10) in 1992 (WHO 1992). There were several inherent limitations with the guidelines on eating disorders in this version of the ICD (Claudino et al. 2019). However, there are other classifications such as the Diagnostic and Statistical Manual of Mental Disorders (DSM; American Psychiatric Association 2013), and indeed, classifications can change in the light of ongoing scientific dialogue (Rajendram et al. 2022).

The management of a mental health disorder is often defined by its classification. Thus, the development of more accurate, clinically relevant tools to classify, identify, prevent, and treat eating disorders is an important public health priority (Claudino et al. 2019).

In 2022, the 11th revision (ICD-11) was officially released and is available online at https://icd.who.int/browse11/l-m/en (WHO 2022). Many changes were made in an attempt to rectify the shortcomings of the ICD-10 with respect to eating disorders (Claudino et al. 2019).

During the intervening 30 years between the release of ICD-10 and ICD-11, the literature on eating disorders and the evidence to inform clinical practice advanced greatly (Claudino et al. 2019). Several areas are covered in Patel and Preedy (2023), but eating disorders are still actively being studied. As we often highlight, even the most experienced researchers and clinicians struggle to stay up-to-date, and some new researchers need some guidance on what online resources they should use. We have therefore produced tables containing resources as recommended by active researchers and practitioners, which draws upon their wealth of experience and acumen acquired over many years. The list below acknowledges all the experts who helped to prepare these valuable resources.

Resources

Tables 1, 2, 3, 4, and 5 list the most up-to-date information on the regulatory bodies (Table 1), professional societies (Table 2), books (Table 3), and other resources of interest (Table 4) that are relevant to an evidence-based approach to eating disorders. Some organizations are listed in more than one table as they occasionally fulfill multiple roles.

Other Resources

The Wellcome Collection (https://wellcomecollection.org/collections) and The British Library (https://www.bl.uk/) also list material on topics related to eating disorders.

Other chapters on resources relevant to nutrition (recommended by authors and practitioners) may also be relevant to eating disorders. These include diet quality (Rajendram et al. 2013a) nutrition and oxidative stress (Rajendram et al. 2020), maternal nutrition (Rajendram et al. 2017), nutrition and the menopause (Rajendram et al. 2013b), biomarkers of nutrition (Rajendram et al. 2022) glutamine (Rajendram et al. 2014), branched chain amino acids (Rajendram et al. 2015), famine, starvation, and nutrient deprivation (Rajendram et al. 2019a), aging (Rajendram et al. 2019b), diet and nutrition in critical care (Alzaid et al. 2015), and the metabolism and physiology of bariatric surgery (Rajendram et al. 2016).

Other chapters on resources relevant to mental health (recommended by authors and practitioners) may also be relevant to eating disorders. These include cognitive behavioral therapy (Rajendram et al. 2022), post-traumatic stress disorder (Rajendram et al. 2015), and substance misuse (Rajendram and Preedy 2016a, b, c).

This list of material in these tables is included to provide general information only. It does not constitute any recommendation or endorsement of the activities of

National Eating Disorders Association (NEDA)	https://www.nationaleatingdisorders.org/
Society of Biological Psychiatry (SOBP)	https://sobp.org/

This table lists the professional societies involved with eating disorders. The links were accurate at the time of going to press but may move or alter. In these cases, the use of the "Search" tabs should be explored at the parent address or site. In some cases, links direct the reader to pages related to eating disorders within parent sites. Some societies and organizations have a preference for shortened terms, such as acronyms and abbreviations. See also Table 1

Table 3 Books on eating disorders

Book title	Authors or editors	Publisher	Year of publication
Adonis Complex: How to Identify, Treat and Prevent Body Obsession in Men and Boys	Pope HG, Phillips KA, Olivardia R	The Free Press	2002

What Causes Eating Disorders – And What Do They Cause?	Frank GKW	Booklocker.com, Inc.	2016
Wiley Handbook of Eating Disorders, Assessment, Prevention, Treatment, Policy, and Future Directions	Smolak L, Levine MP	Wiley	2015
Your Dieting Daughter: Antidotes Parents Can Provide for Body Dissatisfaction, Excessive Dieting, and Disordered Eating	Costin C	Routledge	2013/2021

This table lists books relevant to eating disorders

these sites, facilities, or other resources listed in this chapter, by the authors or editors of this book.

Summary Points

Eating disorders are characterized by abnormalities of eating behavior.
In 2022, the 11th revision of the International Classification of Diseases (ICD-11) was officially released and is available online at https://icd.who.int/browse11/l-m/en.
In the 30 years between ICD-10 and ICD-11, the literature on eating disorders and the evidence to inform clinical practice advanced greatly.
Eating disorders are actively being studied.
This chapter lists the most up-to-date resources relevant to eating disorders.

Contributions to the Development of This Resource

The following authors made valuable contributions to the development of this resource. We apologize if some of the suggested material was not included in this chapter or has been moved to different sections.

Ali, Sarrah; Desousa, Avinash; Goldfield, Gary; Howard, Lindsay; Jahrami, Haitham; Karia, Sagar; Keel, Pamela; Malcolm, Amy; Memedi, Imran; Morganti, Wanda; Motwani, Shorouq; Muzi, Stefania; Nuhii, Nexhibe; Pace, Cecilia Serena; Papežová, Hana; Phillipou, Andrea; Procházková, Petra; Quadflieg, Norbert; Richson, Brianne; Roubalová, Radka; Saif, Zahra; Stankovska, Gordana; Strahler, Jana; Wentz, Elisabet; Wons, Olivia; and Yamada, Kenichi.
